My Parents \& Teachers

# Investigation of the Hyperfine Structure of Praseodymium-Transitions using Laser Spectroscopy 

#### Abstract

A comprehensive knowledge of the electron levels in an atom is one of the prerequisite for understanding the electron-electron and electron-nucleus interactions inside an atom and for the classification of the atomic spectrum of an element. The spin-orbit interaction is the largest relativistic effect and is responsible for the fine structure splitting in an atom. The hyperfine structure splitting of the fine structure atomic energy levels arise as a result of the interaction between spinning and orbiting electrons and electromagnetic multipole nuclear moments. The major contributions are due to the magnetic dipole and electric quadrupole moments. The electronic ground state configuration of praseodymium ${ }^{59} \operatorname{Pr}_{141}$ is [Xe] $4 \mathrm{f}^{3} 6 \mathrm{~s}^{2}$, with ground state level ${ }^{4} \mathrm{I}_{9 / 2}$. Because of its 5 outer electrons Praseodymium has a high density of energy levels which give rise to an extremely line rich emission spectrum. Due to this fact praseodymium serves as an efficient testing ground for hyperfine structure studies.

The thesis is mainly devoted to the finding of previously unknown energy levels by the investigation of spectral lines and their hyperfine structures. In a hollow cathode discharge lamp praseodymium atoms and ions in ground and excited states are excited to high lying states by laser light. The excitation source is a tunable ring-dye laser system, operated with Stilbene 3, Rhodamine 6G, Kiton Red, DCM and LD 700. A high resolution Fourier Transform spectrum is used for extracting excitation wavelengths. Then the laser wavelength is tuned to a strong hyperfine component of the spectral line to be investigated, and a search for fluorescence from excited levels is performed. From the observed hyperfine structure pattern, J-values and hyperfine interaction constants A of the combining levels are determined. This information, together with excitation and fluorescence wavelengths, allows us to find the energies of the involved levels. During the course of this dissertation 313 new energy levels of $\operatorname{Pr}$ I and 4 new energy levels of Pr II were discovered. Using these newly discovered energy levels 652 spectral lines were classified via laser excitation, 836 spectral lines were classified as fluorescence lines and 178 lines were classified by their hyperfine structure and wave number.

The present work not only enhances the number of classified lines in the spectrum of Pr I but also demonstrates the advantage of laser induced fluorescence spectroscopy. The new levels might contribute also to a future theoretical analysis of the level structure of Pr I.

# Untersuchung der Hyperfeinstruktur von Praseodym-Übergängen mit Hilfe von Laserspektroskopie 

## Kurzfassung

Die umfassende Kenntnis der elektronischen Energieniveaus eines Atoms ist Voraussetzung für das Verständnis der Wechselwirkungen der Elektronen untereinander sowie ihrer Wechselwirkungen mit dem Atomkern. Die Klassifikation der Linien eines Atomspektrums kann ebenfalls nur mit Hilfe der Energieniveaus erfolgen.
Die Spin-Bahn-Wechselwirkung ist der größte relativistische Effekt und verantwortlich für die Feinstrukturaufspaltung im Atom. Die Hyperfeinstrukturaufspaltung der Feinstrukturniveaus entsteht als Resultat der Wechselwirkung der Elektronenbewegung (Bahnbewegung und Eigenrotation) und den elektrischen Multipolmomenten des Atomkerns. Abgesehen von der Coulomb-Wechselwirkung werden die Hauptbeiträge durch das magnetische Dipolmoment und das elektrische Quadrupolmoment des Kerns verursacht.
Der elektronische Grundzustand von Praseodym $\left({ }^{59} \mathrm{Pr}_{141}\right)$ hat die Elektronenkonfiguration [Xe] $4 f^{3} 6 s^{2}$, mit der spektroskopischen Bezeichnung ${ }^{4} \mathrm{I}_{9 / 2}$. Wegen seiner 5 äußeren Elektronen hat Praseodym eine hohe Dichte der elektronischen Niveaus, was zu einem extrem linienreichen Emissionsspektrum führt. Daher ist Praseodym ein ideales Testobjekt für Hyperfein-Studien.

Die Hauptaufgabe dieser Arbeit bestand im Auffinden neuer, bislang unbekannter Energieniveaus durch Untersuchung von Spektrallinien und ihrer Hyperfeinstruktur. In einer Hohlkathodenentladung werden Praseodym-Atome und -Ionen von Grund- und angeregten Zuständen aus mit Hilfe von Laserlicht in hochliegende angeregte Zustände gebracht. Die Anregung erfolgt mit dem Licht eines durchstimmbaren FarbstoffRinglasers, der mit verschiedenen Farbstoffen (Stilben 3, Rhodamin 6G, Kiton Red, DCM and LD 700) betrieben wurde. Ein hochauflösendes Fourier-Spektrum wird zum Auffinden geeigneter Anregungswellenlängen benutzt. Dann wird die Wellenlänge des Farbstofflasers auf eine starke Hyperfeinstruktur-Komponente der zu untersuchenden Spektrallinie eingestellt, und es wird nach laser-induzierten Fluoreszenzlinien gesucht. Aus dem registrierten Hyperfein-Linienprofil werden die J-Werte und A-Faktoren der beteiligten Energieniveaus ermittelt. Diese Information, zusammen mit der Anregungsund den Fluoreszenzwellenlängen, erlaubt es, die Energien der beteiligten (zum Teil bislang unbekannten) elektronischen Niveaus zu finden.

Während dieser Untersuchung wurden 313 bislang unbekannte Energieniveaus des PrAtoms (Pr I) und 4 neue Niveaus des Pr-Ions (Pr II) entdeckt. Mit Hilfe dieser neuen Niveaus konnten 652 Spektrallinien durch direkte Laseranregung, 836 als Fluoreszenzlinien und rund 180 weitere Linien aufgrund ihrer Lage und Hyperfeinstruktur im Fourier-Spektrum klassifiziert werden.
Die vorliegende Arbeit erweitert nicht nur die Anzahl der klassifizierten Linien im Prspektrum sondern demonstriert auch das Potential der laser-induzierten FluoreszenzSpektroskopie. Die neuen Niveaus werden auch bei zukünftigen theoretischen Untersuchungen der Energieniveaustruktur von Praseodym hilfreich sein.

## Declaration

This dissertation is submitted to the Institute of Experimental Physics, Graz University of Technology, Graz Austria, in partial fulfillment of the requirement for the degree of Doctor of Technical Sciences.

The thesis is entitled:

## Investigation of the Hyperfine Structure of Praseodymium-Transitions using Laser Spectroscopy

written by Shamim Khan and has been approved by the Institute of Experimental Physics, Graz University of Technology, Graz Austria.

The final copy of this thesis has been examined by the under signed authority, and find that both the content and the form meet acceptable presentation standards of scholarly work in the above mentioned discipline.

Univ. Prof. Dip.-Ing. Dr. tech. Laurentius Windholz

Date $\qquad$

## Acknowledgements

All appreciation to Almighty Allah, without His will and consent we can't proceed a single step. It is through His boundless and infinite mercy that I have been able to complete this research work. Respect and humble thanks to Holy Prophet Muhammad peace be upon him who is like a beacon in every aspect whether it is the purpose of education or how to work in a group of people.

I pay my heartiest gratitude to my research advisor Prof. Dr. Laurentius Windholz for supervising this research work. His guidance, valuable discussions and encouragement, lead to this research endeavor to come to an end. I am deeply thankful to him for always being so kind in addressing to my research problems affably. No matter how hectic his schedule and how insignificant my question, he always spared some time to listen my problems. During my entire stay, I never felt hesitated in communicating with him and always found him in a welcome attitude.

I am very much thankful to the Head of the Institute, Prof. W. E. Ernst for giving me this opportunity to work here as a research student. I thank all the members of the institute for their help at various occasions. I am also thankful to the people from machine workshop of the institute for providing me technical support during the years.

On this occasion, I would also like to acknowledge all my teachers that play a key role in my success throughout my education career.

It is worth to mention the role being played by Higher Education Commission (HEC) of Pakistan. The present pursuit for PhD studies was only possible with financial assistance from HEC.

This gives me pleasure to thanks my co-workers Syed Tanweer Iqbal, Betina Gamper, Imran Siddiqui and other Pakistani and Austrian colleagues in the institute for their cooperation at various occasions during my PhD studies. Special thanks are for Imran Siddiqui for his continuous support in the lab, valuable discussions and helping me in other difficult situations. Thanks are also due to all my friends in Graz. I will not forget the pleasant time which I have spent with them.

Last but not least, I wish to express my heartfelt gratitude towards my parents for their support, love and guidance in every field of life. Without their support, I would not be standing where I am now. It gives me satisfaction and pleasure to think that they are always praying for my success. I am also very much thankful to my sister Rukhsana Hafeez and brothers Arshad Iqbal and Abid Iqbal for their prayers and love.

## 1 Introduction

### 1.1 Preface

The major Coulomb interaction between positively charged nucleus and electrons determines the radial distribution of electrons around the nucleus. Inside the nucleus, the distribution of charges and currents give rise to other multiple electromagnetic moments. Two major multipole electromagnetic moments are magnetic dipole moment (associated with the nuclear spin) and electric quadrupole moment (associated with a deviation from a spherical charge distribution in the nucleus). In the former case, the nuclear magnetic dipole moment interacts with the magnetic field produced by the spinning and orbiting electrons. In the latter, the interaction occurs when, at the position of a nucleus, the electronic charge distribution produces an electric field gradient with which the nuclear quadrupole moment can interact. These interactions give rise to splitting of fine structure levels into hyperfine levels which results in hyperfine structure of a spectral line. Magnetic dipole interaction leads to splitting of fine structure levels where as the electric quadrupole interaction produce a shift in the hyperfine structure levels.

Hyperfine structure investigations of an element not only give information regarding the electron structure but also provide useful information about the nucleus of an atom without probing the nucleus directly. Thus, the atomic hyperfine structure has been extensively investigated for various elements and much valuable information has been obtained.

The chemical element praseodymium belongs to the group of lanthanide series (rare earth group) where the spectroscopic properties are determined by the fact that binding energies of $4 f, 5 d, 6 s$ and $6 p$ electrons are of the same magnitude. These similarities give rise to overlapping complex configurations with region of high energy level density and thus, to complex rich line spectra. This motivated the investigations of spectrum of Pr.

Extensive experimental work has been done in past on the investigation of hyperfine structure of praseodymium. Nevertheless, the experimental data are not complete and it is expected that many unassigned transitions and missing levels exist. Therefore the purpose of this study is to perform systematic measurements of spectrum of Pr I using the laser induced fluorescence technique in hollow cathode discharge lamp and to deepen the understanding of atomic structure of Pr I.

### 1.2 Historical Background of Spectroscopy

Although Sir Isaac Newton first used a prism to generate the spectrum of the sun in 1666, spectroscopy did not emerge as a systematic empirical science until the middle of nineteenth century, when Kirchhoff clearly defined the principles of spectrum analysis. Newton in 1666 showed that the white light from the sun could be dispersed into a continuous series of colours. Newton introduced the word "spectrum" to describe this phenomenon. Newton's analysis of light was the beginning of the science of spectroscopy.
Fraunhofer extended Newton's discovery by observing that the sun's spectrum, when sufficiently dispersed, was crossed by a large number of fine dark lines, now known as Fraunhofer lines. W.H. Wollaston had earlier observed a few of these lines but failed to attach any significance to them. These were the first spectral lines ever observed, and Fraunhofer employed the most prominent of them as the first standards for comparing spectral lines obtained using prisms of different glasses. Fraunhofer also studied spectra of
the stars and planets, using a telescope objective to collect the light. This laid the foundation for the science of astrophysics.

In the early 1800's many workers, J.F.W. Herschel, W.H.F. Talbot, C. Wheatstone, A.J. Angstrom, and D. Alter among them, studied spectra from terrestrial sources such as flames, arcs and sparks. These sources were found to emit bright spectral lines, which were characteristic of the chemical elements in the flame. Foucault, the French physicist, observed in 1848 that a flame containing sodium would absorb the yellow light emitted by a strong arc placed behind it. This was the first demonstration of a laboratory absorption spectrum.

By recognizing that each atom and molecule has its own characteristic spectrum, Kirchhoff and Bunsen established spectroscopy as a scientific tool for probing atomic and molecular structure, and founded the field of spectrochemical analysis for analyzing the composition of materials. In 1868 Ångström published the first accurate tables of wavelengths of lines, which was later supplemented by those of Rowland in 1887, obtained with the aid of a concave reflection grating. Langley's invention of the bolometer in 1881 extended spectral measurements to the infrared region while Schumann in 1893 devised spectrographs for use in the vacuum ultraviolet region.

At first, spectroscopy was mainly an analytical tool. Balmer showed in 1885 that there is a simple numerical relationship between the wavelengths of the emission lines of the hydrogen atom. This work was extended by Rydberg, Ritz, Runge, and Schuster to include the lines of many other elements, but a proper theoretical basis for the subject only appeared with the development of quantum mechanics in the nineteen-twenties. Since then spectroscopy and quantum mechanics became closely interlinked, enabling modern spectroscopic theory to develop.

In the 1920s, attention turned to the spectra of diatomic molecules, the theoretical foundations for their study being laid by Hund, Mulliken, and Van Vleck, among others. Later on considerable attention has been given to spectroscopy of polyatomic molecules and ions as a means of elucidating their structures and dynamics.

Radar techniques developed in wartime opened up the new field of microwave and radio frequency spectroscopy. Microwave spectroscopy has led to an accurate determination of geometries of a large number of simple polyatomic molecules. Other important related developments are electron spin resonance and nuclear magnetic resonance spectroscopy, the latter providing valuable information concerning the neighborhood forces and interactions to which a given atom in a molecule or crystal is subjected.

### 1.3 The Element Praseodymium

In 1841 Mosander extracted the rare earth didymium from lanthanum; in 1879, Lecoq de Boisbaudran isolated a new earth, samaria, from didymia obtained from the mineral samarskite. Six years later, in 1885, von Welsbach separated didymium into two others, praseodymium and neodymium, which gave salts of different colors.

Praseodymium is soft, silvery, malleable, and ductile. It is somewhat more resistant to corrosion in air than europium, lanthanum, cerium, or neodymium, but it does develop a green oxide coating that falls off when exposed to air. As with other rare-earth metals, it should be kept under a light mineral oil or sealed in plastic.

Misch metal, used in making cigarette lighters, contains about 5\% praseodymium metal. The rare-earth oxides, including $\mathrm{Pr}_{2} \mathrm{O}_{3}$ are among the most refractory substances known.

Along with other rare earths, it is widely used as a core material for carbon arcs used by the motion picture industry for studio lighting and projection. Salts of praseodymium are used to colour glasses and enamels; when mixed with certain other materials, praseodymium produces an intense and unusually clean yellow colour in glass. Didymium glass, of which praseodymium is a component, is a colorant for welders goggles.
The naturally occurring praseodymium is composed of one stable isotope ${ }^{141} \mathrm{Pr}$ with nuclear spin $I=5 / 2$ and $\mathrm{Z}=59$. Its nuclear electromagnetic moments are as follows: the magnetic dipole moment $\mu_{I}=4.2754$ (5) $\mu_{N}$ [1], the electric quadrupole moment $Q=$ 0.0024 b [2]. Two of the radioisotopes of $\operatorname{Pr}$ are relatively stable being ${ }^{142} \mathrm{Pr}$ with half life of about 19 hours and ${ }^{143} \mathrm{Pr}$ with half life of 13.57 hours. One of the prominent ${ }^{141} \mathrm{Pr}$ electron configuration with three valance electrons inside the $4 f$ shell is [Xe] $4 f^{3} 6 s^{2}$. The lowest term of this configuration is ${ }^{4} I$, where ${ }^{4} I_{9 / 2}$ corresponds to the electronic ground state of ${ }^{141} \mathrm{Pr}$.

### 1.4 History of Spectral and Hyperfine Investigations of Pr I

In 1929, H. E. White [3] published an article devoted to the study of hyperfine spectra in ionized Pr atoms. In this study, he investigated fine-structure components of 173 spectral lines out of which, about one hundred lines were seen to consist of six hyperfine components. From this he assigned an angular momentum $i=(5 / 2)(h / 2 \pi)$ to the nucleus of Pr atom. Brix [4] in 1953 further extended the work of White and determined the magnetic hyperfine interaction constant $a_{6 s}=0.416 \pm 0.015$ for the $\sigma s$ electron in the configuration $4 f^{3}\left({ }^{4} I\right) 6 s$. By the application of formula of Goudsmith and Fermi Segre, he also calculated a value $\mu\left(\operatorname{Pr}^{141}\right)=3.9 \pm 0.3$ nuclear magnetons for nuclear moment.
The hyperfine structure of the ground multiplet ( $4 f^{3} 6 s^{24} I_{9 / 2}$ ) was first studied in 1953 by Lew [5] using atomic beam magnetic resonance method. He determined nuclear spin, total electronic angular momentum and $g_{J}$ value of ground state. J. M. Baker and B. Bleaney [6] in 1955 investigated the hyperfine structure of Pr lines and calculated the hyperfine structure constants of the level involved. K. Murakawa [7] in 1960 classified three lines in the spectrum of Pr I and measured their hyperfine structure from which he determined the interval factor of the level $4 f^{3} 6 s^{24} I_{1 / 2 / 2}$. Y.C. Amado et al. [8] in 1962 studied the hyperfine structure of ${ }^{142} \mathrm{Pr}$ in the electronic ground state ${ }^{4} I_{9 / 2}$ by atomic beam magnetic resonance method. They measured the electronic splitting factor $g_{j}\left({ }^{4} I_{9 / 2}\right)=-0.7322(3)$, nuclear spin $I$ $=2$, magnetic dipole hyperfine constant $|A|=67.5(5) \mathrm{Mc} / \mathrm{Sec}$, electronic quadrupole hyperfine constant $|B|=70.0(2.0) \mathrm{Mc} / \mathrm{Sec}$, nuclear moment $\left|\mu_{I}\right|=0.297(15) \mathrm{nm}$ and $|Q|=$ $0.035(15)$ b. In 1973 R. Zalubus et al. [9] measured energy levels of Praseodymium. They observed the spectra of Pr I and Pr II in emission for the range $350-120 \mathrm{~nm}$ and in absorption for the range 200-870 nm. They reported three lowest levels of $4 f^{3} 6 s^{2}{ }^{4} I_{9 / 2}$ ground term. These three levels combine with 62 high even levels, accounting for 150 lines. J. Reader and J. Sugar [10] in 1964, studied the nuclear moment of $\operatorname{Pr}^{141}$ from the hyperfine structure of doubly ionized Pr. They calculated the probability density of the 6 s electron at the nucleus and the quantum difference for the configurations $4 f^{2} 6 s$ and $4 f^{2} 7 s$. They also calculated a value $4.09 \pm 0.06 \mathrm{~nm}$ for nuclear moment of $\operatorname{Pr}^{141}$. Böklen et al. [2] in 1975 used the same technique as that of Lew et al. but with Ramsey separated field technique, to measure the ground state hyperfine structure to extremely high precision.

A first analysis of fine structure and hyperfine structure of the even configuration of Pr I was presented by Ginibre [11] in 1981 on the base of two configuration system ( $4 f^{2} 5 d 6 s^{2}$ and $4 f^{2} 5 d^{2} 6 s$ ) restricted to the lower energy range, where the mixing effect with other excited configurations are rather small. In 1981, Childs and Goodman [12] published their
results of precise measurements of the hyperfine structure of metastable levels obtained with the method of the laser radiofrequency double resonance on an atomic beam, which allowed more precise determination of magnetic dipole and electric quadrupole moments of the Pr nucleus. In 1982, R. M. Macfarlane et al.[1] measured the nuclear magnetic moment of ${ }^{141} \mathrm{Pr}$ to be $\mu_{I}=4.2754$ (5) $\mu_{N}$ and in 1985 K.T. Cheng and W. J. Childs [13] determined the electric quadrupole moment of $\operatorname{Pr}$ and found a value $Q=0.066$ b. Reddy and Rao [14] in 1988 investigated the Pr I and Pr II spectra in the range of 576-625 nm and obtained the information of the hyperfine structure of four spectral lines by using optogalvanic spectroscopy. They also identified about 78 atomic transitions of Pr I and 43 transitions of Pr II. In 1988 A. Ginibre, in addition to her published work [11, 15-17], discovered lot of new lines both in Pr I and Pr II which were never published. This work is now part of her Ph.D thesis [18].

In 1996, T. Kuwamoto et al. [19] investigated the hyperfine structure of neutral praseodymium by means of the atomic beam laser spectroscopy. They reported hyperfine structure of 34 atomic transitions in the wavelength range from $544-596 \mathrm{~nm}$ and determined the hyperfine constants $A$ and $B$ for 57 levels. They determined the energies and electronic angular momenta of 11 fine structure for the first time. In 1997 A. Krzykowski et al. [20] determined the values of hyperfine structure of the lower levels belonging to the configuration of $4 f^{3} 5 d 6 s$ by using the method of laser induced fluorescence spectroscopy. In continuation to the previous experimental results, J. Ruczkowski et al. [21] in 2003 analyzed the hyperfine structure in the even configuration system $4 f^{2} 5 d 6 s^{2}+4 f^{2} 5 d^{2} 6 s+4 f^{3} 6 s 6 p+4 f^{3} 5 d 6 p+4 f^{2} 5 d^{3}$ by applying a semi-empirical method. The hyperfine structures of 546 energy levels have been interpreted.

In 1998 M. Song et al. [22] measured the lifetimes of low lying states in neutral Pr atoms and calculated the 14 new lifetimes of Pr I by monitoring the time-resolved fluorescence from the studied excited state. In 2006, Furmann et al. [23] reported 57 new electron levels of odd parity in Pr I in spectral range $560-590 \mathrm{~nm}$. These levels have been found on the basis of an analysis of hitherto unclassified spectral line with the method of LIF.
As remarked earlier Praseodymium has five outer electrons, which gives it a high density of levels leading to an extremely line rich spectrum. Using this property of Praseodymium S. Oppel et al. in 2010 [24] performed active frequency stabilization of a diode laser on several lines between 1105 and 1123 nm . Employing the standard laser locking technique, they are able to eliminate the frequency drift of the unlocked laser of more than $30 \mathrm{MHz} / \mathrm{h}$ and achieved the laser frequency stability to within $1.4(1) \mathrm{MHz}$ for averaging times $>0.2 \mathrm{~s}$.

In 2011, B. Gamper et al. [25] reported the recording of new highly resolved Fourier Transform (FT) spectrum of the neutal praseodymium atom. With the help of this new FT spectrum 1194 lines were classified as transitions between energy levels of Pr I atom and 19 as transitions of the Pr II. They also reported 23 new atomic energy levels of odd parity and one of even parity.

### 1.5 History of Spectral and Hyperfine Investigations of Pr II and Pr III

Praseodymium, like other elements in the rare earth group (Lanthanides), has a very complex energy spectrum. This is also true in all of its ionization stages. Furthermore the spectra of singly ionized atoms or of higher stages of ionization are difficult to produce as compared to neutral atomic spectrum. Also frequently the strong lines are observed in regions of spectrum where high dispersion apparatus cannot readily be used. Therefore it is not only interesting from the standpoint of atomic physics to investigate the spectra of
neutral atoms or ions of praseodymium but also the spectral lines of Pr II are being extensively investigated from the point of view of other fields in physics specially astrophysics.
H. E. White [3] in 1929 published the investigation of fine and hyperfine structure of singly ionized praseodymium atoms and determined its spin quantum number. He investigated 200 lines in the spectral region $390-500 \mathrm{~nm}$ exhibiting the complex structure and measured the component separation for 33 of those lines. At that time the insufficient resolution was the major hurdle in the measurement of the wave numbers of the involved energy levels. It could only be realized when in 1941 Rosen et al. [26] using their high resolution Zeeman Effect data for praseodymium that the wavenumbers of the levels of Pr II could be determined. They covered the spectral range from $240-710 \mathrm{~nm}$. In addition to this, using the resolved Zeeman pattern for 141 lines, they determined the $g$ and $J$-values for 74 Pr II levels.

In 1988 using the high resolution data in the range $2783-27920 \mathrm{~cm}^{-1}$, A. Ginibre [16] calculated new energy levels in the odd configuration $4 f^{2} 5 d 6 p$ and in the mixed even configurations $4 f^{2} 5 d^{2}+4 f^{2} 5 d 6 s+4 f^{3} 6 p$ for singly ionized praseodymium. She also corrected a number of spectral parameters such as energy, $J$ and hyperfine splitting of already known 105 odd levels and 187 even levels. Extending her work [17], she further calculated new experimental even levels in the range $5854-31654 \mathrm{~cm}^{-1}$ of singly ionized praseodymium on the basis of the 3 mixed configurations $4 f^{2} 5 d^{2}+4 f^{2} 5 d 6 s+4 f^{3} 6 p$.
In 1990 H . Iimura et al. [27] using the technique of collinear laser ion beam spectroscopy studied the hyperfine structure of Pr II and measured the magnetic dipole and electric quadrupole constants for the investigated transitions. Then in 1991, Kim [28] studied the hyperfine structure of doubly ionized Pr III. In 1994, H. Iimura et al.[29] by means of laser ion beam spectroscopy measured the magnetic dipole moment and electric quadrupole moment of a Pr isotope $\left(\operatorname{Pr}^{143}\right)$. In 2000, Maosheng Li et al. [30-31] using collinear laser ion beam spectroscopy investigated the atomic spectra of singly ionized praseodymium and neodymium. They measured the hyperfine structure of atomic transition in the wavelength range 560 to 590 nm .

In 2001, S. Ivarsson et al. [32] investigated singly and doubly ionized praseodymium by means of high resolution Fourier transform spectra in the region $280-800 \mathrm{~nm}$. They improved the wavelengths of 49 lines and measured $g f$-values for 31 lines by means of branching fractions and lifetimes data. Hyperfine structure pattern of 44 levels was analyzed and magnetic hyperfine constants $A$ were determined for 8 odd and 18 even levels. B. Furmann et al. [33] in 2001 discovered experimentally three new low-lying levels of Pr II by using the method of laser induced fluorescence spectroscopy in a hollow cathode discharge. This work also include the investigation of already known levels in the spectral range $562-602 \mathrm{~nm}$ with the determination of $J$-quantum numbers and $A$-values for the ionic levels.
In 2002 Ma Hong-Liang [34] by using technique of collinear fast-ion-beam laser spectroscopy measured the hyperfine structure of singly ionized lanthanum and praseodymium. Magnetic dipole and electric quadruple coupling constants were also determined for already known levels.
In 2005 B. Furmann et al. [35] investigated the hyperfine structure of singly ionized praseodymium and determined their hyperfine structure constants $A$ and $B$ using the method of laser induced fluorescence in a hollow cathode discharge. They discovered 42 new electron levels in singly ionized praseodymium which consist of 28 low lying odd levels with $f^{3}$ core and 14 even levels.

## 2 Atomic Structure

The light emitted by an atomic gas, say in a hollow cathode discharge, is due to the distribution and motion of electrons around the nucleus of an atom. The investigation of this light gives information about the electronic structure of the atom which determines the physical and chemical properties of the atom. The discrete spectrum of frequencies of any atom is the characteristic of the periodic motion of electrons, confined to specific positions. Such a motion is referred to as bound motion. Early spectroscopists interpreted the spectra of atoms in terms of models by applying classical laws of mechanics and electrodynamics to the motion of particles with suitably chosen properties. Inspite of this simple and general approach, difficulties of fundamental nature arise such as integral ratios of frequencies which is true for every classical system but is not found in atomic spectra.

In 1911 Lord Rutherford, based on his series of experiments with radioactive alphaparticles, gave revolutionary view of the structure of the atom. He suggested that the atom consisted of a small, dense core of positively charged particles in the center (or nucleus) of the atom, surrounded by a swirling ring of electrons. The nucleus is so dense that the incoming alpha particles bounce off from it, whereas the electrons are so tiny and spread out at large distances that the alpha particles pass through them. Rutherford model of atom resembled that of a solar system and the electrons under the influence of the electrostatic attraction by the nucleus, together with their mutual repulsion, perform complicated planetary motion around the nucleus. But from the laws of classical mechanics and electrodynamics it can easily be inferred that the electron would gradually lose energy by emitting light of continuously increasing frequency and would eventually fall into the nucleus. Thus laws of classical mechanics proved to be insufficient in explaining the spectra or the stability of atoms.

A completely new and more general set of laws were required which led to the development of quantum physics. Bohr and Sommerfeld took the first step in this development of the so called "old quantum theory" and were able explain to a certain extent the spectra and stability of atoms. Bohr-Sommerfeld model accounts for the allowed energies and the spectral frequencies of the atomic one-electron systems. Inspite of this, the model has serious deficiencies and is not complete. Among such deficiencies are
i) Assignment of quantized angular momentum to atomic states is in highly arbitrary manner i.e. assignment is done merely on the basis that leads to the results which agree with the observations.
ii) No satisfactory explanation is given as to why the accelerating electrons in stable orbits does not radiate. Radiation is assumed to be emitted when the electron jumps from one stable orbit to another.
iii) The model does not explain the mechanism of electron jumps between various stable orbits. As a consequence, the model does not account for the observed intensities of the spectral emission frequency.
iv) Bohr-Sommerfeld model is incapable of giving correct results for atomic systems with more than one electron and is one of the major limitations of the model.
E. Schrödinger, W. Heisenberg and others, following the ideas of L. de Broglie removed the discrepancies in the Bohr-Sommerfeld model and explained the finer details of the internal structure of one-electron as well as many electron atoms. This laid the foundation of quantum mechanics and the development of non-relativistic and later relativistic
quantum mechanics as the theoretical framework for the structure of an atom. The literature consulted for writing chapters 2,3 and 4 is given in 9.1 .

### 2.1 One Electron Systems

The first quantum mechanical treatment that gave the explanation of the discrete spectra of atomic emission was based on the equation proposed by Schrödinger in 1926. For the calculations of the energy state of one-electron atoms such as $\mathrm{H}, \mathrm{He}^{+}, \mathrm{Li}^{++}, \mathrm{Be}^{3+}$ etc., the time independent Schrödinger equation is written as

$$
\begin{gather*}
\hat{H} \psi(r, \theta, \phi)=E \psi(r, \theta, \phi)  \tag{2.1}\\
{\left[-\frac{\hbar^{2}}{2 m} \nabla^{2}+V(r)\right] \psi(r, \theta, \phi)=E \psi(r, \theta, \phi)} \tag{2.2}
\end{gather*}
$$

where $\hat{H}=\left[-\frac{\hbar^{2}}{2 m} \nabla^{2}+V(r)\right]$ is called the quantum mechanical Hamiltonian or total energy operator; in simple systems it is the sum of kinetic energy and potential energy operators. The nucleus of the atom is considered a point charge Ze , where $Z$ is the atomic number of the atom. The motion of electron around the nucleus is primarily governed by the electrostatic potential around the nucleus. Therefore

$$
V(r)=-\frac{Z e^{2}}{4 \pi \varepsilon_{o} r}
$$

Furthermore, in order to account for the motion of the nucleus, the reduced mass is used which is given by

$$
m=\frac{m_{e} M}{m_{e}+M}
$$

where $M$ is the mass of the nucleus and $m_{e}$ is the mass of the electron. Since the potential operator depends only on the scalar distance $r$ of the electron from the nucleus, therefore the wave Eq. (2.2) can be separated in spherical polar co-ordinates. After substituting the Laplacian operator $\nabla^{2}$ of Eq. (2.2), in spherical polar co-ordinates, the Schrödinger equation can be written as,

$$
\begin{equation*}
-\frac{\hbar^{2}}{2 m}\left[\frac{1}{r^{2}} \frac{\partial}{\partial r}\left(r^{2} \frac{\partial \psi}{\partial r}\right)+\frac{1}{r^{2} \sin \theta}\left(\frac{\partial}{\partial \theta} \sin \theta \frac{\partial \psi}{\partial \theta}\right)+\frac{1}{r^{2} \sin ^{2} \theta} \frac{\partial^{2} \psi}{\partial \phi^{2}}\right]+V(r) \psi=E \psi \tag{2.3}
\end{equation*}
$$

The exact solution of the Schrödinger equation for arbitrary atoms is very difficult because of the complex nature of this second order differential equation. However, for some simple systems exact solutions are possible. Otherwise numerical solutions or some approximations are used. One such approximation is the variable separation technique; here one can assume that various motions associated with the systems can be decoupled (like in Born Openheimer approximation applied to molecules). Using this approximation to the atomic system, the eigenfunction can be written as the product of a radial part associated with the radial motion and an angular part associated with its angular
momentum, i.e.

$$
\psi_{n l m}(r, \theta, \phi)=R_{n l}(r) Y_{l m}(\theta, \phi)
$$

A further separation is also possible:

$$
Y_{l m}(\theta, \phi)=\Theta(\theta) \Phi(\phi)
$$

These separation lead to three differential equations, one each in the co-ordinates $r, \theta, \phi$

$$
\begin{gather*}
\frac{d^{2} \Phi}{d \varphi^{2}}=-m_{l}^{2} \varphi  \tag{2.4}\\
-\frac{1}{\sin \theta} \frac{d}{d \theta}\left(\sin \theta \frac{d \Theta}{d \theta}\right)+\frac{m_{l}^{2}}{\sin ^{2} \theta} \Theta=l(l+1) \Theta  \tag{2.5}\\
\frac{1}{r^{2}} \frac{d}{d r} r^{2} \frac{d R}{d r}-\frac{l(l+1)}{r^{2}} R-\frac{2 m}{\hbar^{2}} V(r) R+\frac{2 m E}{\hbar^{2}} R=0 \tag{2.6}
\end{gather*}
$$

where $-m_{l}{ }^{2}$ and $l(l+1)$ are separation constants.
The solution of Eq. (2.4) is

$$
\begin{equation*}
\Phi=e^{i m_{l} \phi} \tag{2.7}
\end{equation*}
$$

where $m_{l}$ can have values

$$
m_{l}=0, \pm 1, \pm 2, \pm 3
$$

Integer values for $m_{l}$ follow from the condition

$$
\begin{equation*}
Y(\theta, \phi)=Y(\theta+2 \pi, \phi+2 \pi) \tag{2.8}
\end{equation*}
$$

The solution of equation involving $\theta$ is given by

$$
\begin{equation*}
\Theta(\theta)=A P_{l}^{m_{l}}(\operatorname{Cos} \theta) \tag{2.9}
\end{equation*}
$$

where $P_{l}^{m_{l}}(\cos \theta)$ is the associated Legendre function and is defined as,

$$
\begin{equation*}
P_{l}^{m_{l}}(x)=\left(1-x^{2}\right)^{\frac{\left|m_{l}\right|}{2}}\left(\frac{d}{d x}\right)^{\left|m_{l}\right|} P_{l}(x) \tag{2.10}
\end{equation*}
$$

and $P_{l}(x)$ is called the Legendre Polynomial, given by Rodrigues formula

$$
\begin{equation*}
P_{l}(x)=\frac{1}{2^{l} l!}\left(\frac{d}{d x}\right)^{l}\left(x^{2}-1\right)^{l} \tag{2.11}
\end{equation*}
$$

It is clear from the Eq. (2.9) that $l$ can only take non-negative integral values otherwise Rodrigues formula $P_{l}(x)$, which involves the differential operator applied "l" times, does not make sense at all. Moreover, if $\left|m_{l}\right|>l$, then the associated Legendre function $P_{l}^{m_{l}}(x)$ is equal to zero and hence, ultimately $\psi(r, \theta, \phi)$ is zero. Therefore no solution exists for $\left|m_{l}\right|>l$. The possible values of $m_{l}$ are then restricted to the following range,

$$
m_{l}=-l,-l+1,-l+2, \ldots \ldots ., l-2, l-1, l
$$

In order to find the solution for the radial function $R(r)$, the boundary condition that the probability of finding the electron should be zero at infinity, i.e. $R(r) \rightarrow 0$ as $r \rightarrow \infty$ is employed. This leads to the determination of the energy of the electrons in the $n^{\text {th }}$ orbit from the nucleus viz.,

$$
\begin{equation*}
E_{n}=-\frac{e^{4} Z^{2} m}{2\left(4 \pi \varepsilon_{o}\right)^{2} \hbar^{2} n^{2}} \tag{2.12}
\end{equation*}
$$

where $n$ is an integer satisfying the relation $n \geq l+1$. For positive energies there is no such restriction because for positive energies the electron will no longer be bound to the nucleus. The number $n$ is called the principal quantum number.

Therefore to summarize, electron in an atom is characterized by three quantum numbers i.e. $n, l, m_{l}$. For a given value of $n$, the quantum number $l$ (called the azimuthal quantum number) can take the values $0,1,2, \ldots,(n-1)$ and to each value of $l$, there correspond $(2 l+1)$ states, differing by the values of the quantum number $m_{l}$ which is often called the magnetic quantum number. The energy of an atom in the state $n, l, m_{l}$ is uniquely determined by the assignment of the principal quantum number and does not depend on $l$ or $m_{l}$. Thus, an $n^{2}$-fold degeneracy of levels takes place for a particle in a Coulomb field. For the level $n$, there are $1+3+5+\ldots+2 n-1=n^{2}$ different states, differing in the quantum numbers $l$ and $m_{l}$. The independence of $m_{l}$ in the energy has a simple physical meaning. In a field having central symmetry all directions in space are equivalent and therefore the energy cannot depend on the spatial orientation of the angular momentum. The $l$ degeneracy is a direct result of the Coulomb potential and is peculiar to hydrogen atom. When the spin-orbit interactions and the relativistic effects are taken into account, this degeneracy is partially removed.

### 2.2 Fine Structure of Atoms

For a hydrogenic atom, the gross structure energy levels only depend on the principal quantum number $n$. However, a more accurate model takes into account relativistic and spin effects, which break the degeneracy of the energy levels and split the spectral lines. The scale of the fine structure splitting relative to the gross structure splitting is of the order of $(Z \alpha)^{2}$, where $Z$ is the atomic number and $\alpha$ is the fine-structure constant which gives the strength of electromagnetic interaction i.e. how strongly a charge particle interacts with electromagnetic field, viz.

$$
\alpha=\frac{e^{2}}{\hbar c}=\frac{1}{137.035999679}
$$

The fine structure can be separated into three corrective terms: the kinetic energy term, the spin-orbit term, and the Darwinian term. The full Hamiltonian is then given by

$$
H=\hat{H}_{0}+\hat{H}_{\text {Kinetic }}+\hat{H}_{s o}+\hat{H}_{\text {Darrinian }}
$$

### 2.2.1 Kinetic Energy Relativistic Correction

Classically, the kinetic energy term of the Hamiltonian is:

$$
T=\frac{p^{2}}{2 m}
$$

However, according to special relativity, the kinetic energy (i.e., the difference between the total energy and the rest mass energy) of a particle of rest mass $m$ and momentum $p$ is

$$
\begin{equation*}
T=\sqrt{p^{2} c^{2}+m^{2} c^{4}}-m c^{2} \tag{2.13}
\end{equation*}
$$

where the first term is the total relativistic energy, and the second term is the rest energy of the electron. Expanding this gives

$$
T=\frac{p^{2}}{2 m}-\frac{p^{4}}{8 m^{3} c^{2}}+\ldots \ldots
$$

The first term on the right-hand side of this equation is the standard non-relativistic expression for the kinetic energy. The second term is the first order relativistic correction to this energy viz.

$$
\begin{equation*}
H_{\text {Kinetic }}=-\frac{p^{4}}{8 m^{3} c^{2}} \tag{2.15}
\end{equation*}
$$

In comparison to $\frac{p^{2}}{2 m}, H_{\text {Kinetic }}$ is smaller by a factor of $\frac{p^{2}}{m^{2} c^{2}}=\frac{v^{2}}{c^{2}} \approx(Z \alpha)^{2}$. It is of the order of $0.1 \mathrm{~cm}^{-1}$.

The energy corrections $\Delta E_{1}$ due to relativistic effects can be calculated in first-order perturbation theory as:

$$
\begin{align*}
\Delta E_{1} & =\left\langle n l m_{l}\right|-\frac{\hat{p}^{4}}{8 m^{3} c^{2}}\left|n l m_{l}\right\rangle \\
& =-\frac{1}{8 m^{3} c^{2}}\left\langle n l m_{l}\right| \hat{p}^{4}\left|n l m_{l}\right\rangle \\
& =-\frac{1}{8 m^{3} c^{2}}\left\langle n l m_{l}\right| \hat{p}^{2} \hat{p}^{2}\left|n l m_{l}\right\rangle \tag{2.16}
\end{align*}
$$

Since the unperturbed Hamiltonian $\hat{H}_{0}$ is

$$
\begin{align*}
& \hat{H}_{0}=\frac{\hat{p}^{2}}{2 m}-\frac{Z e^{2}}{4 \pi \varepsilon_{o} r} \\
& \hat{p}^{2}=2 m\left(\hat{H}_{0}+\frac{Z e^{2}}{4 \pi \varepsilon_{o}} \frac{1}{r}\right) \tag{2.17}
\end{align*}
$$

By using Eq. (2.17) in Eq. (2.16)

$$
\Delta E_{1}=-\frac{1}{8 m^{3} c^{2}}\left\langle n l m_{l}\right| 4 m^{2}\left(\hat{H}_{0}+\frac{Z e^{2}}{4 \pi \varepsilon_{o}} \frac{e^{2}}{r}\right)^{2}\left|n l m_{l}\right\rangle
$$

$$
\begin{equation*}
=-\frac{1}{2 m c^{2}}\left[E_{n}^{2}+2 E_{n}\left(\frac{Z e^{2}}{4 \pi \varepsilon_{o}}\right)\left\langle\frac{1}{r}\right\rangle_{n l m_{l}}+\left(\frac{Z e^{2}}{4 \pi \varepsilon_{o}}\right)^{2}\left\langle\frac{1}{r^{2}}\right\rangle_{n l m_{l}}\right] \tag{2.18}
\end{equation*}
$$

To complete the evaluation of $\Delta E_{1}$, the expectation values of $\left\langle\frac{1}{r}\right\rangle$ and $\left\langle\frac{1}{r^{2}}\right\rangle$ are required viz.

$$
\begin{align*}
& \left\langle\frac{1}{r}\right\rangle_{n l m_{l}}=\frac{1}{a_{0} n^{2}}  \tag{2.19}\\
& \left\langle\frac{1}{r^{2}}\right\rangle_{n l m_{l}}=\frac{1}{a_{0}^{2}} \cdot \frac{1}{n^{3}(l+1 / 2)} \tag{2.20}
\end{align*}
$$

Each of which can be expressed in terms of $E_{n}$ i.e.,

$$
\begin{align*}
& \left\langle\frac{1}{r}\right\rangle_{n l m_{l}}=-2\left(\frac{4 \pi \varepsilon_{o}}{e^{2}}\right) E_{n}  \tag{2.21}\\
& \left\langle\frac{1}{r^{2}}\right\rangle_{n l m_{l}}=4 \frac{n}{(l+1 / 2)}\left(\frac{4 \pi \varepsilon_{o}}{e^{2}}\right)^{2} E_{n}^{2} \tag{2.22}
\end{align*}
$$

Inserting Eq.(2.21) and (2.22) in Eq.(2.18)

$$
\begin{equation*}
\Delta E_{1}=-\frac{E_{n}^{2}}{2 m c^{2}}\left[-3+\frac{4 n}{(l+1 / 2)}\right] \tag{2.23}
\end{equation*}
$$

Because $E_{n}=-\frac{1}{2} m c^{2} \frac{(Z \alpha)^{2}}{n^{2}}$

$$
\begin{equation*}
\Delta E_{1}=-E_{n} \frac{(Z \alpha)^{2}}{n^{2}}\left[\frac{3}{4}-\frac{n}{(l+1 / 2)}\right] \tag{2.24}
\end{equation*}
$$

### 2.2.2 Spin-Orbit Correction

The spin-orbit correction term arise as a result of the interaction between the spin and orbital motion of the electron. The interaction is basically between the magnetic field generated by the orbital and the spinning motions of electron.
The correction term for spin-orbit coupling in the Hamiltonian is given by

$$
\begin{equation*}
H_{s o}=\xi(r) \vec{L} \cdot \vec{S} \tag{2.25}
\end{equation*}
$$

where

$$
\xi(r)=\frac{1}{2 m^{2} c^{2}} \frac{1}{r} \frac{d V}{d r}
$$

In this case $V=-\frac{Z e^{2}}{\left(4 \pi \varepsilon_{o}\right) r}$

So that

$$
\begin{equation*}
\xi(r)=\frac{1}{2 m^{2} c^{2}} \frac{Z e^{2}}{4 \pi \varepsilon_{o}} \frac{1}{r^{3}} \tag{2.26}
\end{equation*}
$$

Total angular momentum $\vec{J}$ can be constructed as the sum of the orbital angular momentum $\vec{L}$ and spin angular momentum $\vec{S}$, i.e.

$$
\begin{equation*}
\vec{J}=\vec{L}+\vec{S} \tag{2.27}
\end{equation*}
$$

squaring this vector sum gives

$$
\begin{align*}
& J^{2}=\vec{J} \cdot \vec{J}=(\vec{L}+\vec{S}) \cdot(\vec{L}+\vec{S})  \tag{2.28}\\
& J^{2}=L^{2}+S^{2}+2 \vec{L} \cdot \vec{S}  \tag{2.29}\\
& \vec{L} \cdot \vec{S}=\frac{\left(J^{2}-L^{2}-S^{2}\right)}{2} \tag{2.30}
\end{align*}
$$

so the spin-orbit Hamiltonian becomes

$$
\begin{equation*}
H_{s o}=\xi(r) \frac{\left(J^{2}-L^{2}-S^{2}\right)}{2} \tag{2.31}
\end{equation*}
$$

The energy shift due to spin-orbit interaction is given by

$$
\begin{gather*}
\Delta E_{2}=\left\langle\hat{H}_{s o}\right\rangle \\
\Delta E_{2}=\left\langle j m_{j} l s\right| \xi(r) \frac{\left(J^{2}-L^{2}-S^{2}\right)}{2}\left|j m_{j} l s\right\rangle \\
\Delta E_{2}=\langle\xi(r)\rangle\left\langle j m_{j} l s\right| \frac{\left(J^{2}-L^{2}-S^{2}\right)}{2}\left|j m_{j} l s\right\rangle \\
\Delta E_{2}=\frac{1}{2 m^{2} c^{2}} \frac{Z e^{2}}{4 \pi \varepsilon_{o}}\left\langle\frac{1}{r^{3}}\right\rangle \frac{\hbar^{2}}{2}[j(j+1)-l(l+1)-s(s+1)] \tag{2.32}
\end{gather*}
$$

The expectation value of $1 / r^{3}$ is given by

$$
\begin{equation*}
\left\langle\frac{1}{r^{3}}\right\rangle_{n l}=\frac{Z^{3}}{a_{0}^{3} n^{3} l(l+1 / 2)(l+1)} \tag{2.33}
\end{equation*}
$$

Using Eq. (2.33) in Eq. (2.32) and after doing some mathematical manipulation, the final results is

$$
\begin{equation*}
\Delta E_{2}=-E_{n} \frac{(Z \alpha)^{2}}{2 n}\left[\frac{j(j+1)-l(l+1)-3 / 4}{l(l+1 / 2)(l+1)}\right] \tag{2.34}
\end{equation*}
$$

Because $j$ can take on the values $l \pm 1 / 2$, the correction in terms of $l$ can be written as

$$
\begin{array}{ll}
\Delta E_{2}=-E_{n} \frac{(Z \alpha)^{2}}{2 n(l+1 / 2)(l+1)} & \text { for } j=l+1 / 2 \\
\Delta E_{2}=E_{n} \frac{(Z \alpha)^{2}}{2 n(l+1 / 2)} & \text { for } j=l-1 / 2 \tag{2.35}
\end{array}
$$

Thus, as for the relativistic kinetic energy correction, the spin-orbit interaction produces a correction that is $(Z \alpha)^{2}$ times the Bohr energy.

For $l=0$, the spin-orbit interaction vanishes and therefore $\Delta E_{2}=0$ in that case.

### 2.2.3 Darwin Term

The Darwin term appears for the s-orbital due to a phenomenon in Dirac theory called Zitterbewegung, where the electron does not move smoothly but instead undergoes extremely small-scale fluctuations, causing the electron to see a smeared-out Coulomb potential of the nucleus. The Hamiltonian for the Darwin term is given by

$$
\hat{H}_{D}=\frac{\pi \hbar^{2}}{2 m^{2} c^{2}}\left(\frac{Z e^{2}}{4 \pi \varepsilon_{o}}\right) \delta(r)
$$

And the first-order correction to the energy due to the Darwin Hamiltonian is

$$
\begin{gather*}
\Delta E_{3}=\left\langle n l m_{l}\right| \hat{H}_{D}\left|n l m_{l}\right\rangle \\
\Delta E_{3}=\frac{\pi \hbar^{2}}{2 m^{2} c^{2}}\left(\frac{Z e^{2}}{4 \pi \varepsilon_{o}}\right)\left\langle n l m_{l}\right| \delta(r)\left|n l m_{l}\right\rangle \tag{2.36}
\end{gather*}
$$

Because of the $\delta$-function, the expectation value of $\Delta E_{3}$ will be non-zero only for s-states because all radial wavefunctions vanish at $r=0$ except those having $l=0$

$$
\begin{align*}
& \Delta E_{3}=\frac{\pi \hbar^{2}}{2 m^{2} c^{2}}\left(\frac{Z e^{2}}{4 \pi \varepsilon_{o}}\right)\langle n 00| \delta(r)|n 00\rangle \\
& \Delta E_{3}=\frac{\pi \hbar^{2}}{2 m^{2} c^{2}}\left(\frac{Z e^{2}}{4 \pi \varepsilon_{o}}\right) \cdot \frac{1}{\pi a_{0}^{3} n^{3}} \\
& \Delta E_{3}=-E_{n} \frac{(Z \alpha)^{2}}{n}, \quad \text { for } l=0 \tag{2.37}
\end{align*}
$$

### 2.2.4 The Lamb Shift (Radiative Correction)

The lamb shift or radiative correction is similar in nature as Darwin term and results due to vacuum or zero-point fluctuations of the quantized electromagnetic field. Due to these fluctuations, a shift in the position of electrons occur. The shift in the position of electron is given by

$$
\begin{equation*}
\left\langle(\delta x)^{2}\right\rangle \approx \frac{2 \alpha}{\pi}\left(\frac{\hbar}{m c}\right)^{2} \log \frac{1}{\alpha Z} \tag{2.38}
\end{equation*}
$$

and the Lamb shift in energy is given by

$$
\begin{equation*}
\Delta E_{4} \approx \frac{4}{3 \pi} \frac{m c^{2} Z^{4} \alpha^{5}}{n^{3}} \log \frac{1}{\alpha Z} \delta_{l, 0} \tag{2.39}
\end{equation*}
$$

For hydrogen, the Lamb shift is $\Delta \approx 660 \mathrm{MHz}$ from $2^{2} \mathrm{~S}_{1 / 2}$ towards $2^{2} \mathrm{P}_{1 / 2}$. As compared to Darwin term, the radiative corrections are smaller by a factor of $\alpha \log (1 / \alpha)$.

### 2.3 The Total Fine-Structure Correction

Because the Darwin correction to the Bohr energy can be included in the spin-orbit correction term, the total fine-structure correction can be written as

$$
\begin{equation*}
\Delta E_{F S}=\Delta E_{1}+\Delta E_{2} \tag{2.40}
\end{equation*}
$$

If $l=0$ then $\Delta E_{2}$ in Eq. (2.36) represents the Darwin term.

$$
\begin{array}{ll}
\Delta E_{F S}=E_{n} \frac{(Z \alpha)^{2}}{n^{2}}\left[\frac{n}{(l+1)}-\frac{3}{4}\right] & \text { For } j=l+1 / 2 \\
\Delta E_{F S}=E_{n} \frac{(Z \alpha)^{2}}{n^{2}}\left[\frac{n}{l}-\frac{3}{4}\right] & \text { For } j=l-1 / 2 \tag{2.41}
\end{array}
$$

Because the maximum value of $l$ is $(n-1)$, it is clear that the terms in square brackets in Eq. (2.41) can never be negative. Therefore, because $E_{n}$ is intrinsically negative, the fine structure corrections will always lower the Bohr energy.
Using $j=l \pm 1 / 2$, Eq. (2.41) can be written in terms of $j$, viz.,

$$
\begin{equation*}
\Delta E_{F S}(n, j)=E_{n} \frac{(Z \alpha)^{2}}{n^{2}}\left[\frac{n}{(j+1 / 2)}-\frac{3}{4}\right] \quad \text { For } j=l \pm 1 / 2 \tag{2.42}
\end{equation*}
$$

Although the three separate contributions depend on $l$ but the total shift in energy, $\Delta E_{F S}$, depends only on $j$, the total angular momentum quantum number.

### 2.4 Fine Structure Splitting

The non-relativistic energy levels $E_{n}$ are $2 n^{2}$ times degenerate, the factor of 2 arises due to spin of electrons. This degeneracy is partly removed by Dirac theory of relativistic treatment of electronic levels. According to Dirac theory, the non-relativistic levels $E_{n}$ depending on the principal quantum number $n$ splits into $n$ sublevels, one for each value of total angular momentum $(j=l+s)$ quantum number $j=1 / 2,3 / 2, \ldots \ldots n-1 / 2$. This splitting is called 'fine structure splitting', and $n$ levels $j=1 / 2,3 / 2, \ldots \ldots . n-1 / 2$ are said to form a 'fine structure multiplet'. The dimensionless constant $\alpha \cong 1 / 137$ controls the scale of splitting and it is for this reason that it has been named as fine structure constant. All three
relativistic corrections, i.e. $H_{r}, H_{s o}, H_{D}$, contribute to the fine structure splitting but for the most part, the dominant is the spin-orbit correction.

### 2.5 The Central Field Approximation

Schrödinger's equation (both relativistic and non relativistic) are single particle equations i.e. they can only model the dynamics of a single particle. In a one electron system, one only needs to take into account the interaction between the electron and the nucleus. However, in a multielectron system the interaction with other electrons within the system must also be considered.

In moving from one electron systems to N electron systems, the following interaction must be taken into account:

- The kinetic energy of the electrons and their potential energy in the electrostatic field of the nucleus.
- The electrostatic force of repulsion between electrons within the atom.
- The magnetic interactions of the electronic spin with their orbital motion.
- Small effects such as spin-spin interactions between the electrons, the relativistic effects, radiative corrections and nuclear corrections.

The Hamiltonian of an N electron system is thus given as:

$$
\begin{equation*}
H=\sum_{i=1}^{N}\left(-\frac{\hbar^{2}}{2 m} \nabla_{i}^{2}-\frac{Z e^{2}}{4 \pi \varepsilon_{o} r_{i}}\right)+\frac{1}{2} \sum_{i \neq j}^{N} \frac{Z e^{2}}{4 \pi \varepsilon_{o} r_{i j}}+\sum_{i} \xi\left(r_{i}\right)\left(\vec{l}_{i} \cdot \vec{s}_{i}\right) \tag{2.43}
\end{equation*}
$$

where $r_{i}$ denotes the relative co-ordinates of the electron $i$ with respect to the nucleus, $r_{i j}=\left|r_{i}-r_{j}\right|$. The first sum in Eq. (2.43) is the single-particle Hamiltonian, the second is the mutual interaction between electrons, also known as the electrostatic interaction, and the last is the spin-orbit interaction.

The most important and fundamental aspect of a multielectron atom is the electron-electron non-symmetrical interactions and fermionic nature of electrons as indistinguishable particles. In this case Schrödinger equation cannot be separated into radial and angular part as is possible in one-electron atom. Calculations of energy eigenvalues and eigenfunctions become much more complicated and require intensive mathematical operations. Even for a simplest case of a multielectron atom, namely the two-electron He atom, an exact theoretical treatment is not possible.

To circumvent these difficulties either numerical methods or approximate models are used for such calculations. One such approximation is the Central Field Approximation in which all electron-electron and electron-nucleus interactions are averaged together to produce an effective field and any arbitrarily chosen electron $e_{i}$ moves in this effective field, that is independent of the momentary location of the other electrons. The effective field is different for each of the electrons and the field must be computed self-consistently for all the electrons. This approximation reduces the multielectron problem into one electron problem which could be solved relatively with less complexity. In order to compute effective field $\mathrm{V}_{\mathrm{c}}$ Hartree-Fock methods or self-consistent field approach is used. The method is based on a supposition of a trial centrally symmetric field which then could be
plugged into Schrödinger equation. The solution of Schrödinger equation results in energy eigenvalues and eigenfunctions.

### 2.6 Angular Momentum Coupling Schemes

In many electron atoms, for example an atom containing N electrons, there are more than two elementary angular momenta i.e. N orbital angular momenta $l_{\mathrm{i}}$ and N intrinsic spin momenta $s_{i}$. Therefore under different circumstances the order in which the momenta are coupled together can be chosen in many different ways and any specific choice is known as a coupling scheme. The eigenstates constructed for the total angular momentum out of the eigenstates of the separate angular momenta will correspond most closely to the various physical states of the atom if the coupling scheme used corresponds to the coupling of successive momenta in the order of decreasing strength of the various interactions.
Generally, the coupling schemes depend on many features. In central field approximation approach two broad limits can be set by considering the relative magnitudes of the last two terms in the many electrons Hamiltonian given in Eq. (2.43). These two terms describe two distinct interactions between the electrons: (i) residual electrostatic and (ii) spin-orbit. When residual electrostatic interaction between electrons is large compared with the spin orbit interaction, the electrons couple according to the $L S$ or Russell-Saunders [36] coupling scheme. At the other extreme end in the central field approximation is the case in which the spin-orbit interaction is large compared with the residual electrostatic interaction. The electrons then couple according to coupling scheme known as $j j$-coupling.

The ground state is usually well represented by $L S$-coupling whereas $j j$-coupling is dominated in atoms where one electron is in highly excited, for example in a Rydberg state. When neither dominates, an intermediate coupling scheme must be employed which can occur for low-lying excited states of heavy atoms.

## (i) LS-Coupling

If the physical coupling conditions existing in the atom closely approximate LS-coupling conditions i.e. when the residual electrostatic interaction is large compared to spin-orbit interaction, then the individual $\vec{l}_{i}$ are to be thought of as precessing rapidly in some complicated manner about the resultant $\vec{L}$, and the individual $\vec{s}_{i}$ similarly as precessing about their resultant $\vec{S}$. Neglecting all other interactions except the residual Coulomb interactions, then $\vec{L}$ and $\vec{S}$ are constants of the motion. The coupling of the total orbital angular momentum, $\vec{L}$ and the total spin, $\vec{S}$ give rise to the total electronic angular momentum $\vec{J}$. The maximum and minimum value of $J$ are $|\vec{J}+\vec{S}|$ and $|\vec{J}-\vec{S}|$, respectively. The electrostatic interaction usually dominates in low-lying states of light atoms where the electron(s) in the outer shell interact strongly with electrons in the inner shells known as the core. This coupling scheme is often appropriate for the ground states of atoms as well.

The electrostatic Coulomb repulsions affect only the orbital angular momenta and not the spins. Therefore it is appropriate first to couple together all the individual orbital angular momenta and the spin momenta. This gives the total orbital angular momentum i.e.,

$$
\begin{equation*}
\vec{L}=\sum_{l} \vec{l}_{i} \quad \text { and } \quad|\vec{L}|=\sqrt{L(L+1)} \hbar \tag{2.44}
\end{equation*}
$$

and the individual spins add together to give the total spin momentum i.e.

$$
\begin{equation*}
\vec{S}=\sum_{i} \vec{s}_{i} \quad \text { and } \quad|\vec{S}|=\sqrt{S(S+1)} \hbar \tag{2.45}
\end{equation*}
$$

of the atomic states. Therefore the total angular momentum of the electron shell is given by

$$
\begin{equation*}
\vec{J}=\vec{L}+\vec{S} \text { and }|\vec{J}|=\sqrt{J(J+1)} \hbar \tag{2.46}
\end{equation*}
$$

The wave functions and the quantum states can be decribed in terms of four good quantum numbers $L, S, M_{L}$ and $M_{S}$. Physically, however, the vectors $\vec{L}$ and $\vec{S}$ are always coupled together by weak spin-orbit interactions and precess about their resultant $\vec{J}$. Precession is taking place sufficiently slowly such that the magnitudes of $\vec{L}$ and $\vec{S}$ are well-defined and sum of the z-components $\left(M_{J}=M_{L}+M_{S}\right)$ is defined. Now the quantum states are described in terms of four quantum numbers $L, S, J$ and $M_{J}$.

## (ii) jj Coupling

With increasing atomic number Z , the spin-orbit interactions become more dominant and in the limit in which these interactions become much stronger than the Coulomb repulsion, the coupling conditions approach the pure $j j$-coupling scheme. The reason for its being so named is that if the residual electrostatic interaction between electrons is neglected, the electrons move quite independently of each other in a central field, each electron separately being subjected to a spin-orbit interaction. For example in a situation in which the two electrons are sufficiently far from each other such that the electrostatic interaction between them is weak then only their total electronic angular momenta, $j$, are constants of the motion because there are no torques on one electron due to the others. This is most often the case when the excited electron is in a high $n$ state and thus spends most of its time far from the others confined to the core near the nucleus.
Initially $\vec{l}_{i}$ and $\vec{s}_{i}$ of individual electrons couple to form the resultant angular momentum

$$
\begin{equation*}
\vec{j}_{i}=\vec{l}_{i}+\vec{s}_{i} \tag{2.47}
\end{equation*}
$$

Then the vectors $\vec{j}_{i}$ of different electrons couple together to give total angular momentum vector $\vec{J}$ of the atomic state, given by,

$$
\begin{equation*}
\vec{J}=\sum_{i} \vec{j}_{i} \tag{2.48}
\end{equation*}
$$

For example for two electron system, $\vec{j}=\vec{j}_{1}+\vec{j}_{2}$. The possible values of $j$ lie between $\left|\vec{j}_{1}+\vec{j}_{2}\right|$ and $\left|\vec{j}_{1}-\vec{j}_{2}\right|$.

In vector atom model each $\vec{l}_{i}$ and $\vec{s}_{i}$ precess rapidly about their resultant $\vec{j}_{i}$ and afterwards application of the residual electrostatic interaction acting as a small perturbation causes a
slower precession of $\vec{j}_{i}$ about their resultant $\vec{J}$ which is a constant of motion in both $L S$ and $j j$-coupling schemes. But in the $j j$-coupling scheme $L$ and $S$ have no meaning.
The manifold of $J$ values and the total number of quantum states are the same in all coupling scheme. There are many situations for which neither $L S$ - nor $j j$-coupling scheme are valid approximations. In such cases the Coulomb repulsion and the spin-orbit interaction for each value of $J$ is diagonalized. The coupling is then said to be intermediate.

### 2.7 Electronic Configuration in an N-electrons System

For any given value of $n$ (principle quantum number) there are $n$ possible values of $l$ (the azimuthal quantum number), for each value of $l$ there are $2 l+1$ values of $m_{l}$ and for each of these there are two possible values of $m_{s}$. The total number of electrons in state $n$ is thus $2 n^{2}$. Different states within an atom are denoted by the $s, p, d, f \ldots$. , after $f$ the sequence become alphabetical. The first four alphabets do not have any theoretical interpretation; they are historically named after the first series identified in the spectra of the alkali metals: sharp, principal, diffuse and fundamental.
These alphabets correspond to $0,1,2,3 \ldots$ values of the azimuthal quantum number respectively. The principle quantum number is written as the co-efficient of the alphabetical symbol while the number of electrons in each is written as its power.
As one move from lower level states to higher lying levels (in terms of energy), the orbital start overlapping each other; a situation called configuration mixing or configuration interaction. Since the parity is a good quantum number, configuration mixing takes place only within configurations of same parity.

## 3 Hyperfine Structure

The term Hyperfine structure refers to a collection of different effects leading to small shifts and splittings in the energy levels of atoms, molecules and ions. The name is a reference to the fine structure which results from the interaction between the magnetic moments associated with the electron spin and the electrons orbital angular momentum. Hyperfine structure, with energy shifts typically orders of magnitude smaller than the fine structure, results from the interactions of the nucleus with the internally generated electric and magnetic fields.
In 1924, Pauli suggested that many nuclei have an angular momentum, which is characterized by quantum number $I$ and associated with it a magnetic dipole moment $\mu_{I}$ which is of the order of 1000 times smaller than a Bohr magneton. The interaction of this moment with the magnetic field produced by the valance electrons causes a small splitting of the energy levels of an atom and provides the largest contribution to the observed hyperfine structures.

Anomalies in the spacing of these hyperfine structures later led to the discovery of an electrostatic interaction due to the deviations of nuclear charge distribution from spherical symmetry which can be expressed as quadrupole moment $Q$.

Different isotopes of an element have generally different values of $I, \mu_{I}$ and $Q$ and shows different hyperfine structures. But also the centres of gravity of these hyperfine structures are often found to be displaced relative to one another. This isotopic shift is most easily observed in isotopes where the nuclei having no spin and therefore the energy levels show no hyperfine structure.

Isotopic shifts are due to two entirely different causes. The difference in the nuclear mass for different isotopes gives rise to a shift which is appreciable for the lighter elements but decreases rapidly with increasing atomic weight. The larger isotopic shifts observed in heavy elements are caused by the finite size of the nuclear charge distribution which differs for different isotopes and causes a slightly different electrostatic field to act on the electrons in the immediate vicinity of the centre of attraction (due to differences in the charge distribution of the nucleus for different isotopes). The study of these volume- or field-effects has contributed to the knowledge of the size and shape of nuclei. The quantity which governs the isotopic shift is the second radial moment of the nuclear charge distribution. This quantity is called "nuclear mean square charge radius", and can be considered as a monopole moment of the nucleus.

### 3.1 Nuclear Magnetic Moments

The magnetic moment of a nucleon is made up of the orbital and spin angular momenta

$$
\begin{equation*}
\mu=g_{l} l+g_{s} s \tag{3.1}
\end{equation*}
$$

The orbital magnetic moment of a proton is defined by the formula

$$
\begin{equation*}
\mu=\frac{e \hbar}{2 m_{p} c} l, \tag{3.2}
\end{equation*}
$$

where $m_{p}$ is the mass of the proton.

The magnetic moments of nuclei is usually express in nuclear magnetons, i.e. in the units

$$
\begin{equation*}
\frac{e \hbar}{2 m_{p} c}=\left(\frac{m}{m_{p}}\right) \mu_{o} \tag{3.3}
\end{equation*}
$$

In term of these units the factor $g_{l}$ for a proton equals unity and neutrons with zero electric charge has $\mathrm{g}_{l}=0$.

The intrinsic magnetic moment of a proton is directed along the spin and its experimentally measured value is $\mathrm{g}_{s}=5.58$. The intrinsic magnetic moment for a neutron is directed against the spin and $\mathrm{g}_{s}=-3.82$. Thus,

$$
\begin{array}{lll}
\text { Proton: } & \mathrm{g}_{s}=5.58, & \mathrm{~g}_{l}=1,  \tag{3.4}\\
\text { Neutron: } & \mathrm{g}_{s}=-3.82, & \mathrm{~g}_{l}=0
\end{array}
$$

In the framework of the independent-particle model, the operator of the magnetic moment of the nucleus is defined by the sum of single-nucleon operators i.e.

$$
\begin{equation*}
\mu=\Sigma\left(g_{l} l+g_{s} s\right) \tag{3.5}
\end{equation*}
$$

The mean value of Eq. (3.5) in a state with a given value of nuclear spin $I$ is directed along $I$, therefore $\langle\mu\rangle$ can be expressed in terms of $I$

$$
\begin{equation*}
\langle\mu\rangle=g_{I} I . \tag{3.6}
\end{equation*}
$$

The factor $g_{I}$ in Eq. (3.6) is called the gyromagnetic ratio. To find $g_{I}$, it is necessary to calculate the matrix element of one of the components of $\mu$, for example

$$
\begin{equation*}
\left\langle\gamma m_{I}\right| \mu_{z}\left|\gamma m_{I}\right\rangle=\left\langle\gamma m_{I}\right| \Sigma\left(g_{l} l_{z}+g_{s} s_{z}\right)\left|\gamma m_{I}\right\rangle \tag{3.7}
\end{equation*}
$$

The matrix element Eq. (3.7) is proportional to $m_{I}$. Therefore, taking $m_{I}=I$, we obtain

$$
\begin{equation*}
g_{I}=\frac{1}{I}\langle\gamma I| \Sigma\left(g_{l} l_{z}+g_{s} s_{z}\right)|\gamma I\rangle \tag{3.8}
\end{equation*}
$$

The magnitude $g_{I}$ essentially depends on how the angular momenta $l$ and $s$ of the nucleus add up to the total angular momentum $I$. In the $j j$-coupling approximation the following scheme of addition of angular momenta occurs:

$$
l_{a}+s_{a}=j_{a}, \quad \sum_{a} j_{a}=J .
$$

Just as an atom, closed shells do not contribute to the nuclear spin, and so it is sufficient to take into account only the nucleons outside the closed shells. The ground state of a nucleus is always a state for which there is the maximum possible number of closed pairs $j^{2}$ with an angular momentum equal to zero. Thus, if the nucleus contains an even numbers of protons and even number of neutrons (even-even nuclei), the spin of the nucleus I and magnetic moment $\mu$ are equal to zero. If the number of neutrons and the number of protons are both odd (odd-odd nuclei), the protons and neutrons being in the states with identical values of
$j$ and the same parity, then $I=2 j$. If the number of protons is even and the number of neutrons is odd (even-odd nuclei), the spin of the nucleus is same as the angular momentum of the neutron $j_{(N)}$. On the contrary if the number of protons is odd and the number of neutrons is even (odd-even nuclei), the nuclear spin $I=j_{(P)}$. Thus, for even-odd and odd-even nuclei the spin and magnetic moment of the nucleus are determined by the last unpaired particle,

$$
I=J, \quad \mu=g_{I} I=g_{j} j .
$$

This shows that the magnitude of the magnetic moment of a nucleus essentially depends on the particular features of the construction of the nucleus. For this reason the measurement of magnetic moments of nuclei enables one to obtain valuable information about the nuclear structure.

### 3.2 Magnetic Dipole Interaction

The motion of the electrons produces a magnetic field $\vec{B}_{e}$ at the nucleus, which interacts with the nuclear magnetic moment $\vec{\mu}_{I}$. Consideration of the classical energy of orientation in the field, allows the Hamiltonian describing this interaction to be written in the form:

$$
\begin{equation*}
H_{\mu}=-\vec{\mu}_{I} \cdot \vec{B}_{e} \tag{3.9}
\end{equation*}
$$

It is assumed that this term can be treated as a small perturbation when compared with the zeroth-order Hamiltonian, $H_{0}$, which describes the central electrostatic field of atom, the repulsion between electrons, and the spin orbit interaction. Considering only the effects of $H_{\mu}$ on the states labeled by the quantum numbers ( $\gamma L S J$ ). It follows that $J$ and $I$ are good quantum numbers and that the nuclear magnetic moment may be written in the form

$$
\begin{equation*}
\vec{\mu}_{I}=g_{I} \mu_{N} \vec{I} \tag{3.10}
\end{equation*}
$$

where $g_{I}$ is the nuclear $g$-factor and $\mu_{N}=\frac{e \hbar}{2 M}$ is the nuclear magneton which depends on the proton mass $M$. The sign adopted in Eq. (3.10) differs from that of the corresponding equation for the electronic magnetic moments because the nucleus is positively charged.

The nuclear magnetic moment of the atom, $\mu_{I}$, is defined as the largest observable component of $\vec{\mu}_{I}$ :

$$
\begin{equation*}
\mu_{I}=\left\langle I, m_{I}=I\right| \mu_{z}\left|I, m_{I}=I\right\rangle=g_{I} \mu_{N} I \tag{3.11}
\end{equation*}
$$

Nuclear magnetic moments are typically 2000 times smaller than electronic magnetic moments since $\frac{\mu_{N}}{\mu_{B}}=\frac{m}{M} \approx \frac{1}{1836}$.

The nuclear $g$-factor, which is of the order of unity, takes account of the way the resultant nuclear moment is built up from the magnetic moments of individual nucleons. It therefore contains information about the detailed internal structure of the nucleus.

For a given atomic level characterized by the resultant electronic angular momentum quantum number $\vec{J}$ coupling with nuclear angular momentum quantum number $\vec{I}$ gives the total angular momentum quantum number $\vec{F}$ of the atom i.e.,

$$
\begin{align*}
& \vec{F}=\vec{I}+\vec{J}  \tag{3.12}\\
& F^{2}=I^{2}+J^{2}+2 \vec{I} \cdot \vec{J}  \tag{3.13}\\
& \vec{I} \cdot \vec{J}=\frac{F^{2}-I^{2}-J^{2}}{2} \tag{3.14}
\end{align*}
$$

$F$ remains a good quantum number under the application of the perturbation $H$, for hyperfine interaction does not give a torque on the atom as a whole.

Since the magnetic field at the nucleus, $\vec{B}_{e}$, is determined by the motion of orbital electrons, it follows that $B_{e} \propto J$. Thus (from the $I J$ coupling approximation) Eq. (3.9) becomes

$$
\begin{equation*}
H_{\mu}=A_{J} \vec{I} \cdot \vec{J} \tag{3.15}
\end{equation*}
$$

where $A_{J}$ is called the magnetic hyperfine interaction or coupling constant and is the quantity which is determined directly from experimental measurements. For a hydrogenic atom, or an atom with just one electron outside closed shells, $\vec{B}_{e}$ and $\vec{J}$ are anti-parallel and the constant $A_{J}$ will be positive if the nucleus has a positive value of $g_{I}$. The magnetic field at the nucleus will be zero for atoms with closed sub-shells and will be largest for those atoms with electrons in penetrating orbits. Therefore largest hyperfine splitting would be observed in atoms with unpaired s-electrons, e.g. hydrogen and the alkalis.

The interaction energy can be obtained by using the matrix elements of the operator $H_{\mu}$ i.e.

$$
\begin{equation*}
\Delta E_{\mu}=\left\langle\gamma J F m_{F}\right| H_{\mu}\left|\gamma J F m_{F}\right\rangle \tag{3.16}
\end{equation*}
$$

By substituting Eq. (3.14) in Eq. (3.16) we get an expression for the hyperfine structure energies of all $F$ levels of a hyperfine structure multiplet with respect to the atomic fine structure level $J$, viz.,

$$
\begin{gather*}
\Delta E_{\mu}=\frac{A_{J}}{2}\{F(F+1)-I(I+1)-J(J+1)\}  \tag{3.17}\\
\Delta E_{\mu}=\frac{A_{J} C}{2} \tag{3.18}
\end{gather*}
$$

where

$$
\begin{equation*}
C=F(F+1)-I(I+1)-J(J+1) \tag{3.19}
\end{equation*}
$$

and

$$
\begin{align*}
& A_{J}=\frac{\mu_{I}\langle\vec{B}\rangle}{I J} \\
& A_{J}=\frac{g_{I} \mu_{B}\langle\vec{B}\rangle}{1836 J} \tag{3.20}
\end{align*}
$$

### 3.3 Electric Quadrupole Interaction

The quadrupole moment of a nucleus is a measure of the departure of the mean distribution of nuclear charge from spherical symmetry. It is positive for a distribution which is prolate ellipsoidal, negative for an oblate distribution, and zero for a spherically symmetric distribution. Thus a non-zero electric quadrupole moment implies that the charge distribution within nucleas is no longer spherical and the nucleus is deformed.
The electrostatic interaction between a single electron and nucleus containing Z protons is

$$
\begin{equation*}
W=-\sum_{p=1}^{z} \frac{e^{2}}{\left|r_{e}-r_{p}\right|} \tag{3.21}
\end{equation*}
$$

where the origin of co-ordinates is the centre of mass of the (infinitely heavy) nucleus, $r_{e}$ is the position vector of the electron, $r_{p}$ is the position vector of pth proton and the sum is taken over all Z protons.
In order to discuss the departure of the nuclear charge distribution from spherical symmetry, higher order electric multipole moments need to be considered. Assume that $r_{e}>r_{p}$ and expanding the factor $\frac{1}{\left|r_{e}-r_{p}\right|}$ in powers of $r_{p} / r_{e}$ and in Legendre polynomials $P_{l}\left(\cos \theta_{e p}\right)$ where $\theta_{e p}$ is the angle between $r_{e}$ and $r_{p}$, Eq. (3.21) becomes:

$$
\begin{align*}
W & =-e^{2} \sum_{p=1}^{Z}\left[r_{e}^{2}+r_{p}^{2}-2 r_{e} r_{p} \cos \theta_{e p}\right]^{-1 / 2} \\
W & =-e^{2} \sum_{p=1}^{Z} \sum_{l} \frac{r_{p}^{l}}{r_{e}^{l+1}} P_{l}\left(\cos \theta_{e p}\right) \tag{3.22}
\end{align*}
$$

Applying spherical harmonic addition theorem i.e.

$$
\begin{equation*}
P_{l}\left(\cos \theta_{e p}\right)=4 \pi \sum_{m=-l}^{l} \frac{1}{2 l+1} Y_{l m}^{*}\left(\theta_{p}, \phi_{p}\right) Y_{l m}\left(\theta_{e}, \phi_{e}\right) \tag{3.23}
\end{equation*}
$$

where $Y_{l m}$ are spherical harmonics of rank $l$ and projection $m$.
Eq. (3.22) becomes

$$
\begin{equation*}
W=-4 \pi e^{2} \sum_{p=1}^{Z} \sum_{m=-l}^{l} \frac{1}{2 l+1} \frac{r_{p}^{l}}{r_{e}^{l+1}} Y_{l m}^{*}\left(\theta_{p}, \phi_{p}\right) Y_{l m}\left(\theta_{e}, \phi_{e}\right) \tag{3.24}
\end{equation*}
$$

Expressing Eq. (3.24) in more compact notation viz.,

$$
\begin{align*}
& \sum_{m=-l}^{l} Y_{l m}^{*} Y_{l m}=\sum_{m}(-1)^{m} Y_{l,-m} Y_{l m}=Y^{(l)}(\Omega) \cdot Y^{(l)}(\Omega), \\
& \left(\theta_{p}, \phi_{p}\right) \equiv\left(\Omega_{p}\right), \quad\left(\theta_{e}, \phi_{e}\right) \equiv\left(\Omega_{e}\right) \\
& Q^{(l)} \equiv e \sum_{p=1}^{Z} \sqrt{\frac{4 \pi}{2 l+1}} r_{p}^{l} Y^{(l)}\left(\Omega_{p}\right)  \tag{3.25}\\
& U^{(l)} \equiv-e \sqrt{\frac{4 \pi}{2 l+1}} r_{e}^{l+1} Y^{(l)}\left(\Omega_{p}\right) \tag{3.26}
\end{align*}
$$

Eq. (3.24) can be written as

$$
\begin{equation*}
W=\sum_{l} Q^{(l)} \cdot U^{(l)} \tag{3.27}
\end{equation*}
$$

When $l=0$, Eq. (3.27) becomes

$$
\begin{equation*}
W=Z e^{2} / r_{e} \quad(l=0) \tag{3.28}
\end{equation*}
$$

which is just the Coulomb interaction with Z being the sum over the protons. For a nucleus of finite size, there is a correction term to be added in Eq. (3.28):

$$
\begin{equation*}
\frac{2}{3} \pi e^{2} Z|\psi(0)|^{2}\left\langle R^{2}\right\rangle \tag{3.29}
\end{equation*}
$$

In which $\left\langle R^{2}\right\rangle$ is the mean square charge radius of the nucleus and $\mathrm{e}^{2}|\psi(0)|^{2}$ is the electronic charge density at the nucleus.
The term $l=1$ in Eq. (3.27) vanishes because it corresponds to the interaction between a nuclear electric dipole moment and the electric field established by the electrons. Nuclear states have well-defined parity so that the expectation value of nuclear electric dipole moment (which is an odd operator) vanishes. The next term, with $l=2$, is the electric quadrupole interaction which is the Hamiltonian $H_{Q}$

$$
\begin{equation*}
H_{Q}=Q^{(2)} \cdot U^{(2)} \tag{3.30}
\end{equation*}
$$

and is a scalar product of nuclear and electronic tensor, each of rank 2.
The matrix elements of the scalar product of two tensor operators $T^{(k)}$ and $U^{(k)}$ in the coupled representation is given by [37-38]

$$
\left\langle\alpha j_{1} j_{2} j m\right| T^{(k)} . U^{(k)}\left|\alpha_{\left.j_{1}^{\prime} j_{2}^{\prime} j_{2}^{\prime} m^{\prime}\right\rangle}\right\rangle=(-1)^{j_{1}+j_{2}+j_{1}^{\prime}} \delta_{i j j^{\prime}} \delta_{m m^{\prime}}\left\{\begin{array}{ccc}
j_{1}^{\prime} & j_{2}^{\prime} & j  \tag{3.31}\\
j_{2} & j_{1} & k
\end{array}\right\} \times \sum_{\alpha^{\prime}}\left\langle\alpha j_{1}\left\|T^{(k)}\right\| \alpha^{\prime \prime} j_{1}\right\rangle\left\langle\alpha^{\prime \prime} j_{2}\left\|U^{(k)}\right\| \alpha_{j_{2}^{\prime}}^{\prime}\right\rangle
$$

Suppose that the electronic state is characterized by angular momentum quantum numbers $J, m_{J}$, the nuclear state by $I, m_{I}$ and when the two angular momenta are coupled the
quantum numbers are $I, j, F, m_{F}$. In this case, Eq. (3.31) becomes

$$
\left\langle I J F m_{F}\right| Q^{(2)} \cdot U^{(2)}\left|I J F^{\prime} m_{F}^{\prime}\right\rangle=(-1)^{F+J+1} \delta_{F F^{\prime}} \delta_{m_{F} m_{F}^{\prime}}\left\{\begin{array}{lll}
I & J & F  \tag{3.32}\\
J & I & 2
\end{array}\right\}\left\langle I\left\|Q^{(2)}\right\| I\right\rangle\left\langle J\left\|U^{(2)}\right\| J\right\rangle
$$

The quantity in the curl bracket is a 6 j symbol whose value is given by

$$
\left\{\begin{array}{lll}
I & J & F  \tag{3.33}\\
J & I & 2
\end{array}\right\}=(-1)^{F+J+I} \times \frac{2[3 X(X+1)-4 I(I+1) J(J+1)]}{\sqrt{(2 I-1) 2 I(2 I+1)(2 I+2)(2 I+3)(2 J-1) 2 J(2 J+1)(2 J+2)(2 J+3)}}
$$

where

$$
X=I(I+1)+J(J+1)-F(F+1)
$$

In order to solve Eq. (3.32), the reduced matrix elements are evaluated. Consider the reduced matrix element for the nuclear quadrupole moment $Q$, viz.,

$$
\begin{equation*}
Q=\left\langle\operatorname{Im}_{I}=I\right| \sum_{p}\left(3 z_{p}^{2}-r_{p}^{2}\right)\left|\operatorname{Im}_{I}=I\right\rangle \tag{3.34}
\end{equation*}
$$

since

$$
\begin{equation*}
\sum_{p}\left(3 z_{p}^{2}-r_{p}^{2}\right)=2 \sum_{p} \sqrt{\frac{4}{5} \pi r_{p}^{2}} Y_{20}\left(\Omega_{p}\right)=(2 / e) Q_{0}^{(2)} \tag{3.35}
\end{equation*}
$$

where the second equality comes from Eq. (3.25), we have

$$
\begin{equation*}
\frac{1}{2} e Q=\left\langle\operatorname{Im}_{I}=I\right| Q_{o}^{(2)}\left|\operatorname{Im}_{I}=I\right\rangle \tag{3.36}
\end{equation*}
$$

Using the Wigner-Eckart Theorem i.e.,

$$
\left\langle m_{I}\right| Q_{o}^{(2)}\left|m_{I}\right\rangle=(-1)^{I-m}\left(\begin{array}{ccc}
I & 2 & I  \tag{3.37}\\
-m_{I} & 0 & m_{I}
\end{array}\right)\left\langle I\left\|Q^{(2)}\right\| I\right\rangle
$$

Setting $m_{I}=I$ and evaluating the $3 j$ symbol gives,

$$
\begin{align*}
\left\langle m_{I}=I\right| Q_{o}^{(2)}\left|m_{I}=I\right\rangle & =\sqrt{(2 I-1) 2 I(2 I+1)(2 I+2)(2 I+3)}\left\langle I\left\|Q^{(2)}\right\| I\right\rangle  \tag{3.38a}\\
& =\frac{1}{2} e Q \tag{3.38b}
\end{align*}
$$

or

$$
\begin{equation*}
\left\langle I\left\|Q^{(2)}\right\| I\right\rangle=\sqrt{(2 I-1) 2 I(2 I+1)(2 I+2)(2 I+3)} e Q \tag{3.39}
\end{equation*}
$$

It can be emphasized here from Eq. (3.38) that the nuclei with spin $I=0$ or $\frac{1}{2}$ have no quadrupole moment.

The reduced matrix element for $U^{(2)}$ can be solved in an analogous manner.
The component of $\left\langle J\left\|U^{(2)}\right\| J\right\rangle$ proceed in analogous fashion. Now a quantity "eq" is defined as

$$
\begin{equation*}
\frac{1}{2} e q=\left\langle J m_{J}=J\left\|U_{0}^{(2)}\right\| J m_{J}=J\right\rangle \tag{3.40}
\end{equation*}
$$

where, from Eq. (3.26),

$$
\begin{equation*}
U_{0}^{(2)}=\sqrt{\frac{4}{5} \pi r_{e}^{2}} Y_{20}\left(\Omega_{e}\right)=-\frac{1}{2} e \frac{3 z_{e}^{2}-r_{e}^{2}}{r_{e}^{5}} \tag{3.41}
\end{equation*}
$$

Note that

$$
\begin{equation*}
\frac{\partial^{2}}{\partial z^{2}}\left(-\frac{e}{r}\right)=-e \frac{3 z_{e}^{2}-r_{e}^{2}}{r_{e}^{5}} \tag{3.42}
\end{equation*}
$$

is the $z z$ component of the electric field gradient tensor produced by an electron at a point whose co-ordinates with respect to the electron are $(x, y, z)$. Since the origin of the coordinate system has been positioned at the nucleus, $2 U_{0}^{(2)}$ in Eq. (3.41) is the $z z$ component of the electric field gradient tensor at the nucleus produced by an electron at a distance $r_{e}$ from the nucleus, or

$$
\begin{equation*}
U_{0}^{(2)}=\frac{1}{2}\left(\frac{\partial^{2} V_{e}}{\partial z^{2}}\right)_{0} \equiv \frac{1}{2} V_{Z Z} \tag{3.43}
\end{equation*}
$$

where $V$ is the potential due to the electron and the second derivative is evaluated at the origin (nucleus). Therefore the product "eq" can be written as

$$
\begin{equation*}
e q=\left\langle J m_{J}=J\right| V_{z z}\left|J m_{J}=J\right\rangle=\left\langle V_{z z}\right\rangle \tag{3.44}
\end{equation*}
$$

which is the average or expectation value of $V_{z z}$ taken over the electronic state $|J J\rangle$.
Again the use of Wigner-Eckart theorem leads to the result

$$
\begin{equation*}
\langle J| U^{(2)}|J\rangle=\frac{1}{2} \sqrt{(2 J+1)(J+1)(2 J+3) /(2 J-1)} e q \tag{3.45}
\end{equation*}
$$

On substituting Eq. (3.33), Eq. (3.39) and Eq. (3.45) into Eq. (3.32), we have

$$
\begin{equation*}
\left\langle I J F m_{F}\right| Q^{(2)} \cdot U^{(2)}\left|I J F^{\prime} m_{F}^{\prime}\right\rangle=\frac{e^{2} q Q}{2 I(2 I-1) J(2 J-1)}\left[\frac{3}{4} X(X-1)-I(I-1) J(J+1)\right] \tag{3.46}
\end{equation*}
$$

The quantity $e^{2} q Q$ is known as the quadrupole coupling constant and $X$ is the same quantity as in Eq. (3.33). The quadrupole coupling constant may be positive or negative, depending upon $Q$ is positive or negative respectively. Using vector sum and scalar product of $\vec{I}$ and $\vec{J}$ i.e.

$$
\vec{F}=\vec{I}+\vec{J} \quad \text { and } \quad-2 \vec{I} \cdot \vec{J}=I^{2}+J^{2}-F^{2}
$$

Eq. (3.46) becomes

$$
\begin{equation*}
\left\langle I J F m_{F}\right|-2 \vec{I} . \vec{J}\left|I J F^{\prime} m_{F}^{\prime}\right\rangle=I(I+1)+J(J+1)-F(F+1)=X \tag{3.47}
\end{equation*}
$$

Thus

$$
\begin{equation*}
\left\langle I J F m_{F}\right| 3(\vec{I} . \vec{J})^{2}+\frac{3}{2}(\vec{I} . \vec{J})-I^{2} J^{2}\left|I J F^{\prime} m_{F}^{\prime}\right\rangle=\frac{3}{4} X(X-1)-I(I+1) J(J+1) \tag{3.48}
\end{equation*}
$$

Comparing the above equation with Eq. (3.46) gives,

$$
\begin{equation*}
H_{Q}=Q^{(2)} \cdot U^{(2)}=\frac{e^{2} q Q}{2 I(2 I-1) J(2 J-1)}\left[3(\vec{I} \cdot \vec{J})^{2}+\frac{3}{2}(\vec{I} . \vec{J})-I^{2} J^{2}\right] \tag{3.49}
\end{equation*}
$$

Eq. (3.49) can be written alternatively as

$$
\begin{equation*}
H_{Q}=Q^{(2)} \cdot U^{(2)}=\frac{B_{J}}{2 I(2 I-1) J(2 J-1)}\left[3(\vec{I} \cdot \vec{J})^{2}+\frac{3}{2}(\vec{I} \cdot \vec{J})-I^{2} J^{2}\right] \tag{3.50}
\end{equation*}
$$

where $B_{J}$ is known as the electric quadrupole interaction and can be expressed as a product of the quadrupole moment and the electric field gradient produced by the orbital electrons at the position of the nucleus i.e.

$$
\begin{equation*}
B_{J}=e Q\left\langle\frac{\partial^{2} V_{e}}{\partial z^{2}}\right\rangle \tag{3.51}
\end{equation*}
$$

Hyperfine structure measurements on free atoms enable the values of $B_{J}$ to be determined experimentally. However, the nuclear electric quadrupole moment can then only be calculated if theoretical estimates of the field gradient exist.

The quadrupole interaction causes a shift in hyperfine structure levels and do not produce splitting. The shift in energy is given by

$$
\begin{gather*}
\Delta E_{Q}=\left\langle I J F m_{F}\right| H_{Q}\left|I J F^{\prime} m_{F^{\prime}}\right\rangle \\
\Delta E_{Q}=\frac{B_{J}}{4} \frac{\frac{3}{2} C(C+1)-2 I(I+1) J(J+1)}{I(2 I-1) J(2 J-1)} \tag{3.52}
\end{gather*}
$$

where $C$ is

$$
C=F(F+1)-J(J+1)-I(I+1)
$$

This interaction vanishes for $S$ terms, because $\left\langle\frac{\partial^{2} V_{e}}{\partial z^{2}}\right\rangle$ vanishes when the electron charge distribution is spherically symmetrical. The interaction also vanishes unless $I \geq 1, J \geq 1$.

### 3.4 Hyperfine (hf) Structure

In the absence of nuclear magnetic dipole or electric quadrupole interactions, the zerothorder wavefunctions $\left|\gamma I m_{J} m_{I}\right\rangle$ are $(2 I+1)(2 J+1)$-fold degenerate in the nuclear and electronic magnetic quantum numbers. To evaluate the energy shift arising from the hyperfine interaction, we take linear combinations of the functions $\left|\gamma I m_{J} m_{I}\right\rangle$ to form new zeroth-order wavefunctions $\left|\gamma J I F m_{F}\right\rangle$ for which the total angular momentum $F$ and the projection $m_{F}=m_{J}+m_{I}$ are good quantum numbers. The magnetic interaction $A_{J} \vec{I} \cdot \vec{J}$ cause $\vec{I}$ and $\vec{J}$ to precess rapidly about the resultant total angular momentum

$$
\begin{equation*}
\vec{F}=\vec{I}+\vec{J} \tag{3.5}
\end{equation*}
$$

The energy of a specific hyperfine level is then given by

$$
\begin{gather*}
E_{F}=\left\langle\gamma J I F m_{F}\right| H_{0}+H_{H F S}\left|\gamma J I F m_{F}\right\rangle  \tag{3.54}\\
E_{F}=E_{J}+\frac{1}{2} A_{J} C+\frac{B_{J}}{8 I(2 I-1) J(2 J-1)}\{3 C(C+1)-4 I(I+1) J(J+1)\} \tag{3.55}
\end{gather*}
$$

where $C$ is

$$
\begin{equation*}
C=F(F+1)-I(I+1)-J(J+1) \tag{3.56}
\end{equation*}
$$

The first term in Eq. (3.55) is the energy of a fine structure multiplet level with total electronic angular momentum quantum number $J$, the second term is the magnetic hyperfine interaction which causes the splitting of fine structure level and the third term is the electric quadrupole interaction producing shift in energy.
Eq. (3.55) shows that the magnetic and electric interaction between a nucleus and the orbital electrons which splits a given fine structure level into hyperfine structure multiplet. The number of hyperfine structure levels depend on the number of possible orientations of the angular momentum vectors $\vec{I}$ and $\vec{J}$ i.e. a fine level splits into $2 I+1$ if $J \geq I$ and $2 J+1$ if $I \geq J$ hyperfine structure levels.

The total width of the splitting between levels $|I-J|$ to $|I+J|$ is

$$
\begin{gathered}
\Delta W=A_{J} I(2 J+1) \text { for } J>I \\
\text { and } \\
\Delta W=A_{J} J(2 I+1) \text { for } J<I
\end{gathered}
$$

The hyperfine structure splitting is in the range of $10^{-3}$ to $1 \mathrm{~cm}^{-1}$ and is smaller than the fine structure splitting. This is due to the fact that $\vec{S}$ and $\vec{L}$ are strongly coupled to each other as compared to their resultant coupling with the nuclear spin $\vec{I}$.

When $A_{J}>0$ the hyperfine level having smallest possible value of $F$ has the lowest energy value, and known as normal hyperfine multiplet. When $A_{J}<0$ then the level having largest possible value of $F$ has the lowest energy value. Such hyperfine multiplet is known as inverted multiplet. Physically it can be explained in the following manner: If the spinning
electron and nucleus are considered as small magnets which influence each other at a certain distance, then the most stable position would be one for which their magnetic moments are in opposite directions and the mechanical moments are in the same direction. This leads to normal hyperfine splitting of fine structure level such that smallest F lies deepest. In the reverse case the highest F value lays deepest i.e. inverted hyperfine structure levels.

### 3.5 Radiative Transitions between Hyperfine Structure Components

The electric dipole transitions between the components of the hyperfine structure of two levels $\gamma J$ and $\gamma^{\prime} J^{\prime}$, assuming that transitions between these levels are allowed depending on selection rules, obey additional selection rules

$$
\begin{equation*}
\Delta F=0, \pm 1 ; \quad F+F^{\prime} \geq 1 \tag{3.57}
\end{equation*}
$$

The electric dipole transitions between components of the hyperfine structure of the same level are forbidden by the parity selection rule. Only the magnetic dipole transitions and the electric quadrupole transitions are allowed. In the first case, the selection rules (3.57) apply and in the second

$$
\begin{equation*}
\Delta F=0, \pm 1, \pm 2 ; F+F^{\prime} \geq 2 \tag{3.58}
\end{equation*}
$$

### 3.6 Landé Interval Rule

The relative spacing of hyperfine levels obeys Landé interval rule which states that "the energy spacing between successive hyperfine levels $F-1$ and $F$ is proportional to $F$ ' i.e.

$$
\begin{gather*}
\Delta E_{\mu}(F, F-1)=E_{\mu}(F)-E_{\mu}(F-1) \\
\Delta E_{\mu}(F, F-1)=\frac{A_{J}}{2}[F(F+1)-(F-1) F]=A_{J} F \tag{3.59}
\end{gather*}
$$

This rule is analogous to the Landé interval rule for the fine structure multiplet splitting. Just as in the case of the fine structure splitting "the centre of gravity" of the hyperfine structure of a level is not shifted.

$$
\begin{equation*}
\sum_{F}(2 F+1) \Delta E_{F}=0 \tag{3.60}
\end{equation*}
$$

The energy of a particular hyperfine structure level is given by

$$
\begin{equation*}
E_{F}=E_{J}+\frac{1}{2} A_{J} C+\frac{B_{J}}{8 I(2 I-1) J(2 J-1)}\{3 C(C+1)-4 I(I+1) J(J+1)\} \tag{3.61}
\end{equation*}
$$

where $C$ is

$$
C=F(F+1)-I(I+1)-J(J+1)
$$

From Eq. (3.61) it is clear that the quadrupole interaction gives rise to a departure from the interval rule because its dependence on $F$ is different from that of the magnetic dipole
interaction. Therefore interval rule for the hyperfine levels is valid only for $B_{J}=0$. Also deviation from the interval rule is more prominent whenever the quadrupole constant $B_{J}$ is comparable in magnitude with the magnetic constant $A_{J}$. Furthermore it is to be noted that the interval rule for a line with the hyperfine splitting is valid only if:

- The interval rule is obeyed by the individual hyperfine structure splitting of both the combining levels
- $\Delta J=0$

For $\Delta J= \pm 1$, it does not hold with the exception of one situation where A-value of one of the combining levels is so small as compared to the A-value of the other level that it can be neglected. In such a situation the hyperfine structure pattern of the line reflects the hyperfine splitting of the level with $\mathrm{A} \neq 0$.

### 3.7 Intensity Rule for Hyperfine Components

The hyperfine structure term with a given $F$ has a statistical weight $(2 F+1)$. In hyperfine multiplets, this statistical weight is important for the determination of intensity ratios between hyperfine structure components. The relative intensities within a hyperfine multiplet is found to obey the intensity or the sum rule discovered empirically by Ornstein, Burger and Dorgelo [39-40]. It can be stated as
"within a hyperfine multiplet, the ratio of the sums of the intensities of all the transitions from two states with quantum numbers $F$ and $F^{\prime}$ are in the ratio of their statistical weights $(2 F+1):\left(2 F^{\prime}+1\right)$ ".

If the splitting of one of the levels is negligibly small, the intensities of the lines are simply in the ratio of the values $2 F+1$ of the level whose splitting causes the structure. This offer a means for determining the value of $I$.
In order to determine the value of $I$ from a measured intensity ratio, one only has to distinguish between either different half-integral or different integral values, according to whether the mass number is odd or even. It is evident that the accuracy needed for the determination of $I$ is greater, the higher the value of $I$.

If the value $J$ of the level causing the splitting is sufficiently large, the nuclear spin $I$ can be deduced from the number of components, provided the resolution is complete enough. The number of component is, then, simply equals to $2 I+1$.

For a dipole transition the connecting atomic states with total electronic orbital angular momentum $J_{o}$ and $J_{u}$ and with nuclear spin $I$, the line strength $S\left(F_{o} \rightarrow F_{u}\right)$ of the hyperfine components connecting $F_{o}$ and $F_{u}$ is given by the expression

$$
S\left(F_{o} \rightarrow F_{u}\right)=\frac{\left(2 F_{o}+1\right)\left(2 F_{u}+1\right)}{2 I+1}\left\{\begin{array}{lll}
J_{o} & F_{o} & I  \tag{3.61}\\
F_{u} & J_{u} & 1
\end{array}\right\}^{2}
$$

Above equation is applicable in cases where interactions between neighbouring levels are weak, so that $J_{o}$ and $J_{u}$ are good quantum numbers. The strongest components of hyperfine structure multiplet are those for which $F$ and $J$ change in the same direction and are called diagonal lines or components, i.e.

$$
\begin{equation*}
\Delta F=\Delta J \tag{3.62}
\end{equation*}
$$

and the line strength of diagonal lines increases with increasing $F$. The other two groups of weaker lines with $\Delta F \neq \Delta J$ are called off-diagonal lines and usually are strongest for intermediate values of $F$. For $\Delta J \neq 0$, one group of off-diagonal lines with $\Delta F=0$ are stronger than the other group i.e. $\Delta F=-\Delta J$. For $\Delta J=0$, both groups of off-diagonal lines are of equal intensity. Physical interpretation of Eq. (3.62) is that since the nuclear spin is so weakly coupled to the electronic system that it does not affect the total radiation of the atom with a given $J$. But by forcing $J$ into a certain orientation with regard to $F$ it affects the statistical weight of the level and causes a certain distribution of radiation over the hyperfine structure components.

### 3.8 Experimental Determination of Hyperfine Constants

The hyperfine interaction energy has two contributions, (i) magnetic moment of the nucleus interacting with the magnetic field produced by the spinning and orbiting electrons, (ii) electrostatic interaction of electrons with asymmetric charge distribution inside the nucleus. Eq. (3.46) can be written as

$$
\begin{equation*}
\Delta E=\alpha . h . A_{J}+\beta . h . B_{J} \tag{3.63}
\end{equation*}
$$

where $\alpha$ and $\beta$ are Casimir Factors and are functions of total orbital angular momentum of electrons $J$ and total angular momentum $F$ of atom with spin $I$, viz.

$$
\begin{equation*}
\alpha=\frac{1}{2}[F(F+1)-I(I+1)-J(J+1)]=\frac{C}{2} \tag{3.64}
\end{equation*}
$$

and

$$
\begin{equation*}
\beta=\frac{\frac{3}{4} C(C+1)-I(I+1) J(J+1)}{2 I J(2 I-1)(2 J-1)} \tag{3.65}
\end{equation*}
$$

The electric dipole transition between the two different fine structure levels having hyperfine splitting $\Delta E$ follows selection rules $\Delta J=0, \pm l$ and $\Delta F=0, \pm l$. As photon carries angular momentum therefore transition between two hyperfine levels each having $F=0$ is forbidden. For electric dipole transitions parities of the combining fine structure levels must be different. Each allowed transition represents a component of the hyperfine structure pattern of a spectral line with component positions given by

$$
\begin{equation*}
v=v_{c}+\alpha_{o}\left(F_{o}, J_{o}, I\right) A_{o}+\beta_{o}\left(F_{o}, J_{o}, I\right) B_{o}-\alpha_{u}\left(F_{u}, J_{u}, I\right) A_{u}-\beta_{u}\left(F_{u}, J_{u}, I\right) B_{u} \tag{3.66}
\end{equation*}
$$

$v_{c}$ is the energy difference between the fine structure levels and experimentally it is the excitation energy for the combining lower and upper fine structure levels. The upper level is labelled by the letter 'o' (German word "oben", means upper) and lower level is labelled by the letter 'u' (German word "unten", means lower). Apart from $v_{\mathrm{c}}$, Eq. (3.66) contains $A_{o}, B_{o}, A_{u}$ and $B_{u}$ as unknown quantities. Thus, for experimental determination of hyperfine constants from a given spectrum, it is necessary to identify the quantum numbers of at least 5 hyperfine components and to measure their (absolute or relative) positions. If one can identify more than 5 components, a least square method has to be used to calculate the hyperfine constants.

## 4 Laser Spectroscopy

The invention of the laser has brought spectacular advances in all fields of science and technology and especially in the branch of precision spectroscopy of atoms and molecules. Classical spectroscopic techniques have two major drawbacks (i) low intensity of excitation source (ii) lack of resolution of the dispersing device. The availability of widely tunable and intense highly monochromatic laser light sources has not only greatly increased the sensitivity and resolution of classical spectroscopic techniques, but also helped in rediscovering old spectroscopic techniques such as Raman spectroscopy and discovering many powerful new techniques of non-linear spectroscopy. Furthermore, laser light interaction with atoms and molecules is not just limited to their spectroscopic investigations but now the laser light is also used as a tool to manipulate atoms such as in the field of laser cooling and trapping of atoms. The high resolution and high monochromaticity of the laser beam can be used in Doppler free spectroscopy where highresolution spectra can readily be obtained. In recent years, femtosecond (fs) lasers have been developed which are able to generate very short pulses as short as 4 femtoseconds. Commercially available femtosecond lasers can generate pulses less than 30 fs. Many processes in physics, chemistry and biology occur on a very short time scale and femtosecond laser spectroscopy has been widely used to investigate such processes. In multiphoton spectroscopy, where the high peak power of a short pulse laser allow the absorption not of one photon but two or more photons. This method has an advantage that it allows for the excitation energies not available from one photon, for instance excitation of molecules in the UV or VUV using visible light. Furthermore, multiphoton spectroscopy follows different selection rules and has different polarization dependence and therefore can be used to reach states not accessible with one photon.

In the following sections a detailed description of various line broadening mechanisms is given which is then followed by a short description of tunable lasers, with a particular emphasis on a ring dye laser system. The rest of the chapter is devoted to the discussion of different laser spectroscopic techniques.

### 4.1 Spectral Line Profile

The theories of atomic and molecular structure give the concepts of quantum numbers and angular momenta which provide an insight concerning the discreteness of energy levels of atoms, ions and molecules. This discrete nature of energy levels leads to discrete spectral features which are characteristic of particular atomic or molecular specie. Furthermore, selection rules provide basic criteria for the radiative transitions which occur between energy levels. From this one might infer that the spectroscopic transitions involve purely monochromatic radiations and that the associated observed spectral lines would be infinitely narrow, delta function "spikes".
Contrary to this, even the most casual inspection of any spectrum cast strong doubts on such an inference. Experimentally it is observed that the spectral lines consists of some intrinsic distribution of frequencies, $I(v)$, about the center frequency $v_{o}$. This distribution of frequencies give a characteristic shape to a spectral line and is known as spectral line profile. The characteristic shape and finite line width of spectral lines are determined by the physical conditions existing within the source of the spectrum.
Depending on the physical conditions prevailing inside an ensemble of atoms, the spectral line broadening mechanisms can be divided into two broad categories i.e.
(i) homogeneous broadening, and (ii) inhomogeneous broadening.

The spectral line profile is said to be homogeneously broadened if all of the atoms within the sample experience identical physical conditions. In other words, the spectral line profile for the transition $\Psi_{k} \rightarrow \Psi_{i}$, is homogeneously broadened if the transition probability as a function of frequency $P(\omega)$ is identical for all atoms within the ensemble that are in the initial state $\Psi_{k}$.
The spectral line profile is said to be inhomogeneously broadened if different subsets of the atoms within the sample experience different physical conditions. In other words, the spectral line profile for the transition $\Psi_{k} \rightarrow \Psi_{i}$, is inhomogeneously broadened if the transition probability $P(\omega)$ is different for different sub-ensembles of atoms that are in the initial state $\Psi_{k}$.

Natural, collisional and power broadening mechanisms are examples of homogenous broadening mechanism and are well described by normalized Lorentzian line profiles with center frequency $\omega_{o}$ and full width $\gamma$. Doppler broadening is a form of inhomogenous broadening and is described by a Gaussian line profile.

### 4.1.1 Natural Linewidth and the Lorentzian Line Profile

Consider a hypothetical two energy level atom, which is isolated and is at rest. One of the level is the stable ground level $E_{i}$ and the other is the excited level $E_{k}$. Furthermore, it is assumed that each energy level is singly degenerate and excited state decay only via spontaneous radiative transition $E_{i} \rightarrow E_{k}$. The energy separation between excited and stable ground levels is given by

$$
\begin{equation*}
\Delta E=h v_{o}=\hbar \omega_{o} \tag{4.1}
\end{equation*}
$$

Corresponding to such an idealized atom the spectral line profile associated with transition is examined. The system can be described by a classical damped harmonic oscillator with characteristic frequency $\omega_{o}$ and mass $m$. Radiative energy loss leads to damping of the oscillations which is characterized by the damping constant $\gamma$. The amplitude of oscillation can be obtained by solving second order differential equation, viz.

$$
\begin{equation*}
\ddot{x}+\gamma \dot{x}+\omega_{o}^{2} x=0 \tag{4.2}
\end{equation*}
$$

In the limit of small damping i.e. where $\gamma$ is much smaller than $\omega_{0}$, the time dependent amplitude of the oscillation is given by

$$
\begin{equation*}
A(t)=A_{o} \exp \left(\frac{-\gamma t}{2}\right) \cos \omega_{o} t \tag{4.3}
\end{equation*}
$$

where $A_{o}$ is the amplitude at time $t=0$ and the exponential term describes the time dependent damping. Using Eq. (4.3) and an expression for the energy of the oscillator, damping constant can be determined and is given as

$$
\begin{equation*}
\gamma=\frac{2}{3} \frac{e^{2} \omega_{o}^{2}}{m c^{3}\left(4 \pi \varepsilon_{o}\right)}=\frac{2 \pi e^{2} v_{o}^{2}}{3 \varepsilon_{o} m c^{3}} \tag{4.4}
\end{equation*}
$$

Now damped oscillations are of the form shown in Figure 4.1(a) with the amplitude decaying exponentially in time. The oscillations have a lifetime $\tau_{\text {class }}=1 / \gamma$. An infinite
wave train of constant amplitude is truly monochromatic. Thus the frequency of the emitted radiation is no longer monochromatic. The Fourier transformation of Eq. (4.3) from the time domain into the frequency domain gives Eq. (4.5) which describes the intensity of the line as a function of frequency, viz.

$$
\begin{equation*}
I\left(\omega-\omega_{o}\right)=I_{o}\left[\frac{1}{\left(\omega-\omega_{o}\right)^{2}+(\gamma / 2)^{2}}\right] \tag{4.5}
\end{equation*}
$$

Changing from $\omega$ to $\nu$, gives

$$
\begin{equation*}
I\left(v-v_{o}\right)=I_{o}\left[\frac{(\gamma / 4 \pi)^{2}}{\left(v-v_{o}\right)^{2}+(\gamma / 2)^{2}}\right] \tag{4.6}
\end{equation*}
$$

where $I_{0}$ is the central intensity. $\mathrm{I} / \mathrm{I}_{\mathrm{o}}$ in Eq. (4.6) gives the normalized Lorentzian line profile as shown in Figure 4.1 (b).

The Lorentzian or natural line profile is defined completely by two quantities; (i) the center frequency at which the line intensity is at its maximum and (ii) the full width at half maximum (FWHM) intensity, that is the width between the two points at which $I(\omega)=$ $I\left(\omega_{o}\right) / 2$. Inspection of Figure 4.1(b) clearly illustrates that the center frequency is exactly the characteristic frequency of the damped harmonic oscillator, $\omega_{o}$; and that the full linewidth is exactly given by the damping coefficient $\gamma$. The linewidth can also be expressed in terms of frequency or in terms of wavelength by the following equation, i.e.

$$
\begin{equation*}
\gamma=\Delta \omega=2 \pi \Delta \nu=\frac{2 \pi c \Delta \lambda}{\lambda_{o}^{2}} \tag{4.7}
\end{equation*}
$$

and the relative width are the same and are given as;

$$
\begin{equation*}
\left|\frac{\Delta \omega}{\omega_{o}}\right|=\left|\frac{\Delta v}{v_{o}}\right|=\left|\frac{\Delta \lambda}{\lambda_{o}}\right| \tag{4.8}
\end{equation*}
$$

The derivation of natural or Lorentzian line profile is based on the assumption that a single oscillator corresponds to a single isolated atom. But the result applies equally well to an ensemble of randomly phased oscillators corresponding to a collection of identical atoms under identical physical conditions that radiate at the identical center frequency, but at random times.
Heisenberg's Uncertainty Principle can also be used for an equivalent description of the natural line profile. This quantum mechanical approach is more consistent with the description of atoms and provides greater insight in physical conditions prevailing inside the atom. The uncertainty principle expressed in terms of momentum and position is given by

$$
\begin{equation*}
\Delta p \Delta x \geq \frac{\hbar}{2} \tag{4.9}
\end{equation*}
$$

where $\Delta p$ and $\Delta x$ are the uncertainties in linear momentum and position, respectively. The uncertainty principle can be utilized for any pair of conjugate variables of dimension energy Xtime viz.

$$
\begin{equation*}
\Delta E \Delta t \geq \frac{\hbar}{2} \tag{4.10}
\end{equation*}
$$

where $\Delta E$ is the uncertainty in energy measurement and $\Delta t$ is the uncertainty in time. Now for an excited electronic state $\Psi_{k}$, having a mean radiative lifetime $\tau_{k}$, the energy can best be determined with an inherent uncertainty of

$$
\begin{equation*}
\Delta E \geq \frac{\hbar}{2 \tau} \tag{4.11}
\end{equation*}
$$

Figure 4.1: (a) Time-dependent amplitude of a classical damped harmonic oscillator. (b) Corresponding normalized Lorentzian line profile

Combining Eq. (4.1) and Eq. (4.11) gives an uncertainty in frequency $\Delta \omega$ for a transition terminating in a stable ground state, i.e.

$$
\begin{equation*}
\Delta \omega \approx \frac{1}{\tau_{k}} \tag{4.12}
\end{equation*}
$$

Thus from the above equation one can conclude that for an idealized two-level atom, the natural line width is determined by the mean spontaneous radiative lifetime, $\tau_{k}$, of the upper state. The transition probability $A_{k i}$ or Einstein coefficient for spontaneous radiative decay from the upper state $\Psi_{k}$ to the ground state $\Psi_{i}$ in the idealized two-level atom is given by

$$
A_{k i}=\frac{1}{\tau_{k i}}
$$

From quantum electrodynamics the transition probability or Einstein coefficient for spontaneous radiative decay from the upper state $\Psi_{k}$ to the ground state $\Psi_{i}$ is proportional
to the matrix elements of the operator $H^{\prime}(r)$ i.e.

$$
\begin{equation*}
\left.A_{k i} \propto\left|\left\langle\psi_{i}(r)\right| H^{\prime}(r)\right| \psi_{k}(r)\right\rangle\left.\right|^{2} \tag{4.14}
\end{equation*}
$$

where $H^{\prime}(r)$ is the perturbation, or physical interaction that couples the atom and the photon thus resulting in the spontaneous radiative transition. The potential perturbations are the electric dipole ( $E 1$ ), magnetic dipole ( $M 1$ ), or electric quadrupole ( $E 2$ ) interactions. For the specific case of an electric dipole (E1) allowed, spontaneous radiative transition, Eq. (4.14) becomes:

$$
\begin{equation*}
\left.A_{k i}=\left(\frac{\omega_{k i}^{3}}{3 \pi \varepsilon_{o} \hbar c^{3}}\right)\left(\frac{1}{g_{k}}\right)\left|\left\langle\psi_{i}(r)\right|+e \vec{r} \cdot \vec{E}\right| \psi_{k}(r)\right\rangle\left.\right|^{2} \tag{4.15}
\end{equation*}
$$

where
$\omega_{k i}$ is the center transition frequency in radians per second
$\varepsilon_{o}$ is the vacuum permittivity
$\hbar$ is the reduced Planck's constant
$c$ is the speed of light in vacuum
$g_{k}$ is the statistical weight of level $k$
$e$ is the charge of the electron
$\vec{r}$ is the position vector of the electron and
$\vec{E}$ is the electric field vector of the photon
Since the upper state is degenerate within the resolving power of the instrument, its statistical weight must be included. For example, with total angular momentum $J_{k}$, the state $\Psi_{k}$ has a statistical weight given by:

$$
\begin{equation*}
g_{k}=2 J_{k}+1 \tag{4.16}
\end{equation*}
$$

From the transition probability of spontaneous radiative decay, the intensity $I_{k i}$ of the spectral emission line is determined. Assuming that the population of excited states is uniformly distributed throughout the sample volume, and that the radiation is emitted isotropically from an optically thin source such that each emitted photon escapes from the source volume rather than being reabsorbed, the line intensity is given explicitly by

$$
\begin{equation*}
I_{k i}=\frac{n_{k} V \omega_{k i} A_{k i}}{4 \pi} \tag{4.17}
\end{equation*}
$$

where
$n_{k}$ is the number density of excited states, and
$V$ is the source volume
The number density of excited states, $n_{k}$, is determined by the physical conditions that excite the source. Thus if the relevant Einstein coefficients are known, direct comparison of observed line intensities for different transitions within the same atom can provide substantive information on the physical conditions within the source.

Now consider a more realistic atom with three energy levels i.e. two excited states and a stable ground state. In order to determine the natural linewidth of transitions from the higher excited to the lower excited electronic state, it is assumed that upper excited state $E_{i}$ decays only via spontaneous radiative transition to the lower excited state and that the lower, or intermediate excited state $E_{k}$ decays only via spontaneous radiative transition to the stable ground state. The upper and lower excited states have life times $\tau_{i}$ and $\tau_{k}$ respectively. The uncertainties of both states i.e. $\Delta E_{i}$ and $\Delta E_{k}$ contribute to the linewidth of transition. Therefore the total uncertainty

$$
\begin{align*}
\Delta E & =\Delta E_{i}+\Delta E_{k} \\
\Rightarrow \Delta \omega & =\left(\frac{1}{\tau_{i}}+\frac{1}{\tau_{k}}\right) \tag{4.18}
\end{align*}
$$

Generally the decay from both the states is not only due to spontaneous emission but also has a non-radiative relaxation contribution; therefore the line profile is determined by the total decay constants $\gamma_{i}$ and $\gamma_{k}$. The normalized line profile function is given by

$$
\begin{equation*}
g\left(\omega-\omega_{i k}\right)=\frac{\frac{1}{2 \pi}\left(\gamma_{i}+\gamma_{k}\right)}{\left(\omega_{i k}-\omega\right)^{2}+\left[\left(\gamma_{i}+\gamma_{k}\right) / 2\right]^{2}} \tag{4.19}
\end{equation*}
$$

where both $\gamma_{i}$ and $\gamma_{k}$ have contributions from radiative and non-radiative relaxations, therefore both can be expressed as a sum. $\gamma=\gamma_{R}+\gamma_{N R}$

For an electric dipole (E1) allowed emission line occurring in the visible region of the spectrum and with a typical excited state lifetime of the order of $10^{-8}$ seconds, the natural linewidth is of the order of 16 MHz or $10^{-4} \AA$. Although the excited state lifetime appear to be exceedingly short and the natural linewidth exceedingly small but both these quantities can be measured experimentally in the laboratory.

### 4.1.2 Doppler Broadening

Doppler broadening belongs to the class of inhomogeneous broadening mechanisms and is due to the random thermal motions of the atoms within the gas. In gases at low pressure, Doppler broadening is one of the major contributions to the broadening of the spectral line. Doppler broadened line profile completely conceals the Lorentzian line profile with natural linewidth.

Consider an ensemble of atoms in gas phase at low pressure which are in an effective state of thermal equilibrium within the laboratory rest frame and moving with a velocity $\vec{v}=$ $\left\{v_{x}, v_{y}, v_{z}\right\}$ relative to this rest frame. For such an ensemble the distribution of atomic speeds, $f(v) \mathrm{d} v$, is well described by a Maxwell-Boltzmann distribution such that

$$
\begin{equation*}
f(v) d v=4 \pi v^{2}\left(\frac{m}{2 \pi k_{B} T}\right)^{3 / 2} \exp \left(\frac{-m v^{2}}{2 k_{B} T}\right) d v \tag{4.20}
\end{equation*}
$$

where $v$ is the speed, m is the mass of the atom, $T$ is the temperature of the ensemble and
$k_{B}$ is the Boltzmann constant. For such an ensemble the most probable speed of any atom within the sample, $\langle v\rangle$, is a simple function of the temperature and the mass of the atom i.e.,

$$
\begin{equation*}
\langle v\rangle=\left(\frac{2 k_{B} T}{m}\right)^{1 / 2} \tag{4.21}
\end{equation*}
$$

Consider an atom in an excited state $\psi_{k}$ which undergoes a spontaneous radiative decay to a lower state $\psi_{i}$ with a characteristic central frequency $\omega_{o}$ in the rest frame of the atom. Now let the atom moving with velocity $\vec{v}$ with respect to the laboratory rest frame, then the observed frequency of the emitted photon $\omega^{\prime}$ is shifted by the Doppler effect and is given by:

$$
\begin{equation*}
\omega^{\prime}=\omega_{o}+\vec{k} \cdot \vec{v} \tag{4.22}
\end{equation*}
$$

where $\vec{k}$ is the wave vector of the photon. For an atom moving towards the observer, $\vec{k} \cdot \vec{v}>0$ and the apparent frequency is shifted to the blue of $\omega_{o}$. For an atom moving away from the observer, then $\vec{k} \cdot \vec{v}<0$ and the apparent frequency is shifted to the red of $\omega_{o}$. Assuming that the observations are made along the z-direction, then $\vec{k}=\left\{0,0, k_{z}\right\}$ and only the z-component of the velocity is of significance. Eq (4.22) with $|k|=2 \pi / \lambda$ becomes

$$
\begin{equation*}
\omega^{\prime}=\omega_{o}\left(1+\frac{v_{z}}{c}\right) \tag{4.23}
\end{equation*}
$$

At thermal equilibrium, the number of atoms $n_{k}\left(v_{z}\right) d v_{z}$ in the excited $\psi_{k}$ per unit volume within the speed interval $v_{z}$ to $v_{z}+d v_{z}$ is given by

$$
\begin{equation*}
n_{k}\left(v_{z}\right) d v_{z}=\frac{N_{k} c}{\langle v\rangle \sqrt{\pi}} \exp \left\{-\left(\frac{v_{z}}{\langle v\rangle}\right)^{2}\right\} d v_{z} \tag{4.2}
\end{equation*}
$$

where $N_{k}$ is the total density of atoms in state $\psi_{k}$, and $\langle v\rangle$ is the most probable speed as given by Eq. (4.21). Substituting the value of $v_{z}$ from Eq. (4.23) in Eq. (4.24) gives the number of atoms in state $\psi_{k}$ which are observed to emit a photon of frequency $\omega^{\prime}$ that is shifted from $\omega_{o}$ within the frequency interval $\omega$ and $\omega+d \omega$ :

$$
\begin{equation*}
n_{k}(\omega) d \omega=\frac{N_{k} c}{\omega_{o}\langle v\rangle \sqrt{\pi}} \exp \left\{-\left(\frac{c\left(\omega-\omega_{o}\right)}{\omega_{o}\langle v\rangle}\right)^{2}\right\} d \omega \tag{4.25}
\end{equation*}
$$

Since the emitted radiant power $P(\omega) d \omega$ is directly proportional to the number density $n_{k}(\omega) d \omega$ as given in Eq. (4.25), this leads to the intensity profile of a Doppler broadened spectral line, viz.

$$
\begin{equation*}
I(\omega)=I_{o} \exp \left\{-\left(\frac{c\left(\omega-\omega_{o}\right)^{2}}{\omega_{o}\langle v\rangle}\right)\right\} \tag{4.26}
\end{equation*}
$$

This describes the Gaussian line profile characterized by full linewidth $\Gamma_{\mathrm{D}}$, where the FWHM is given by

$$
\begin{equation*}
\Gamma_{\mathrm{D}}=2 \sqrt{\ln 2} \frac{\omega_{o}\langle v\rangle}{c} \tag{4.27}
\end{equation*}
$$

Substituting the value of $\langle v\rangle$ from Eq. (4.21) in Eq. (4.27) yields

$$
\begin{equation*}
\Gamma_{\mathrm{D}}=\frac{\omega_{o}}{c}\left(\frac{8 k_{B} T \ln 2}{m}\right)^{1 / 2} \tag{4.28}
\end{equation*}
$$

This quantity is known Doppler width and therefore Eq. (4.26) written in terms of Doppler width

$$
\begin{equation*}
I(\omega)=I_{o} \exp \left\{-\left(\frac{\left(\omega-\omega_{o}\right)^{2}}{0.36 \Gamma_{\mathrm{D}}^{2}}\right)\right\} \tag{4.29}
\end{equation*}
$$

From Eq. (4.28) it is clear that Doppler width is directly proportional to the transition frequency and to the square root of the temperature, and inversely proportional to the square root of the mass of the atom. Thus the largest Doppler widths are observed for high frequency spectral lines; high temperature sources; and light atoms, especially hydrogen and helium.
A comparison between Lorentzian and Gaussian line profiles is given in Figure 4.2. The line profiles have been normalized to the identical center frequency, identical maximum amplitude, and identical linewidth, thus facilitating comparison of their individual characteristics. It can be noted that the line kernels, that area of the line profile falling between the half-maximum points, are virtually indistinguishable. However, the properties of the wings are fundamentally different. Therefore at the wings the Lorentzian profile clearly has much larger amplitudes for large values of $\left(\omega-\omega_{o}\right)$ than does the Gaussian profile, this means that the intensity I approaches zero for large argument ( $\omega-\omega_{o}$ ) much faster for a Gaussian line profile than for a Lorentzian profile. Although the Gaussian linewidth is much larger than natural or Lorentzian linewidth of a spectral line even then the information about the Lorentzian line profile can be obtained from the extreme line wings. Furthermore the Doppler broadened line profile cannot be strictly represented by a pure Gaussian line profile. This is due to the fact that not all atoms with definite velocity component $v_{z}$ emit or absorb radiation at the same frequency $\omega^{\prime}$. Due to the finite lifetimes of the energy levels, the frequency response of these atoms is represented by Lorentzian line profile. In our investigation of hyperfine structure of Praseodymium atoms and ions using laser spectroscopy the observed Doppler width is around 800 MHz , while the natural width is approximately 20 MHz .

Figure 4.2: Comparison between Lorentzian and Gaussian line profile of equal halfwidth and equal height. The area below the curves is different.

### 4.1.3 Collisional or Pressure Broadening

An isolated atom will emit a spectral line of finite width. Contrary to this in any real source the atoms are subjected to the interaction forces of the neighbouring atoms, ions and electrons. This shifts the energy levels of the radiating atom and will lead to the broadening of the spectral line which is often greater than natural linewidth. The increase in linewidth depends on the density of the perturbing species and the broadening of the spectral line is known as collisional or pressure broadening.

Consider an ensemble of atoms at low pressure that is in an effective state of thermal equilibrium within the laboratory rest frame. Before addressing the effects of collisions on the spectral line profile, it is advantageous to discuss fundamentally two different kinds of collisions that occur between atoms within the ensemble. These can be distinguished as reactive or non-reactive in nature.

Chemical reactions between neutral atoms, ions or free electrons constitute reactive collisions. Such collisions change the chemical composition of the ensemble resulting in changes in the number densities of the various species present in the ensemble. This changes the intensities of the observed spectral features. Although such processes are important for excitation mechanisms leading to emission spectrum but have little relevance to the discussion of the effects of collisions on the spectral line profile. The reactive collisions are excluded as a consequence of the assumption that the atoms in the ensemble are chemically inert.

Non-reactive collision between two atoms or particles is the case in which the respective atoms or particles come into a finite separation such that the potential energies of one or both of the atoms changes which leads to changes in the energy level structure of the atoms.

Non-reactive collision is a complicated phenomenon which involves the electrostatic Coulomb interactions between each electron with both nuclei, the nuclear-nuclear Coulomb repulsion, and all electron-electron Coulomb repulsions. These interactions affect the electronic energy levels of the atoms of interest and thereby have an effect on the
observed spectrum of that atom. There are two general categories of non-reactive collisions i.e., elastic collisions and inelastic collisions. In an elastic collision only a change in the momentum and kinetic energy of the collision partners takes place and there is no change in the populations of the internal quantum states. An elastic collision between atom A in quantum state $i$ and atom $B$ is represented by the following stoichiometric equation:

$$
\begin{equation*}
A\left(v_{1}, i\right)+B\left(v_{2}\right) \rightarrow A\left(v_{1}^{\prime}, i\right)+B\left(v_{2}^{\prime}\right) \tag{4.30}
\end{equation*}
$$

where $v_{1}, v_{2}$ are velocities before collision and $v_{1}^{\prime}, v_{2}^{\prime}$ velocities after collision of the colliding partners. The quantum state, $i$, of atom $A$ is not changed in the elastic collision.
In an inelastic collision the internal quantum state populations of one or both of the collision partners change. Such an inelastic collision between atoms $A$ and $B$ with atom $A$ in an initial quantum state $k$ is also represented by a stoichiometric equation:

$$
\begin{equation*}
A\left(v_{1}, i\right)+B\left(v_{2}\right) \rightarrow A\left(v_{1}^{\prime}, k\right)+B\left(v_{2}^{\prime}\right) \quad i \neq k \tag{4.31}
\end{equation*}
$$

the atom $A$ ends up in a different quantum state $k$. In an inelastic collision the internal energy of an atom can either increase or decrease, but the total energy of the system must be conserved such that:

$$
\begin{equation*}
E_{i}+\frac{\mu v^{2}}{2}=E_{k}+\frac{\mu v^{\prime 2}}{2} \tag{4.32}
\end{equation*}
$$

where $E_{i}$ and $E_{k}$ are the initial and final internal energies of the atom, $\mu$ is the reduced mass of the system. Inelastic collisions are often called quenching collisions when they decrease the number of excited level atoms and therefore quench the fluorescence intensity.

Now let the two atoms, $A$ and $B$, separated by time-dependent distance $R_{t}(A, B)$. Further assume the energy levels of atom $A, \psi_{i}$ and $\psi_{k}$, are influenced as the atoms first approach and then recede from one another. As the atoms approach and then separate from each other, the two energy levels of atom $A$ can be differentially shifted in energy as a direct result of the varying Coulomb interactions which are functions of $R_{t}(A, B)$. Depending upon the internal structures of the respective collision partners, the electronic energy levels of atom $A$ can be shifted either to higher or to lower energy during the time interval of the collisional interaction. An energy level will be shifted to higher energy if the interaction between atoms $A$ and $B$ is repulsive and it will be shifted to lower energy if the interaction is attractive.

Both elastic and inelastic collisions cause spectral line broadening. The elastic collisions may additionally cause a line shift which depends on the potential energy curves $E_{i}(R)$ and $E_{k}(R)$. The collisional broadening produces a Lorentzian line profile, the same as that of natural broadening. But it is of increased width. In order to avoid collisional or pressure broadening, the pressure in the spectral source should be kept low. By changing the pressure and observing the corresponding change in line width the information about the collisions occurring in the gas can also be obtained. The collisions which have large impact parameter cause noticeable line broadening but can also shift the line center.

### 4.1.4 Stark Broadening

The levels of atoms or molecules in the presence of electric field split into $(2 J+1)$ stark components where $J$ is the total angular momentum quantum number. This splitting of
levels and corresponding splitting of spectral lines is called Stark effect named after $J$. Stark who first studied this effect in 1913 for hydrogen atom. In gas discharges due to strong electrical fields experienced by atoms colliding with electrons and ions can also occur. This also contributes to total line broadening and is known as Stark Broadening.

### 4.1.5 Saturation Broadening

A laser of sufficiently high intensity operating at near resonant frequency can significantly change the population densities $N_{1}$ and $N_{2}$ of an atomic system by induced absorption and emission. This saturation of population densities also causes additional line broadening and is known as Saturation Broadening. Saturation broadening is also called power broadening. The spectral line profiles for saturation broadening are different for homogeneously and for inhomogenously broadened lines. For a homogeneously broadened spectral line, the line profile is Lorentzian and for inhomogeneouly broadened spectral line, the line shape is Gaussian.

### 4.1.6 Self-Absorption Broadening

Photons emitted in one region of a source may partly be absorbed when they pass other regions, of the source. These photons may be lost as a contribution to the original spectrum line either as a result of radiative decay to a different lower level or through collisional deexcitation of the absorbing atom. This process of re-absorption is known as self-absorption. Since the absorption profile is of the same shape as the emission profile, therefore energy is selectively absorbed from the emission line, i.e., the absorption coefficient is a maximum at the centre of the line or central wavelength. This means that the intensity of spectral line is reduced proportionately more in the center then elsewhere altering the line shape and making the line appear broader. This is termed as self- absorption broadening.

### 4.1.7 Combined Line Profile or Voigt Profile

In any experiment the different line broadening mechanisms contribute to the total line width of the emitted or absorbed spectral line. One can reduce a specific line width contribution by modifying experimental parameters, e.g. Doppler broadening can be reduced by cooling the ensemble of atoms by using liquid Nitrogen or water, pressure or collisional broadening is reduced by reducing pressure, by reducing the intensity of laser light saturation broadening can be minimized. Ultimately it comes down to natural line width which is limited by the finite lifetime of the energy state.

A spectral line profile $I(\omega)$ can be obtained which include contributions from all the broadening mechanisms i.e.,

$$
\begin{equation*}
I(\omega)=I_{N}(\omega) * I_{D}(\omega) * I_{P}(\omega) * I_{S}(\omega) \tag{4.33}
\end{equation*}
$$

Where

$$
\begin{aligned}
& I_{N}(\omega) \equiv \text { Natural line profile } \\
& I_{D}(\omega) \equiv \text { Doppler line profile } \\
& I_{P}(\omega) \equiv \text { Pressure or Collisional line profile } \\
& I_{S}(\omega) \equiv \text { Saturation line profile }
\end{aligned}
$$

Natural and Collisional line broadening mechanisms have Lorentzian line shape, Doppler broadening has Gaussian Line shape, whereas Saturation broadening depending on homogeneous or inhomogeneous class give Lorentzian or Gaussian line shape. Therefore depending on line shape all the broadening mechanisms can be grouped into two classes i.e. Lorentzian and Gaussian types. So the combined line profile of a spectral line is a convolution of Lorentzian and Gaussian line profiles and is known as Voigt Profile, $I_{V}(\omega)$ i.e.

$$
\begin{equation*}
I_{V}(\omega)=I_{L}(\omega) * I_{G}(\omega) \tag{4.34}
\end{equation*}
$$

where $I_{L}(\omega)$ is the Lorentzian line profile due to broadening mechanisms which give Lorentzian line shape, $I_{G}(\omega)$ is the Gaussian line profile due to broadening mechanisms which give Gaussian line shape. In our investigations of hyperfine structure of atoms and ions we mainly observe Gaussian line profile and rarely saturation broadening is observed as excitation probability is less then what is needed for saturation effect. However, in cases where excitation probability is high, saturation effects leads to saturation broadening and we observe Voigt line profiles.

### 4.2 Laser Light Source for Spectroscopic Investigations

Lasers as coherent and monochromatic light sources for excitation, have significant advantage over the conventional light sources. Some of the characteristics are listed below:

- High spectral power density, significantly improve the signal-to-noise ratio and by using this characteristic nonlinear spectroscopic techniques can be explored.
- Due to small divergence of the collimated laser beam, long path length through the absorbing sample can be obtained.
- Extremely narrow spectral linewidth of lasers is particularly advantageous for high resolution spectroscopy. In laser spectroscopy usually the spectral linewidth of the absorbing or emitting atoms or molecules determines the resolution of the spectroscopic technique.
- Continuous tunability over wide range of frequencies has made lasers an alternative to conventional intense light sources and ultrahigh resolution spectrometers.

Laser basically consists of three components (a) active medium, where population inversion takes place, (b) energy pump (for example flash lamp or electrical discharges) that generates population inversion, (c) optical resonator which stores the light emitted by active medium in few modes of the radiation field. Different frequencies at which the laser resonator oscillates are determined by two factors:

- the gain profile of the amplifying medium
- eigenfrequency spectrum of the resonator

Without any wavelength selective elements inside the laser cavity, laser oscillation on all resonator modes are possible with wavelengths within the gain profile above threshold because for all modes gain exceeds the total losses. This is true for resonators which have completely inhomogeneous gain profile such that no gain competition occurs between different modes. On the basis of the width of the gain profile, lasers can be classified as:
(i) Fixed wavelength or fixed frequency lasers where laser wavelength is restricted to a narrow gain region such as in gas lasers, for example He-Ne lasers, or in solid-state lasers, for example Nd:YAG lasers.
(ii) Multiline fixed wavelength lasers. In this case the active medium shows gain on several transitions and the laser can oscillate simultaneously on many lines. In this case also the wavelength of each line is restricted to its narrow gain range. For example Argonion laser or Krypton-ion laser with multiline operation.
(iii) Tunable lasers. Here the gain profile extends over a broad spectral range of laser wavelength that can be tuned continuously over a wide range. For example dye-lasers, where stimulated emission from the excited state to many vibronic levels of the electronic ground state is possible.

The difference between fixed wavelength lasers and tunable lasers lies in the width of the tuning range which is narrow for the "fixed wavelength" lasers and broader for the so called "tunable" lasers.

### 4.2.1 Energy Level Diagram of a Dye Molecule

In the visible part of electromagnetic spectrum dye lasers are by far most widely used excitation sources for doing laser spectroscopy. The main advantage is their continuous tunability over a wide range of frequencies.
Active media in dye lasers are organic dye molecules dissolved in liquid solvents and, upon irradiation by visible or UV light, show a strong broad-band fluorescence spectrum. Figure 4.3 is an energy level scheme of an organic dye molecule showing rovibronic singlet ( $S$ ) and triplet $(T)$ states.

Dye molecules are pumped from rovibronic levels of the ground singlet state $S_{o}$ to higher rovibronic levels of excited singlet state $S_{I}$. Collisions with the solvent molecules induce a fast radiationless transition to the lowest rovibronic level of $S_{I}$ state with relaxation times of $10^{-11}$ to $10^{-12} \mathrm{~s}$. This level is depopulated either by spontaneous emission into different rovibronic levels of ground state $S_{o}$ or by radiationless transition into the lower triplet state $T_{1}$. Transition to the ground state $S_{o}$ determines the laser frequency. Due to strong interaction of dye molecules with the solvent the fluorescence spectrum of dye molecules is continuous rather than discrete, in essence this gives a continuous tunability over the wide range of frequencies.
High pump intensity ensures a population inversion between the rovibronic level $v_{o}$ of $S_{l}$ and higher rovibronic levels $v_{k}$ of $S_{o}$ which have negligible population at room temperature, due to its small Boltzmann factor $\exp \left[-E\left(v_{k}\right) / k T\right]$. As soon as the gain on the transition $v_{o}\left(S_{l}\right) \rightarrow v_{k}\left(S_{o}\right)$ exceeds the total losses, laser oscillation starts. The lower level $v_{k}\left(S_{o}\right)$ which now is populated by stimulated emission, is depleted rapidly by collisions with the solvent molecules to the lowest vibrational level $v_{o}$ of the ground singlet state $S_{o}$.

The population inversion between $S_{o}$ and $S_{l}$ is strongly affected by transitions from $S_{l}$ into the long-living triplet state $T_{1}$. Furthermore, transitions from lower triplet state $T_{1}$ into higher triplet states can also take place. To minimize these effects, molecules with populated state $T_{l}$ should be removed from the laser active zone in a time scale much shorter than the life-time of $T_{1}$. One way of doing this is by forming a flat stream of dye solution (dye jet) in a nozzle and inserting this free jet in the cavity, where the path inside the cavity and the focused pump beam overlap. At high enough pressure, the time of flight of the dye through the active region satisfies the above condition.

Figure 4.3: Energy level diagram of an organic dye molecule

### 4.2.2 Ring Dye Laser

Active medium in a ring-dye laser system (see Figure 4.4) is a thin liquid jet of the dye solution oriented at Brewster angle for avoiding reflection losses. A pump beam which is focused by a spherical mirror onto the dye jet excites the dye molecules in the jet. Four mirrors $M 1, M 2, M 3$ and $M 4$ are used which closes the laser beam path on to itself forming a ring resonator arrangement with a running laser wave only in one direction. Transmissivity of $M 4$, which is the output coupler, depends on the dye being used. In contrast in a linear dye laser system a standing wave is established in the cavity. The advantage of ring-cavity scheme over linear scheme is that no nodes of the electromagnetic field within the jet are present and whole inversion of the active medium can contribute to the laser amplification. Unidirectional propagation of laser wave is achieved by inducing more losses for one direction as compared to the other. This can be achieved by a unidirectional device known as optical diode. An optical diode consists of a Faraday glass in a longitudinal magnetic field and a polarization rotator, which turns the birefringent rotation back to the input polarization for the wave incident in one direction, but increases the rotation for the other direction. Waves with incorrect polarization direction suffers large losses at the many Brewster surfaces in the resonator cavity and therefore do not reach the threshold. Mirror M2 is mounted on a Piezo-Electric Transducer ( $P Z T$ ) also known as tweeter mirror and a Galvo or Brewster Plate is inserted in front of the output coupler M4 inside the laser cavity. Both these elements work in conjunction with each other for tuning the laser wavelength. To select one of the modes of laser cavity, a number of mode selection elements with different finesse and free spectral range (FSR) are inserted. These include birefringent filter and two Fabry-Perot etalons, i.e. a thick etalon and a thin etalon.

A Birefringent filter is a Lyot type filter consisting of more than one quartz plate each plate being four times the thickness of the previous one and inserted at Brewster angle in the
cavity. The Birefringent filter has low finesse and an FSR of the order of THz. Due to its low finesse the birefringent filter alone cannot select a single mode of the laser cavity. Therefore thin and thick Fabry-Perot etalons are also placed inside the cavity. Thin etalon is a glass plate of 0.5 mm thickness with a reflectivity of $R \approx 20 \%$ and is inserted at close-to-normal incidence. Last of the mode selection elements is the thick etalon which is a 10 mm solid prism etalon and is divided into two parts. It is piezo driven and is also inserted at nearly normal incidence. Thick etalon also has a reflectivity of $R \approx 20 \%$ and is most effective in selecting one mode of laser cavity. The FSR of both thin $(200 \mathrm{GHz})$ and thick ( 10 GHz ) etalons is in GHz .

Figure 4.4: Ring Dye laser system
Optical layout : Coherent Inc.
Mechanical Layout: Institute of Experimental Physics, TU Graz
Proper alignment of etalons and laser cavity avoids any sudden jumps in laser frequency. This sudden jump in laser frequency is known as "mode hopping". In addition to misaligned etalons and laser cavity, mode hopping may also be due to thermal fluctuations, turbulence in the dye jet, presence of microbubbles in the dye jet etc. In order to avoid mode hopping and to perform frequency stabilization, thick etalon and laser cavity each need an electronic feedback loop. This feedback signal or the "error signal" is generated by a temperature stabilized confocal external reference cavity. With the help of a beam splitter mounted outside the laser cavity, a fraction of the linearly polarized laser beam is passing through the reference cavity and detected by a photodiode known as reference diode. Another fraction of the main laser beam is directly reflected to a second photodiode known as power diode which is used to detect the total power level. A side-locking technique is used in which laser wavelength is directly locked to one side of a transmission peak of the confocal reference cavity. Therefore the signal from reference photodiode acts as an error signal for the feedback loop. To avoid intensity fluctuations the signal from the reference photodiode is divided by the total power level using the signal from the power diode. The error signal generated is then divided into a low frequency and high-frequency parts. The high-frequency part is feedback to the tweeter mirror $M 2$ whereas low-frequency part is
used to drive the Galvo plate. Both these tuning elements allow changing the length of the cavity for stabilizing the frequency of laser.

If the transmission peaks of all these elements are tuned to same wavelength $\lambda$, the laser will oscillate at this wavelength as a single mode laser. Laser wavelength can be scanned continuously without mode hopping if all the elements are synchronously tuned using this electronic feedback control system.

### 4.3 Laser Spectroscopy

Classical absorption spectroscopic techniques utilizing conventional radiation sources with broad emission continuum (for example high pressure Hg arcs or Xe flash lamps etc.) are mainly limited by detection sensitivity and in spectral resolution which in turn is limited by the resolving power of the apparatus profile. The detection sensitivity defined as minimum detectable absorbed power is limited by the detector noise and intensity fluctuations in radiation source. In classical absorption spectroscopy a collimated beam of light is passed through an absorption cell containing the sample to be investigated. Absorption of light at specific frequencies occurs inside the absorption cell. Using a dispersing device the intensity of the transmitted light $I_{T}(\lambda)$ is measured as a function of wavelength. By comparing the intensity of the transmitted light beam with the intensity of the reference beam $I_{R}(\lambda)$, the absorption spectrum of the sample is obtained.

Contrary to absorption spectroscopy in laser spectroscopy the radiation sources with broad emission continuum are replaced by tunable laser sources with extremely narrow line width. Tunable lasers offer a wide spectral region extending from UV to IR with extremely
narrow bandwidths and with power densities much greater than conventional incoherent light sources. Therefore due to high power densities and extremely narrow line width of lasers, high detection sensitivity and high spectral resolution are achievable in laser spectroscopy. Some of the main features of laser spectroscopy are listed below:

The absorption coefficient $\alpha(\omega)$ and its frequency dependence can be measured directly from the difference $I(\omega)=a I_{R}(\omega)-I_{T}(\omega)$ (' $a$ ' represent reflection losses) between the intensities of the reference beam and transmitted beam. A monochromator is not required. With the use of tunable single-mode lasers the spectral resolution is much higher than in conventional spectroscopy and is only limited by the line width of the absorbing transition.
i. Due to high power density achievable with lasers, the detector noise is generally negligible. This increases the signal-to-noise ratio and enhances sensitivity.
ii. Because of low divergence long absorption paths are possible by multiple reflections back and forth through the absorption cell. Such long absorption paths facilitate the measurements of transitions with small absorption coefficients.
iii. By allowing a small fraction of main laser beam to pass through a Fabry-Perot interferometer with a separation d of the mirrors, a photodetector receives intensity peaks each time the laser frequency $v_{L}$ is tuned to a transmission maximum of interferometer at $v=m c / 2 d$. These equal spaced intensity peaks serves as accurate wavelength markers which allow measurement of adjacent absorption lines. The separation between two adjacent transmission maxima or this wavelength interval is called free spectral range of interferometer (FSR).
iv. The laser frequency may be stabilized onto the center of an absorption line. The need for frequency stabilization can be relaxed if the frequency jitter is small compared to absorption line width.
v. It is possible to tune the laser frequency over the spectral region of interest. For example the transitions between hyperfine levels of two fine structure levels can be observed in a single scan of laser.
vi. With high intensity and small laser line width appreciable population in selectively excited states can be achieved. This is advantageous for doing absorption and fluorescence spectroscopy of excited states.

Despite of all the above advantages the achievable resolution is finally limited by finite line width of the absorption line. This could be due to the natural line width of the atomic or molecular levels, as energy levels have an energy uncertainty related to their finite life time, or it may be due to the Doppler broadening of the absorption line which is caused by the thermal motion of atoms or molecules, usually $\Delta v_{D} \approx 100 \Delta v_{N}$ for gases. Spectroscopic techniques in which Doppler broadening limits the achievable resolution are known as Doppler limited techniques. In these techniques primarily the level structures are determined without any regard to their finer details such as their hyperfine structure. Two photon absorption spectroscopy, optogalvanic spectroscopy, optical double resonance and level crossing spectroscopy are few examples of Doppler limited laser absorption spectroscopy.

In Doppler free high resolution spectroscopy extremely narrow band single mode lasers are utilized. The collimated atomic beam spectroscopy and saturation spectroscopy are the examples of the Doppler free absorption spectroscopy. The saturation spectroscopy is based on nonlinear spectroscopic techniques.

### 4.3.1 Two-Photon Spectroscopy

In 1929, Maria Göppert-Mayer predicted theoretically that an atom might absorb two or more photons simultaneously. She subsequently first published the concept in her doctoral dissertation [41] in 1931. The prediction allows an electron to make a transition to states unreachable by single photon absorption. Because the effect could only be observed with a very intense beam of radiation so her prediction could not be investigated experimentally until the construction of the first laser in 1960.

Two-photon excitation can be described as two successive one-photon excitations. Excited levels with same parity can be reached via two-photon excitation. The probability that two photons are absorbed simultaneously is extremely low. Therefore a very high density of photons is required usually using a pulsed laser. In a simple case of single photon transitions, the selection rules for such transitions are such that the change in angular momentum $\Delta J= \pm 1$. When an atom absorbs two photons simultaneously, the electron will change angular momentum by $\Delta J=0$ or $\pm 2$, this is due to the fact that each photon has an angular momentum of +1 or -1 .
Two-photon excitation can be distinguished either as a step-wise excitation with intermediate eigenstate where two photons are in resonance with the successive excitations, or it is a simultaneous absorption of two photons with an intermediate virtual state, undergoing a transition from $E_{i} \rightarrow E_{f}$. Two photons may either come from a single laser beam passing through the absorbing sample or they may come from two separate lasers. These virtual states are not eigenstates and do not correspond to specific $n$ or $l$ state. Instead, they are merely superpositions of waves. No population of electrons accumulates in virtual state. The lifetime of a virtual state is short, relative to eigenstates. Actually, the closer the virtual state is to an actual eigenstate, the longer the lifetime of the virtual state. Nevertheless, the above mentioned transition rules hold also for virtual levels.

In an atom or molecule at rest, two photons with energy $\hbar \omega_{1}$ and $\hbar \omega_{2}$ either coming from two laser beams, or two photons with energy $\hbar \omega$ from the same laser, induce a transition from an initial level $\langle i|$ to the final level $\langle f|$, using conservation of energy; viz.

$$
\begin{equation*}
E_{f}-E_{i}=\hbar\left(\omega_{1}+\omega_{2}\right) \tag{4.35}
\end{equation*}
$$

For an atom or molecule moving with velocity v , the frequency $\omega$ of the light wave is shifted in the atomic or molecular frame to

$$
\begin{equation*}
\omega=\omega^{\prime}-\vec{k} \cdot \vec{v} \tag{4.36}
\end{equation*}
$$

Therefore the resonance condition given in Eq. (4.35) becomes

$$
\begin{equation*}
\left|E_{i}-E_{f}\right|=\hbar\left(\omega_{1}+\omega_{2}\right)-\hbar \vec{v}\left(\vec{k}_{2}+\vec{k}_{2}\right) \tag{4.37}
\end{equation*}
$$

Now if the two photons come from the two beams of the same laser but traveling in opposite direction, i.e. $\omega_{1}=\omega_{2}$ and $\vec{k}_{1}=-\vec{k}_{2}$ then as a consequence the last term in Eq. (4.37) vanishes. This implies that the absorption of two photons becomes independent of the velocity of atoms or molecules. This means that all atoms or molecules independent of their velocity group contribute to the two photon absorption, making two-photon absorption Doppler-free. Experimentally the two-photon absorption is monitored by laser-
induced fluorescence emitted from the upper level $E_{f}$ by an allowed one-photon dipole transition into a lower level $E_{m}$.

As the laser frequency $\omega$ is tuned over the two-photon resonance, the resulting signal consists of a narrow peak produced by two photons with opposite $\vec{k}$ vectors and a Doppler-broadened background produced by two photons coming from the same beam with parallel $\vec{k}$ vectors. The main characteristics of two photon spectroscopy:

- Optical transitions which are parity forbidden by a single photon excitation can be excited via a two photon transitions.
- The final state may have an excitation energy in the far UV, while the incident light beam has a frequency in the near UV or visible region,
- By proper combination of participating photons, it is possible to eliminate momentum transfer between electromagnetic fields and atoms or molecules, this allows one to get Doppler free spectrum. However the cross section of two photon absorption is usually very small compared to that of a direct transition, this make this process not of general use.

### 4.3.2 Saturation Spectroscopy

Saturated absorption spectroscopy is a precision spectroscopic technique and is one of the frequently used techniques for measuring narrow-line atomic spectral features, limited by saturation broadening and by the natural linewidth $\Gamma$ of the transition. In all the labs involved with laser cooling and trapping of atoms, the technique of Doppler-free saturated absorption spectroscopy is frequently used as a tool for locking the lasers to particular atomic lines. The first saturation spectroscopy experiments using a tunable narrow-band laser were performed by Hänsch, Schawlow [42-43] and co-workers and by Borde [44].
A monochromatic laser beam with frequency $\omega$ propagating in x direction passes through a vapor cell containing an ensemble of atoms or molecules. Since the atoms are in thermal motion with velocity distribution given by Maxwell-Boltzmann statistics, so the Dopplerbroadened absorption profile is of Gaussian line shape with center frequency $\omega_{o}$. Atoms which are Doppler-shifted into resonance with the laser frequency can absorb the laser photons with Doppler shifted frequency given by $\omega=k v_{x}$ and inducing a transition from an initial level $i$ to the final level $f$. The population $N_{i}$ of these atoms in the absorbing level decreases whereas population $N_{f}$ in the final level increases accordingly. Therefore a narrow dip is burnt in the velocity distribution $N_{i}\left(v_{x}\right)$ of these atoms in initial level and correspondingly a narrow peak appears in the distribution $N_{f}\left(v_{x}\right)$ of atoms in the upper level.

In saturation spectroscopy instead of a single laser beam two counter propagating laser beams derived from the same laser with frequency $\omega_{L}$ are sent through the vapor cell. The experimental setup is as shown in Figure 4.6. The laser beam from a tunable laser source is split by a beam splitter BS into a strong pump beam and a weak probe beam that passes through the absorption cell in opposite direction. The probe and pump beams must have a good overlap inside the absorption cell. The pump beam is intensity modulated by a mechanical chopper and the modulation frequency is fed into the lock-in amplifier as reference frequency. A detector sees the transmitted probe beam intensity as a function of the laser frequency $\omega_{L}$ whose output goes to the lock-in amplifier as second input.
Laser frequency is tuned over the Doppler-broadened absorption profile of the ensemble of atoms moving with different velocities. When the laser frequency $\omega_{L}$ coincides with the
center of absorption line $\omega_{o}$, only one velocity class in the interval $d v_{x}$ around $v_{x}=0$ interacts with the laser beam.

Figure 4.6: Experimental setup for saturation spectroscopy
The pump beam is strongly absorbed, depleting the population in the initial level $i$ with corresponding increase in the population of the final level $f$. A narrow hole or dip is burnt in the velocity distribution $N_{i}\left(v_{x}\right)$ of the initial level and a corresponding narrow peak appears in the distribution $N_{f}\left(v_{x}\right)$ of atoms in final level. The absorption coefficient $\alpha(\omega)$ with a Doppler-broadened profile has a dip around the center frequency $\omega_{o}$. The counter propagating weak probe beam interacts with atoms whose absorption is saturated by the strong pump beam, resulting in a sharp decrease of absorption of the weak probe beam at the center of the line. The intensity of the probe beam is modulated only when the probe beam is responsive to the hole burnt in the Doppler profile by the strong modulated pump beam. The modulated part of the probe beam intensity recorded by a phase sensitive lockin amplifier depends only on the saturated absorption and is not sensitive to the unsaturated part of the Doppler profile. The dip at the center of Doppler-broadened absorption profile caused by the saturation of the population, which is probed by the second weak probe beam is called Lamb Dip named after Willis Lamb who first explained this effect quantitatively. Since the detector measure the intensity of the transmitted probe beam so each time Laser frequency coincides with the center frequency of atomic transition, a Lamb peak appears in the transmitted intensity, because the absorption exhibits a dip at this frequency.

For monitoring laser induced fluorescence (LIF) signal two counter propagating laser beams must be of equal intensity and the Lamp dips can seen easily. The total LIF intensity is proportional to

- Laser intensity
- Number density in the initial sate
- Einstein coefficient for absorption, and
- Quantum yield ( ratio of the number of photons to the number of photons absorbed

Obviously the Lamb dip is much narrower than the Doppler width. If the intrinsic frequency width or linewidth of the laser used in the experiment is small enough, the
observed width of the Lamb dip is always limited by saturation broadening. The Dopplerbroadened background can be eliminated when the pump beam is periodically chopped. A lock-in detector measures the difference of the transmitted probe intensity with the pump beam on and off. The result is a Doppler-free spectrum with a better signal-to-noise ratio.

### 4.3.3 Collimated Atomic Beam Spectroscopy

In 1936, long before the invention of lasers, D. A. Jackson and H. Kuhn [45] experimentally investigated the absorption in atomic beams. In their work the absorption was analyzed by means of a high resolution Fabry Perot interferometer. The first application of atomic or molecular beams in laser spectroscopy was described S. Ezekiel and R. Weiss [46].

In high resolution spectroscopy a typical atomic beam experiment is performed by irradiating a well collimated atomic beam at right angles with a narrow-band, single-mode laser. The advantage of this method comes from the fact that the atoms in the collimated beam do not have velocity components in the direction of laser beam. Doppler width is reduced by the collimation ratio $C$ (Figure 4.7) and very small absorption width of atoms is formed.

The main characteristics of atomic beam spectroscopy are:

- An atomic beam can be produced easily for any element.
- The Doppler width is reduced by a factor of $\sin (\varepsilon)$ which is equal to the collimation ratio.
- The number of collisions are small subsequently collisional broadening is reduced. This is because all atoms have almost same velocity so fewer collisions occur as compared to a gas at equivalent pressure.
- Fluorescence light radiates in $4 \pi$ steradians and very few of them reach the photodetector.

Figure 4.7: Collimation Ratio C

## Detection techniques:

Detection by fluorescence: The most direct way to study the optical resonance is to observe fluorescence light, released after excitation.
Detection by photoionization: Here the atomic beam interacts simultaneously with a narrow band laser and an intense laser. The narrow band laser brings the atoms to an excited state and an intense laser, having sufficient energy, ionizes the atoms in excited states. The photoelectrons or the ions are detected in an electron detector [47]. This process has also been demonstrated for isotopes separation [48].

Detection of recoil atoms: When an atom absorbs a photon, the momentum of the photon is transferred to the atom. As a result the atom is deflected from the beam. In the de-excitation process the recoil momentum transferred either is cancelled (stimulated emission) or is transferred to the atomic beam (spontaneous emission). The latter result in a spreading and broadening of the atomic beam. The deflection of an atomic beam was first demonstrated by R. Frish in 1933 [49]. A. Ashkin [50] proposed to use this technique for isotope separation. P. Jacquinet et al. [51] first time recorded the hyperfine structure by beam deflection for the sodium D lines.

Detection of change in magnetic sublevels in an atomic beam deflected by an inhomogenous magnetic field: The first application of the magnetic resonance principle was made with the introduction of atomic beam magnetic resonance technique by I. I. Rabi, J. R. Zacharias, S. Millman, and P. Kusch in 1938 [52]. They discovered that any change in magnetic sub levels of an atom in the atomic beam can be detected by a change in the deflection of the beam in an inhomogeneous magnetic field. In 1952 I. I. Rabi [53] suggested that this technique could be used in the study excited states if atoms are illuminated resonantly in the interaction region. He also suggested that this method could be used to study isotope shifts. In 1965 Marrus [54] used Rabi's arrangement and by using the change in magnetic sub levels of ground state he detected and measured optical transitions.

### 4.3.4 Laser Induced Fluorescence (LIF) Spectroscopy

Laser induced fluorescence (LIF) is one of the powerful spectroscopic techniques for investigating the spectra of neutral atoms and ions. LIF technique offers the advantage of selective excitation not only from the excited states but also from the ground states and provides high resolution only limited by the linewidths of the absorbing transition. The principle is very simple and is as follows: Laser beam is allowed to pass through an absorption chamber containing atoms or molecules to be investigated. One or several photons from the laser beam are absorbed, provided that the laser frequency is in resonance with the atomic or molecular transition. The probed atoms or molecules are pumped from an initial state ( $i$ ) to an excited state $(f)$ and the atoms or molecules thus excited can relax or de-excite in a number of ways for example by spontaneously emitting light or by collisional de-excitation. Thus a transition takes place from the excited state $(f)$ to final state ( $k$ ) and in the process the spontaneously emitted light constitutes a fluorescence signal. Employing good collection geometry, part of the emitted radiation is detected. By means of a dispersing device such as a monochromator, it is possible that the light is detected at a wavelength different from the laser wavelength meaning that the states $(i)$ and $(k)$ are different. This eliminates any spurious signal due to scattered laser light. The dispersing device also serves to reduce the background radiation. Since the fluorescence signal is laser induced so such a spectroscopic investigation of atoms and molecules is known as laser induced fluorescence spectroscopy.

Dye lasers have narrow linewidths and are easily tunable over large wavelength domains, LIF measurements can be made by tuning the laser frequency across the atomic or molecular resonances and capturing the resulting fluorescence signals. The fluorescence intensity recorded as a function of the laser wavelength is usually called an excitation spectrum. The observed fluorescence intensity reflects the change of population of the upper excited state $(f)$. The strength of the signal depends on a number of factors such as laser intensity, number of atoms or molecules, temperature of ensemble of atoms or
molecules and also on the collisional environment of the investigated atoms or molecules.
When exciting sufficiently higher lying states, a number of fluorescence wavelengths are observed due to the decay to lower states according to allowed dipole transitions as shown in Figure 4.8. The strength of a LIF signal is determined by the branching ratio of the upper excited level. The hyperfine transition of the LIF lines does not play any role, since the monochromator selecting one LIF line does not resolve the hyperfine structure of this line, but acts only as a filter to suppress other lines of the discharge.
This dissertation is mainly dedicated to the investigation of the hyperfine structure of the fine structure energy levels characterized by a number of parameters such as level energy, parity, total electronic orbital angular momentum $J$ and nuclear spin $I$. Besides these other parameters of interest are the hyperfine constants and Lande ' $g$ ' factor. These parameters characterize a specific energy level.

### 4.3.4.1 Detection of LIF Signal and Decay Mechanisms

LIF signal is monitored by a technique called phase-sensitive detection. The lock-in amplifier is tuned to the modulation frequency (reference frequency) which is the chopping frequency of the incoming excitation light beam. The detail of this electronic detection of LIF signal is as follows:
Laser frequency is tuned across hyperfine components of a line and those atoms which are in resonance with the laser light are excited. This modulates the population of the levels involved in the transition which results in the modulation of fluorescence intensity of only those fluorescence lines originating from the levels involved in the excited transition. These modulated fluorescence lines are selected by tuning the transmission wavelength of a monochromator across the spectrum. The optical signal is detected by a Photomultipler tube mounted at the exit slit of the monchromator. Finally phase sensitive detection is carried out by a phase sensitive lock-in amplifier which has two input signals (i) modulated fluorescence intensity (ii) modulation or chopping frequency of the laser beam. These two signals are combined; this has an advantage that only those fluorescence lines which are inphase with the modulation frequency of the laser beam are detected. As a result the modulated and non-modulated fluorescence lines are distinguished. The other advantage of phase sensitive detection by lock-in amplifier is the distinction between fluorescence lines originating from the upper or from the lower transition levels. Accordingly as the modulation phases of the fluorescence lines are in phase or out of phase with respect to intensity modulation phase of the laser beam. This can be understood as follows. The intensity of a fluorescence line is proportional to the population of the upper level of the fluorescence line. Laser induced absorption increases the population of the upper level of the excited transition in phase with the modulation frequency of the laser beam therefore the fluorescence lines originating from the upper level are also in phase. At the same time laser induced absorption also diminishes the population of the lower level of the excited transition and thus the corresponding fluorescence lines originating from lower level are antiphase modulated i.e. are 180 degrees out of phase compared with the intensity modulation phase of the laser beam. According to experimental terminology the fluorescence lines originating from the upper level of an excited transition are termed as positive fluorescence and the fluorescence lines originating from the lower level are termed as negative fluorescence.

Figure 4.8 shows a simple scheme of transitions between various levels. The observed fluorescence lines can be categorized in the following manner:
(i) Fluorescence with positive LIF Signal: Due to the resonant transition from lower
level $E_{2}$ to the upper level $E_{3}$, the population of excited level $E_{3}$ increases and at the same time population of lower level $E_{2}$ decreases. A subsequent decay occurs to more than one lower levels i.e. $E_{4}$ and $E_{5}$ by emitting fluorescence light of wavelengths $\lambda_{34}$ and $\lambda_{35}$. Laser frequency is modulated at a chopping frequency ' $f$ ' which acts as a reference frequency for phase-sensitive detection (Lock-in amplifier). If LIF signal and reference frequency are in phase, maximum LIF signal is observed. Since the LIF signal intensity increases with laser light on, this type of fluorescence is called a positive phase or a positive fluorescence. This type of fluorescence which is observed as a result of decay from the upper level of excited transition is also termed as direct fluorescence.
(ii) Impact or Collisional Coupling: If other level energies lie close to a level populated or depopulated by laser light, the probability of impact or collisional transfer of population is high. In such a situation through impact or collision an excited state atom transfers its energy to another atom whose excited level energy happens to lie close by which subsequently decays to lower level by emitting fluorescence light. This type of fluorescence is also positive phase fluorescence. As shown in Figure 4.8 due to an impact a population transfer occurs from $E_{3}$ to $E_{6}$ which decays to $E_{7}$ by emitting a fluorescence wavelength $\lambda_{67}$. This is an indirect fluorescence as it is observed due to decay from an upper level which is not directly excited in original transition. Population transfer between lower levels, $E_{2}, E_{8}$ is also possible.
(iii) Negative Fluorescence: In situations where the lower level of a certain transition is high lying as compared to very low lying levels, this lower level decays to the further low lying levels by emitting fluorescence light. Such LIF signal is negative in phase and is known as negative fluorescence. In Figure 4.8 for the resonance excitation from $E_{2}$ to $E_{3}$ some of the atoms in lower level $E_{2}$ decay to level $E_{1}$ by emitting a fluorescence wavelength $\lambda_{12}$. The population of level $E_{2}$ decreases when the laser light is on and the fluorescence observed has $180^{\circ}$ phase shift as compared to a positive fluorescence. Negative fluorescence wavelengths are useful in identifying the lower level of an excitation transition. Furthermore if exact fluorescence wavelengths are determined the lower level of fluorescence decay can also be identified.
(iv) Self-absorption: Usually in optically thin light sources the photon emitted by the spontaneous emission has a little chance of being re-absorbed. For spectral lines involving ground state of the atom this assumption in most cases breaks down. Especially true for spectral lines arising due to combination between the ground state and the lower excited states. These are very strong lines and are called resonance lines. For such lines it may happen that a photon emitted by an atom at one point in a light source may be re-absorbed by a different atom before it has a chance to escape from the source. This phenomenon is known as self-absorption. It can happen if the photon which is being re-absorbed has an energy coincidence with the energy difference of the two levels involved in the re-absorption excitation. Due to self-absorption line shape changes, making it appear broader. Since the probability of emission is greatest at the center of the line, the probability of absorption is also greatest at the center. Thus as a result of re-absorption within the light source, the intensity of the spectral line decreases proportionately more in the center of the line than elsewhere. If the self-absorption is strong, then an intensity minimum develops in the center of the spectral line and the line is said to be self-reversed.

Figure 4.8: Direct and collisionally coupled LIF signals

### 4.3.4.2 Advantages of LIF Spectroscopy

- Blend situation: In elements like praseodymium where there are regions of high energy level density, more than one level is excited simultaneously in a single range of laser. So the observed LIF patterns corresponding to all excited levels show a complex structure caused by this blend situation. LIF spectroscopy has the advantage that individual transition lines can be separated by searching for fluorescence decay channels corresponding to a specific upper level. In this way the hyperfine structure of each line can be recorded and the level energy is determined by using the information from the recorded structure, wave number of the excitation line and the energy of lower level.
- LIF signal of free atoms: In a hollow cathode discharge it is easier to produce free atoms than free ions, therefore LIF signal of an atomic line of comparable intensity should be stronger than that of an ionic line.
- Large laser intensity: Availability of lasers with high intensities makes it possible to achieve of large population densities in the excited states, yielding high intensities of the fluorescence lines even for transitions with low transition probabilities.
- Higher sensitivity for Fluorescence Signal: Using Lock-in techniques higher sensitivity is achievable for the fluorescence signals as compared to absorption measurements.

### 4.3.5 Optogalvanic Spectroscopy

In 1928, F. M. Penning [55] discovered the light induce changes in the electrical properties of plasma. He observed a perturbation of a gas discharge caused by the light of a second discharge. This effect as a spectroscopic tool had to await till the invention of tunable dye laser. In 1976 Green et al. [56] gave the first spectroscopic investigation of this effect, named it as an 'optogalvanic effect'. They used a commercially available hollow cathode lamp as a gas discharge tube. Laser light is tuned to the transition frequency of one of the species present in the discharge. The effect was apparent as a change in the tube voltage. The use of this effect opened a new branch of spectroscopy know as Optogalvanic Spectroscopy which is a very sensitive and simple technique of performing laser spectroscopy in a hollow cathode gas discharge. The standard experimental setup is shown in Figure 4.9.

Figure 4.9: Experimental setup for Optogalvanic Spectroscopy
Laser frequency is tuned to a resonance transition $E_{i} \rightarrow E_{f}$ between levels of atoms or ions in a hollow cathode discharge. Due to excitation a change in the population densities $n_{i}\left(E_{i}\right)$ and $n_{f}\left(E_{f}\right)$ of the combing levels occurs. Since atoms in different stationary states $E_{i}$ and $E_{f}$ have different ionization probabilities this change in population results in a change of discharge current $\Delta I$ which could be detected as a voltage change $\Delta V=R \Delta I$ across the ballast resistor $R$. In order to have a good signal-to-noise ratio, the excitation is done by mechanically chopping the laser beam and a lock-in amplifier is used for phase-sensitive detection. Periodic changes in tube voltage can be detected by connecting one of the electrodes via a capacitor $C$ to the input of the lock-in amplifier. The effect is more pronounced for high lying levels as they have a reasonable probability of collisions and ionization compared to low lying levels. Both positive and negative signals are observed, depending on the levels $E_{i}$ and $E_{f}$ involved in the laser-induced transition $E_{i} \rightarrow E_{f}$. Since the absorbed laser photons are detected by optically induced current change of discharge, therefore this sensitive technique for doing spectroscopy is so named as Optogalvanic Spectroscopy.

Several competing processes may contribute to ionization of an atom in level $E_{i}$. Some of them are discussed below:
(i) Direct ionization by electron impact

$$
\begin{equation*}
A+e^{-} \rightarrow A^{+}+2 e^{-} \tag{4.38}
\end{equation*}
$$

This process dominates at low pressure.
(ii) Two step ionization or multi step ionization:

$$
\begin{equation*}
A+e^{-} \rightarrow A^{*}+e^{-}, A^{*}+e^{-} \rightarrow A^{+}+2 e \tag{4.39}
\end{equation*}
$$

In noble gases this process is particularly important if excited states are metastable states.
(iii) Collisional ionization by metastable atoms:

Two atoms in metastable states collide with one another; one of the atoms absorbs sufficient energy and becomes ionized

$$
\begin{equation*}
A^{*}+B^{*} \rightarrow A^{+}+B+e^{-} \tag{4.40}
\end{equation*}
$$

### 4.3.5.1 Advantages/Disadvantages of Optogalvanic Spectroscopy

(i) The experimental setup is very simple since it does not require a monochromator and a detector such as photomultiplier tube or photodiode detector to obtain the investigated spectra. This is because the discharge itself acts as a detector.
(ii) Only excitation wavelength is required no need to monitor fluorescence signal.
(iii) The substantial disadvantage of this type of spectroscopy is unstable discharge condition. For recording optogalvanic signal the discharge must be burning very calmly.
(iv) The optogalvanic signal has nothing to do with the fluorescence light, hence nothing can be said about the levels involved in the transition. Of course the excitation probability and thus the hyperfine structure of the excited transition are mirrored in the OG signal.

### 4.3.5.2 Application of Optogalvanic effect

(i) Determination of the hyperfine constants by exciting classified lines.
(ii) When exciting an unclassified line, OG signal can help in recording the hyperfine structure of the line, and to place the laser frequency when later searching for LIF lines.
(iii) To study the collision process and ionization probabilities in a gas discharge.
(iv) This technique can be used for wavelength calibration in laser spectroscopy [57].
(v) The study of Rydberg states is also possible by optogalvanic spectroscopy [58].
(vi) It is very efficient for the investigation of Autoionizing levels [59].
(vii) The optogalvanic signals may be used for laser frequency stabilization [60-61].

## 5 Experimental Setup

Invention of intense, highly monochromatic, tunable lasers with good frequency and intensity stabilization covering UV, visible and infrared regions have revolutionalized the field of experimental atomic spectroscopy in an unprecedented way. This results in a transition from classical spectroscopy to laser spectroscopy which is far more superior in terms of sensitivity, resolution and measurement accuracy. The present work is based on the investigation of spectral lines of praseodymium using laser induced fluorescence spectroscopy in a hollow cathode discharge lamp, where free Pr atoms and ions are produced in ground and excited states. These excited atoms and ions decay to lower states by emitting light which is recorded as a fluorescence signal. Excitation by direct absorption of electromagnetic radiation is only possible if the resonance condition $\Delta E=h v$ is fulfilled. Apart from the metastable states the lifetime of excited states is of the order of $10^{-8} \mathrm{sec}$. so the excited states decay spontaneously by emitting electromagnetic radiation at discrete frequencies. A dispersing device resolves the emitted radiation into components or discrete lines. The observed spectrum (distribution of intensity as a function of frequency or wavelength) is characteristic for a specific element. Using high resolution techniques, the hyperfine structure of the spectral lines can be investigated, provided that the spectral lines have sufficiently high intensity. A large number of spectral lines must be experimentally investigated to have a complete and reliable knowledge of the electron structure of the emitting atom. This requires a high resolution spectrum from UV to far infrared. Such a high resolution spectrum is a Fourier Transform (FT) spectrum which is being used in our research group for the investigation of spectral lines of praseodymium, tantalum, lanthanum, and neodymium.

### 5.1 Experimental Layout

Laser Induced Fluoerescnce (LIF) spectroscopy in combination with a hollow cathode lamp (HCL) is a sensitive and widely used technique for hyperfine structure investigations of various elements. This method of investigation is useful since, in addition to the information about the hyperfine structure of the spectral line under investigation, one also obtains information on the fluorescence wavelengths which mark the excited upper level. Naturally occurring praseodymium has only one stable isotope and in most cases hyperfine splitting of a fine structure level is large enough, therefore LIF spectroscopy in a HCL is particularly efficient and even with large Doppler width the hyperfine structure spectrum of $\operatorname{Pr}$ is quite legible.
The experimental setup for LIF spectroscopy in HCL is shown in Figure 5.1 which can be divided into three major sections.
i. Excitation source
ii. Sample whose spectrum has to be investigated
iii. Detection system

Ar-ion laser operating at 7.5 watts was used to pump the dye laser. The lasing action in dye laser produces laser light which has a certain range of wavelengths depending on the type of dye used for lasing. By adjusting different optical elements, the laser can be set to any wavelength or frequency within this spectral range.

The single mode laser light from a tunable dye laser is splitted into two parts by beam splitter B1. The minor portion of the beam falls on beam splitter B2 which further divide it into two parts. One part of the beam after reflection from mirror M1 goes into wavemeter
for reading wavelength and the other part is again splitted into two parts by beam splitter B3. One portion goes to the spectrum analyzer to monitor the mode structure of laser and the other portion after reflection from M2 goes to marker etalon.

Figure 5.1: Schematic representation of experimental setup
HKL...Hollow Cathode Lamp, M1-M4, M6-M7...Mirrors, M5...Mirror with central hole, L1-L4 lenses, B1-B2...Beam splitters, Ar ${ }^{+}$-Laser...Pump Laser, Dye-Laser...Ring Dye Laser, Osz...Oscilloscope, Sp. Analyzer...Spectrum-Analyzer, Marker Et...Marker etalon for measuring frequency markers, $\lambda$-meter...Wavemeter, Monochr...Monochromator, R...Ohmic resistance, C...Capacitive reactance

The major portion of the laser beam passes through a mechanical chopper 1 which modulates the intensity of the laser beam. The intensity modulated laser light after reflection from mirror M3 passes through a telescope arrangement of lenses L1 and L2 and goes through a hole in mirror M5 to the hollow cathode lamp. Inside the hollow cathode the sputtered Pr atoms and ions are excited by laser light at resonance.

The fluorescence light that leaves the HCL is collected by mirror M5 and directed to the entrance slit of a monochromator by a set of mirrors and lenses. A tunable monochromator (Jobin Yvon HRS 2) with tuning range from 300-750 nm is used to filter single LIF wavelength out of a total florescence spectrum. A photomultiplier tube (Hamamatsu R955) with high sensitivity for the visible spectrum is mounted at the exit slit of monochromator which allows the detection of extremely low fluorescence signal changes. A mechanical chopper 2 placed in front of the entrance slit of monochromator is used to chop the fluorescence light intensity coming from the hollow cathode lamp. This is used in case, if we need a more accurate measure of the fluorescence wavelengths.

The frequency spacing between various hyperfine components of the recorded hyperfine structure must be measured exactly. For this a small portion of the laser beam is given to a temperature stabilized confocal Fabry-Perot interferometer which gives equidistant frequency marks along with the hyperfine structure of the spectral line. Conventionally such a device is known as a marker etalon. The difference between the adjacent transmission peaks of the marker etalon is known as Free Spectral Range (FSR) and its magnitude is dependent on a specific interferometer. The interferometers available in our laboratory for blue, red and yellow regions have FSRs $150.2976 \mathrm{MHz}, 149.7 \mathrm{MHz}$ and 367.33 MHz , respectively. The LIF signal together with the signal from marker etalon is recorded simultaneously on a computer as well as on a strip chart recorder for further analysis.

### 5.2 Excitation Source

The source of exciting radiation for the investigations of the hyperfine structure of Pr spectral lines is cw (continuous wave) single mode tunable ring dye laser optically pumped by $\mathrm{Ar}^{+}$-Laser, $\mathrm{Kr}^{+}$-Laser or by diode pumped, frequency doubled $\mathrm{Nd}:$ Vanadate ( $\mathrm{Nd}: \mathrm{YVO}_{4}$ ) Verdi V-18 laser system. Noble gas ion lasers such as $\mathrm{Ar}^{+}$-Laser or $\mathrm{Kr}^{+}$-Laser are not very efficient due to high energy requirement. This is due to the fact that the atoms are first ionized and only after ionization, a population inversion can be established in the ion population. Despite of high energy requirements, the ion lasers are advantageous mainly because
i. The optical gain of plasmas is very high. This makes laser oscillation easy to achieve.
ii. Ion lasers provide numerous lines in the visible and UV part of the spectrum.

For $\mathrm{Ar}^{+}$-Laser, a number of different wavelengths are emitted simultaneously but the strongest are at 488 and $514.5 \mathrm{~nm} . \mathrm{Kr}^{+}$-Laser as pumping laser produces about nine lines in the range $476-800 \mathrm{~nm}$, with the 647.1 nm being the most intense. The Verdi laser produces single frequency light at 532 nm . For pumping the ring-dye laser system, the power of pump laser range from 4 to 7.5 watts.

Single mode cw tunable laser frequency operation can be achieved by using various laser dyes. The lasing action in dye laser produces a broad frequency spectrum and to obtain a stable single mode laser light within the spectral range of dye, various mode selective elements in ring-dye laser cavity are tuned synchronously. Frequency stabilization is achieved by locking the laser wavelength to a very stable external reference cavity.

The wavelength regions of different laser dyes which were used for the investigation of spectral lines of Pr are:
Laser dyes range / nm

Stilbene $3 \quad 420-460$
Rhodamine 6G 560-620
Sulforhodamine B 598-650
DCM 630-690
LD $700 \quad 690-780$

### 5.3 Hollow Cathode Lamp

A hollow cathode lamp (HCL) is a kind of glow discharge lamp and is an efficient light source producing comparatively narrow spectral lines. The width of emission lines from HCL is usually limited only by Doppler Broadening.

HCL was first used by Paschen [62] for the investigation of spectral lines of helium. Hollow cathode made by Paschen consists of central cathode with two anodes. Schüler [63-64] also used a HCL however it had one anode. Feldmann [65] was the first who introduced a discharge with clear path through the electrodes. Later on Miyazaki et al. [66] modified Feldmann design by placing the hollow cathode between two hollow anodes. Behrens and Guthöhrlein [67-68] also developed modified Schüler-type hollow cathode for generating atoms of the various elements under investigation.
Hollow cathode lamps are used in a variety of applications, for example in ion etching, thin film deposition, surface treatment, ion gas lasers and in spectroscopic analysis. In spectroscopy, HCL can be used as emission source, allowing direct excitation and analysis of a sample or as light source in absorption spectroscopy because of its sharp and intense spectral lines.

In case of metallic samples, the whole cathode is made up of the material to be investigated. On the other hand, for non metallic sample, a hollow cylindrical piece of the material is well fitted into a copper or aluminum hollow cylinder. In this case the cathode itself does not or very little contribute to the discharge. An advantage of hollow cathode is that the plasma is more localized inside the cathode which increases the efficiency of excitation. Furthermore, the metal concentration obtained by sputtering is far enough sufficient for spectroscopic purposes.
The home made HCL especially designed for the spectroscopic investigations of the hyperfine structure of spectral lines of praseodymium consist of several parts. The central element of the HCL is a copper tube into which an axially hollowed cathode is screwed which is filled on the inner wall with praseodymium. The typical length of the cathode is approx. 20 mm with optimum inner bore diameter of 3 mm . Two axially hollow anodes made of aluminum are placed on both sides of the hollow cathode. The anodes are electrically insulated from the metal tube and also from the cathode using ceramic holders. The separation between anode and cathode is approximately 0.75 mm . The anodes, the cathode and the ceramic parts had coaxial hole of almost same diameter which serve as a path for laser beam.
The copper tube together with the cathode and anodes is enclosed in a glass tube which extends symmetrically at both ends forming the actual discharge container. The anodes are provided with conducting pins, led to the outside of the device through a feedthrough. The ends of glass tube are sealed by the two circular quartz glass plates acting as windows of hollow cathode lamp. The complete hollow cathode lamp is shown in the Figure 5.2.

Before the discharge is switched on, the device is normally evacuated for $10-12$ hours by a rotary vane pump to create a good vacuum. Hollow cathode lamp is then filled with argon as a carrier gas at a pressure ranging from 0.3-0.8 mbar depending on the type of specie to be investigated i.e. neutral atoms and ions, region of investigation and discharge conditions. Discharge current is typically 60 mA and DC voltage varies from 350 to 650 V . HCL with vacuum system is shown in Figure 5.3.

Figure 5.2: Hollow cathode lamp HC...Hollow Cathode, A...Anode current feedthrough F...Quartz windows, D...O rings, H...Glass stop cocks

Figure 5.3: Schematic design of the vacuum system
HKL...hollow cathode lamp, H1 H2...Glass stop cocks, S1-S2...Slide valves, V1-V7...Shut-off and gauge valves, KF1, KF2...Cold traps, M...Manometer, P...Two-stage rotary vacuum pump, G...Gas inlet, Ne...Reservoir for Neon, Ar...Reservoir for argon.

A DC voltage applied across the discharge lamp ionizes the buffer gas into positive ions and electrons. The field distribution around the co-axial hole is such that the discharge burns down into the hole. The carrier gas ions are accelerated and hit the inner wall of the cathode material which in our case is praseodymium. If the bombarding ions have sufficient energy which is in excess of the binding energy of the atoms of the cathode material then the atoms can be ejected from the surface. This process is called cathode sputtering. The probability that an atom or an ion is ejected from the cathode surface is
defined by sputtering yield. Sputtering yield is "the number of sputtered particles per incident particle as a function of the energy and the identity of the incident particle". Both mass and energy of the incident particle are important factors which govern the sputtering yield. For example an incident Ar ion has a higher sputtering yield with lower energy threshold as compared to the Ne ion which has a lower sputtering yield with higher energy threshold for the same kind of sputtered material.
The sputtered species consists predominantly of ground state neutral atoms, and a small fraction of excited atoms and ions. The ejected atoms may be excited or ionized due to collisions with the energetic ions and electrons of the discharge with broad range of energies.

This broad-band collision induced excitation mechanism in the hollow cathode discharge give rise to a highly excited plasma having a population distribution predominantly among various atomic energy states. This makes HCL particularly useful to investigate the level schemes of high lying states using LIF technique. For example in case of Pr levels up to $35000 \mathrm{~cm}^{-1}$ above the ground state can be investigated. The cloud of free atoms and ions both in ground and excited states gives an intense light emission with a color which is characteristic of the sputtered material. For a stable discharge, the HCL is cooled by liquid nitrogen. The nitrogen cooling results in a reduction in the thermal velocities of the sputtered species which greatly reduces the Doppler width of the spectra. For Pr the typical Doppler width is around 800 MHz .

### 5.4 Measurement and Fluorescence Detection

The laser induced fluorescence signal is detected and measured by means of a lock-in amplifier using phase sensitive detection technique. A lock-in amplifier is a very sensitive instrument and is able to detect very weak AC signals as low as a few nanovolts. DC signal such as photomultiplier tube dark current are not amplified. This is done by a technique known as phase sensitive detection which filters out the component of the signal at a specific reference frequency and phase. In fluorescence signal measurements, the phase of the signal is tuned such that lock-in amplifier output is maximum. This would correspond to a signal that is in phase with the intensity modulated laser excitation wavelength. In this way, even very low intensity LIF signal in an extremely noisy environment can be observed and recorded.

In our experimental setup (Figure 5.1) the intensity of the incoming laser beam is modulated by a mechanically chopper 1 and the modulation frequency is given as reference frequency to the lock-in amplifier. Initially the phase of the lock-in amplifier is set by means of a known LIF signal. This is done by first tuning the laser frequency to the strongest hyperfine component of a spectral line and setting the transmission wavelength of the monochromator to a detection line having a strong LIF signal.
The experimental investigations of the hyperfine structure of the spectral line is performed in two steps. In first step the laser frequency is set to one of the hyperfine components of the line, usually to the strongest hyperfine component and the transmission profile of the monochromator is varied to search the fluorescence lines originating from the levels that are involved in the excitation of line (Figure 5.4).

Figure 5.4: Searching for fluorescence lines
In the second step, the hyperfine structure of the spectral line is recorded using the observed fluorescence wavelengths. For this purpose the monochromator is set to a preselected transmission wavelength, which were observed previously in the first step, and laser frequency is scanned ( $\sim 45 \mathrm{GHz}$ ) across the hypefine components of the spectral line (Figure 5.5). In order to avoid laser stray light a detection line for laser induced fluorescence is chosen which is different from the excitation line. In this way, the hyperfine structure of the excitation line together with the information of fluorescence wavelengths is studied.

Figure 5.5: Recording the hyperfine structure of a spectral line.
The nominal reading precision of the monochromator used is about $1 \AA$, but sometimes it is necessary to determine the fluorescence line wavelength more accurately. This is done by placing a second chopper wheel in front of the entrance slit of the monochromator. This modulates the intensity of fluorescence light coming from HCL. The output signal of the photomultiplier is given to a second lock-in-amplifier, with the modulation frequency of second chopper as a reference. Laser frequency is tuned to the strongest hyperfine component of the excited transition, and the grating monochromator is automatically scanned over a certain spectral range.

The output signals of both lock-in-amplifiers are recorded simultaneously on separate traces. In this way the spectrum of HCL can also be used to calibrate the monochromator wavelength scale. Comparison of the recorded hollow cathode spectrum with the corresponding part of FT-spectrum gives the wavelength of LIF line with an accuracy of $\pm 0.05 \AA$ despite the relatively low resolution of the monochromator. Accurate measure of fluorescence wavelengths is also beneficial in situations where the excited transition could not be identified meaning in the involved transition both lower and upper level could be unknown. In such cases fluorescence wavelength information provides a clue to identification of the upper level.

### 5.5 Fourier Transform Spectrum

The progress of Fourier transform (FT) spectroscopy has made it possible to record spectra with resolutions down to $0.01 \mathrm{~cm}^{-1}$, over spectral ranges from the ultraviolet ( $\sim 2000 \AA$ ) to the infrared $(\sim 5 \mu \mathrm{~m})$. Such spectra are characterized by a very high accuracy of wavenumbers assignable to the observed lines and by a wide dynamic range of intensities. A further advantage is that the spectrum is available in electronic form, which makes it easy to handle the data and to fit the hyperfine patterns using shape functions for the individual hyperfine components.

The FT-spectrum of praseodymium was recorded in the Institute of Quantum Optics at the Leibniz University in Hanover Germany as a part of a diploma thesis [25]. This was done by continuously scanning high resolution FT-IR spectrometer model number IFS 120 HR. A hollow cathode discharge lamp was used as an emission source and the emitted light is focused on to an entrance slit of the FT spectrometer. The recorded Fourier-transformed emission spectrum covers a very wide region ranging from $2380 \AA$ to $12500 \AA$. The resolution of the recorded spectrum is a convolution of the instrumental profile and the Doppler width of the spectral lines. Multiple scans were taken and were then averaged to improve the signal-to-noise ratio and to get a typical resolution of $0.03 \mathrm{~cm}^{-1}$. A small portion of a spectrum is shown in Figure 5.6.

Figure 5.6: Fourier Transform spectrum in the region 5822.0 Å to $5820.0 \AA$
The recorded data files were in the form of intensity versus wave numbers. The files were
then converted by employing the dispersion formula given by Peck and Reader [69] into a spectrum with intensity versus air wavelength.

Wave number of a line is equal to the difference between the term values of the levels involved in its formation. For those spectral lines in FT-spectrum whose hyperfine structure is fully resolved, the hyperfine structure constants can be determined by fitting the line profile obtained from FT-spectrum to a mathematical function. In the FT-spectrum the majority of spectral lines have only partially resolved hyperfine structure for such lines, LIF signal need to be recorded for the determination of the hyperfine structure constants of the involved levels.

## 6 Computer Programs for Data Analysis

Various computer programs are used for the analysis of the experimentally recorded data. Two main programs are
(i) Classification Program 'Elemente' is used to manage the huge number of spectral lines found in an element such as praseodymium.
(ii) Fitter Program is used to fit the experimentally recorded hyperfine structure of a spectral line or a line profile extracted from FT-spectrum to a mathematical function which then gives a best estimate of the spectroscopic parameters of the levels involved in the formation of the line.

### 6.1 Classification Program 'Elemente'

One of the most difficult tasks in investigating the spectrum of an element is to manage and classify the huge number of spectral lines belonging to that element. This can be done in a conveniently manner by a specially designed computer program known as 'Elemente'. The program not only manages the large number of spectral lines but also allows the classification of known and unknown lines via their center-of-gravity wave number and expected hyperfine structure. The program was developed by L. Windholz [70] and its viewer version is available on the internet. The program is designed in such a way that it can be used for any element. Our research group is using this program to study spectral lines belonging to various elements such as Praseodymium, Tantalum, Lanthanum, and Neodymium. It can simultaneously handle both atomic and ionic lines. The program also includes several search strategies for finding unknown energy levels from unclassified lines. The program needs three data files to work:
(i) The wavelength file or table, containing all the known spectral lines whether classified or unclassified. The Pr wavelength table has presently more than 29000 entries in the following format:
5699.305, nl 4, , , , 30576.861,4.5 ,o, 770.47, , ${ }^{*} \operatorname{Sm080}$, 13035.73 ,5.5 ,e, 795.9v, -, Helmri,(Pr I) in Pr5003 vorh. \#Sm080809 pr214055 a5699.305 f4787 f+4656 f5155 f5180 f5255

The first entry is line wavelength in $\AA$ in air, next four entries are intensities from different sources. If the line is classified the next entries are the energy, angular momentum, parity, $A$ and $B$ values and comment about the upper level. Then the next entries are for lower levels in the same order as for the upper level. Finally, it is possible to comment the lines, for example to give excitation wavelengths, fluorescence wavelengths and so on.
(ii) A data file containing all the known neutral atom levels, e.g. in case of praseodymium this file is named Level_pr.dat, for example,
0.5, o, 30400.042, 1890(10), $\quad$ *Sm080318 pr127038 a5756.53 pr350039 $\mathbf{a 5 1 4 1 . 7 0} \mathbf{f 5 1 4 1 . 7 0 3} \mathbf{f 5 2 5 1 . 1 1 4 , ~ f 5 4 4 8 . 5 1}$
(iii) A data file containing all known ionic levels, e.g. lev_prii.dat, for example,

3, o, 33850.957, 937, $\quad$ *Sm110201 pr641010 a4275.15 pr641013 a4385.45 $\mathbf{f}+\mathbf{3 8 4 1} \mathbf{f 3 7 5 7} \mathbf{f 4 0 7 7} \mathbf{f 4 2 4 3} \mathbf{f 4 4 4 6}$
The newest version of the classification program has two main frames, an upper main window and a lower graphic window displaying the FT-spectrum. The program has an
option to show or hide the FT-spectrum. The main window is divided into three sections. The middle section lists all the suggestions for the selected spectral line. For each listed suggestion the spectroscopic parameters such as energy, angular momentum $J$, parity and hyperfine interaction constants $A$ and $B$ for the combining levels are displayed. Wavenumber of the line from wavelength file, center-of-gravity wavenumber of the spectral line, the difference between the energies of the combining levels and center-ofgravity wavelength of the spectral line are also displayed. The leftmost section on the main window displays the classification of the spectral line as contained in wpr and the rightmost graphical section gives the graphical representation of all the list suggestions for a quick overview.

Spectral line is selected by the option "GoTo Lambda" for already known classified line or by the option "Insert Line" for an unknown unclassified line. The program calculates and searches for all possible transitions (number of possible suggestions depends on the selectable bandwidth) by comparing the wave number of the line with the difference of energies of the pairs of levels which fulfill selection rules. The classification suggestions are then displayed in the middle section of the main window. Atomic suggestions are listed in the beginning and the ionic at the end, anyone can be suppressed by using an option in the menu bar. The listed suggestions are sorted by energy and parity of the upper level with low energy and odd parity having higher priority. The program calculates the graphical hyperfine structure for each suggestion based on $J, A$ and $B$ values of the combining levels. This graphical representation is displayed in the bottom frame of the middle section.

Figure 6.1: Main window of classification program
The program reads the data from $w \operatorname{Pr}$ for the selected line and if the selected line is already classified, it is displayed in the leftmost section of the main window of the program. Some of the main features of the classification program are:

- Navigation from one spectral line to another can be done using Prev. and Next options.
- GoTo Lambda is used to move to a selected wavelength.
- Insert Line is used to insert a new spectral line to a wavelength table and placed it in a properly position.
- Select for Entry selects a specific suggestion for a possible classification of the current spectral line. A dialog box appears which display specific information regarding the line such as wavelength, relative intensity, comment window, etc.
- Detail displays the hyperfine pattern of the current suggestion for the spectral line along with its level scheme.
- Simulate show the hyperfine pattern like using "Detail" option but also allows to simulate a hyperfine pattern by changing all hyperfine constants. It is usually used if the classification suggestion contains levels for which the
 hyperfine constants are not known.
- Save permanently store the information about the classified line in the wpr.dat file without ending the program.
- GoTo moves to a selected spectral line if it is already contained in the wavelength table, to the lowest and the highest wavelength or to the start wavelength (beginning of work).
- Marked Line. The current wavelength can be marked by using this menu option which can be visited later on.
- Scale is used to select the width of the graphic fields. This is needed when comparing the calculated hyperfine structure pattern with the FT-spectrum.
- Settings set certain parameters for the classification program. It has various options. Some of them are the wave number difference used for finding classification suggestions, the wavelength difference used later on in transition list frame of a specific level, the Doppler width to set the width of the hyperfine components.
- Search is used to select either atomic or ionic levels schemes or both. Arbitrary selections rules for $J$ can also be selected independently.
- Transitions show all the transitions having the upper or the lower level of the current line as their upper level. A specific line can be selected which then displays selected suggestion with its hyperfine structure pattern.
- Classification facilitates a faster movement from one spectral line to another by suppressing the Classification Routine. In this option, suggestions for the line are not displayed.
- Show Levels displays atomic or ionic levels from the respective database.
- Seek New Levels. It has four menu options
- Based on Current Line: It calculates the possible odd or even levels using the wavelength table (wpr.dat in case of praseodymium). Calculations are performed for atomic or ionic or for both levels using selection rules.
- Based on Fluorescence line: It has two options "Seek New Levels" and "Seek Known levels". In each case, the experimentally observed fluorescence wavelengths are given to the search routine, the routine then selects all the lines from the wavelength table (wpr.dat) within a specified interval of wavelength of fluorescence lines. It then uses these lines to calculate new level or known level.
- Based on A and J: A new upper or lower level is searched based on the spectroscopic parameters as obtained from the analysis of the experimentally recorded hyperfine structure.
- Reload Levels allows reloading of the atomic and ionic levels from the respective data bases.
- Delete is used either to delete a classification entry by "Delete Classification" or entirely delete the line by using "Delete Current Line". This is beneficial when a wrong line has been inserted.
- WN-WL Converter is a small program which converts the wavelength in air to vacuum or vice versa or from wavenumber to wavelength. It also displays the difference between two wavelengths in wavenumber or difference between two wave numbers in terms of wavelength.
- Extra is used to calculate all possible levels just by adding the wave number of the lines contained in the wavelength table to all known levels.
- FT Spectrum displays a separate frame for Fourier transform spectrum. It also has option to calculate wavelength/wave number difference between two points in FT spectrum.
- End ends the program.

### 6.2 Hyperfine Structure Simulation Program

A simulation program is used to have an approximate estimate of the spectroscopic parameters such as angular momentum values for the upper and lower levels, the magnetic hyperfine interaction constant $A$ and the electric quadrupole interaction constant $B$.

Figure 6.2: Hyperfine structure simulation program

The inspection of the recorded hyperfine structure of the line gives some idea about the spectroscopic parameters of the combining levels involved in the formation of the hyperfine structure. Using some initial guesses about the angular momentum values, the recorded hyperfine structure is simulated by varying the $A$ and $B$ values in the simulation program for the lower and upper levels. In this way, using these estimated $J, A$ and $B$ values, further analysis of the recorded hyperfine structure is performed. The Doppler width and nuclear spin can also be changed in the simulation program, if needed.
In situations where either the linearized recorded hyperfine structure or the line profile from the FT-spectrum is to be simulated, the simulation program which is the part of classification program is used to estimate the spectroscopic parameters related to the line profile. Using these estimated parameters as the starting point give best fit spectroscopic parameters of the experimentally recorded hyperfine structure or of a line profile from FTspectrum. This helps in the identification of the levels forming the spectral line. The program can also be used in situations where one of the listed suggestions in the classification program can be classified by simulating the hyperfine structure line profile from FT-spectrum

Figure 6.3: Simulation program. Left is the simulation of the recorded hyperfine structure line profile (red curve). Right is the simulation with line profile from FT-spectrum (red curve)

### 6.3 Data Viewer Program

A data viewer program is used to display the unlinearized recorded hyperfine structure of various investigated spectral lines (see Figure 6.4). The program consists of two frames. The smaller frame or window is used to convert wavelength in air to wavelength in vacuum or vice versa or to convert wave numbers to wavelengths. In addition, it can also calculate the differences in terms of wavelength in air, wave numbers in $\mathrm{cm}^{-1}$ and frequency MHz . The large window has three sections: a dialog box for displaying names of the recorded data files, a text window for the comments and a graphic window for displaying the recorded hyperfine structure of the line. The program has the facility to calculate roughly the position of any hyperfine component provided the free spectral range (FSR) and starting wavelength of the recorded hyperfine structure are known. The program also has the facility to convert the recorded data file in to a format suitable for the fitter program.

Figure 6.4: Data viewer program

### 6.4 Classification of a Line

Praseodymium with its five outer electrons has a large number of electron levels and this leads to an exceptionally high density of lines. This is evident from the FT-spectrum of praseodymium where one can observes large number of classified and unclassified spectral lines formed by the combination of energy levels which are yet to be discovered. In the classification program a spectral line is inserted, the program first calculates the wave number of the line and then lists only those transitions for which difference of levels energies fit (within some specified limit) with the wavenumber of the line. These listed transitions are called suggestions. The classification program generates the hyperfine structure pattern for each suggestion provided the hyperfine structure constants for combining levels are known. The hyperfine structure pattern is then compared with the hfs of the line in FT-spectrum or with the recorded hyperfine structure of the line. If the calculated hyperfine structure is in a good agreement both in terms of the shape and position of hyperfine components then the line can be classified as a transition between known lower and upper levels as shown in Figure 6.5.

Figure 6.5: Classification of the line $5820.325 \AA$

In case, if the hyperfine structure profile in FT spectrum or the recorded hyperfine structure does not match with any of the listed suggestions then at least one of the combining levels is not known. There are a number of search strategies present in the classification program for finding new energy levels, some of them are discussed below.

### 6.4.1 Determination of New Levels by the Combination of Wave Numbers

Ritz combination principle [71] together with the wavenumber of an unclassified line can be used to determine a new level. The line then can be classified with the help of the new level and its hyperfine structure parameters. The method can be understood in following steps.

1. The first step in the search for a new level is to assume certain parity for the new level, for instance taking the parity of the new level to be odd. Now all the even levels are sorted with respect to their energy in ascending order. The energy of the new odd level is determined by adding the wave number of the unclassified line to the energy of the lowest energy even level.
2. In the second step, the energy of this new odd level is compared with the energies which are obtained by adding the wave numbers of all the lines in our line list to other even level energies. The energies obtained in this manner which is coincident with the energy of the predicted new odd level, the wavelength and the even lower levels are listed.
3. In the third step, the steps 1 and 2 are repeated but now taking the next higher even level from the sorted list as the basis of the calculation.
4. Completing the process for all even parity levels give a number of possible lower even parity levels.
5. The $J$-value for the possible new odd level is determined by employing the selection rules for the combining new odd level and one of possible lower even level in the list.
6. For each of the calculated transition, the hyperfine structure is simulated by varying the $A$ and $B$ values for the new odd level and using the known $A$ and $B$ values of the lower even levels. If the simulation for this combination is not possible then this suggestion is excluded.
7. In case the simulation is possible the $A$ and $B$ values for the new odd level are obtained. The new level is introduced and the hyperfine structure pattern of other lines can be calculated and compared with their hyperfine structure appearing in FT spectrum.
8. If after executing above step no new odd level is suggested then the whole process from step 1 is repeated but now assuming a new even parity level.
The strategy enumerated above is used for investigating the spectrum with not too many spectral lines such as the spectrum of Ta , but is not useful for Pr since it has a very high density of lines and this may lead to many coincidences appearing just by an accident.

### 6.4.2 Finding of a New Level by Fluorescence Lines

If an unclassified line is excited by laser light and some fluorescence lines are observed, then a possible new energy level involved in the excitation can also be determined by using fluorescence information. This method is again based on the Ritz combination principle with the difference that this time it only uses the current line and lines from the database in a certain wavelength range around the observed fluorescence lines. For the method to work
at least three fluorescence lines with accurate measure of fluorescence wavelengths must be observed which decay to known lower levels.

To seek a new level, the center-of-gravity wavelength (in air) of the excitation line is inserted in the classification program as the current line. The observed fluorescence wavelengths $\lambda_{f l, n}$ are given to the search routine of the classification program using the option "Search for New Levels based on Fluorescence Lines" as shown in Figure 6.6.

Figure 6.6: Window for seeking a level based on fluorescence lines
We assume a certain parity of the new level for example odd parity and seek for the new level. Program calculates the wave number of the line, takes the lower even levels from the list of known levels and add the wave number of the line. This gives the wave number of the hypothetical new upper level. Program then calculates the transition wavelengths from the new hypothetical upper level and displays possible suggestions for the lower and upper energy levels with fluorescence wavelengths within a certain specified limit as shown in Figure 6.7

Figure 6.7: An unclassified line at $5808.71 \AA$, with a new level $26915.499_{7 / 2}^{o} \mathrm{~cm}^{-1}$

The hypothetical level which explains most of the observed fluorescence lines $\lambda_{f b, n}$ can be treated as the level which is being searched. If none of the suggestion explains the observed fluorescence lines, then the process is repeated but this time searching for new even parity level. This method is especially suitable in cases where both lower and upper levels in an excited transition are unknown but then one of the fluorescence lines has to be chosen as the current line.

### 6.4.3 Finding a New Level by Analysis of the Hyperfine Patterns of Unclassified Lines

Knowledge of the pair of hyperfine interaction constants and $J$-values in most cases is sufficient to identify a level involved in the formation of a spectral line. The angular momentum values and hyperfine interaction constants for the combining levels i.e. $J_{o}, J_{u}$, $A_{o}, B_{o}, A_{u}, B_{u}$ are estimated by fitter program. Assuming that one of the levels involved in the transition is known, the level is searched in the database of known levels. This is done by using the search routine in the classification program called "Seek New Levels Based on $A$ and $J$ ".
As an example consider the excitation of spectral line at $\lambda=5966.38 \AA$. A hyperfine structure with well splitted components was recorded on fluorescence wavelengths $4304 \AA$, $4385 \AA, 4683 \AA, 5257 \AA$, and $5568 \AA$. Fitting the recorded hyperfine structure of the line by "Fitter program" gave the best fit values as $J_{o}=9 / 2, J_{u}=11 / 2, A_{o}=919 \mathrm{MHz}, A_{u}=295$ MHz . Assuming an unknown upper level is involved in the excited transition, best fit $A$ value of the lower level and the $J$ - values of both upper and lower levels are given to the search routine. The program searches the database for a known lower level of specified $J$ value and $A$-value (within specified interval). It then displays number of suggestions for possible upper level along with its transition list both in even and odd parity as shown in Figure 6.8

Figure 6.8: Possible new upper levels for the excitation of line at $5966.38 \AA$

The observed fluorescence wavelengths are then searched in the transition list of each suggestion. In this example, first listed suggestion in odd parity explains all the observed fluorescence wavelengths. The next step is to assume that this lower level is involved in the observed transition, and to fit the recorded hyperfine structure again with $A_{u}=295$ MHz and $B u=-22 \mathrm{MHz}$ being fixed. The energy of the new level is calculated by adding the wavenumber of the line, $16755.991 \mathrm{~cm}^{-1}$ to the enrgy of lower level, $11904.07 \mathrm{~cm}^{-1}$. Finally one gets for the new upper level $27660.001 \mathrm{~cm}^{-1}, J=9 / 2 A=925 \mathrm{MHz}$. The new level explains the observed fluorescence lines which confirm the energy and existence of level.

### 6.4.4 Determination of Both New Lower and Upper Levels

In some cases, it is observed that J-value and hyperfine constants determined from the recorded hyperfine structure cannot be associated with the values of a known level. This implies that both lower and upper involved in the formation of the spectral line might be unknown. The identification of such levels is based on the observed fluorescence wavelengths provided that the number of observed fluorescence wavelengths is three or more and fluorescence lower levels are known. The basic idea behind this procedure is to look for known lower levels to which fluorescence lines from the unknown upper level decay. The procedure is as follows:

1. The exact fluorescence wavelengths are measured and converted in to wave numbers. For each pair of fluorescence lines the wave number differences i.e. $\Delta_{i j}=\left|\sigma_{i}-\sigma_{j}\right|$ are calculated.
2. The data base of known levels is search for known lower levels with same parity, based on the criteria that the differences between the wave numbers of these searched lower levels are within some margin of error equal to the wave number differences $\Delta_{i j}$ of fluorescence lines.
3. Once such a set of lower levels are found which fulfills the criteria listed in step 2, then by using the energy of the any of lower level in the set and the wave number of fluorescence line the energy of the unknown upper level is calculated.
4. Parity of the estimated upper can be set opposite to that of the set of lower levels.
5. Now the energy of the excitation lower level is determined using the energy of the proposed upper level and the wave number of the excitation line.
Hyperfine structure constants and $J$-values of the unknown lower and upper levels are determined using the mathematical fit of the recorded hyperfine structure.

This procedure can be performed by the classification program (see 6.4.2) if a fluorescence line decaying to a known level is used as a current line (fictitive excitation of the fluorescence line).

### 6.5 Mathematical Fitting of Hyperfine Structure Pattern

In order to determine the spectroscopic parameters (such as angular momentum J values and the hyperfine interaction constants $A$ and $B$ ) for combining levels from the experimentally recorded hyperfine structure of the spectral line, it is necessary to fit the recorded hyperfine structure profile to an appropriate mathematical function using the "method of least squares". It is an iterative process in which a curve is fitted to a set of data points so as to minimize the sum of the squares of the deviation of the points from the curve. Usually a pre-fit analysis of the recorded hyperfine structure profile is helpful in
evaluating best fit spectroscopic parameters. The spectroscopic parameters such as nuclear spin quantum number $I$, angular momentum $J$ values of upper and lower levels and hyperfine interaction constants $A, B$ characterizes a particular hyperfine splitting of a fine structure level.

A rough estimate of the magnitudes of the hyperfine interaction constants A and B can be given by inspecting the amount of splitting of a fine structure level in to the hyperfine structure levels. Assuming that the hyperfine interaction constants for both upper ( $A_{o}$ ) and lower ( $A_{u}$ ) levels are positive (which is mostly the case with praseodymium), then from relative intensities of diagonal $(\Delta F=\Delta J)$ components it can be decided whether $A_{o}>A_{u}$ or $A_{o}<A_{u}$ accordingly if the relative intensities of diagonal components are decreasing towards shorter or longer wavelength. The relative intensities and spacing between the diagonal components give a suggestion about the $J$-values of the combining levels with an error of $\pm 1$. It is also possible to suggest a change in J values of fine structure levels for a transition from lower to upper level. If the off-diagonal $(\Delta F \neq \Delta J)$ components appear on both sides of diagonal components then there is no change in J value in going from lower to upper level i.e. $\Delta J=0$. If the off-diagonal components appear either on the longer or on the shorter wavelength side then the $J$-value changes by +1 or -1 respectively. One can also use the rough estimate of the recorded hyperfine structure profile by using the simulation program (see section 6.2).
These roughly estimated spectroscopic parameters together with the center of gravity excitation wavelength are used to fit the recorded hfs patterns to an appropriate mathematical profile function. The mathematical profile function can be chosen between Gaussian or Lorentzian, depending on the intensity profile of the recorded hyperfine structure. If both Gaussian and Lorentzian profiles are observed in the recorded hyperfine pattern then a convolution or mixture of both functions is used. Such a function is known as the Voigt function.
In order to determine the hyperfine interaction constants and the center-of-gravity wavelength, a especially designed computer program known as Fitter is used. The program fits the recorded hyperfine structure to a mathematical function. The program can also fit the hyperfine structure profile of a line extracted from FT spectrum.

### 6.5.1 Fitter

This program was developed in University of Bundeswehr Hamburg, Germany as a part of diploma thesis [72]. The program calculates the spectral intensity distributions associated with various hyperfine structures of spectral lines recorded experimentally. These hyperfine structures are electronically recorded in a digital form as a function of changing laser frequency. The recorded file containing the data points must be converted in a form acceptable to the fitter program. The fitter program fits the recorded hyperfine structure of an excited line or a hyperfine structure of the line profile from FT-spectrum to a mathematical function using the method of least squares. The program determines the hyperfine constants and center of gravity wavelength. In this way, the physical information embedded in the recorded hyperfine structure of an excited line or a profile from FTspectrum is extracted.

In an experiment, the intensity distribution of an excited transition is recorded in time domain i.e. as a function of equidistant time intervals. The data points representing the intensity distribution are not equally spaced in frequency. This is due to the non-uniform scanning behavior of the laser. Therefore a process known as linearization of the recorded data is adopted. The process converts the recorded spectrum which is in time domain $I(t)$
into frequency domain $I(v)$ using the marker etalon signal which is simultaneously recorded with the LIF spectrum. The process of linearization works only if the start wavelength of the laser scan and the free-spectral range (FSR) of the marker etalon are given to the electronically recorded data file.
The mathematical least square routine has a rapid convergence towards the best fit situation for the data points if the data points are equally spaced. Program calculates the position of individual hyperfine components and the hyperfine constants by the following relation

$$
\nu=v_{c}+\alpha_{o} \cdot A_{o}+\beta_{o} \cdot B_{o}-\alpha_{u} \cdot A_{u}-\beta_{u} \cdot B_{u}
$$

where $\alpha_{o}, \beta_{o}, \alpha_{u}, \beta_{u}$ are the Casimir factors for upper and lower energy levels respectively (see section 3.9). Intensity of each component is taken from the theoretical intensity formula using $6 j$ symbols (see section 3.8). A suitable mathematical model (Gaussian or Lorentzian or Voigt model depending on the shape of the recorded hyperfine structure profile) is used with physical boundary conditions as input parameters. The program gradually varies the values of these parameters, and the model progressively evolves and adjust according to the method of least squares or Gauss-Newton method to the series of experimentally recorded data points, i.e. minimizing squared error sum given by the function $E S S$,

$$
E S S=\sum_{k=1}^{n}\left[I_{v}(k)-I_{v}\left(v_{k}, \vec{a}\right)\right]^{2}
$$

where $I_{v}(k)$ is the measured intensity at a given frequency point $v_{k}, I_{v}\left(v_{k}, \vec{a}\right)$ is the calculated intensity at the corresponding position and $\vec{a}$ is a set of fit parameters. Using Tayler series the expansion of the above equation gives a system of nonlinear, inhomogeneous equations. The number of such equations in the system equals the number of parameters in $\vec{a}$. The method of least square is an iterative process so a solution of these equations is obtained in such a way that the deviation from the measured intensity becomes less and less and a new set of parameters values are obtained for the next iteration. The procedure is repeated until termination criterion is reached. Important input parameters are hyperfine constants of lower and upper levels, the frequency of a certain hyperfine component, the half width of the components, the underground intensity and center of gravity wavelength.
The program is based on a complicated iterative procedure and runs only in a pure mathematical sense with only objective of minimizing the squared error sum. This pure mathematical evaluation sometimes leads to unreasonable values of the physical parameters such as negative intensities or negative frequencies. One way of avoiding this is to reduce the number of input parameters. This can be done by fixing certain parameters according to a specific situation. For example if one of the levels involved in a transition is known then by fixing the hyperfine constants of this level the number of parameters are reduced by 2 . If half-width is known then the number of parameters is reduced by 1 . Furthermore this can also be done by coupling the relative intensities of various components together. So by coupling, the intensity coupling parameters are reduced by 1 . Coupling of components can also be done in situations where saturation effects change the relative intensity of hyperfine components.
In addition to the single line fit, fitter program can also be used for multi-line fitting. In cases where simultaneously more than one hyperfine structure patterns are overlapped such as in a blend situation or more than one isotopes are involved in a transition, multi-line
fitting procedure is adopted. Figures 6.9 and 6.10 show a single line and two line best fit situations respectively.

Figure 6.9: Fitting of single Pr I line at $6181.39 \AA$

Figure 6.10: Fitting of two Pr I lines at $5594.57 \AA$ and $5594.36 \AA$

## 7 Results and Discussion

The spectrum of praseodymium due to the open f-shell electrons has a very complex structure and high line density, because of this its spectrum is referred to as 'quasicontinuous'. Consequently on the average 5 to 10 lines per $\AA$ are frequently observed in the spectrum of praseodymium. The spectrum of praseodymium has been investigated thoroughly over the past few decades. These investigations are performed not only by our group but also by several other groups[11, 16, 20, 23, 73]. So far we have in our level database more than 2500 energy levels of even and odd parity belonging to Pr I and around 300 energy levels belonging to Pr II. Around 29000 lines are known to us in the spectral range from 320 nm to $3.5 \mu \mathrm{~m}$ and more than half of them have been classified.
During the course of this dissertation large numbers of unclassified and classified spectral lines were experimentally investigated using laser induced fluorescence spectroscopy. The hyperfine structure of these lines is used for the identification of energy levels involved in the transition. The investigations not only led to a proper identification of already known levels but also, in large number of cases, resulted in the discovery of new energy levels. The experimental investigations are organized as follows:

- New Pr-I and Pr-II energy levels in even and odd configurations by laser excitation.
- Classification of lines using known or unknown levels via laser excitation.
- Classification of lines by position and shape of the hyperfine pattern as shown in our FT spectrum.

A high resolution FT-spectrum of praseodymium, extending from UV to far infrared is helpful for our investigations. Excitation wavelengths of the lines are extracted from FTspectrum and laser excitation is performed. In case the recorded hyperfine structure of the line could not be explained using known levels, then either the upper level or the lower level is unknown, or it may happen in an extreme case that both the combining levels are not known. The level energy is then calculated and the line is classified. Spectral lines appearing in the FT-spectrum with good signal-to-noise ratio and fully resolved hyperfine components can be classified without laser excitation, provided the combining levels are known. Conversely, if the line could not be explained by any of the known levels, then the estimated hyperfine structure constants from the simulation can be used to determine the possible unknown involved levels.
It is observed in certain cases that some lines in FT-spectrum are very weak, this may be due to the fact that the upper level is less populated, or the transition probability to the lower level involved in the formation of such a line is low. For such lines laser excitation spectroscopy is far more advantageous than emission spectroscopy. Also, if a line in FTspectrum whose hyperfine splitting is not quite legible or line profile appears as a convolution of more than one lines, i.e. a blend of lines, then it is useful to study their hyperfine structure by laser induced fluorescence technique. Each line in the convolution can then be separated with help of the fluorescence information. In case of praseodymium, which has a very dense population of lines, blend situations are quite common and most of the investigations in this dissertation are performed by laser excitation. The spectral lines in praseodymium are so numerous that one frequently observes a LIF signal from two or more distinct levels at a specific excitation wavelength. This means that in the same scan range of laser either two very closely spaced lines involving different pairs of levels are excited simultaneously or a single upper level is excited from two very closely lying lower levels.

### 7.1 Hyperfine Structure of Praseodymium

The hyperfine multiplet is one of the characteristic features of any element. For praseodymium with nuclear spin quantum number $I=5 / 2$, mostly a well resolved hyperfine structure is observed having six main or diagonal hyperfine components. As is common with the hyperfine spectra of other elements, a regular decrease of spacing and intensities of hyperfine components is seen. This can be explained in terms of the fact that one of the combining levels has a larger width of hyperfine splitting and this in turn means that the magnitudes of the hyperfine interaction $A$ constants of the combining levels differ appreciably. Conversely, in situations where the magnitudes of the hyperfine interaction constants of the upper and lower levels are comparable, a hyperfine structure with closely spaced hyperfine diagonal components, forming a single peak, is observed. The spacing between the hf components of a level is governed by Lande's interval rule i.e. "in a multiplet, the differences between adjacent levels are in the ratio of the two $F$-values, where for each interval the higher of the two $F$-values is to be taken". The intensities within the hyperfine multiplets are governed by intensity rule i.e. "within a hf multiplet, the ratio of the sums of the intensities of all transitions from two states with quantum numbers $F$ and $F^{\prime}$ are in the ratio of their statistical weights $(2 F+1):\left(2 F^{\prime}+1\right)$ ". If one of the combining levels has a negligible splitting, the intensities of the lines are simply in the ratio of the values $(2 F+1)$ of the level whose splitting caused the structure.

The interaction between the electronic and nuclear moments leads to the splitting of fine structure level in to (2I $+1)$ or $(2 J+1)$ hyperfine levels accordingly as $J>I$ or $J<I$. The transition between different hyperfine levels of two fine structure levels give rise to $6(J>I)$ main or diagonal hyperfine components. Beside these main components two additional groups of weaker off-diagonal hyperfine components can also be observed. The number of off-diagonal hyperfine components depends upon the change in $J(\Delta J)$. If $\Delta J=0$ then one

Figure 7.1 : A sketch showing diagonal and offdiagonal compnents. can find 10 Off-diagonal components whereas if $\Delta J= \pm 1$ only 9 off-diagonal components can be observed (Figure 7.1). Each hyperfine component has a Doppler profile which arises from the plasma conditions within the hollow cathode lamp.

This research work is based on hyperfine structure investigations of more than 1500 spectral lines in Praseodymium using laser induced fluorescence spectroscopy. These investigations are performed in very wide spectral region ranging from $4300 \AA$ to $7500 \AA$. The major part of the investigations belongs to atomic transitions but few singly ionized levels have also been discovered. In most of the investigated transitions an upper level is unknown and only in few cases lower or both lower and upper levels were found to be unknown. These investigations led to the discovery of more than 300 new previously unknown energy levels, both in even and odd configurations. Angular momentum quantum number of these newly discovered atomic energy levels range from $1 / 2$ to $21 / 2$. Level energies are corrected at various observed fluorescence lines using the FT-Spectrum. Furthermore, the existence of the new level and its energy is confirmed by more than one
excitation. In general, the magnetic hyperfine interaction constant " $A$ " can be positive or negative, which give rise to normal or inverted hyperfine multiplets, respectively. In case of praseodymium, the value of constant $A$ is mostly positive. The quadrupole moment $Q$ for praseodymium is very small therefore the magnitude of quadrupole interaction constant " $B$ " in most cases is taken as zero. All wavelengths, excitation and fluorescence, are measured in air. In the following sections some of the newly discovered energy levels of $\mathrm{Pr}-\mathrm{I}$ and Pr -II are discussed.

### 7.1.1 Discovery of New Pr-I level via Laser Excitation of Line $7573.761 \AA$

In an attempt to classify systematically lines in FT-spectrum, a line at $7573.761 \AA$ (Figure 7.2) was observed. The line in FT-spectrum shows a well separated and resolved hyperfine structure with $\mathrm{S} / \mathrm{N}$ ratio of 78 . The suggestions listed in the classification program were compared with hyperfine structure of the line, but none of the listed suggestion had any agreement neither in terms of the shape nor in terms of position of hyperfine components. Therefore, it was concluded that either both or at least one of the levels involved in the formation of the line with the observed hyperfine structure in FT-spectrum is not known so far and yet to be discovered.

Figure 7.2: FT-spectrum for the line $7573.761 \AA$
The first step in the investigation is to search for LIF signals. This is done by setting the laser frequency to the strongest hyperfine component of the line i.e. $7574.00 \AA$ and then searching for fluorescence wavelengths by tuning the transmission wavelength of the monochromator. In such a way, LIF signals were observed at fluorescence wavelengths $5861 \AA, 6136 \AA, 6157 \AA, 6214 \AA, 6376 \AA, 6615 \AA, 6640 \AA, 6791 \AA, 7059 \AA, 7095 \AA$. The hyperfine structure of the line is then recorded on all observed fluorescence wavelengths by scanning the laser frequency across the hyperfine components of the line. Since the hyperfine structure of the line is larger than the scanning range of the laser ( 30 GHz ), the scan is done in three parts and then using a program, the recorded parts were merged to form a single data file containing the entire hyperfine structure of the line. Two different hyperfine structures were recorded at these fluorescence wavelengths. The hyperfine structure recorded at $6157 \AA, 6214 \AA, 6640 \AA, 6791 \AA$ can be explained as a transition between the known levels $\mathbf{2 7 9 9 9 . 6 2 3} \mathbf{1 9} / 2_{\mathrm{e}}^{\mathbf{c m}^{-1}}$ to $\mathbf{1 4 7 9 9 . 8 4 2} \mathbf{1 9}_{19 / 2}^{\mathbf{o}} \mathbf{c m}^{-1}$. On all other remaining observed fluorescence wavelengths, a widely splitted hyperfine structure was recorded as shown in Figure 7.3

Figure 7.3: Laser excitation of the line $7573.761 \AA$ showing a widely splitted hyperfine structure

A gradual decrease in the intensity of the diagonal components and the separation between them suggest high angular momentum values of the combining lower and upper fine structure energy levels of the excited transition. The intensity of the diagonal components decreases towards high frequency indicating that $A_{u}>A_{o}$ (valid in case of praseodymium where the $A$ values are mostly positive). Also the off-diagonal components appear on both sides of diagonal components which shows that $\Delta J=0$. In the next step, the recorded LIF spectrum is fitted to a theoretical curve using "Fitter Program". The evaluation gave the following results with a quality factor of 6.35 (Figure 7.4).

Center of gravity wavelength $=7573.761 \AA$
$J_{o}=19 / 2, A_{o}=337 \mathrm{MHz}$ and $J_{u}=19 / 2, A_{u}=847 \mathrm{MHz}$,

Figure 7.4: Best fit situation of the recorded hyperfine structure of the line 7573.761 Å

Using these best fit spectroscopic parameters as a finger print for a fine structure level, the combining levels are then search in the database of known levels. Assuming an unknown upper level is involved in the excited transition, a known lower level is searched in the database by using the search routine 'seek new level based on A and J'. A number of suggestions for possible new upper levels along with its fluorescence lines are displayed.
One of the suggestions for a possible new upper level explains all the observed fluorescence lines. The lower combining level of the said suggestion is $13626.672 \mathrm{~cm}^{-1}, J=$ $19 / 2$ even parity, $A=865 \mathrm{MHz}$. The recorded hyperfine structure is again fitted with the $A$ value of the lower level being fixed. The energy of the upper level is then determined by adding the wave number of the excitation line, $13199.845 \mathrm{~cm}^{-1}$, to the energy of the lower level, $13626.672 \mathrm{~cm}^{-1}$. The new upper level with spectroscopic parameters $26826.517 \mathrm{~cm}^{-1}$, $\boldsymbol{J}=\mathbf{1 9} / \mathbf{2}$, odd parity, $\boldsymbol{A}=\mathbf{3 4 1}(\mathbf{5}) \mathbf{M H z}$ is obtained. The level is introduced in the classification program and explains all the observed fluorescence lines from upper level in accordance with FT-spectrum. The comparison of the hyperfine patterns of observed fluorescence lines in FT-spectrum at $7059.326 \AA$ and $7095.327 \AA$ with the predicted hyperfine patterns calculated using $\mathrm{A}_{u}$ and $\mathrm{A}_{0}$, confirmed the existence and reliability of newly measured upper level (Figure $7.5 \& 7.6$ ).

Figure 7.5: Comparison of the observed and predicted hyperfine pattern of the fluorescence line $7059.33 \AA$

Figure 7.6: Comparison of the observed and predicted hyperfine pattern of the fluorescence line $7095.33 \AA$

Laser excitation was also performed at $7059.327 \AA$ (Figure 7.7) to further consolidate the newly found upper level.

Figure 7.7: Recorded hyperfine structure of the line $7059.327 \AA$

### 7.1.2 Discovery of Pr-I Level $25788.548_{7 / 2}^{o} \mathrm{~cm}^{-1}$ via Laser Excitation

In FT-spectrum a blend of two or more lines is clearly visible in the vicinity of $5624.172 \AA$, see Figure 7.8. A well resolved six peak hyperfine structure can be seen, the intensity of the second and last diagonal hyperfine components of the line show a blend situations. This suggested that possibly two other lines with their hyperfine structure are present at these positions. At center-of-gravity wavelength $5624.067 \AA$, the widely splitted six peak hyperfine structure is explained as a known transition between $24668.723_{13 / 2}^{o}$ $6892.934_{11 / 2}^{e}$. At $5624.006 \AA$ laser excitation was performed and a single peak hyperfine structure at fluorescence wavelength $5194 \AA$ was recorded. This line could be explained as already known transition between $20622.677_{13 / 2}^{\mathrm{e}}-\mathbf{2 8 4 6 . 7 4 1 _ { 1 3 / 2 } ^ { \circ }}$.
Now the laser wavelength is fixed at $5624.172 \AA$ and the transmission wavelength of the monochromator is varied to search for LIF signals. Since the last diagonal hyperfine structure component of the already known transition is coincident at $5624.172 \AA$, a number of fluorescence lines were observed belonging to the upper levels of both lines. By excluding those fluorescence lines appearing in the transition list of the already known upper level, the remaining observed lines $5007 \AA, 5192 \AA, 5501 \AA, 5863 \AA, 5831 \AA, 6215 \AA$ could not be explained by any of listed suggestions in the classification program. Now the laser wavelength is scanned across the hyperfine pattern of the line in FT-spectrum and successively on each of the observed fluorescence wavelengths, a hyperfine structure is recorded.

Figure 7.8-: FT-spectrum for the line $5624.172 \AA$
A narrowly spaced single peak hyperfine structure was recorded on all observed fluorescence wavelengths, see Figure 7.9. Apparently all the diagonal and off-diagonal hyperfine components are bunched together, suggesting that the hyperfine splitting of the levels involved is small, which in turn means small values of the hyperfine interaction $A$ constant. The recorded hyperfine structure for the line is compared with listed suggestions in the classification program but none of the suggestion explained the observed pattern. This implies that at least one or both of the combining levels for the line are unknown and yet to be discovered. A pre-fit analysis of the recorded structure by using simulation
program suggests small angular momentum values of upper and lower levels having small values of hyperfine interaction $A$ constants.

Figure 7.9: Recorded hyperfine structure of the line $5624.172 \AA$
Taking the simulated $J$ - and $A$-values for the combining levels as the start values, the recorded hyperfine structure was mathematically fitted using the fitter program. A best fit situation of the recorded structure was obtained for $\Delta J=0$ at $J_{o}=7 / 2, J_{u}=7 / 2, A_{o}=125$ MHz and $A_{u}=162 \mathrm{MHz}$, see Figure 7.10. $B_{o}$ and $B_{u}$ are assumed to be zero which is usual for praseodymium.

Figure 7.10: Best fit situation of the recorded hyperfine structure of the line $5624.172 \AA$
With an assumption that the upper level in the excited transition is unknown, the best fitted $J$-values for the combining levels and the best fit $A$ value of the lower level are used for
searching a known lower level in the data base of known levels. A lower level with parameters $8013.089 \mathrm{~cm}^{-1}$, even parity, $J=7 / 2$ and $A_{u}=165 \mathrm{MHz}$ combining with a possible new upper level was found. This possible new upper level explained all the observed fluorescence lines. Assuming this to be a correct combination of involved levels, the recorded structure was again fitted but now keeping fix the $A$ value of the lower level. The energy of the assumed newly found upper level was calculated by the center-ofgravity wave number of the excited line and the energy of the lower level. The spectroscopic parameters of the upper level are $\mathbf{2 5 7 8 8 . 5 4 8} \mathbf{~ c m}^{-1}$, odd parity, $J=7 / 2$ and $\boldsymbol{A}_{\boldsymbol{o}}=\mathbf{1 3 1 . 1 4 \mathrm { MHz } \text { . The level is introduced in the database of known levels and after }}$ reloading the levels from the data base the classification program generates a transition list for the newly found upper level. All the observed fluorescence wavelengths are present in the transition list of the newly computed upper level and as seen in the FT-spectrum fluorescence lines were fully explained. As an example the simulation of line at 5501.713 $\AA$ is shown in Figure 7.11. The simulation shows an agreement of the predicted hyperfine pattern of the line with the line profile in FT-spectrum. At the first approximation the existence and the assignment of the newly found upper energy level is confirmed.

Figure 7.11: Comparison of the observed and predicted hyperfine structure pattern of the fluorescence line $5501.713 \AA$

A second laser excitation was performed at one of the observed fluorescence wavelengths i.e. at center-of-gravity wavelength $5831.080 \AA$. The LIF signal at all previously recorded fluorescence wavelengths was observed and the hyperfine structure of the line at center-ofgravity wavelength $5831.080 \AA$ was recorded, see Figure 7.12 . The recorded hyperfine structure of the excited line at $5831.080 \AA$ is in full agreement with the hyperfine pattern calculated with the now already known hf constants. To further substantiate the agreement the recorded structure of line at $5831.080 \AA$ was fitted keeping fix the $A$ value of the newly discovered upper level (Figure 7.13), the fitting process reproduce the $A$ value of the lower level at this line. This confirmed beyond doubt the existence of the newly discovered upper energy level. As a final step in the analysis, the level energy is corrected at various spectral lines whose hyperfine structure is clearly visible in FT-spectrum. Provided the energy of the lower level is correct, the energy of the upper level can be corrected with an accuracy governed by the recorded resolution limit of the FT-spectrum of praseodymium which is typically $0.03 \mathrm{~cm}^{-1}$

### 7.1.3 New Pair of Pr-I Energy levels via Laser Excitation

In the vicinity of $5700.92 \AA$, the structure in the FT-spectrum apparently suggests a blend of more than one lines with weak signal-to-noise ratio having a relative intensity of 13 , see Figure 7.14. The classification program suggests only few transitions with a small wave number difference. Furthermore for these few transitions the predicted hyperfine pattern is in poor agreement with line profile in FT-spectrum. So the line or lines in the neighborhood of 5700.92 Å cannot be classified without laser excitation.

Figure 7.14: FT spectrum for the line $5700.92 \AA$

Laser excitation wavelength was set to $5700.92 \AA$ and LIF signal was observed on a number of fluorescence lines at wavelengths $4928 \AA, 4978 \AA, 5293 \AA$, $5340 \AA, 5363 \AA$, $5446 \AA, 5578 \AA$. Now the hyperfine structure was recorded on all observed fluorescence wavelengths and two different hyperfine structure patterns with good signal-to-noise ratio were recorded. One of the hyperfine structure is recorded at fluorescence wavelengths $4928 \AA, 5363 \AA$ (Figure 7.15) and the other on $4978 \AA, 5293 \AA, 5340 \AA, 5578 \AA$ (Figure 7.16). At fluorescence wavelength $5446 \AA$, a mixture of both hyperfine structures were recorded suggesting a possible fluorescence blend situation. A blend situation occurs in case the laser may have excited two or three transitions to two or three different levels which by chance have almost the same wave number difference. The recorded structure would then be a convolution of two or three hyperfine structures apparently depicting an excitation and fluorescence blend situation. From the experimentally recorded hyperfine structures center-of-gravity wavelengths were estimated as $5700.92 \AA$ and $5700.94 \AA$. Once again the suggestion list in the classification program for both lines was inspected but none of the listed suggestions explained the recorded hyperfine structure patterns. It was concluded that either the upper or lower level or all involved levels for both lines are not yet known. Pre-fit analysis using a simulation program give an approximate estimate of $J$ and $A$-values of the combining levels for both recorded structures. Taking these estimated values as start values, the recorded hyperfine structures were mathematically fitted by using the fitter program.

Figure 7.15: Recorded hyperfine structure of the line $5700.92 \AA$

Figure 7.16: Recorded hyperfine structure of the line $5700.94 \AA$
The best fit situation for the hyperfine structure recorded at center-of-gravity wavelength $5700.90 \AA$ is shown in Figure 7.17 with fitted parameters $J_{o}=3 / 2, J_{u}=3 / 2, A_{o}=985.08$ MHz and $A_{u}=712 \mathrm{MHz}$. For the hyperfine structure recorded at center-of-gravity wavelength $5700.94 \AA$ the fit result is shown in Figure 7.18 with fitted parameters $J_{o}=5 / 2$, $J_{u}=3 / 2, A_{o}=704.55 \mathrm{MHz}$ and $A_{u}=712 \mathrm{MHz}$. It is noticeable that for both structures the fitter program gave the same $J$ and $A$ values for the lower level. Center-of-gravity wavelengths were inserted in the classification program and it was assumed that for both lines the upper levels are unknown. Taking the best fit $J$ values and A value of lower level the data base of known levels is searched for a lower level using the searching routine in classification program. This was done separately for both lines. In each case the classification program generated a number of suggestions for possible new upper levels. Two possible new upper levels explained all the observed respective fluorescence wavelengths.

Figure 7.17: Best fit situation for the line $5700.92 \AA$

Figure 7.18: Best fit situation for the line $5700.94 \AA$
Interestingly, the same lower level at each excited transition combines with the two different upper levels. The parameters for this lower level are $12464.369 \mathrm{~cm}^{-1}$, even parity, $J_{u}=3 / 2$ and $A_{u}=712(4) \mathrm{MHz}$. The energy of the two upper levels at center -of-gravity excitation wavelengths $5700.92 \AA$ and $5700.94 \AA$ were calculated by using center-ofgravity wave numbers for each line and the energy of the common lower level. The spectroscopic parameters for the upper level with center-of-gravity excitation wavelength $5700.92 \AA$ are $30000.532(20) \mathrm{cm}^{-1}$, odd parity, $J_{o}=3 / 2$ and $A_{o}=1000(15) \mathrm{MHz}$ and for the upper level at center-of-gravity excitation wavelength $5700.94 \AA$ are $30000.493(20) \mathrm{cm}^{-1}$, odd parity, $J_{o}=5 / 2$ and $A_{o}=708(8) \mathrm{MHz}$. Both newly discovered upper levels were then introduced in the database of known levels and after reloading, the classification program generates a transition list for both newly found upper levels. Both upper levels were then
confirmed separately at other excitation wavelengths, i.e. $30000.532(20) \mathrm{cm}^{-1}$ was confirmed by a second excitation at $6121.87 \AA$ and $30000.493(20) \mathrm{cm}^{-1}$ was confirmed at $6121.88 \AA$. Interestingly here again at second excitation wavelengths for both closely lying upper levels, a common lower level combines. The predicted hyperfine structures for both lines are in complete agreement with the recorded hyperfine structures, see Figures 7.19 and 7.20. This confirms the existence and energy of the newly discovered upper levels beyond any doubt.

Figure 7.19: Comparison of the recorded hyperfine structure (Red curve) of the line $6121.87 \AA$ with the predicted hyperfine structure (Blue curve).

Figure 7.20: Comparison of the recorded hyperfine structure (Red curve) of the line $6121.88 \AA$ with the predicted hyperfine structure (Blue curve).

The level scheme for both spectral lines is shown in Figure 7.21. A fluorescence blend is observed in the original excitation at fluorescence wavelength $5446 \AA$ where both level decay to a common fluorescence lower level.

Figure 7.21: Level scheme for the excitation of $30000.532(20) \mathrm{cm}^{-1}$ and $30000.493(20) \mathrm{cm}^{-1}$
It is important to note that although the two newly discovered upper levels are in a close proximity with each other i.e. with an energy separation of only $0.039 \mathrm{~cm}^{-1}$, the intensity distribution of hyperfine components for both structure show a normal behavior. Furthermore, at the initial center-of-gravity excitation wavelengths $5700.92 \AA$ and 5700.94 $\AA$ a hyperfine structure was recorded at the fluorescence line $5446 \AA$. The recorded structure show a mixture of both lines which is due to the fact that $5446 \AA$ is appearing in the transition list of both the newly discovered upper levels $30000.532(20) \mathrm{cm}^{-1}$ and $30000.493(20) \mathrm{cm}^{-1}$. A center-of-gravity wave number difference of $0.040 \mathrm{~cm}^{-1}$ was obtained from a two line fit of the recorded structure (Figure 7.22). This is in agreement with the difference, calculated from level energies of the newly discovered levels.

Figure 7.22: Best fit situation for multiline fit for the lines $5700.92 \AA$ and $5700.94 \AA$

### 7.1.4 Discovery of Pr-I Levels $33264.21_{17 / 2}^{e} \mathrm{~cm}^{-1}, 16180.200_{15 / 2}^{o} \mathrm{~cm}^{-1}$ and $16865.034_{15 / 2}^{\circ} \mathrm{cm}^{-1}$ via Laser Excitation

The laser excitation of the spectral line $5851.80 \AA$ was performed. In the FT -spectrum, the line has a weak signal-to-noise ratio with a relative intensity of 6 , see Figure 7.23. The listed suggestions for the line in the classification were inspected for a possible match. Since none of the suggestions has any coincidence with the hyperfine structure of the line, so possibly one or both the combining levels are not known and yet to be discovered.

The laser excitation wavelength was set to $5851.80 \AA$ and LIF signals were searched. A number of fluorescence lines with good signal-to-noise ratio at wavelengths $3460 \AA, 5001$ $\AA, 5414 \AA, 6096 \AA, 6153 \AA$ were observed. Now the hyperfine structure of the line was recorded by setting the monochormator at $3460 \AA$ which has the best signal-to-noise ratio and scanning the laser frequency across the hyperfine components of the line (Figure 7.24).

Figure 7.23: FT-spectrum of the line $5851.80 \AA$

Figure 7.24: Recorded hyperfine structure of the line $5851.80 \AA$.

The recorded LIF spectrum shows a widely splitted hyperfine structure with appreciable separation between diagonal components. The suggestion list was again inspected for a possible match but proved unsuccessful. Using the simulation program, the spectroscopic parameters for the lower and upper combining levels in the formation of the spectral line were estimated. Taking these parameters as an initial guess, the recorded hyperfine structure was fitted to a mathematical function using the fitter program. A best fit situation is obtained (Figure 7.25) which gave the following spectroscopic parameters for the combining levels:

$$
\begin{array}{ll}
J_{o}=17 / 2 & J_{u}=15 / 2 \\
A_{o}=546.92 \mathrm{MHz} & A_{u}=885.47 \mathrm{MHz}
\end{array}
$$

Figure 7.25: Best fit situation of the recorded hyperfine structure of the line $5851.80 \AA$
As is usual, initially assuming that the upper combining level is unknown, a known lower level is searched in the database of known levels based on best fitted $J$-values for upper and lower levels and $A$-value of the lower level. The search routine in the classification program computes a number of suggestions both in even and odd parity but none of the suggested upper levels explain the observed fluorescence lines. The procedure was again repeated but this time assuming an unknown lower level and searching for a known upper combining level. In searching for an unknown lower level, best fit $A$-value of the assumed upper level is given to the searching routine. But once again the computed suggestions for a possible new lower level combining with a known upper level do not explain the observed fluorescence lines. It was thus concluded that both the lower and upper levels in the formation of the excited line were yet to be discovered.
Two of the observed fluorescence lines i.e. $6096 \AA$ and $6151 \AA$ lie in the wavelength range of our dye laser, if the same upper level combines with the known lower levels at these lines then the unknown upper level can be identified. The exact fluorescence wavelengths were measured for the excitation of these lines. This is done by setting the laser frequency to the highest hyperfine component of the original excitation line and chopping the fluorescence light intensity coming from the hollow cathode lamp. The monochromator is automatically scanned across the fluorescence wavelength and discharge emission spectrum along with laser induced signal is recorded. A computer program called 'Comparison' is used to determine the exact fluorescence wavelengths which takes as input the wavelength range containing the fluorescence wavelength, the recorded file and the FT
spectrum file corresponding to the specified wavelength range. The exact values determined with the help of the program were $6096.21 \AA$ and $6151.54 \AA$ (Figures $7.26 \&$ 7.27).

Figure 7.26: Exact measure of fluorescence wavelength $6096.19 \AA$

Figure 7.27: Exact measure of fluorescence wavelength $6151.50 \AA$

In the FT spectrum the spectral line profile in the vicinity of $6096.21 \AA$ appears to be a mixture of more than one line with a good signal-to-noise ratio having a relative intensity of $\sim 65$, see Figure 7.28 . The line at center-of-gravity wavelength $6096.32 \AA$ belongs to a transition with known combining lower and upper levels, i.e. $27721.206_{13 / 2}^{e}-11322.443_{11 / 2}^{o}$.

Figure 7.28: FT-spectrum for the line $6096.18 \AA$
To investigate the line at $6096.21 \AA$, the monochromator was set to $3460 \AA$ which has the strongest LIF signal. Now by scanning the laser frequency around $6096.21 \AA$. LIF signal at this wavelength was observed. The intensity of the LIF signal increases to maximum at $6096.11 \AA$ corresponding to the largest hyperfine diagonal component of line. The fluorescence signal was also observed on all other previously recorded fluorescence wavelengths as well as on the original excitation wavelength i.e. $5851 \AA$. This indicates to some extent that the same upper level is excited in the excitation of this line. The hyperfine structure of the line was then recorded by scanning the laser wavelength across the hyperfine components of the line. A hyperfine structure with good signal-to-noise ratio and well resolved diagonal components was recorded on all previously observed fluorescence wavelengths, see Figure 7.29. The suggestions listed for the line in the classification program were inspected but none show any coincidence neither in terms of shape nor in terms of positions of hyperfine components.

Figure 7.29: Recorded hyperfine structure of the line $6096.18 \AA$.

The recorded hyperfine structure for this line with best signal-to-noise ratio was fitted using fitter program and a best fit situation was obtained on the same $J$ - and $A$-values of the upper level as obtained for the fitting of hyperfine structure of the line at $5851.80 \AA$, see Figure 7.30.

Figure 7.30: Best fit situation of the recorded hyperfine structure of the line $6096.18 \AA$
The best fit situation gave the center-of-gravity wavelength as $6096.18 \AA$ and the spectroscopic parameters of the combining lower and upper level as $J_{o}=17 / 2, J_{u}=15 / 2$, $A_{o}=541.91 \mathrm{MHz}$ and $A_{u}=287.79 \mathrm{MHz}$. Using the same procedure, the combining levels for the line were searched independently by first assuming an unknown upper level and a known lower level and vice versa. For this line, again neither of the combining levels can be identified. It is then again concluded that both the lower and upper levels combining at this line are unknown. If the same upper level is combining with different lower levels at lines $5851.80 \AA$ and $6096.18 \AA$ then all together three levels are unknown.

In FT-spectrum the line profile in the vicinity of $6151.54 \AA$ again appears to be a blend of more than one line. Here the signal-to-noise ratio is weak with a relative intensity of only 1 (Figure 7.31).

Figure 7.31: FT-spectrum for the line $6151.54 \AA$

The laser excitation wavelength was set at $6151.54 \AA$ and again the monochromator was set at $3460 \AA$. A strong LIF signal was observed when the laser wavelength was set to $6151.52 \AA$ on all previously observed fluorescence wavelengths, implying that possibly the same upper level has been excited but now from a third different lower level at this line. The hyperfine structure of the line was recorded by setting the monochromator to the strongest fluorescence wavelength which in this case is $3460 \AA$ and scanning the laser frequency across the hyperfine components of the line. Again the recorded LIF spectrum has a good signal-to-noise ratio, see Figure 7.32.

Figure 7.32: Recorded hyperfine structure of the line $6151.53 \AA$.
The same hyperfine structure was recorded on all other observed fluorescence wavelengths. The suggestions for the spectral line in the classification program was inspected for a possible match with the recorded hyperfine structure but again none of the suggestions show any coincidence with the recorded hyperfine structure.

The recorded hyperfine structure with best signal-to-noise ratio was independently fitted using fitter program. Best fit situation was obtained (Figure 7.33) giving a center-ofgravity wavelength at $6151.54 \AA$ with spectroscopic parameters $J_{o}=\mathbf{1 7} / \mathbf{2}, \boldsymbol{J}_{u}=\mathbf{1 5} / \mathbf{2}, \boldsymbol{A}_{o}=$ 539.09 MHz and $\boldsymbol{A}_{\boldsymbol{u}}=492.06 \mathrm{MHz}$.

Figure 7.33: Best fit situation of the recorded hyperfine structure of the line $6151.53 \AA$

Based on the fluorescence information obtained in the excitation of this line and previous two lines ( $5851.80 \AA$ and $6096.18 \AA$ ), it was assumed that this same newly found upper level is involved in the excitation of lines at $5851.80 \AA$ and $6096.18 \AA$ and further assuming that lower combining levels at both these lines are unknown, the energy of these unknown lower levels were determined using the energy of the newly discovered upper level $33264.21 \mathrm{~cm}^{-1}$ and the respective wave numbers of the lines at $5851.80 \AA$ and $6096.18 \AA$.
The group of these three newly calculated levels is:
$16180.200 \mathrm{~cm}^{-1}$, odd parity, $J_{u}=15 / 2$ and $A_{u}=883.26 \mathrm{MHz}$
$16865.034 \mathrm{~cm}^{-1}$, odd parity, $J_{u}=15 / 2$ and $A_{u}=290.96 \mathrm{MHz}$
$33264.21 \mathrm{~cm}^{-1}$, even parity, $J_{o}=17 / 2$ and $A_{o}=544.65 \mathrm{MHz}$
In order to confirm the energies and existence of the newly found levels, the levels must be confirmed at some other lines from FT-spectrum with their hyperfine structure profile in agreement with the hyperfine structure predicted by the classification program. It would further consolidate if laser excitation at these or other lines could be performed where the newly discovered levels combine with known lower and upper levels and the resulting hyperfine structure is in agreement both in terms of shape and hyperfine component positions with the predicted hyperfine structure by the classification program.

### 7.1.4a Confirmation of $33264.21 \mathrm{~cm}^{-1}$ :

The upper level in the group is confirmed from FT-spectrum at lines $3461.236 \AA$ and $5414.331 \AA$. The hyperfine structures of the lines as predicted by classification program are in good agreement with the hyperfine structure line profile in FT-spectrum (Figure 7.34 and 7.35). Experimentally, the level was confirmed by a laser excitation at line $6066.498 \AA$ where it combines with a known lower level $16784.800_{15 / 2}^{o}$. Figure 7.36 shows the experimentally recorded hyperfine structure of the line and the simulation with the predicted hyperfine structure as given by classification program. This confirms the level energy and existence of the level beyond doubt. The level energy was corrected and the lines were then classified.

Figure 7.34:Confirmation of $33264.21 \mathrm{~cm}^{-1}$ at $3461.236 \AA$

Figure 7.35: Confirmation of $33264.21 \mathrm{~cm}^{-1}$ at $5414.332 \AA$

Figure 7.36: Comparison of the recorded hyperfine structure (Red curve) of the line $6066.498 \AA$ with the predicted hyperfine structure (Blue curve).

### 7.1.4b Confirmation of $16180.200 \mathrm{~cm}^{-1}$ :

In order to confirm the lower level $16180.200 \mathrm{~cm}^{-1}$, laser excitations were performed at lines $5651.35 \AA, 6399.562 \AA$ and $6429.226 \AA$. The lines at $5651.35 \AA$ and $6429.23 \AA$ in FTSpectrum appear in a mixture of more than one line with partially resolved hyperfine components whereas line at $6399.562 \AA$ in FT-spectrum has good signal-to-noise ratio with resolved hyperfine components. The level $16180.200 \mathrm{~cm}^{-1}$ combines with different already known upper levels at the respective lines (Figure 7.37, 7.38 \& 7.39) i.e.

$$
\begin{aligned}
& \operatorname{cog} \lambda=5651.35 \AA \rightarrow 33870.186_{13 / 2}^{e}-16180.200_{15 / 2}^{o} \\
& \operatorname{cog} \lambda=6399.562 \AA \rightarrow 31801.951_{17 / 2}^{e}-16180.200_{15 / 2}^{o}
\end{aligned}
$$

$\operatorname{cog} \lambda=6429.23 \AA \rightarrow 31729.874_{13 / 2}^{e}-16180.200_{15 / 2}^{o}$

Figure 7.37: Comparison of the recorded hyperfine structure (Red curve) of the line $5651.35 \AA$ with the predicted hyperfine structure (Blue curve).

Figure 7.38: Comparison of the recorded hyperfine structure (Red curve) of the line $6399.562 \AA$ with the predicted hyperfine structure (Blue curve).

Figure 7.39 Comparison of the recorded hyperfine structure (Red curve) of the line $6429.23 \AA$ with the predicted hyperfine structure (Blue curve).

### 7.1.4c Confirmation of $\mathbf{1 6 8 6 5 . 0 3 4} \mathrm{cm}^{-1}$ :

The level $16865.034 \mathrm{~cm}^{-1}$ was also confirmed experimentally at three other positions i.e. $5953.48 \AA, 6546.12 \AA$ and $6583.66 \AA$ as a lower level for the respective transitions. The lines in FT-Spectrum appear with a very weak signal-to-noise ratio but contrary to this, recorded LIF spectrum for all three lines show a good signal-to-noise ratio. At the respective lines, the level combines with already known upper levels (Figure 7.40, 7.41 \& 7.42) i.e.

$$
\begin{aligned}
\operatorname{cog} \lambda & =5953.48 \AA \rightarrow 33657.265_{17 / 2}^{e}-16865.034_{15 / 2}^{o} \\
\operatorname{cog} \lambda & =6546.12 \AA \rightarrow 32137.040_{17 / 2}^{e}-16865.034_{15 / 2}^{o} \\
\operatorname{cog} \lambda & =6583.65 \AA \rightarrow 32049.984_{13 / 2}^{e}-16865.034_{15 / 2}^{o}
\end{aligned}
$$

Figure 7.40: Comparison of the recorded hyperfine structure (Red curve) of the line $5953.48 \AA$ with the predicted hyperfine structure (Blue curve).

Figure 7.41: Comparison of the recorded hyperfine structure (Red curve) of the line $6546.12 \AA$ with the predicted hyperfine structure (Blue curve).

Figure 7.42: Comparison of the recorded hyperfine structure (Red curve) of the line $6583.65 \AA$ with the predicted hyperfine structure (Blue curve).

A set of three levels were discovered with a high angular momentum values. All the three levels were independently confirmed by excitation to or from already known upper and lower levels. The hyperfine interaction $A$ constant and level energies were corrected. All the excited lines were then classified. The energy level diagram is shown in Figure 7.43.

Figure 7.43: Energy level diagram for the set of newly discovered levels

### 7.1.5 Doublet Hyperfine Structure: Excitation from a Pair of Lower Levels to a New Upper Level

Continuing the systematic investigations of the spectrum of praseodymium, the FTspectrum in the vicinity of $5594.56 \AA$ was investigated. More than one line appears to be in a close proximity with each other with their hyperfine components mixed together, see Figure 7.44. The signal-to-noise ratio is not good with a relative intensity of 8. Although the classification program shows a number of suggestions but due to the mixed appearance of hyperfine structure components, the lines in this segment of FT-spectrum could not be explained without laser excitation. Laser excitation was performed by tuning the laser frequency to each hyperfine component in FT-spectrum and searching for fluorescence lines.

Figure 7.44: FT-spectrum for the line $5594.56 \AA$
Initially laser excitation wavelength was set to $5594.56 \AA$ and fluorescence lines were searched by tuning the monochromator. LIF signal was observed on $4716 \AA, 4827 \AA, 5823$ $\AA$ with best signal-to-noise ratio at $4827 \AA$. LIF spectrum was then recorded by scanning the laser wavelength starting from $5594.73 \AA$ down to a 45 GHz length. The recorded LIF spectrum (Figure 7.43) shows two groups of hyperfine structure components with an approximate center-of-gravity separation of $0.700 \mathrm{~cm}^{-1}$. The appearance of two hyperfine structures in a single scan can be attributed to an excitation or fluorescence blend situation due to the fact that praseodymium has high line density. To clarify the observed behavior, LIF spectrum was recorded on all observed fluorescence lines. Interestingly, the same two groups or doublet was recorded on all other observed fluorescence lines. In both groups intensity ratios of the diagonal hyperfine components are in agreement with the intensity rule for a normal hyperfine structure pattern. The first group of hyperfine components at lower frequency with an approximate center-of-gravity wavelength $5594.56 \AA$ gives an impression of a narrow peak structure with closely lying diagonal components. The offdiagonal components appear on one side and are not well separated from diagonal components. The second group of hyperfine structure components at higher frequency with an approximate center-of-gravity wavelength $5594.36 \AA$ shows a hyperfine structure with six diagonal hyperfine components, the last two of which are very close to each other. Comparatively faster decrease in spacing between diagonal hyperfine structure
components is observed. The off-diagonal components appear only on the high frequency side.

Figure 7.45: Recorded hyperfine structures of the lines $5594.56 \AA$ and $5594.36 \AA$
Since the same two groups appear on all observed fluorescence lines so a model is proposed (Figure 7.46) in which two lower levels are excited to a single upper level in a single scan range of laser.

Figure 7.46: Suggested model scheme for the combining levels

Since the intensity ratios of the hyperfine components in the recorded structure follow the normal intensity ratios for hyperfine pattern, the recorded structure is fitted by using a multiline fitting procedure in the Fitter program. A best fit situation with a quality factor $Q$ $=11$ (Figure 7.47) was obtained for $\Delta J=-1$ for hyperfine structure at lower frequency with
center-of-gravity excitation wavelength $5594.562 \AA$ and $\Delta J=+1$ for the hyperfine structure at higher frequency with center-of-gravity excitation wavelength $5594.36 \AA$. As a result of fitting process, the $A$ - and $J$-values for the upper level i.e. $A_{o}=647 \mathrm{MHz}, J_{o}=5 / 2$, turn out to be same for the hyperfine structure of both lines but for lower levels in both cases the values were different i.e. for the hyperfine structure of the line at $5594.562 \AA$ the interaction constant $A_{u}=905 \mathrm{MHz}$ and $J_{u}=3 / 2$ and for the hyperfine structure of the line at $5594.36 \AA$ the interaction constant $A_{u}=892 \mathrm{MHz}$ and $J_{u}=7 / 2$. The same $A$-values for the upper levels and different $A$-values for the lower levels of the two hyperfine structures of the lines give an indication to a first approximation that two different lower levels are excited to a single upper level as initially suggested in the proposed model.

Figure 7.47: Multiline fitting for two Pr I lines $5594.562 \AA$ and $5594.36 \AA$

Now with an initial assumption that an unknown upper level is involved in the excitation of both lines, the two lower levels were searched in the data base of known levels using fitted $A$-values of lower levels $\left[A_{u}(5594.562 \AA)=905 \mathrm{MHz}\right.$ and $A_{u}(5594.36 \AA)=892$ MHz ] and corresponding $J$-values [ $J_{0}=5 / 2, J_{u}=3 / 2, J_{o}=5 / 2, J_{u}=7 / 2$ ]. The search for lower levels was done successively for both lines using the searching routine in the classification program. First the line at $5594.562 \AA$ was inserted in the classification program and a known lower level is searched. Number of suggestions was computed for the line and an even parity lower level was found, this lower level combines with a possible new odd parity upper level which explained all the observed fluorescence lines, (Figure 7.48). The spectroscopic parameters for the lower level are $13033.280 \mathrm{~cm}^{-1}$, even parity, $\boldsymbol{J}_{u}=\mathbf{3 / 2}$ and $\boldsymbol{A}_{\boldsymbol{u}}=\mathbf{9 0 5 ( 4 )} \mathbf{M H z}$. Next the line at $5594.36 \AA$ is inserted and a known lower level is searched at this line. Again from among the listed suggestions, a known even parity lower level was found combining with an odd parity upper level with approximately the same energy. This new odd parity upper level explained the same observed fluorescence lines (Figure 7.49). The spectroscopic parameters for the lower level in this case are $\mathbf{1 3 0 3 2 . 6 3 4} \mathrm{cm}^{-1}$, even parity, $J_{u}=7 / 2$ and $A_{u}=892.6 \mathrm{MHz}$.

Figure 7.48: Possible suggestions for the line $5594.56 \AA$, a possible new odd parity upper level $30902.82 \mathrm{~cm}^{-1}$

Figure 7.49: Possible suggestions for the line $5594.36 \AA$, a possible new odd parity upper level $30902.82 \mathrm{~cm}^{-1}$

The recorded hyperfine pattern was fitted again using multiline fit procedure but this time keeping fix the $A$-values of the known lower levels at both lines. A best fit situation was obtained with the same quality factor $Q=11$. The $A$-value obtained for the upper level is $A_{o}=639 \mathrm{MHz}$, the center-of-gravity wavenumber and wavelength of the recorded hyperfine structure at lower frequency are $17869.538 \mathrm{~cm}^{-1}, 5594.562 \AA$ and for hyperfine structure at higher frequency are $17870.183 \mathrm{~cm}^{-1}, 5594.36 \AA$.
The energy of the upper level at both lines was separately determined by using the respective center-of-gravity wavenumbers of the lines and the energy of the corresponding lower levels, at both lines i.e. $5594.562 \AA$ and $5594.36 \AA$, the energy of upper level determined is $30902.82 \mathrm{~cm}^{-1}$. Corresponding to the lower level, the parity of upper level is taken to be odd, total electronic angular momentum $J_{o}=5 / 2$ and magnetic hyperfine interaction constant $A_{o}=647 \mathrm{MHz}$. The fit gives us the possibility to determine more accurately the energy difference of the two lower levels, since they combine with the same upper level. From the multiline fit of the recorded structure (Figure 7.47) the estimated difference of the cg. is $19200 \mathrm{MHz} \triangleq 0.640 \mathrm{~cm}^{-1}$ which is in close agreement with the wave number difference of the two lower levels involved in the excitation of lines.

In order to confirm the existence and energy of the newly found upper level more than one laser excitation from a different lower level was performed. At one of the observed fluorescence lines i.e. $5823 \AA$, the newly found upper level was excited from another known lower level. This line also exists in the transition list of the upper level. The hyperfine structure profile of the line at $5823.34 \AA$ predicted by the classification program does not appear in FT-spectrum (Figure 7.50) so possibly a blend of more than one lines exist in FT -spectrum.
Laser excitation was performed by tuning the laser frequency at $5823.34 \AA$ and setting the monochromator transmission wavelength to previously observed strongest line i.e. $4827 \AA$. LIF signal was observed not only on $4827 \AA$ but also on $4716 \AA$ and $5594 \AA$. LIF spectrum was then recorded on all observed fluorescence lines by scanning the laser frequency.

Figure 7.50: FT -spectrum for the line $5823.34 \AA$

The recorded hyperfine structure of the line is in good agreement with the hyperfine pattern of the line predicted by classification program (Figure 7.51). This confirms the existence of the upper level and the level scheme adopted earlier in the first excitation. The
upper level energy and the value of A constant was corrected which gives $\mathbf{3 0 9 0 2 . 8 2 ( 3 )} \mathrm{cm}^{-}$ $I^{I}$, odd parity, $J_{o}=5 / 2$ and $A_{o}=636(6) \mathrm{MHz}$.

Figure 7.51: Comparison of the recorded hyperfine structure of the line $5823.34 \AA$ (Red curve) with the predicted hyperfine pattern of line (Blue curve).

The two closely spaced lower set of levels are not always excited simultaneously but only dipole allowed transitions occur from both lower levels to a single upper level. This similar behavior was also observed in the investigation of lines at $5764.39 \AA$ and at $5764.17 \AA$ in which the two levels were excited to a known upper level in a single scan range of laser (Figure 7.52).

Figure 7.52: Recorded LIF spectrum of the lines $5764.39 \AA$ and $5764.17 \AA$

Furthermore despite of the fact that the two lower levels are in a close proximity with each other, the intensity distribution of hyperfine components for both structure show a normal behavior. This is contrary to an investigation conducted in our group [74] where three closely lying lower levels simultaneously excite a single upper level. The recorded hyperfine structure profile in this case show transitions from all three lower levels but the intensity distribution of hyperfine components appears disturbed.

### 7.1.6 Discovery of a New Pr-I Level with a Low Angular Momentum Value i.e. $\mathrm{J}=1 / 2$

In order to systematically classify the spectral lines in FT-spectrum, the spectral region in the neighborhood of $5756.53 \AA$ was experimentally investigated. A trace of FT-spectrum showing the region of investigation is shown in Figure 7.53.

Figure 7.53: FT-spectrum for the region around $5756.53 \AA$
Initially the laser wavelength is set to $5756.53 \AA$ and fluorescence lines were searched. LIF signal was observed on fluorescence lines at wavelengths $4067 \AA, 4151 \AA, 4189 \AA, 4388 \AA$, $4635 \AA, 4695 \AA, 4823 \AA, 5129 \AA, 5141 \AA, 5202 \AA, 5251 \AA, 5351 \AA, 5395 \AA$ and $5448 \AA$. Two different hyperfine structures were recorded at these fluorescence wavelengths i.e. one hyperfine structure was recorded at $5141 \AA, 5251 \AA$ and $5448 \AA$ and the other on 4067 $\AA, 4151 \AA, 4189 \AA, 4388 \AA, 4635 \AA, 4695 \AA, 4823 \AA, 5129 \AA, 5202 \AA, 5351 \AA, 5395 \AA$. The hyperfine structure (Figure 7.54) at center-of-gravity wavelength $5756.52 \AA$ was identified as a transition between known levels i.e. $30399.423_{9 / 2}^{o} \mathrm{~cm}^{-1}-13032.634_{7 / 2}^{e} \mathrm{~cm}^{-1}$ The line was then classified.

Figure 7.54: FT-spectrum for the Line $5756.52 \AA$

The recorded structure of the line at fluorescence wavelengths $5141 \AA, 5251 \AA$ and $5448 \AA$ reveal (Figure 7.55) a smaller number of hyperfine components suggesting that the combining levels have small angular momentum values. The recorded hyperfine structure at fluorescence lines $5141 \AA, 5251 \AA$ and $5448 \AA$ is not visible in FT-spectrum and is completely masked by the hyperfine structure components of the other line involving levels with angular momentum $J_{\text {upper }}=9 / 2$ and $J_{\text {lower }}=7 / 2$. In order to ascertain the shape of recorded structure and to filter out any blend situation (convolution of more than one line) which is common in praseodymium, entrance and exit slit sizes of the monochromator is reduced and the hf structure of the line is again recorded. No change was observed and same hyperfine structure pattern was recorded on all fluorescence lines.

Figure 7.55: FT-spectrum for the line $5756.53 \AA$
To evaluate $J$ and $A$ values of the involved lower and upper levels, the recorded structure is fitted by using Fitter program. Table 7.3 gives the $A$ and $B$ values determined by the Fitter program for different pair of $J$ values of the combining lower and upper levels.

Table 7.3: Possible A and B values for different pairs of $J$ values of the combining levels. The quality (inverse proportional to the error squares sum) of the fit result indicates the best pair of J values.

| Upper Level <br> $\mathbf{J}_{\mathbf{u p}}$ | Lower level <br> $\mathbf{J}_{\mathbf{l o}}$ | Quality of <br> $\mathbf{f i t}$ | Upper level |  | Lower level |  |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: |
|  |  |  | $\mathbf{A}_{\mathbf{u p}}$ <br> $(\mathbf{M H z})$ | $\mathbf{B}_{\mathbf{u p}}$ <br> $(\mathbf{M H z})$ | $\mathbf{A}_{\mathbf{l o}}$ <br> $(\mathbf{M H z})$ | $\mathbf{B}_{\mathbf{l o}}$ <br> $(\mathbf{M H z})$ |
| $1 / 2$ | $3 / 2$ | 7.97 | 1881.82 | 0.00 | 910.21 | 3.24 |
| 1 | 2 | 2.65 | 1668.74 | -52.40 | 799.03 | 4.24 |
| 1.5 | 2.5 | 1.81 | 1549.10 | -646.54 | 745.27 | -534.66 |

The highest quality of fit is obtained for $J_{o}=1 / 2$ and $J_{u}=3 / 2 . J_{o}=1 / 2$ implies $L=0$ i.e. $S$ orbit for which $B=0$. Assuming an unknown upper level is involved in the excited
transition, a known lower level is searched using $J, A$ and $B$ values in the database of known levels. A level with energy $13033.280 \mathrm{~cm}^{-1}, J=3 / 2$, even parity and $A=905(4)$ MHz was found. The recorded structure is again fitted taking $J$ and $A$ values of the known lower level. This gives a best fit with $A_{o}=1881.82 \mathrm{MHz}$ of the upper level, the best fit situation is shown in Figure 7.56. The energy of the upper level is determined by adding the center-of-gravity wavenumber of the recorded structure. A newly discovered fine structure level with parameters $30400.04 \mathrm{~cm}^{-1}, \boldsymbol{J}_{0}=\mathbf{1} / \mathbf{2}$, odd parity and $\boldsymbol{A}_{\boldsymbol{o}}=\mathbf{1 8 8 1 . 8 2}$ $\mathbf{M H z}$ is obtained. This level is then introduced into the classification program which generates a transition list.

Figure 7.56: Best fit situation of the recorded hyperfine structure of the line $5756.53 \AA$
The correct assignment of the energy of the newly calculated upper level is only ensured if it explains all the observed fluorescence lines. A laser excitation at $5141.703 \AA$, which is one of the observed fluorescence line, is performed. The recorded hf structure of the line at $5141.703 \AA$ is in full agreement with the predicted hf structure pattern of the excited line, see Figure 7.57.

Figure 7.57: Comparison of the recorded hyperfine structure of the line $5141.703 \AA$ (Red curve) with the predicted hyperfine structure of the line (Blue Curve)

The lines at $5141.703 \AA$ and $5251.114 \AA$ have suitable SNR (4 and 15, respectively) to determine finally the level energy to be $30400.042(30) \mathrm{cm}^{-1}$. The observed fluorescence line at $5448.506 \AA$ appears in a blend situation and its hf structure is not visible, and the line was classified on the basis of observed fluorescence wavelength.

Thus the following lines are then classified:
$5756.529 \AA$ (wavelength calculated from level energies): $30400.042_{1 / 2}^{\circ}-13033.280_{3 / 2}^{e}$
$5448.506 \AA$ (wavelength calculated from level energies): $30400.042_{1 / 2}^{\circ}-12051.488_{3 / 2}^{\mathrm{e}}$
$5251.114 \AA$ (wavelength from FT): $30400.042_{1 / 2}^{\circ}-11361.746_{3 / 2}^{\mathrm{e}}$
$5141.703 \AA$ (wavelength from FT): $30400.042_{1 / 2}^{\circ}-10956.651_{1 / 2}^{\mathrm{e}}$
For the A constant the average of all recordings at both excitation wavelengths were determined, this gives $\mathrm{A}=1890$ (10) MHz .

The energy of the upper level is correct and its existence is beyond all doubts. A level scheme for the involved levels is shown in Figure 7.58.

Figure 7.58: Level scheme for the excitation of $30400.042(20) \mathrm{cm}^{-1}$

### 7.1.7 Discovery of Pr-I Level 29341.96 ${ }_{1 / 2}^{\circ}$

The hyperfine structure profile appearing in FT-spectrum at $5854.17 \AA$ cannot be explained by any of the listed suggestions of the line in classification program (Figure 7.59). Therefore laser excitation was performed in order to investigate the line.

Figure 7.59: FT -spectrum for the line $5854.17 \AA$
The laser wavelength is set $5854.17 \AA$ and fluorescence lines were searched by tuning the transmission wavelength of the monochromator. LIF signals were observed on $5560 \AA$, $5720 \AA, 5781 \AA$. LIF spectrum was then recorded on all observed fluorescence wavelengths showing a hyperfine structure with small number of hyperfine components (Figure 7.60).
Q Data Viewer
回园

Figure 7.60: Hyperfine structure of the line $5854.17 \AA$
Using simulation program a hyperfine structure profile is simulated showing a nice agreement with recorded structure at $J=1 / 2$ for the combining levels and $A_{o}=900 \mathrm{MHz}$ and $A_{u}=1530 \mathrm{MHz}$. For $J<I$, the statistical weight of a fine structure level is given by $2 J$
+1 which means that a fine structure level splits into 2 hyperfine structure levels. This gives two diagonal and two off-diagonal hyperfine components. It is important to note here that middle two components i.e. $F_{o}=3$ to $F_{u}=3$ and $F_{o}=2$ to $F_{u}=2$ are the diagonal components and the other two i.e. $F_{o}=2$ to $F_{u}$ $=3$ and $F_{o}=3$ to $F_{u}=2$ are off diagonal components. This shows that the intensity rule is different for a transition with combining levels $J<I$.

Figure 7.61: Simulation of the recorded line profile

The recorded hyperfine structure is then fitted taking $J$ - and $A$-values from the simulation program. The best fitted values $\boldsymbol{J}_{o}=\mathbf{1 / 2}, \boldsymbol{J}_{u}=\mathbf{1 / 2}, \boldsymbol{A}_{\boldsymbol{o}}=\mathbf{9 1 1 ~ M H z}$ and $\boldsymbol{A}_{\boldsymbol{u}}=\mathbf{1 5 4 3} \mathbf{~ M H z}$ are obtained with a quality factor $Q=2.4$ (Figure 7.62).

Figure 7.62: Best fit situation of the hyperfine structure of line $5854.17 \AA$
In a similar manner assuming one of the combining levels are known, say, the lower level of the excited transition is known, a possible new upper level was found which explained all the observed fluorescence lines. The known lower level has the parameters $\mathbf{1 2 2 6 4 . 8 6 4}$ $\boldsymbol{c m}^{-1}$, even parity, $\boldsymbol{J}_{\mathbf{u}}=\mathbf{1 / 2}$ and $\boldsymbol{A}_{\boldsymbol{u}}=\mathbf{1 5 3 4} \mathbf{~ M H z}$. The energy of the possible new upper level was determined by the center-of-gravity wave number of the line and the energy of the lower level. This gives the new upper level $29341.96 \mathrm{~cm}^{-1}$, odd parity, $\boldsymbol{J}_{o}=\mathbf{1} / \mathbf{2}$ and $\boldsymbol{A}_{\boldsymbol{o}}$ $=915.26 \mathrm{MHz}$. The newly determined level is then introduced in the database of known levels and is loaded in the classification program which generates a transition list from this level.

Usually the correct assignment of energy of a new level is only guarantied if the transition list of the upper level explains all the observed fluorescence lines and their hyperfine structure predicted by the classification program is in agreement with the hyperfine structure of these lines in FT-spectrum.
In case of lines involving levels with low angular momentum values ( $J=1 / 2$ or $3 / 2$ ),
usually the hyperfine components are overlapped by the hyperfine structure components of the nearby lines involving levels with angular momentum values $\mathbf{J}>3 / 2$. This is common in praseodymium which has high line density. This is one of the reasons that lines involving levels with low angular momentum values are most times not visible in FT spectrum and laser excitation must be performed in order to confirm their energy and existence.
Two of the observed fluorescence lines i.e. at $5720 \AA, 5781 \AA$ lie in the emission spectrum of Rhodamine 6G, further the line at $5735.44 \AA$ also exist in the transition list of the newly found upper level so laser excitations were performed at lines $5735.44 \AA$ and $5781.93 \AA$. At both lines, a LIF signal was seen on the previously observed fluorescence line at 5560 $\AA$. The detection of LIF signal is not possible at or near $5854.17 \AA$ due to laser stray light. The recorded LIF spectrum at lines $5735.44 \AA$ and $5781.93 \AA$ are in full agreement with the predicted hyperfine structure of lines by the classification program both in terms of shape and hyperfine component positions (Figure $7.63 \& 7.64$ ).

Figure 7.63: Comparison of the recorded hyperfine structure (red curve) of the line $5735.44 \AA$ with the predicted hyperfine structure pattern (blue curve).

Figure 7.64: Comparison of the recorded hyperfine structure (red curve) of the line $5781.93 \AA$ with predicted hyperfine structure pattern (blue curve).

This confirms the existence of the newly discovered upper level. The level energy was then corrected and the lines were then classified as transitions between

$$
\begin{aligned}
& 29341.96_{1 / 2}^{o}-12264.864_{1 / 2}^{e} \\
& 29341.96_{1 / 2}^{o}-11911.350_{3 / 2}^{e} \\
& 29341.96_{1 / 2}^{o}-12051.488_{3 / 2}^{e}
\end{aligned}
$$

It should be noted that at each of the excited line, the hyperfine structure of the line is not visible in FT-spectrum and appears in a blend of lines. In each case, the hyperfine components of the line are overlapped by the hyperfine components of the neighboring lines involving levels with large angular momentum values.

### 7.1.8 Discovery of New Pr-I Level at Line $5636.940 \AA$

A very prominent line in FT-spectrum at $5636.940 \AA$ was investigated using laser excitation. The line has a very good signal-to-noise ratio with a relative intensity of 140 and has clearly visible hyperfine components, see Figure 7.65. The suggestions listed for the line in the classification program were examined but none of the suggestion coincides with the hyperfine structure profile given in FT-spectrum.

Figure 7.65: FT-spectrum of the line $5636.940 \AA$
Laser excitation was performed by tuning the laser wavelength to the highest hyperfine component which in this case is $5636.92 \AA$. A single fluorescence line at $5228 \AA$ was observed in the transmission range of the monochromator from $3000 \AA$ to $7000 \AA$. This can happen if the upper level has a few number of decay channels or has a very low transition probability for other lines. It could also happen that the upper excited level is a low lying level, excited either from the ground level or from a very low lying level.
In this case two decay channels are apparent, one to the same lower level from where it is excited and the second is the fluorescence lower level. In any case hyperfine structure of the line is recorded by scanning the laser frequency across the hyperfine components of the line. As expected the recorded LIF spectrum has good signal-to-noise ratio with the same hyperfine structure pattern as displayed in FT-spectrum (Figure 7.66).

Figure 7.66: Recorded hyperfine structure of the line $5636.940 \AA$

The recorded structure was then fitted and a best fit situation was obtained for $\boldsymbol{J}_{o}=\mathbf{1 3 / 2}, \mathbf{J}_{\mathbf{u}}$ $=\mathbf{1 1} / \mathbf{2}, \boldsymbol{A}_{\boldsymbol{o}}=\mathbf{7 6 2} \mathbf{~ M H z}$ and $\boldsymbol{A}_{\boldsymbol{u}}=\mathbf{7 3 3} \mathbf{~ M H z}$ with quality factor $Q=8$ (Figure 7.67). The center-of-gravity wavelength obtained from fitter program is $5636.940 \AA$. Inserting the center-of-gravity wavelength in the classification program, a known lower level is initially searched in the database of known levels. This is done by giving the J -values of the lower and upper levels and the A-value of the lower level to the searching routine. A number of suggestions for the possible new upper levels with their fluorescence lines were displayed. But none of the suggestion neither of even parity nor of odd parity could explain the only observed fluorescence line at $5228 \AA$. Once again fitting procedure was revised with different values of angular momentum (including ionic values) for lower and upper levels but in each case the quality of fit was not good.

Figure 7.67: Best fit situation of the recorded hyperfine structure of line $5636.940 \AA$

As a next step assuming an unknown lower level, a known upper level was searched in the database of known levels using fitted $\mathbf{J}$ values of the combining levels and A -value of the upper level. This gives again number of suggestions for possible unknown lower level combining with known upper level. Again none of the listed suggestions could explain the only observed fluorescence wavelength.
It can then be concluded that possibly both the lower and upper combining levels at the excited line $5636.940 \AA$ are still unknown and yet to be discovered. In situations like this another method is used which require fluorescence information for the identification of the lower combining level at the fluorescence line. For the method to work successfully, atleast three fluorescence lines with exact measure of their wavelength must have been observed experimentally with known lower combining levels. But in this case only single fluorescence line at $5228 \AA$ was detected which means that the method is not applicable. In any case the exact value of the fluorescence wavelength was determined. This was done by using a second lock-in amplifier in our experimental setup. Modulated fluorescence light from hollow cathode lamp is given to the monochromator and the LIF signal together with the emission spectrum of the hollow cathode in the desired spectral range is recorded. Exact value of the fluorescence wavelength is determined using a computer program called "Comparison" which turns out to be $5227.967 \AA$. This program takes as input the recorded file and the FT-spectrum file of the desired spectral range, see Figure 7.68.

Figure 7.68: Exact measure of fluorescence wavelength $5227.967 \AA$
The line at $5227.968 \AA$ was inserted in the classification program which displays number of suggestions for the line. A classified line at slightly different center-of-gravity wavelength i.e. $5227.968 \AA$ with a transition from ground to a known low lying upper level $19122.567_{11 / 2}^{\mathrm{e}}$ was seen in FT-spectrum. The line has a very good signal-to-noise ratio with a relative intensity of 5171 (Figure 7.69).

Figure 7.69: Spectral line in FT spectrum at $5227.968 \AA$

Furthermore the predicted hyperfine structure of the line by the classification program is in extremely good agreement with the hyperfine structure profile seen in FT-spectrum. Assuming an unknown lower level is involved in the excitation of line at $5636.940 \AA$, the recorded hyperfine structure of the line was again fitted but now taking $J$-values in accordance with the $J$-value of the assumed known upper level i.e. $19122.567_{11 / 2}^{e}$. For fitting, the hyperfine interaction $A$ constant of the known upper level was taken as fixed and letting free the hyperfine interaction $A$ constant of the assumed unknown lower level. The fit of the recorded structure gave a very poor result for the pair of $J$-values and $A$ values of upper and lower levels. This indicates that the upper level involved in the excitation of line at $5636.940 \AA$ is not $19122.567 \mathrm{~cm}^{-1}$ and again one could say that both the combining levels may not be known till now.
There could now be two possible models (i) both the combining levels at $5636.940 \AA$ are unknown and the lower level at the fluorescence line $5227 \AA$ is also unknown or (ii) lower combining level at the excited line $5636.940 \AA$ is known and the observed fluorescence signal at $5227 \AA$ is an indirect fluorescence i.e. not originating from the excited upper level but in the hollow cathode glow region, collisional coupling had occurred between the excited unknown upper level at the line $5636.940 \AA$ and $19122.567_{11 / 2}^{\mathrm{e}}$. This results in the excitation of level $19122.567 \mathrm{~cm}^{-1}$ which then decay via fluorescence line at $5227 \AA$. So might be a low lying unknown upper level with energy comparable to the energy of $19122.567 \mathrm{~cm}^{-1}$ is involved.

For the first model to be true requires more fluorescence lines possibly in the infrared region. Since our monochromator works best in the region from $3000 \AA$ to $7000 \AA$ and so fluorescence lines in IR were not observed. If such fluorescence lines exist one can then investigate those lines to solve the problem. As far as second model is concerned one could inspect the list of possible suggestions for new upper level at the line $5636.940 \AA$ based on $A$-value of the lower combining level and $J$-values of both combining levels and look for a level with low energy and having hyperfine $A$ constant of lower known level to be nearly of same value as determined by the fitting process, see Figure 7.70.

Figure 7.70: Possible suggestions for the line $5636.940 \AA$

The first even parity suggestion has exactly the same hyperfine interaction constant as determined by the fitting process of the experimentally recorded file. The suggestion show a known lower level i.e. $\mathbf{1 3 7 6 . 6 0 2} \mathrm{cm}^{-1}$, odd parity, $J_{u}=\mathbf{1 1 / 2}$ and $\boldsymbol{A}_{u}=\mathbf{7 3 0 . 3 9 3} \mathrm{MHz}, B_{u}$ $=\mathbf{- 1 1 . 8 7 7} \mathbf{~ M H z}$. The possible new upper combining level determined using this lower level and center-of-gravity wave number is $19111.80 \mathrm{~cm}^{-1}$, even parity, $J_{u}=13 / 2, A_{u}=$ 761.83 MHz. The level was introduced in the database of known levels and is uploaded in the classification program. The transition list generated by the classification program does not explain the single observed fluorescence line $5227 \AA$ but at the line $6146.447 \AA$ the hyperfine structure calculated by classification program appears to have some coincidence with the hyperfine structure profile shown in FT-spectrum. Laser excitation at the line $6146.447 \AA$ was performed and an LIF signal was observed at $5227 \AA$. The recorded hyperfine structure of the line at $6146.447 \AA$ is in excellent agreement with the predicted hyperfine structure by the classification program both in terms of hyperfine pattern and wave number (Figure 7.71). This confirms the existence of the newly found upper level first excited at the line $5636.940 \AA$. The center-of-gravity wavelength determined by the fitting process is $6146.447 \AA$. The energy of the newly found level was then corrected and the excited lines were then classified.

Figure 7.71: Comparison of the recorded hyperfine structure (Red curve) of the line $6146.447 \AA$ with the predicted hyperfine structure (Blue curve).

It can now be said beyond doubt that the single fluorescence line observed at $5227 \AA$ is an indirect fluorescence line occurred as a result of collisional coupling between newly found upper level with energy $19111.800 \mathrm{~cm}^{-1}$ and known level with energy $19122.567 \mathrm{~cm}^{-1}$ as depicted in Figure 7.72. The observed fluorescence line originates from the known upper level $19122.567 \mathrm{~cm}^{-1}$.

Figure 7.72: Level scheme showing collisionally coupled upper levels

### 7.1.9 Discovery of a New Pr-I Level at Line $4660.92 \AA$ using FT-Spectrum

The line at $4660.916 \AA$ in FT-spectrum show clearly resolved hyperfine components with a good signal-to-noise ratio and has a relative intensity of 192 (Figure 7.73). None of the suggestions listed in the classification program match hyperfine structure profile in FT spectrum.

Figure 7.73: FT-spectrum for the line $4660.916 \AA$
This motivated the investigation of the spectral line by extracting the line profile from FTspectrum and fitting it to a mathematical function using fitter program. Provided the hyperfine components of a line in FT-spectrum are clearly resolved, this method of investigation could give a reasonable estimate of the spectroscopic parameters of the levels involved in the formation of the line even if the line is not experimentally investigated. The disadvantage in this approach of investigation is the unavailability of fluorescence information which is very important in the identification of the involved levels. This can be avoided by using a search routine in classification program based on the A- and J-values which generate possible number of suggestions and depending on the reliability and authenticity of the estimated spectroscopic fitted parameters of the combining levels, one of the suggestion can be selected.
The line profile comprising the hyperfine components of the line at $4660.916 \AA$ is extracted from the FT-spectrum. This gives a set of data points which is stored in the form of a data file. A program converts the data file in to linearized data file in a format acceptable to the fitter program. Best fit situation with theoretical coupling between intensities of all components was obtained for spectroscopic values $J_{o}=\mathbf{9 / 2}, J_{u}=\mathbf{1 1} / \mathbf{2}, A_{o}=\mathbf{5 6 4} \mathbf{M H z}$ and $\boldsymbol{A}_{u}=\mathbf{7 2 8} \mathrm{MHz}$ with a quality factor $\boldsymbol{Q}=\mathbf{3 8}$ (Figure 7.74). Assuming an unknown upper level is involved in the formation of the line a known lower level is search in the database of known levels. Taking $A$-value of the assumed known lower level and $J$-values of the both upper and lower levels the searching routine gives a number of suggestions for possible new upper levels with their fluorescence lines (Figure 7.75). In the absence of the fluorescence information, the key to a reliable identification of the combining levels is to look for the known lower level with $A$-value nearly the same as determined by the fitter program. In case more than one suggestion has nearly the same $A$-value then from all such
suggestion the possible (new) upper levels are selected and introduced in the database of known levels. For each possible upper level classification program generates a transition list.

Figure 7.74: Fitted line profile from FT-spectrum of the line $4660.916 \AA$

Figure 7.75: Possible suggestions for the line $4660.916 \AA$

Those suggestions in which none of the fluorescence lines could be explained from the FT spectrum are rejected. There is a certain margin of error in this process because it might happen that the involved upper level has a low emission probability although this is not true in this case. The first even suggestion has a lower level with parameters $\mathbf{1 3 7 6 . 6 0 2} \mathrm{cm}^{-}$ ${ }^{1}$, odd parity, $\boldsymbol{J}_{u}=\mathbf{1 1 / 2}$ and $\boldsymbol{A}_{u}=\mathbf{7 3 0 . 3 9 3} \mathbf{~ M H z}, \boldsymbol{B}_{u}=\mathbf{- 1 1 . 8 7 7} \mathbf{~ M H z}$. The $A$-value of this lower level is almost the same as the fitted $A$-value. Assuming this as a known lower level involved in the formation the line at $4660.92 \AA$, the line profile from FT-spectrum was again fitted keeping fix the $A$ and $B$ values of the lower combining level. The possible new upper level with parameters $22825.61 \mathrm{~cm}^{-1}$, even parity, $J_{o}=\mathbf{9 / 2}$ and $\boldsymbol{A}_{\boldsymbol{o}}=\mathbf{5 6 6 . 8 3} \mathbf{~ M H z}$ is obtained. This newly found upper level is introduced in the database of known levels and is reloaded in the classification program which generates a transition list. At two lines i.e. $4379.81 \AA$ and $7145.88 \AA$ the predicted hyperfine structure of lines are partly in agreement with the hyperfine structure profile of the respective lines in FT-spectrum.

In order to confirm the existence of this upper level laser excitation is performed at $7145.88 \AA$. A strong LIF signal was observed on $4660 \AA$. The hyperfine structure of the line is then recorded by scanning the laser frequency across a certain range. The recorded hyperfine structure of the line at $7145.88 \AA$ is in excellent agreement with the hyperfine structure of the line predicted by classification program (Figure 7.76).

Figure 7.76: Comparison of the recorded hyperfine structure (Red curve) of the line $7145.88 \AA$ with the predicted hyperfine structure (Blue curve).

This confirmed the existence of the upper level. In order to have a good estimate of the hyperfine interaction $A$ constant of the new upper level, the recorded hyperfine structure of the line at $7145.88 \AA$ is fitted using fitter program. The best fit situation with a quality factor $Q=14$ was obtained. The corrected energy of the new upper level together with best fit values are $\mathbf{2 2 8 2 5 . 6 1 1} \mathrm{cm}^{-1}$, even parity, $\boldsymbol{J}_{\boldsymbol{o}}=\mathbf{9 / 2}$ and $\boldsymbol{A}_{\boldsymbol{o}}=\mathbf{5 7 0 ( 5 )} \mathbf{M H z}$. The lines $4660.916 \AA$ and $7145.88 \AA$ were then classified.

### 7.1.10 Discovery of a New Pr-II Level at Line 4328.42 Å

During the systematic investigation of the spectrum of praseodymium, a number of singly ionized praseodymium levels were also discovered. One such example is presented in this section. Due to discharge conditions inside the hollow cathode lamp, the population of singly ionized Pr ions is not very large and amounts to only $10 \%$ of plasma. This may be the reason that in most cases the ionic lines are not visible in FT-spectrum. One such line in FT-spectrum at $4328.42 \AA$ with a very weak signal-to-noise ratio and having a relative intensity of only 1 is shown in Figure 7.77. Since the hyperfine components of the line are not visible in FT-spectrum, an optogalvanic signal was first recorded to have some idea about the hyperfine component positions of the investigated line.

Figure 7.77: FT-spectrum for the line $4328.42 \AA$
Laser excitation wavelength was set to $4328.42 \AA$ which is the strongest hyperfine component position obtained from the optogalvanic scan. LIF signal was observed on a number of fluorescence line i.e. $3820 \AA, 3912 \AA, 4156 \AA, 4517 \AA$. Hyperfine structure was then recorded by scanning the laser frequency across a certain range and setting successively the transmission wavelength of the monochromator to all the observed fluorescence wavelengths. On all observed fluorescence lines, same hyperfine structure was recorded with best signal-to-noise ratio at $3820 \AA$ (see Figure 7.78). The recorded hyperfine structure was then linearized and fitted using the Fitter program. Table 7.5 gives the $A$ and $B$ values determined by the Fitter program for different pair of $J$ values of the combining lower and upper levels. The highest quality of fit with $Q=26$ was obtained for an ionic transition i.e. between $J_{o}=3$ and $J_{u}=3$. Assuming an unknown upper level is involved in the excited transition, a known lower level is searched in the database of known levels. A number of suggestions for a possible new upper level are displayed with their calculated fluorescence lines. One of the odd parity suggestions for a possible upper level explained all the observed fluorescence lines. The known lower connecting level was discovered by Furmann et. al.[35] with level parameters $10289.48 \mathrm{~cm}^{-1}, \boldsymbol{J}_{u}=3$, even parity and $\boldsymbol{A}_{u}=2114 \mathrm{MHz}$. The energy of the possible new upper level was determined using the center-of-gravity excitation wave number and the energy of the lower level. The recorded hyperfine structure was again fitted but now keeping fix the $J$ and $A$ values of the
known lower level. A best fit was obtained with $A_{o}=1348.21 \mathrm{MHz}$ of the upper level see Figure 7.79.

Figure 7.78: Recorded hyperfine structure of the line $4328.42 \AA$

Table 7.5: For different pair of $J$ values the possible $A$ and $B$ values of the combining levels are obtained. Quality of fit indicates the best pair of $J$ values.

| Upper Level | Lower level | Quality <br> of fit |  | Upper level | Lower level |  |
| :--- | :--- | :--- | :--- | :--- | :--- | :--- |
|  |  |  | $\mathbf{A}(\mathbf{M H z})$ | $\mathbf{B}(\mathbf{M H z})$ | $\mathbf{A ( M H z )}$ | $\mathbf{B}(\mathbf{M H z})$ |
| $7 / 2$ | $7 / 2$ | 5.25 | 1197.18 | 0.00 | 1880.59 | 0.00 |
| 3 | 3 | 26 | 1352.98 | 0.00 | 2123.02 | 0.00 |
| $5 / 2$ | $5 / 2$ | 3.26 | 1547.33 | 0.00 | 2416.23 | 0.00 |

Figure 7.79: Best fit situation of the line $4328.42 \AA$

The spectroscopic parameters of the newly found upper level are $33386.2 \mathrm{~cm}^{-1}$, odd parity, $J_{o}=3$ and $A_{o}=1348 \mathrm{MHz}$. The level is introduced in the database of known levels and is then uploaded in the classification program. Besides the observed fluorescence lines, the hyperfine structure of the line at $4241.249 \AA$ in FT-spectrum sufficiently explains the hyperfine structure predicted by the classification program. In any case for the confirmation of the energy of the newly found ionic upper level a second laser excitation from some other known lower level needs to be performed. A line at $4361.81 \AA$ is selected which is present in the transition list of the newly found upper level. Although at this position FT-spectrum the line is not visible but in any case laser excitation was performed for this line and a hyperfine structure with good signal-to-noise ratio was recorded. The recorded hyperfine structure was in agreement with the hyperfine structure of the line predicted by classification program (Figure 7.80).

Figure 7.80: Comparison of the recorded hyperfine structure (Red curve) of the line $4361.81 \AA$ with the predicted hyperfine structure (Blue curve).

The energy of the newly found upper level and its hyperfine interaction $A$ constant was then corrected. The corrected spectroscopic parameters are $33386.215 \mathrm{~cm}^{-1}$, odd parity, $J_{o}$ $=3$ and $A_{o}=1352(5) \mathrm{MHz}$. Both the excited lines were then classified.

### 7.2 Tables

Table 7.4 lists the data of new atomic levels sorted according to J value and energy. Column 1 gives the angular momentum J, in column 2 energy values are given in $\mathrm{cm}^{-1}$, in column 3 values of hyperfine structure constant A (in MHz ) are given for the newly discovered levels. Column 4 presents the wavelength of the excitation lines in $\AA$ (in air) and column 5 lists the observed fluorescence lines in $\AA$ (in air). In all cases B value is very small and is neglected. In most cases the existence of a level is checked by one or two further laser excitations, from other known lower levels. In some cases a newly discovered level is confirmed by analyzing up to now unclassified lines in the FT spectrum, the wavelength of such lines is given in brackets in column 4 . This happens in cases where the wavelengths for further laser excitations do not lie in the available spectral range of our laser dyes.

The energies of the newly discovered levels are calculated using the center-of-gravity wave number of the excited lines and the energies of the already known levels involved in the transitions. Therefore the energy accuracy of newly discovered levels not only depend on the energy accuracy of the already known level in the excited transition but also on whether or not the excitation and fluorescence lines appear in FT spectrum with good signal-to-noise ratio (SNR). Since the FT spectrum is only roughly intensity calibrated, the given SNR is only an indication for the line intensity. In cases where a line is excited and neither excitation nor fluorescence lines appear in the FT spectrum with good SNR, then the accuracy of the determined level is limited by the reading accuracy of our lambda meter $( \pm 0.01 \AA)$. This limits the accuracy of the calculated level to $\pm 0.05 \mathrm{~cm}^{-1}$.
Table 7.5 contains a list of spectral lines investigated by laser excitation in the discovery/confirmation of the newly found levels. Column 1 gives the center-of-gravity excitation wavelengths in $\AA$ (in air), column 2 gives the SNR of the line observed in FT spectrum. The designation ' nl ' means a new line not appearing in published wavelength tables. The accuracy in center-of-gravity wavelength for lines with SNR > 3 is better than $0.003 \AA$. The SNR of a line which does not appear in FT spectrum but nevertheless was successfully observed with LIF method is set as ' $<1$ '. For lines appearing in a blend situation in which the SNR cannot be estimated from the FT spectrum, SNR is indicated by ' - '. In such cases the center-of-gravity wavelength listed in column 1 is calculated from the level energies and has an estimated uncertainty of 0.01 Å. Columns 3 and 5 gives the J and columns 4 and 6 give the energies for the even and odd levels, respectively, explaining the line.

Table 7.6 lists spectral lines classified by observed fluorescence and has the same structure as table 7.5 except that column 1 gives the observed fluorescence wavelength in $\AA$ (in air).

Table 7.7 lists additional lines in which the new levels are involved, classified by means of their hyperfine patterns and wave numbers.

Table 7.8 lists the newly discovered lower levels combining with already known levels.
Table 7.9 list new levels of Pr I found by the analysis of hyperfine patterns in the FT spectrum.

Table 7.10 lists the newly found ionic levels.

Table 7.4: Up to now unknown Pr I energy levels discovered within this work

## 8 Conclusion

An experimental investigation of the hyperfine structure of a large number of spectral lines of the praseodymium atoms has been carried out using laser spectroscopy in a hollow cathode discharge lamp. The investigated spectral region lie in the range $4200 \AA-7500 \AA$. The main emphasis was directed to the discovery of fine structure levels using the hyperfine structure of the investigated spectral line. Excitation wavelengths are extracted from a high resolution Fourier transform spectrum of praseodymium. The levels were discovered by analysis of the recorded hyperfine patterns of the investigated transitions. A total of 313 levels of Pr I were discovered, out of which 148 are even parity and 165 are odd parity energy levels. With the help of these newly discovered levels 652 spectral lines were classified directly by laser excitation and 836 spectral lines were classified as fluorescence lines. In addition to this, 178 lines in the FT spectrum were also classified by their hyperfine structures and wave numbers involving these newly discovered levels. 4 new levels of singly ionised praseodymium were also discovered during the course of this dissertation.

The electronic angular momentum J values of the newly discovered levels range from $1 / 2$ to $21 / 2$ for neutral praseodymium. Most of these newly found levels have angular momentum values lying in the mid range and only few levels were discovered with angular momentum values $\mathrm{J}=1 / 2$ and $\mathrm{J}=21 / 2$. Lines with combining levels having $\mathrm{J} \leq 5 / 2$ are very rarely visible in the FT spectrum. In most cases, the hyperfine structure of these lines is completely or partially masked by the hyperfine structure of nearby lying lines involving levels with high angular momenta. Nevertheless, carefully done laser spectroscopic investigations made it possible to find 54 up to now unknown levels with small J: 4 levels having $\mathrm{J}=1 / 2$, 19 levels having $\mathrm{J}=3 / 2$, and 31 levels having $\mathrm{J}=5 / 2$. On the higher side i.e. for large J value, also a small number of levels were found. About 54 levels were experimentally discovered i.e. 29 levels having $\mathrm{J}=15 / 2$, 15 levels having $\mathrm{J}=17 / 2$, 6 having $\mathrm{J}=19 / 2$ and 4 levels having $\mathrm{J}=21 / 2$. This is consistent with the theoretical predictions that only a small number of LS terms is possible for small and large J values.
Apart from the applications in other branches of physics, the hyperfine structure investigations presented in this dissertation will be helpful for further theoretical analysis and understanding of the atomic structure of praseodymium.
