Considering the utmost importance of the combined use of monitoring systems and numerical models for dam safety control, it is presented the software *DamDySSA2.0,* which has been developed in recent years in LNEC to study the dynamic behavior of dams (Fig. 5). This is a 3D FE program for dynamic state space analysis of arch dam-reservoir-foundation systems, based on a 3DFE coupled model that enables to simulate the dynamic dam-reservoir interaction, considering linear elastic behavior and generalized damping. The outlined Boundary Values Problem for the discrete coupled system is solved through a FE formulation in displacements (solid) and pressures (fluid), considering the solid-fluid motion coupling at the dam-reservoir interface and the hydrodynamic pressure waves propagation throughout the reservoir, which is a semi-infinite domain terminated by a radiation boundary [8]. The dynamic calculations are performed in time domain based on a novel coupled state space approach with two state matrices using complex modal coordinates [9,10,11]. The implemented coupled approach results in the computation of non-stationary vibration modes, which are usually associated to systems with non-proportional damping, as is the case of arch dams, whose dynamic behavior is highly influenced by dynamic water-structure interaction.

DamDySSA2.0. Coupled model and state space approach.

5. MODAL IDENTIFICATION RESULTS. COMPARISON WITH NUMERICAL RESULTS

In this chapter the modal identification outputs are compared with numerical results computed using *DamDySSA2.0,* to demonstrate the potential of the combined use of monitoring and modelling to support dam safety control, as well as to validate and calibrate the numerical models and implemented formulations. For the case of Cabril dam, it is necessary to analyze the identified frequencies with great care, in order to distinguish between the dam vibration modes and vibrations related to the intake tower motion or the power groups.

To simulate the dynamic behavior of Cabril dam the coupled model was used, considering a dynamic elasticity modulus (E_{dyn}) of 32.5 GPa and a Poisson coefficient (υ) of 0.2 for the dam. Various water levels are assumed, and a fluid velocity of 1440 m/s is used. Regarding *Modal_ID2.0*, the main modal parameters were obtained based on acceleration records measured on April 1st of 2014, between 10 and 11 a.m., in which the reservoir water level (H_w) was of 291.45 m. As for *Modal_ID_auto2.0,* automatic modal identification was carried out for measured accelerations between February and October of 2014, corresponding to a water level variation between 266 and 296 m. In this work, the modal identification outputs were obtained using the FDD(RD)-SV technique.

First a comparison between *Modal_ID2.0* and *DamDySSA2.0* is performed (Fig.6a). A graphic representing the evolution of the computed natural frequencies in function of the reservoir water level is shown (colored lines), which also contains the modal identification frequencies for H_w = 291.45 m. Second, the outputs obtained from automatic modal identification are presented and compared with *DamDySSa* results (Fig.6b)). A different graphic is presented, containing the natural frequencies obtained from automatic modal identification over time (green and red circles), which are compared with lines representative of numerical natural frequencies, for the referred water level variation (266-296 m). In both cases, identified and computed mode shapes are compared.

By analyzing the presented study, one can note that an excellent agreement was achieved between the results obtained from interactive and automatic modal identification software and the numerical results calculated with a 3D FE program, concerning both natural frequencies and vibration mode shapes. Also, the implemented numerical model enables to compute non-stationary vibration modes, as can be measured in situ. Finally, it is relevant to state that such a close agreement between numerical and experimental results was not possible in previous studies, performed using classic added water mass models [3,4].

6. CONCLUSIONS

A comparative study regarding the dynamic behavior of Cabril dam was presented, namely in terms of the dam's natural frequencies and vibration mode shapes, for different reservoir water levels. The excellent agreement achieved between modal identification outputs and numerical modelling results demonstrates the value of Cabril dam's monitoring system and associated software (*Modal_ID_auto2.0* and *Modal_ID2.0*), and simultaneously proves the reliablity of the state space formulation implemented in the 3D FE program *DamDySSa2.0.* Therefore, as intended, this work has proven the importance of vibrations monitoring systems in the scope of dam safety control, which must comprise quality hardware (e.g. accelerometers, data concentrators, etc.) and appropriate software for data analysis and management, as well as the potential of their combined use with numerical models of dam-reservoir-foundation systems.

SUMMARY

This work addresses the subject of monitoring and modelling the dynamic behavior of large arch dams. The continuous vibrations monitoring system installed in Cabril arch dam (132 m high) is described, as well as the associated cutting-edge software for automatic and interactive data analysis and management (*Modal_ID2.0*), based on the frequency domain modal identification techniques. Cabril dam’s dynamic behavior is simulated using a recently developed 3DFE program (*DamDySSA2.0*), for dynamic state space analysis of arch dam-reservoir-foundation systems.

A comparative study between modal identification outputs and numerical modelling results is presented, namely in terms of the dam’s natural frequencies and vibration mode shapes, for different reservoir water levels. The excellent agreement achieved demonstrates the value of Cabril dam’s monitoring system and associated software, and simultaneously proves the reliability of the state space formulation implemented in *DamDySSa2.0.* Therefore, this work showed the importance and potential of the combined use of monitoring systems and numerical models in the scope of dam safety control.

Keywords: Vibrations; Monitoring; Modelling; Cabril arch dam.

RÉSUMÉ

Ce travail porte sur l’auscultation et la modélisation du comportement dynamique des grands barrages. Le système d’auscultation des vibrations installé dans le barrage du Cabril (132 m de haut) est décrit, ainsi que le logiciel de pointe développé pour l'analyse et la gestion automatique et interactive des données (Modal_ID2.0), basé sur des techniques d'identification modale au domaine de la fréquence. Le comportement dynamique du barrage du Cabril est simulé à l'aide d'un programme EF3D récemment développé (DamDySSA2.0), pour l'analyse dynamique des systèmes barrage-réservoir-fondation en utilisant des formulations d’état.

Une étude comparative entre les sorties d'identification modale et les résultats de la modélisation numérique est présentée, notamment en termes de fréquences naturelles du barrage et des modes de vibration, pour différents niveaux d'eau du réservoir. L'excellent accord obtenu démontre la valeur du système d’auscultation du barrage du Cabril et des logiciels associés, et prouve simultanément la fiabilité de la formulation dans l'espace d'état implémentée dans DamDySSa2.0. Par conséquent, ces travaux ont montré l'importance et le potentiel de l'utilisation combinée de systèmes d’auscultation et modèles numériques dans le cadre du contrôle de sécurité des barrages.

Mots-clés: Vibrations; Auscultation; Modélisation; Barrage-voute du Cabril.

ABSTRACT

Earth dams' failure may occur due to different reasons such as structural instability conditions, hydraulic conditions, seepage through the dam body and/or rapid drawdown. The determination of factor of safety for the dam slope stability, under different cases of operations, is vital to ascertain the dam overall safety. In this work, Finite Element modeling is employed for simulating seepage and stress analysis of earth dam problems via GeoStudio software. Thus, phreatic seepage surface, pore water pressure distribution and total hydraulic head variation of an earth dam are analyzed. The model is verified, then it is employed to analyze seepage and stability of Mandali Dam (Iraq). For three different cases of operation, four major analytical methods are used to verify the stability of the dam side slopes. Benchmark safety regulation criteria (USACE and BDS) are obeyed. The results confirm the safety of Mandali dam against combined seepage and slope instability under all cases of operation. The case of rapid drawdown is the most critical operating case; compared to other cases of operation.

Keywords: *Earth dams, Seepage, Stability of slopes, Finite element modeling, Mandali Dam.*

1. Introduction

Dams are built for specific functions such as water supply, irrigation, flood control and hydroelectric power generation. Most of the large dams in the world were built during the middle decades of the twentieth century. There are two types of modern dams, namely: embankment dam and concrete dam. Embankment dams can be classified into two main categories earth-fill dams and rock-fill dams. Embankment dams represent about 85% of dams all over the world. There are several factors to be considered in selecting an earth dam type such as: topography; foundation conditions; environmental impacts, construction facilities and socio-economic studies. A feasible dam should be; built from locally available materials; stable under all operating and loading conditions; watertight enough to control seepage; have appropriate outlet works to crest dam overtopping **[1-3]**.

2. Literature Review

Seepage and slope stability failures are addressed via many authors since ***Henry Darcy, 1856*** **[4]**, who gave the basic law of flow through porous media. ***Darcy's*** law was based on series of experiments conducted in a vertical pipe filled with sand. ***Fellenius*** **(1936) [5],** developed the Ordinary Method of Slices (OMS) known as Felonious or Swedish method. It is assumed that the forces acting on sides of any slice are neglected. ***Zienkiewiez and Chung, 1967*** **[6]**, published the first finite element simulation to solve the Laplace equation for steady ground water seepage**.*, Taylor and Chow, 1976*** **[7]**, recorded that the Finite Element Method was used to assess the potential seepage flows and uplift pressure in the foundation rock for Bannett Dam in Canada. ***Kratutich, 2004*** **[8],** used thermal mode at ANSYS computer code to simulate numerically the case of no stationary free surface in earth dams. ***Karjani, 2009*** **[9]** used Geostudio computer software to analyze Maroon dam, estimate flow net at passing condition and slope stability factor at overall stability for different operating conditions has been calculated. ***Zomorodian and Abodollahzadeh, 2010*** **[10],** used Geostudio software to investigate the effect of horizontal drains on upstream slope of earth fill dams during rapid drawdown. ***Tatewar and Laxman N. Pawade, 2012*** **[11],** used Geostudio software to investigate the slope stability of the 21m high Bhimdi earth dam, by changing different parameters such as changing berm width and changing position of filter drains. ***Hasani et al., 2013*** **[12],** studied the seepage analysis in Ilam earth dam for four mesh size in order to assess the effect of meshing on results accuracy.

3. Seepage flow through Earth Dams

Seepage flow of water through porous media depends on the soil media, type of flow, properties of liquid and hydraulic gradient. Seepage piping account for approximately 40% of all earth dam failures. Different methods have been developed to solve seepage problems, these methods can be classified as analytical, experimental and a numerical methods. Ground water flows in the direction of decreasing potential energy caused by differences in pressure and elevation. A common measure of this potential energy is the total head, $\boldsymbol{\phi}$ which is simply the sum of pressure head and elevation head. The volume rate of flow per unit area is directly proportional to the rate of change of head as given by the differential form of ***Darcy's*** Law. The following general governing equation for seepage through earth dams can be considered as **[1, 3]**:

$$\frac{\partial}{\partial x}\left[\mathbf{K_x}\frac{\partial \mathbf{H}}{\partial x}\right]+\frac{\partial}{\partial y}\left[\mathbf{K_y}\frac{\partial \mathbf{H}}{\partial y}\right]+\frac{\partial}{\partial z}\left[\mathbf{k_z}\frac{\partial \mathbf{H}}{\partial z}\right]=\mathbf{S}\frac{\partial h}{\partial t} \quad \text{In} \quad \Omega \quad \ldots\ldots\ldots\ldots\ldots (1)$$

where, $\mathbf{K_x}$, $\mathbf{K_y}$ **and** $\mathbf{K_z}$ are the coefficient of permeability in x, y, z directions, respectively, **S** is specific yield and **H** = $p/\gamma_w + z$ = total fluid head, P = pressure, γ_w = unit weight of water and z = elevation head. Equation (1) is known as Laplace's equation which is considered as the governing equation for groundwater there dimensions flow through aquifers. For an isotropic, homogeneous aquifer under steady state conditions, Equation (2) can be simplified to the following equation:

$$\frac{\partial^2 \mathbf{H}}{\partial x^2}+\frac{\partial^2 \mathbf{H}}{\partial z^2}=\mathbf{0} \quad \text{In} \quad \Omega \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (2)$$

It is assumed that; the soil media is homogeneous, isotropic, and physically stable; the pressure is atmospheric everywhere on the water table (phreatic surface); the flow of ground water through the flow domain is steady and the hydraulic conductivity through the dam body is constant everywhere.

3.1 Boundary Conditions

Figure (1) shows a schematic representation for the problem statement and boundary conditions for a typical earth dam. These boundary conditions can be briefly summarized as follows:

3.1.1 Entrance Surface (Γ_1)

The upstream boundary surface (Γ_1) is the entrance surface at which the percolation of reservoir water through the media starts. This surface is considered as an equipotential line which is known as *Dirchlet Condition* for a prescribed head as:

$$\mathbf{H}(x, y) = H_1 \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (3)$$

3.1.2 Phreatic Surface (Γ2)

The boundary surface (Γ_2) is the phreatic surface of the flow through the dam. This boundary is considered as a stream line. The phreatic surface, although it is considered as a boundary condition, its location and its profile are unknown a priori. For the unknown phreatic surface the boundary condition is:

$$\mathbf{H}(x, y) = y \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (4.\ a)$$

$$\frac{\partial \mathbf{H}}{\partial n} = 0 \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (4.\ b)$$

where n is the normal directions to the boundary (Γ_2).

3.1.3 Exit Surface (Seepage surface) (Γ_3)

The boundary surface (Γ_3) is the exit surface or seepage surface. This boundary is considered as an isobar at which the pressure along it is atmospheric, hence, the boundary condition along such a surface is:

$$\mathbf{H}(x, y) = y \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (5)$$

The geometry of the seepage surface is known, except its upper limit the exit point, which is laying on the unknown phreatic surface. The location of this point is a part of the required solution.

3.1.4 Dam Foundation Boundary (Γ_4)

The boundary surface (Γ_4) is the dam foundation boundary, which is also known as *Neumann Condition*. In the present study, this boundary is assumed to be impervious i.e. this surface prevents the flow of water across it such that:

$$\frac{\partial \mathbf{H}}{\partial n} = 0 \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (6)$$

where n is the normal directions to the boundary (Γ_4).

4. Stability of Earth Dam Slopes

Every soil mass which has a slope at its end is subjected to shear stresses on internal surfaces or failure plans in the soil mass near the slope. This is due to the gravitational forces that try to pull down parts of the soil mass adjoining the slope. Several models and analytical techniques have been developed to determine the critical slip surface and the associated factor of safety such as method of slices. The factor of safety is:

$$\text{F.S.} = \frac{\tau_f}{\tau} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (7)$$

where, F.S. factor of safety, τ_f failure shear strength of the soil, and τ shear stress of the soil. The stability of earth fill dam depends on its geometry, components, materials, properties of each component and the forces to which it is subjected. There are some analytical tools for assessing the stability of a slope by using simple failure models. These techniques are limited to slopes of homogenous material, soils, fractured rocks which are behaving like soils and for plain strain (2-D) problems only. Some of these tools are listed by **[13].** For steady state seepage condition the factor of safety using Fellenius method is **[5, 14]:**

$$\text{F.S.} = \frac{\sum_{i=1}^{i=n}(cL_i + (W_i \cos\alpha_i - u_i L_i)\tan\varphi)}{\sum_{i=1}^{i=n} W_i \sin\alpha_i} \quad \text{.................................. (8)}$$

For steady state seepage condition the factor of safety using Bishop Method is:

$$\text{FS} = \frac{\sum_{i=1}^{i=n}(cb_i + (W_i - u_i b_i)\tan\varphi)\frac{1}{m_{\alpha i}}}{\sum_{i=1}^{i=n} W_i \sin\alpha_i} \quad \text{.. (9)}$$

where, $m_{\alpha i} = \cos\alpha_i + \frac{\tan\varphi \sin\alpha_i}{FS}$

c = effective soil cohesion, **L** = length of the bottom of the slice, **b** = width of the slice and equal to (**L** $\boldsymbol{\cos\alpha}$), **u** = pore water pressure, **W=** weight of the slice, $\boldsymbol{\alpha}$ =inclination of the bottom of the slice and $\boldsymbol{\varphi}$ = effective internal friction angle.

5. Finite Element Formulation

The basic concept of the finite element method is to divide the problem region into subdomains (finite elements) connected at their common nodal points and that the unknown function of the field variable is defined approximately within each element. The approximate solution of each element expressed by continuous function is as follows **[3]**:

$$\mathbf{H} = \sum_{e=1}^{noe} [N_i^e]\{\mathbf{H}_i^e\} \quad \text{... (11)}$$

where, $\mathbf{H}_i^e$ = nodal value of (**H**) for i[th] node in element (e), noe = total number of elements and N_i^e = shape function of element (e).

There are more different approaches to formulate the approximate solution of the problem. In the present study, the standard weighted residual method with Galerkin's criterion **[6]** is used to approximate the solution of the unknown variable (**H**). Thus, equation (2) can be written in a matrix form as **[3]**:

$$[\mathbf{K}].\{\mathbf{H}\} = \{\mathbf{F}\} \quad \text{... (12)}$$

in which $\{\mathbf{H}\}$ is the unknown nodal potential head vector, $\{\mathbf{F}\}$ is the nodal external flux vector and $[\mathbf{K}]$ is the conductivity matrix given by:

$$\mathbf{K}_{ij} = \int_{V^e}\left(\frac{\partial N_j}{\partial x}\mathbf{K}_x\frac{\partial N_i}{\partial x} + \frac{\partial N_j}{\partial y}\mathbf{K}_x\frac{\partial N_i}{\partial y}\right) dx\, dy \text{...................... (13)}$$

where, V^e = the domain of element (e) and N_i = interpolation or shape function. Derivations of the above functions are given in detail by **[3]**.

The solution of seepage problem with phreatic surface require a successive adjustment for the location of the phreatic surface and the finite element mesh size till the desired degree of convergence for the head **H** is achieved. In all iterative methods, the solution is started by using initial guess for the unknown values and the solution is obtained by repeating the solution of the system of equations successively through recurrence relations to update the old values until the solution converges closely enough to the true values within some prescribed tolerance of error **[3]**.

6. Safety Criteria and Verification of Model

Design and safety evaluation of embankment dams should satisfy the recommended criterion of the experienced agencies in the design of embankment dams. Among the numerous dam safety regulation **[13, 15, 16, 17],** both USACE (2003) **[18]** and BDS (1994) **[19]** criterion are considered as the benchmark for their broad area of validation in the present study. Geostudio computer code **[20]** is employed in the present study to simulate seepage and stability analysis of atypical earth dam. The model is verified with reference **[21]** for a solved example with a zoned embankment dam for slope stability analysis. The verification is done for three cases of operation using Bishop's method. Figures (2- 4) and Table (1) show the factor of safety (F.S.) simulation of upstream and downstream slope for all cases of operations. For upstream slope, the absolute mean error (AME) is about 0.16

and the average absolute percentage difference (AAPD) is about 8.8%. For downstream slope, (AME) is about 0.075 and (AAPD) is about 4.1% which are all within the acceptable accuracy.

Table (1): Minimum calculation results of factor of safety

Methods of calculation	F.S upstream slope		F.S downstream slope	
	Rapid drawdown	End of construction	End of construction	Steady state
Present study GeoStudio software (Bishop's)	1.618	2.25	1.911	1.90
Referance **[21]** Analatical solution (Bishop's)	1.515	2.03	1.86	1.80
Absolute percent difference	6.79%	10.83%	2.47%	5.56%

7. Application of Geostudio on Mandali Dam

Mandali dam is an earth fill dam which is located on Harran Wadi, in the governorate of Diyala which is extends to the northeast of Baghdad, Iraq (Fig.5). The dam has been designed by Directorate General of Dam and Reservoirs, Iraq. The Wadi bed is gravely and permeable to some depths as it is clear from the geological investigations Mandali dam has a central core and the dam total length is about 1316 m. The maximum height of the dam is about 14m [Ministry of water Resources, Iraq] **[22]**. Figure (6) shows the dam cross-section, while Table (2) gives the material properties of the dam components. The dam geometrical properties can be seen in Table (3).

Table (2): Material properties of Mandali dam, Iraq **[22, 23]**.

Layer (soil type) / **Physical and mechanical properties**	**Shell (Sandy soil)**	**Clay core (Very stiff clay)**	**Foundation (Stiff clay)**	**Filter (Sandy gravel soil)**
Bulk density (γ) [KPa]	21	19.2	22	21
Angle of internal friction (ϕ) [degree]	40	15	30	37
Cohesion (c) [KPa]	0.0	40	5	0.0
Permeability (k) [m/sec]	$1.37*10^{-5}$	$9.88*10^{-9}$	10^{-8}	10^{-2}
Poison′s ratio (ν)	0.3	0.36	0.32	0.4
The elastic Modulus (E) [KPa]	35000	19000	100000	30000

7.1 Safety Criteria of Mandali Dam

The Geometric properties of Mandali dam were checked using BDS (1994) **[19]**. Table (3) gives the results of the comparison. It can be noticed that the geometric design of the dam is acceptable based on the recommendations of The British Dam Society (1994) **[19]**.

Table (3): Comparison between original section of Mandali dam and (BDS) safety limits

Parameter	**Mandali Dam**	**(BDS) Safety limits**	**Safety of dam status**
Crest width	8.0 m	Not less than 2.0 m	Acceptable
Upstream slope	2.7:1	2.5:1	Acceptable
Downstream slope	2.4:1	2:1	Acceptable
Free board	1.50 m	Min. free board = 1.50 m at Max. Fitch = 4 km.	Acceptable (Maximum head over spillway = 2.5 m)
Bed width of core	58 m	Not less than $\frac{H}{3}$ = (4.67 m)	Acceptable
Core slope	1:1.77	1:12	Acceptable

7.2 Seepage Analysis of Mandali Dam

The Finite Element Mesh of the model can be seen in Figure (7). While figures (8) and (9) present the water head variation and pore water pressure through the dam body, respectively. Figure (7) shows that the phreatic line has been lowered down effectively by the central clay core. Figure (8) confirms that the pore water pressure in the internal surface of downstream are far away from downstream which ensures stability of the downstream against seepage failure. Figures (7) and (8) show that the variations of pore water pressure as well as energy lines follow (BDS) safety regulations. Moreover, the flow lines are diverge from the downstream toe of the dam and the drainage filter minimize excess developed pore water pressure, which ensures the stability of the downstream slope.

8. Analysis of Mandali Dam and Results

To investigate the stability of dam slopes, the dam was simulated, using Geostudio software, three different cases of operation are considered, as follows:

Case (1): Just after construction; where reservoir is empty and significant pore pressure development is expected either in the embankment or foundation during construction of the embankment.

Case (2): Steady-state seepage; where reservoir is full and the long-term phreatic surface within the embankment has been established.

Case (3): Rapid drawdown; in the reservoir is drawn down faster than the pore pressures can dissipate within the embankment after the establishment of steady-state seepage conditions.

The considered analytical methods in the present study are Ordinary, Bishop's Simplified, and Janbu's Simplified and Morgenstern-Price methods. The obtained factors of safety (F.S.) are compared to the Limits of USACE (2003) **[18]** and BDS (1994) **[19]**.

Figures (10 - 14) present F.S. for the dam slopes under different cases of operation using the four analytical tools. Table (4) summarizes the determined upstream and downstream factor of safety (F.S.) for all cases of operation and used analytical tools.

Table (4): Results of Mandali dam stability analysis by Geostudio with Limit of USACE (2003) and BDS (1994).

Critical Stability Condition	End of construction		Steady state		Rapid drawdown	
USACE (2003)	Upstream	Downstream	Upstream	Downstream	Upstream	Downstream
	1.3		1.5		1.2	
BDS (1994)	(1.5-1.3)		(1.5-1.3)		(1.3-1.2)	
Ordinary	1.985	2.394	2.343	2.008	1.958	2.008
Bishop's	2.082	2.427	2.488	2.154	2.061	2.154
Janbu's	1.922	2.357	2.205	1.962	1.895	1.962
Morgenstern-Price	2.12	2.444	2.543	2.187	2.103	2.187
Remark	Stable	Stable	Stable	Stable	Stable	Stable

For steady state condition, the maximum water level was 182.5 m [AMSL], where the dam crest level is 184 m [AMSL] (1.50 m free board). While for rapid drawdown case, the water level was lowered from the estimated maximum flood level of 182.5 m [AMSL] to the minimum operating level of 170 m [AMSL]. As can be seen in the presented figures and table, the factor of safety (F.S.) values ranges from 1.895 to 2.543 which satisfies the minimum limits of factor of safety (F.S.) in USACE (2003) and BDS (1994). The factor of safety (F.S.) values reflects stable slopes of the dam for all operating cases. The least values of factor of safety (F.S.) are given by Janbu method. This is mainly due to the moment equilibrium equations that are not satisfied by Janbu's method. While the largest factor of safety (F.S.) values are given by Morgenstern-price method, as Morgenstern-price method relates the shear and normal force [13].

9. Conclusions

Finite element modeling was employed in this study to analyze the combined seepage and slope stability of Mandali earth dam (Iraq). Three different cases of operation were considered, and four different analytical tools were used to analyze the slope stability. The dam safety check was based on the minimum required F.S stated in USACE and BDS. The results showed that the geometric design of the dam is acceptable according to BDS criteria and the seepage through the dam is within the code recommendations. The factor of safety (F.S.) values of upstream and downstream slopes stability satisfy the minimum limits for all cases of operation. Rapid drawdown case is the most critical case compared to other operating cases. It can be concluded that Mandali dam is safe against seepage failure and slope failure under the different cases of operation. As a conclusion, developing of software for earth dam safety is essential.

INDONESIA

1. INTRODUCTION

Indonesia is one of many countries that have the highest number of dams in the world. Related to climate change in the world with so many dams in Indonesia (286 dams) needs to be assessed, the risk assessment action plan is very important to be done. Modified ICOLD Method (MIM), is a risk assessment model that is often used in Indonesia. However, this method has the disadvantage that only provides data on the number of people at risk (PAR) not to the point Loss of Life (LoL). According to the downstream dam area where dominated by densely populated areas and economic centers in Indonesia, which makes the risk level of dam is high or even extreme and considering the effects of climate change that can lead to the destruction of a dam at any time, the aspect of LoL shall be a priority for concerned. Although considered to be a lot of uncertainty, further study of PAR is the prediction of the number of LoL at least a measurable picture for various efforts to reduce the amount of LoL.

2. METHODS

Because this paper only discusses PAR in the innundation area then some conditions, such as PAR who are in the dam and LoL due to traffic accidents due to drift on the highway when disaster does not take into account. Basically, this method involves basic map preparation, parameters affecting the amount of LoL in the innundation area, the development of interaction matrix, coding on the matrix, parameter classification, rasterization, potential risk assessment of LoL, making of risk maps and simulating the reduction of the amount of LoL. Raster method is a method that describes the relationship between risk determinant parameters to a threat in each sub unit of the inundation area. The total number of LoL predictions of the raster method will be calibrated by the empirical equations of regression results from the number of catastrophic collapse events in Indonesia and the world. If the results are not significantly different, then the prediction of the amount of LoL can be considered close to and can be an additional reference in risk assessment in the Modified ICOLD method.

3. RESULTS

3.1 Basic Map Preparation

The base map is a spatial data that is important in the final decision-making process. The completeness of the base map will have an indirect effect on the final result to be obtained. The basic map used in this paper is the result of running simulated dam and software with ZhongXing HY-21. For example used dam break innundation map at the Cacaban Dam in Central Java, Indonesia.

3.2 General Data of Cacaban Dam

Location	:	Slawi, Central Java, Indonesia
River	:	East Cacaban River
Year Builted	:	1952 - 1958
Owner	:	Department of Public Works Indonesia
Type	:	Homogeneus Earthfill
High	:	38 meter (from deepest foundation) - El. + 80,50 meter
Long of Dam	:	168 meter
Width	:	6 meter
Capacity 2015	:	53,08 million m^3 (Normal)
		101,70 million m^3 (Flood)
		0,10 million m^3 (Minimum)
Elevation	:	+ 77,50 meter (Normal) - 790 ha
		+ 78,75 meter (Flood) - 900 ha
		+ 50,00 meter (Minimum) - 100 ha
Catchment Area	:	59 km^2
Q design	:	800 m^3 / s (Free Spillway) T : 125 year
Long of Spillway	:	58 meter
Benefits	:	Irrigation
Down Stream	:	- Area : 281,71 km^2 (Innundation Area)
		- Tc : 0,5 hour
		- PAR : 519.518 persons
		- House : 129.880 unit
Instruments	:	Piezometer (30 unit - Standpipe)
		Inclinometer (2 unit)
		V Notch (1 unit)

3.3 Developing of Interaction Matrix

In general, the parameters to be used, determined based on the knowledge and experience of experts related to the field to be studied. The more parameters studied, the matrix will have better quality. In this paper, the parameters to be used include the anticipated aspects of flood characteristics that affect the prediction of the amount of LoL. Development and linkages between parameters are labeled as follows:

Table 1. Development of Interaction Matrix

Anticipation of Downstream Dams to Natural Disasters Event	Anticipation Of Disaster That Can Come Every Moment Unexpectedly	Anticipation Of Large Flood That Will Happen	Anticipation Of Disaster Affects Total PAR / PENRIS	Anticipating Disaster Affects Readiness PAR and Related Agency for Evacuation	Quality of Disaster Anticipation Determining Preparedness of Evacuation Sites	Short, Medium and Long Term Anticipation	Main Anticipation is One Vision Reduces Risk Levels to a Safe Level
The Most Extreme Impact of Disasters Affects Anticipation Against Disaster	Disaster Failure of The Dam	Type of Dam Collapse Damning Flood Characteristics	Possible Disaster Affects to Number of PAR / PENRI	The Possibility of an Influential Disaster Against Readiness PAR / PENRIS faces Disaste	The Possibility of an Influential Disaster on the Readiness of Evacuation Site	Incidence of Dam Collapse The Effect of LoL Amount	Disaster Damage Collapse Affects Risk Assessment
Flood Characteristics Affect Anticipation of Disaster	Type of Dam Collapse Damning Flood Characteristics	Flood Characteristic (H, V and WT)	Flood Characteristics affects the number of PAR / PENRIS	Flood Characteristics Affects Readiness PAR and Related Institution	No	Flood Characteristics Affect the Prediction of LoL Amount	Karakteristik Banjir Mempengaruhi Prediksi Jumlah LoL
The number of PAR affects the type of anticipation of disaster	No	No	Amount of People at Risk (PAR)	No	No	The number of PAR affects the Prediction of the LoL Amount	Amount of PAR Affects Prediction of LoL Amount
Quality of Readiness Determining the Value of Anticipatory Efforts	No	No	No	Readiness of PAR and Related Agency Disaster For Evacuation	Depending on the Current Quality of Coordination Between Related Parties Evacuation	Readiness of PAR and Related Agency Affects the Prediction of LoL Amount	PAR Readiness Affects Risk Assessment

3.4 Encoding in Matrix

To know the interaction of all parameters with each other, semi-quantitative method is used with 5 categories with range 0 to 4 with categories: No Interaction (0), Weak Interaction (1), Medium Interaction (2), Strong Interaction (3) and Critical Interaction (4). Encoding In Matrix based on interrelationship between parameters is labeled as follows:

Table 2. Encoding in Matrix and Interrelationship between Parameters

Anticipation of Downstream Dams to Natural Disasters Event	4	4	3	3	3	3	3
3	Disaster Failure of The Dam	3	3	3	3	3	3
3	3	Flood Characteristic (H, V and WT)	4	4	3	3	3
3	0	0	Amount of People at Risk (PAR)	0	0	4	4
3	0	0	0	Readiness of PAR and Related Agency Disaster For Evacuation	3	3	3
3	0	0	0	4	Readiness from Evacuation Site and Post-Disaster Handling	3	3
3	0	0	3	3	3	Prediction of LoL	3
3	3	3	1	2	2	3	Risk Assessment LoL for Developing Modified ICOLD Method

Table 3. The Weighting of the cause and effect relationships for the predicted number parameters of the LoL

Parameter	Cause	Effect	C+E	(C+E) %
Anticipation of Downstream Dams to Natural Disasters Event	23	21	44	32,59
Disaster Failure of The Dam	18	6	24	17,78
Flood Characteristic (H, V and WT)	17	3	20	14,81
Amount of People at Risk (PAR)	8	4	12	8,89
Readiness of PAR and Related Agency Disaster For Evacuation	9	9	18	13,33
Readiness from Evacuation Site and Post-Disaster Handling	6	5	11	8,15
Prediction of LoL	3	3	6	4,44
Total			135	100,00

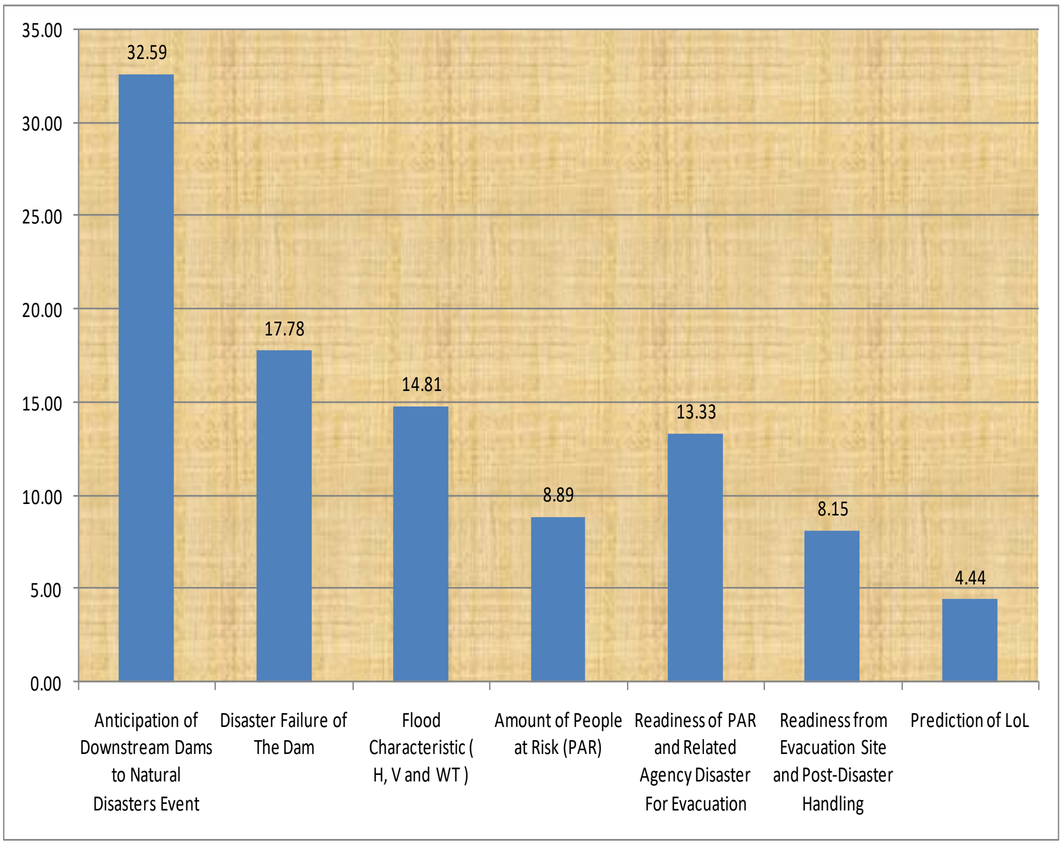

Fig 2. The Weighting Histogram of the Causal Relationship Between Parameters

Based on results with Semi Quantitative Method, it is known that anticipating factors related to natural disasters (32,59 %) , especially the disaster of dam collapse (17,78%), are the dominant parameters that influence the modification effort of dam security risk assessment. The prediction of the amount of LoL itself depends heavily on these two factors. Meanwhile, two other factors that are balanced but interrelated is the information factor predicting the flood flow (14,81%) that will occur with the PAR preparedness factor facing the disaster related evacuation action (13,33%) and evacuation site plus post disaster handling (8,15%). The information (8,89%) and prediction of PAR (4,44%) factor has the lowest weight compared to other parameters.

3.5 Assessment

In accordance with the size of the weighting and classification of predefined parameters, the minimum / lower and upper limit which describes the predicted condition of the LoL amount is as follows :

$$N_{min} = [1x(32.59+17.78+14.81+8.89+13.30+8.15+4.4)+(0x14.81)] = 99,92 \qquad [1]$$

$$N_{max} = [5x(32.59+17.78+14.81+8.89+13.30+8.15+4.4)+(1x14.81)] = 514.41 \qquad [2]$$

Thus, the final value classification of the predicted spatial analysis of the LoL amount is labeled as follows:

Table 4. Classification of Results Spatial Analysis to Risk of LoL

No.	Range	Classification	Pixel Color
1	99,92 - 205,92	Very Critical	Red
2	205,93 - 311,93	Critical	Yellow
3	311,94 - 417,94	Fair	Blue
4	417,95 - 514.41	Safe	Green

3.6 Rasterization

The sum of the weights of each parameter per pixel in a flood map area due to the dam break is illustrated as follows:

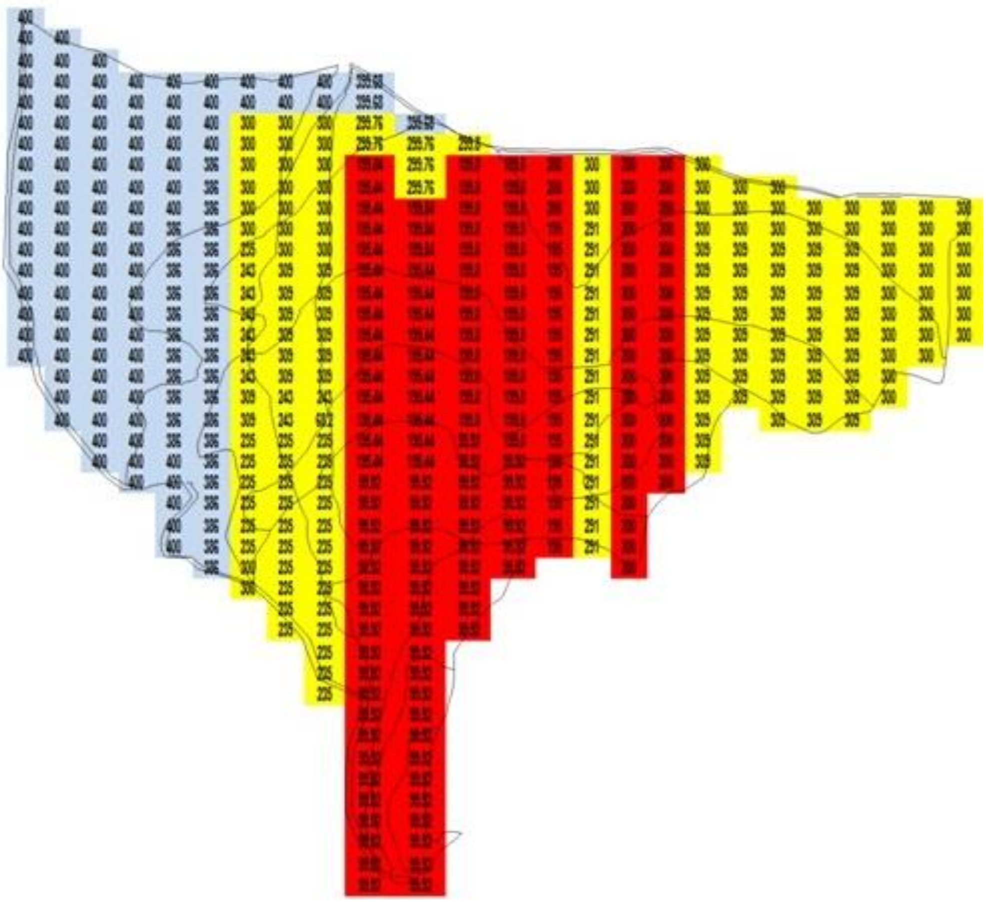

Fig 3. Potential Risk of LoL Map

Based on the potential risk map for the fall of LoL can be seen that the yellow and red areas are still the dominant color. The biggest weight of the parameters is on the anticipation aspect. The ideal step to decrease the risk value is by removing the PAR in the red and yellow areas but as long as it is difficult, risk reduction efforts can be made by further intensifying the three main points of the parameters: anticipation of dam disasters, preparedness to evacuate and the readiness of the evacuation site and post-disaster handling. If PAR is assisted by the relevant agency is deemed ready for disaster, then the red and yellow color can be changed to blue. Under these conditions, the PAR assessments at the downstream of the dam in MIM can be reduced again with the consideration that PAR together with the anticipated agencies anticipating the disaster has been deemed ready to face the dam disaster that can happen at any time.

3.7 Improving Modified ICOLD Method With LoL Index

In the Modified ICOLD Method, the PAR evacuation requirements at the downstream of the dam have a point 18 (Extreme) where PAR > 250,000 persons, 12 (High) for PAR between 10,000 to 250,000 and 8 (Moderate) for PAR between 1 to 10,000 persons. This condition makes the big dams in Indonesia have high and even extreme categories which gives the impression that it is difficult to reduce the risk level because for the condition of Indonesia, risk assessment with the current condition up to 0 (Low) assessment is difficult to achieve given the increase and mobility of people in Indonesia. so high that it tends to ignore the safety due to future dam breakthroughs. If based on the regression graph that has been created for the condition in Indonesia can be predicted the number of LoL and anticipation can be done to accommodate the amount of LoL it can be said that the result of the assessment that the dam in extreme conditions for example can be proposed down to condition point 6 (Moderate) for PAR between 1 to 10.000 persons. Especially if long and short term action programs are implemented intensively to manage downstream areas of dams at the time of the dam is still standing well, it is not impossible to be reduced to moderate category even though the number of PAR is in the high category and even extreme. The results of this thinking are proposed in order to accompany the action of parallel intensive monitoring of conditions on the dam structure itself. The regression charts that were previously featured in the ICOLD 2017 Symposium in Prague last year are presented as follows:

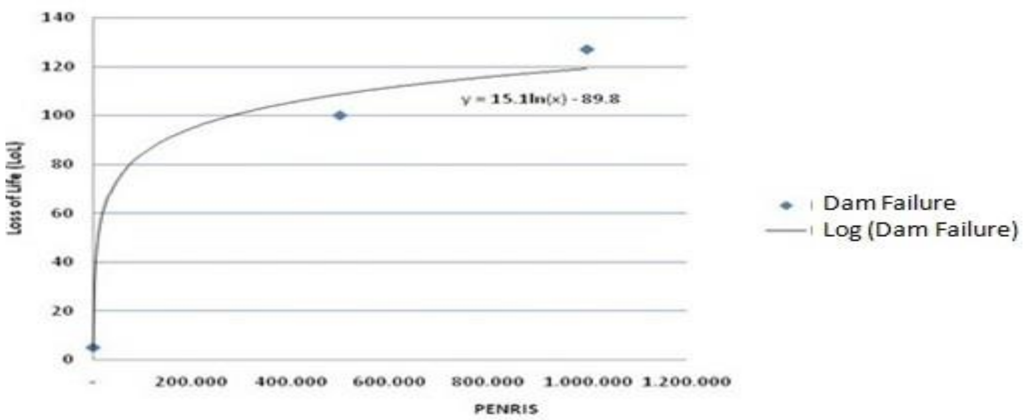

Fig 5 . PENRIS/PAR vs LoL for 3 Dams in Indonesia

The number of LoL predictions of the original Indonesian formula, compared with the calculation formula of De Kay (2003) commonly used in the world, is presented as follows:

No.	Name of Dam	LoL	
		Indonesian	De Kay
1	Wadaslintang	107	1346
2	Penjalin	88	546
3	Cengklik	119	4187
4	Cacaban	109	1188
5	Darma	89	2
6	Wlingi	103	1060
7	Simo	39	87
8	Sanggeh	39	207

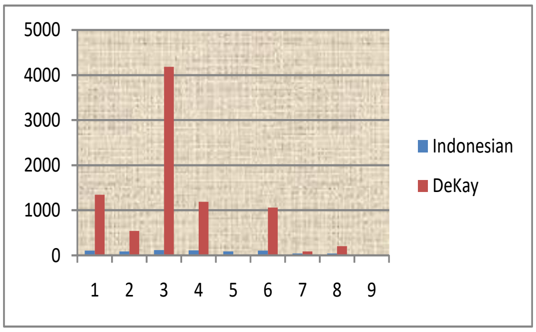

Fig 6 . Comparison of LoL Indonesia vs De Kay - Mc. Clelland for 8 Dams in Indonesia

Indeed there is a considerable difference in the number of LoL from the comparison results from the above table but at least a description of the predicted number of LoL already exists. With such measurable amounts at least if the commitment to take anticipatory action against the dam damage will be more mapped if it will proceed with the amount of costs that must be backed up later by the government and related parties. As an illustration, based on the dam risk assessment at year 2015, Cacaban Dam is categorized as high risk with point 55 and is in the interval 46 to 75. If efforts to reduce the amount of LoL have been well accommodated then no need to worry again to reduce its risk to 43 because it is reduced by 12 points into interval 16 to 45 so it can fit in Moderate category.

4. SUMMARY

Although the prediction of the LoL amount, has the smallest weight but the prediction of the amount of LoL is considered to provide a new argument for efforts to reduce the level of security risks of dams in Indonesia. Dams that with the downstream conditions of densely settled values of extreme or high conditions can be lowered risk level if the downstream preparedness of the disaster is considered good. One of the assessment factors is if it has been able to apply well to the risk reduction effort of LoL with short term anticipation (evacuation preparedness) and long term (preparation of disaster-based spatial design). The calculation of the predicted number of LoL by Raster method should be developed in the form of software program so that it can be applied directly in the field in order to take proper follow-up as well as measured in technical and financial aspects.

5. ACKNOWLEDGMENTS

The author would like to thank PT. Virama Karya (Persero) and KNIBB INACOLD as a sponsor to attend the ICOLD 2018 annual symposium this year. Also to the Parahyangan Catholic University Bandung, for the other support during the preparation of this paper.

1. INTRODUCTION

Near-fault ground motions recorded close to a ruptured fault can be significantly different than those observed further away from the seismic source [1]. The near-fault zone is dependent on the earthquake magnitude. In the near-fault area, depending on the rupture mechanism and slip direction relative to the site, the ground motion may exhibit a unique characteristic known as directivity effects. There is also another property resulted by the permanent ground displacement at the site which is called fling-step. These special aspects of near-fault ground motions should be accounted for in the analysis and design of structures in near-fault areas [2]. The directivity effects, in particular, would lead to high specific pulses in the velocity time-history of the record in the direction perpendicular to the fault rupture. It has been shown that the amplitude and period of the pulse are parameters that control the performance of structures; it cannot be easily predicted by typical measures such as response spectra [1-11]. It has been observed that pulse-like motions have larger elastic spectral acceleration values at moderate to long periods. For the concrete dams, Bayraktar and co-workers [10,11] determined near-fault ground motion effects on the nonlinear response of dams including dam-reservoir-foundation interaction. They selected four different types of dam, which are gravity, arch, concrete faced rockfill and clay core rockfill dams, to investigate the near-fault ground motion effects on dam responses. They showed that near-fault ground motions have different impacts on the dam types. Wang and co-workers [12,13] presented results of a study aimed at evaluating the effects of near-fault and far-fault ground motions on seismic performance of concrete gravity dams. They selected Koyna gravity dam as a numerical application. Four different near-fault ground motion records with an apparent velocity pulse were used in the analyses. The results obtained from the analyses showed the effects of near-fault ground motions on seismic performance of concrete gravity dams and demonstrated the importance of considering the near-fault ground excitations.

2. SEISMIC VULNERABILITY ASSESSMENT

Seismic vulnerability is commonly assessed by estimating the probability distribution of EDP for a given IM, EDP|IM. The complementary cumulative distribution function of EDP|IM is used to compute the probability that EDP exceeds a certain level edp, given that IM = im. This estimation can be combined with a ground motion haza14rd hIM(im), to compute the mean annual rate of exceeding the EDP level edp [9]:

$$R_{EDP}(edp) = \int_{IM} P(EDP > edp \mid IM = im) \cdot dh_{IM}(im) \tag{1}$$

The ground motion hazard hIM(im) is the mean annual rate of exceeding the IM level im, obtained using probabilistic seismic hazard analysis. The conditional probability P(EDP>edp|IM=im) is called as the seismic fragility which is a plot of this probability against various IM levels. REDP(edp) is a measure of seismic reliability of structure. Relationships between ground motion IM and structural response EDP have been well established for various types of structures in the context of probabilistic seismic demand models. In this approach, probabilistic estimations of the EDP as a function of the IM is computed through statistical analysis of nonlinear dynamic analysis results under a set of earthquake ground motions [9].

3. PULSE-LIKE RECORDS

The near-field earthquakes are recorded close to active faults; they possibly include velocity pulses resulted from the forward-directivity. So they are categorized as “pulse-like” or “non-pulse-like”. The forward-directivity effects may be generated when the site is located at one end of the fault, and rupture initiates at the other end of the fault and travels towards the site, the arrival of the wave front is observed as a pulse with large amplitude that occurs at the beginning of the record. These effects are normally long period and are typically observed in the velocity time-history. However there may be backward- and neutral-directivity depending on the fault orientation and rupture propagation [1]. The velocity pulse may occur in the fault-normal direction; ground motion shaking in the fault-parallel direction is typically less intense. Directivity effects are a major concern for researchers studying velocity pulses, and the effects of these pulses on structures [9]. The period of the velocity pulse Tp, can be determined as the period associated with the peak of the original ground motion’s velocity response spectrum. It is an important parameter such that the ratio of the pulse period to the fundamental period of the structure can greatly affect the structure's response [9]. In this study, a set of seventy-five pulse-like near-field ground motions collected by Baker [9] is utilized. The pulse in this set has been identified using a wavelet analysis. Sixty non-pulse-like (ordinary) near-field ground motions with no velocity pulse are also used for comparison with the pulse-like record set. Using large number of earthquake records implies an aleatory uncertainty due to record-to-record variability. All ground motions were recorded on firm soil or rock sites. The processed ground motions come from the Next Generation Attenuation project database (http://peer.berkeley.edu/nga/), and are oriented in the fault-normal direction. They are from earthquakes with large magnitudes in the range of $5 < Mw < 8$. The acceleration response spectra of the two earthquake sets are shown in Fig. 1. At large periods, the pulse-like ground motions tend to cause larger elastic spectral acceleration than the non-pulse-like ground motions.

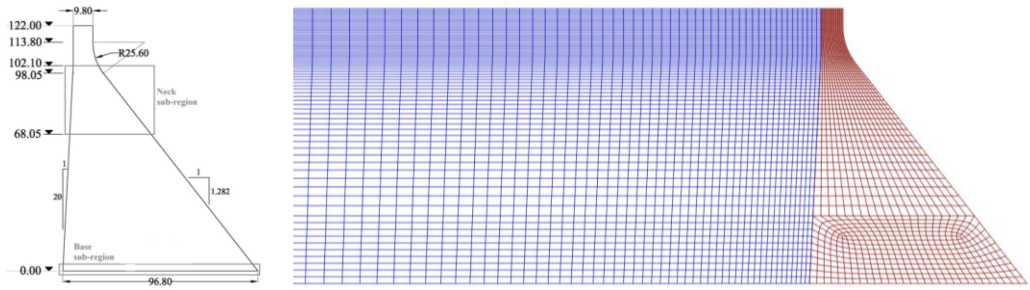
Fig. 1. Acceleration response spectra of the selected earthquakes: (a) pulse-like, (b) non-pulse-like records

4. DAM MODEL

The selected dam model is the tallest non-overflow monolith of Pine Flat gravity dam shown in Fig. 2(a). It is modeled along with its full reservoir using the finite element method; the adopted mesh is illustrated in Fig. 2(b). The water-structure dynamic interaction is taken into account employing Eulerian-Lagrangian formulation. The reservoir length is considered to be five times the dam height and transmitting boundary condition is assigned to its truncated far-end. Zero-pressure condition is assumed for the free surface of the reservoir. The foundation is assumed rigid where the selected earthquakes are uniformly applied.



(a) (b)

Fig. 2. (a) Non-over-flow monolith of Pine Flat dam used in this study (all dimensions are in meters). (b) finite element mesh of the dam and part of the reservoir.

The nonlinear behavior of dam concrete is modeled using plastic-damage method. In this method, the stiffness of the concrete is degraded beyond its strength using a reduction coefficient of (1-dt), where dt is the tensile damage parameter which is assumed to be function of the plastic strains. The damage parameter can take values from zero, representing the undamaged material, to one, which represents total loss of strength. Previous research on this dam showed that only the tensile damage is important in its seismic performance. It is related to concrete tensile cracking which is one of the most important failure modes of gravity dams. The constitutive behavior of the dam concrete is shown in Fig. 3. The finite element mesh of the dam body has been sufficiently refined such that it properly captures its nonlinear response. The concrete properties are: mass density of 2400 kg/m3, initial elastic modulus of 30 GPa, Poisson's ratio of 0.2, and tensile strength of 2.9 MPa. The water has density of 1000 kg/m3 and Bulk modulus of 2.07 GPa.

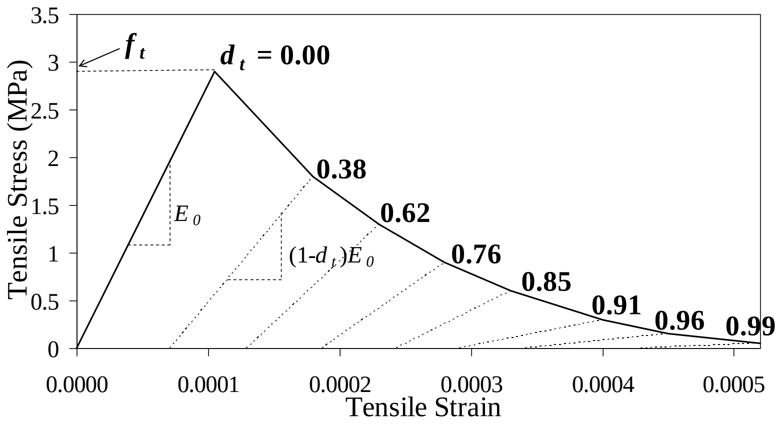


Fig. 3. Constitutive behavior of mass concrete in uniaxial tension

The model is first loaded statically under the self-weight of the dam and the hydrostatic pressure of the full reservoir. Then, it is dynamically analyzed under the selected earthquake ground motions. The Rayleigh damping is employed for structural elements with the coefficients such that produce 5% critical damping in the first and third vibration modes of the intact model. Based on the mentioned properties, the first five natural periods of the dam-reservoir system are: T1=0.38s, T2=0.33s, T3=0.30s, T4=0.26s, T5=0.22s.

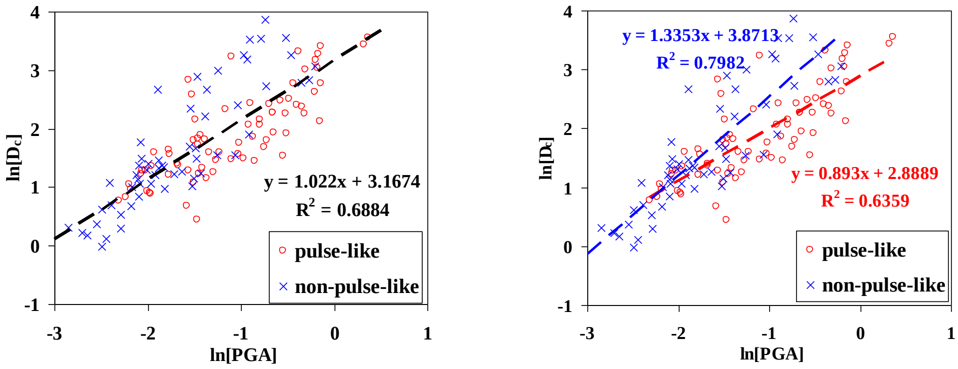
The considered EDPs are the crest maximum relative displacement Dc, and the peak hydrodynamic pressure P imposed to the dam heel. Because the dam body has un-symmetric geometry, the crest relative displacements can be separately monitored into the upstream DcU, or the downstream DcD directions. Two local damage indices are defined which are directly related to the cracking response of the dam body. They are computed in the cracking-susceptible sub-regions of the dam body shown in Fig. 2(a) as base and neck sub-regions. These local damage indices, Λ, for both sub-regions are defined as

$$\Lambda_i = \frac{\sum_{e|i} d_{t|e} A_e}{\sum_{e|i} A_e} \qquad i = "b" \ or \ "n" \tag{2}$$

where dt|e is the tensile damage of element e with area of Ae. The computation is done on the entire sub-region i. Subscripts b and n show the base and neck sub-regions, respectively. These damage indices are a measure of the amount of damage that the dam may locally experience. Another EDP can be defined as the energy dissipated through cracking process, EC, which can be considered as a global measure of damage imposed to the dam body.

5. RESULTS

The dam-reservoir coupled system is analyzed under the selected pulse-like and non-pulse-like records, and the EDP values are computed. The difference between the pulse-like and non-pulse-like records can be investigated by assessing the cloud of data of, say, ln[Dc]-ln[PGA] shown in Fig. 4. Considering all of data as response under the near-field earthquake records (Fig. 4(a)) would result in regression line with slope of 1.022 and goodness of fitting R2=0.69. But, separating the data as response under the pulse-like and the non-pulse-like records (Fig. 4(b)) causes an increase in slope and R2 value for the non-pulse-records that shows better correlation for this kind of near-field records. An opposite trend is observed for the pulse-like records. The same trends are observed for other IMs. It is concluded that the pulse nature would lead to more scattered response results. Therefore, it is important to separately investigate the response parameters considering the pulse nature of the earthquake records.



(a) (b)

Fig. 4. Cloud of data of Dc-PGA in logarithmic scale: (a) regression line for all of data, (b) separate regression lines for the pulse-like and the non-pulse-like records.

An important parameter of pulse-like motions that affects the structural response is the ratio of the pulse period to the fundamental period of the structure Tp/T1. It is particularly important for the first-mode dominated structures such as gravity dams. The response data of the dam-reservoir coupled model under the pulse-like motions are plotted versus the ratio Tp/T1 in Fig. 5. Because the fundamental period of the model is as low as 0.38s, the ratio of Tp/T1 is more than 1 for all selected pulse-like motions; this ratio becomes even as high as 34. The local variation of the data is represented using a local average employing the Nadaraya-Watson kernel-weighted average, with a Gaussian weight function. Also shown are the mean and median responses under the non-pulse-like motions; the mean response is totally higher than the median that shows a bias into the higher values. The response of the pulse-like motions may be higher or lower than the average response of the non-pulse-like records. As the ratio of Tp/T1 increases, approximately, lower response values are observed specifically for the damage dissipated energy which is a global measure of the imposed cracking damage. This trend is somewhat observed for the base local damage index, but it is not so clear for the neck damage index. No all of pulse-like motions would result in Λn, i.e. neck cracking; this parameter is observed for motions with Tp/T1 < 22 for only 49 out of 75 records. For the larger period ratios, the pulse period is so much high that it cannot excite the lower main vibration modes of the dam which cause large movements and neck cracking.

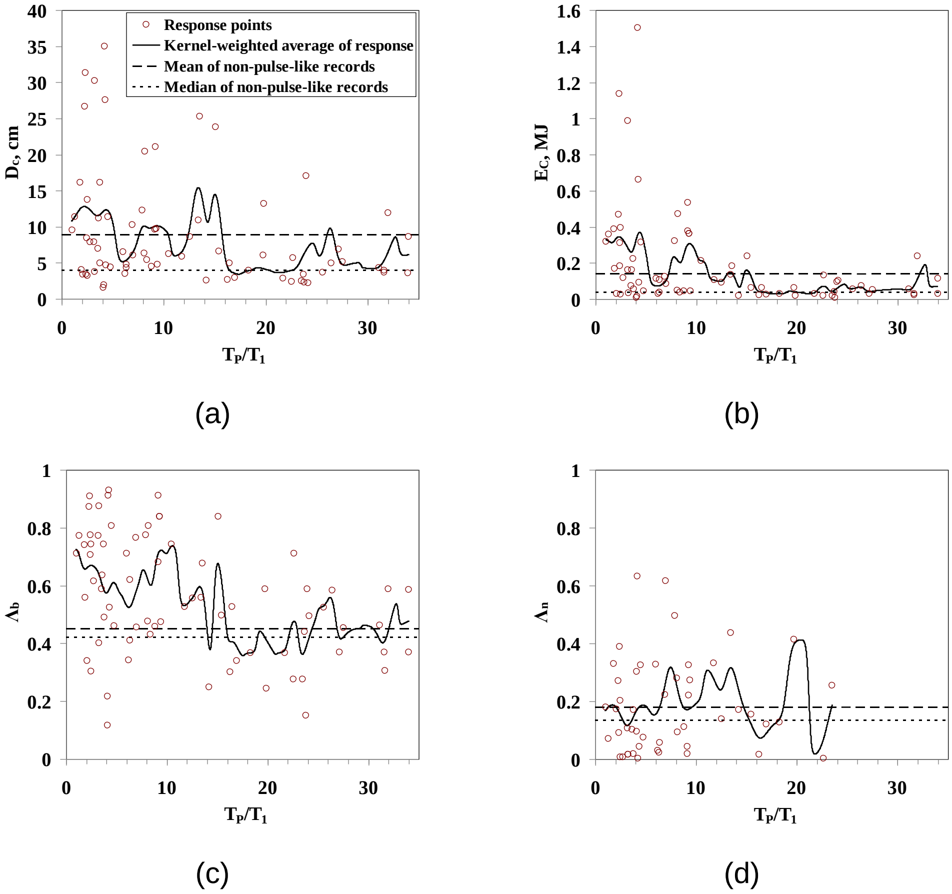


Fig. 5. Response results under the pulse-like records in terms of T_p/T_1: (a) maximum crest relative displacement, (b) damage dissipated energy, (c) base local damage index, (d) neck local damage index.

Because Sv(T1,5%) and Sd(T1,5%) was shown as good predictors of dam's structural response under both pulse-like and non-pulse-like records, the conditional probability of failure is computed using these two parameter as IM. Considering Dc, Λb and Λn as EDP, the obtained fragility curves are depicted in Fig. 6. The failure threshold of Dc, Λb and Λn are assumed as 2cm, 30% and 5%, respectively. Although these thresholds are subjective, but they have illustratively used to compare the fragility curves. The probability of failure is higher for the pulse-like records than the non-pulse-like records; however, the fragility curves are very close for Dc and Λn. But, the probability of base cracking is much higher under the pulse-like records with respect to non-pulse-like records. The probability of cracking of 30% of the dam's base length under the near-field records with Sv(T1,5%) = 20cm/sec is 45% and 85% for the non-pulse-like and the pulse-like records, respectively.

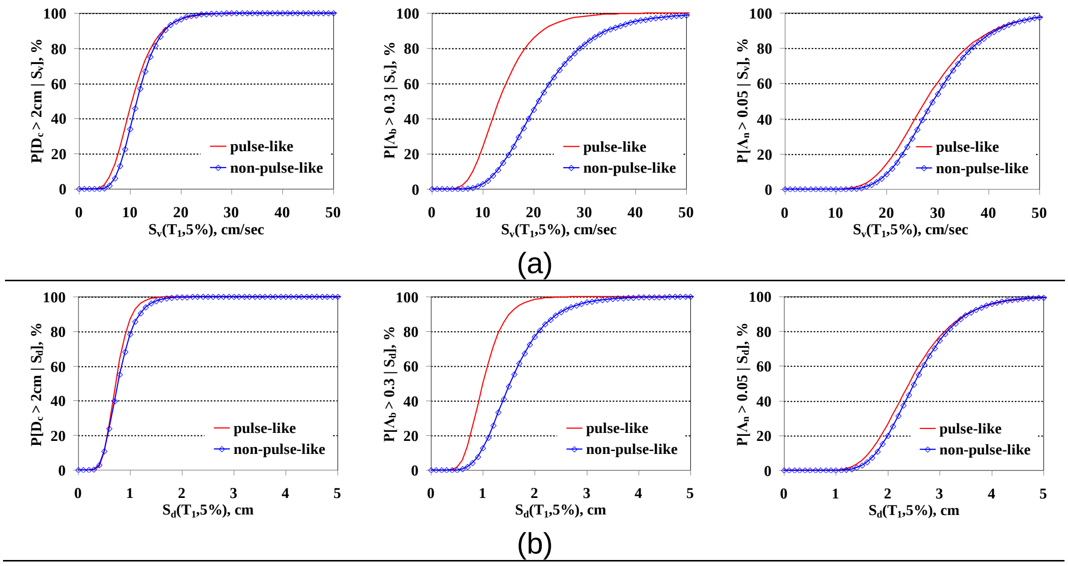

Fig. 6. Fragility curves considering IM as (a) Sv(T1,5%), and (b) Sd(T1,5%). Both pulse-like and non-pulse-like records.

6. CONCLUSIONS

Pine Flat gravity dam was modeled along with its full reservoir as case study. The dam-reservoir coupled system was analyzed under some selected pulse-like and non-pulse-like records, and it was shown that earthquake characteristics other than pulse nature may govern the seismic responses. Also, it was concluded that the pulse nature would lead to more scattered response results. Investigating the seismic EDPs against Tp/T1 showed that as this ratio increases, approximately, lower response values were observed specifically for the damage dissipated energy which is a global measure of the imposed cracking damage. This trend was somewhat observed for the base local damage, but it was not so clear for the neck damage. Finally, the seismic vulnerability of the dam was assessed by building its seismic fragility curves separately under the pulse-like and the non-pulse-like earthquakes.

1. INTRODUCTION

Water supply techniques have always been the most important part of the human needs in all of the era. Concrete arch dams are among the main structures in today industrial life. They are built for various purposes such as hydroelectric power generation, water storage for agricultural, industrial, flood control, and preparation of drinking water. It is of particular importance to achieve an adequate safety of dams against earthquakes, because many large dams are constructed in seismic regions.

2. METHOD

In this study, Response Surface Method (RSM) is used for calculate the Limit State Function (LSF) of drift failure mode of KARUN IV arch concrete dam. A three-dimensional model of dam-foundation-reservoir of the dam is created by ABAQUS 6.11 FEM software and the ratio of foundation modulus to dam modulus (Ef/Ed) is considered as the random variable. Material properties of dam and foundation are defined in linear domain and the water is modeled using equations of state (EOS).

Interaction between water and solid areas is considered as frictionless and LAYZMER boundary condition is considered for the free end of the lake. Sliding of the dam heel and abutments is neglected because of being small (2). USBR code is also employed for calculation of the dead, seismic, uplift, hydrostatic and hydrodynamic loads.

3. RESULTS

Five LSFs of drift failure mode for KARUN IV arch concrete dam under earthquakes loading have been extracted by RSM. The functions have been analyzed with six approaches and the $\hat{p}_f$ of dam is presented. RSM is adjusted in polynomial mode. The LSF then obtained by considering the failure drift and the performance of dam (i.e. $g(\boldsymbol{x} = E_f/E_d) = 0.0025 - Drift$). Obtained results by six mentioned approaches are presented.

4. CONCLUSION

It is concluded that CHI-CHI earthquake has the most impact on dam failure and the failure probability is much more than the other earthquakes, considering the foundation flexibility as a random variable. It is also concluded that Subset Simulation method has the best performance in terms of standard deviation of answers and it's results are very close to MCS. Importance Sampling can be also employed for reliability analysis of dam because it is able to find the approximate (near to MCS) failure probability with a few number of function calls.

1. INTRODUCTION

The investigation of soil improvement of problematic soils as foundation of soil embankments drew the attention of many researchers. Many techniques have been developed to overcome the negative impact of such problematic soils. In the case under investigation, the presence of deep soft clay layer form an obstacle for adapting the available techniques like soil fracturing and vibro replacemet. Control of seepage water through the soil media was investigated and discussed in many research works. The automated digging apparatus with extensive support facilities required to construct plastic concrete diaphragm wall around Sizewell B. power station at UK was described in [1]. Typical examples of walls to prove the adaptability and advantages of the secant bored pile wall method were summarized in [2]. Field studies have indicated the importance of the monitoring activities in understanding the interaction between the utilized pile and the surrounding soil [3]. Based on the rapid progress in analytical and monitoring techniques, graphs for the design of laterally loaded piles in clay was presented in [4].

In the present work, a stabilizing system of an embankment of one of the major canals north of Egypt was monitored and the collected data are discussed. The soil properties, the embankment cross-section, and the design concept of the proposed upgrading system were pointed out by [5]. The Atlas pile type is used in constructing both seepage control and stability improvement systems. The cast insitu screw piles with very rough shaft (Atlas type) proved to be the most suitable pile type to handle the presence of deep soft clay deposits. A complete review of the developments in Atlas type design and the main factors affecting its performance is in [6]. The monitoring system utilized for evaluating the seepage pattern inside the embankment and the performance of the cutoff secant piles are discussed in the present paper. The main conclusions that prove the effective performance of the tested system are pointed out.

2. MONITORING SYSTEM CONFIGURATION

Figure 1 shows the arrangement the monitoring system. The suggested secant-pile wall consisted of reinforced concrete piles with a diameter of 60 cm spaced at 90 cm from center to center intersected with bentonite piles with a diameter of 60 cm and the over lapping distance is not less than 15 cm. The reinforced concrete pile penetrated the upper fill layer and the soft clay layer and extended in the lower sand layer to about 50 cm with a total length equal to 16.50 m. The bentonite piles extended to 6 m in the soft clay layer with a total length approximately equal to 10 m.

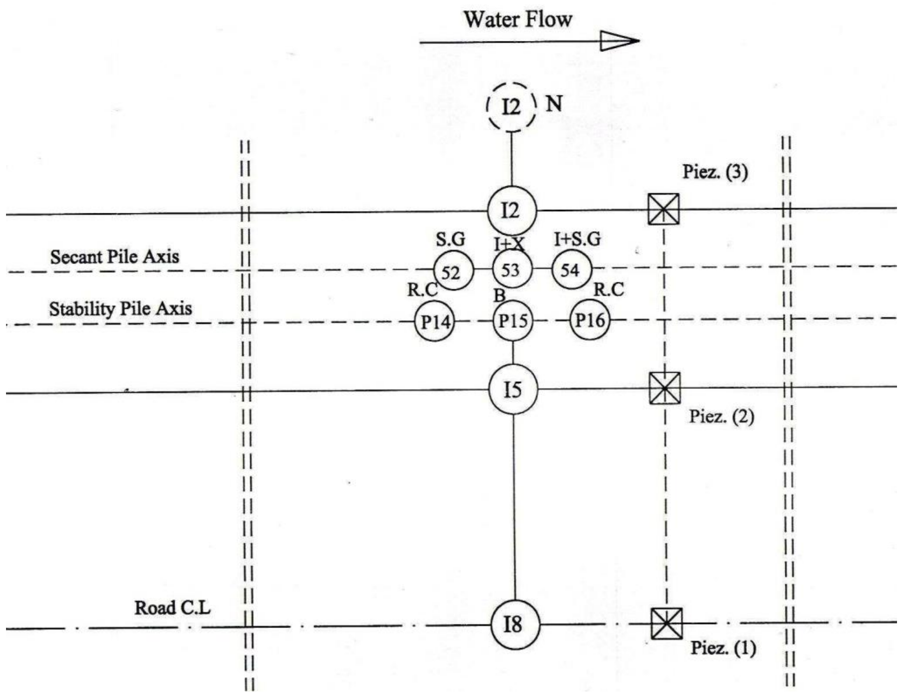

Fig. 1: The arrangements of the monitoring system

The monitored reinforced concrete piles in the wall were named P52 and P54 and the monitored bentonite pile was named P53. Pile P52 was instrumented with vibrating wire strain gages (s.g) on the reinforcing steel bars at levels of -1.80 m, -5.50 m, and –11.00 m relative to the zero sea level. Pile P54 was instrumented with vibrating wire strain gages at levels of -1.80 m, -4.50 m, -7.80 m, -10.80 m, and -13.80 m. In addition to the strain gages, P54 was provided with inclinometer casings and magnetic rings of sondex system at levels of -0.90 m, -3.93 m, -6.94 m, -9.95 m, and -12.96 m. Pile P53 (the bentonite pile) was instrumented with an inclinometer casing and magnetic rings of sondex system at levels of -0.93 m, -2.93 m, and -5.97 m. In addition to the instrumented piles, three piezometers were installed to monitor the variation of water level. Piezometer (1) was installed at the centerline of the road, piezometer (2) was installed adjacent to the secant wall in the roadside, and piezometer (3) was installed close to the secant wall in the canal side. The overall performance of the embankment mass was monitored through inclinometer I2 in the berm at the canal side, inclinometer I5 in the berm at the road side and inclinometer I8 at the center line of the road.

The monitoring data were collected just after installation of the monitoring equipments, during construction of the secant-pile wall, and during loading of the embankment. The loading process was carried out in three stages. Stage one (LI) covered a distance of 15.00 m to the left of the pile P52, the second stage covered a distance of 15.00 m at the center line of the monitored wall around pile P53, and the third stage covered a distance of 15.00 m to the right of pile P54. In each loading stage an area of 15.00 m × 3.00 m was loaded with a 60-ton lorry load.

3. RESULTS AND DISCUSSION

3.1. EFFECT OF THE SECANT PILE WALL ON THE WATER SEEPAGE IN THE EMBANKMENT MASS

The piezometer readings were collected before the beginning of the secant-pile wall construction, during wall construction, after the end of wall construction, and during the loading stages. Figure 2 shows the variation in the piezometer readings.

The effect of the canal water level on the piezometer readings was the same after the beginning of the wall construction until the construction of the left half of the wall was completed. When completing the construction of the left half of the wall, its left end reached a line passing through the points I8, I5, P53, and I2 in Sept. 17. After Sept. 17, a noticeable difference in the rate of change in the readings between piezometer (3) and both piezometers (1) and (2) was recorded. There are no difference between the readings of piezometer (1) and piezometer (2).

During the different loading stages there was no clear relationship between the readings of piezometer (3) and piezometers (1) and (2). However, the readings of piezometers (1) and (2) still match each other. The difference between the reading of the piezometer in the canal side of the wall and the piezometer in the roadside was increasing with time until eleven days after the end of loading activities where monitoring activities stopped.

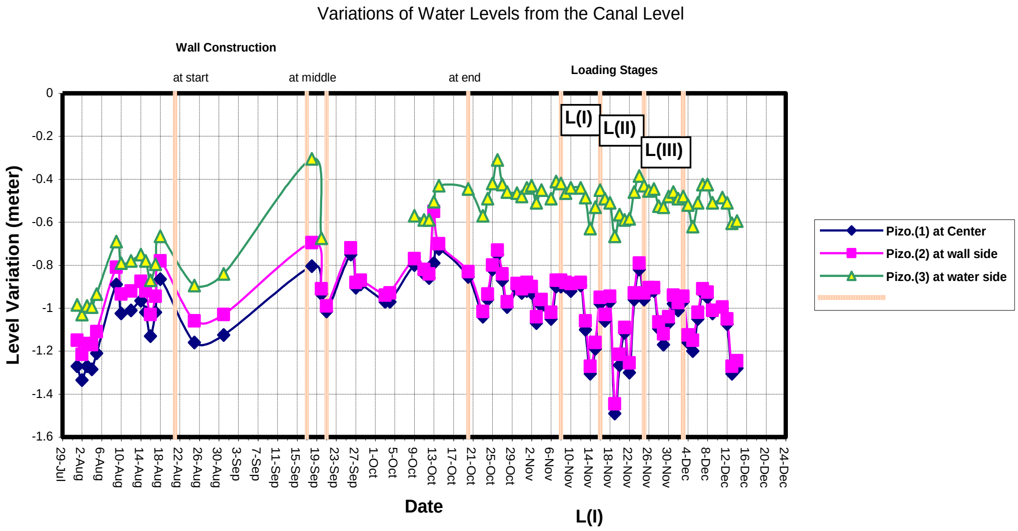

Fig. 2: The variation in the piezometer readings

3.2. EVALUATION OF THE LATERAL DISPLACEMENT OF THE EMBANKMENT AND THE SECANT-PILE WALL

The second monitoring activities were meant to evaluate the lateral displacements of the embankment mass and the monitored piles. The inclinometers I2, I5, and I8 were used to monitor the lateral movement of the embankment mass. Figure 3 shows, as a sample, the readings of inclinometer I2 that is close to the canal section. It can be shown from Fig. 3 that the maximum lateral displacement occurred at the top of the casings in the peat and clay layer with a value of about 17 mm. The maximum lateral displacement occurred during the installation of the inclinometer itself with minor changes due to the installation of the secant-piles wall. It is also clear that while the lateral displacement of the deep sand layer did not exceed 3.5 mm, the soft clay layer suffered from large displacement, which ranged between 12 mm and 16 mm toward the waterside. The previous observation shows the soft nature of the embankment and the high effect of losing the unconfined stress due to canal cut.

Figure 4 shows the collected data of the lateral displacement of the bentonite pile P53. Analysis of the data collected from the inclinometers embedded in the reinforced and the bentonite piles in the wall shows that the 10-m-long bentonite pile P53 suffered from relatively large displacements. Analysis of the collected data reflects the flexibility of the bentonite pile. While the maximum displacement experienced during the different loading and construction activities does not exceed 30 mm, the end toe approximately experienced no lateral displacement. Taking into account that the intersection between the reinforced and bentonite piles is about 150 mm, the maximum lateral displacement doesn't exceed 20% of such value. It can also be noted that despite such high displacement, the piezometer readings reflect no leakage or escape of water.

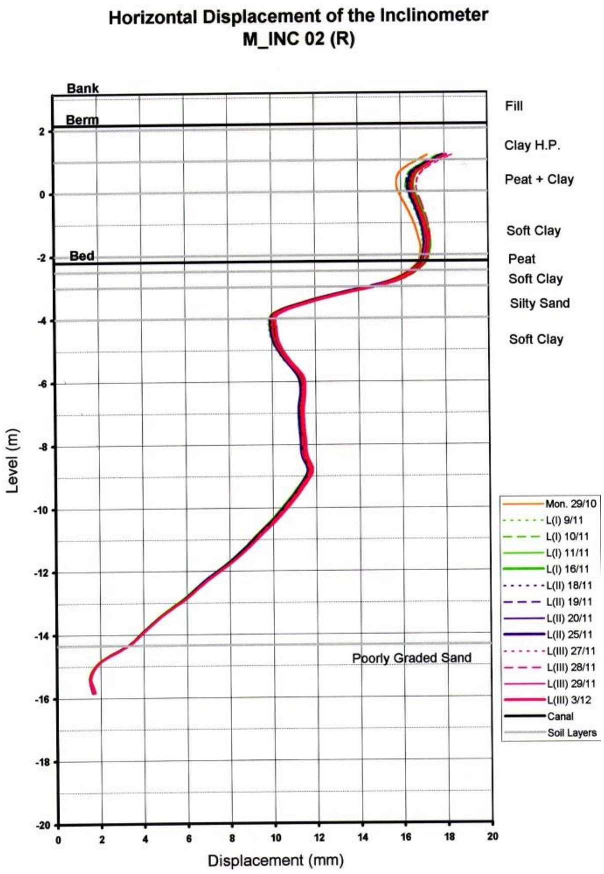

Fig. 3: The readings of inclinometer I_2

Figure 5 shows the lateral displacements of the reinforced concrete pile P54. It is clear from the distribution of the data that the pile experienced lateral displacement smaller than that experienced by P53. The previous observation is true for all the loading and construction stages. The loading stages L(I), L(II), and L(III) resulted in considerable increase in the lateral displacement all over the pile length. The presence of silty sand lenses in the soft clay layers played a vital role in the value of the experienced lateral displacement. It is clear also that the pile experienced high lateral displacement just after loading and then the value of the displacement tends to decrease with time.

It is worth mentioning that the vertical movements of the wall piles were monitored and evaluated but not covered in the present paper. The analysis of the lateral and vertical displacements (movements) of P53 and P54 reflects the ability of the designed monitoring system in tracing the performance of the secant-pile wall. The monitoring system was able to reflect the difference in installation time among its components, and what took place during the construction and the loading stages. The monitoring system was also able to reflect the effect of the presence of different soil lenses within the soft clay layer on the experienced movements especially during the installation and construction stages.

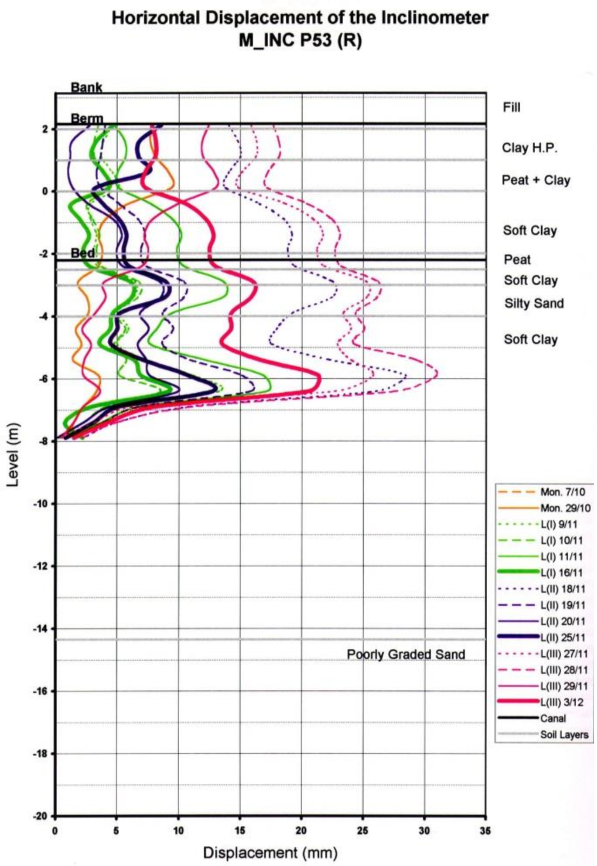

Fig. 4: The lateral displacement of the bentonite pile P_{53}

3.3. EVALUATION OF THE STRAINING ACTIONS OF THE WALL PILES

The strain gages, based on vibrating wire technology, were adapted in measuring the strain in the reinforcement of the reinforced concrete piles in the wall. The vibrating wire was utilized in the monitoring program due to its long-term stability as proved by many investigations such as [7]. In the present monitoring program, both piles P52 and P54 were instrumented with the vibrating wire strain gages.

The strain gages were fixed at the canal side (C) and the roadside (R). Most of the strain gages at the roadside were damaged in the Pile P52. The damage of the strain gages limited the benefit of the collected data for that pile. For the pile P54, the strain gages at both sides C and R were in good condition throughout all activities that took place in the field.

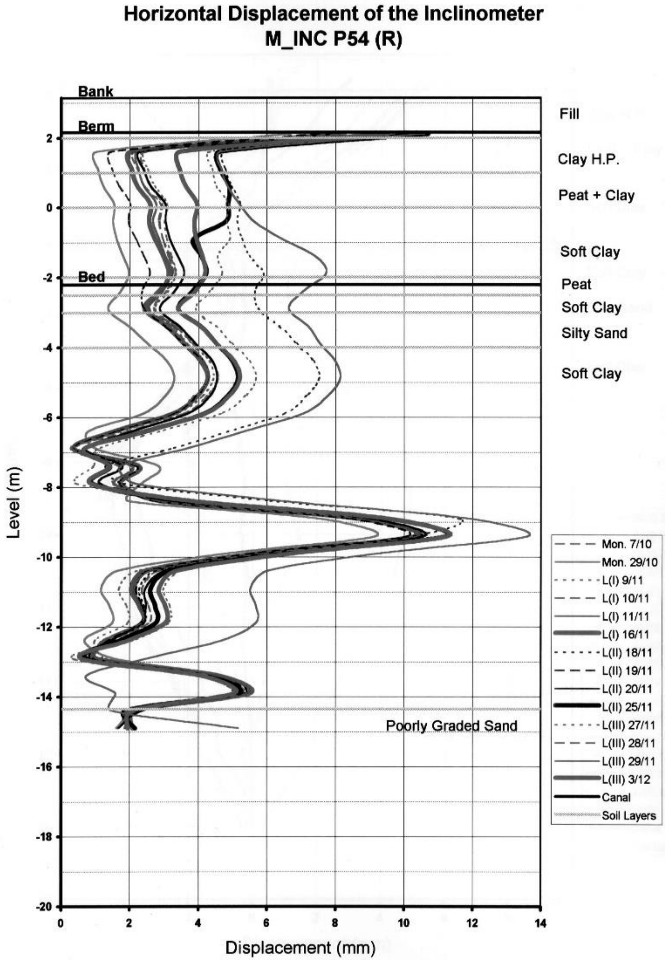

Fig. 5: The lateral displacements of the reinforced concrete pile P_{54}

Fig. 6 shows the readings of the strain gages fixed on the reinforcement bars at side R of the pile P54 shaft. The strain gages were fixed at levels -1.80 m, -4.50 m, -7.80 m, and -10.80 m along the pile shaft. The bending moment, calculated based on the measured strains, reflects high concentration moments at the upper silty sand and the lower very soft clay lenses within the soft clay layer. These sand and clay deposits controlled the pile movements especially during the construction stage, which resulted in concentration of stresses.

4. CONCLUSIONS

The readings of the piezometers embedded in the embankment proved the high efficiency of the secant-pile wall in controlling the seepage through the tested section of the canal embankment. The effect of the secant-pile wall was reflected after finishing the construction of half the wall in the tested section. The readings of piezometer (2), which is adjacent to the wall at the roadside, and piezometer (1), which lies at the center line of the road, were almost the same from the beginning of the construction of the left half of the wall until the end of the monitoring activities. Hence, it could be concluded that after the construction of the wall, there is no hydraulic gradient through the embankment, which in turn means that there is no erosion due to seepage forces.

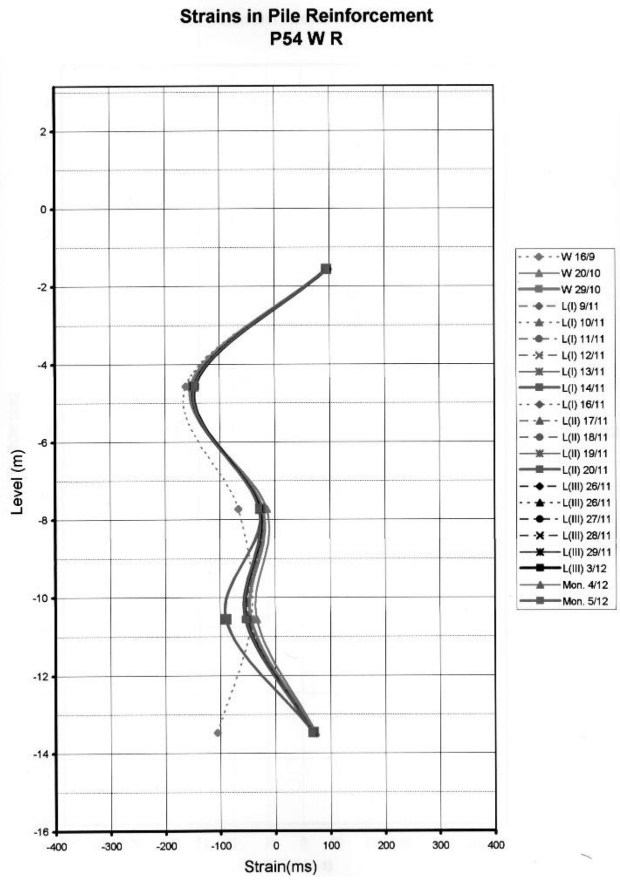

Fig. 6: The readings of the strain gages of direction (r) of pile P_{54}

The readings of the inclinometers embedded in the bentonite piles indicated its high flexibility because of the heave action of the pile after each construction or loading activities. The bentonite piles experienced high lateral displacement compared with the adjacent reinforced concrete pile.

The monitoring system succeeded in reflecting the effect of the presence of hard and/or very soft soil deposit lenses within the soft clay layer on the developed strains and stresses. Monitoring of the reinforced concrete piles showed that they experienced small stresses compared with its ultimate capacity. The shallow embedment of the reinforced concrete pile in the lower poorly graded sand layer did not allow for any fixation or partial fixation of the pile in the sand.

SUMMARY

In recent decades great attention was directed toward reclamation of new areas close to the Nile valley in Egypt. North of the Nile delta is one area that has a great potential for developing. Deep deposits of soft clay form an obstacle for such developing process. The embankments of a major canal were made of uncompacted marine deposits and founded over soft clay soil in the north of Egypt. Peat lenses caused slope instability and the sand and Gypsum lenses increased seepage potential and resulted in piping downstream the embankments. The present paper represent the measurements of a monitoring system used to evaluate the performance of an upgrading system of the poorly compacted embankment founded on soft clay. The upgrading is to be achieved through two systems of pile. The first system is meant to handle internal seepage problem while the other is utilized to provide extra stability for the embankment. In the present paper, the monitoring data of the secant-pile wall is presented, discussed, and analyzed. The monitoring system helped to evaluate the performance of the different components of the secant-pile wall. The relative movement between the reinforced concrete pile and bentonite slurry pile, the lateral and vertical displacement of the bentonite pile and concrete pile, and the strains in the reinforcement of the concrete piles were measured and analyzed. The results show that the seepage control system significantly improved the embankment performance and prevented internal erosion and seepage problems.

RÉSUMÉ

Au cours des dernières décennies, une grande attention a été accordée à la remise en état de nouvelles zones proches de la vallée du Nil en Egypte. Le nord du delta du Nil est un domaine qui a un grand potentiel de développement. Les dépôts profonds d'argile molle constituent un obstacle à ce processus de développement. Les remblais d'un grand canal étaient faits de dépôts marins non compacts et fondés sur un sol d'argile molle dans le nord de l'Égypte. Les lentilles de tourbe ont provoqué une instabilité des pentes et les lentilles de sable et de gypse ont augmenté le potentiel d'infiltration et ont entraîné la formation de tuyaux en aval des remblais. Le présent document représente les mesures d'un système de surveillance utilisé pour évaluer la performance d'un système de valorisation du remblai mal compacté, fondé sur de l'argile molle. L'amélioration doit être réalisée à travers deux systèmes de pile. Le premier système est destiné à gérer les problèmes d'infiltration interne tandis que l'autre est utilisé pour fournir une stabilité supplémentaire pour le remblai. Dans le présent article, les données de surveillance de la paroi de la pile sécante sont présentées, discutées et analysées. Le système de surveillance a aidé à évaluer la performance des différents composants du mur à pieux sécants. Le mouvement relatif entre le pieu de béton armé et le tas de lisier de bentonite, le déplacement latéral et vertical du pieu de bentonite et du pieu de béton, et les déformations dans le renforcement des pieux de béton ont été mesurés et analysés. Les résultats montrent que le système de contrôle des infiltrations a considérablement amélioré les performances du remblai et a empêché l'érosion interne et les problèmes d'infiltration.

1. INTRODUCTION

Dams are critical in terms of population life support and ensuring sustainable economic development. Dams not only for flood control but also provide water for some mutipurpose activities such as hydropower, irrigation water supply, domestic consumption, industrial water use, tourism, aquaculture, navigation, etc. Sutami dam is one of the large dams located in Brantas River Basin. Sutami dam (locally named as Karangkates dam) located at Brantas River Basin in Indonesia. The dam is a multifunction dam, which is used for flood control (with the capacity of 1,650 m3/sec), providing irrigation water supply for 34,000 hectares, and also to generate hydro power plant with installed capacity of 3 x 35 mW. Sutami dam has 180 million m3 storage capacity (based on 2016 bathimetry survey) and 1,500 hectares reservoir surface area. The public safety around dam issues surrounding the safety concerns for Sutami dam existed from its beginning of operation because of its critical water storage capacity, structures and massive human activities' surrounding it. This paper addresses some of those public safety requirements throughout the facility and more specifically following the more recent safety risk assessments and mitigation strategies implemented to meet the anticipated safety requirements nowadays.

2. DAM SECURITY

Conceptual approach that used in Dam security is by consider the intersection of the Venn's diagram of dam safety, dam security and public safety around dams comprises intervening activities can be seen in fig.1 below. The activities may be shared, but the objective or narrative of each area may differ.

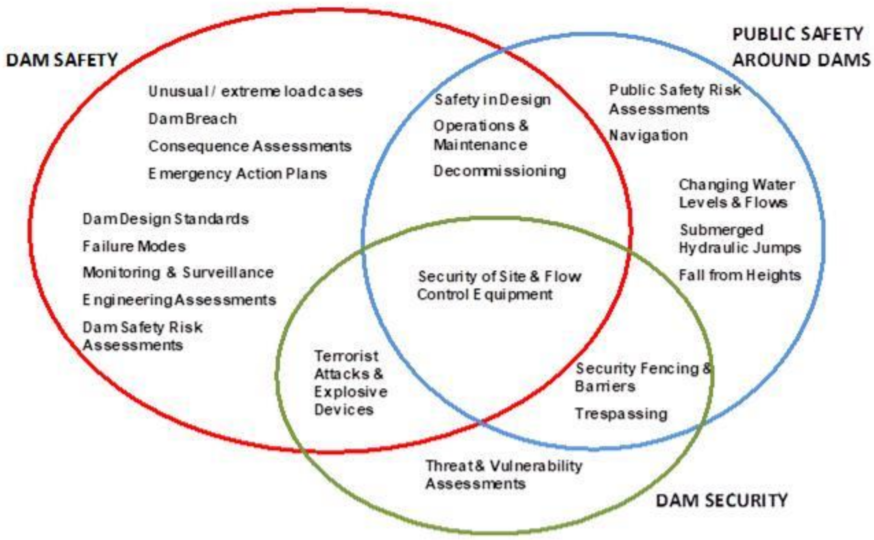

Fig. 1
Venn's diagram of dam safety

To promote the safety of dams, dam operator (PJT I) conducts dam safety management as a part of operation and maintenance activities of water resources infrastructures. As accidents happen at dams all of the time and more people die or are injured in accidents around dams that are not associated with structural failure of dams, Dam operator has a responsibility to safeguard the public and to control hazards that present significant risk of serious harm to the public. Human factor is and remain as an important issue in public safety around dams with the main aim of it was protecting people (visitors and workers) from accidents, drowning, suicide attempts, etc.

Jasa tirta I Public Corporation was implementing ISO as quality management system so Plan-do-actuating-check (PDCA) cycle is an important management approach towards public safety around dams.

- Pre-emptive actions:
  - Installation of proper warning signs
  - Restriction of visitors flow
- Monitoring
  - Close circuit televisons
  - Routine surveillance by reservoir operators
- Restrictions
  - Limitation of traffic flow

– Trashbooms
– Reservoirs zoning

3. IMPLEMENTATION

In implementing the obligation to secure vital objects in in Sutami Dam, Jasa Tirta I Public Corporation as the river basin organization that manage Sutami Dam carries out several activities such as:

a) Installation of warning signs

b) CCTV Installation

c) Vehicles Restricted Area

d) Limitation of Vehicle Tonnage

e) Security Fences around Main Dams

f) Trash boom around hydropower intakes

The example of several activities conducted in order to maintained public safety around dam can be seen in pictures below

Fig. 2
Installation of warning signs

Fig. 3
CCTV Installation

Fig. 4
Vehicles Restricted Area

Fig. 5
Security Fences around Main Dams

Fig. 6
Trash boom around hydropower intakes

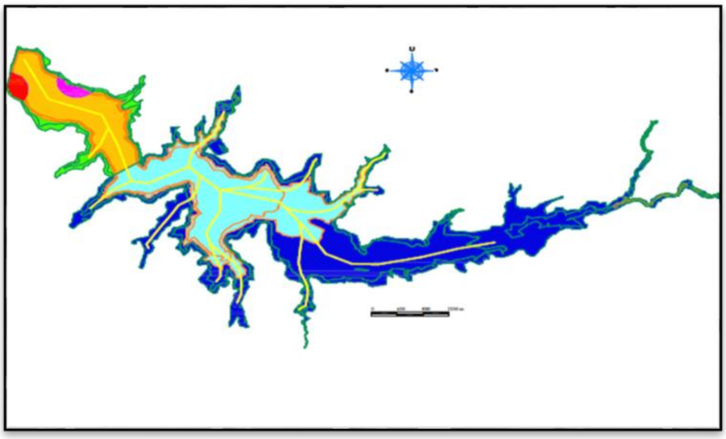

Fig. 7
Reservoir Zoning

4. CONCLUSION

- There are several activities that can be conducted to maintained public safety around dam.
- Dam operator has a responsibility to safeguard the public and to control hazards that present significant risk of serious harm to the public.
- Human factor is and remain as an important issue in public safety around dams with the main aim of it was protecting people (visitors and workers) from accidents, drowning, suicide attempts, etc.

ACKNOWLEDGEMENTS

The study was conducted by Jasa Tirta I Public Corporation, an Indonesian state owned company for river basin organization.

RISK BASED APPROACH AT THE DAM SAFETY ASSESSMENT DURING ITS RECONSTRUCTION

Jaromír ŘÍHA, Miroslav ŠPANO

Water Structures Institute, BRNO UNIVERSITY OF TECHNOLOGY

CZECH REPUBLIC

1. INTRODUCTION

The management of floods is of fundamental importance for dam safety. Overviews mentioned in Bulletins [8] and [9] indicate that flood events have been the main reasons for dam failures. According to the recommendations of the International Committee on Large Dams (ICOLD) the dam safety criteria have been significantly stiffened, namely in terms of the design and check flood probabilities related to spillway capacity. In the Czech Republic the criteria were implemented into the decree No. 367/2005 Coll. [6] which was incorporated into the standard CSN 75 2935 [3]. At recent time a wide and systematic reassessment of dams´ hydraulic safety have been performed over the whole country. Common result of the assessment is that the dam does not comply with new requirements and should be upgraded as soon as possible.

The experience based on numerous case studies and re-assessments of dam safety in the Czech Republic shows that the crucial problems lie in insufficient spillway capacity, low elevation of clayey core due to imperfections during the construction and also dam settlement and also in lower dam crest than required in terms of prescribed freeboard. One of the reasons of inadequate dam parameters are also less strict requirements on hydraulic safety of dams in the times of their construction.

The reconstruction of the above mentioned dam components practically always calls for provisional disassemble of the dam crest and also significant intervention into the spillway entrance profile and chute line. The crucial question arises about the degree of dam and construction site safety during remedial works. Relevant dam safety can be usually achieved only through the significant reservoir level drawdown providing sufficient volume to trap potential flood arriving to the reservoir during construction period. The drawdown temporarily harms reservoir purposes like water supply, recreation, hydropower production etc.

This study contains careful examination of aspects and requirements related to the dam safety during its reconstruction. The discussion on the proportion between individual purposes and benefits of the dam is also carried out. The experience with safety analysis during dam reconstruction is mentioned together with the method used. Practical examples demonstrate individual potential conflicts entering into analysis.

2. THE DEGREE OF DAM SAFETY DURING ITS RECONSTRUCTION

The safety issues during the reconstruction of the dam concern two aspects:

- the protection of the construction site during the flood;
- dam safety against its total collapse usually due to water erosion.

2.1. THE PROTECTION OF THE CONSTRUCTION SITE

The construction site protection concerns individual workplaces like spillway, chute, stilling basin, upstream slope lining, dam crest etc. In a view of safety rate these parts should be assessed individually. Some of them like repair of the dam crest or spillway directly relate to overall dam safety (Section 2.2). For other structures not influencing overall safety of the dam some guidance is given by [3]. As a rule cost-benefit analysis has to be performed in case of the threat of significant losses, terms of construction site insurance against floods should be taken into account too. Guidelines in [3] applied in the Czech Republic recommend the following return period *N* of the flood for preliminary construction site protection:

$$N = T + 1, \qquad [1]$$

where *T* is duration of the construction in years.

2.2. THE SAFETY AGAINST THE DAM FAILURE

The safety of the dam against its collapse during the remedial works should be assessed considering:

- current dam safety;
- potential material losses due to dam break flood;
- potential loss of life.

Usually, it is not advisable to provide higher dam safety during construction than current dam safety.

The material losses contain losses at the dam itself, benefit losses (water supply, power generation, recreation, fish and wildlife), direct losses to the third parties and indirect economic consequences like water shortage, labor reduction, loss of tourism, etc. [5]. The dam break flood extent modelling and hazard mapping is performed by contemporary hydraulic models combined with GIS tools (fig. 1). The census data serve for the assessment of direct losses.

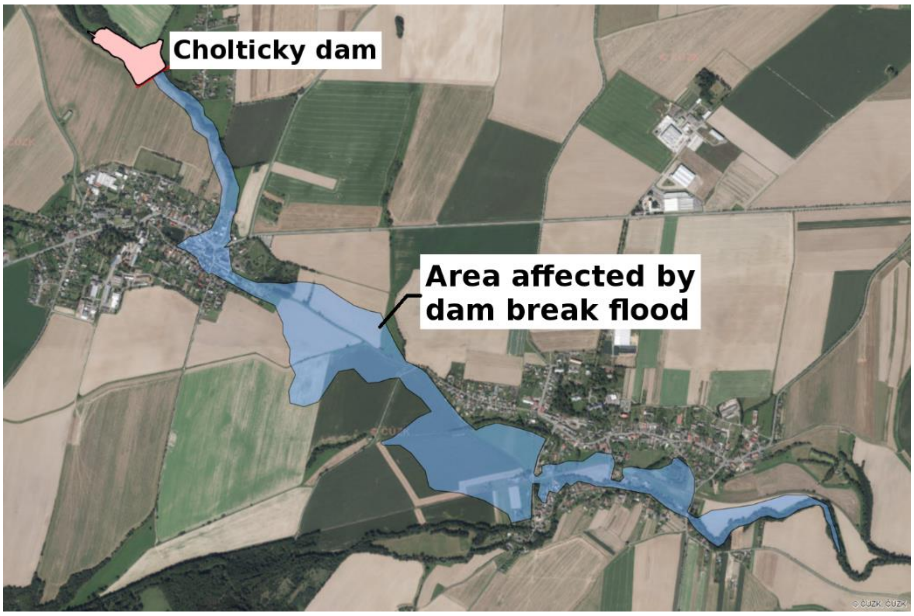

Fig. 1
Area affected by dam break flood cause by breaching of the Cholticky dam [11]

As the principal task is to specify necessary reservoir water level drawdown, losses caused to environment, fish population, recreation and others due to drawdown should be taken into account for selected variants of water levels. The cost benefit analysis should be applied as an appropriate tool for the balancing of material consequences.

The annual probability p_K of the flood for the dam protection during its reconstruction can be determined using the material losses due to dam failure L_K and financial losses L_L due to reservoir level drawdown during the remedial works:

$$p_K \leq \frac{p_L \cdot L_L}{L_K} \qquad [2]$$

Probability p_L depends on the duration of necessary drawdown, e.g. in case of one year drawdown p_L = 1.

For the potential loss of life estimate numerous guidelines [1; 2; 7] have been published. The experience from the real dam incidents and failures [10] shows extremely strong dependence on warning time, when about 50% of the population at risk can be evacuated in the first hour, 75% within two hours, and that complete evacuation requires more than 10 hours. Expected warning time depends on the level of warning and rescue systems and may significantly differ from country to country. Definitely the loss of life depends on the density of population in the area in danger. However, certain fatalities cannot be avoided due to randomness in the population migration, behaviour and also day time of dam incident (tab. 1).

Table 1
Numbers of fatalities during the real dam failures [10]

28	Texas Hill Country, 1978	2 070	0.75	25
29	Vega De Tera Dam, Spain, 1959	500	0	150

The dam safety requirements concerning potential fatalities may be assessed using so called F-N curves [4]. The estimated number of fatalities is related to the probability of dam failure which many times directly corresponds with the probability of the arrival of given flood wave during the reconstruction period. Figure 2 shows an example of relevant failure probabilities corresponding to 10 expected fatalities. During the reconstruction special non-structural measures are usually temporarily undertaken like more careful rainfall observations in the catchment, flood forecasting directly linked to actuated flood committee which is ready to initiate prompt evacuation and rescue provisions. This develops sufficient warning time and efficient activities in case of emergency situation. Therefore, the probability may be assumed within the "tolerable" risk zone in the diagram in fig. 2. It can be seen that failure probability fits the range 10^{-3} to 10^{-5} which corresponds to 1000 to 100 000 years return period.

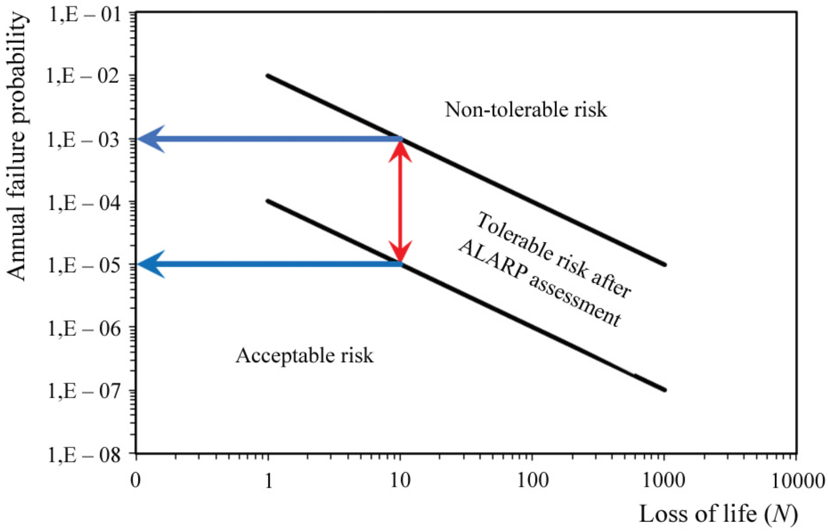

Fig. 2
F-N curves showing situation in case of 10 expected fatalities [4]

For given dam the maximum tolerable failure probability should be specified taking into account previous two aspects – material losses and loss of lives.

The above mentioned procedure gives the guidance for the determination of appropriate probability of the flood for the dam safety assessment during the reconstruction (hereinafter called as "check flood"). The specified probability has to be adapted to the period of the hazard situation, e.g. decreasing of the dam crest level, dismantling the spillway entrance, etc. It reads:

$$P_{adjusted} = 1 - \left(1 - \frac{1}{N}\right)^{T} \quad [3]$$

where: T is the length of hazardous phase during reconstruction; N is the return period of the flood wave related to one-year occurrence.

It is evident that in case of T < 1 year the required return period may be shorter. In tab. 2 the required return periods N are related to the hazardous period T for originally determined return period N_{1year} = 1 000 years.

Table 2
Approximate required return periods N corresponding to hazardous phase duration T

T (months)	N (years)
12	1000
6	500
2.4	200
1.2	100

3. SAFETY ASSESSMENT DURING THE FLOOD

At the dam safety assessment during floods the maximum water level (MWL) reached while the check flood wave passes the reservoir is compared with the so-called “threshold water level” (TWL) at which the dam is still considered as safe enough (fig. 3).

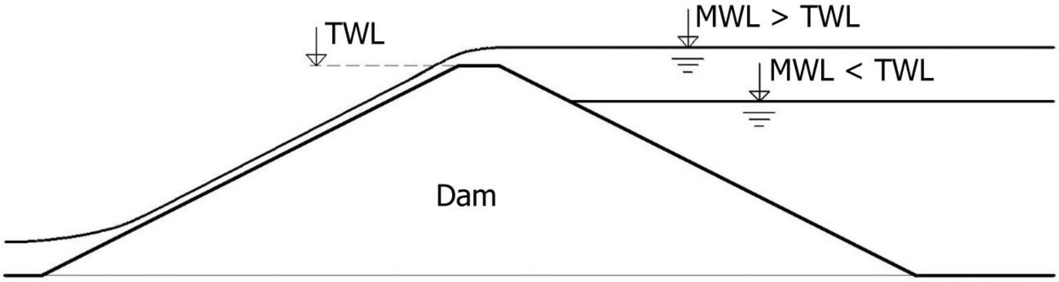

Fig. 3
Scheme depicting the water levels considered in dam safety assessment

During the assessment the reservoir water level drawdown during remedial works is searched to satisfy the condition MWL ≤ TWL for given check flood (chapter 2) taking into account the chart flow of the reconstruction works (tab. 2).

4. MAXIMUM WATER LEVEL

The MWL is determined via flood routing procedure for the check flood specified in chapter 2. It is obvious that the construction methods and their duration strongly affect dam safety and its failure probability during refurbishment. The flow chart of the construction steps should be therefore elaborated in variants in advance to enable specification and negotiation of necessary structural and non-structural arrangements and measures in early stage of the preparation of works.

The procedure usually uses trial-and-error method for searching initial reservoir water level (representing the drawdown) during the construction and recommendations on the arrangements on manipulation with water and technical arrangements on appurtenant works.

The flood routing through the reservoir should take into account all appurtenant works available during the reconstruction period. The relevant considerations should contain expected reliability and functionality of bottom outlets and available intakes including possible adaptable measures (e.g. forced opening) in hazardous situation. An example is the opening of the side wall of the emergency spillway at the Mostiště dam (fig. 4) which would attenuate arriving flood more efficiently. Operative measures can be also adapted when the reconstructed dam belongs to the dam cascade to make the flood routing through the system more efficient.

Fig. 4
Opened side spillway during the dam reconstruction

5. THRESHOLD WATER LEVEL

The TWL is determined for each construction phase according the actual state of the dam and its appurtenant works. The vulnerability of the dam has to be assessed during the construction. Mostly the effect of surface erosion is considered. This is generally represented by the overtopping of the dam body and erosion of subsoil at foundation of the spillway or chute.

The critical phases may be as follows:

- the removal of the breakwater or parapet wall from the dam crest;
- decreasing the dam crest due to increase of clayey core;
- necessary stabilisation of upstream slope/face;
- opening of the spillway chute;
- reconstruction of the chute and stilling basin adjacent to the dam body, etc.

During the construction period, temporarily arrangements improving (heightening) the TWL may be installed.

Theses consist of the following elements:

- cofferdams, fusegates or protecting walls are increasing TWL and protecting the construction site against raising of water level in reservoir (fig. 5);
- wavebreaking arrangements like riprap fill;
- sandbags located along the dam crest to protect it against overtopping (fig. 6).

Some of the above mentioned arrangements are installed for the whole construction period (like cofferdams) some are used as an emergency measure during the flood (like sandbags or fills).

Fig. 5
Concrete cofferdam at the reconstructed dam Šance

Fig. 6
Sandbags located at the crest of the dam Znojmo to reduce risk of overtopping

6. CONCLUSIONS

To assure high dam safety during its reconstruction is essential. In the paper the general guidance is presented to specify the probability of the check flood for dam safety assessment during the remedial works. However, construction activities may, during certain period, call for temporarily both structural and non-structural arrangements which keep dam safety at the prescribed level. These measures concern the attenuation of arriving flood and thus lowering maximum water level during the specified check flood. Here an examples are reservoir water drawdown and/or lowering spillway crest during critical construction phases. Another possibility is to increase threshold water level by cofferdams or also operatively by sandbags. Final safety assessment must prove that the threshold water level is higher than the maximum water level at any construction phase.

7. ACKNOWLEDGEMENTS

This research was supported by the TACR TH03030182 project “Protection of hydraulic structures against action caused by oscillatory wind waves” and FAST-S-17-4066 “The assessment of the filtration instability origin in the soils by the limit state method”.

SUMMARY

Due to the stricter requirements on the hydraulic safety of the dams in the Czech Republic lot of hydrological and dam safety studies and also extensive remedial works at numerous dams are in progress. The reconstructions concern namely improvement of spillway capacity, adjusting of the dam crest and also clayey core elevation to withstand the check flood according present regulations. As the construction activities often call for provisional reduction of the dam crest elevation and opening of the spillway profile, the dam safety during the civil works has to be carefully analyzed. Usually, considerable drawdown of reservoir water level during the construction period is essential. This however may significantly interfere with main purposes of the dam and may also harm subsidiary effects of the scheme. In the paper the risk based approach is demonstrated at the safety analysis of the dams in the Czech Republic. The results of the analysis may also give some guidance for the optimal sequence of works at the site.

1. INTRODUCTION

The Nile River represents the main source of fresh water in Egypt providing more than 90% Egypt's water resources. To control, regulate and manage Nile water, Egypt has about 1270 different hydraulic control structures on the Nile and the waterways within a network of 33,000 km, to manage water and match between Supply and Demand. These hydraulic structures vary from large dams to small regulators. Their main functions are to provide water for agriculture, domestic potable water, agriculture, industry, navigation and hydropower generation.

Downstream of Aswan high dam and Aswan old dam, seven main large diversion dams/Grand Regulators (known in Egypt as Barrages) are built on the Nile River and its two branches. These Barrages are considered as the most important and sensitive hydraulic structures in Egypt. Their height varies between

* PLAN DIRECTEUR POUR LA SECURITE DES STRUCTURES HYDRAULIQUES MAJEURES EN EGYPTE

10 to 20 m. They all pass discharges greater than 2000 m^3/s; they are all classified, according to ICOLD, as large dams.

The second Group of Regulators (Diversion dams) is the Head (Intake) of Major Canal from Nile (known in Egypt as RAYAH). The third group of regulators is the Intermediate ones that built on the main and branch canals in the points of canal width or bed slope changes. The fourth group is for all other regulators.

Excluding Aswan dams, the grand hydraulic control structures on the Nile and delta in Egypt are under the jurisdiction of the Reservoirs and Grand Barrages Sector (RGBS) in the Ministry of Water Resources and Irrigation. The structures under the jurisdiction of RGBS are 153 structures. RGBS is responsible for their construction, maintenance, and rehabilitation or replacement whatever necessary to maintain efficiently functioning.

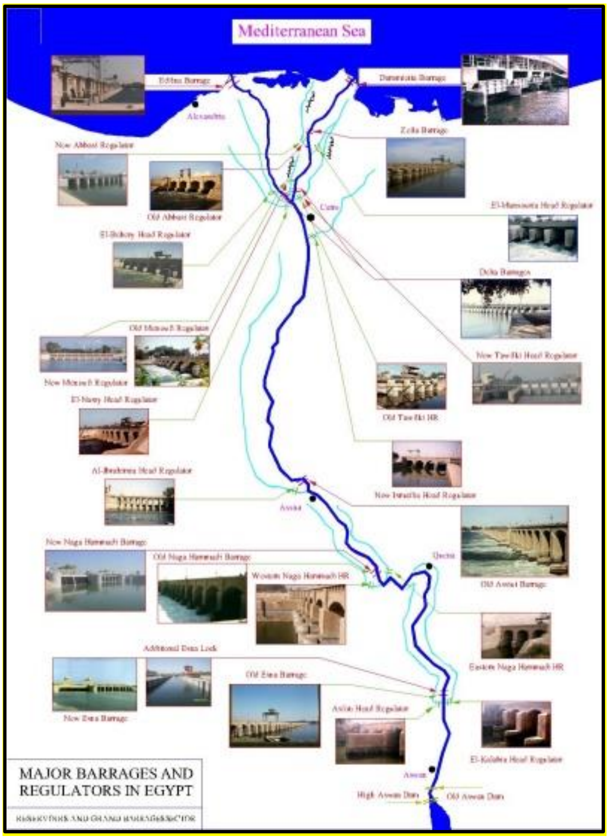

Fig. 1
Major hydraulic control structures in Egypt
Les principales structures de contrôle hydraulique en Egypte

Hydraulic control structures in Egypt are mostly masonry structures, with few cases of earth fill dam portions. As a concrete or a masonry structure with movable gates, its defects occur due to deterioration and loss of material strength after many years of different operational circumstances, weathering effects, and rusting. The lifetime of such structures, depend on many variables in design, construction, operation and maintenance procedures.

Some experts estimate the lifetime of these structures in the range of 100 – 200 years. Anyway, these structures must be rehabilitated or replaced after a defined period of time. The oldest functioning regulators in Egypt are Dairout Group of Regulators that were built in 1872.

Table 1
Number of main hydraulic structures according to year of construction and location on the waterway

Sub-total	14	9	37	58	35	153

2. PROBLEM DEFINITION

Having in mind the water scarcity challenges that Egypt face and the vital need to adopt all required measures that improve water allocation and use efficiencies, RGBS initiated a replacement programme to many of these structures several years ago. This programme is in parallel with a continuous maintenance and rehabilitation programme. The rehabilitation programme was generally adopted yearly by reporting urgent defects in certain structures and allocating the required budget for the necessary remedy actions. Longer planning was not possible for more than a 5 year ahead plan.

The (RGBS) authority was in need to have longer ahead plans up to the year 2050. In order to decide action for a certain structure, remedy action or rehabilitation, the optimisation between urgency of remedy action and the importance of the structure was always a debate that could only be settled by own experience of the decision maker.

Capacities and state-of-the-art tools to support informed decisions were not available. Moreover, unavailability of such tools could lead to wrong decisions that cause misuse of the authority's resources, and even could not achieve the target of the proper management of Nile Water to ensure the reduction of water losses and improve efficiency in water allocation and distribution.

3. CONCEPT FOR SOLUTION

Proper planning should be based on a decision support system that facilitates handling many data about the structures with the planning constraints in order to optimise the best use of the resources with time, achieving the goals in all plans.

A Master Plan (MP) study based on a decision support model for the improvement of structures' functionality and efficiency in water allocation and distribution was adopted. The MP would contribute to the overall River Nile water resource management. The MP study aimed to produce a detailed description of the necessary measures and remedial actions to be undertaken for the selected approximately 150 major existing structures, estimate costs and time schedules for interventions on these structures up to the year 2050, taking into account current and any anticipated future socio-economic and environmental changes.

The study aimed at achieving acceptable efficiency of the Egypt's major control structures with the optimal solution of multi constrained problem. The MP was directed to include all significant criteria that affect the decision of actions in the plan and their proper timing. A multi criteria decision analysis (MCDA) was adopted to obtain the possible plans related to different planning scenarios.

4. METHODOLOGY

First, get a baseline condition. This means to assess current safety, stability and efficiency conditions for all structures.

Second, define all remedy actions required for all structures in order to regain favourable levels of safety and efficiency.

Third, estimate cost for all required actions.

Forth, define criteria that affect prioritising actions in one structure before other actions in another structure.

Fifth, define criteria for different scenario plans.

Sixth, integrate all data and criteria in a multi criteria decision analysis model and obtain the target plan.

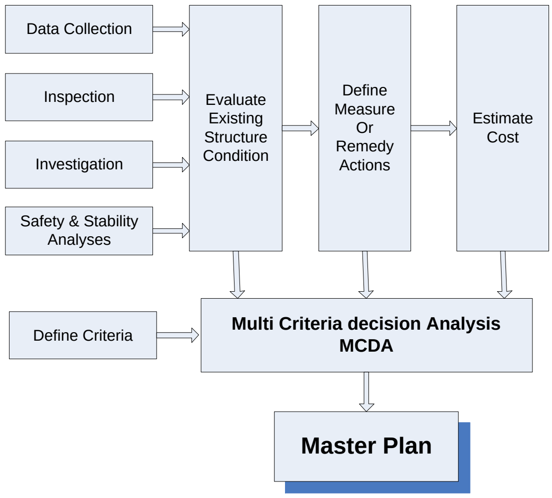

Fig. 2
Flowchart of methodology for preparation of the MP
Organigramme de la méthodologie pour la préparation du PD

5. WORK DONE

5.1. EVALUATE CURRENT STATUS OF EXISTING STRUCTURES

5.1.1. Database

The starting point for evaluation of structures is the collection of basic information about them, then compile in a database. The database was composed of two parts. One part forms the constant or the static data that are almost in need for no regular update, while the other part includes the dynamic data that are in need for periodic update.

The static data portion included:

- Hydraulic structure data (drawings, reports)
- Structure geotechnical investigation (sections, reports, photos)
- Historical events and main rehabilitations (reports, photos)
- Social and environmental data (reports)

The dynamic data portion included:

- Site visual inspection (reports, photos)

- Topographic and bathymetric survey (sections, reports, photos)
- Under water structure inspection (videos, photos, reports)
- Dewatering inspection (videos, photos, reports)
- Structural stability and safety Analysis (reports)

5.1.2. Inspection of current conditions

Inspection of existing structures took place to provide any missing or doubtful data collected and integrated in the Database. Apart from data collection, the main purpose of this activity was to inspect the current situation of the existing structures indicating level of deterioration or inefficiency. The inspection covered the structural and the mechanical elements of the structure.

The inspection programme included different types of inspection as follows:

1. Site visual inspection, collection of missing data for 153 structures.
2. Topographic and bathymetric survey for 150 structures summing a total survey area of 4.264.000 m^2.
3. Underwater inspections for 192 vents in 48 structures.
4. Dewatering inspections for 19 vents in 15 structures.

5.1.3. Structural and Geotechnical investigations

This is to estimate the current material strength after the age passed since construction in order to perform different technical analyses to check safety and stability of the structures. The decided tool to get this data was to take core samples from the piers and foundations of the existing structure.

Structural and Geotechnical in-site investigations and lab tests for 94 structures have been executed by cores and boreholes summing 4877 m-long.

5.1.4. Analyses for Safety and Stability

Calculations of factors of safety (FOS), for different stability checks, were done to assess the current safety level of the structures. The calculations were based on the material recent properties assessed by the structural and geotechnical investigations.

After fulfillment of parameters requests from the site exploration programme, and the operation data of each regulator, numerical 3D modeling for each structure was carried out to explore the regions of stress concentrations. Implementing the concepts of soil structural interaction (Winckler Assumptions); and the variation of loading within the annual cycle and/or the lock operation was inducted into the model for analysis.

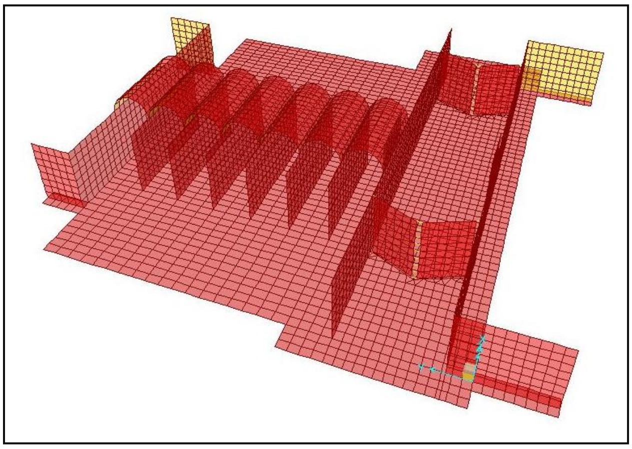

Fig. 3

Example of a 3d model for a control structure (a regulator with a navigation lock)
Exemple de modèle 3D pour une structure de contrôle (un régulateur avec un verrou de navigation)

5.2. DEFINE CRITERIA FOR DECISION MAKING

The criteria for the decision making are those objectives and constraints that should be considered while looking for the best solution for the problem. There were two types of criteria in this study. The first criteria type included those affecting prioritising of the structure to have the remedy action over other structures. Alternatively, these criteria were named priority factors. They were estimated by the means of an expert system that converted the collected data quantitatively or qualitatively into an arithmetic score. 20 factors were defined expressing the importance of the hydraulic structure (8 factors) and the performance condition of it (12 factors).

Each of these factors has been given a standard scale for scoring. As an example, the first factor is called "Hydraulic structure entity"; and it is related to the classification of the structure accordingly to its location on the waterway and its controlling role. The scale for scoring is as shown in figure 4. The 20 criteria are shown in Figure 5.

Scoring system				
1	2	3	4	5
Intermediate and Spillway (small)	Intermediate Regulator	Head Regulator (small)	Head Regulator (large)	Main Barrage (Nile River)

Fig. 4

Scale for scoring system of the criterion "hydraulic structure entity"

Fig. 5

Criteria used for prioritising actions in the MCDA model

Critères utilisés pour hiérarchiser les actions dans le modèle MCDA

The second criteria type included those affecting prioritising the actions according to their financial conditions. Different criteria were used to produce different plans till year 2050. Any plan to year 2050 was divided into five year plans. The criteria were:

- Absolute cost of actions
- Different/ equal 5-year-plan budgets
- Benefit/cost-ratio of actions
- Action type
- Structure grouping

5.3. DEFINE THE REHABILITATION ACTIONS NEEDED

After evaluation of current condition of each structure, the required remedy actions were defined. The action in this study varies from maintenance corrective action to rehabilitation or replacement of the structure. Cost of each action was estimated. Expected benefit from that action was assumed as the due enhancement in the scoring system related to the deterioration dealt with by the action.

5.4. MULTI CRITERIA DECISION ANALYSIS (MCDA)

MCDA establishes preferences between options by reference to an explicit set of objectives that the decision-making body has identified, and for which it has established measurable criteria to assess the extent to which the objectives have been achieved.

The scoring and weighting technique was used for the MCDA in this study. Both scoring and weighting rules were set by a series of discussions and meetings by specialised experts in the hydraulic structure work field. Combining the scores and weights of each criterion, shown in figure 6, gave an overall value that reflected the priority of actions.

$$StructureScoring = \sum_{i=1}^{n} (\,Priorityfactorscore)_n x (Priorityfactor\ weight)_n$$

Where n is the total number of factors $= 20$.

Combining these priority results with the financial criteria led to 6 different scenario plans. The model can handle any number of criteria and lead to many scenarios. But finally, when one set of criteria is selected, only one scenario plan is valid, and that is the best decision.

Table 2

Combination of criteria and corresponding scenario plans

Combinaison de critères et de plans de scénario correspondants

	Plan 1	Plan 2	Plan 3	Plan 4	Plan 5	Plan 6
Absolute cost of actions	●	●	●			
different 5-year-plan budgets	●			●	●	●
Top benefit/cost-ratio actions		●		●		●
Group similar actions in different structures			●		●	●

6. CONCLUSION AND RECOMMENDATIONS

The major hydraulic control structures in Egypt represent the means to manage allocation and distribution of the Nile water with the maximum possible manner. Water scarcity that Egypt is facing adds a pressure on the responsible authority to maintain these structures functioning properly and efficiently to be in-line with other parallel activities the ministry is adopting for better water allocation and use.

The authority prepared a master plan of timely actions for rehabilitation/ replacement of these structures till the year 2050. The master plan is based on a multi criteria decision analysis model that represents an effective tool that allow dynamic planning upon changes of actual efficient conditions of the structures.

It is recommended to follow same methodology in preparation of master plans for other vital infrastructures to provide decision support for decision makers in a way that takes all criteria affecting decision into consideration and have clear rules for decisions.

INDONESIA

1. INTRODUCTION

Lahor dam is located in Malang Regency, East Java Province of Indonesia. It is one of the dams in Brantas watershed on the tributary of the Lahor River. Lahor dam was constructed in 1972 for adding capacity of Sutami hydropower. Not only provides great benefits, dam also creates a potential risk to neighboring populations, property, and the natural environment. Therefore, assessment and monitoring of the dam have to be carried out comprehensively and periodically. Formal investigation of Lahor dam aim to evaluate the dam condition during design and construction compare to recent. It is also including visual inspection, instrumentation and slope stability analysis, hydrology and geology condition, and sedimentation analysis. Based on those parameters, the condition of the Lahor dam was ready to be operated.

2. METHOD

Formal investigation of Lahor dam consist of two stages: preliminary stage and advance stage. The former aims to collect all of the information about dam design, construction document, and dam record book (operating and maintenance). While there is an anomaly on the preliminary study, advance study must be carried out that are including re-evaluation of design document, construction method and material type, analysis of operation and maintenance document, and engineering analysis.

3. RESULT AND DISCUSSION

3.1. VISUAL INSPECTION

Visual inspection activities include dam body and complementary building, water quality analysis in laboratory, monitoring of dam instrumentation, hydro mechanical equipment, and concrete structure condition on spillway and access tunnel. The water quality was monitored on BOD (biochemical oxygen demand), COD (chemical oxygen demand) and DO (dissolved oxygen) parameters from 2013 to 2017. Those BOD, COD, and DO parameters met the standard.

3.2. HYDROLOGY

Spillway design of Lahor dam based on design flood with 1000 years time period and resulted inflow debit 790 m^3/second with spillway capacity 399 m^3/second. Flood routing with initial elevation of water table +272,70 m obtained maximum flood elevation +274,11 m for 1000 years time period (Q_{1000}) and +277,09 m for Q_{PMF}. The elevation of parapet is +279,00 m.

3.3. INSTRUMENTATION

Some instruments (pore pressure meter, V-Notch, and observation well) was installed in Lahor dam. The pore water pressure at each location is always up and down as the reservoir water level changes. Based on the monitoring results of the seepage discharge shows normal conditions, no significant fluctuations occur, the magnitude is still below the maximum threshold. The amount of seepage discharge depends on reservoir water level and rainfall. The maximum of seepage discharge on toe dam is 1,105.20 liter/minute, the maximum seepage discharge that occured in toe dam is 896,99 liter / min (April 25, 2017) at water level +273,21 m with seepage water condition looks clear. The amount of spring water discharge at the right bank and left bank (including on the rail way) was fluctuated, because it was influenced by rainfall that occurs. The ground water level conditions also fluctuate along with the water level of the reservoir

3.4. SEDIMENTATION

Based on echo sounding measurement that was carried out in 2016, the dead storage capacity of Lahor reservoir is 3.38 million m^3 or 50.45% of the initial dead storage capacity (6.70 million m^3). The effective capacity is 28.73 million m^3 or 97.72% of the initial effective storage capacity (29.40 million m^3) and the total storage capacity is 32.11 million m^3 or 88.95% of the initial total storage capacity (36.10 million m^3). Sedimentation rates in the Lahor Reservoir from 1977 to 2017 is ± 99,750 m^3/year or 0.623 mm/year.

3.5. GEOLOGY

Geological structure (unconformity and fault) around the dam caused several problems during construction. There are agglomeratic tuff as the rock basement, grey clay layer at the middle, and tuffaceous loam as overburden. Those condition lead to land slide around the reservoir. Therefore, in the foundation was carried out rim grouting along the dam axis (433 m). This method could solve the probem effectively.

4. CONCLUSION

Based on formal investigation result in Lahor dam can be concluded that its condition was normal and ready to be operated. There is no anomaly on each inspection parameter.

EGYPT

1. INTRODUCTION

The Nile Delta in Egypt is one the most venerable areas in the world to sea level rise which could cause devastating damages to water resources, agriculture land, people and properties if occurred. Therefore, adaptation measures must be carried out on the ground to protect inhabitants, properties and infrastructure in the Nile Delta. These measures need to be low cost and environmental friendly in order to protect the Delta and preserve the environment in a cost effective way. Therefore, the Government of Egypt (GoE), among its efforts to adapt to Climate Change in different sectors, the Global Environmental Facility (GEF) and the UNDP have jointly funded the Adaptation to Climate Change in the Nile Delta through ICZM project (ACCNDP). The ACCNDP[3] has piloted and assessed the performance of Flexible (soft) techniques to protect the Nile Delta from the anticipated inundation impacts of sea level rise and consequently improve the livelihood of the local population. This paper provides a detailed description of those adaptation options aiming at sharing such experience so they can be up-scaled at local, regional and international scales in similar environments and also present the assessment results of suck work.

2. ADAPTATION OPTIONS

Based on the work undertaken by Egyptian researchers at the Coastal Research Institute (CoRI), practitioners at the Shore Protection Authority (SPA) and indigenous people in the Nile Delta, the ACCNDP constructed a number of flexible (soft) dike options. Those options are mainly built from local material to protect the Nile Delta such as sand fences to capture sand blown by wind to accumulate and build sand dunes and dikes with clay and geo-tube cores. These options were constructed at a low laying pilot location between Rasheed (or Rosetta) and El-Burulus. This location was selected based on a survey that was undertaken for the whole area (a length of 60km and a depth of 0.5km) [2].

The construction started in November 2015 and completed in April 2016. The layout of three options is shown in Fig. 1. In the following sections, a description of each option is given.

Fig. 1
Site layout

2.1. SAND FENCES DIKE

This option was selected based on the consultation that was undertaken by the project with the local people in the Nile Delta. They use wooden fences to capture the sand that is blown by the wind to build natural sand dunes around their land and properties to protect them from inundation from the sea (See Fig. 2Fig. 5). This option was designed by researchers at CoRI and practitioners at SPA according to the Egyptian standards with a length of 250 m and as shown in Fig. 3.

Fig. 2
Local people fences

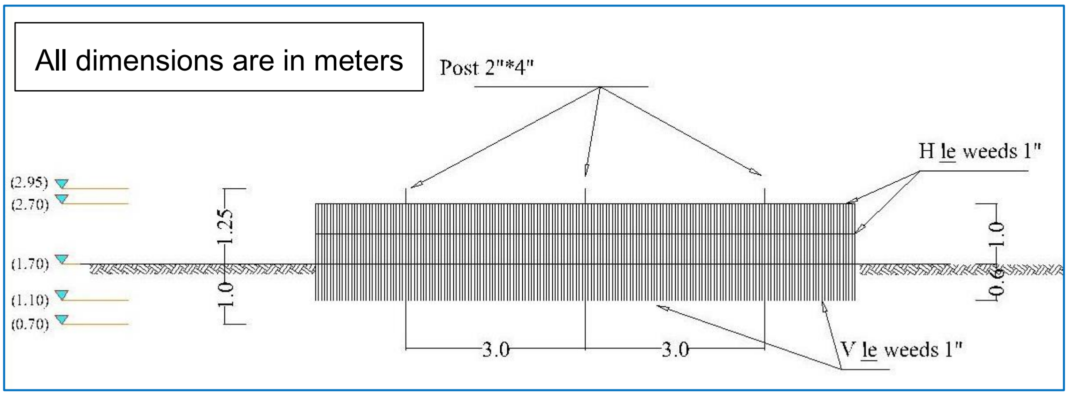

Fig. 3
Send fences dike design

The sand capturing was monitored since the end of the construction [1] and it was found that the average height of sand accumulation at the fence was increased by approximately over one meter in 8 months, which is considered a good rate of accumulation.

2.2. CLAY CORE DIKE

This option was designed by researchers at CoRI. In this design, the dredged material from El-Burulus Lake was used as a core for the dike. The core is covered with sand up to a level of 3.00 m. Vegetation within sand fence boxes was used to protect the dike faces and crest as shown in Fig. 4. The length of the dike is also 250m. Five monitoring wells were installed within the dike body to monitor the water levels (i.e. seepage) within the dike.

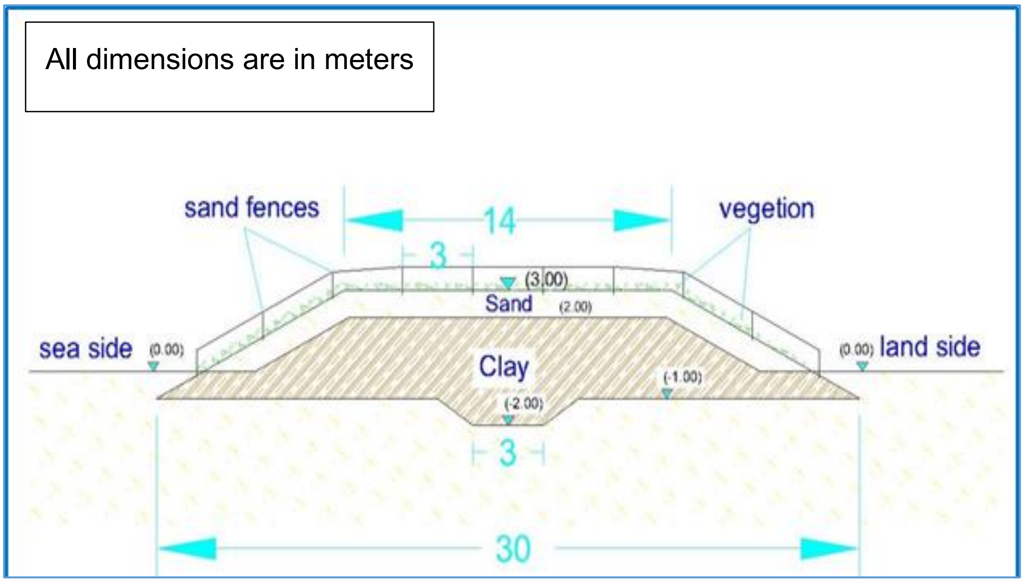

Fig. 4
Clay core dike design

Based on a survey undertaken by the Desert Research Center [DRC] on the natural vegetation in the pilot site location, eight plant species were chosen to protect the sand that cover the dike. These species are:

- Sarcocornia fruticosa (L.) A.J. Scot.
- Juncus rigidus Desf.
- Imperata cylindrica (L.) roeusch
- Elymus farctus (viv) Runem
- Panicratium maritimum L.
- Ipomoea stolonifera (cyr.) J.F. Gmel.
- Calligonum comosum (L, Her.) Soskov.
- Tamarix nilotica (Ehrenb.) Bunge.

2.3. GEO-TUBE DIKE

This option was designed by practitioners at SPA. In this design, a Geo-tube core was covered with a clay layer from the dredging of El-Burulus Lake up to a level of 3.00 m. Dolomite stones were used to protect the dike faces and crest as shown in Fig. 5. The length of the dike is also 250m. A monitoring basin was constructed behind the dike body to monitor the overtopping and seepage.

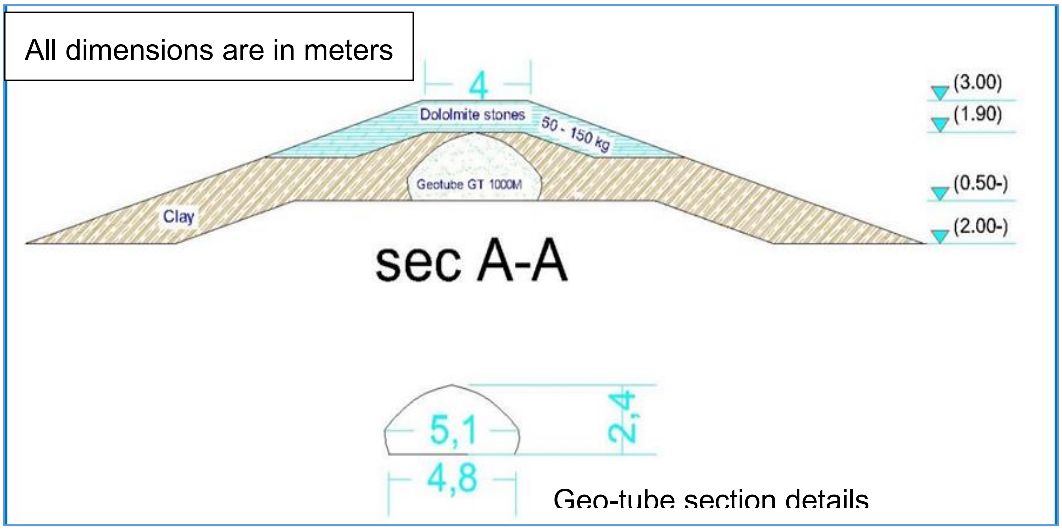

Fig. 5
Geo-tube core dike design

Fig. 6 a, b and c shows a photo of each dike option after the completion of construction in April 2016.

a) Sand fences dike

b) Clay core dike

c) Geo-tube core dike

Fig. 6
Dike options after construction

3. ASSESSMENT RESULTS

The performance of the above options was assessed during the winters of 2016, 2017 and early 2018. A number of extreme events occurred during those winters but no damages were observed on the dikes and they remained intact.

The sand fences dike continued to build up and during the events, water did not penetrate through the dike body as no erosion was noted on the whole length of the dike. Water either formed a small pond in front of the dike or flowed within the gaps left between the three dike options.

The clay core dike fences also continued to build up since the end of the construction. Vegetation also grows but at a different rate for each specie [1]. Current results show that Pancratium maritimum and Elymus farctus are of superior quality at the different locations on the dike (wind and leeward and crest) followed by both Sarcocorina fruticosa and Juncus rigidus. Monitoring of the five wells revealed that there is no significant increase the water level within each well even after the extreme events which is an indication that seepage is insignificant within the dike body.

The Geo-tube core dike performance was similar to the above two dikes. No wet patches was observed on the back (dry) slope of the dike indicating that seepage is also insignificant within the dike body. The monitoring basin remained dry (apart from small wet batches due to rainfall) indicating that no significant overtopping occurred during the event.

Fig. 7 a, b and c shows a photo of each dike option after a recent extreme event in 2018. Fig 8a shows that a second row of fences was constructed to widen the natural dike (or dune) that was created by capturing the blown sand by wind. Fig. 8b and c show that sea water accumulated in front of the dikes but caused no damage to them.

b) Clay core dike

c) Geo-tube core dike

Fig. 7
Dike options after a recent storm event

4. CONCLUSION

Low cost and environmental friendly adaptation options have been constructed in Egypt. An assessment of those options against extreme events in 2016, 2017 and early 2018 shows that they provide protection against sea inundation.

Based on the success of this pilot project, The GoE has been able with assistance from the UNDP to secure a grant from the Green Climate Fund. This grant will enable Egypt to almost protect the entire low land in the Nile Delta using flexible techniques covering a length of 69 kms.

SUMMARY

The Nile Delta in Egypt is one the most venerable area in the world to sea level rise, which could cause devastating damages to water resources, agriculture land, people and properties if occurred. Therefore, adaptation measures must be carried out on the ground to protect inhabitants, properties and infrastructure in the Nile Delta. These measures need to be low cost and environmental friendly in order to protect the Delta and preserve the environment in a cost effective way. Therefore, the Government of Egypt (GoE), among its efforts to adapt to Climate Change in different sector, the Global Environmental Facility (GEF) and the UNDP have jointly funded the Adaptation to Climate Change in the Nile Delta through ICZM project (ACCNDP). The ACCNDP has a component to pilot and assess the performance of new innovative techniques to protect the Nile Delta from the anticipated inundation impacts of sea level rise and consequently improve the livelihood of the local population. Based on the work undertaken by Egyptian researchers, practitioners and indigenous people, the ACCNPD constructed a number of flexible dike options that are mainly built from local material to protect the Nile Delta such as sand fences to capture sand blown by wind to accumulate and build sand dunes and dikes with clay and geo-tube cores. In this paper, a detailed description of those options will be given aiming at sharing such experience so it can be up-scaled at local, regional and international scales in similar environments.

Le delta du Nil en Egypte est l'une des régions les plus vénérables au monde à l'élévation du niveau de la mer qui pourrait causer des dommages dévastateurs aux ressources en eau, aux terres agricoles, aux personnes et aux propriétés si elles se produisaient. Des mesures d'adaptation doivent donc être prises sur le terrain pour protéger les habitants, les biens et les infrastructures du delta du Nil. Ces mesures doivent être peu coûteuses et respectueuses de l'environnement afin de protéger le Delta et de préserver l'environnement de manière rentable. Par conséquent, le Gouvernement égyptien, parmi ses efforts d'adaptation au changement climatique dans différents secteurs, le Fonds pour l'environnement mondial (GEF) et l'UNDP ont conjointement financé l'Adaptation au changement climatique dans le delta du Nil à travers le projet GIZC. L'ACCNDP a un volet pour piloter et évaluer les performances des nouvelles techniques innovantes pour protéger le delta du Nil contre les effets d'inondation anticipés de l'élévation du niveau de la mer et améliorer ainsi les moyens de subsistance de la population locale. Basé sur le travail entrepris par les chercheurs égyptiens, les praticiens et les indigènes, l'ACCNPD a construit un certain nombre d'options de digues flexibles principalement construites à partir de matériaux locaux pour protéger le delta du Nil telles que les barrières de sable pour accumuler et construire du sable. Dunes et digues avec des noyaux d'argile et de géotube. Dans ce document, une description détaillée de ces options sera donnée afin de partager cette expérience afin qu'elle puisse être étendue aux échelles locale, régionale et internationale dans des environnements similaires.

AN INTELLIGENT COOLING CONTROL METHOD AND SYSTEM FOR XILUODU ARCH DAM CONSTRUCTION

Peng Lin, Zeyu Ning

Department of Hydraulic Engineering, TSINGHUA UNIVERSITY, BEIJING 100084

CHINA

1. INTRODUCTION

In hydraulic engineering, heat of hydration develops in fresh concrete, associated with the exothermic chemical reactions of the cement [1]. Due to the poor conductivity of concrete, high temperature gradients may occur between the interior and the surface of the structural elements or between parts of an element with sequential concreting phases [2]. The temperature gradients may lead to tensile stresses and excessive tensile strength will result in the young concrete to crack [3]. Artificial water pipe cooling is an important method used to reduce the interior temperature rise of mass concrete, which can keep the concrete temperature stay near the designed value and to make the construction procedure and property controllable. The first time that water cooling used in hydraulic engineering dated back to the 1930s, when U.S. Bureau of Reclamation tested it in Owyhee concrete arch dam and got a satisfactory result in 1931. Two years later, in the construction of Hoover dam, pre-planted cooling pipes were applied in total concrete pouring blocks and the cooling result was good. Since then, cooling pipes were widely used in concrete dam for its flexibility, reliability and versatility. The method of pre-planted cooling pipes was used in the first concrete arch dam, Xianghongdian dam, for the first time in China and the result of cracking prevention was good. After that, the method was applied in many large hydraulic engineering projects like the Three Gorges Dam, Ertan dam, Xiluodu dam etc. Much engineering practice proved that the method of water cooling has been an indispensable measure of temperature control and crack prevention in concrete dam [4, 5]. But, the pipe cooling of mass concrete are used in manual mode before Xiluodu (Dam concrete pouring started in March 2009). This pattern of construction and work is very rough, which cannot take full account of the related factors, such as air temperature, pouring temperature, spacing of water pipes, construction process, data collection and control method etc.

In fact, with the rapid development of information and automation control technology, the research and application of intelligent control technology in the civil industry are booming in recent years. There have been many successful cases of applications for some specific areas [6-8]. How to apply information technology and automation control technology to the dam concrete temperature control construction, to solve the drawbacks of the traditional manual pipe-cooling construction mode, and to further improve the quality of concrete in construction and ensure the structural safety? This becomes an urgent problem to be solved in front of water conservancy workers.

A real-time, online and personalized intelligent cooling control method and system for a mass concrete structure (ICCS) is developed in this paper. The proposed method is an important engineering measure to prevent the mass concrete structure from cracking during the construction period. The proposed controlling method and system were successfully used to guide the temperature controlling of Xiluodu arch dam construction. The proposed novel method will be beneficial to the design and construction of the similar projects for controlling thermal stress of mass concrete structure. The following is a detailed introduction to this system.

2. THE METHOD AND PRINCIPLES OF INTELLIGENT COOLING CONTROL

2.1. BASIC PRINCIPLES OF INTELLIGENT TEMPERATURE CONTROL

Temperature is an important index of crack prevention of concrete dam. To achieve the target, the intelligent control method changes the model of setting flow as the control factor into the model of setting temperature as key factor. It follows the three principles below: (1) control the highest temperature during the procedure of cooling down, as well as the highest value in 3-7 days after the pouring of concrete. (2) coordinate the temperature gradient in the whole procedure of cooling down. (3) forecast or warn for anomalous values when the temperature suddenly goes up or goes down. The principles are explained respectively as below.

2.1.1. *control the highest temperature*

Temperature of concrete is related to several factors including the concrete grade, position and duration of the concrete. Controlling the highest temperature is to prevent overlarge difference in temperature of foundation, temperature of adjacent layers or internal and external temperature of concrete, and then to prevent cracking in concrete. The targeted value of highest temperature is determined as following: (1) it should be no higher than the sum of grouting temperature and the allowed difference, for controlling stress caused by temperature difference of the foundation. (2) it should be no higher than the maximum temperature difference between internal and external values. (3) it should be determined differently in confined and unconfined sections. In practice, these different sections include bank sections and riverbed sections. (4) it should vary in different seasons. The previous practice in China generally shows that it is 27℃ for confined section and 31 to 33℃ for the unconfined. As to large engineering like Xiluodu, the standard is more restricted. The controlled temperature can be determined by local construction practice and the design standard. If the concrete is weak in crack resistance, it should be under 27℃.

2.1.2. *coordinate the temperature change*

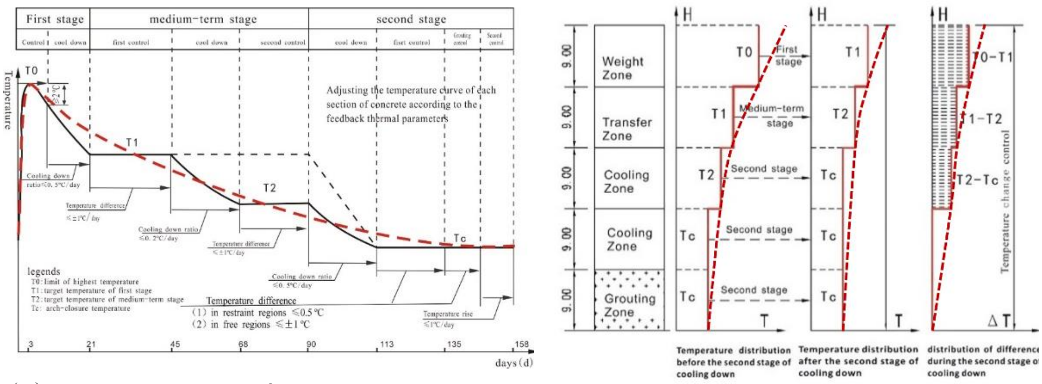
Coordinating the temperature change contains three aspects:

(1) keep the temperature curve smooth all along the period of cooling down, as in figure 1(a). In former practice, the temperature curve was manually designed in steps, which added difficulty and labor cost for actual procedure. Assuming that we can automatically adjust the limit of temperature change ratio according to the local highest temperature, then we can keep the temperature curve smooth. Practice in Xiluodu has showed that it is realizable.

(2) make different designed curve in different concrete sections. The stepped time-varying temperature in one concrete section (figure 1(a)) is called time variable curve. It's aimed at limiting the temperature difference between the upper and lower layers from the grouting section to the weighting section of one dam section (figure 1(b)), which is called space variable curve. In a dam, concrete at the bottom is strongly confined while the upper concrete is unconfined. To avoid cracking, it's important to reduce the difference between upper and lower layers. In Xiluodu project, the difference in the range of 1/4 length of old aged concrete (over 28 days) section is limited in 15 to 18℃. In a word, only both time varying and space varying curve controlled can achieve intelligent control. By measures like stage cooling and coordinating temperature change, we can make the temperature gradient in different concrete sections suitable and reduce the concrete stress.

(3) limit the difference in foundation and the difference between interior and exterior. In Xiluodu project, according to the concrete property, using three-dimensional FEM and the design standard method, the difference in confined concrete is 14℃, in base that the cracking-resistance safety factor is no less than 1.8. If the thermal insulation is well conducted, the superficial temperature is 2 ℃

to 4 ℃ higher than the air temperature. In Xiluodu project, according to the stress analysis, the difference should be under 16℃ in the most unfavorable condition.



（a） Schematic diagram of concrete cooling process control

（b） Difference temperature control zone of different dam section

Fig. 1

The time-space control method of the concrete temperature[9]

2.1.3. *warn for over transfinite temperature value*

Local environment is an important factor affecting the concrete temperature, besides the grouting temperature. Both cold wave in summer and hot wave in winter will cause transfinite temperature. Therefore, the control system has to connect to the system of weather forecasting and timely adjust the limits, considering the principle of coordinating temperature and the problem of cracking in early aged concrete. Like in Xiluodu project, the temperature drop ratio is limited no more than 0.5℃ per day in the whole period of cooling down. Particularly, in the middle term of cooling down, the ratio is limited in 0.2℃ per day. In practice, continuously and gently reducing the temperature is an important measure for reducing temperature stress. The system must automatically adjust the temperature gradient to the feedback.

2.2. ANALOG PID CONTROL THEORY

In current engineering, the temperature of concrete is affected by many factors. The process is very complex as following: (1) too many unknown factors affect the process. (2) a concrete section is a system of great inertia and delay. (3) the temperature gradient must be limited to as small as 0.2 to 0.5℃ per day and the temperature curve must be smooth and steady, neither suddenly going up nor down. (4) temperature in concrete is non-linear distributed. Since these characteristics, classic theory of control cannot meet the requirements. We should combine the modern and classic theory and work out an analogous PID system with property of fuzzy.

First, we get the data such as boundary temperature, temperature difference and change ratio and we can calculate the designed flow and pass the data to the local controller. Then, the controller adjusts the control valve according to PID method thus controlling the temperature of concrete. The system can automatically and timely collect the temperature data and then provide individual method for different concrete sections. It can choose proper thermal parameters for each concrete section thus exactly controlling the flow and temperature. The PID method used by local controller is composited as figure 2. In this system, the output constant r(t), the flow difference, practical integration and differential are combined as a controlled variable to adjust the temperature of concrete.

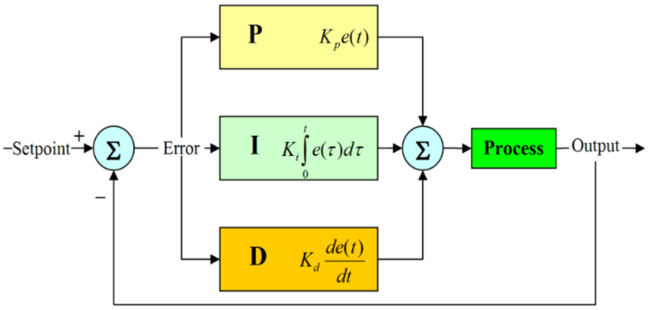


Fig. 2
Control system diagram of analog PID

3. INTELLIGENT COOLING CONTROL SYSTEM

The intelligent cooling control system mainly includes devices for heat exchange, the control device, and the device of monitoring. Here they are introduced respectively.

The device for heat exchange: it is installed inside the concrete or on the surface, for exchanging heat with cooling pipes and achieving individual controlling of temperature of concrete section.

The control device: it mainly includes an integrated control device of temperature and flow, which contains a flow meter, control valve and a thermometer. The integrated device is installed in each closed pipe loop. Under normal circumstances, the system can intelligently calculates the required flow and transmits control commands to the control device. Of course, when an abnormal situation is encountered, manual intervention can also be performed to manually control the integrated device.

The device of monitoring: it includes temperature sensors installed inside the concrete and in the import and export of the cooling pipes. Besides, the system also has a computer server and a software platform for data display data query and control operations. The data acquired by the sensor is transmitted to the computer server through wired or wireless means, and the user can view it on the mobile phone or the computer at any time through the software platform.

In addition, the system also includes an industrial control cabinet, in which many integrated circuit boards, power supply and switches, Plc modules and other electronic components are installed.

4. CASE OF XILUODU ARCH DAM

4.1. THE TEST AND THE FILED APPLICATION

In order to further explore the evolution law of three-dimensional real temperature field of large-volume concrete through water-cooling, and in the same time improve the system based on the site construction environment, the indoor experiment (at Tsinghua university) and field test (at Xiluodu arch dam) are conducted in the early construction period of Xiluodu.

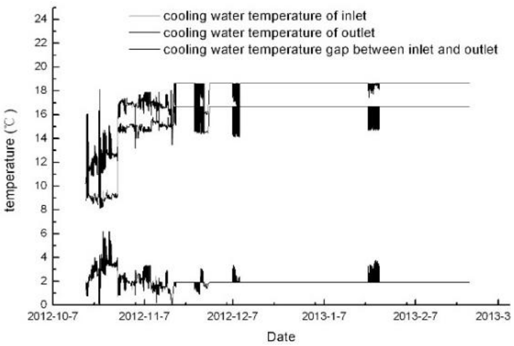
After the pre-test, the system was initially applied on a large scale at Xiluodu Site. The site installation in Xiluodu project is shown in figure 3. The system control cabinets are set at different elevations of the left and right banks. Each cabinet controls 50 to 100 units of integrated device of temperature and flow. Take the cabinet installed at EL.527m, on the permanent bridge behind the dam and the corresponding integrated devices for example. The pump station is at EL.559m elevation, involving dam sections from number 21 to 29, and its control elevation is from 510m to 630m. The entire local data is transmitted through a wireless bridge to the platform at elevation of 610m at the right bank. And the platform is connected to the server platform in the rear base through the optical fiber.

Fig. 3
The image of intelligence cooling control system in field

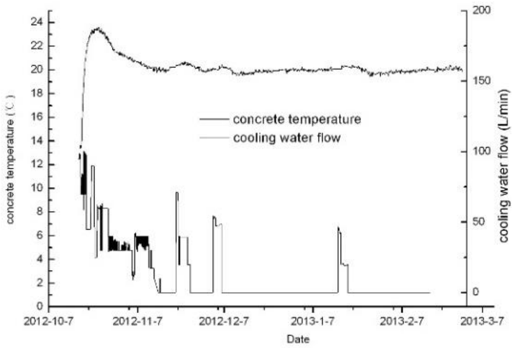
4.2. RESULTS AND BENEFITS

This intelligent system can efficiently and accurately collect the real-time data and then transmit it to a unified information platform. The interval of data collecting can be as short as 2 seconds. Using this method can reduce dependence on labor work and avoid data difference caused by personal interference and field cross-operation, thus ensuing the data collected in time and in high accuracy. Take one test section for example, as shown in figure 4.

The cooling intelligent temperature control curves have the following characteristics: (1) compared to the highest temperature value and the point in time of the manually controlled concrete sections, the results of the intelligent controlled sections are basically the same, showing that the intelligent method can effectively control the designed highest temperature; (2) intelligent controlled curves are more smooth and continuous, proving that the data is real-time and the system can coordinate the temperature change; (3) compared to the manually controlled curve, the intelligent controlled one is more fluctuated of flow. This is because the intelligent control platform adjusts the flow size according to the real-time concrete temperature and the entire flow is more saving than that of the traditional method.



（a） 23#67 cooling water temperature curve of inlet and outlet



(b) 23#67 internal cooling water temperature curve

Fig. 4

Cooling intelligent temperature control curves of 23 # 67 of dam[9]

5. CONCLUSIONS

The intelligent cooling control system for mass concrete achieves the online, real-time, intelligent acquisition and control during the operation. It can analyze and control water temperature, flow size and direction as required and provides scientific support for exact, procedural and individual management and control of quality of dam concrete. Through the preliminary application test, the method, which is based on real-time variation of concrete temperature and combined with control of water temperature at the import and export of the cooling pipe, has got a reasonable result of prediction and control of concrete temperature. It proves that the intelligent cooling control system for mass concrete is feasible.

Based on the current system, more development can be done in directions as following: build an integrated system including monitoring, analysis, control and prediction; synthetically analyze the combination of data like water temperature at the import and export of cooling pipes, temperature of concrete and flow of cooling water; calculate the real-time temperature field and temperature stress of concrete; and at last, control the temperature according to the stress-based indicators and early warning mechanism.

SUMMARY

A real-time, online and personalized intelligent cooling control system for a mass concrete structure(ICCS) is developed in this paper, the proposed method is an important engineering measure to prevent the mass concrete structure from cracking during the construction period. Its main features include: the digital temperature sensors installed in the new pouring mass concrete blocks for real-time measurement of temperature change; one flow, temperature opening measuring and feedback controlling device is installed in the inlet and outlet of cooling pipe, an average reduction of concrete temperature is obtained online through calculating the cooling temperature difference; Thus, according to the Fourier law and conservation of energy the real-time water flow is determined for cooling, then, the intelligent personalized temperature control is carried out by control platform system based on design curve of time with temperature, thereby reducing the concrete tensile stress to achieve purpose of pouring non-cracking concrete dam. The proposed controlling method and system were successfully used to guide the temperature controlling of Xiluodu arch dam construction. The proposed novel method will be beneficial to the design and construction of the similar projects for controlling thermal stress of mass concrete structure.

ABSTRACT

As the high rock-fill dam being constructed to 300m, the dam anti-seepage safety attracts much more attention. For the high rock-fill dam constructed at the place where the overburden is deep and the river valley is steep and narrow, the construction quality of foundation treatment, ant-seepage system and dam body filling becomes particularly important. The dam of Changheba Power Station is gravel soil core-wall rock-filling dam, which is construction on the deep overburden, with the dam height of 240m. The height of overburden and dam is 293m in total. The seismic intensity reaches 9 degree. For the above reasons, the control of dam deformation stability and seepage stability is very difficult and it requires high design index and construction quality standard. The deep scientific research was carried out for this project and it made plentiful achievements. This article briefly introduces the engineering characteristics and construction difficulties of

Changheba Power Station dam and describes the key technology adopted during the dam filling works, which has a reference value on the construction of similar projects.

CONCLUSION

The application of the new technologies and new techniques in Chang-he Dam project efficiently guarantees the construction quality. The dam was filled to the crest on 10th September, 2016, which is 4 months ahead of the contract construction period. After 13 times quality inspection carried out by quality monitoring station, it shows that the dam filling is totally under control and the quality is well received by experts. At present the dam seepage controlling and deformation both meet the design requirement and the dam is in good operation condition.

The systematical construction and quality controlling technology developed from the research on Chang-he Dam construction key technology and engineering practices, the engineering problems in 300m high core wall rock fill dam constructed on thick overburden have been solved and the engineering quality and anti-seepage safety have also been guaranteed. 3 industrial standards are formed, more than 50 national patents are obtained and many national and provincial-level construction methods are also formed. The relevant technologies have been applied in some large-scaled hydropower projects, such as the Lianghekou project and the Shuangjiangkou project. It brings remarkable economic and social and environmental benefits and has wide application prospect.

1. INTRODUCTION

Dams are critical components of civil infrastructure of any country. They provide a range of economic, environmental and social benefits like hydroelectric power, irrigation, water supply, flood control and recreation. However, like other assets, dams also age and deteriorate posing a potential threat to life, health, property and environment. The safe functioning of the dam is an important matter of economic benefit and public safety.

Aging dams need to be strengthened and rehabilitated. Improvement of dam instrumentation is an important structural aspect of dam rehabilitation program. This includes replacement of faulty instruments to the extent necessary and practicable. Additional instruments are installed depending on the feasibility and health of the dam.

Continuous monitoring to ensure early detection of failures and to enhance response times to prevent disasters. Changes in the behavioural characteristics of the structure may be indicative of impending dam failure and it is the primary goal of the monitoring system to detect such changes. This calls for online monitoring systems that are capable of near real-time monitoring of the installed instrumentation.

2. DAM INSTRUMENTATION & MONITORING SYSTEM

It is necessary to have a combination of instruments across different sensing technologies to give complete information about potential deformations in a dam. Ease and practicality of installation/replacement of the old instruments for the and communication setup are equally important, apart from proven sensor types and core-technologies to achieve an effective and long-term dam monitoring system. Various building blocks of the system are described in the following paragraphs:

2.1 FIELD INSTRUMENTS

Some surface and subsurface sensors that may be used are mentioned below. Subsurface monitoring gives important information on ground/soil movement which may affect the stability of the structure.

- Tiltmeter and plumb lines to monitor dam tilt/inclination
- Crack meter and joint meter to monitor cracks/joint openings in blocks
- Borehole extensometers to monitor subsurface settlement and deformation
- In-place inclinometers to monitor lateral movement
- Water level & barometric pressure sensors to monitor reservoir level
- Piezometer/uplift pressure sensors to monitor pore and uplift pressure variations
- Seepage/flow meter
- Temperature meter
- Weather station for rainfall, wind velocity, air temperature, humidity and solar radiation

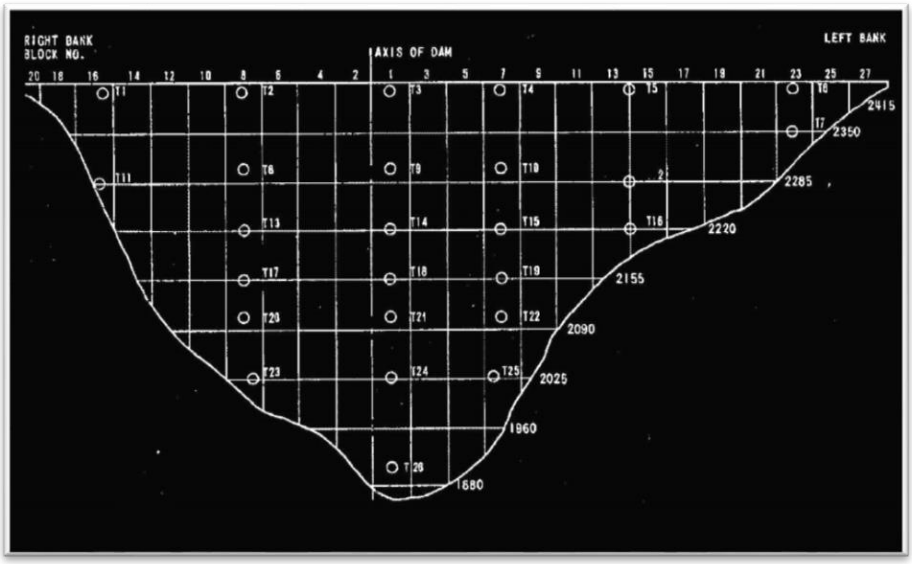
2.2 AUTOMATIC 3-D DEFORMATION MONITORING SYSTEM (ATDMS)

The ATDMS measures movements of targets fixed at critical locations on the dam's structure in three dimensions (x, y & z). It comprises of the following major components:

- 3D prism targets
- Automatic total stations (ATS)
- Control box

- Monitoring database

Fig. 1
Prism target components



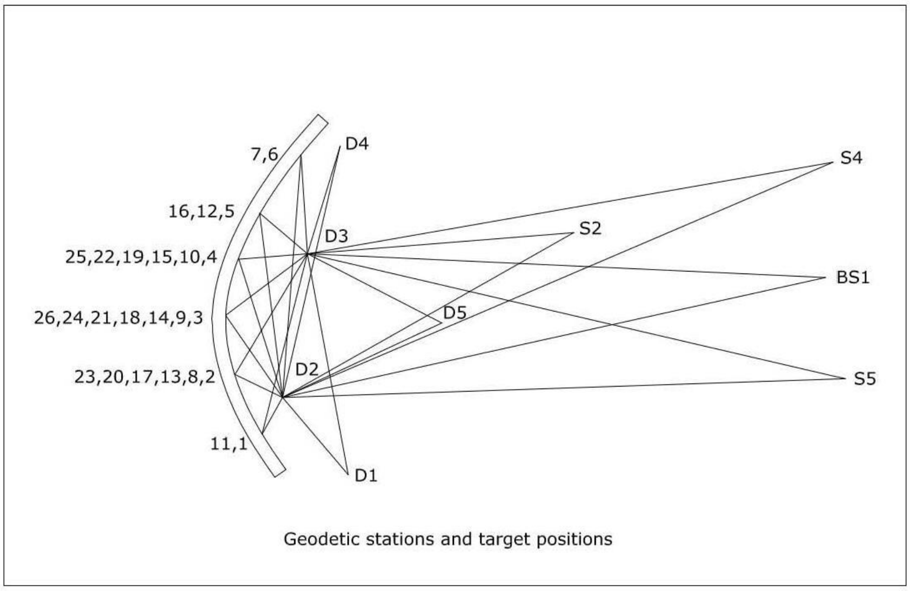


Fig. 2 (Top & Bottom)
Typical locations of targets on the downstream side of an arch dam

3D prism targets (Fig. 1) are installed on the face of the downstream side of the dam in a grid form or at critical locations (Fig. 2)

One or more high precision servo driven, computer controlled ATS is installed at a suitable location on concrete/steel pillar with protective enclosure to automatically sight these points sequentially and record data. Reference prism targets at stable locations make the system complete. Refer to figure 3 for possible mounting arrangements of the ATS.

The ATS is controlled by a control box (Fig. 4) which is essentially rugged field computer. It is powered by 220 V, 50 Hz AC mains and in turn power up the ATS. Solar panels can be used where mains power supply is not available. The control box features GSM/GPRS modem with dual SIM slots for data transmission using the cellular network. Data is collected by the public cloud-based web data monitoring service described in section 3. Alarms can also be programmed in the database resulting in sending SMS/e-mail alerts automatically to the concerned personnel, in case deformation of any point breaches a predetermined trigger value.

Fig. 3
ATS with different mounting arrangements

.

Fig. 4
ATS control box

2.3 SENSOR COMMUNICATION & DATA TRANSMISSION

2.3.1. Monitoring system with SDI-12 Interface sensors

The SDI-12 system is a bus communication system in which a wide array of dam monitoring sensors can be connected to a single 3-core cable. This is a great advantage and is possible as the electrical interface for the protocol involves three lines: a serial data line, a 12 V power line, and a ground line. The datalogger, featuring GSM/GPRS modem transmits the logged data over the cellular network to the web-based data monitoring service described in section 3. Refer to Fig. 5 for a block diagram of dam monitoring instruments network built on an SDI-12 bus.

Fig. 5
Dam monitoring instruments on an SDI-12 network

The datalogger can be powered either by Lithium or Alkaline cells or by a 12V SMF battery chargeable from AC mains or solar panel.

2.3.2. Wireless monitoring system using radio frequency (RF)

) and features long-range communication on ISM frequency range of permitted in the country of use, of up to 15 km in open field conditions. The low power consumption of the system results in datalogger batteries lasting up to 5 years. Refer to Fig. 7 for a block diagram of a dam monitoring instruments network built on RF data communication technology.

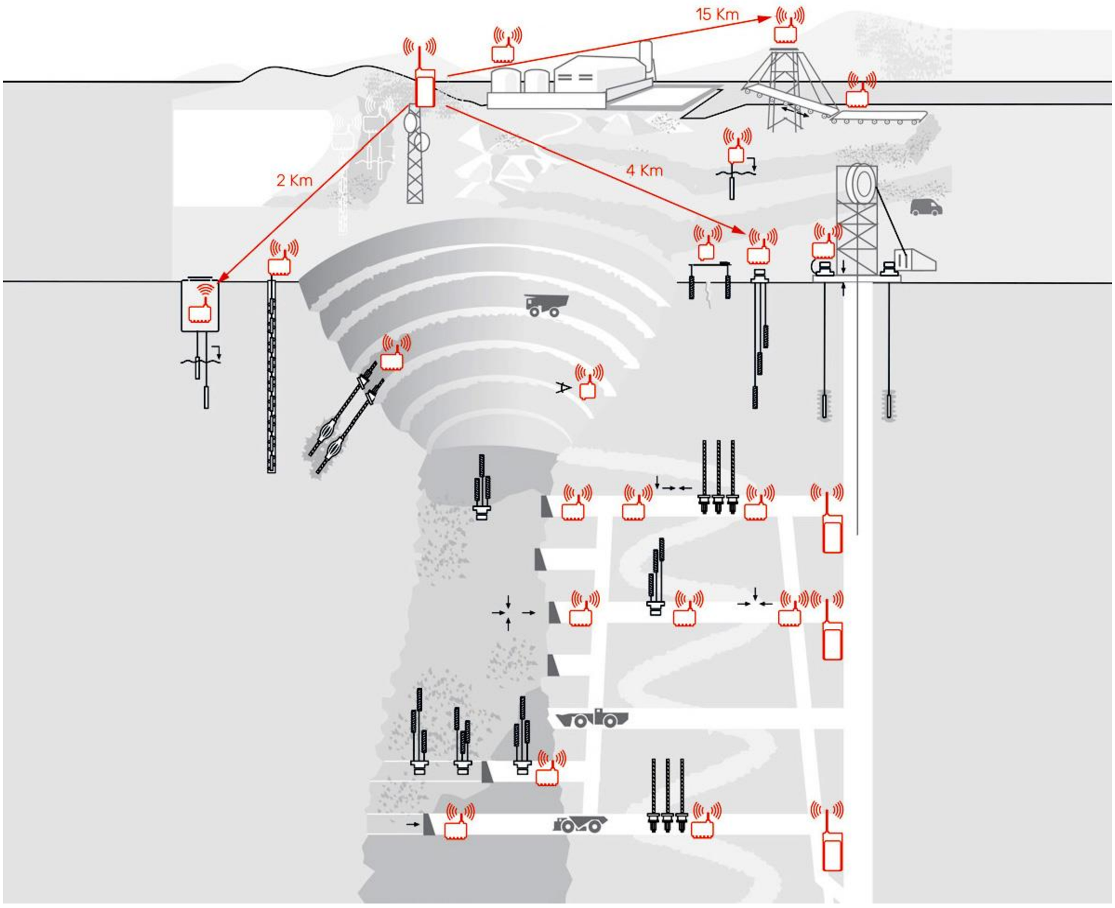

Fig. 6
Typical RF sensor network at field

The RF dataloggers, often called the ‘nodes’ of the wireless network, can be easily configured in the field using the smartphone Android app provided. These are available in single and multichannel configurations suitable for receiving the vibrating wire and analogue inputs and automatically collect, store and transmit data from the connected sensors. The RF gateway (

Fig. **8**) controls the network and is the aggregator of all data collected by the nodes. It has an integrated 3G modem with antenna supporting HSDPA, EDGE & GPRS, and a high sensitivity GPS-GNSS module. The gateways transmit the data over the cellular network to web data monitoring service described in section 3.

The system offer benefits by means of hassle-free installation- as cable runs-often long and tedious at the dam sites are not involved, cost & time savings, remote monitoring of hard to access locations, easy expansion of the system, if required in future, and easy maintenance.

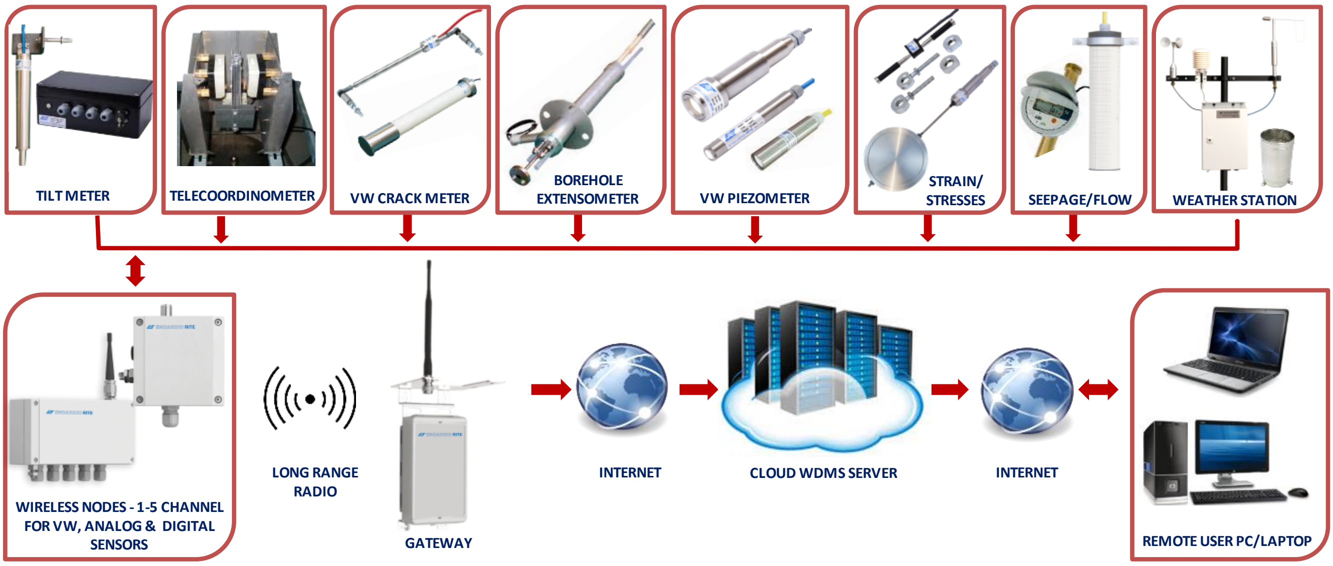

Fig. 7
Dam monitoring sensors connected to an RF network

Fig. 8
RF gateway

3. WEB BASED DATABASE MANAGEMENT SYSTEM

Cloud-based web data monitoring service is available with major geotechnical instrumentation service providers for retrieving data from the dataloggers, archiving retrieved data in a SQL database, processing data and presenting the processed data in tabular and most suitable graphical forms (Fig. 9) for easy interpretation of logged data. This is a highly flexible online monitoring system that can combine data from structural, geodetic and environmental sensors.

Cloud-based WDMS usually work on a rental model. The user has to pay a small setup fee for the first time and then a monthly rental has to be paid for accessing the data over the cloud as long as required.

Web data monitoring service's database management software acts as a data collection agent, a database server and a web server and is hosted on a high-reliability server computer. Choice of the software depends on the measurement technologies deployed.

A master plan of the project is incorporated into the database with locations of each monitoring sensor. From this master plan, the user can get data in the graphical form of any sensor with just a mouse click.

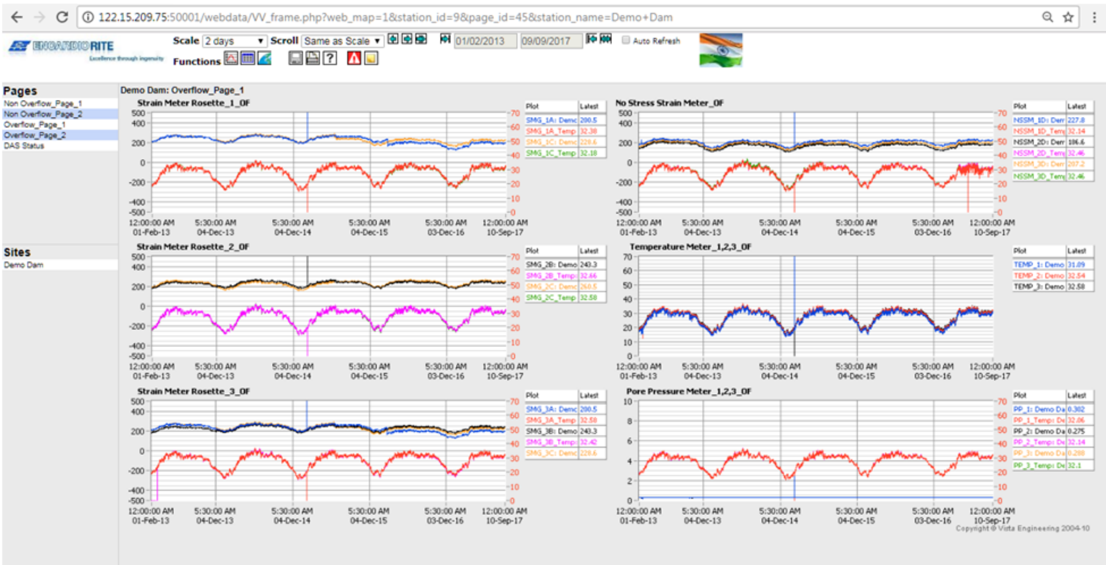

Fig. 9
Graphical data presentation on WDMS

Multiple authorized users at different locations assigned with an individual password are allowed to view any data or report from the structure simultaneously. Graphs & reports can be viewed using popular web browsers like Microsoft Internet Explorer or Mozilla Firefox amongst others.

Details like sensor identification tag, last recorded sensor reading and values of programmed alert levels can generally be viewed on the master plan of the project. If any of the alarm levels of any sensor exceeds, the colour of the marker representing the sensor location changes. Clicking the pop-up table brings up an associated data window where the sensor data can be seen either as a table or as a graph.

Site administrators can set alarm limits, which are generally considered as “alert level” and “evacuate level”. WDMS can also be programmed to send SMS alert messages or e-mail to selected users as soon as any sensor data crosses its predefined alarm levels, either while going above or going below the alarm level.

Features of the data management software can be summarized as follows:

- Data from multiple sensor types are converted into meaningful information in graphical as well as numerical format
- Results available on a wide variety of fixed and mobile devices
- Access to all sensors on one screen
- Instant alerts via SMS or e-mail to authorized personnel
- Combined charts in one report
- Create graphs from any combination of parameters and time period
- Variety of visualization and analysis tools to identify potential failure scenarios
- No special software required for accessing the user sites as information can be viewed using most standard and popular web browsers

4. CONCLUSIONS

While rehabilitation and improvement of dams and its operations and regular maintenance result in restoring their full operational capacity, a balanced and well-executed instrumentation system can provide data for greater understanding triggering mechanisms and deformation behaviour of a dam in great detail. It ensures improved performance on a long-term basis with reduced risk of failure/safety incidents. By monitoring a dam, corrective action may become possible earlier than the occurrence of any failure. The solution for setting up a dam safety instrumentation & on-line monitoring system is not expensive with the advent of new technologies in this field. Considering holistically, the cost of instrumentation and monitoring is a small fraction of what is spent later on in repair and rehabilitation operations.

SUMMARY

For control and mitigation of disastrous consequences caused by the failure of an ageing dam, it is essential not only to take preemptive corrective action at the site by strengthening and rehabilitating it but also by implementing a good monitoring and forewarning system. The latter is vital for identification of hazardous conditions or developments well before a catastrophic failure takes place and alert personnel with authority to take remedial measures as early as possible. This paper describes advanced instrumentation for dam safety monitoring comprising of field-proven and rugged geotechnical instruments, advanced automatic surveying techniques and public cloud-based web database management system. The field sensors for measuring parameters such as surface and subsurface deformations, porewater pressure, anchor load, rainfall etc. are connected to the field dataloggers either through an SDI-12 bus or through RF signals thus minimizing the cabling costs and increasing system's reliability. Deployment of the robotic total station to automatically monitor 3D prisms at critical locations adds to the comprehensiveness of the data collected and system's integrity. The data collected by the field instruments and sensors, transmitted using GSM/GPRS network, is readily available in real time to the different stakeholders, who may be located in any part of the world. Automatic notification of alarm conditions through e-mail or SMS is realized by the system. The dam safety monitoring network is cost-effective and value-wise is just a small fraction of what is spent later on in repair and rehabilitation.

RÉSUMÉ

Pour maîtriser et atténuer les conséquences désastreuses de la défaillance d'un barrage vieillissant, il est essentiel non seulement de prendre des mesures préventives préventives sur le site en le renforçant et en le réhabilitant, mais aussi en mettant en place un bon système de surveillance et d'alerte. Ce dernier est vital pour l'identification des conditions ou des développements dangereux bien avant qu'une défaillance catastrophique se produise et alerte le personnel avec l'autorité de prendre des mesures correctives le plus tôt possible. Cet article décrit une instrumentation avancée pour la surveillance de la sécurité des barrages comprenant des instruments géotechniques éprouvés et robustes, des techniques de levés automatiques avancés et un système de gestion de base de données web basé sur le cloud public. Les capteurs de terrain pour mesurer les paramètres tels que les déformations de surface et souterraines, la pression d'eau interstitielle, la charge d'ancrage, les précipitations, etc. sont connectés aux dataloggers sur un bus SDI-12 ou par RF, minimisant ainsi les coûts de câblage. Le déploiement de la station totale robotisée pour surveiller automatiquement les prismes 3D à des emplacements critiques ajoute à l'exhaustivité des données collectées et à l'intégrité du système. Les données collectées par les instruments de terrain et les capteurs, transmises via un réseau GSM / GPRS, sont facilement accessibles en temps réel aux différents acteurs, qui peuvent être situés dans n'importe quelle partie du monde. La notification automatique des conditions d'alarme par e-mail ou par SMS est réalisée par le système. Le réseau de surveillance de la sécurité des barrages est rentable et la valeur n'est qu'une petite fraction de ce qui est dépensé plus tard dans la réparation et la réhabilitation.

1. INTRODUCTION

Keuliling Reservoir most well known as the first dam in Aceh Province has been serving nearly 10 years. The operation and its maintenance controlled under the surveillance of River Basin Organization Sumatera I - the Ministry of Public Works and Housing of Indonesia. Dam Operation Unit (DOU) is a unit in River Basin Organization Sumatera I which conducting the dam monitoring works in every week, month and year. Three outline duties and responsibilities of DOU; firstly, arranging water reservoir through intake gate in accordance with the needs of water users and operating patterns of Keuliling Reservoir; secondly, supervising the dam instrumentation and hydro-mechanical equipment; and third, maintaining and controlling the dam structure from human activities or animal behavior that may caused a trigger to dam damage.

The Keuliling Reservoir provides as a source of irrigation water supply located in Aceh Province – Indonesia (Fig.1). It is precisely positioned in Bak Sukon Village, Cot Glie Sub-District, Indrapuri, Large Aceh District, Aceh Province. It has 38.2 km^2 of watershed and an average annual rainfall of 1,791 mm. The flood discharges implied by the Keuliling Reservoir amounted to 203.03 m^3/sec for the return period of 20 years and 725.08 m^3/sec for the flood discharge of the PMF value. Beside the positive benefits, the dam can cause tremendous flash floods which will result in many casualties, property, public facilities and severe environmental damage due to dam failure state. In preventing such calamities, the dam must always be monitored and maintained properly. The success of Keuliling Dam monitoring supported by routine, periodic and large inspections. Periodic inspections consist of periodic inspections carried out every 1 (one) year and major inspections undertaken at least once within 5 (five) years.

The River Basin Oraganization of Sumatera I held the first five years inspection of dam surveillance which evaluated by Dam Safety Committee. The result of the major inspection shows that the dam still able to serve as its main function. The Dam Safety Committee evaluated the dam structure, stability, and its operation system and management. Several recommendation issued for the dam safety and other for dam maintenance. One significant proportion is the human activity surrounding dam area. Hence, the River Basin Organization of Sumatera I interrelated to Dam Safety Committee is implemeting and improving dam safety regulation for Keuliling Dam.

Fig. 1. Keuliling Reservoir as the First Dam in Aceh Province, Indonesia

2. BACKGROUND

Considering a dam as multipurpose construction which has a great potencial hazard to public salvation, it needs a safety and maintenance guidelines in order to obtain the maximum benefit in long time period. The safeguards and maintenance of the dam need to be followed up with the preperation of operational guidance, maintenance, observation and monitoring of dam. Several government regulations had been establised associated with dam construction guadlines in Indonesia that described as follows (Directorate of Water Resources, 2003);

(1) Law No. 11/1974 on watering;
(2) Government Regulation No. 22/1982 on the regulation of water;
(3) Government Regulation No. 35/1991 about river;

(4) Government Regulation No.25/2000 regarding authority of government and authority of province as autonomous region;
(5) Presidential Decree No.44/1974 on the principal of departmental organization;
(6) Presidential Decree No. 102 of 2001 on the status, duties, functions, authority of the organizational structure and working procedures of the department;
(7) Decree of the Minister of Settlement and Regional Infrastructure No. 01/KPTS/M/2001, on the Organization and Working Procedures of the Department of Settlements and Regional Infrastructure;
(8) Decree of the Minister of Public Works No. 378/1987, on the Ratification of 33 Indonesian Building Construction Standards;
(9) Decree of the Minister of Public Works No. 72/PRT/1997, on Dam Safety,Decreeof the Minister of Settlement and Regional Infrastructure No. 296/KPTS/M/2001, regarding the amendment;
(10) Presidential Decree No. 105/M/2002 on the appointment and designation of the Director General of Water Resources, the Ministry of Settlement and Regional Infrastructure;
(11) Indonesian National Standard Number 1731-1989-F concerning Dam Safety Guidance; and
(12) Government Regulation of the Republic of Indonesia Number 37 Year 2010 concerning Dams.

Referring to those government regulations mentioned above, the Director General of Water Resources established an operation, maintenance and monitoring dam protocol. There are five subdivisions that include in the operation and maintenance guidance;

Part 1, General :
A guideline on the preparation of the operation, maintenance and dam observation guide, covering general requirements, procedures or operating procedures.

Part 2, Management of Operations dan Maintenance :
Contains detailed description of the implementation of maintenance/operation management and maintenance of dams/reservoirs and their facilities, including a description of their funding needs.

Part 3, Instrumentation and Monitoring :
Describes the basic understanding of the system and the types of instrumentation suitable for the dam and the concrete dam and the procedures for the implementation of the monitoring

Part 4,Dam Inspection for Hydromechanical and Electrical equipment : Guidance regarding the subjects and targets of inspection and procedures

Part 5, Operational and Hydromechanical and Electrical Maintenance.

3. LARGE INSPECTION DAM

3.1. KEULILING DAM INSPECTION

The regular and large inspection is part of the dam safety evaluation and monitoring process, which purposed to comprehend the condition of a dam related to the security of its structure, hydraulics and operations, identifying the existing problems and establishing suggestions for improving dam security. Large inspection, ie thorough inspection of technical and non-technical aspects supposed to evaluate the dam safety and emergency preparedness. This inspection was led by an expert team who is experienced in the field of dams and at least assisted by Geologists and Hydromechanists.The main work of the large dam inspection executed in five of scope works;

a. Inventoring and reviewing the existing data
b. Field inspection work
c. Instrumentation and interpretation monitoring program
d. Analysis of inspection result
e. Report compiling

Three main surveillance conducted in the large inspection of Keuliling Dam were visual inspection, underwater inpsection and major inspection. Visual inspection was for ground and water investigating objects, such as dam surfaces, auxiliary buildings, ridges and reservoir cliffs, hydro-mechanical equipment including dam and supplementary buildings. The investigation was for cracks, sub-drainage, crushing, dissolving, leaking, indication of deterioration of quality or chemical reaction, and damage caused by erosion and cavitations. Also, it is aimed to check the contraction joints for water resistance, as well as large signs of expansion or contraction, and the difference in motion of adjacent concrete blocks, the connection of the construction of either vertical or horizontal joints. Elevation of dam crest, cantilever, supporting wall, column, or other wall examined by using previous results as a benchmark to determine the movement of construction. The aeration holes and other openings on the overflow launcher or on the door must be free from mud and other deposits. This action was directed to problems related to scouring and abrasion. Further, the construction alsoinvestigated for: cracks, leaks, basins, springs, evaporating holes, incidence of reed erosion, scouring, abrasion, excessive cultivation of plants, crest straigthness, bumps and slopes, animal holes, deterioration of riprap quality as well as other slope protective materials and so forth.

Underwater inspection is an investigation of objects under water that executed by beaming or diving method. The objects explored in the upper slope surface of the dam in order to determine the possibility of embankment, avalanches, deterioration of slope protective quality and so on. Upper face of a dam inspected to determine the possibility of cracks, material degradation or openings resulting in increased seepage and leakage.

The main large inspection done through with field investigation and data processing to check the condition of the dam safety in terms of structural, hydraulic, seepage and operational readiness in both normal and extraordinary conditions. Additionally, it is to monitor and evaluate the dam security which consist of the strenghtness of the dam structure, monitoring and operation and maintenances systems and the early warning system of the dam. The main report contains the results of the evaluation and analysis of main dam and its complementary building, hydrology, geology,hydro mechanical and electrical equipments,environmental, dam stability and abundance, sedimentation, operating and maintenance systems, reservoir survey and emergency action plans Keuliling Dam (Multi Karadiguna Jasa Consultant, 2013).

3.2. DAM INSPECTIONS RESUME

The result of major inspection work that was done for 8 (Eight) months start from 23rd March to 19th November 2013 had shown that the main dam of Keuliling Reservoir and its appurtenance in a proper condition. The dam crest has no significant settlement, seepage, crack, joints, sliding and gully erosion but a little deflection and debris. The seepage measurements in downstream area that using a v-notch was found that this gauge had a broken telemetring tool. The spillway of the dam was having no substantial crack, debris, or erosion condition. The intake house of Keuliling Reservoir still in appropriate condition, however it is recommended that there should be an immidiate treatment in a structure of the tunnel due to its leaking situation in the joint concrete part. Also, the tunnel should be given a protective paint to maintain the quality of tunnel construction.

The main report for the work of the Large Dam Inspection is the result of the implementation of the inspection work. The main report contains reports of the evaluation and analysis of Keuliling dam and its appurtunance included several evaluations as follow;

- Visual Evaluation of Dam and Complementary Building;
- Hydrological Evaluation and Analysis;
- Evaluation and Analysis of Technical Geology;
- Evaluation and Analysis of Hydro mechanical and Electrical Tools;
- Evaluation and Analysis of Dam Stability and Abundance;
- Evaluation and Analysis of Instrumentation on Body Dam;
- Evaluation and Analysis of Environmental Condition of Reservoir;
- Evaluation and Analysis of Sedimentation Reservoir Survey;
- Evaluation and Analysis of Operating and Maintenance Systems;
- Evaluation and Analysis of Emergency Action Plans;
- Evaluation and Analysis of Dam Security.

It was proposed that the Keuliling Reservoir is provided an emergency control facilities such as gate shaft, controling system from mechanical and electrical tools and a particular emergency road. Geological condition of Keuliling Reservoir in the main dam, saddle dam, the toehold dam in right and left area, spillway, outlet channel, and its surrounding area had no degradation or deviriation settlement. The dam seismicity investigation resulted in acceptable state where it had no ground tilting, dam cracking, liquefaction processing, and seiches action. In conlucion, the overall assessment of major inspection of Keuliling Reservoir presented that the dam can serve and operate optimally.

4. DAM OPERATION UNIT

The operation and maintenance of a dam must be organized in accordance with standards, operations and its guidelines. The observation works of Keuliling Dam aims in analysing provision data that will result in the state and behavior of the dam whether something is running normally or not. Here, the Dam Operation Unit performing the dam monitoring as one of the main tasks of River Basin Organization of Sumatera – I.

The most recent Keuliling Dam monitoring conducted in November 2017 where it is the third investigation in one year. The unit was monitoring and observing the behavior of dams visually, also reading the instrumentations equipment as a basis and analysis material to evaluate the performance of the dam in order to be followed up if there is a critical situation.

The organizational structure of observation and maintenance of Keuliling Dam is organized under the Dam Operation Unit (DOU) – River Basin Organization of Sumatera I. The organizational structure with number of personnel and the quality of personnel required is a matter of concern in preparing an effective and efficient operation and maintenances organization. The need for personnel required in a dam organization structure is determined by the level and type of complex of a dam construction. Organizational structure of observation and maintenance of Dam Operation Unit in Keuliling Dam is presented in Figure 2.

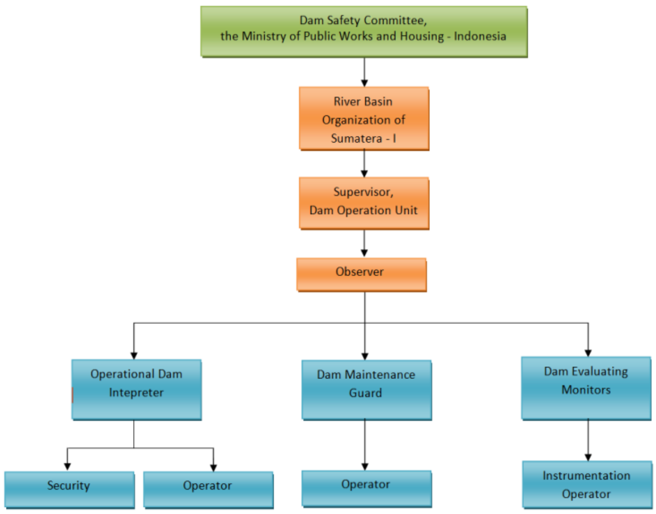

Fig. 2 The Organizational structure of Operation and Maintenance of Keuliling Dam in River Basin Organization of Sumatera – I

4.1. VISUAL EVALUATION

Based on the recent observation works at the end year of 2017, it is desirable that the downstream channel needs to be normalized. It is suggested due to the rainfall in the canal that flowing into the diversion tunnel may affect the stability of the dam. It is also found that there has been no follow-up for sediment removal of a v-notch drainage channel. Thus, may result that the water from v-notch pools cannot be monitored manually.

In invistigation of saddle dam 5 and saddle dam 6, it is proposed that there should be re-emphasized to ban illegal connections (water suction) from River Basin Organization Sumatera I, as there have been scoursing on the dam body of saddle dam 5 and rock pairs of saddle dam 6 due to the wild connections made by the community (Dam Operation Unit Report, 2017) (see Fig. 3).

Fig. 3. The Water Siphoning Activities by the Community

4.2. MONITORING RESULTS AND RECOMMENDATION

In general, the reading of instrumentation shows a good result without any symptoms of anomaly or deviation. The piezometer at the core zone indicates the filter is working properly and the other located at the foundation illustrates that the wall diaphragm is functioning well. The fluctuation of seepage discharge occurred mostly influenced by the amount of rainfall.

The periodic observation works issued some suggestions. Some buildings and instruments have not been in an optimum maintenance. As a deduction, the Dam Operation Unit (DOU) of River Basin Organization of Sumatera - I submitted a several recommendation for the urgent maintenance of Keuliling Dam as shown in the the following table 1.

Table 1. The Urgent of Operation and Maintenances Work of Keuliling Dam

No	Building and Instruments	Recent Condition	Recommendation
1.	Data Logger (Instrumentation house)	The automatic instrumentation reading is in a damaged state (data can not be read) caused by lightning that interfere with the program.	Need an immediate reparation.
2.	Vibrating wire piezometer	- Readings were done manually on the house - - Vibrating wire piezometer in the body of the main dam, the data was readable for 5 of 18 points attached to the main dam - Not perfectly accessible digitally on the instrument house	Need a calibration data
3.	Inclinometer	-The box cover is in broken condition -The inclinometer equipment need to be calibrated and the battery should be renewed	The close box need to be repaired immediately to avoid from further destruction which may result in the error reading of inclinometer and the device needs to be re-calibrated
4.	Openstandpipe Piezometer (OP)	The box cover of Openstandpipe is damage	The close box need to be fixed to avoid the clogged pipe holes.
5.	The inundation area	There are fish cages	Control and prohibit the activities of fish cages for water quality and sediment in the reservoir.

5. SUMMARYS

River Basin Organization of Sumatera – I (RBO) as a dam owner has been conducting an operation and maintenance system in Keuliling Reservoir. The monitoring activities operated by Dam Operation Unit. It is found that Keuliling Dam still need an improving of instrumentation monitoring system and it should be controlled 4 (four) times within a year to get an optimum maintenances for a long lifetime of the dam.

Some human activities in Keuliling Reservoir has caused a significant damage. Thus, it is highly recommend that the River Basin Organization of Sumatera I prohibit the illegal activities that may caused a dam destruction. Also, it is suggested that there should be a regional regulation established by the governor about dam preservation including in upstream and downstream area and admissible human activities control surrounds dam area for Keuliling Dam and also the next dam project in Aceh Province.

ACKNOWLEDGEMENT

The great and sincere gratitude is given to Mr. M. Basuki Hadimuljono, the Minister of Public Works and Housing – Indonesia and Mrs. Ni Made Sumiarsih the Head of Dam Project Center from Water Resources Directorate, Ministry of Public Works and Housing Indonesia, for giving all the support to young engineers in participating in the event of international annual meeting ICOLD 2018 and giving the idea of the paper about the operation and maintenance of Keuliling Dam – Aceh, Indonesia.

SOUTH KOREA

1. GENERAL INTRODUCTION

Earthquake was unusual case in South Korea until 2 years ago. However, earthquakes occurring in Gyeongju and Pohang region made people living in South Korea aware that Korea is no longer safe from earthquake.

Especially, Gyeongju Earthquake currently has the largest record since 1978 which seismological observation of South Korea has begun. The fore shock measured to magnitude 5.1 occurred at 9 km point south-south-west in Gyeongju, 7:44 pm on September 12, 2016. After 48 minutes, the main shock measured to magnitude 5.8 occurred at 8 km point south-south-west in Gyeongju.

Table 1. Ranking for magnitude in South Korea

Rank	Magnitude	Date & Time	Epicenter		
			Lat.	Long.	Site
1	5.8	20:32, 12th Sep. 2016	35.8	129.2	Gyeongju
2	5.4	14:29, 15th Nov. 2017	36.1	129.4	Pohang
3	5.2	19:14, 29th May 2004	36.8	130.2	Sea near Uljin
4	5.2	02:07, 16th Sep. 1978	36.6	127.9	Sangju
5	5.1	19:44, 12th Sep. 2016	35.8	124.5	Gyeongju

Figure 1. Epicenters and Damage due to earthquake
(Source : www.arirang.com & www.ytn.co.kr)

Gyeongju is one of cities that retain many historical and cultural heritages. Many structures having ancient traditional style are in this region but some of them were damaged by earthquake.

Therefore, KISTEC (Korea Infrastructure Safety & Technology Corporation) thought that main infrastructure near Gyeongju were influenced by earthquake and they performed urgent inspection for a dam which is not far from epicenter.

As a part of dam inspection, the behaviors of a dam were analyzed by comparing with the real-time measured data for before and after earthquake.

In order to perform behavior analysis, displacement and leakage measuring data were selected among entire measuring data. Because these systems are very important for management of type of fill dam and considered to have a relatively high reliability.

Table 2 and Figure 2 show specification of subject dam. Type of Subject dam is C.F.R.D (Concrete Faced Rock fill Dam), operating beginning year is December in 2005 and built purpose of dam is water supply.

This paper shows the results of this analysis and overall conclusions for inspection of a dam after earthquake.

Table 2. Main specification of the subject dam

Dam	Type	Concrete Faced Rock fill Dam	Spillway	Type	Radial Gate (3-Gate)
	Purpose	water supply		Weir crest	EL.117.5 m
	Length	192 m		Length	206.5 m
	Height	52 m		Designed discharge	1,840 m^3 /sec
	Volume	528,000 m^3			
	Crest	EL.126.8 m	Intake facility	Type	Surface intake
	Slope	Upstream : 1:1.4 Downstream : 1:1.8		Scale	D : 4.0 m H : 39.3 m

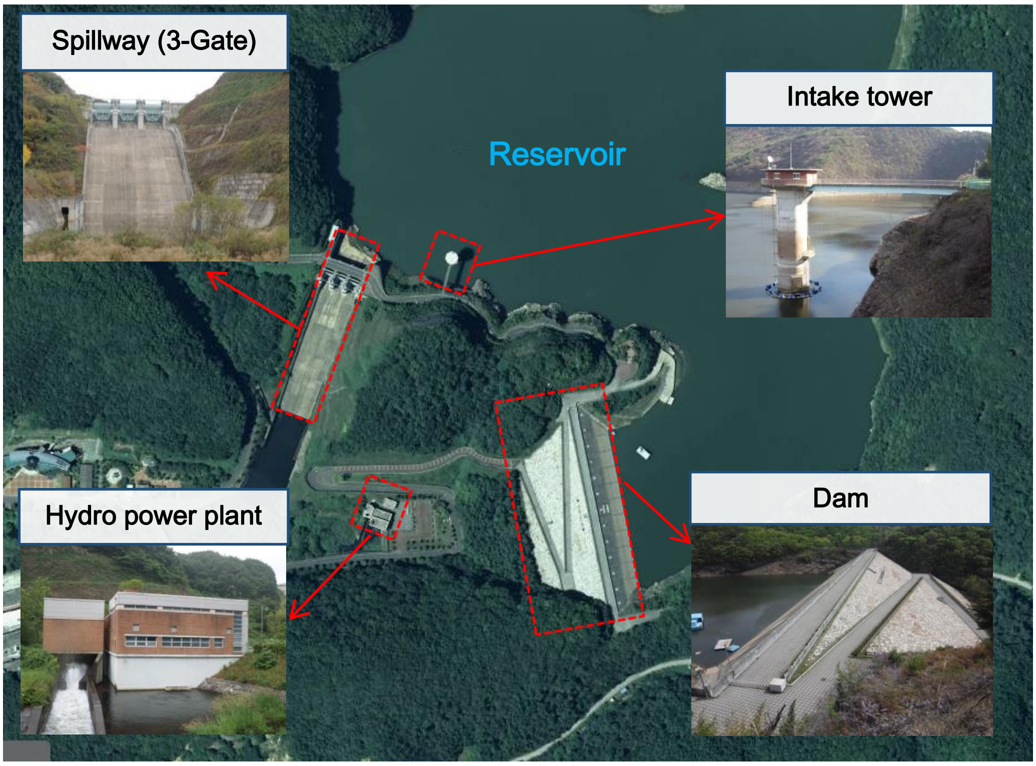

Figure 2. Main specification of The subject dam

2. ANALYSIS RESULTS

2.1. DISPLACEMENT MEASURING

The number of displacement measuring points in subject dam is 14 and these are located at divided section of the subject dam. 5 points are on the dam crest section, 3 points are on the upstream slope section, the others (6 points) are on the downstream slope section. Currently, the displacements of each point are measured automatically every hour.

In order to analyze the influence on earthquake, subject analysis period was decided to 2 months which are Before and after 1 month based on the day (12^{th}, Sep. 2016) of occurring earthquake.

Table 3. Status for displacement measuring points of the subject dam

Classification	Dam crest	Slope		Total
		Upstream	Downstream	
Displacement points (operated)	5	3	6	14

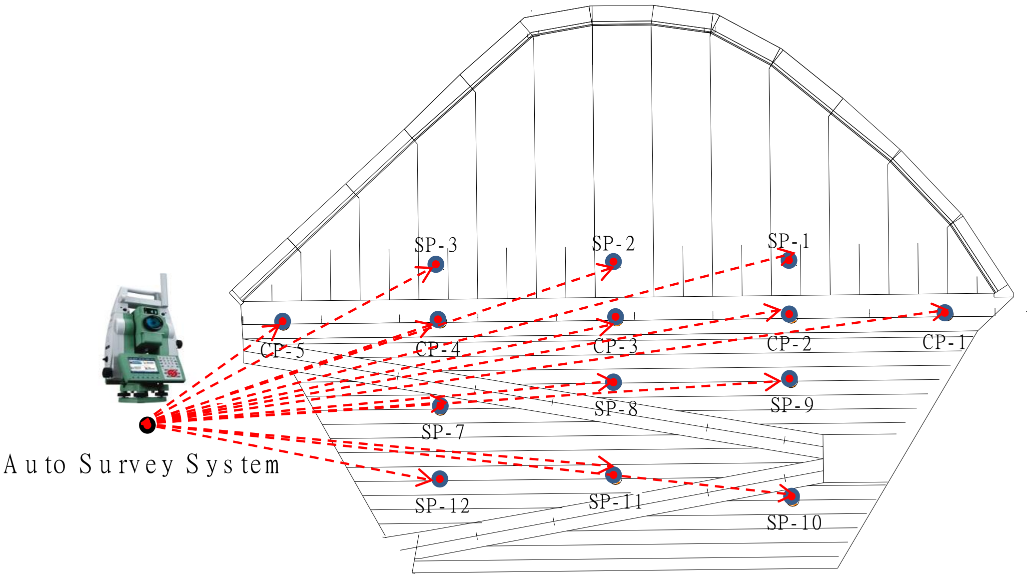

Figure 3. Location of displacement poins for the subject dam

Displacement of dam can be measured as 3-Directions (X, Y, Z) and Figure 4 shows displacement direction of the subject dam. X axis is left & right direction and Y axis is upstream & downstream direction. Z axis is up & down direction for the dam crest.

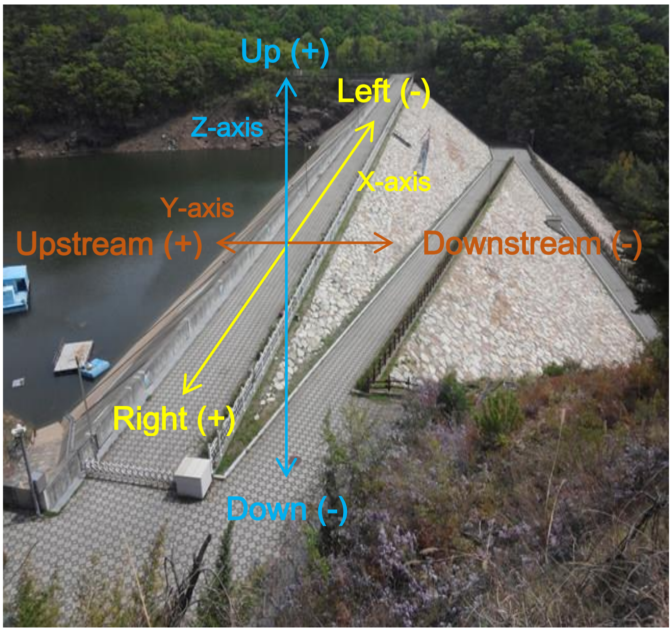

Figure 4. Axis direction of displacement poins for the subject dam

Figure 5~6 show status of displacement points for the subject dam. Analysis on SP-12 point excluded because this point needed calibration. In addition, there were unmeasured sections due to the electric errors of measuring instrument.

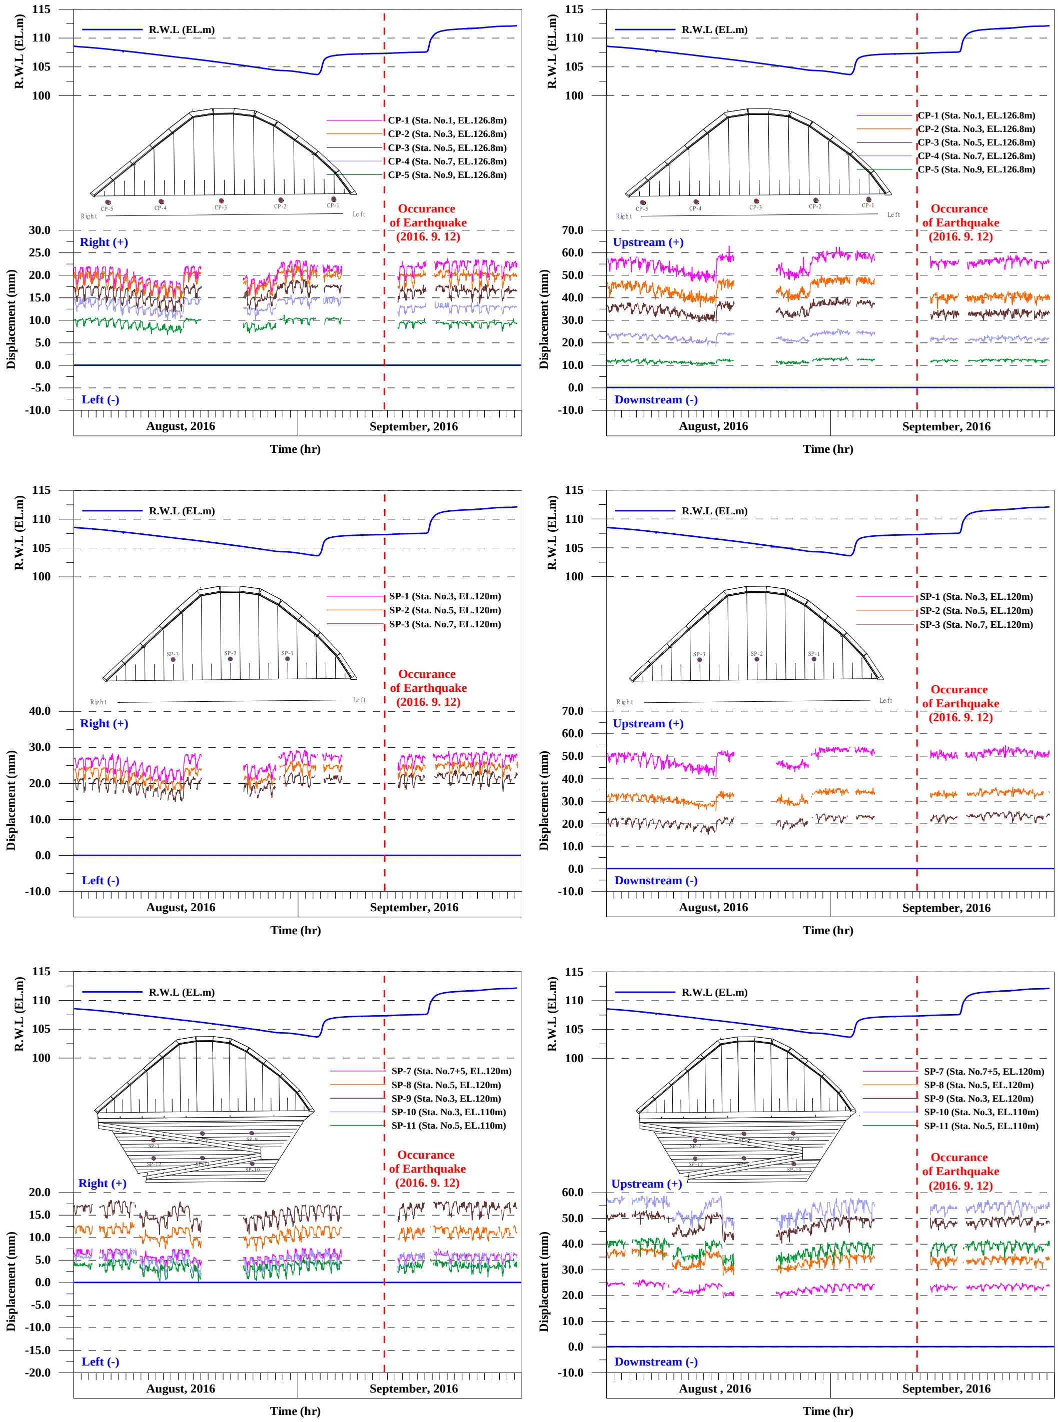

Figure 5. Status of displacement poins for the subject dam (X, Y axis)

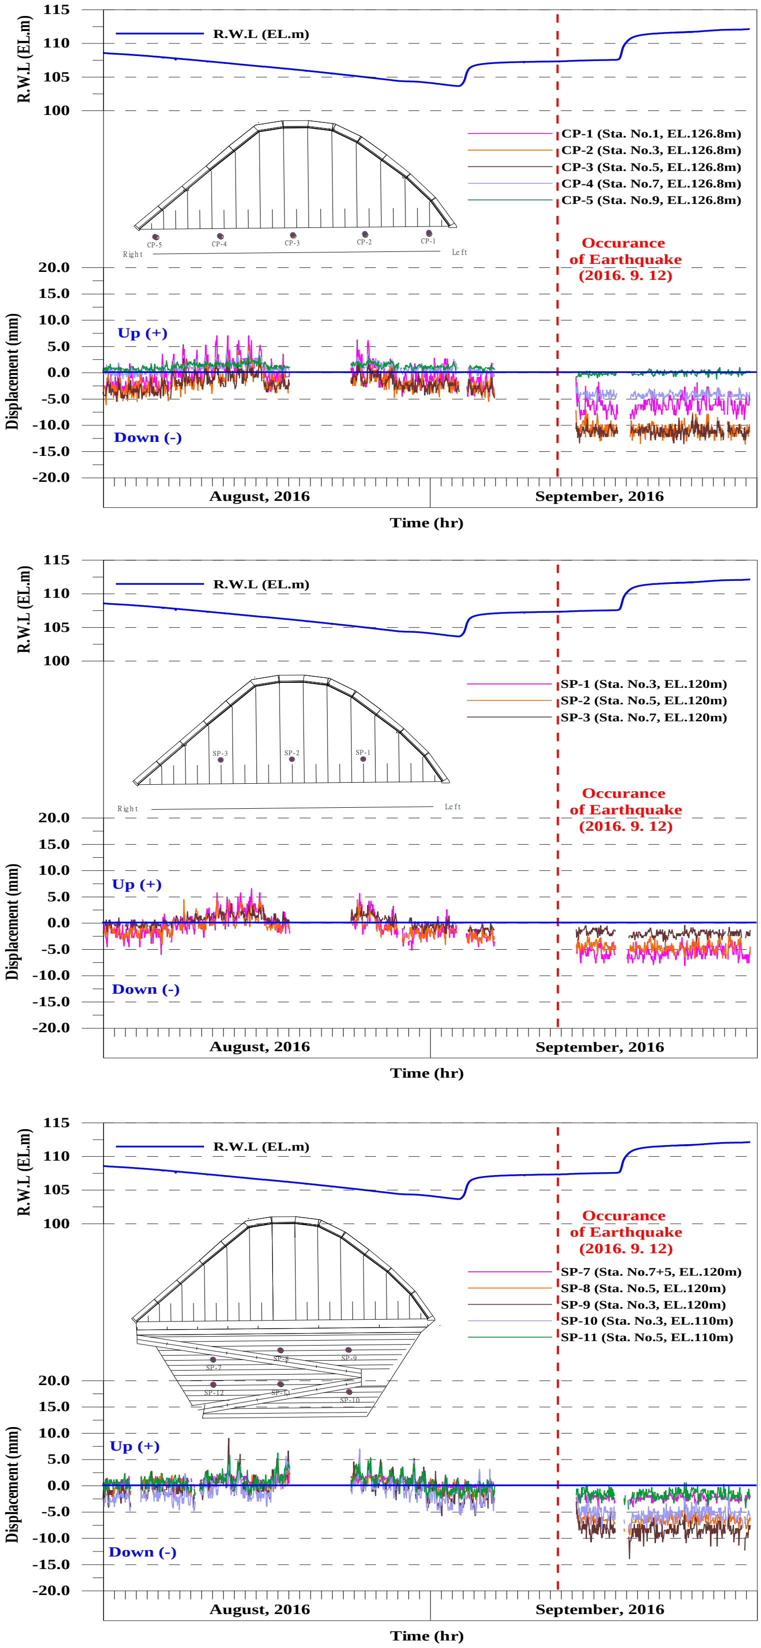

Figure 6. Status of displacement poins for the subject dam (Z axis)

Figure 5 shows displacement of x & y directions. As a result, there was little difference between before and after earthquake, but figure 6 shows that displacement of z direction before earthquake was different from after that. This could mean that all points had a change and small displacement occurred on a dam. It was difficult to estimate exactly how much settlement occurred or whether settlement occurred really or not because survey system also had a possibility to be affected by earthquake

Due to a change of only vertical displacements, it was analyzed additionally how much vertical displacement for all points changed.

Figure 7 shows vertical displacement of all points. Lines with rectangular shape are average measured data before earthquake. Period of data is 2 years ago from occurring gyeongju earthquake. Lines with circle shape are average measured data after earthquake. Period of data is 1 month from occurring gyeongju earthquake.

As a result, middle section of dam structure changed larger than other sections. Maximum displacement was about 8.5mm on the middle of dam crest.

Figure 7. Status of vertical displacement before & after gyeongju earthquake

2.2. LEAKAGE MEASURING

Dam structure is always storing amount of water, but perfect blocking of infiltration water is difficult. If infiltration water is increased, dam operators or engineers can think that an Interlocking of rock fill zone or a joint between faced concrete have a problem.

Therefore, in order to properly operate and maintain structures for rock fill dam type, it is very important to check leakage measuring.

The number of leakage measuring points in subject dam is one and this is located at the tip of downstream slope. Currently, quantity of leakage and water quality is measured automatically every hour.

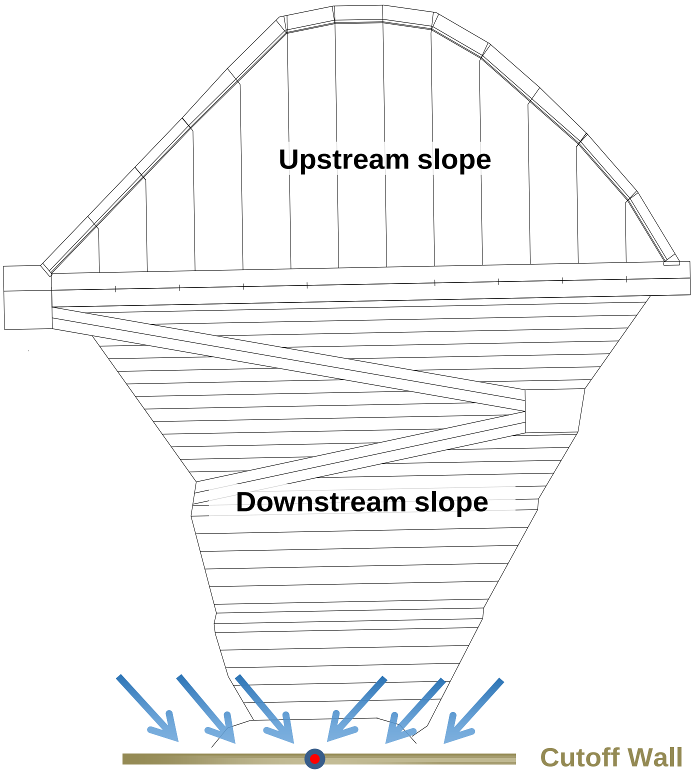

Figure 8. Location of leakage measuring system for the subject dam

In order to analyze the influence on earthquake, subject analysis period is decided to 2 months which are Before and after 1 month based on the day (12th, Sep. 2016) of occurring earthquake in common with displacement measuring.

Analysis for measured leakage data was performed by excluding the data of rainy period because precipitation is negative influence to exact leakage measuring.

Figure 9 shows status of leakage measuring for the subject dam. Simply comparing with quantity of leakage before and after earthquake is not reasonable because precipitation quantity and duration are different every times and analysis period is relatively short term. Important point was that leakage status before and after earthquake was similar, variation was stable. 16th September, Quantity of leakage and turbidity were increased but decreased gradually after that. The reason that leakage increased was precipitation.

Therefore, it seemed that leakage was not affected by earthquake and the leakage measuring system be considered to have no problem to operate.

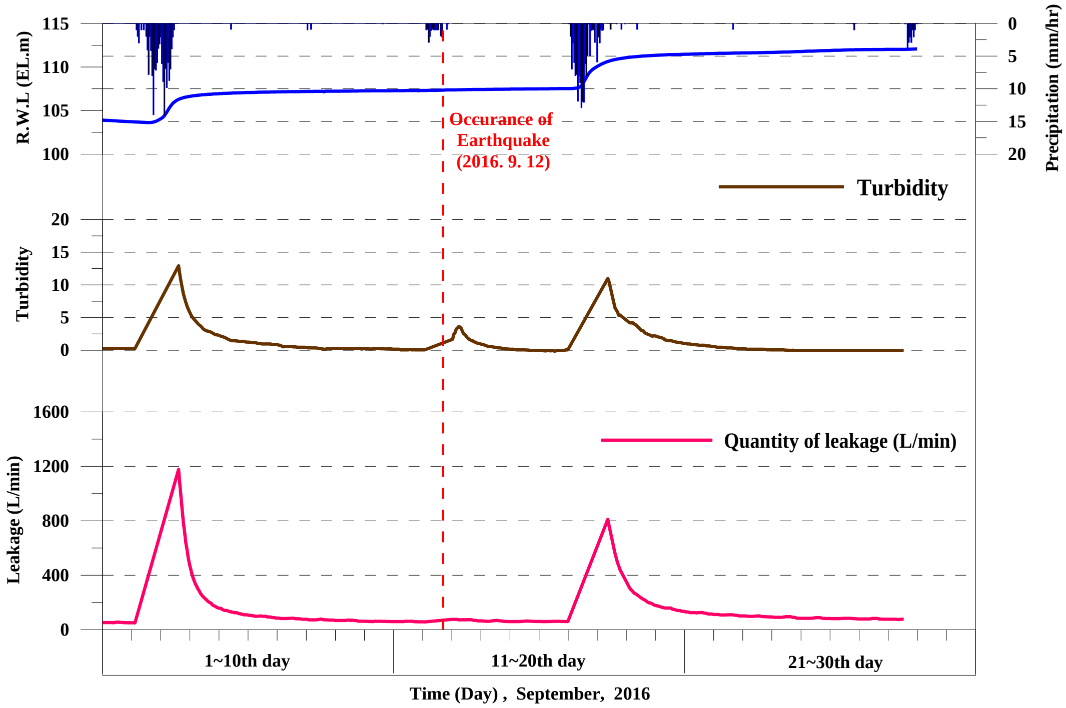

Figure 9. Status of leakage for the subject dam

3. CONCLUSION

In case of displacement behaviors, x & y directions were little difference between before and after earthquake, but z direction after earthquake was different from before that. This could mean that all points had a change and small displacement occurred on a dam. In additional analysis about change of vertical displacement, maximum displacement occurred on the middle of dam crest.

In an urgent field inspection, however, there were no damages by gyeongju earthquake such as crack or breakage of pavement on dam crest, faced slab and change of arrangement for downstream slope.

The leakage status before and after earthquake was similar, variation was stable. It seemed that leakage was not affected by earthquake and the leakage measuring system was considered to have no problem to operate.

As a comprehensive result of inspection and behavior analysis, there are no external damages in the subject dam and leakage measuring was normal and stable. Therefore, it seemed that the subject dam was affected by earthquake but safety and operation of dam structure was evaluated to have no problem.

In spite of no problem about dam safety, dam structure needs in-depth survey using control points because influenced by earthquake.

DAM SAFETY REGULATION IN SOUTH AFRICA: 32 YEARS DOWN THE LINE

Louis C. HATTINGH

Chief Executive Officer, HATTINGH ANDERSON ASSOCIATES CC, PRETORIA

Ivor SEGERS

Principal Engineer: Civil Engineering, EXXARO RESOURCES LTD, PRETORIA

SOUTH AFRICA

1. INTRODUCTION

South Africa is the 30th driest country in the world. This is due to low levels of rainfall (relative to the world average) and high variability (60% of river flow arises from only 20% of the land area) as well as high levels of evaporation. Of the total mean annual runoff of 49 000 million m^3 per year, only 10 000 million m^3 is annually available as assured yield (98% assurance) [1]. As a result, South Africa has been one of the major dam building countries in the world. It is the country with the seventh most large dams (more than15 m high) on the ICOLD register of dams [2]. It also has a significant number of small dams (less than 15 m high).

Of the total available water resources 67% is currently allocated for irrigation while the rest is made up of domestic and industrial use (22%), mining (5%), afforestation (3%) and power generation (mainly thermal power) and transfers between catchment basins (3%) [1].

This paper not only summarize the history of Dam Safety implementation in South Africa from its earliest humble beginnings in the 1970s to the implementation of Dam Safety legislation in 1980s [3] and the update of the relevant regulations in

2012 [4] but also provide insight into the required regulatory processes during the lifespan of a dam.

A summary is provided of the lessons learnt in the implementation of the legislation including the positive influence of effective dam safety legislation and the fact that it takes time and significant resources to implement a dam safety regulatory system. It is also important to note that these lessons learnt were used to help some other African countries starting with the implementation of Dam Safety regulatory systems in their countries [5][6].

2. LEGISLATION

2.1. HISTORY

Legislation on the safety of dams was formally introduced in 1984 in South Africa (after earlier attempts dating back to the early 1970s was not successful). It is interesting to note that initially the political decision makers in South Africa considered dams to be inherently safe. This was obviously not correct considering the failure statistics of dams before the 1970s. A visit to the US, UK and several European countries by a team of officials from the Department of Water Affairs in the 1980s lead to the first attempts to introduce dam safety principles in South Africa based on the experiences gained during their visit.

Apart from defining the structures subjected to control, authority has been given to the Minister of Water Affairs (and Forestry) to promulgate dam safety regulations in which conditions and requirements for the design, operation, maintenance, inspection and even decommissioning of dams are prescribed. This was done for the first time in 1986. It is important to note that these regulations initially did not specifically take into account any environmental aspects with regards to dam safety.

Although the Constitution of South Africa of 1996 [7] drawn up after the advent of democracy in 1994, is primarily human centered, it also highlights the protection of the environment. Subsequently a National Water Act was promulgated in 1998 that includes a section on dam safety [8] that also included environmental aspects pertaining to dam safety (impacts). As a result, revised dam safety regulations were promulgated in 2012 [4] which for the first time included the potential impact of a dam on the resource quality downstream of the dam.

2.2. DAM SAFETY LEGISLATION

The National Water Act [8] as well as the Dam Safety Regulations of 2012 [4] aim at “improving the safety of the new and existing dams with a safety risk so as to reduce the potential harm to the public, damage to property or to resource quality". It is important to note these only pertain to dams with a safety risk. A "dam with a safety risk" is defined as a dam with a storage capacity of more than 50 000 m^3 and a vertical height of equal to or more than 5 m. This definition of height differs from the ICOLD definition – the height is measured from the lowest natural bed level at the downstream toe of the dam wall to the non-overspill crest. Smaller dams that do not satisfy these requirements do not form part of the dam safety legislation. It is of extreme importance to note that these dams, however, still have to comply with water use and environmental legislative requirements.

The authority of dam safety lies with the Minister of Water and Sanitation (DWS). The Minister is assisted with the regulation of the dam safety legislation by the Dam Safety Office (DSO) which forms part of DWS (as designated by the Director-General of DWS) – one could call the DSO the regulator in South Africa. The Minister is also assisted by the Engineering Council of South Africa with the approval of appropriately qualified and experienced professional persons (Approved Professional Persons - APPs) to perform tasks at dams with a safety risk. The mandatory involvement of APPs for all tasks carried out at certain categories of dams is one of the important principles of the dam safety legislation in South Africa.

As in other countries that also had their major dam development in the 20th century, South Africa is experiencing a rapid decrease in the number of available APPs as the majority have either reached and are close to retirement. This is a major area of concern.

One of the founding principles of Dam Safety in South Africa and the rest of the world is that dam owners are responsible for the safety of their dams (the term "dam owners" also includes operators). It is therefore the responsibility of dam owner/s to register their dam with a safety risk with the DSO (including all new or planned dams). Once the registration information is received, the DSO would then classify the dam into one of three categories which determines the required level of control at that particular dam. The classification is based on the size and the hazard potential rating of a dam. The size class is determined by the maximum wall height. The size classification is given in Table 1. It is important to note that in many cases the classification date could be different from the registration date.

Table 1
Size classification (using the South African definition for height)

Size class	**Maximum wall height (m) (from the river bed level to the highest point of the dam)**
Small	< 12 m
Medium	≥ 12 m but < 30 m
Large	≥ 30 m

The hazard potential is based on an assessment of the potential loss of life (PLL), potential economic loss (PEL) (with respect to downstream development) as well as the potential adverse impact on resource quality (PIRQ) that may result from failure of a dam. In determining the hazard potential rating the PLL, PEL and

PIRQ are considered separately and the highest rating obtained, is accepted. The hazard potential classification is given in Table 2.

Table 2
Hazard potential classification

Hazard potential rating	Potential loss of life	Potential economic loss	Potential adverse impact on resource quality
Low	None	Minimal	Low
Significant	≤ 10	Significant	Significant
High	> 10	Great	Severe

The structural condition of a dam does not influence its category classification (only the size of the dam and its hazard potential are taken into account). There are three categories in the category classification (Category 1, 2 and 3). The relation between the category classification, size class and hazard potential are given in Table 3.

Table 3
Category classification of dams with a safety risk

Size class	Hazard potential rating (*)		
	Low	Significant	High
Small	Category 1	Category 2	Category 2
Medium	Category 2	Category 2	Category 3
Large	Category 3	Category 3	Category 3

(*) Highest level as determined by separate consideration of the potential loss of life, potential economic loss and potential adverse impact on resource quality downstream of the dam

To perform any task at a dam (including construction, enlargement, alteration, repair or decommissioning), the owner needs to obtain a licence for construction from the DSO. This normally includes the completion of an application form accompanied with the required design reports and engineering drawings as well as evaluation of the safety of the existing development. For Category 2 dams all tasks must be carried out under supervision of an APP whereas for Category 3 dams, an APP must be assisted by an approved professional team of experts. For Category 1 dams the involvement of an APP is not required but the dam owner has to fulfil the requirements of the dam safety regulations which includes completing an official application form, submitting design reports and engineering drawings and an evaluation of the safety of the existing development. Most of the small dams in South Africa are classified either as Category 1 or 2. In certain instances dam owners have decided to make use of a panel of experts over and above the APP and the accompanying professional team. This in certain circumstances leads to uncertainty regarding professional responsibilities.

Once construction is completed for Category 2 or 3 dams, the owner needs to obtain a licence to impound water (this is not required for Category 1 dams).

This includes the completion of an application form accompanied by a construction completion report and associated as-built drawings, an operation and maintenance manual, emergency preparedness plan and an affidavit from the owner stating that all residential areas and buildings in the dam basin have been vacated.

With regard to dam safety evaluations, the involvement of an APP and/or supporting professional team are similar to the other tasks (Category 2 dams only require an APP while Category 3 dams require an APP and supporting professional team). Depending on the category and the hazard potential, dam safety evaluations are required at intervals between 5 and 10 years (5 years for Category 3 dams and longer intervals for Category 2 dams).

The dam safety legislation and regulations clearly set out the steps required to satisfy dam safety practice, but within the legislation or regulations there are no specific norms or standards prescribed. The APP has the responsibility to determine appropriate standards for a particular dam and the legislation provides for a review of such standards by the DSO. The appropriate norms are considered to be current acceptable dam engineering practice for site-specific conditions. This is significantly different to a number of other countries in the world where specific norms and standards are applicable. There are, however, a number of guidelines available for use in South Africa including these on Dam Break Floods [9], Safety in Relation to Floods [10] and Freeboard for Dams [11].

Again, it is important to note that the legislation is as such that the owner/s of a dam is at all times responsible for the safety of their dam – South Africa's common law responsibility is applicable in addition to the dam safety responsibility. Included is the responsibility for the implementation of the recommendations of the dam safety evaluations by the owner. The DSO may instruct the owner to implement the recommendations. Failure of the DSO to give such an instruction does however not take the responsibility away from the owner.

2.3. WATER USE AND ENVIRONMENTAL LEGISLATION

In addition to the dam safety requirements of the National Water Act of 1998 [8], a dam owner is also required to satisfy the water use requirements of the act by applying for a water use licence when wanting to construct any new dam or increase the storage capacity of an existing dam (Section 21 of the Act). No construction work may be carried out before a water use licence or written authorization has been obtained from the DWS.

For so called "dirty water" dams (or dams for water containing waste), a dam owner must also comply with the Regulations on the "Use of Water for Mining and related Activities aimed at the protection of Water Resources" promulgated in 1999 [12].

A dam owner must also satisfy the provisions of the National Environmental Management Act and its accompanying regulations [13] with regards to activities which may have a detrimental effect on the environment (construction, enlargement, alteration, repair or decommissioning of a dam or storage of "dirty water" in most cases may be listed as such an activity). This normally requires an environmental impact assessment (EIA). One of the conditions of the water use licence is the environmental authorization. In other words, no listed activity at a dam may take place before receiving the necessary environmental authorization.

3. LESSONS LEARNT FROM LONG TERM IMPLEMENTATION OF DAM SAFETY LEGISLATION

According to the latest database of the DSO [14] a total number of 5 462 dams with a safety risk according to the Dam Safety Regulations were registered in South Africa at the end of February 2018 (see Table 4). The large majority of these dams (more than 75.3%) can be classified as small (less than 12 m high) while only 3.46% can be classified as high. The rest is classified as medium dams. When comparing the number of dams with the ICOLD definition of a small dam it is evident that there are 458 dams between 12 m high and 15 m high.

Table 4
General dam statistics (using the South African definition for height)

Height of dam (from the river bed level to the highest point of the dam) (m)	Number of dams
Less than 12 m	4 158
12 m to < 15 m	458
15 m to < 30 m	672
30 m and higher	174
Total	5 462

It is important to note that of the 5 462 dams registered, 5 434 dams have been classified by the DSO. Of these 5 434 dams, 57.3% are Category 1 dams that does not require any further regulatory actions other that registration and classification. The remaining classified dams consist of 36.3% Category 2 dams and 5.4% Category 3 dams - both Categories requiring the involvement of an APP and a supporting professional team (for Category 3 dams) and 0.9% dams that does not warrant a classification. In other words, a significant portion of small dams are classified as Category 2 dams due to their adverse hazard ratings.

Fig. 1 provides a graphical presentation of the number of dams registered as well as classified annually since the inception of dam safety regulations in 1986. As expected a large number of dams were registered within the first 5 years (2 632 dams in total). What is however interesting to note is that although the number of dams registered per year has decreased since, the number of annual registrations basically stayed constant since 2000. An increase is evident since 2012 – this could be attributed to the implementation of the revised dam safety regulations in 2012 with an increased focus of the so-called dirty water dams. It has taken another

27 years of dedicated registrations by the DSO to double the amount of registrations to the current 5 462 dams.

However, when considering classification, it is clearly evident from Fig. 1 that all the effort in the beginning was spent on the registration of dams and the classification of dams lagged significantly behind especially the first 2 years after implementation. So, in comparison only 1 692 dams were classified within the first 5 years. This lag was basically eliminated in 2012 with the implementation of the revised dam safety regulations in 2012 with an increased focus on the so-called dirty water dams as the lag was mostly made up of the so-called dirty water dams.

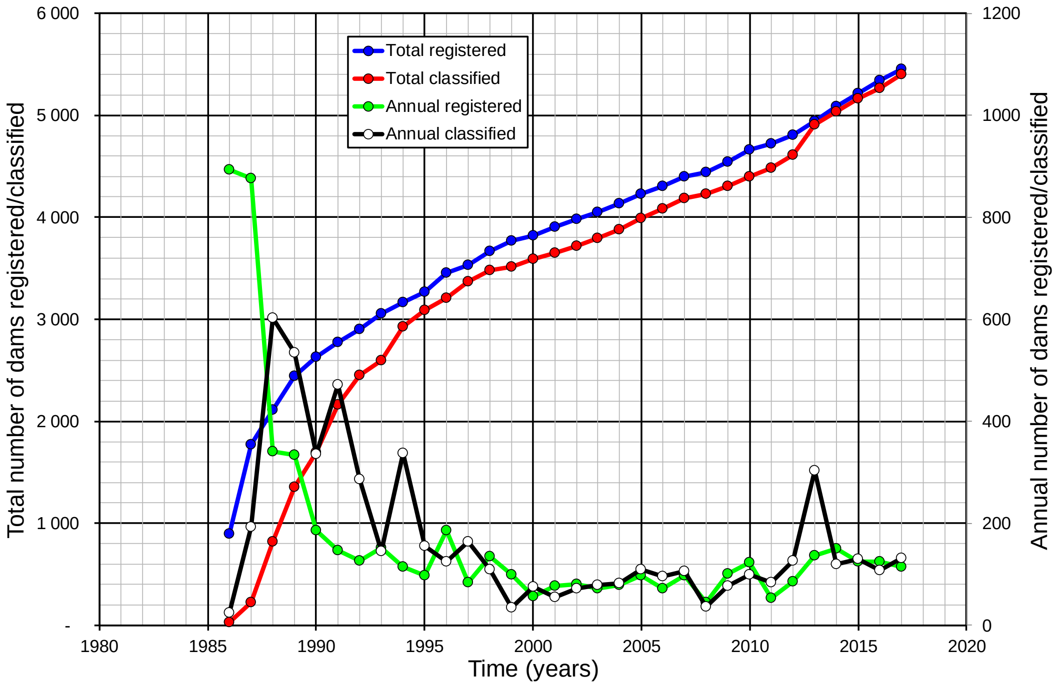

Fig. 1
Number of dams registered and classified since inception of dam safety regulations

Fig. 2 provides more detail on the distribution of completion dates of the dams registered during each year since the first implementation of dam safety legislation. It can therefore be concluded that to effectively implement a Dam Safety regulatory system takes time and effort even for the most basic things like registration and classification of a dam with a safety risk.

The building of dams in South Africa went through a boom period from the 1950's to the 1990's, peaking during the 1980's for both small as well as large dams. Since the 1990's the number of dams constructed has drastically reduced. One of the main reasons can be attributed to a change in the water related legislation in South Africa in 1998 [8]. The old system based on riparian rights changed to a system that recognizes water for the environment and for human consumption as a basic right. Authorization for all other water uses has to be obtained from the DWS acting as custodian of water resources and responsible for distributing water in an equitable manner.

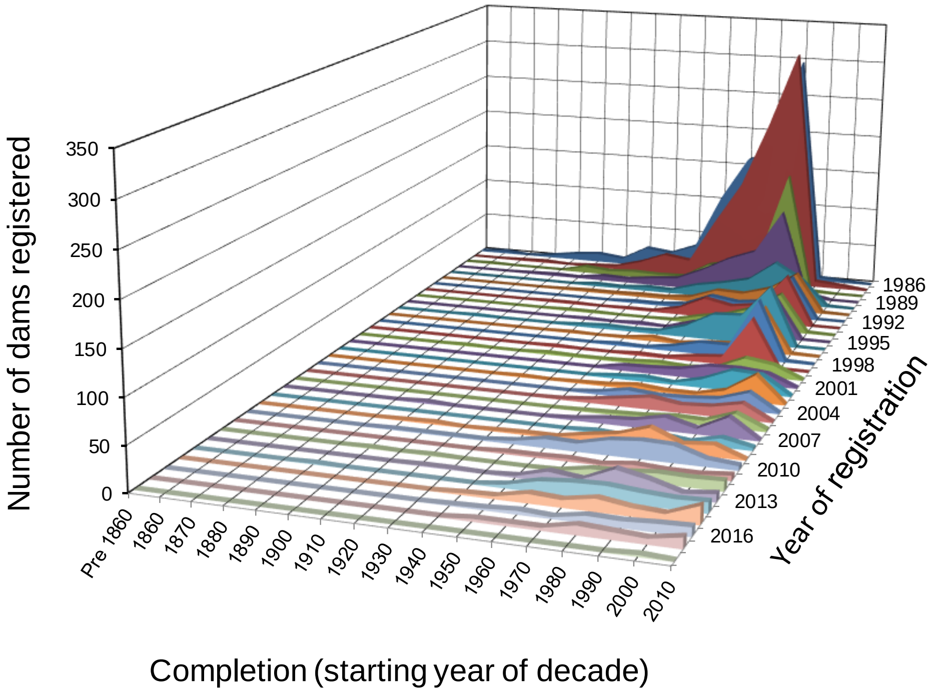

Fig. 2
Timeline of dams registered

So, where a land owner in an uncontrolled area could build a dam on his property up to 250 000m^3 without a licence before 1998, presently a licence is required taking into account the water resource situation in the relevant catchment as well as the possible redistribution of water resources. This process together with the scarce nature of the water resources in the majority of South African catchments has subsequently led to fewer dams being built during the last two decades (only 257 small dams were completed in the 2000s and 90 so far in the 2010s compared to a total of 1 303 dams completed during the 1980s). In many catchments the best dam sites have already been utilized and additional storage will not significantly increase the yield of the system.

Prior to the introduction of legislation on the safety of dams in the 1980s not a lot of attention was given to the recording of failures and incidents in South Africa. So much so that in an ICOLD publication on failures and incidents in 1973 [15], only 2 incidents at South African dams were described. Subsequent to the promulgation of the first dam safety regulations in 1986 and the formation of a “DSO” that acts as regulator, failures and/or incidents have been recorded in a “Catalogue of incidents” as part of the information system of the DSO. A number of publications were published with the majority focusing on failures and incidents of large dams. Hattingh and Oosthuizen published a paper in 2017 [16] that provides a summary of both large as well as small dams. The most important conclusions are as follows:

- With regards to large dams, only earthfill and tailings dams (no large concrete dams) have failed in South Africa. With regards to small dams, the large majority of failures are earthfill dams although some smaller concrete weir structures have also failed.
- Overtopping due to inadequate spillway discharge capacity as well as piping and internal erosion make up the large majority of causes of incidents at and failures of small dams

4. CONCLUDING REMARKS

From the lessons learnt from the implementation of dam safety legislation in South Africa the following is of importance:

- It is of prime importance to convince political decisions makers about the necessity for Dam Safety implementation including the necessary legislative and regulatory environment.
- It takes time and significant resources to successful implement a dam safety regulatory system – for example after more than 30 years existing dams are still being registered in South Africa. It also takes time and effort to classify the dams as well as establish regulatory compliance;
- Dam Safety legislation, enforced by dedicated and experienced officials (in the DSO), has a positive correlation with the decrease in the number of incidents and failures of dams built since promulgation of dam safety legislation in South Africa. This has also ensured the formal recording of incidents and failures. Not all incidents and failure of especially small dams are however reported to the DSO as required.

ACKNOWLEDGEMENTS

The authors wish to express their gratitude to all other present and past members of the Dam Safety Office as well as Sub-directorate Dam Safety Surveillance of the DWS that contributed in some or other way to the development of the above-mentioned paper.

SUMMARY

This paper not only summarize the history of Dam Safety implementation in South Africa from its earliest humble beginnings in the 1970s to the implementation of Dam Safety legislation in 1980s and the update of the relevant regulations in 2012 but also provide insight into the required regulatory processes during the lifespan of a dam.

A summary is provided of the lessons learnt in the implementation of the legislation including the positive influence of effective dam safety legislation and the fact that it takes time and significant resources to implement a dam safety regulatory system. It is also important to note that these lessons learnt were used to help some other African countries starting with the implementation of Dam Safety regulatory systems in their countries.

From the lessons learnt from the implementation of dam safety legislation in South Africa the following is of importance:

- It is of prime importance to convince political decisions makers about the necessity for Dam Safety implementation including the necessary legislative and regulatory environment.
- It takes time and significant resources to successful implement a dam safety regulatory system – for example after more than 30 years existing dams are still being registered in South Africa. It also takes time and effort to classify the dams as well as establish regulatory compliance;
- Dam Safety legislation, enforced by dedicated and experienced officials (in the DSO), has a positive correlation with the decrease in the number of incidents and failures of dams built since promulgation of dam safety legislation in South Africa. This has also ensured the formal recording of incidents and failures. Not all incidents and failure of especially small dams are however reported to the DSO as required.

1. INTRODUCTION

Asphalt concrete cores as central water barrier provide a cost-effective and highly flexible solution even for small and high embankment dams. The stress and deformation behaviour of such dams is completely different compared to other dam types like surface sealed, homogenous or zoned dams. Worldwide almost 200 asphalt concrete core embankment dams have been built or are under construction in different countries. There are now more than 50 years of successful experience for this dam type. Over the past decades comprehensive material research has been performed and new asphalt concrete placing equipment has been developed.

The comparatively thin asphalt concrete core must withstand the induced deformations of the dam shoulders and the water load without cracking or leaking. Even if an asphalt concrete core tolerates high deformations without structural damage, the understanding of the deformation behaviour of ACE dams is of basic importance. This paper presents fundamental aspects on the stress distribution and the deformation behaviour of ACE dams. Therefore, basic theoretical considerations and monitoring data on existing dams are compared with results of numerical analyses.

2. THEORY OF SHEAR ZONE DEVELOPMENT

Measurements of ACE dams [1][4][5][6] have shown that the deformation behaviour of those types of dams differs from the deformation behaviour of other dam structures. Since the measurements provide only fragmentary information about the overall behaviour of the dam, theoretical considerations are necessary to supplement the data in order to obtain a fundamental understanding about the ongoing effects in the dam. For a long time there have also been presumptions about the existence of shear zones in the dam body, however, general knowledge about the development and the effect on the stability was not theoretically explored in detail. The following chapter provides theoretical considerations about typical stress paths in ACED dams and the formation of shear zones.

When analysing the stress and deformation behaviour of dams, at least two significant load stages have to be considered: end of construction and first impounding. The loads acting on the core and the stress distribution in the dam body completely change when the dam is impounded which means that the dam material undergoes significant stress paths during the impounding as well as during the reservoir operation under fluctuating reservoir levels. Arising stress differences between upstream and downstream are compensated by deformations. The asphalt concrete core acts as a thin impervious and flexible membrane and transfers the horizontal water load to the supporting downstream dam shoulder. Since the core provides limited resistance to the applied horizontal loads, the AC tries to reach an equilibrium state, which can only be achieved by a horizontal deformation in order to mobilize the resistance of the downstream dam shoulders. The magnitude of horizontal deformation depends on the stiffness of the adjacent zones and on the shear strength of the shoulder material. As a result of the horizontal core deformation towards downstream, the horizontal stress in the upstream dam zone adjacent to the core significantly decreases.

For the upstream dam shoulders the stress paths can easily be visualised by a $\sigma - \tau$ diagram as depicted in Figure 1. For the end of construction, the stress state which is depicted by Mohr's circle is far off the Mohr-Coulomb failure line. Due to impounding and the buoyancy of the upstream shoulder material, σ_1 and σ_3 are reduced, whereby Mohr's circle is shifted, but does not reach the Mohr-Coulomb failure line. The horizontal deformation of the asphalt concrete core to the downstream side reduces the minor principal stress σ_3, $K'_0 = \sigma_3/\sigma_1$ decreases and the diameter of the Mohr circle increases until it reaches the Mohr-Coulomb failure line, activating a sliding wedge. The inclination of the sliding plane ψ and therefore the size of the mobilized wedge depends on the shear strength of the dam shoulder material and can be determined from the $\sigma - \tau$ diagram by Equation 1.

$$\psi = 45 + \varphi/2 \qquad [1]$$

The mobilized wedge closes the rising joint between the downstream dam shoulder and the deformed asphalt concrete core. The mobilization of a shear zone reduces the shear stress in the surrounded area and protects those zones against shear deformations.

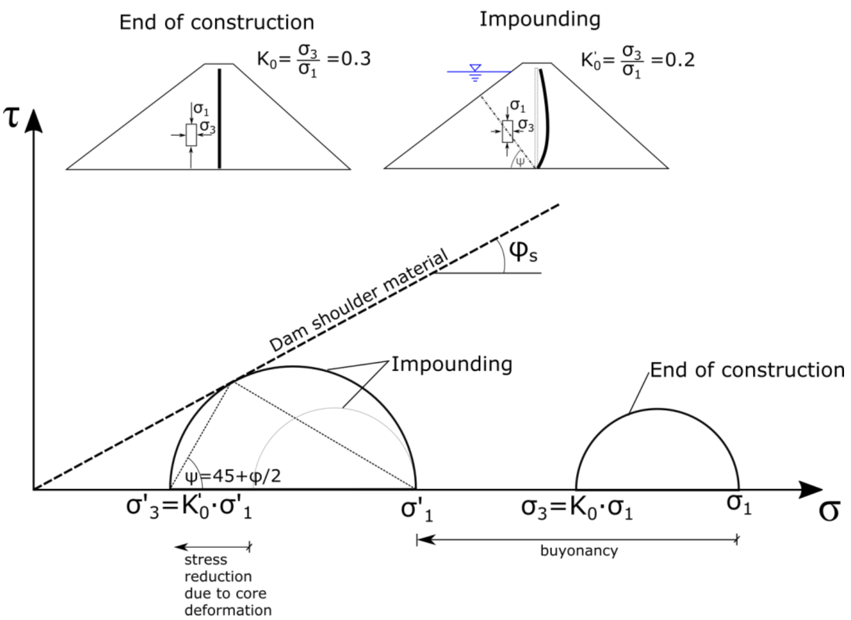

Fig. 1: Stress state in the upstream dam shoulder

At high reservoir levels, the water pressure acts on the core and provides the upstream horizontal support for the core. The horizontal water pressure on the water barrier leads to high horizontal stress in the core and in the adjacent zones downstream of the core. Since the asphalt concrete core material is impermeable, internal water pressures cannot develop and therefore the effective core stress is equivalent to the total stress upstream the core. Due to this high horizontal stresses during impoundment, the stress state in the core is almost isotropic ($\sigma_1 \sim \sigma_3$) and the Mohr´s circle is reduced and therefore in a stable stress state far off the failure line. The core and the shoulder are shifted downstream. When the reservoir level is lowered, the horizontal support of the core by the water pressure is lost and a sliding wedge which developed during the first impounding provides the necessary horizontal support to stabilize the core and the adjacent upstream "braking" zone. It can be seen from deformation measurements of asphalt concrete cores (see Chapter 3), that the back-deformation due to drawdown is only small compared to the initial deformation during impounding. Figure 2 shows the theoretical model of the mobilized sliding wedge for a vertical core and for an inclined core.

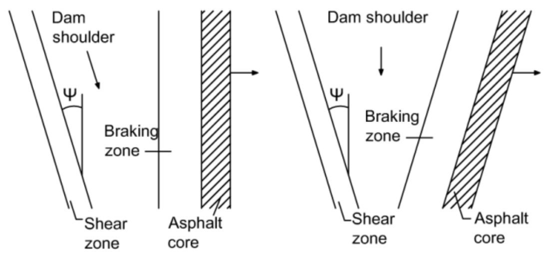

Fig. 2: Mobilization of sliding wedges for vertical (Feistritzbach Dam) and inclined AC core (Finstertal Dam)

During construction, the stress state of the asphalt concrete core depends on the stiffness of the core and the adjacent zones. It is of interest, how the additional shear stress due to the mobilization of the sliding wedge influences the stability of the core. Figure 3 depicts the situation in the core during impounding, when shear stress τ'' from the mobilization of the wedge superimposes a vertical stress state $\sigma'_1 = \sigma'_v$ and $\sigma'_3 = \sigma'_h$, leading to a rotation of the principal stress with the angle of β. σ''_1 and σ''_3 are the state of the principal stresses after rotation with τ''/z, the mobilization rate of the shear strength. The diagram clearly shows that even if high shear stresses burden the core, the rotation of the principal stresses only have little impact on the mobilization rate of the shear strength τ/z.

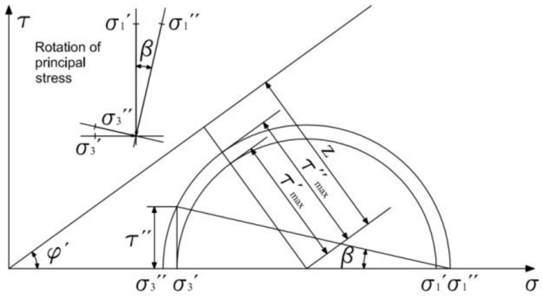

Fig. 3: Stress state in the core (σ_1', σ_3'), superimposed by shear stress τ'' from the mobilization of an upstream wedge

3. MEASUREMENTS

Different measurements on dams with central sealing membranes [1][4] showed some indications about the existence of shear zones in the upstream dam shoulder. In order to complete the theoretical considerations in Chapter 2, measurements of the 85 m high Feistritzbach Dam and the 155 m high Finstertal Dam (core height 96 m) are presented below.

The Feistritzbach Dam is situated in southern Austria and is designed with a 70 - 50 cm thick vertical asphalt concrete core, slightly inclined in the upper part. Particular tests were performed to examine the physical and mechanical properties of the asphalt concrete core material. In accordance with the design of the dam and the rockfill material properties, a softer bitumen and a less stiff mix were chosen. The tests on the asphalt concrete core material showed a soft behaviour for primary loading and a stiff response for unloading and reloading conditions. If the strain exceeded 5 to 6% (depending on the confining pressure), the material was dilative and the volume increased significantly. The failure criteria of the material was determined with φ' = 37°, c = 0 kN/m², ν = 0.25.

Due to partly servere weathered rockfill materials the settlements of the dam reached about 1.0% of the total dam height after first impounding. Despite large deformations, the dam has been operated for over 28 years and the asphalt concrete core behaves quite well and no leakage through the core was observed. The dam is well instrumented with horizontal and vertical inclinometers, as well as different settlement gauges and earth pressure cells etc. The measurement data provides a good example for the theoretical considerations discussed in Chapter 2.

(1) AC core; (2) filter; (3) fine-graded zone; (4) upstream and (5) downstream shell; (6) horizontal seepage section; (7) drainage toe; (8) grouting gallery; (9) grout curtain

Figure 5 shows the settlements of the dam for different stages. The magnitude of the construction settlements in the core was about 55 cm and increased up to 80 cm before the impounding started. The settlements after construction were distributed equally throughout the entire cross section of the dam. During first impounding, the settlements in the upstream dam shoulder increased up to 95 cm whereas the settlements downstream of the core only increased up to 87 cm. During impounding, almost no significant horizontal core deformations were observed until the reservoir level reached 2/3 of its maximum. Above, the horizontal core deformation amounts up to 10 cm to the downstream leading to a decreasing relative densitiy in the upstream adjacent zone.

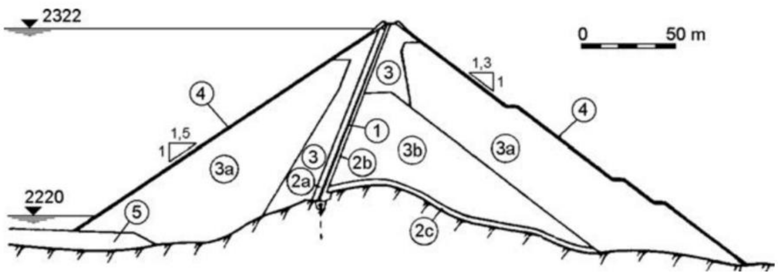
Fig. 5: Settlements of Feistritzbach Dam [5]

The largest rates of differential settlements were observed upstream in a distance of about 20 m to 25 m from the core. The section between this shear zone and the AC core showed only translatoric movements and no essential differential settlements were observed, which precludes additional saturation settlements. The results indicate that the shear zone was mobilized together with a sliding wedge deformation, closing the gap between the core and the adjacent upstream zone. After 12 years of reservoir operation the differential settlements between the upstream and downstream side of the core continuously increased up to approx. 36 cm and the maximum horizontal core displacements increased up to 13.5 cm.

The Finstertal Dam is a rockfill dam with an inclined asphalt concrete core and an asymmetric dam body. The plinth for the core is situated on a rock cusp and the foundation of the dam shoulders is inclined on both sides. Figure 6 depicts a typical cross section and the zoning of the dam. The asphalt concrete core with a total height of 96 m is inclined with 1H:4V. The width of the core is 70 cm at the bottom and 50 cm at the top. The core is located at a distance from the dam axis which means it is outside the area with the highest level of strain [7]. A filter and transition zone was designed on the upstream side of the core. Downstream, the core is supported by a drainage zone as well as a stiff zone with moraine (zone 3b) and rockfill (zone 3 and 3a) material.

The dam has a very extensive monitoring equipment with horizontal deformation gauges, vertical inclinometers, earth and pore water pressure cells, piezometers, extensometer, geodetic monitoring devices, perpendiculars, strong motion instruments, seepage collecting systems and three devices to measure a widening of the asphalt core on different elevations (5 m, 21 m and 40 m below storage level) [3].



(1)	Core	(3b)	Moraine
(2a)	Upstream filter layer	(4)	Protective lining
(2b,c)	Drainage zone	(5)	Moraine material
(3,3a)	Rockfill		

Fig. 6: Cross-section of Finstertal Dam [3].

In 1981 the AC core thickness devices indicated a widening of the core during the impounding. Figure 7 shows the differential displacements between the upstream filter zone and the downstream core surface at two different elevations (40 m and 5 m below the maximum reservoir level). At the beginning of the first impounding, the dam first behaves as anticipated but when the reservoir level almost reached its maximum, the core was shifted downstream for

12 – 14 cm over the entire height within a short period. The measurement data 5 m below the maximum reservoir level shows a differential horizontal displacement between the upstream filter zone and the downstream core surface of about 3 cm. The first drawdown leads to a back-deformation of the core to the upstream side of about 3 cm. For the reservoir operation until 1999, the measurements show a continuing enlargement of the differential settlements between upstream and downstream while the horizontal deformations remain almost constant. The horizontal deformation of the core between maximum reservoir level and drawdown is elastic with a differential deformation of about 4 cm.

It can be concluded that the deformations as shown in Figure 7 are parallel to the core and a widening of the asphalt concrete core can therefore be excluded. The Finstertal Dam has been successfully operated for 38 years and is consolidated without any problem of the asphalt concrete core.

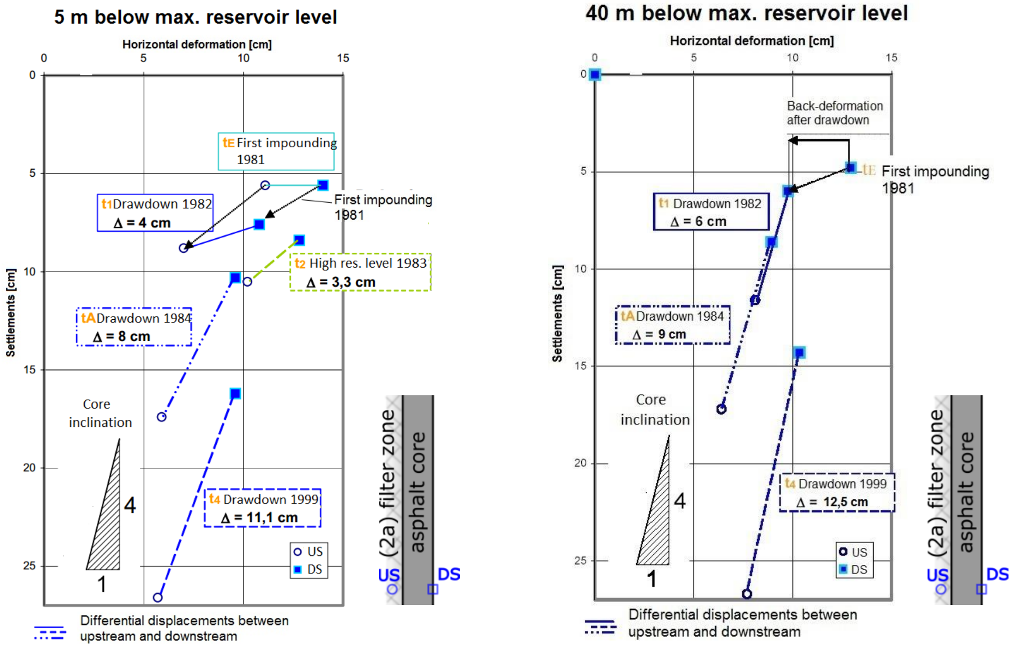


Fig. 7: Finstertal Dam – Absolute and differential displacements between the upstream filter zone and the downstream core surface

4. BEHAVIOUR OF AC DAMS BASED ON THE RESULTS OF NUMERICAL ANALYSES

For the contribution, a numerical simulation of a 128 m high ACRD (asphalt core rockfill dam) was carried out in order to show a typical behaviour of an asphalt concrete core rockfill dam during construction and impounding. Numerical analyses are a useful tool to provide a detailed picture about the stress and deformation behaviour of dams in order to improve the understanding and to verify theoretical considerations.

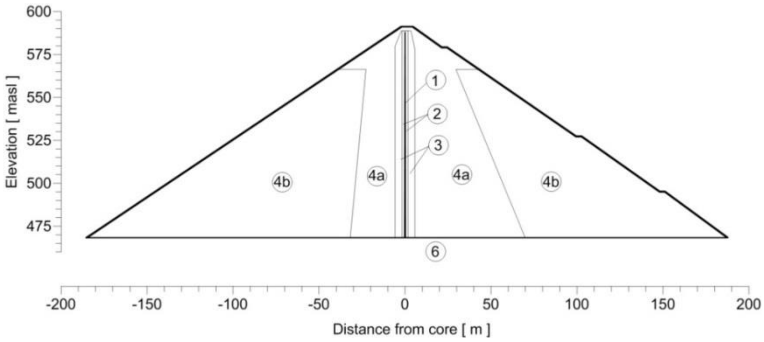

Fig. 8: Model and dam zoning

Figure 8 shows the zoning of the cross section of the dam which was used for the current simulation. The upstream dam slope is inclined with 1:1.5 (V:H) and the downstream slope with 1:1.4. The width of the vertical asphalt core is 95 cm at the bottom decreasing gradually to 50 cm, which is maintained for the top 50 meters. The foundation of the dam is assumed to be on stiff rock. The finite element program Plaxis 2D was used throughout this analysis. The simulations were carried out with a 2D-plane strain model. The non-linear, elastoplastic Hardening Soil Model was used for the numerical analysis. The stress dependency is modeled with three different stiffness moduli: E_{50}^{ref} for primary loading, $E_{\mathrm{oed}}^{\mathrm{ref}}$ for oedometric loading, $E_{\mathrm{ur}}^{\mathrm{ref}}$ for unloading and reloading and the parameter m for the amount of the stress dependency. For details on the numerical analysis and material parameters, reference is made to [6]. Table 1 shows the material parameters used in the study.

Figure 9 depicts the vertical stress distribution of the analysed dam for the end of construction and for the first impounding. It can be seen from the graphs that the stress distribution at the end of construction is depending on the material stiffness of the dam zones. Arching effects may arise at the end of construction due to the stiffness difference between the core and the adjacent zones, slightly reducing the vertical stress in the core. During impounding, the stress distribution in the dam significantly changes due to the rotation of the principal stresses and the buoyancy of the upstream dam shoulder. Arching effects originating from the dam construction mostly disappear.

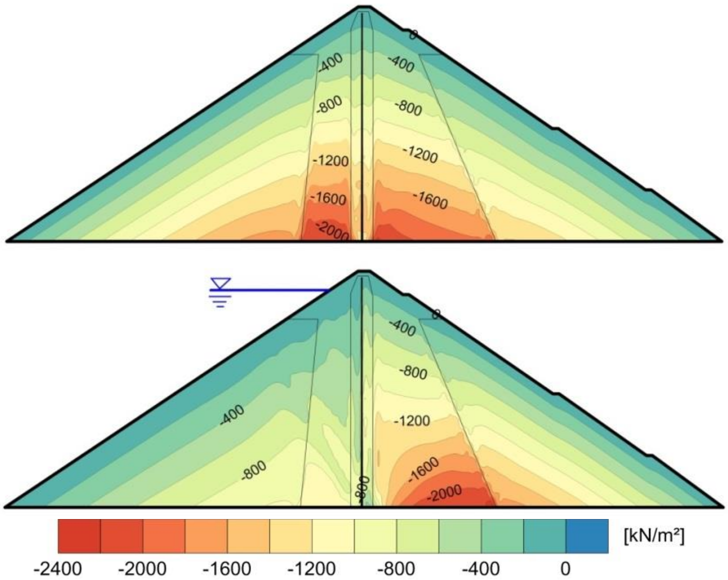

Fig. 9: Effective vertical stress at the end of construction and for impounding

Figure 10 shows the horizontal effective stress distribution during construction and impounding. At the end of construction, the graph shows a homogenous distribution. For the impounded state, the horizontal stress significantly changes in the bottom zones adjacent to the core. While the horizontal stress decreases in the upstream dam shoulder, high horizontal stress arises downstream close to the plinth.

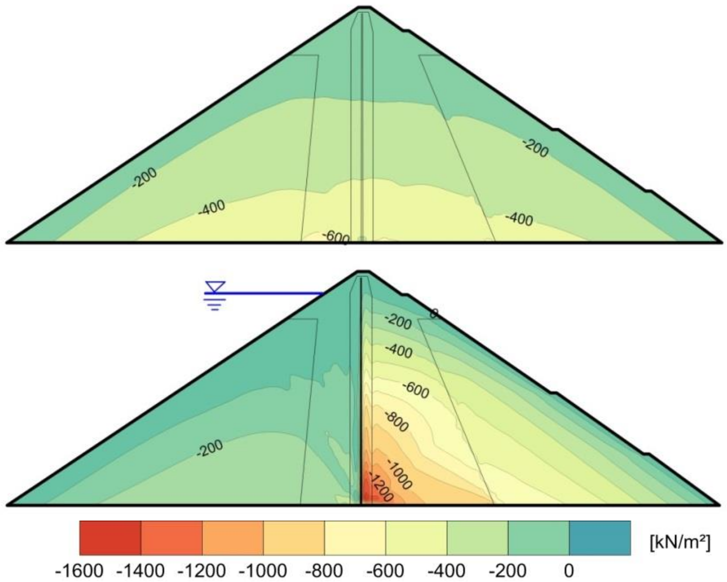

Fig. 10: Effective horizontal stress at the end of construction and for impounding

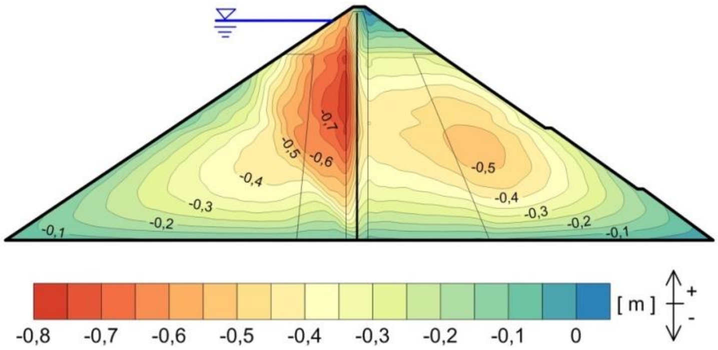

Fig. 11: Settlements after first impounding

The deformation behaviour of dams with a thin impervious central membrane is mainly governed by the dam zoning, material stiffness and shear strength as well as the dam foundation conditions (stiffness, surface inclination). Figure 11 shows the settlements of the analysed dam for the first impounding. Since the stiffness of the asphalt concrete core is generally lower than the stiffness of the adjacent zones, the settlements of the core are governed by adjacent dam zones. The graph shows that the settlements after impounding are concentrated upstream. Figure 12 depicts the horizontal deformations of the analysed dam. Due to impounding, the additional water load, acting on the core leads to a horizontal deformation of the core to the downstream side. The magnitude of those displacements depends on the resistance (stiffness and shear strength) of the downstream shoulder. The largest horizontal deformations occur in the upper part of the dam. The graph clearly shows the mobilization of a wedge in the upstream dam shoulder which is triggered by the downstream deformation of the core due to impounding.

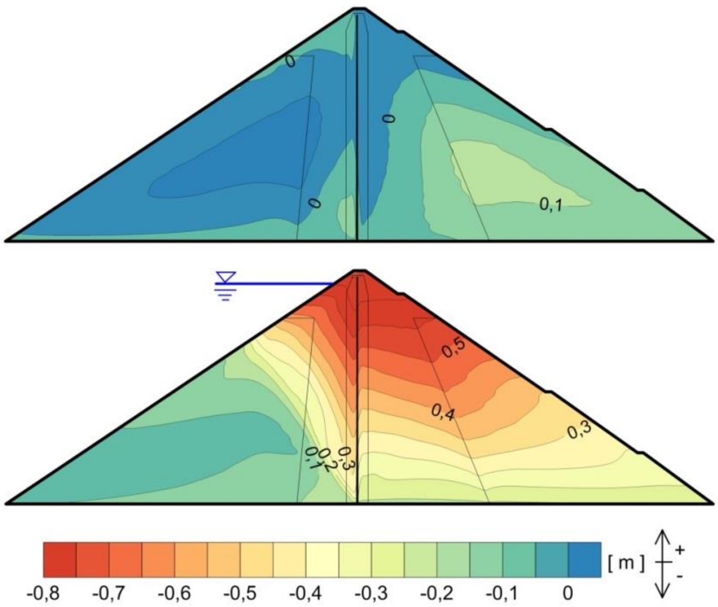

Fig. 12: Horizontal deformations: end of construction and first impounding

The shear strains after impounding are shown in Figure 13, illustrating the deformation characteristics of the dam and indicate the degree of mobilization in the upstream dam shoulder. It can be seen from the graph that the highest shear strains occur in the shear plane on the bottom of the wedge. The inclination ψ of the shear plane is around 60° which is in a good accordance with the theoretical considerations ($\psi = 45 + \varphi/2 = 67{,}5°$) presented above.

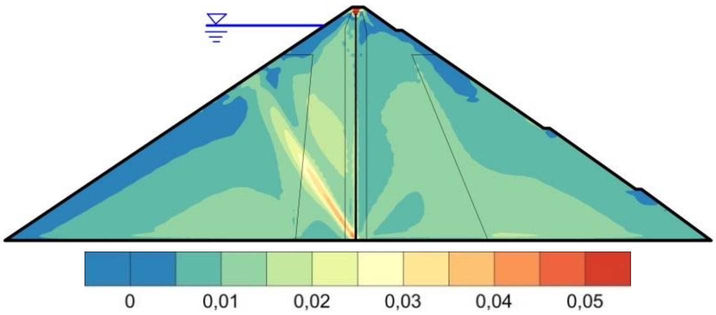

Fig. 13: Shear strains after impounding

SUMMARY

Dams with an asphalt concrete core show a different deformation behaviour compared to homogenous or surface sealed dams. In this contribution, theoretical considerations about the typical behaviour of AC dams during impounding are presented and discussed. It has been demonstrated that the core deformation during the first impounding leads to a mobilization of an upstream wedge. The mobilized wedge closes the joint between the core and the adjacent upstream zone. It also stabilizes the core when the reservoir level decreases and the horizontal support from the water pressure is lost. It has been also demonstrated that the rotation of the principal stresses in the asphalt concrete core, which arise as a result of additional shear stresses along the upstream core, have only little impact on the mobilization rate of the shear strength in the core.

Finally, the measurements of two different Austrian AC dams (Feistritzbach Dam and Finstertal Dam) are discussed in the contribution. The measurements of both dams confirm the theoretical results and showed the development of a shear zone in the upstream shoulder which stabilizes the core.

The results of intense numerical investigations on a typical AC dam are also presented and discussed. The analyses are in a good accordance with the measurements and the theoretical findings. The upstream wedge with the formed shear zone was also clearly evaluated in the numerical analyses.

The presented results and findings contribute to a better understanding of the deformation behaviour of AC dams.

EJECTOR POWER PLANT – VERTICAL KAPLAN

Rudolf FRITSCH

CEO of ZT Fritsch GmbH / CEO of Hydro-Construct GesmbH

AUSTRIA

1. INTRODUCTION

As a contribution to the transition from fossil to renewable energy sources, we need to focus also on power generation from small scale Hydropower plants. The key objective should be to maximize the exploitation of hydro power and one solution in this regard is the utilization of the ejector effect in low head schemes.

A research project was carried out by ZT-Fritsch GmbH / Steyr in collaboration with the Institute HFM (Prof. Dr. Jaberg) - Graz University of Technology in 2013 – 2016.

From this research, and from the appended dissertation on the subject, authored by DI Rudolf Fritsch, scientifically based dimensioning norms for specialized ejector plants in different conditions have been determined.

2. HISTORICAL OVERVIEW

The historical development of ejector power plants goes back to the early 20th century. The first experimental investigations took place in 1905. Mosonyi [1] cites Herschel as having applied special solutions as early as 1909. There were three main types of construction here.

- excess discharge is jetted into the draft tube through the ejector channel
- excess discharge is released through overfall spillways around the draft tube
- excess discharge is released through spillway chute over the draft tube

The heyday for ejector power plants was the 1930s. Especially in the Soviet Union, but also in Europe and the United States, plants of various kinds were planned and built (Hodenpyl power station USA, Kembs power plant on the Rhine, and Alcona power station USA). Hydropower plants utilizing the ejector effect to reduce the loss of drop height in flood conditions by lowering the water level in the tail race were examined in greater detail, for example, in the early 1950s on the basis of built facilities in the then Soviet Union [2].

3. PRINCIPLE OF OPERATION - CURVED DRAFT TUBE

This special concrete hydropower ejector system in a run off river hydropower layout is equipped with a vertical kaplan turbine and a laterally displaced suction tube (Fig. 1), curved in the plan view. This leads to downstream under a special spillway chute, the so-called ejector ramp. In case of excess water, the ejector ramp is activated by opening an ejector gate at the upper side of the ramp. Downside the ramp the energy of the access flow helps to lower the pressure in area of suction tube outlet and so to increase the useable head for the vertical Kaplan Turbine. The annual energy production can be significantly increased by the use of the hydraulic potential.

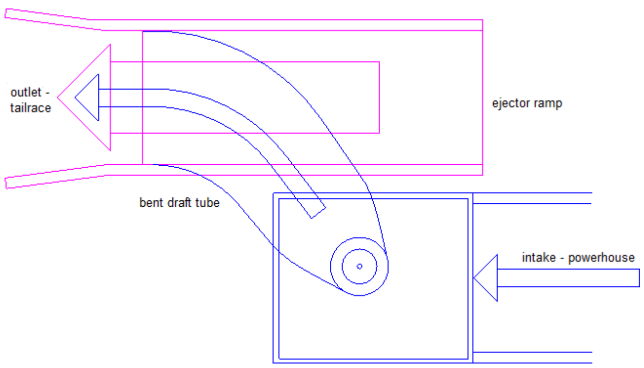

Fig. 1
Situation of the curved draft tube and the ejector ramp in plan view

The goal should therefore be to accelerate the surplus water volume as much as possible in order to achieve a high momentum in the tail race. This increases the suction or creates a lower pressure at the draft tube outlet end and keeps the point of energy conversion as far away as possible from the outlet (Fig. 2), in order to maximize efficient confluence of the two streams.

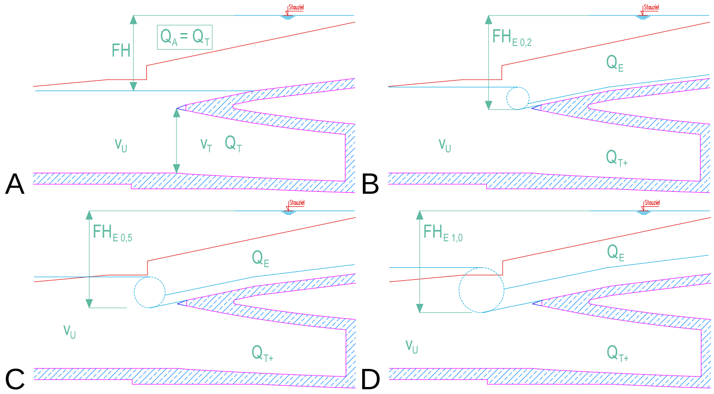

Fig. 2
Principle and effect of the ejector flow

The change in head out of stepwise increased ejector ramp flow is shown in Fig. 2:

A) Situation without ejector, where Q_T represents the turbine design flow

B) Flood conditions, ejector operational, increase of the tail race water level

C), D) Augmented flood condition, showing the shift of hydraulic surge downstream, increasing the useable head

As a result of the momentum, it's clear to see the lowering of the tailrace water level at the draft tube outlet of the turbine, accompanied by an increase in the energy generating head, turbine flow and performance.

A positive side effect of this special draft tube duct under the spillway or ejector ramp, is the elimination of sedimentation problems when flooding occurs. With regard to the operational safety of the plant, safe operation can be ensured even in the event of heavy surplus water or flooding, which nowadays leads to many power plants having to be disconnected from the grid.

As described in Fig. 3 and Fig. 4 the main components of a typical ejector power plant are:

(1) vertical Kaplan Turbine
(2) curved suction tube
(3) intake with horizontal screen
(4) ejector gate
(5) ejector ramp
(6) turbine outlet

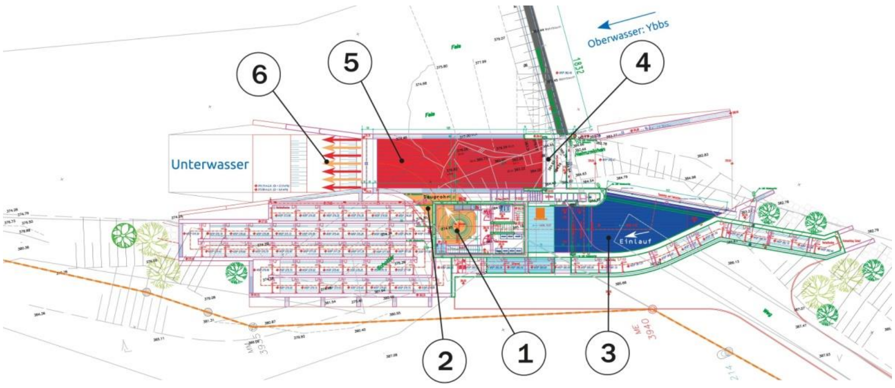

Fig. 3
Plan view of a typical ejector power plant

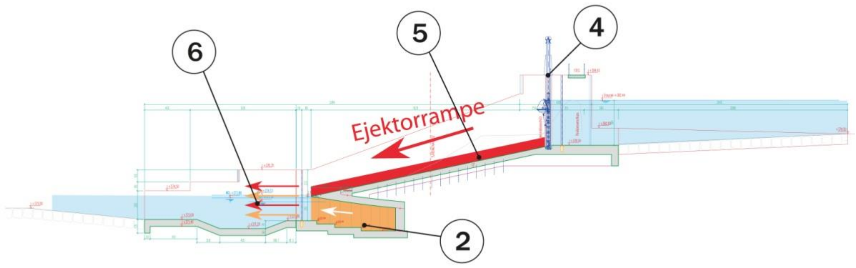

Fig. 4
Section of ejector ramp

Fig. 5
Curved draft tube – example pilotproject KW Stadtwehr Waidhofen / Ybbs

Care must be taken to maintain constant contours throughout the length of the draft tube in order to render negligible any curvature loss.

Fig. 6
Waidhofen Power Station: ejector flow at the end of the ejector ramp (mixing zone)

A striking drop in water level at the convergence point of the two water streams, where the ramp water mixes with the turbine flow from the draft tube is shown in Fig. 6.

Fig. 7
Ejector ramp flow – Waidhofen Power Station

The ejector flow, regulated at the ejector gate, is accelerated on the ejector ramp and displaces the tail race water body, creating a clearly visible roller wave (Fig. 7).

4. FIELD OF EFFICIENT USE

In low head hydro electric power plants the useable energy height (head) ratios are highly dependent on the runoff conditions within the body of water.

As a rule, the design of the turbine is geared towards the average water flow, in order to ensure optimum operational efficiency of the plant over the longest possible time span.

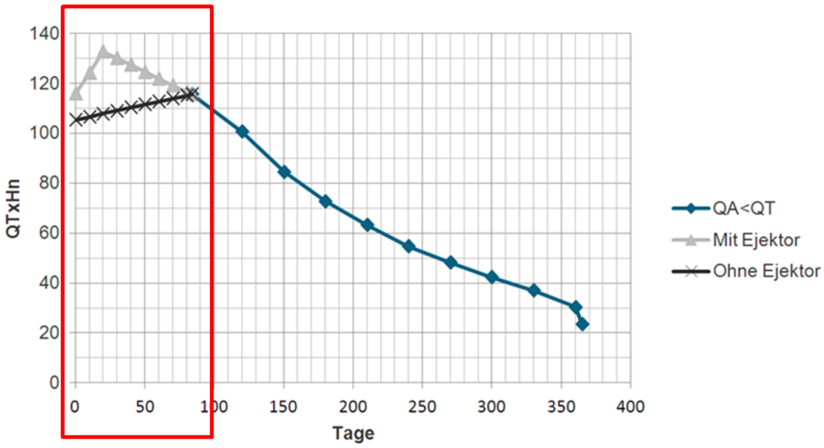

Fig. 8
The hydraulic performance is based on flow duration

The scope of ejector efficiency is limited by full load conditions, where surplus water is present.

5. SCIENTIFIC AND RESEARCH BACKGROUND

In 2013 a scientific research project was started by ZT-Fritsch GmbH in collaboration with TU Graz – Institute HFM (Prof. Dr. Jaberg).

1.1. EXPERIMENTAL INVESTIGATION

In order to achieve an experimental investigation close to reality the substantial parts of the reference power plant WAIDHOFEN were replicated using a scale model (M = 1:10).

The three dimensional CAD-model of the designed test rig is shown in Fig. 9. The water delivered by the main pump of the test rig enters the open headwater tank (2) via the inlet pipe (1). With the help of the turbine pipe section (3) a part of the water Q_{Tu} is directed to the draft tube of the turbine (4). The other part of the water flow Q_{Ej} is regulated by an ejector gate (6) and runs in the ejector chute (5) to the mixing zone (7).

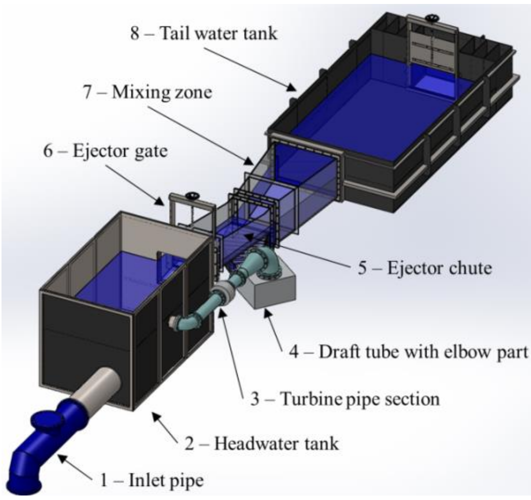

Fig. 9
Three-dimensional view of the CAD-model of the ejector test rig [4]

One of the results of the experimental model is shown in the diagram below (Fig. 10), namely the increase of available hydraulic power due to the ejector effect detected in the course of the measurement program.

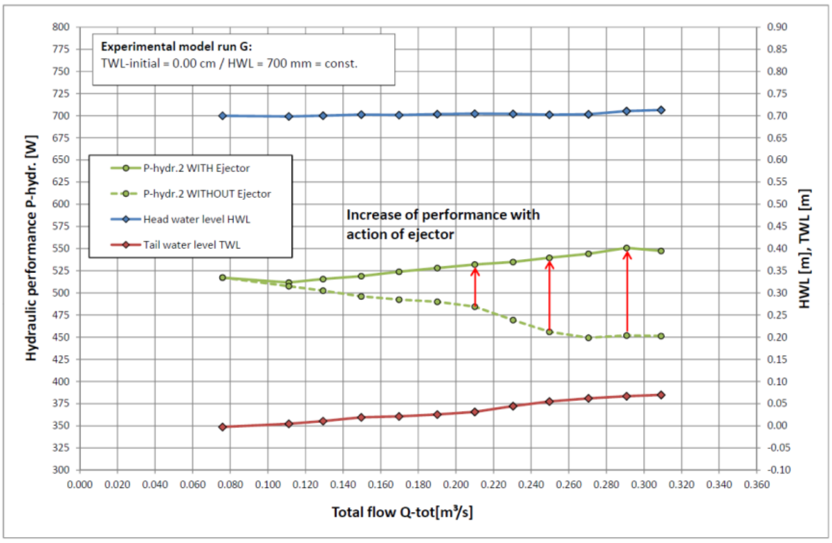

Fig. 10
Experimental model – hydraulic performance with and without ejector [3]

At the operation point with the highest flow rate the hydraulic power available for the turbine is still around 22 % higher than compared to the situation without ejector.

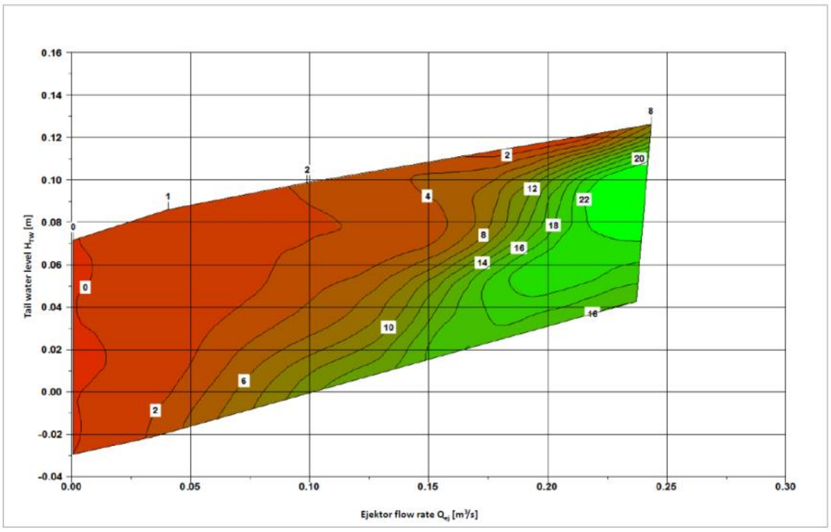

Fig. 11
Contour plot of the percentage of the increased power output due to the ejector effect valid for the experimental model run G

In order to verify whether the increase of the available hydraulic power is reached by an increased turbine head or an increased turbine flow rate the diagram below provides a more detailed analysis of the measurement results. The diagram presents the turbine flow rate Q_{Tu} and the turbine head HTU plotted against the total flowrate Q for the situation with and without ejector.

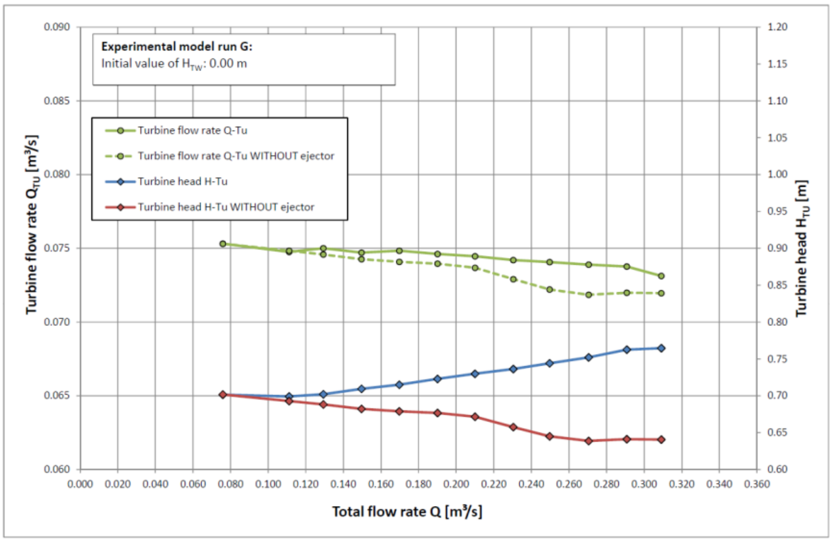

Fig. 12
Turbine flow rate and turbine head measured with and without ejector

It turns out that the ejector effect does not only cause an increase of the turbine head H_{Tu} but also of the turbine flow rate Q_{Tu} which is – though decreasing – higher than the “normal” turbine flow rate. This is due to a suction effect closely connected with the reduction of the tail water level at the draft tube outlet.

1.2. PILOT PROJECTS – MEASUREMENT

At the same time, in our first two ejector pilot projects at hydropower stations KW Mühltalwehr and KW Stadtwehr Waidhofen, measurement instruments were installed to show the efficiency of ejector technology.

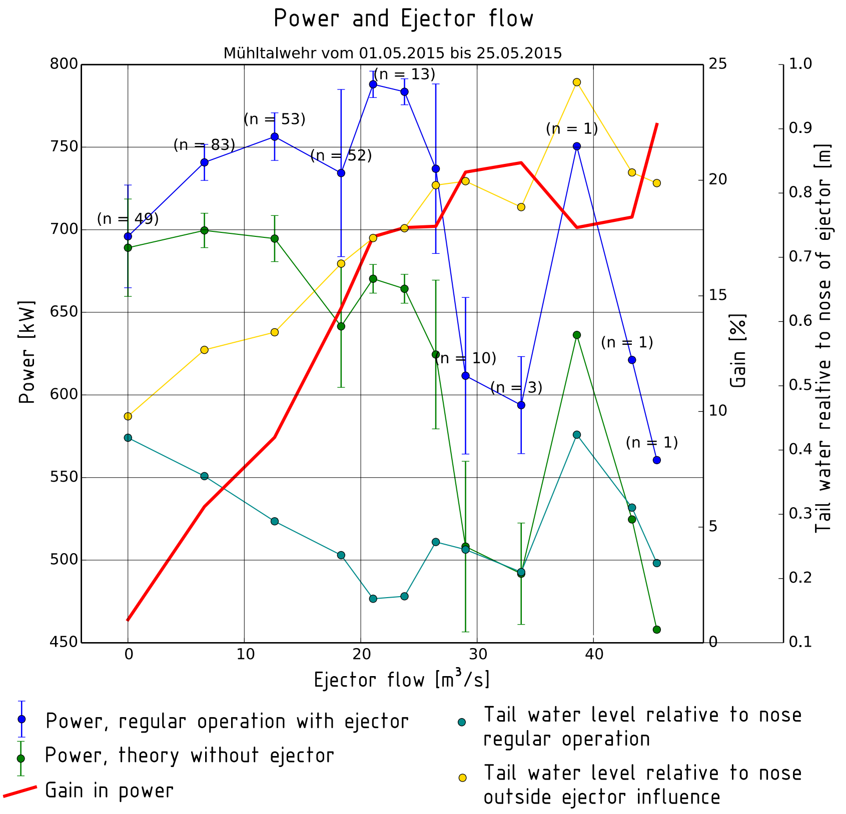

Fig. 13
Documentation main values – May 2015 / KW Mühltalwehr/Alm [3]

In the diagram above (Fig. 13) the gain in power, the power with ejector, without ejector and also the upstream and downstream level are documented.

1.3. CFD ANALYSIS

Numerical computation was also carried out to verify the experimental model testing with CFD-analysis.

Distinct water waves appear in the tail water especially in the region around the draft tube outlet.

The flow rate dependent change of the wave structure in the tail water is presented by the following Figure.

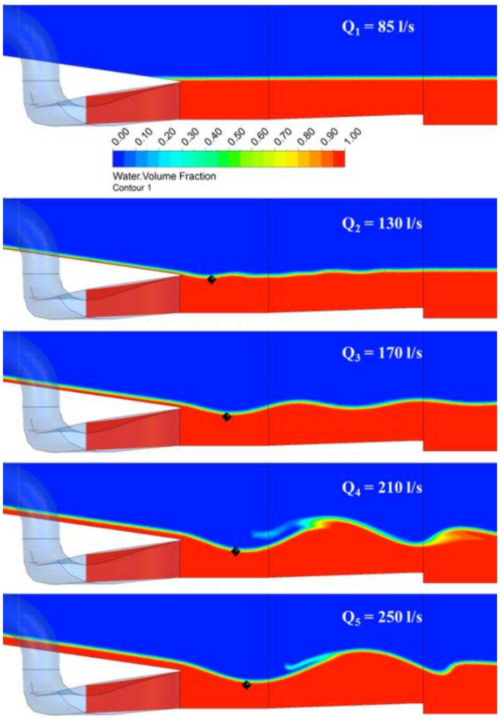

Fig. 14
Water Volume Fraction plotted on a cross sectional area for
Q_1 = 87.5 to Q_5 = 250 l/s [4]

On the one hand it turns out that the ejector is capable of increasing the hydraulic power available at the turbine by a maximum of 18 %. On the other hand an analysis of the presented data shows that the positive effect of the ejector does not only depend on the ejector flow rate but also on the tail water level with respect to the level of the ejector nozzle. If the tail water level is too high even a comparably high ejector flow rate does not cause an increase of power output.

6. SIGNIFICANT COMPONENT – EJECTOR GATE

The purpose of the ejector gate is to regulate the dam level at times of floodwater and to lend the highest possible speed to the water emerging onto the ramp by means of a continuously graduated opening of the ejector gate relative to the available water flow.

With a given outflow speed of theoretically $v_1 = \mu\sqrt{2gh_a}$ below the gate, the goal must be to achieve loss reduction via an appropriate shaping of the gate to create a jet effect.

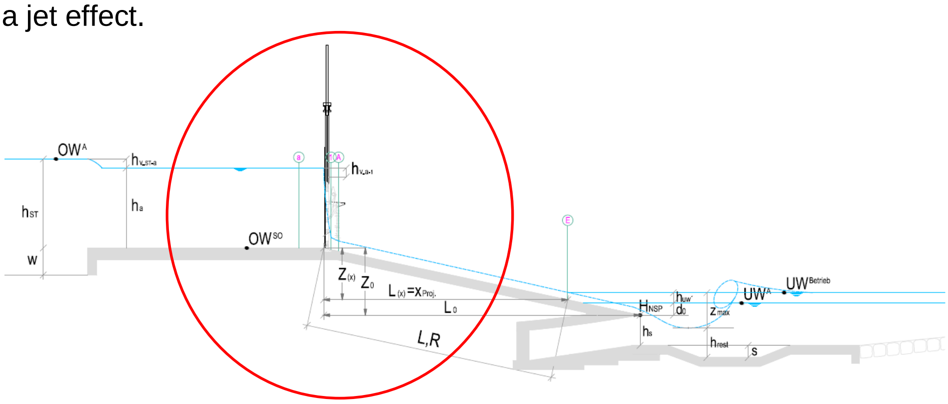

Fig. 15
Location if the ejector gate [3]

The above section (Fig. 15) shows the location of the ejector gate, between ejector channel and ejector ramp. An ejector gate with innovative rounded bottom end in line of the gradient, resulting from our research project, is shown in the section below.

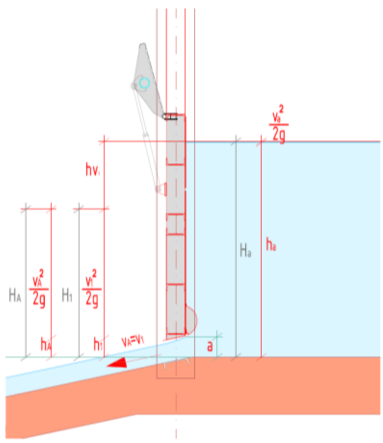

Fig. 16
Detail – ejector gate with rounded bottom end [3]

In our special design the gate is located immediately below the start of the ramp gradient. This gives the added advantage of increased outflow speed with loss prevention by removing the previously present break at the transition to the ramp and avoiding fill surge.

Fig. 17
Fully opened ejector gate – situation at pilot project KW Mühltalwehr / Alm

Extensive software for the calculation and dimensioning of ejector power plants was produced by DI Rudolf Fritsch [3].

For the retroactive calculation from the model conditions, the following velocity curves of v_1 are shown in Fig. 18, with variable Q_E, directly at the ejector gate before entering the ejector ramp.

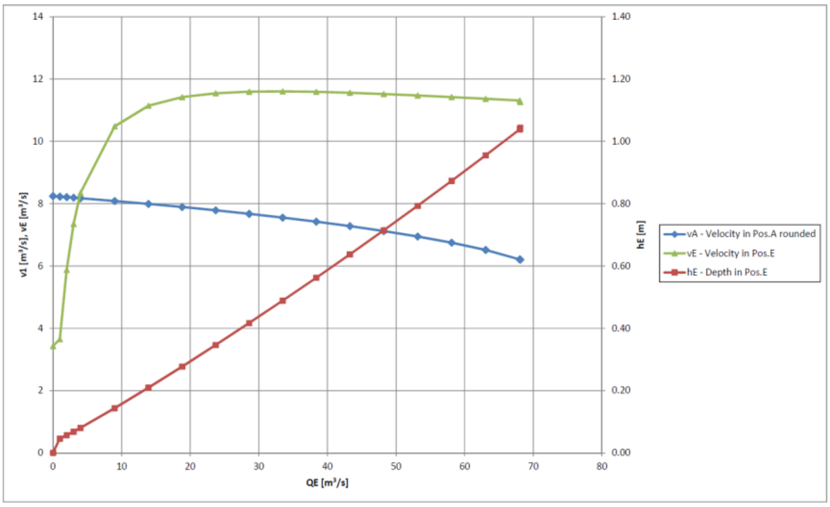

Fig. 18
Example of the typical relation of flow speed (v_E) and height of water on an ejector ramp end to the flow speed (v_A) at the ejector gate [3]

7. GENERATOR OF MOMENTUM – EJECTOR RAMP

A key feature of this installation is the ejector ramp (Fig. 19), whose purpose is to optimize the acceleration of the excess flow.

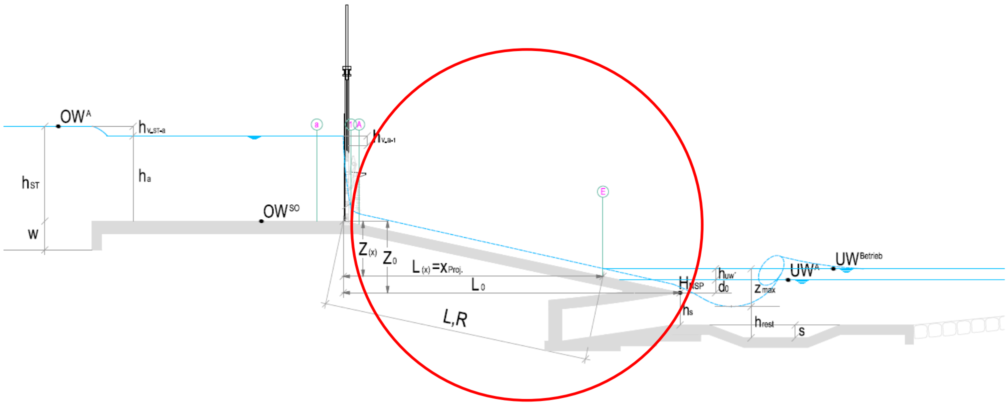

Fig. 19
Section through the ramp with transition to the mixing zone [3]

The spillway and ejector ramp in KW Mühltalwehr is covered with steel plates to reduce losses to a minimum and to avoid erosion.

Ejector ramps are essentially gravity flow tailraces. For tailraces of this kind, the flow conditions for irregular movement can be calculated using the Strickler method.

$$v = k_{St} \cdot R^{2/3} \cdot J^{1/2} \qquad [1]$$

Fig. 20
Ejector ramp – KW Mühltalwehr/Alm with steel covering

Surface Roughness of the ramp

When constructing the ramp, attention must be paid to minimizing surface roughness along a sufficient length and gradation.

An approach to the calculation of the energy equation for run off on the ramp, taking account of losses due to roughness, is as follows:

$$H_A = H_E \quad [2]$$

$$H_{A,0} + Z(x) = H_{E0} + h_v \quad [3]$$

$$H_{A,0} + Z(x) = h_E + \frac{v_E^2}{2 \cdot g} + \frac{v_m^2 \cdot \Delta X}{K_{ST}^2 \cdot R_h^{4/3}} = \frac{Q}{v_E \cdot b} + \frac{v_E^2}{2 \cdot g} + \frac{v_m^2 \cdot \Delta X}{K_{ST}^2 \cdot R_h^{4/3}} \quad [4]$$

Optimal conditions (for example k_{St} = Strickler values) are to be specified in this development project.

Table 1
List of different materials and roughness values are as follows

Material	**Strickler-factor k_{St} in $m^{1/3}/s$**
sheet steel	100
skimmed concrete	85
preformed concrete	80
wood	75
rough concrete	50

As can be demonstrated when considering the design of the ramp of an ejector power plant, the main criterion is the reduction of the roughness to a minimum (for example by utilizing sheet steel plate).

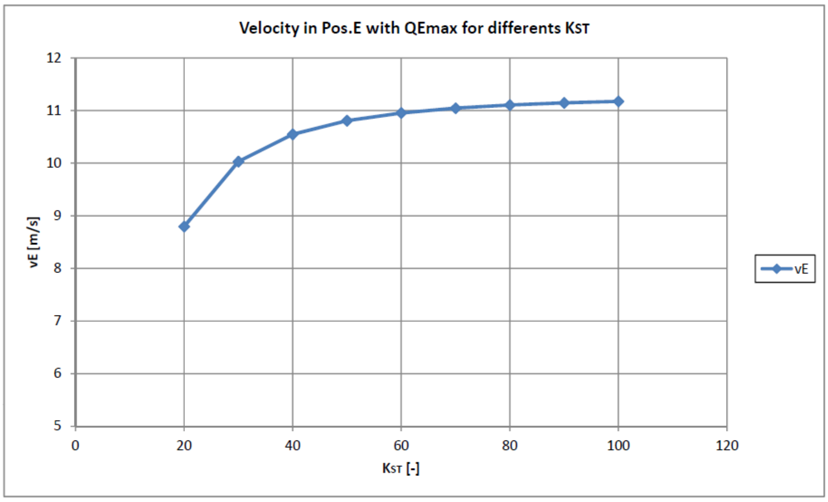

Fig. 21
Water flow speed at the end of the ejector ramp in relation to the roughness [3]

8. ENERGY CONVERSION – MIXING ZONE

Here the core principle of increased head achieved by the ejector comes into play. The analytic approach is based on the equation of energy and the law of momentum

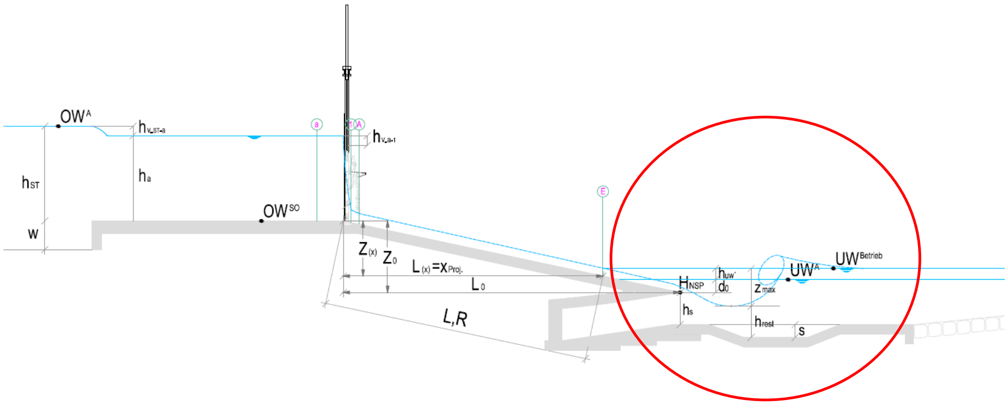

Fig. 22
Section of the ramp with mixing zone [3]

The above scheme (Fig. 22) shows the special configured mixing zone for energy conversion with head increasing effect.

Starting from the energy level, available at the end of the ramp, out of the momentum

Pulse current (I_E) = mass flow $(\rho \cdot Q_E)$ · velocity vector (v_E)

a power transmission occurs to the existing tailrace water with the water flow from the turbine draft tube.

In this application it is important to utilize the acceleration effect on the ramp, or in other words to further accelerate the volume of water entering the sluice by minimizing surface roughness on the ramp until the water is reunited with the head race water.

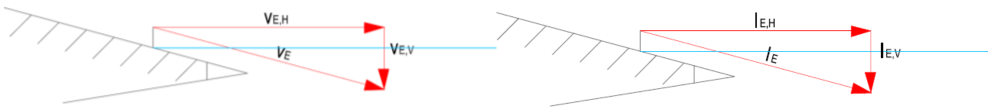

Fig. 23
Influence of ramp gradient [3]

The above sketches (Fig. 23) show the speed and momentum components on the end of the ejector ramp, linked to the gradient.

Analytic modelling

At the point of convergence at the end of draft tube the momentum relationships can be written with the equation of momentum, reduced by the pressure component.

$$\mathrm{I_E} = \sum\left(\mathrm{m}\cdot\frac{\overrightarrow{\mathrm{dv}}}{\mathrm{dt}}\right) = \sum \rho\cdot \mathrm{Q}\cdot\vec{\mathrm{v}} = \rho\cdot\mathrm{Q}\cdot\mathrm{v_E} \qquad [5]$$

$$\sum \rho\cdot\mathrm{Q}\cdot\vec{\mathrm{v}} = \sum P\,\Delta t \qquad \sum P\,\Delta t = 0 \qquad [6]$$

$$\rho\cdot\mathrm{Q_T}\cdot\mathrm{v_T} + \rho\cdot\mathrm{Q_E}\cdot\mathrm{v_{E,H}} = \rho\cdot(\mathrm{Q_T}+\mathrm{Q_E})\cdot\mathrm{v_{comb}} \qquad [7]$$

On the basis of the research project, we determined a factor for the effect of the ejector in our calculation approach, which takes into account the difference between the optically visible water level at the decisive confluence point and the actually effective pressure level in the draft tube.

This factor is linked to the momentum component of the ejector flow, as the determining parameter for the gain in head.

The equation of momentum linked to the energy equation can now be written as:

$$\rho\cdot\mathrm{Q_E}\cdot\mathrm{v_{E,H}}\cdot\mathbf{f_{VE}} + \rho\cdot\mathrm{Q}\cdot\mathrm{v_T} = \rho\cdot(\mathrm{Q_E}+\mathrm{Q_T})\cdot\mathrm{v_{eff}} \qquad [8]$$

The significant result is the useable speed of the mixed flows $(\mathrm{v_{eff}})$ of turbine and ejector:

$$\mathrm{v_{eff}} = \frac{\mathrm{Q_E}\cdot\mathrm{v_{E,H}}\cdot\mathbf{f_{VE}}+\mathrm{Q_T}\cdot\mathrm{v_T}}{\mathrm{Q_E}+\mathrm{Q_T}} \qquad [9]$$

The result for the velocity of the mixed flows $(\mathrm{v_{eff}})$ out of the equation of momentum can be also directly linked to the equation of energy at the confluence point (Fig. 24).

$$h_{UW,B} + \frac{\mathrm{v_{T,B}}^2}{2\,\mathrm{g}} = h_{UW,eff} + \frac{\mathrm{v_{eff}}^2}{2\mathrm{g}} \qquad [10]$$

$$\mathrm{z_H} = h_{UW,B} - h_{UW,eff} \qquad [11]$$

$\mathrm{z_H}$ ... gain in net head

$$\mathrm{z_H} = \frac{\mathrm{v_{eff}}^2}{2\mathrm{g}} - \frac{\mathrm{v_{T,B}}^2}{2\,\mathrm{g}} \qquad [12]$$

The energy related conditions of the convergence point are projected into the confluence point.

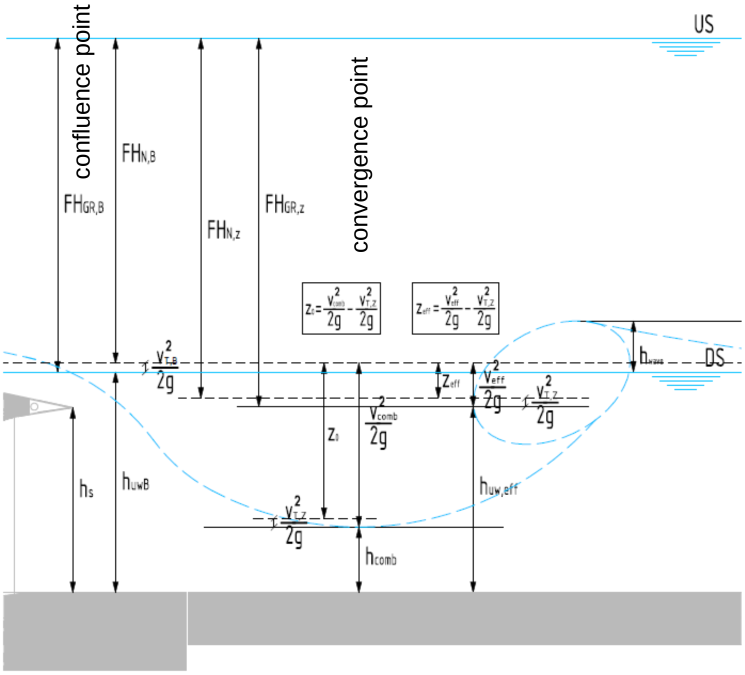

Fig. 24
Energy heights scheme in the mixing zone [3]

A lowering of the water level pressure occurs, together with suction back into the draft tube.

This momentum and consequently the influence on the ejector's effectiveness in increasing drop height can be illustrated in two component parts also, according to influence of the ramp gradient.

$$z = z_H + z_V \qquad [13]$$

Conditions at confluence zone

The design of the draft tube discharge or mixing zone is of great significance for the effectiveness of the ejector. The research project results in a special surface design at bed level optimizing the head increasing effect.

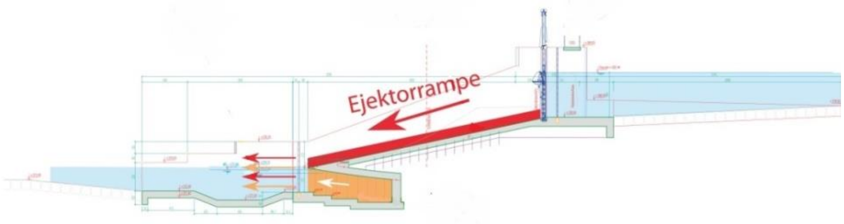

Fig. 25
Section through ejector ramp with the deepened mixing area [3]

The suction effect at the point of confluence, or the point where the ejector exhaust water with higher speed mixes with the slower turbine flow, can of course only take place if the top side of the draft tube is not too severely backed up.

The influence of the draft tube outlet top level is very clearly represented in the results of the model experiment and thus represents a significant boundary condition. The goal should therefore be to determine the underwater conditions very accurately, so that on the one hand during normal to full load operation no risk of air intake to the turbine occurs, but on the other hand water backup remains reduced during ejector operation.

The great importance of the way in which the ejector water and the head race water are brought together is to be seen definitively in the lateral contraction effect we observed in modelling exercise. Increased efficiency from the ejector effect can only be optimized when the water flow from the ejector ramp into the tailrace enables maximum transfer of the energy from the ejector water to the head race water.

The design of the mixing zone which we devised, tested and submitted for patent in this project, ensures an efficient confluence of the two flows and prevents the lateral contraction phenomenon we observed in the test series.

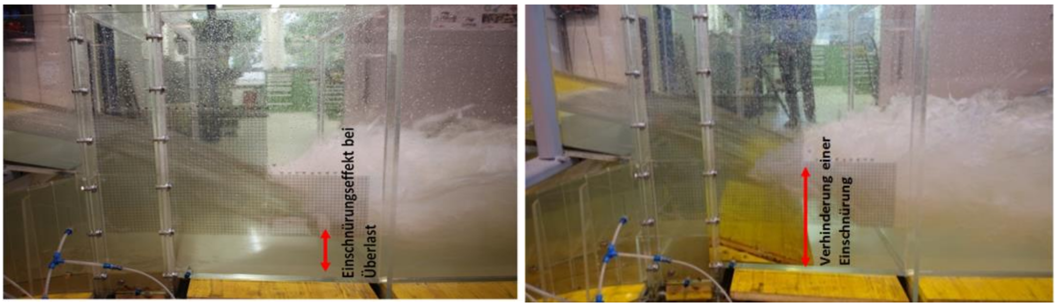

Fig. 26
Pictures with flat bed level in the mixing area in comparison to deepened bed level, show the importance of avoiding a constricting effect, which reduces the positive ejector effect considerably [3].

9. ENERGY PRODUCTION VALUATION

The following chart outlines the results of a comparative study undertaken on the outflows at Gaissulz on Ybbs, taking different heads into account. The key result, in relation to the percentage increase in energy production is, that relative output remains constant.

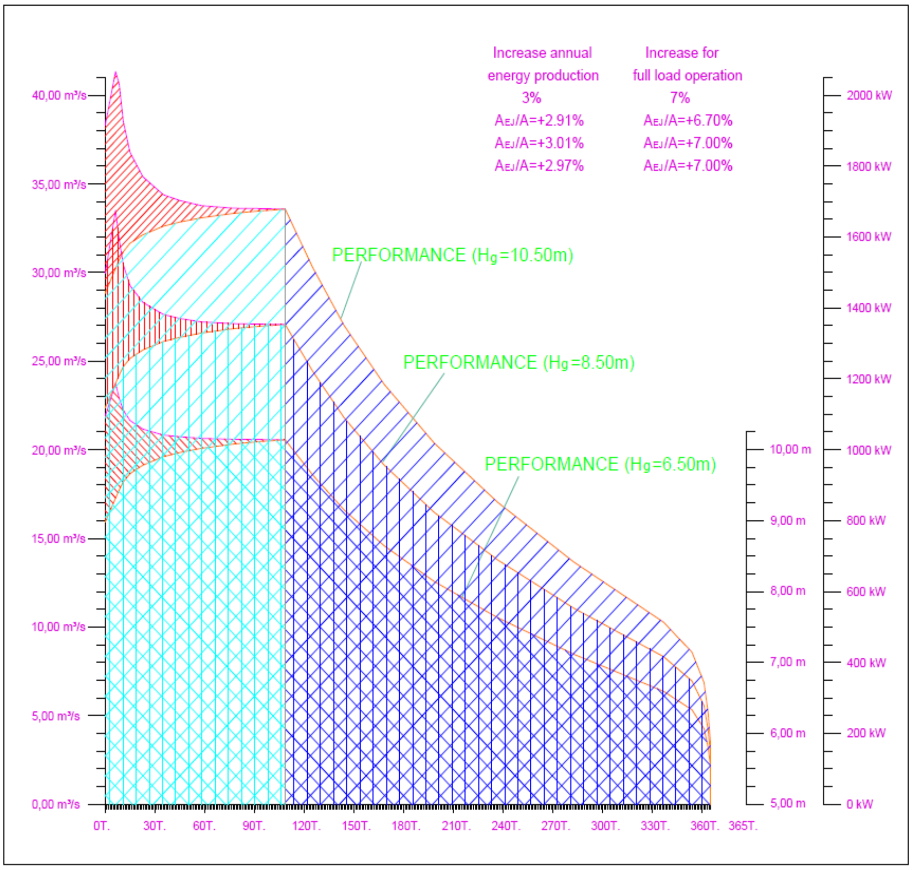

Fig. 27
The duration curve for hydraulic performance is shown in above diagram for different net head with a fixed turbine flow of 20 m³/s [3]

The values for increase of yearly energy production in percentage terms, measured against a fixed full load flow are thus more or less constant and amount to 7% for full load conditions and 3% for the annual average.

Assuming a change in the runoff water volume at a constant drop height, and taking into account the annual 3 – 5 % energy increase, you can calculate an equivalent reduction in the full load volume of approximately 7 – 10 %, which compensates for the energy gains, but does not evaluate the further advantages of location and operation, as shown in the below diagram (example KW Gaissulz / Ybbs).

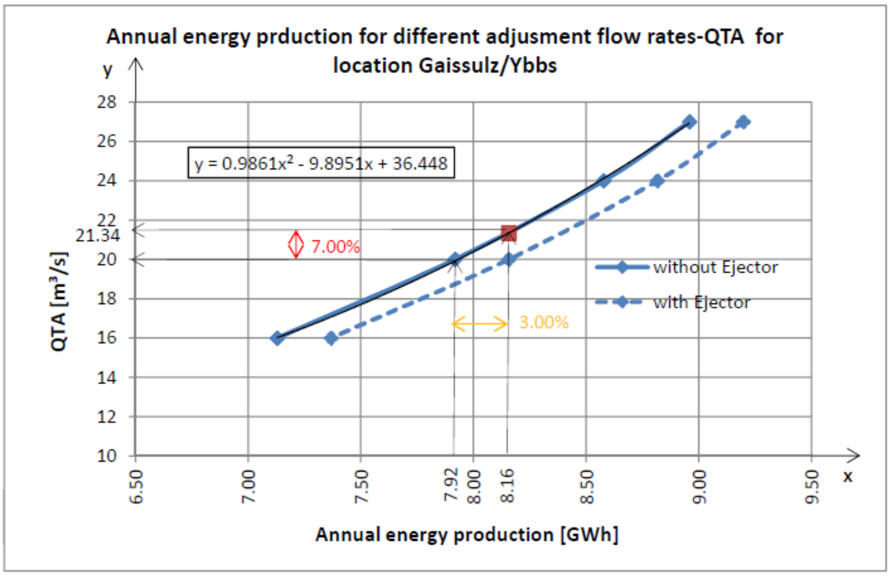

Fig. 28
Annual energy production for different adjustment flow rates Q_{TA} for location Gaissulz/Ybbs [3]

From this comparison and from a desire to reduce the dimensions and costs in general we can conclude the possibility of a smaller design concept using also the further advantages of an ejector power plant.

11. PERFORMANCE PARAMETERS

The performance of ejector is generally considered to be a function of the parameters of hydraulic performance defined in the following:

Internal efficiency parameters

Speed ratio: $\eta^*_{V,WIRK} = \frac{v_{WIRK}}{v_{VER}}$ [14]

Striking drop ratio: $\eta^*_{Z,WIRK} = \frac{z}{z_{BR}}$ [15]

Head increase ratio: $\eta^*_{FH,N} = \frac{z}{FH_{N,Z}}$ [16]

Net head ratio: $\eta^* = \frac{FH_{N,Z}}{FH_{N,B}}$ [17]

Outside total efficiency

Flow ratio: $M = \frac{Q_T}{Q_E}$ [18]

Head ratio: $N = \frac{z}{H_{N,z}}$ [19]

Efficiency – partial: $\eta_{EJ} = M \cdot N = \frac{Q_T \cdot z}{Q_E \cdot H_{N,z}}$ [20]

η_{EJ} gives the ratio of total energy increase of suction flow to the total energy increase of ejector flow.

Efficiency – total: $\eta_{hyd,total} = \eta_T \cdot \eta_G \cdot \eta_{GB} \cdot (1 + \eta_{EJ})$ [21]

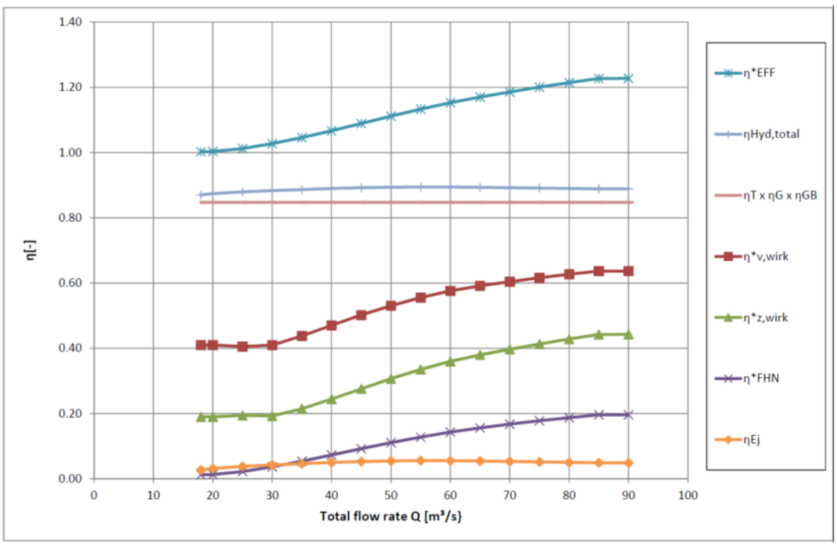

Fig. 29
The diagram shows the different efficiency parameters [3]

SUMMARY

In the course of this study we were able to scientifically determine increased outflow performance by utilizing an ejector, as we had indeed observed already in the pilot projects at

Mühltalwehr/Alm and Stadtwehr Waidhofen/Ybbs. Comparative performance increases were also noted in our 1:10 scale model and in CFD simulation. In particular, we were able to demonstrate in the laboratory and in subsequent analyses that the efficiency of the ejector can be significantly increased by specific design measures between the draft tube and the run off, and also by changes in the position of the ejector sluice gate.

The potential of the interaction of the head race water flow out of the draft tube together with the excess water from the ejector ramp represents the sum of the combination of effective drop height and turbine flow rate. First and foremost, the interaction of these two water volumes is accomplished as a result of a pressure drop, dependent on the momentum coming from the ejector, directly at the draft tube exit point. Increased performance of up to 35% is achievable, as compared to theoretical performance without the ejector in flood or excess water conditions. This breaks down to increased energy output of 7% - 10% at full load and 3% - 5% as an annual average. With consistent annual energy yield the development and head race design costs could be reduced by 5% – 10%, a substantial reduction in the construction and investment costs for new installations.

A not insubstantial side effect is that uninhibited operation is possible even in flood conditions, during which previous design models are required to shut down. Additionally, there is no risk of silt build up in the run off zone.

The curved draft tube also results in space saving design outcomes at the construction stage. Surface area reduction of up to 20% can be put to efficient use in the field of environmental considerations, for example the upstream migration of fish. In a typical design configuration as a bay shaped power plant, with a combination of movable weir system, generously dimensioned ejector exhaust and laterally positioned inlet with turbine system, the entire river profile remains free for flood discharge.

Fig. 30
Aerial photography of ejector plant Gaissulz / Ybbs [3]

In addition to the classic measures of increasing energy yield at existing locations, such as increasing the dam height, underwater excavation, more efficient regulation and increasing the amount of full load, the use of ejectors should be considered as a way forward for the redevelopment of hydropower plants.

This special technology, with patented construction details and special software for design calculation, can be offered by ZT-Fritsch GmbH, the company behind the research project and with many years of experience in hydropower design.

About the presenter Rudolf Fritsch:

- after graduating from high school in Steyr, studied civil engineering at University of Vienna
- civil engineer in the construction industry since 1980
- since 1986 CEO of ZT-Fritsch GmbH, engineering office in Enns, specializing in hydro and bridge design, infrastructure and industrial design; certified legal expert
- since 1994, CEO of Hydroconstruct GmbH in addition a company specializing in rubber dam technology
- since 2000 Head Office in Steyr, Austria, currently spending up to 70% of time on hydropower projects

FEATURES OF MONITORING TEMPERATURE OF AN RCC DAM DURING CONSTRUCTION BASED ON DATA MINING

Jianwen PAN

Assistant Professor in Department of Hydraulic Engineering, TSINGHUA UNIVERSITY

CHINA

Jinting WANG

Professor in Department of Hydraulic Engineering, TSINGHUA UNIVERSITY

CHINA

1. ABSTRACT

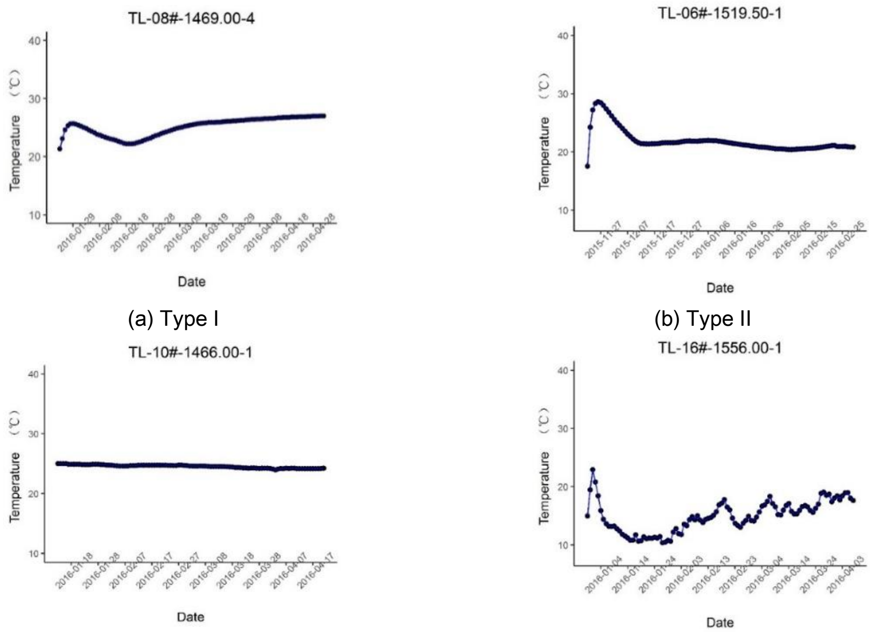
A deep understanding of concrete temperature varying in large concrete dams is of importance for improvement of construction technology. A large number of temperature sensors are installed in the dam blocks as concrete pouring. The temperature of the dam concrete, which increases due to hydration heat in the early stage and decreases when employing water-cooling system, is measured and massive temperature data is stored. The monitoring temperature history varies as time and its changes are affected by many factors, such as the hydration heat temperature rise, the amount and velocity of water flows in the cooling system, environmental temperature, etc. Features of the monitoring temperature may provide insight into possible prevention of temperature-induced cracks in concrete dams.

In this paper, the features of the monitoring temperature data of a roller compacted concrete (RCC) dam (height 203 m), under construction in Yunnan

Province of China, is recognized based on data mining. The raw measured temperature data always contains missing values and outliers. Processing of the missing values and outliers is required before analysis of the data. The density-based spatial clustering of applications with noise method is employed to detect and delete the outliers and the the k-nearest neighbor algorithm is used to estimate and substitute the missing data. The K-means clustering with dynamic time warping algorithm is applied to classified the temperature time series and to find their features.

Four types of temperature series are recognized. Fig. 1 shows the four types of temperature history curves determined by the K-means clustering algorithm. There is a significant difference in the temperature variation between the different types. Type I exhibits a rapid increase due to hydration heat and a decrease as cooling water flows within 20 days after concrete pouring, followed by a gradually increase in the next 3 months. Comparing with Type I, Type II has a stable curve after its drop due to water-cooling. Type III is a approximately horizontal curve, and the hydration heat induced increase and the water-cooling induced drop of temperature are possibly missing. Fluctuation is observed in the later stage of the temperature curve of Type IV, while it is smooth in the other three types, implying that temperature of Type IV is measured near the surface of the dam where the environmental temperature has significant influence and the other three types monitored inside the mass concrete.

This study presents a preliminary analysis of features of monitoring temperature of the RCC dam during construction. Further study based on the big data mining and numerical simulation is needed to understand the cause of the difference between the features and the effect of different features on the concrete dam behavior.



(a) Type I (b) Type II

(c) Type III (d) Type IV

1. INTRODUCTION

Gomti River is a main river in India and is passing the main capital Lucknow in the Indian State Uttar Pradesh. The State Irrigation Department has developed a river rejuvenation program with the following topics:

- Upgrading of the existing Gomti Weir downstream of the Gomti Barrage with a flexible weir structure
- Upgrading comprises also the development of weir cascades
- Improvement of the flood safety by structuring of the river banks
- Creating a water surface with a reservoir with app. 400.000 m³ with a constant water level
- Improvement of water quality in the river stretch by collecting and diverting of the sewage in a new pipe system
- Enabling river boating in the reservoir and passing of boats through the new weir by navigation locks

Alternative Studies carried out came to the solution that a flexible rubber dam with a water filled regulation system meets the requirements as it bests to reach the outlined targets and the economic feasibility. The rubber dam system on the weir is added by navigation locks on both river banks for passing of boats. In the navigation locks there are also moveable rubber dams installed.

2. GENERAL PROJECT DESCRIPTION

2.1. MAIN PROJECT FEATURES

Upgradation of Gomti Weir with water filled rubber dam at Lucknow (at 2.00 km D/S of Gomti Barrage) Uttar Pradesh, India.

The dam system has a length of in total about 256.20 meter and is consisting of 4 sections with inflatable rubber dams and navigation channels on right and left river bank.

The dimensions where chosen by a hydraulic calculation to provide sufficient flood safety.

The system is described with the following data in brief:

- Inflatable main weir sections with rubber dams, 4 main sections (B+C+D+E), each with length 54 m and height 3.00 m
- Navigation channel left side (F), width 16 m and heights 3.30 m at U/S and 3.70 m at D/S, distance between U/s and D/S rubber dam: 17 m
- Navigation channel right side (A), width 16 m and height 3.30 m U/S, provision for a rubber dam on D/S
- Regulation shaft building and water tank
- Connecting pipe system between regulation shafts and rubber dam sections
- Automatic Control & Regulation System (CRS) for all rubber dam sections with SCADA system in control building on top of regulation shaft building
- The Automatic Control & Regulation System (CRS) is maintaining a head water level with up to 3.00 meter over the fixed sill level.
- Manual control of the rubber dams in the navigation locks.

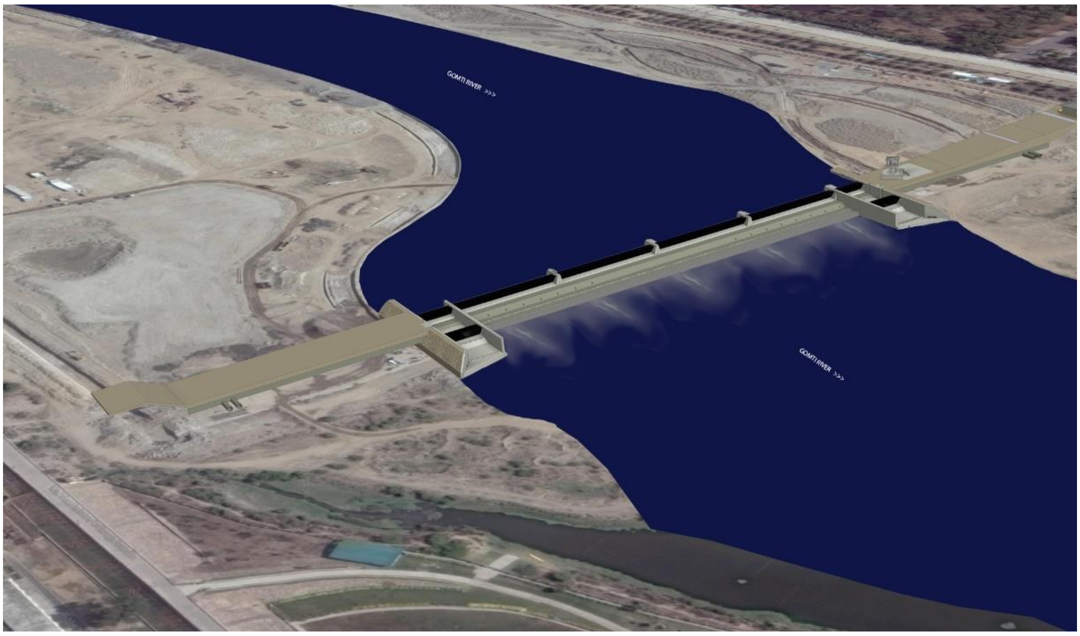

Fig. 1
General view to the new Gomti River Weir

2.2. EXISTING WEIR STRUCTURES BEFORE UPGRADATION

The existing weir was built decades before and serves the river protection measures from erosion and flood control. This old Gomti weir was app. 250 m long and consists of a fixed concrete sill with manually operated flushing channels.

Fig. 2
View to the Gomti Weir in year 2015 before upgradation

The hydraulic behaviour of the old Gomti Weir with a fixed weir sill was resulting in changing water levels depending on river flows. This was resulting in a very small water surface during dry periods.

2.3. DESCRIPTION OF MAIN PARTS

The main sections of the new weir were built on top of the existing concrete structure by removing more than 1 meter of concrete. The new weir slab has a thickness of minimum 1.20 m and is made of reinforced concrete. The crown of the rubber dam lies on EL 106.0 m, the design height of the reservoir at EL 105.50 m.

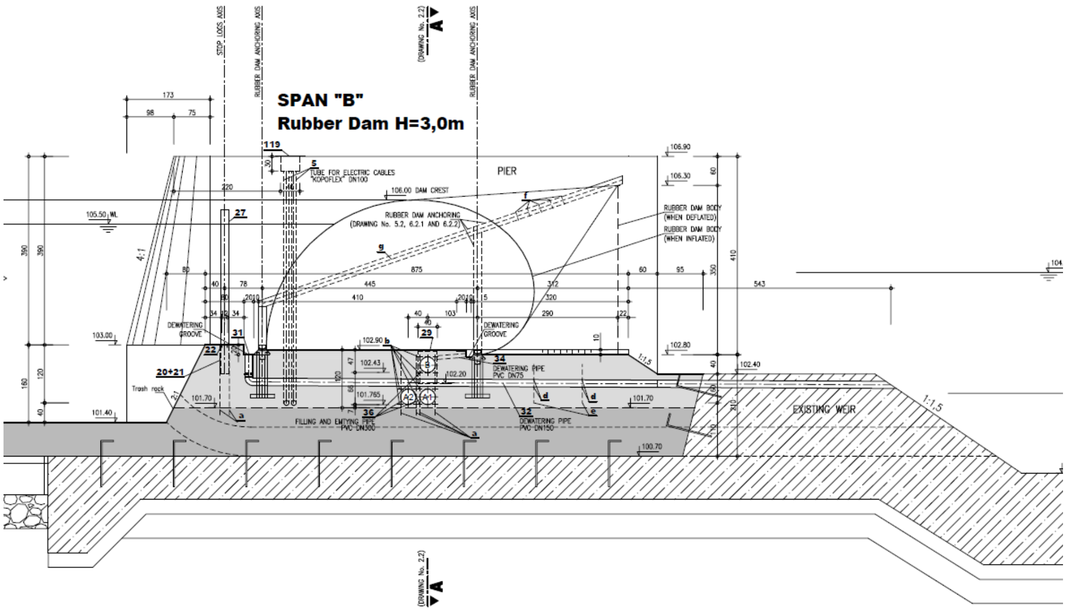

Fig. 3
Cross section through main rubber dam section

For the regulation system water filling is foreseen. This system is providing a more stable and precise regulation range over the whole dam height and is designed for possible tailback up to EL 104.50 m also.

The clamping rail for the 4 weirs sections is fixed in 2 steps with 0.1 m so that the height of rubber dam in downstream side is 3.20 meter.

The rubber membrane is double-clamped and has a minimum wall thickness of 16 millimetres, with three woven fabric reinforcement layers to provide sufficient rupture strength.

In case of flood the rubber dam will be regulated automatically according to the flow until the whole membrane is completely deflated to the fixed weir sill.

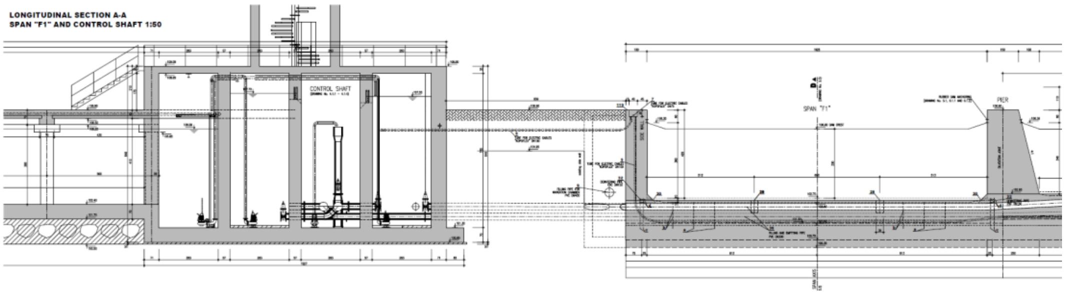

Fig. 4
Longitudinal section through water tank, regulation shaft and weir span “F”

For standard project cases the water for regulation purposes will be taken from the reservoir directly. For the Gomti Project the Irrigation Department has decided to maintain a separate water tank which will be feed by external water from a water pipeline. The volume of the regulation tank was selected with 2,630 m³, which amounts to 60 % of the fill volume (app. 4,000 m³) of all the rubber bodies. This covers the regulation process for almost the whole normal operation of the system.

The general arrangement for the regulation system is consisting of:

- Water Tank with a reservoir volume for 2,630 m³ water
- Regulation Shafts with regulation equipment such as pipes, pumps, valves and safety devices
- Control Building on top of the shaft building at flood safe elevation - with the electric control equipment for the whole rubber dam system including navigation locks.

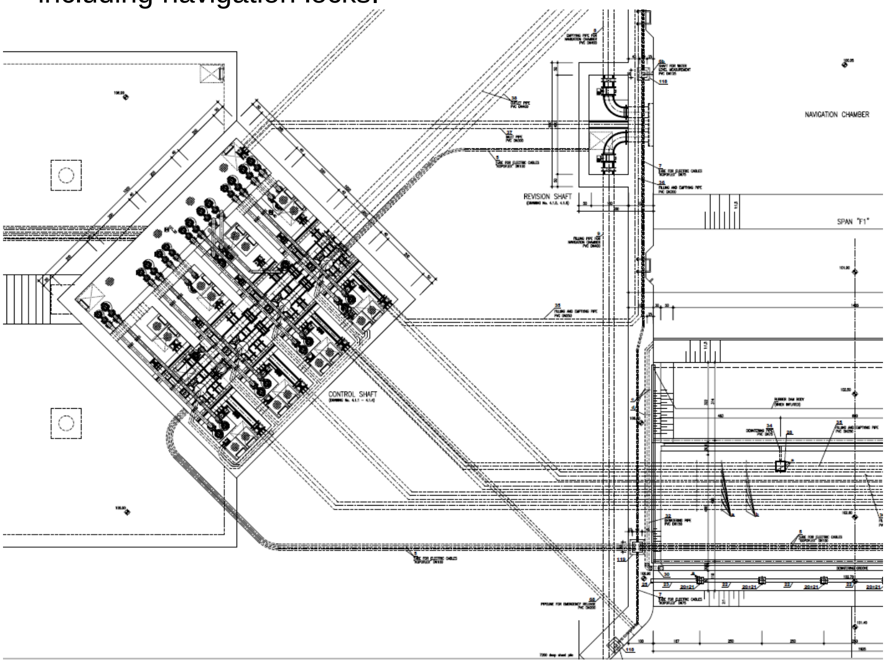

Fig. 5
Layout Control Shafts and Navigation Lock F

Regulation of the upstream level will take place by means of a probe-controlled system. A self-functioning automatic discharge is installed for emergency release. All steel components are hot-dip galvanized; the piping embedded in concrete is made of PE. All screws and bolts are of stainless material.

The control system of the main sections can be operated in manual and automatic mode. Every single section of the rubber dam system can be operated separately. Central control for automatic operation of the rubber dam will be coordinated by means of a PLC and is in a switchboard panel in the control building.

2.4. MAIN DESIGN CONSIDERATIONS

Calculation of the membrane forces assuming firmly inflated water inflated rubber dam shape according to the following figure and equation formula.

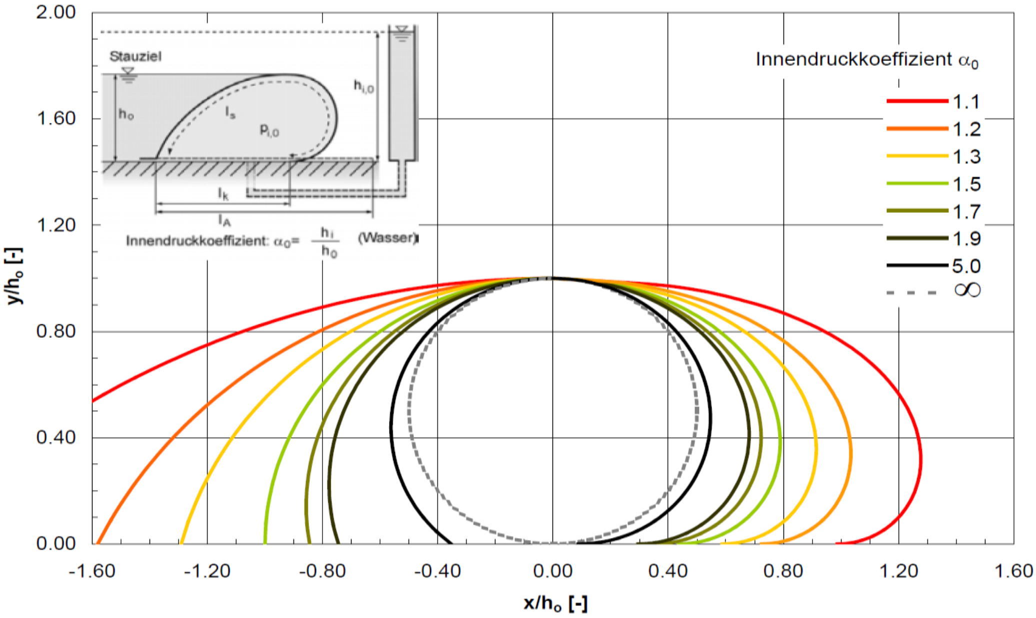

Fig. 6

Inflation pressure coefficient for water filled systems

$$T = \frac{1}{4}(2\alpha - 1)\rho_w g h_s{}^2 \qquad [1]$$

The result of calculation is given in the next following table. The estimated tension force in the membrane has to be held by the membrane and the anchoring system.

hs = ho	[m]	3,2
ρw	[kg/m³]	1000
g	[m/s²]	9,81
γw	[N/m²]	9810

	[-]	1,1	1,2	1,3	1,5	1,7
hi	[m]	3,52	3,84	4,16	4,80	5,44

T	[kN/m]	30,14	35,16	40,18	50,23	60,27
Tsd = γsd * T	[kN/m]	45,20	52,74	60,27	75,34	90,41

γsd = 1.5

Fig. 7
Calculation of membrane forces

Membrane properties have to be tested on the supplied material by authorized test institutes. The rupture strength in longitudinal direction of the membrane for this project was tested in laboratory with minimum 670 kN/m witch gives a considerable safety margin of factor 9.

3. CONTROL AND REGULATION

3.5. RUBBER DAM MAIN SECTIONS

The regulation shaft system is located on the left bank of the Gomti Weir. It is designed as multiple chamber system enabling independent control of each weir section.

To operate the main rubber dam sections there are two modes available:

- Manual operation mode
- Automatic operation mode.

Water supply for regular operation is provided by the water tank which is linked to the pump shaft. This reservoir with active storage volume of 2,630 m³ is large enough to serve as a buffer for regular operation.

Operation mainly acting with two functions: Raising the rubber dam or lowering the rubber dam. Water filled Hydroconstruct rubber dams are operating at any pressure inside the weir membrane. Thus, the rubber body is stable in any position between full inflated and full deflated position. The state of the rubber dam is continuously monitored. The defining parameters are the head water level, the reservoir level and the pressure inside the related weir section.

Capacity of the installed pumps (app. 60 kW) is designed for app. 2.5 hours filling time for the first filling of the main rubber dam sections B+C+D+E. The reacting times for normal regulation are in the range of 5-10 minutes. After big flood events, when the rubber dam was completely deflated, the re-inflation time will be with app. 2 days.

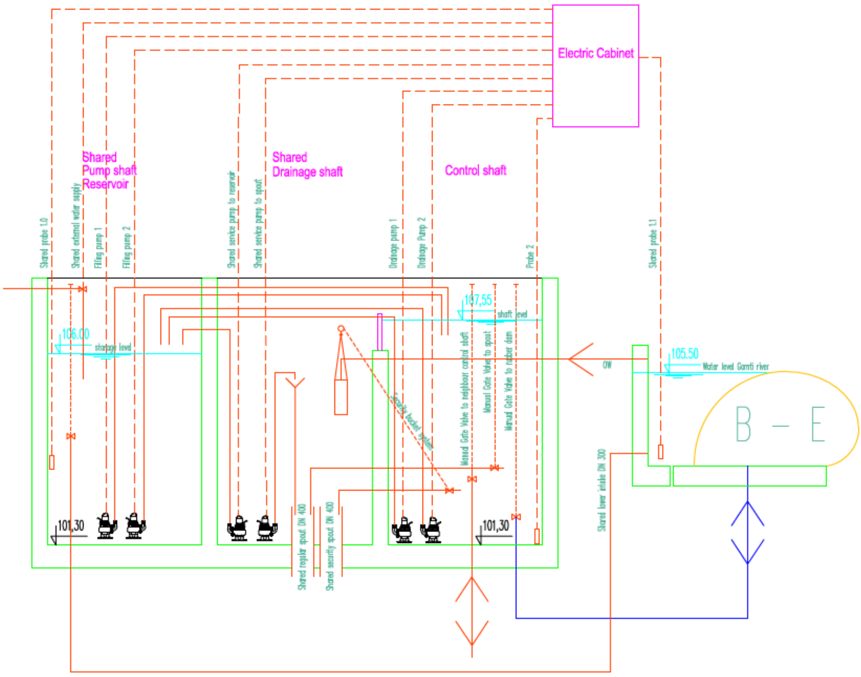

Fig. 8
Control and installation scheme for the 4 main sections B+C+D+E

Automatic operation aims to keep the head water level constant. This is achieved by adjusting the weir crest height according to changes in river flow. In automatic operation the rubber dam will be operated in dependence of the state of the rubber dam and predefined parameters in the control program. An operation priority will be assigned to each of the main weir sections B to E by the operator. It is possible to assign the same priority to two or more sections for parallel operation.

The rubber dam control system for the 4 main weir sections feature a threefold safety system:

- First, there is an overflow section on top of control shaft
- Second, there is a manually operated outlet valve
- Third, the inside pressure in the dam is controlled by an emergency discharge device consisting of a mechanically operating bucket drive for the release valve. This mechanism will be activated if the head water level exceeds a critical elevation.

Water released by the safety system will be drained out to the river through the outlet pipe.

3.6. NAVIGATION LOCKS

The rubber dams of the navigation locks can be used for two purposes. The main purpose of the navigation locks is to give way for boating up and down the Gomti River. Alternatively, they can be used for head water regulation too. The mode of operation can be switched by setting the operational state either to “N”, for navigation lock mode, or to a priority for head water regulation. Since the weir heights of the navigation lock rubber dams differs from the height of the main weir sections, navigation lock rubber dams cannot have similar priorities as any main weir section.

The navigation locks are controlled by the Control & Regulation Shaft System (CRS). Each rubber dam section in the navigation locks can be operated independently. In principle the CRS for the navigation lock systems is the same as for the 4 main weir sections.

SUMMARY

Rubber Dams are known worldwide for applications creating reservoirs in wide rivers for spans up to 100 m and heights up to 4.5 m. Main advantage is the flexible structure for full automatic reservoir level control allowing discharge of sediments, debris and even ice in Nordic conditions. Numerous applications for reservoir control, spillway gates, irrigation purposes and hydroelectric power generation were realized in the last decade. Several rubber dam projects are under operation in India now.

The said main advantages were the reason why a rubber dam system was selected by the Main Client Government of Uttar Pradesh, Irrigation Department to meet the targets for the Upgrading of the Gomti River weir structure. For the Gomti Project a water filled system with the advantage for regulation of the reservoir level was selected.

In this special project case the rubber dam was added by navigation locks on both sides of the river, allowing passing of boats.

This article highlights the key features of the project and main parts are described in detail. Main design considerations are mentioned to give a picture to the calculation required for such a project. Attention was taken to the special arrangement with an external water tank to provide water for the regulation process.

In a second chapter the control and regulation of the rubber dams and the navigation locks are described.

The project supply parts are already installed on site and the last part for installation of control equipment is expected to be finished before summer 2018. The following commissioning of the rubber dam system will be the last part of project execution phase.

1. INTRODUCTION

Glevard Dam project is located in Mazandaran Province and constructed on Neka Rover, and its middle point situated on the coordination of 36.59 N and 53.61 E. The type of dam is CFRD and maximum height of the dam from riverbed is 103 m and from bedrock is 113 m. Dam crest elevation is 739 m.a.s.l. with the dam crest length of 250 m and width of 10 m as shown in figure 1.

Instead of morning glory spillway, the alternative spillway of the Glevard dam has been considered as a free spillway at the left abutment, with an appropriate safety margin from the fault passing from the abutment site. Figure 2 shows cross section of the geotechnical of the spillway route. The bedrock limestone has been identified through drilling in several boreholes. As already mentioned, spillway crest elevation has been considered as 733 m.a.s.l. and that of the approach canal level as 730 m.a.s.1., which is the normal reservoir water level. Capacity of volume between these two elevations has been considered as 8.65 million m3, which can control 50 and 100-yr floods, with small discharge

* *titre de l'article complet*

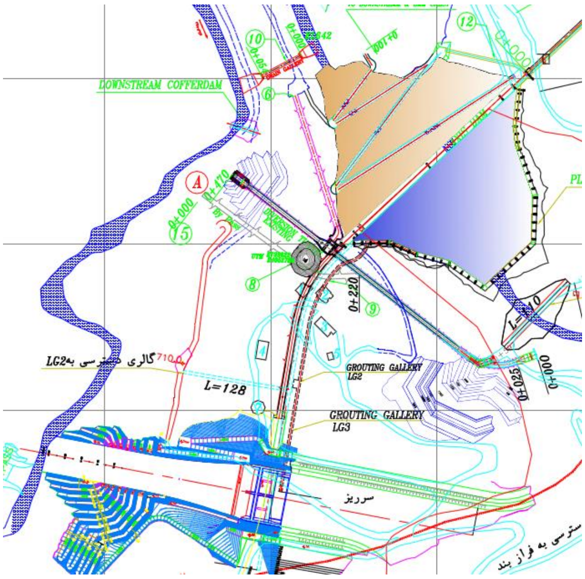

Fig. 1
General Plan of Glevard CFRD

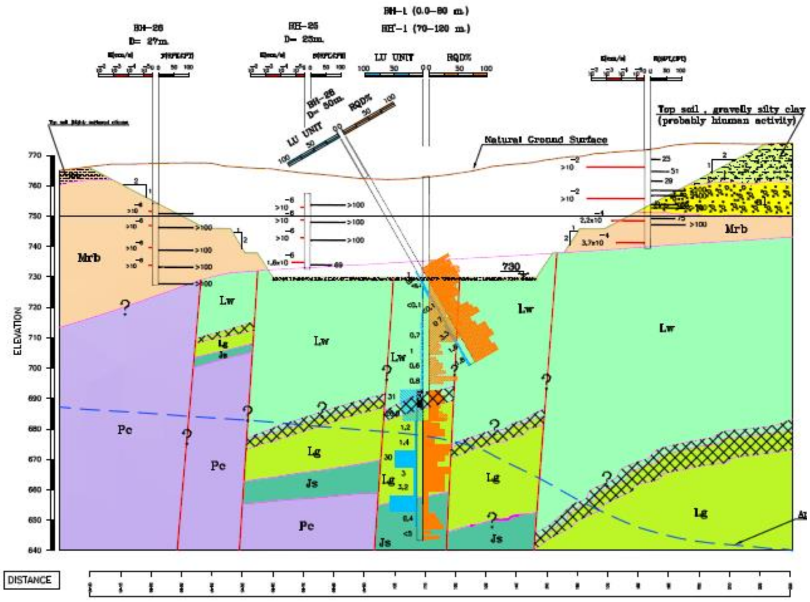

Fig. 2
Geotechnical Cross Section in approach channel of spillway

In accordance with the layout map and geological - geotechnical longitudinal profile as shown in figure 3, after excavation of the top soil, the spillway will be located on an appropriate bedrock. Furthermore, it will be possible to remove the loose soil and rocks and stabilize the trench-excavation slope in approach channel using support Geo-grid as well as cultivation of plants, trees and bushes, in long term surface protection of course after doing slope stability analysis process.

Therefore, trench slope, berms wide and height elaborate and compared base on result of lab tests and “in-situ” test.

The above-mentioned explanations belong to a natural case of cutting with trenches of different heights. To provide slope stability of trenches (with any type of weak materials) the simplest and the major way is to decrease the over burden pressure of the slope, if it is made of soil or eroded, weak rock. Indeed, the lower part will be stable for the required safety factor for all loading cases and various conditions.

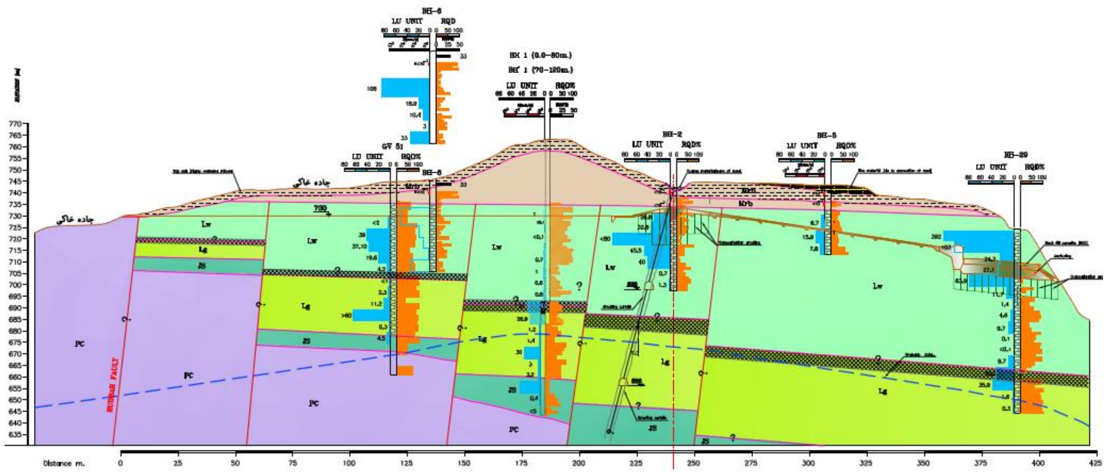

Fig.3.
Geotechnical Longitudinal Section along Approach Channel of Spillway

The geometry shape of trench of left and right banks of spillway approach channel was designed considering using appropriate geo-mechanically parameters from lab and “in-situ” tests and engineering judgment on the results, The main point is that to meet the desired width for spillway channel after cutting with trenches (different height) to provide stability of trenches.

2. PROJECT OVERVIEW

In-situ as well as laboratory tests on the fine-grained materials were carried out and sample materials taken from exploration boreholes obtained from test pits for better understanding of Neogene formation materials in free spillway area of the Glevard dam. The Neogen formation consists of an intercalation of siltstone, mudstone, marlstone and sometimes local loose conglomerate and semi-intercalations of loose limestone. SPT test results of different layers had been used for primary estimation of C and φ parameters had in stability calculations. For more certainty, some "in-situ tests" were carried out to finalize geotechnical parameters of the soil materials of the approach channel and the spillway location, accordingly.

3. THE DIFFERENT BETWEEN THE "IN-SITU" AND LAB TEST IN NEOGEN FORMATION

With regard to the results of in-situ and laboratory tests, following points should be noted in this regard:

A. Laboratory tests on disturbed samples of any depth are actually face with some cracks due to vibrations and rotation of the drilling bit and due to movements and transportation of samples. Indeed, these samples cannot represent the condition of natural soil on that location where the samples are taken and they show considerably lower strength against the natural state. Cracked soil or normal cracks have considerably lower modulus of elasticity compared to the in-situ soil, and due to natural cementation in the materials.

B. Soil obtained from mudstone, siltstone and marlstone intercalations originally, has higher cohesion among their particles compared to the disturbed or cracked soils, even if the cracks are so tiny, due to their old origin, related to millions of years ago, and to their natural compaction during all these years.

Thus, any kind of disturbance or formation of cracks not only decreases or diminishes cementation among particles, but also causes lower cohesion and modulus of elasticity compare to the ones obtained from in-situ tests. The results obtained from Pressure Meter Test provided in table 1. In a considerable number of tests, even in saturated status of the test place, modulus of elasticity is between 1200 to 2000 kg/cm2. Based on the engineering classification of the material strength, as it can be seen, clay, silty clay, grave-sand and clay soils can be classified as hard and very dense soils and their higher modulus of elasticity is an indicative of cementation among the particles. However, triaxial tests (CU or CD) on disturbed soil samples provides a modulus of elasticity of 120 to 230 kg/cm2, as the maximum value the saturated compacted clay. This is while in pressure meter test within boreholes, different values were obtained such as higher value than 330 and 410, and even 930, 1200 and 1880 kg/cm2, which shows cementation and high cohesion of more than the obtained values in triaxial tests. Meanwhile, it is known that the stress of compressive strength of fine-grained soils has direct relation with modulus of elasticity.

C. Plate loading in-situ test results provided in table 2. As it can be seen, the elasticity modulus of 250, 300 and 500 kg/cm2a belong to upper layers (5 to 7 m depth) and it will be increase by depth, unless the layer material is changed. Therefore, this situation was considered in mathematical model of stability analysis.

Table. 1. Pressure Meter Test Results in Exploration Boreholes of Spillway Area

4. LABORATORY TEST RESULTS

In order to determine geotechnical parameters of the sediments and samples taken from exploratory boreholes and test pits, some laboratory tests [4,5,6] were carried out and results have been provided in tables 3 and 4 for the pits (TP-F1 to TP-F5) and exploration boreholes (BH-22) to (BH-24), respectively. Evaluation of laboratory results of these loose and weathered soils which are also sensitive to moisture shows that as their compressive strength has direct relationship with modulus of elasticity, and in in-situ tests these strengths are 3 to 4 times than the strength of the surface soil or the marly layer which is sensitive to water, the laboratory test results generally control field test results and have an appropriate trend, in weakened scale. If due to the cementation of natural undisturbed rocks, their internal friction angle is considered similar to these soils, considering the necessary conservativeness, cohesion values of the natural soil in in-situ case is at least 1.5 to 2 times as the above-mentioned loose, disturbed samples. Certainly, considering the Mohr — Culomb criteria and the obtained in-situ modulus of elasticity and considering the relationship suggested by Bijrum and other researchers in this regard, the mentioned relationship for fine-grained soils, based on the type of the soil would be as follows:

$$E \cong (250 \text{ to } 500)\,(\sigma_1-\sigma_3)_F$$

Hence, it can be seen, due to the high modulus of elasticity obtained in in-situ tests, cohesion of natural soils is higher than the laboratory values of disturbed samples. In table 2, pressure meter tests estimates the minimum cohesion values and considers them for slope stability calculations. However, a conservative approach has been used in selection of the parameters for numerical calculation.

5. DISCUSSION ON "IN-SITU" TESTS RESULT OF GEOTECHNICAL PARAMETERS

As already mentioned, different in-situ tests including pressure meter and plate loading tests (as well as standard penetration tests) have been carried out to determine geotechnical parameters of the bed soil and geo-mechanical parameters of the bedrock mass in the spillway area, to find geotechnical parameter for slope stability analysis; following is a summary result of these tests.

5.1. PROCEDURE IN-SITU TESTS

Plate load test aims to determine the elasticity modulus of the bed with regards to:

$$Es=qB(1-\upsilon2)Iw/\Delta$$

and other geotechnical properties such as the Poisson ratio of the bed, internal friction angle and cohesion values, as a control test and in order to find out anomalies in pressure meter tests.

To attain this objective and perform the test, a number of pits have been tested in different locations and points including the spillway slope, based on the lithological and geological changes of test places in the right and left abutments of the spillway, so that the results are controlled in a number of aspects.

The plate loading test of the soil has been carried out in ASTM-D 1159 method. Steel plates of 30 and 50 cm diameters and a hydraulic jack to implement the load have been used in the tests. At least 3 gauges of 0.01 mm sensitivity have also been used for measurement of plate settlement.

The considered tests have been carried out as cyclic loading, in three consecutive cycles, in accordance with the above-mentioned test method. Table 3 shows the plate loading test results and maximum settlement (St), modulus of elasticity and mean Poisson ratio in the concerned layer have been also been provided for the maximum stress implemented in each cycle, at the end of each phase of loading and unloading cycle.

A considerable point in this regard is the fact that the bed reaction modulus is not a fixed number for the soil and varies due to following the plate diameter and stress. It can be considered equal to the above-mentioned values, considering an appropriate safety factor in the foundation and superstructure calculations.

Delineating the stress-strain curve and calculating total settlement and the residual settlement (in zero bar), elastic settlement at each phase of loading has been obtained. Then the maximum stress diagram of each loading cycle against its corresponding elastic settlement has been delineated. Elastic sub grade reaction (CU) of the soil has been calculated from the delineated diagram. Thus, based on the test, the CU has been calculated from the following relationship:

$$Cu = q/Se \quad (kg/cm3)$$

In this regard, more investigations carried out by Barkan shown that Cu is a function of the load plate area. So that, if CuI and Cu2 are steady elastic pressure factors for the mats with AI and A2 contact areas, respectively, then the following relationship would be applicable:

$$Cu2 = Cu1\sqrt{(A1/A2)}$$

But here, the objective of the test has been controlling the values of the elasticity modulus obtained from the pressure meter tests in the concerned levels.

In the plate loading tests carried out, the values of this parameter in 7 cases out of the 8 tests having been carried out, have been calculated and their first rates have been provided (in test PLT-2 and in the dry state, it has been rejected as the gauge has been dislocated and in the repeated test, only 2 cycles of the 3 have been performed in the test.

In this regard and as far as possible, the loading is carried out in a way that implementing the loading capacity causes it to enter or get near to the plastic ambience of the rock mass and in other words loading is carried out up to near its loading capacity, so as to distinguish the capacity of the bed affected materials.

The test results are provided as pressure-displacement curves or the soil behavior curve and then analysis of the elasto-plastic ambience and analysis of the behavior curve of the mass is carried out with variations in C, φ and γ parameters and finally, the strength parameters can be estimated from the obtained results.

5.2. Considering Test Results of Pressure Meter Testing

In the Glevard dam spillway channel area, due to the deep excavation in soil, a total of 21 pressure meter tests have been carried out in the exploration boreholes drilled in the right abutment, including BH-22, BH-23 and BH-24 (totally 12 cases) and in the left abutment, including BH-25 and BH-26 (totally 9 cases), 3-m paces, from 3 to 30 m, in sedimentary materials, fine-grained sub-surface layers (clayey — silty to marly clayey or clayey sandy) and coarse-grained materials (sand, gravel and marlstone) and in dry and saturated states. Mainly, these tests have been carried out in two parts of alluvial surface and silty layer and the middle marlstone layers. These tests have been detailed in table 2.

5.3. Considering Test Results of Plate Load Tests

Plate loading test has been carried out in totally five locations in the spillway channel slope area and location. They include PLT-1 and PLT-2 locations at the right abutment and PLT-3 and PLT-4 locations at the left abutment and PLT-5 location in the middle of the bed, tending to the right abutment wall. Plate Loading tests have been carried out in saturated state in locations PLT-1, PLT-2 and PLT-3. Test results have been provided in pertaining tables and diagrams in the attachment to the report. In these tables and diagrams, beside determining the tested location, test cycles (1, 2 & 3), maximum load, maximum stress, total settlement (St), elastic settlement (Se), difference between the total and elastic settlements (St-Se) and modulus of elasticity and Poisson ratio have been provided in table 3. Summary results of loading tests have been provided in table 3 and actually the modulus of elasticity in dry state is almost 2 to 2.5 times as the saturated state.

Summing up the obtained results indicates relatively reasonable values for the steady pressure coefficient of the soil with regard to the type of materials and sediments of the right abutment, which are mainly coarse grained, and of the left abutment, which are mainly fine grained. In this regard, calculating the values of modulus of elasticity relating to the tests, the values of these parameters in saturated state for the fine-grained sedimentary materials have been obtained as Es=250 - 350 kg/cm2 and for the coarse grained materials as Es= 500-700 kg/cm2, which are totally correct and reasonable for the loose rock masses of the plate loading location.

5.4. BLOW, STANDARD PENETRATION DENSITY TESTS OF SUB-SURFACE LAYERS

In order to investigate the effect of the blow and standard penetration, the field density tests carried out in the depths of the exploration boreholes and pits drilled in the Glevard dam spillway area. Results obtained in the two states from the exploration boreholes and manual pits were separated and then, with the theoretical description of the samples, the density class of each layer and the fine and coarse grained sediments were determined and finally, with regard to the conclusion and classification of the density in the above-mentioned layers, the expected geometrical parameter values (C, φ , q_u and γ) were determined and the results have been provided in table 5. In other words, with regard to the field tests and the blow and standard penetration test results (SPT / CPT) and using the standard codes and relations between the geotechnical parameters obtained from (NAVFAC) and Bowles reference and other national sources, the limits and values of geotechnical parameters of the sub-surface sediments and layers were determined. Table 4 provides summary specifications of geotechnical parameters of the sub-surface sediments and layers obtained in the Glevard dam spillway structure area.

Table.5.The results test of blow, standard penetration test in the spillway area

6. INTERPRETATION OF GEOTECHNICAL PARAMETER OF SPILLWAY TRENCH SLOPE

Previous research has been carried out location of critical slip surface [1,2,3]. Considering the obtained (field and laboratory) results and summation of the geotechnical parameter values in the sub-surface sediments and layers of the slope and spillway structure area in the left and right abutments allows dividing the sub-surface profile into three parts:

1. Upper part, the silty-clayey surface soil in the first 10 m and mainly in the first 4 to 5 m.
2. Middle part, marly-siltstone layer down to the depth of 20 m,
3. Lower part, including the bed rock-mainly of limestone that continues down to lower depths.

Generally, the conclusion from the obtained results indicates that under natural and dry conditions, mean geotechnical parameters of the sub-surface sediments and layers do show stability of the slope and the spillway structure area. This is while under saturation conditions, strength is decreased, where appropriate excavation slope is selected for stability analysis purposes.

7. SLOPE STABILITY ANALYSIS AT THE APPROACH CHANNEL OF SPILLWAY

In the preliminary Slope Stability Analysis at the Approach Channel of spillway Trench at the Right and Left Abutments, based on estimated values for C and φ of the soil and soft rock mass of the Neogene era and based on Lab and NSPT tests in the spillway, stability safety factor had been calculated. However, to elaborate design of slope stability and excavation procedure to meet appropriate width to constructing broad spillway, based on the in-situ tests, calculations and selection of design parameters in the slope of the spillway approach channel trench slopes should be separately calculated for the right and left abutments.

This additional analyze refined design parameters selected in calculations of the first alternative, where C and F have been estimated based on the NSPT of the exploration boreholes and test pits (it is pointed out that all SPT tests had shown more than 50 blows in different points for 30 cm penetration). Now, with regard to the drilling of three boreholesnBH-22, BH-23 and BH-24 at the right abutment and that of BH-25 and BH-26 at the left abutment and performing pressure meter tests in each meter and in each section, the dry and saturated states have been tested and measured. The results have been provided in table 1 for calculation of the modulus of elasticity, eudiometry, C, φ, Ko factor, and the elastic modulus. Meanwhile, table 2 shows the in-situ plate loading tests for identification of the situation of soft rocks and soils resulted from the Neogene formation (in the dry and saturated states, in the locations shown on the spillway plan). For the limestone, 1 has been considered as 36° and C' as 115 Kpa, in stability calculations.

8. EXCAVATION GEOMETRY

Invert elevation for the approach channel is 730 m.a.s.l. Excavation of trenches will start, with 11-1: 1.5V slope in two 8-m berm and after the first 8 meter, a 4-in berm will be excavated and then, the second 8-m wide berm will be excavated at El. 745 m.a.s.l. After that, the excavation slope will be 2H: 1V for complete excavation to minimize the failure surfaces. In other words, in the first 15 m, there is a 4-m berm at El. 738 m.a.s.l. and then, in a 15-m height, the 8-m berm with 2H: 1V slope will be complied with until excavation in soil is completed. The major excavations to be carried out belong to the approach channel, with a maximum depth of 42 m. However, crossing the approach channel or the access, the concrete flat-edge spillway and its chute will start, whose maximum excavation depth will not exceed 12 to18 m. Excavation for the spillway with its slope shown in the figures.

9. MECHANICAL AND GEO-MECHANICAL SPECIFICATIONS OF TRENCH MATERIALS FOR STABILITY ANALYSIS

BH-22, BH-23 and BH-24 have been drilled at the right abutment and BH-25 and BH-26 at the left abutment, with following characteristics and pressure meter test has been taken into consideration in its different depths. Meanwhile, the in-situ plate loading test has also been carried out to control the in-situ strength and density of the soil and combination of the results. Mechanical and geo mechanical specifications of the materials have been entered into the calculations based on the pressure meter test results in different boreholes, as provided in table 1, which are totally based on the in-situ pressure meter tests carried out at the site. In depths beyond the values mentioned in table 1, the Lar limestone has been entered in the calculations with φ =36° and C=115 Kpa. Most of the concerned soft rocks have had strength more than the foreseen and selected values.

10. ASSUMPTIONS AND CALCULATION PROCEDURE

Calculations have been carried out based on the mechanical and geo-mechanical parameters provided in table 1, limestone properties and drilling section and also based on the specifications of layers in each borehole and its height conditions, which include three analysis sections at the right abutment and two at the left. In other words, the section belonging to borehole BH-22, which is located at elevation 772 m.a.s.l, due to its more height, is more critical than other sections, and this is the fact shown in calculations, too. Calculations have been performed based on the Geo-Slope V5.16 mathematical model, Mohr-Culomb model of discontinuity and also according to the above-mentioned descriptions and assumptions and for each analytical state, calculations in earthquake conditions with 0.15 factor have also been taken into consideration. Mathematical model of excavation in soil and trench has been provided in figure 1, which has been prepared in Geo-Lope software program.

11. CALCULATION RESULTS

Calculation have been performed in Geo-Slope V5.16 software program based on the Mohr-Culomb model of discontinuity and Modified Bishop linear method [7,8,9].

The first analytical section belong to BH-22, which has been drilled at El. 722 m.a.s.l. at the right abutment and its pressure meter test results have been provided in table 1. Based on the information mentioned above, drilling section has been analyzed. The maximum Trench height is 42 m. Its slope stability safety factor, based on the pressure meter information and other tests, in this borehole whose different layers have been provided in the analysis has been calculated as 1.585. As safety factor for excavation geometry as shown in figure 4.

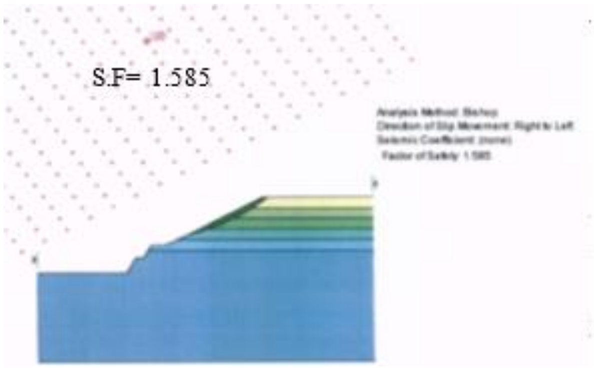

Fig.4.
Numerical model of excavation for slope stability

Allowable values of the safety factor under stability conditions are 1.4 to 1.5 and therefore, the above-mentioned value is acceptable. Figure 2 shows the failure wedge along with the calculated safety factor. Critical failure surface mainly goes beyond the first 8meter.

Section analysis of the borehole BH-22 in the earthquake state with 0.15 factor for pseudo static calculation indicates decrease in the safety factor to 1.153. Under such conditions, the allowable safety factor can also be acceptable for highest slopes in the allowable range. As the obtained factor is higher than the allowable value, the section has no earthquake problems, too. Borehole BH-23 has been drilled at El. 765.2 m.a.s.l. at the right abutment and its drilling depth is 35.2 m.

Based on the above-mentioned conditions, drilling section of the trench different layers has been prepared based on the pressure meter and other tests in Geo- Slope mathematical model and the stability analysis has been carried out under test conditions and with earthquake.

Under conditions without earthquake, the calculations show that the safety factor of the soil or trench excavation at the right abutment in highest slope is 1.798, which is higher than the allowable values of 1.4 to 1.5 and can be acceptable. Calculated safety factor of the analyzed section of borehole 23 under earthquake conditions with 0.15 factor is at least 1.294, which is higher than the allowable value of 1.05 and can be acceptable.

Borehole BH-24 has been drilled at El. 756.28 m.a.s.l. whose maximum excavation is 26.28 m down to the spillway bottom. Analysis of this height under pressure meter test conditions shows the safety factor as 3.351, which is mainly due to the decrease in the excavation height and the safety factor is actually a large one.

Section analysis of borehole BH-24 has been carried out under earthquake conditions with0.15 factor, whose safety factor has been calculated as 2.4. The minimum safety factor under exceptional load condition is 1.05 but the obtained safety factor is considerably larger and this slope is in the safety margin. Critical failure wedge for excavation based on pressure meter test in borehole 24 plus earthquake with 0.15 factor.

Borehole BH-25 has been drilled at the left abutment, at El. 760.51 m.a.s.l. and its analysis has been carried out for both with and without earthquake conditions, where the calculated safety factors have been estimated as 2.094 and 1.464, respectively, which are totally above the comparing allowable minimums of 1.5 and 1.05 and so, it is actually acceptable.

Borehole BH-26 has been drilled at the left abutment, at El. 754.28 m.a.s.l. and its analysis has been taken into consideration based on the carried out pressure meter tests. For the soil excavation height of almost 25 m, the calculated safety factor has been estimated as 2.003. Allowable safety factor in this state has been 1.5, which is acceptable under such conditions. Based on the information obtained from the pressure meter tests, the critical section crosses the berms in the first 15 m, i.e. due to the material properties; it is in lower elevation layers to the bottom excavation.

Calculation of the safety factor in earthquake conditions for the borehole BH-26 has been carried out with earthquake factor of 0.15, where the safety factor has been shown as 1.468, which is higher than the allowable minimum of 1.05 and it is acceptable.

To put it short, the analyses for the slope stability of trench excavation can be provided as per table 2, appropriate with the carried out analyses. Along with the provided allowable values, they can be compared to ensure acceptability of the excavation slope.

12. CONCLUSION

With regards to pressure meter and other in-situ and laboratory test results in addition to the numerical analysis following design for stable slope was proposed: excavation with 1H: 1.5V slope in the first 15 m height with a 4m berm, at El. 738 m.a.s.l. following by a 8m berm at El. 745 m.a.s.l. and then excavation with a slope of 2H : 1V. For the surface soil, instead of initial design (using geogrid to support top soil) in order to prevent erosion using biological methods such as plantation is recommended. Indeed, the biological methods suggeted as the properties of the surface humos soil are instable and can flow down due to rainfall and this support is necessary to prevent erosion and flow of the mud. To support the toe of initial berm gabion is recommended as a facing.

SUMMARY

This paper presents the results of slope stability analysis at the right and left bank of the spillway in Gelevand dam which is a broad- crested spillway by assuming 739 m.a.s.l. As the dam crest elevation, the width of channel trench will be almost 66 m to discharge the 10,000-yr flood. Based on the design criteria, large spillway channel should be located at the toe of the right and left abutment which will require a special design for the excavation of berms at Neogene era in order to reach a stable slope.

To evaluate the strength parameters of fine-grained materials at spillway area, laboratory test were carried out. According to the strength parameters resulted from lab, the stability of trenches slope of the spillway channel was analyzed. Base on the results, to ensure the stability of spillway trenches, the slopes should be excavated with a gentle slope. Considering the geometry of the current slope and analysis results, a width of 80 meters for approach channel could not be achieved at the level of 730 m.a.s.l. Therefore, to meet the desired width for spillway channel, excavating should be implemented with a steeper slope that this is not possible due to the instability of fine-grained material of the Neogene formation at spillway area, unless by using soil improvement methods for fine grained material. In regards to above mentioned conditions, the cost of the project will be increased. Indeed, considering the nature of the Neogenetic fine, it was decided that "in-situ" tests should be perform to obtain the fine-grained material properties at the spillway area. Based on the strength parameters results obtained from "in-situ" tests again the stability of trenches elaborated.

1. INTRODUCTION

In mass concrete temperature monitoring, there are mainly two kinds of methods, i.e., thermometer monitoring (traditional thermocouple or RTD) and optical fiber monitoring based on distributed optical fiber temperature sensing technology. With the rapid development of optical fiber sensing technology, the application of distributed optical fiber temperature measurement technology has been widely used in mass concrete temperature monitoring. Comparing to the conventional thermometer that only is available to the certain spot temperature measurements, the distributed optical fiber temperature measurement techniques can monitor the temperature of concrete along the fibers. With the proper arrangement of optical fiber temperature sensing network, the real-time temperature field information of dam interior could be obtained to actualize the dam temperature control.

In the aspect of foreign development: Barnoski[1] invented the optical time domain reflectometer (OTDR) in 1976. The University of Southampton originally proposed a distributed optical fiber temperature sensor in 1981. Based on liquid optical fiber laser Raman spectroscopy, Hartog[2] conducted the principle experiment of distributed optical fiber temperature sensor in 1983. DaMn[3], Hartog[4] developed subsequently the experimental device of distributed optical fiber temperature sensor by using argon ion and semiconductor laser light source.

In 1987, Sensa firstly released a distributed optical fiber temperature sensing system (DTS) based on backward Raman scattering. After that, the distributed optical fiber temperature measurement techniques have been commercialized by increasing companies.

In the domestic cases, the earliest optical fiber temperature sensing techniques were actually applied to the project of Shimen Dam by Tsinghua University and Munich University of Technology. Zhang Zaixuan[5] developed the FGC-Wl laser distributed Raman temperature sensing system in 1995. Afterwards, the FGC-W2 distributed optical fiber temperature sensing system[6] was further developed and its temperature resolution can reach 0.1 ℃. In 2002, Prof. Cai Desuo[7] introduced a DTS200-8-M2 distributed optical fiber temperature measurement system from Sensa and applied it to the 14th section of the left power house of the Three Gorges Dam. In 2007, Prof. Zhou Yihong[8] applied the distributed optical fiber temperature measurement techniques to Xiluodu Hydropower Station. In 2011, Prof. Zhang Zixuan successfully reduced the temperature drift of the optical fiber temperature measurement system[9].

The Wudongde dam located in the dry and hot valley is a concrete double-curvature arch dam with the foundation surface elevation of 718m, crest elevation of 988m and a maximum dam height of 270m. The temperature difference between morning and evening is large, moreover, the ground temperature is high and the evaporation is large. Therefore, it’s a big challenge to control the dam temperature. The low-heat cement used in Wudongde dam can improve the crack resistance of mass concrete due to its low heat of hydration and the post-concrete performance close to or over that of medium-heat Portland cement. However, the early strength development of low-heat cement concrete is slow and it is also the first time for the large-scale use of full-dam in China. It is hard to make sure the evolution of the true temperature field inside the low-heat mass concrete. Therefore, using the distributed optical fiber for concrete temperature monitoring is very significant.

2. DISTRIBUTED OPTICAL FIBER INTELLIGENT TEMPERATURE MONITORING SYSTEM

2.1. BASIC PRINCIPLE OF THE SYSTEM

Optical fiber temperature measurement system is composed of the host computer of the DTS (Distributed Temperature System), data network, distributed optical fiber, human-computer interface and cloud platform. The host computer of the DTS is an optical instrument which measures the temperature through the optical fiber. The optical fiber is similar to a sensor that monitor the temperature. The host computer provides the operation interface and it can not only measure the temperature intermittently but also measure continuously in real time. Furthermore, it provides the interface of data file and real-time protocol of data exchange for networking. Data networks can use wired or wireless means.

The basic principle(Fig.1.) of DTS is to make use of the principle of optical time domain reflectometer (OTDR) and the temperature effect of Raman backscattering of fiber. The thermal expansion coefficient of optical fiber can modulate the phase of the laser to reflect the temperature information.

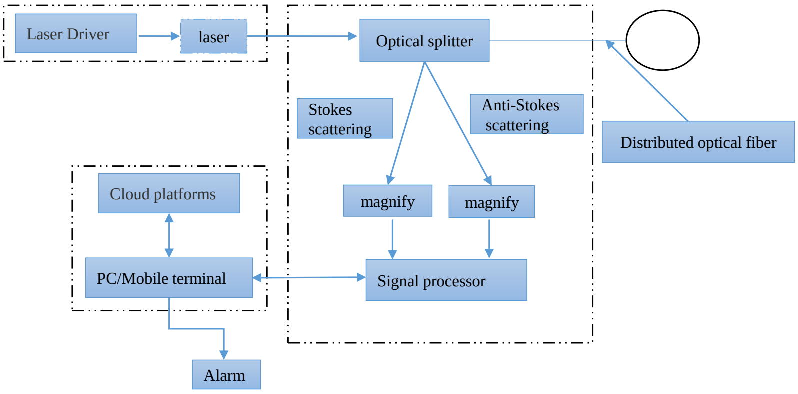

Fig.1
Distributed optical fiber intelligent temperature monitoring system

2.2. FUNCTIONS AND FEATURES OF HARDWARE SYSTEM

In order to obtain the real-time and accurate temperature data of concrete, Tsinghua university has developed the appropriate hardware system in the Wudongde construction site. The hardware system will transmit the temperature data to the cloud platform and the users can read the data from the platform conveniently. The specific functions are as follows:

(1) the methods of system networking: RS485, 4G and WiFi.

(2) the alarm function when fiber has been broken.

(3) visible human-computer interface or mobile terminal interface.

(4) no blind zone and continuance monitoring.

Compared with the traditional temperature measurement by thermometers, optical fiber temperature measurement has a great deal of advantages: no electromagnetic interference, good temperature stability, long-distance monitoring, large amount of monitoring information, high degree of automation, real-time online monitoring.

2.3. SOFTWARE PLATFORM

The software platform of Wudongde optical fiber temperature measurement system is developed independently by the Tsinghua university. The human-computer interface provides two methods. The first method is the WeChat software platform(Fig.2). The second method is the WEB client on PC. The two interfaces are based on the JavaScript programming language.

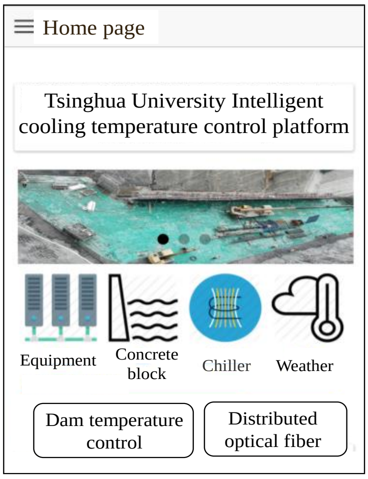

Fig 2

3. THE CONSTRUCTION OF DISTRIBUTED OPTICAL FIBER

Wudongde dam is divided into 15 sections. The distributed optical fiber is buried in the 7 # section. The overall layout of the optical fiber is shown in Fig.3.

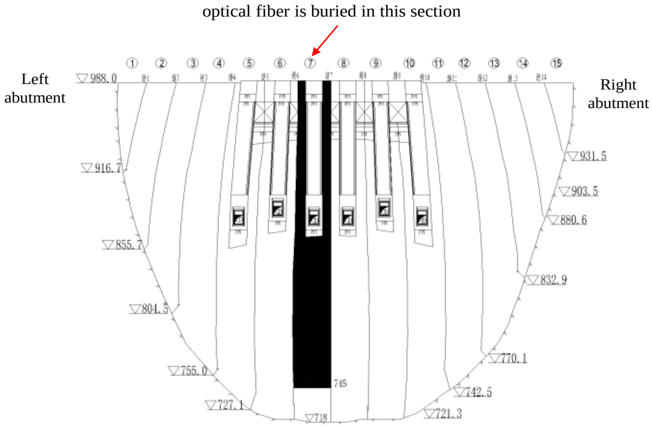

Fig.3

Layout diagram of distributed optical fiber in Wudongde arch dam (unit: m)

In addition to fiber, each dam concrete block is also embedded with three digital thermometers to monitor the temperature. The optical fiber is approximately the same elevation as the buried thermometer during the construction period along the river. The vertical optical fiber at the upstream and downstream surfaces are both 1m away from the upstream and downstream surfaces. The optical fibers below 871m in elevation are laid along the "Z" shape in the 7 # dam section. The optical fibers with an elevation of 871m ~ 988m are laid along the center line of the concrete block.

3.1. THE CONSTRUCTION DESIGN OF VERTICAL OPTICAL FIBER

The optical fibers are alternately in odd and even layers. The odd layers of optical fibers are embedded only in odd-numbered layers and the even layers of optical fibers are embedded in even-numbered layers only (Fig.4).

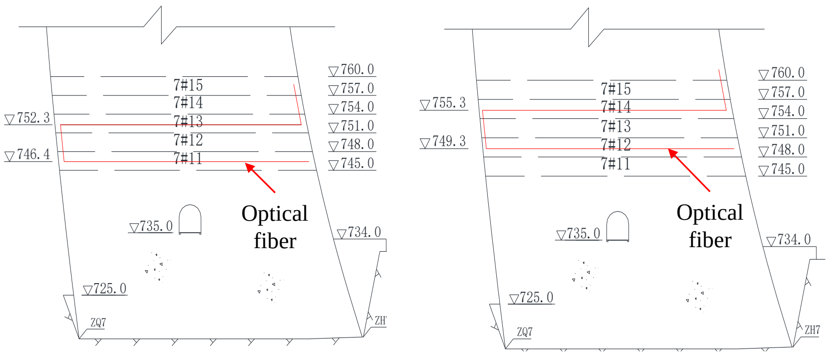

Fig.4
Layout diagram of odd and even layers of optical fiber (unit: m)

3.2. THE CONSTRUCTION DESIGN OF CONCRETE BLOCK OPTICAL FIBER

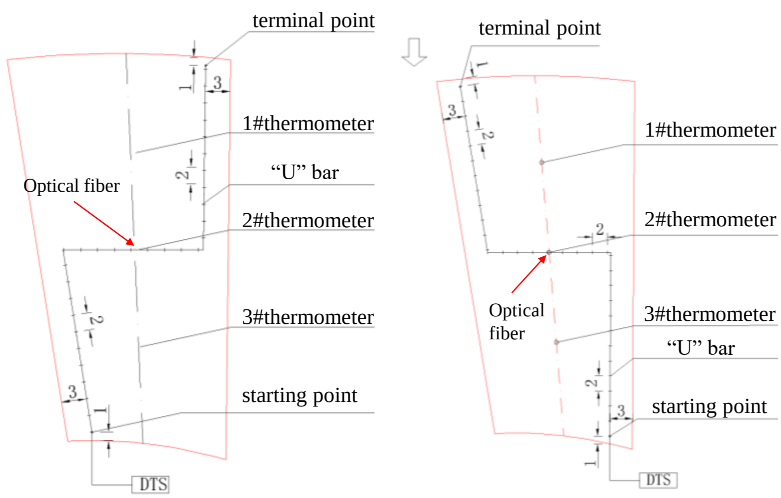

Fig.5
The "Z" shaped alignment of optical fiber in odd and even concrete block

In elevation below 871m, in each concrete block, the optical fibers start from the downstream surface to the upstream surface. The starting point is 1m away from the downstream and 3m away from the transverse joint. when the optical fiber arrives at half of the length of concrete block, it needs to turn to another transverse joint till the distance away from the joint is 3m. Ensuring the turning radius of the fiber is greater than 16cm.The entire fiber is "Z-shaped" (Fig.5).

3.3. THE CONSTRUCTION OF OPTICAL FIBER ON SITE AND COLLECTION OF TEMPERATURE DATA

On-site construction, the workers should embed the optical fiber at the exact location according to design drawings. During the process of the construction of the optical fiber, using the concrete vibrator makes the concrete flaccid. Then pressing the optical fiber vertically into the concrete with a depth of 10-15cm, and fixing it with a U-shaped bar (Fig.6).

After completing the construction of the optical fiber, the workers should test the buried optical fiber with the DTS instrument to ensure that the optical fiber is integrity, has no breakpoint, and is good communication. After confirming that the fiber has survived, the data can be collected and analyzed (Fig.6).

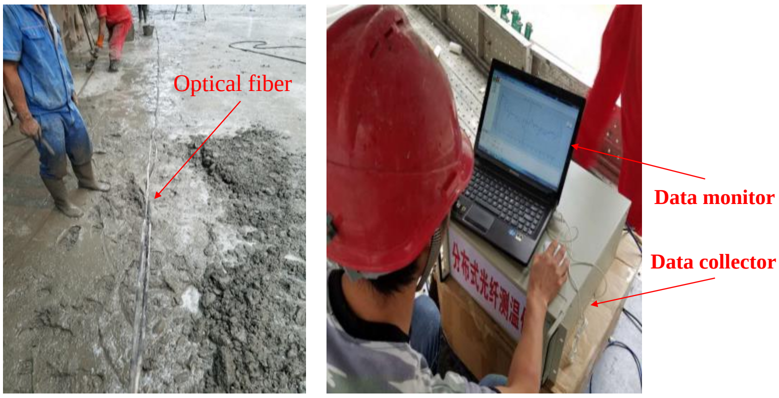

Fig.6
The construction of optical fiber on site and collection of temperature data

4. ANALYSIS OF DISTRIBUTED OPTICAL FIBER TEMPERATURE MEASUREMENT RESULTS

4.1. THE TEMPERATURE DATA CONTRAST BETWEEN OPTICAL FIBER AND CONCRETE THERMOMETER

In order to test the accuracy and reliability of the temperature data by distributed optical fiber, the coincident location of the concrete thermometer and the optical fiber is recorded during the construction process. The temperature at the coincident location is used to compare the data with the two temperature measurement methods later. In 2017/7/25 and 2017/8/4, the temperature data of two different temperature measurement methods are compared (Fig.7 to 8).

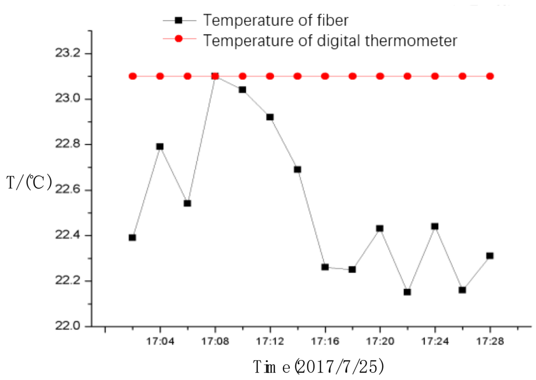

Fig.7
2017/7/25 Temperature data comparison between optical fiber and digital thermometer in 7#11

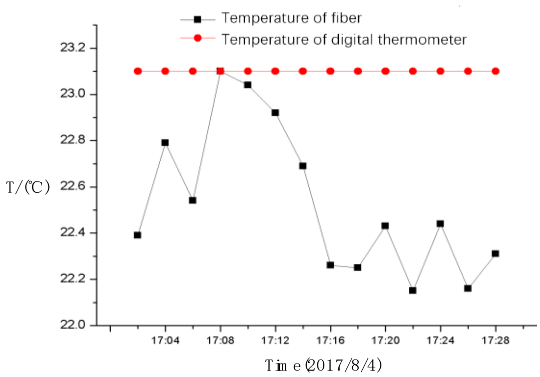

Fig.8
2017/8/4 Temperature data comparison between optical fiber and digital thermometer in 7#11

From Fig.7 and 8, optical fiber temperature measurement data and digital thermometer temperature data are different, but the difference is small. The relative error is within 1 ℃ between the two methods. Therefore, the optical fiber temperature measurement can meet the engineering requirements.

4.2. VARIATION OF TEMPERATURE INSIDE CONCRETE AT EARLY AGE

Taking the unit 7 # 11 of Wudongde Dam as an example, the temperature Variation is analyzed with age at the starting point at downstream surface and the end point at upstream surface(Fig.9).

During the construction period, the temperature of the dam is controlled by the cooling water. In order to facilitate the expansion of transverse joint, the cooling time is generally 2 to 3 days after the placement. Therefore, the change of concrete temperature is the result of the combined effect of hydration heat and cooling water.

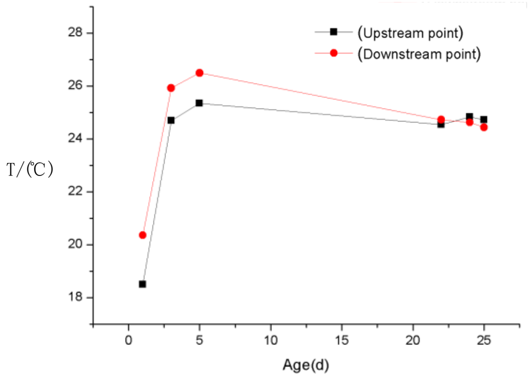

Fig.9

The temperature changes with age at the downstream starting point and upstream end of the optical fiber

From Fig.9, it can be seen that the internal temperature of concrete increases sharply with the increase of the age in the first 2 ~ 3d when there is no effect of the cooling water. Later, under the combined effect of hydration heat and cooling water, the concrete temperature first slowly increases until the maximum temperature (controlled by 27 ℃) and then decreases with the increase of the age, and finally becomes stable.

4.3. EVOLUTION LAW OF THE THERMAL FIELD

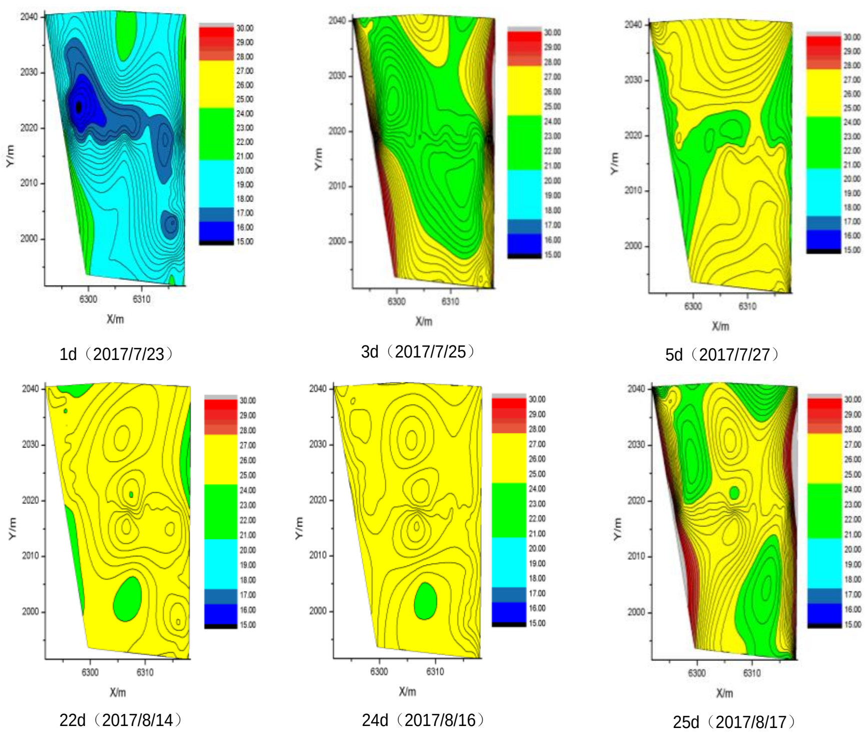

Fig.10

Evolution of the temperature field of unit 11 in 7 # section with age

The thermal field evolution law of unit 11 in 7 # section which bases on distributed optical fiber temperature measurement is displayed as Fig.10.

From Fig.10, when there is no cooling water, the temperature of the upstream and downstream surfaces of the concrete are higher than the temperature at the middle of the concrete block at the age of 1 d. This condition is caused by low pouring temperature and hydration heat, simultaneously, the temperature of the upstream and downstream surfaces is affected by the environment temperature. At the age of 3d, the hydration reaction releases a large amount of heat and causes the temperature inside the concrete to rise sharply. At the age of 5d, under the effect of cooling water, the internal temperature of the concrete continues to rise, but the rate is slowing. When the age reaches 20d and above, the concrete temperature stabilizes at 24 to 26 ℃ and the temperature field distribution is more uniform.

5. CONCLUSION

The distributed optical fiber temperature measurement system is developed to monitor and analyze the temperature change of low-heat cement concrete in Wudongde arch dam. The conclusions are as follows:

Distributed optical fiber temperature measurement can achieve real-time online monitoring under the complex site condition and the monitoring accuracy can reach ± 1°C.

Distributed optical fiber is alternately buried in the odd-even concrete block along the elevation direction and the "Z" shaped layout of optical fiber is used to enhance the accuracy of the temperature field reconstruction of the entire dam.

At present, the monitoring results show that the internal temperature of low-heat cement concrete increases obviously under hydration action after placement without effect of cooling water. Then the temperature increases with the age at a steady rate under the control of cooling water. After it reaches the highest level (the temperature is controlled at less than 27 ℃), the temperature gradually decreases with the age and finally becomes stable under the cooling rate of less than 0.5 ℃ / d. The temperature distribution of the concrete will tend to be uniform.

SUMMARY

Temperature monitoring is the basis for the mass concrete temperature control and is of great significance for the prevention of concrete cracking. According to the requirement of dam concrete temperature control during construction, a set of complete on-site operation technology was put forward based on distributed optical fiber temperature measurement technology and on-line temperature measurement software of optical fiber was also developed. Taking the low-heat concrete of Wudongde arch dam as a case, the temperature data of on-site concrete was collected in real time using the distributed optical fiber temperature measurement system, and the law of temperature evolution of low-heat concrete was analyzed. The results show that the distributed optical fiber temperature measurement system is effective, accurate and reliable, and the real temperature field of concrete can be obtained. The temperature of low thermal concrete in Wudongde is obviously at low level at early age, which helps to reduce cracking risk of dam.

BULGARIA

1. INTRODUCTION

Dams are complex multi-purpose engineering facilities which are always built in connection with a characteristic particular set of local conditions (hydrological, geological, topographical etc.). Their construction is a result of a complicated investment process consisting of several simultaneously running lines of activities such as administrative, financial, technical, economical etc. One activity of special importance in this bunch is the design in all its parts (i.e. special fields) and phases. In the design namely, all parameters, scenarios and modes of the operational life of the dam and its appurtenant facilities incl. the reservoir are formulated with respect to the particular water resources management tasks and to the requirements of the currently active codes and other regulations. It is well known however that the operational life of the dam essentially depends on the maintenance of the facilities, their performance in fulfillment of the operational tasks set with building of the dam is not possible without such proper

* **Exploitation de petits barrages agricoles en Bulgarie - état de l'art**

maintenance. The operation of the dam and its structures ends with conservation or removal of the dam, and such activity also is subject to the development and implementation of special and very particular design solutions.

There are almost 6000 water objects in Bulgaria subject to water right permits. More than 2000 of them are small dams according to the definition of ICOLD [1]. They were built predominantly in the 1960s and 1970s serving most of all agricultural purposes – local irrigation and stock farming. With very few exceptions as parts of some industrial facilities, these are embankment dams. In the decades after the Second World War, large profiled state design and construction enterprises with their local branches were engaged in the design and construction of such dams on the whole territory of Bulgaria for enabling the development of local agriculture besides the large irrigation systems. At the same time, the related national codes and regulations for preliminary surveys, design and maintenance of dams were developed with respect to the obtained experience and the current best practices not only of the Soviet Union and the other socialist countries [2] but also of the world leading countries in the field of Dam Engineering.

After the fundamental political change in 1989 in Bulgaria, all cooperative farms and so-called agricultural-industrial complexes were liquidated. The related administrative procedures were forced in time in connection with the restitution of the land property nationalized after the Second World War. In the frame of this process, many small dams owned previously by cooperative farms and societies were sold, however, without clear definition of the deal conditions as this will be explained in more detail further below. All responsibilities for the further operation of all remaining small dams were administratively transferred to the local municipalities. On the one hand, they still have neither the qualified personnel nor the financial resources to perform proper maintenance of the dams and their facilities. On the other hand, due to the collapse of national agriculture and the steady evacuation of the land population, there is currently in fact almost no need for the water from all these small reservoirs. As a result, the technical maintenance of the small dams as an inherent operation component was disregarded for many years with all related consequences.

The further development up to now is characterized by two other features, too. The municipalities owning small dams have always tried to find mechanisms for financing the technical maintenance of the facilities. Some solutions were found, however, they caused some other problems which will be addressed further below. Simultaneously, there are continuous and intensive attempts for corresponding development of the complicated legislative environment in the field which should enable general solutions of the most important problems related to the dam safety above all.

The present work constitutes an attempt for a short analysis of the current status of the small dams in Bulgaria considering its more recent historical development as well as the wide variety of related problems currently. This is not the first study of these problems, moreover since they become more topical with the time. Here in this connection, the works [3,4] on general and particular issues of the small dams should be mentioned as examples. Of course, a complete study would require large amount of reliable input data, its statistical processing in the time domain over decades and a comprehensive multi-disciplinary analysis with the boundary conditions of the overall national development in the considered time period. Since such task would go far beyond the frame of this report, further below we'll aim only at the qualitative and structured presentation of the main safety-related groups of problems of the small dams operation, the sources of these problems and some ideas for solutions.

2. CURRENT SITUATION, LEGAL AND REGULATIVE ENVIRONMENT

2.1. STATE OF THE SMALL DAMS IN BULGARIA – GENERAL REMARKS

In the last several years, intensive work is being done by all involved parties for qualitative improvement of the conditions for technical maintenance of the dams in Bulgaria. In fact, there are no problems with the large ones owned either by the National Electricity Company and serving with priority production of electricity from hydropower, or by the state enterprise Irrigation Systems, or by the water supply companies. They all have special operational units with experienced staff and the necessary resources for proper maintenance of the facilities. The main problems with the status – both technical and operational, are connected most of all with the small dams owned by local municipalities. However, a key person in the latter relation is the local district governor who is directly responsible for the safety of every dam in the district and its appurtenant structures. Once a year, he/she must organize an expert commission for analysis of the status of these facilities. Twice yearly, every dam owner must arrange thorough technical review of the facilities. In general, this has become a working mechanism recently, however, the governors hardly have the resources needed for implementation of the results from these analyses.

Since July 2015, the State Agency for Metrological and Technical Surveillance (SAMTS) is officially responsible for all issues of the technical operation of the dams in Bulgaria and their safety. This transition was accompanied by a still running substantial transformation of both administrative structures and regulative documents.

The Main Directorate "Supervision of dams and their appurtenant structures" at SAMTS has only control functions, i.e. it is not engaged itself in performing technical operation and / or maintenance of dams and their facilities. In general, the experts there examine the technical state of the dams periodically, formulate improvement requirements if necessary and control their fulfillment. Currently, a global national information system is being developed with online platform for data management and status monitoring of all dams in Bulgaria.

Although the SAMTS works together with all related parties if necessary, some administrative tension sometimes arises, especially when contradictory interests are present – for example, if an act of violation is drawn up of a dam owner while it is objectively evident that he/she has not had the possibility to ensure the required activities for the maintenance needed.

All above considerations are related to the technical maintenance of the dams and their facilities as well as to the dam safety, respectively. The other side of the problem is presented by the water resources management of these small dam reservoirs. As already mentioned, after both the collapse of the Bulgarian agriculture and the population migration following the political change in 1989, many of these reservoirs are simply not needed. Hence, the interest for their ownership, operation and maintenance is directly not present. This is a severe problem since on the one hand, these small dams are extremely valuable facilities of the water infrastructure in the conditions of relatively scarce water resources in Bulgaria. Furthermore, although small but numerous, they contribute to the damping of the peaks of flood events in whole catchment areas as this was the case of the flood in August 2014 in Northwestern Bulgaria [5]. On the other hand however, the long-term absence of proper technical maintenance substantially reduces their safety with all dangerous consequences.

2.2. LEGISLATIVE ENVIRONMENT, CODES AND REGULATIONS

Currently, there are almost 40 acts and subordinated legislative documents covering the whole spectrum of hierarchical range which regulate all aspects of the technical operation of the dams, latters' safety and the technical maintenance of the facilities [6]. Discussing them here would go far beyond the frame of the present report. A special feature in this connection is the fact that the property and the operation of the water reservoir is still strictly separated from the operation of the dam and its facilities. In some cases, this causes severe problems in the operation as a whole set of interrelated activities, and attempts at highest administrative level are made currently to overcome this formal separation.

It should also be noted that this regulatory system is a dynamic structure being continuously in development and improvement in terms of more adequate reflection of the reality for decrease of the identified problems – technical, administrative, legislative, operational, environmental etc.

In all cases when a particular problem is not covered by the current national regulations, the most advanced solutions to this problem available worldwide are applied. To serve this purpose, ICOLD Bulletins (for example Nr. 115, 116, 131, 138, 148), EU Directives and related documents, internationally recognized recommendations and guidelines as well as modern best practices are implemented. Other related sources are considered, too – for example [7, 8]. Last but not least, special attention is also paid to the recent research activities in this field, especially to the ones within the European Union. Here, [9, 10, 11] can be mentioned as examples.

The environmental aspects of the small dams are subject to special concern, too. Recently, the legislative component of these aspects is rapidly growing, especially with the implementation of the strategies, policies and directives of the European Union. One important issue related to the operation of small dams is the water quality in the reservoir. This requires better care not only for the water quality in the dam lake itself but also for the run-off and pollution prevention, respectively in the whole catchment area. Furthermore, the necessity of regular preparation of plans for assessment and management of flood risks (which are regulatory documents) is both formally obligatory and directly related to the dam safety.

3. IDENTIFIED PROBLEMS AND SOME RECOMMENDATIONS

3.1. LEGAL AND ADMINISTRATIVE ISSUES

In this section, the following main issues can be formulated as identified in the operation and maintenance of small dams:

- After having become owners of numerous small dams without having the needed resources for their proper maintenance, many municipalities let the dams for rent. As a result, the renter usually not only restricted the access of any other parties to the reservoir but also to all dam facilities for maintenance. At the same time, the renter had no responsibility for the technical status of the dam and its appurtenant structures. In most cases, the operator used the dam reservoir as a fish farm and installed meshes at the spillway for preventing the fish to escape. Although such installations are indeed extremely dangerous for the dam structural integrity, deficiencies in the actual regulations and in the particular contract formulations made them happen in many cases.
- As mentioned above, the land property was restituted in general in the 1990s. However, during the liquidation of the cooperative farms, many dams were sold by tenders. Later on, it became obvious in many cases that the legal owner of the dam didn't have in fact anything more since the land below the reservoir was returned to its previous owners. The water in the dam lake is public state property, and the dam owner had often even no more access possibility to the facilities. This is indeed a severe issue in many cases still open and directly related to the maintenance and safety of the dam and its structures.
- The previous issue is directly related to the next one as already mentioned above – the rigorous separation between dam with its appurtenant structures and the water in the reservoir. These two items are inherently connected by the purpose of the dam as well as by the Hydraulic and Structural Engineering facilities serving the reservoir water management. Attempts are currently made for overcoming this problem of sharing responsibilities.

- The lack of resources for technical maintenance of the dams and their structures brought some dam owners to the necessity either to keep the corresponding reservoir permanently empty or to cut the dam body and thus to prevent any further impounding. So, they also prevented any flood risks for the downstream residents. Such destruction is usually performed without any technical design and compliance with the related legal requirements. Of course, the result is devastating for the materials of the dam body, too.
- The lack of resources (i.e. finances, qualified personnel, equipment etc.) for technical maintenance of the small dams and their facilities including for carrying out reparatory works sets many municipalities as dam owners between the hammer of the legal requirements and the anvil of resources.
- The emphasis on environmental friendliness has led recently to some curious legal requirements. For example, every new dam must have a fish pass according to the Act for Fishery and Aquacultures. In the process of legislation development, such examples of nonsense should be cleared.

3.2. PERFORMANCE PROBLEMS DUE TO THE LACK OF TECHNICAL MAINTENANCE

The following issues due to the lack or even absence of technical maintenance can be formulated with respect to the performance of the small dams and to the related findings in [3, 4, 5] as well:

- In general, often there has been no technical maintenance of the dams and their facilities. There is no monitoring system, no measurements and analyses of the technical conditions are carried out. Usually, there is no technical documentation including drawings left from the design and construction.
- Settlement of the embankment at the central part of the dam. Thus, the dam crest level has sunk below the maximum water level in the reservoir, and the risk of crest overflow during flood conditions strongly increases with all negative consequences of such event.
- The legal requirement for cleaning the river bed 500 m downstream of the dam is in general not held by the dam owner.
- Many small dams have suffered some damages over the years of operation without proper maintenance. They need a serious and urgent repair for restoring their full operational functionality. Otherwise, subsequent load impacts and floods could lead to heavy damages of the dam body with possibly uncontrolled release of the impounded water. Independantly how small this volume might be, the resulting flood wave could certainly have severe consequences.
- Erosion of the streambed downstream of the spillway. In some cases, the structure of the spillway itself is in a good condition. However, the following spillway race and the stilling basin (if available) have been for

years subjected to erosion without any maintenance and repair. Under some particular geological conditions, this erosion may have become quite intensive.

- Damaged or clogged bottom outlet which leads to the necessity of draining the reservoir only by means of an external temporary siphon.
- With the time and without any maintenance, the spillway inlets of numerous small embankment dams have clogged by floating debris during relatively small flood events. Every time when there was flow in such spillways, additional amounts of debris were added. Thus, without cleaning the spillway inlet, the risk of dam crest overflow increases.
- Non-maintained dam slopes with developed dense plant and tree cover. These slope conditions heavily complicate the access to the dam crest and all appurtenant structures.

3.3. PERFORMANCE PROBLEMS AFTER IMPACTS EXCEEDING NORMAL OPERATING CONDITIONS

At several dams during flood events, the dam crest has been overtopped as well, Fig. 1 [5]. Fortunately, these dams retained their overall structural integrity, and no uncontrolled catastrophic release of the reservoir content occurred. However, the dam body in such cases was damaged, and all necessary repair works had to be carried out as soon as possible, for such dams to be able to further fulfill their basic operational requirements.

Fig. 1
Damaged crest area after overflow
Zone de couronnement endommagée après débordement

It should be noted here that design of such small dams has been performed with relatively high probability of exceedance of the design loads and impacts according to the code requirements. Thus, it is possible that such damages occur during their operational life. This only emphasizes the importance of proper regular maintenance and carrying out of all necessary repair works on time.

3.4. POSSIBLE RECOMMENDATIONS

After the summarizing presentation of the main operation and maintenance problems of the small dams in Bulgaria above, the following recommendations can be formulated:

- The necessary administrative work has to be done for overcoming of the separation in the operational management of the small dams between the dam with its structures and the water reservoir. Careful and justified distribution of the activities and responsibilities, respectively, has to be carried out.
- The performance of the facilities under so-called overload conditions for the particular class of importance has to be regulated.
- The property issues related to the small dams need urgent solution.
- Highest priority has to be assigned to the repair of dams with structural damages of the dam body and to works for restoring the operational ability of the safety-related appurtenant structures.
- The requirements are good but it is a matter of state policy that dam owners have a chance to obtain the resources needed for proper maintenance of the facilities by means of appropriate mechanisms.

4. CONCLUSIONS

From the performed short analysis of the status of the small dams in Bulgaria, the following conclusions can be drawn. First of all, these facilities are essential component of the national water resources management infrastructure at lowest structural level. Hence, their operation and technical maintenance should be subject to strategic national policy in this field.

There is a set of serious problems in several fields related to the operation and maintenance of small dams, as shortly discussed above. The nature of the required solutions is very complex and requires interdisciplinary approach by broader teams of experts. It is quite clear, however, that the process of developing and implementing such solutions is complicated and requires besides expert knowledge high-level skills in the management of sometimes contradictive interests. Moreover, these solutions need considerable resources. One more thing is clear, too. If the state does not set properly its priorities for further development in this field, at least two things will happen. As a result of the decreasing safety of these dams and their facilities, accidents will occur. We cannot allow this to happen. Further, although possible removal of many such dams (which also requires corresponding design, administrative and construction activities and financing, respectively) seems to be a solution, their subsequent building if needed will be much more difficult and expensive. Hence, similar decisions with long-term effect have to be made very carefully.

We are glad to find that currently, there is the general expert and administrative will in Bulgaria for solving the problems with the status and operation of the small dams.

SUMMARY

The font size of the Summary should be MS Unicode Arial 11 point, justified, line spacing “exactly” 14 pt; the heading (SUMMARY) should be all capital letters, and centered.

This work is a summary report about the current frame conditions for the operation of more than 2000 small dams in Bulgaria, almost all of them build for agricultural purposes. It is based on both a vast literature survey and specific national experience, and it presents the results from the performed qualitative analysis from the point of view of the following aspects of dam operation:

1) Legislative base, regulatory documents and guidelines: national legislation and administrative procedures, code requirements, international recommendations and good practices.

2) Physical aspects of the operation of small dams aiming at technical and operational reliability in connection with the most commonly used structural solutions for these facilities;

3) Some particular problems of the operation of small agricultural dams.

Finally, based on the presented results from the analysis performed, conclusions are drawn with respect to particular contemporary research and implementation needs.

RESUME

Ce travail représente un rapport de synthèse sur les conditions de base actuelles pour l'exploitation de plus de 2000 petits barrages en Bulgarie, presque tous construits à des fins agricoles. Il est fondé sur une vaste étude bibliographique et sur l’expérience nationale spécifique et présente les résultats de l'analyse qualitative réalisée du point de vue des aspects suivants de l'exploitation des barrages:

1) Base législative, documents réglementaires et directives: législation nationale et procédures administratives, exigences du code, recommandations internationales et bonnes pratiques.

2) Des aspects physiques de l'exploitation des petits barrages visant à la fiabilité technique et opérationnelle en relation avec les solutions structurelles les plus couramment utilisées pour ces ouvrages;

3) Certains problèmes particuliers de l'exploitation des petits barrages agricoles. Finalement, sur la base des résultats présentés de l'analyse réalisée, des conclusions sont tirées en ce qui concerne les besoins contemporains de recherche et de mise en pratique.

1. PREFACE

Numerical modelling of water flow has been accelerated in recent years by more affordable computer performance and software products for that purpose. Numerical modelling has recently, in some cases, replaced physical models. Sometimes it is worth using their combination, usually with the aim to reduce modelling costs in general. In the case of simple side channel spillways of water works, it is clear that numerical modelling can be used very well for all flow discharges and new possible designs of the spillway geometry as well. Therefore, the objective of this paper was to compare the possibilities of 3D numerical modelling of water flow on the side channel spillway with three software products. The question was not which one is best, but which one is more suitable for special needs of users. The article further describes the difficulty of working with individual software products, especially user interface, setting options, solution speed and accuracy of the results. A common input for all three solvers is an imported STL file, which is individually modified for each program. In the pre-processing section, the differences are mentioned in the settings among the programs themselves. Another objective of the project was to compare these modelling procedures, to show their differences and compare the outputs to each other.

The task outcomes were not primarily focused on the quality (details) of outputs. Also, it was not a priority to compare numerical models with a physical model. The subject of modelling was to create a corresponding virtual model with acceptable simplifications of real geometry. The real structure of the selected spillway was geodetically measured and a 3D spatial model in CAD software was created.

2. PRESUMPTIONS AND SIMPLIFICATIONS OF THE MODEL

These are parameters and facts whose application leads to a partial simplification of the examined phenomenon. In the task, it is not necessary to take into account every detail. Therefore, the task remains with the basic settings of the model, but the examined phenomenon will be sufficiently described. The model should be configured to match the reality or physical model as much as possible.

The following assumptions were implemented to the modelling process:

- *Isothermal system* - is a system where the temperature is constant, throughout the system.
- *Air entrainment* - there are two fluids set in the entire object. It is air and water; however, their mutual mixing is not taken into account, due to pressure changes in the turbulent flow. Requires a very fine computation network.
- *Roughness* - the way to divide this variable into a real object is too complicated. Because the surface is concrete, although partially degraded, there is expected a large flow rate. Therefore, the effect is minimal on the flow rate.
- *Boundary condition* - are for all software products the same (margins = wall, inside = atmosphere, discharge = continuous). Only the inlets are different. It depends on the desired setting of individual software product.
- *Turbulence* - *option* in all software products is used the same two-equation turbulent model $k - \omega$ [1] for calculation of all parameters.

3. CASE STUDY

The comparison of individual programs took place on the existing water work. Slušovice dam is located near the village of Slušovice in the southeast of the Czech Republic and is managed by state owned enterprise Povodí Moravy. Its primary function is the drinking water supply and flood protection as well.

The side channel spillway is located on the left bank of the reservoir. Spillway and chute are reinforced concrete structures. The shape of the overflow edge in the cross section is circular with a radius of 0.75 m. The length of the spillway edge is 26.8 m and the channel width is 6.0 m. The original (designed) flow capacity of the object is 89.5 m^3/s for the maximum level in the reservoir.

4. OPENFOAM

4.1. INTRODUCTION

OpenFOAM (hereafter referred to as OF) is currently the most widely used CFD (computational fluid dynamics) tool, that is available for download. It is distributed under the GPL (General Public License), which means it can be used free of charge and its source code is freely accessible. GPL licenses give users the freedom to modify and redistribute modified code.

Figures and codes are created with using object-oriented programming and operators. It allows user to create their own solvers relatively easy. Users can create their own objects, boundary conditions or turbulence models that will work with existing solvers without redrawing existing source code.

The OF consists of a large basic library, which contains a number of different types of solvers, tools for creating and manipulating the computing network (mesh networking), monitoring the quality of the computing network, counting variables, parallel calculations on multiple computers and others.

4.2. PROCEDURE

Due to the fact that OF as such is a set of tools for CFD simulation solutions, it does not basically include utility programs for processing object geometry, preparing simulation, selecting boundary conditions, creating a computing network, etc. (pre-processor). It also does not include a program with a suitable Graphical User Interface (GUI) to perform visualization, verification or manipulation (postprocessor). However, there is a number of available programs for free that can be used for each phase of CFD modelling.

Here is the process of setting numerical model and examples of other implement software products with which the OF works:

- creating STL geometry in Blender or Salome and defining a computational geometry,
- creating a mesh network with snappyHexMesh. This process runs behind the Command-line interface,
- selection of solver for two-phase liquid (interFoam). Again, associated with Command-line,
- definition of physical parameters of liquid,
- definition of initial and boundary conditions,
- the calculation itself, the convergence tests, the residuals assessment, the verification of the existing results,
- post processing in ParaView, verification of results, their graphical interpretation etc.

4.3. SAMPLES OF WORKING INTERFACE

Here are some figures of working in different sub programs for the purpose of creating a valid model, repairing, also setting the fine mesh and setting the variables.

5. ANSYS FLUENT

5.1. INTRODUCTION

Ansys Fluent is today a very common software that deals with CFD issues. It offers a wide range of physical modelling options for flow modelling, turbulence, heat transfer etc. It describes tasks in various branches such as civil engineering, construction, chemistry, etc. There is the choice from a large number of equations for laminar and turbulent flow and their complementary auxiliary elements.

Thanks to step-by-step distribution of the work desktop, which forces the user to continue step-by-step, makes settings very easy to understand and use. The simpler the setting of conditions and model, the more complicated and the less pleasant is the importing of the model and meshing. The software is quite sensitive to various geometry imperfections. Therefore, for more sophisticated models, the body must be properly inspected and handled by the auxiliary functions.

5.2. PROCEDURE

The sequence of individual property settings is determined by the software itself that leads the user through the following points.

- *Analysis systems - fluent* - first step is about the selection of solvers for adequate operation (Fluent),

- *Geometry* - create/import a spatial model, these models are importing through the software SpaceClaim; another step is to check and repair of imported model,

- *Mesh* - a creation and modification of mesh network,

- *Setup* - gradually expanding the sub items to define variables and conditions, only those involved (clearly presented),

- *Solution* - the running of the calculation itself. Writing of the results and comments from the progress. These variables are set in the" Setup "section. The description of the state of the so-called residuals,

- *Results* - post processing, thus visualization of user-selected parameters and variables, in any environment.

5.3. SAMPLES OF WORKING INTERFACE

Here is a group of figures from Ansys workbench.

6. FLOW-3D

6.1. INTRODUCTION

Flow-3D is software for fluid dynamics in various systems. The user interprets the behaviour of fluids with using numerical methods, the model itself, boundaries and initial conditions, the user interprets the behaviour of fluids. Overall, the survey is performed using the Volume of Fluid mathematical method.

A great advantage is the software's resilience to geometrically complicated and un-repaired models. While other software products require precisely repaired and imported models, Flow-3D also works with very difficult 3D objects without any errors. The software itself includes, among other things, an internal function that corrects the remaining inaccuracies. Its name is Qadmesh. There is lot of tools inside this function, but there is also a risk that the repairing process will change the original model. It will actually fix the imperfections but at the cost of losing real parameters.

6.2. PROCEDURE

After launching the software and looking into the work environment, user can see organized cards. Main cards that have a sub-card group you must expand one after the other and set up the entire process.

Overall, the core part is based on detailed modification of the mesh network. It is simple to create, manipulate and also to import your own shape. Before simulation, it is necessary to know the fact that the smaller cells in the mesh (the smoother the process will be created), the more complicated and longer calculation becomes. Another advantage of the grid is the ability to modify it so that the network is denser at the point where it is needed.

- *New Simulation* - at the beginning user have to choose the type of simulation or physical process (flow over weir),
- *Physics* - another step is to define appropriate condition (gravity, viscous, turbulence etc.),
- *Meshing and geometry* - creating a simple geometry object (or import the complicated) and then create a mesh network,
- *Output and numeric* - in this step user chooses, what he wants to calculate inside the mesh (velocity, pressure, fraction fluid and others),

- *Analyse* - It is used to retrieve the obtained calculations and provide data to plot the process,
- *Display* - It is possible to work separately with the obtained outputs from the previous part of “analyse” (post processing).

6.3. Sample of working interface

There are some figures from post processing part of simulation.

3D view under spillway

7. RESULTS COMPARISON

There is an illustration of flow in spillway cross-section. On the first sight it is evident that Ansys Fluent was set with greater mesh blocks (size = 0,15-0,45 *m*). The main purpose of this setting was to save the time. Flow-3D and OpenFoam has calculated with size of mesh 0,03-0,15 *m*.

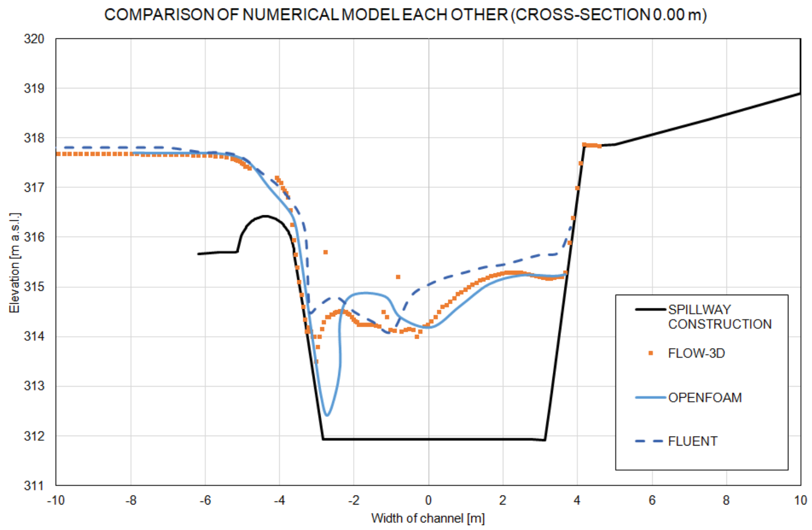

Fig. 15
Cross-section

8. SOFTWARE PRODUCTS COMPARISON

The times given in individual parts in the table below are given approximately. It is only for better understanding, what amount of time the work with software products take. The simulations were handled by single desktop computer (AMD FX 6300 Six-Core, RAM 8.00 GB, NVIDIA GeForce GT 630). That indicates the limited amount of mesh cells, larger amount of time etc. The table below shows the comments to each part of process.

	OpenFoam	Ansys Fluent	Flow-3D
I. Creating of spatial model	in external software (Blender)		
Time for this part	*10 hours*		
II. Modification and corrections	* it is necessary to do this step in Blender. It contains several tools for geometry repair	* more difficult models need to be edited even more hours	* very simple, program handle also very problematic schemes
III. Meshing	* simple mesh creation, possible refinement of edges, faces and volumes	* the creation of a global mesh is really simple if the spatial model is correctly repaired. Important spots must be described separetly	* the possibility of importing, creating of proper interest by dividing into blocks
Time for this part	*2 hours*	*3 hours*	*1 hour*
	OpenFoam	**Ansys Fluent**	**Flow-3D**
IV. Settings	* an organized settings, if user knows the basics the solution is way easier and faster	* clear, step-by-step expansion for each step displays all major and minor parameters	* average, at the first sight is everything arranged, but some of the parameters can not be changed or traced without Help-function
V. Boundary conditions	* the selection depends on the tips in help or source files, for user easy manipulation	* there is a simple way how to input, however with simple input might be the simulation sometimes unstable	* with a larger number of blocks grows the amount of BC, but the conditions are not significanetly different
Time for this part	*2 hours*	*1 hour*	*1,5 hour*
VI. Simulation	* the check of residues, continuisly visualization of results and possibility to change main settings while the calculation is running	* the check of the process depends on residues, it is possible to obtain outputs for verification	* there is possibility continuously evaluate, modify and analyze obtained data
Time for this part	*50 hours*	*62 hours*	*75 hours*
VII. Postprocessing	* the final analysis in postprocessing is available in all dimensions, parameters and output formats. The very clear interpretation and tools help to understand obtained results		
Time for this part	*2 hours*	*4 hours*	*3 hours*

SUMMARY

The main result of numerical simulation is the movement of flowing water in side channel spillway. The level of water surface from all software products is pretty similar, even for the same STL format geometry data. But the STL input must be modified/changed for every solver. Thus, from the beginning are all three processes completely different. They have all their pros and cons and it is delicate question which is better to use. Same desktop computer, similar settings, similar outputs. Today, the numerical modelling is a perfect way how to perform 3D simulation of water flow on water structures. Of course, the difference makes always the price of the software license. All tested software proven to be worth using for some reasons and some users.

1. INTRODUCTION

Within the framework of an in-depth review of an old gravity dam in Germany [1], detailed safety assessments are carried out according to the latest state of standardization. Tremendous work has already been done on this topic and especially on this dam. Investigations and results regarding parameter variations and assessment criteria for 3D models of concrete dams have already been published in [11], with the focus on reducing the parameter space and finding suitable criteria for the reliability analysis. Nevertheless, the following sections in this paper are mostly based on the aforementioned publication [11] for clarification purposes. The main goal of the investigation discussed in this paper is to reduce to amount of needed simulations for the reliability analysis to determine the exceedance probabilities and finding/evaluating suitable assessment criteria.

2. GENERAL INFORMATION

The investigations are based on a three-dimensional finite element model, which takes the loads and resistances into account as realistically as possible. The static and transient thermal analyses are carried out by using nonlinear material laws for the dam (masonry) and brittle rock subsoil, considering the seasonal instationary temperature fields and the load-dependent pore water pressures in the dam body. Additionally, the existing sealing and drainage elements as well as the nature of the rock subsoil are considered.

The investigation of the dam in [11] dealed with the following topics:

- Calibration and verification of the calculation model against measurement results,
- Stability assessment using the EC-compliant safety concept presented in [1] on the basis of partial safety factors,
- Basic studies on the behavior of the dam,
- reliability of the results and main impact factors,
- Stochastic investigations to assess the probability of failure

The gathered knowledge from these topics are the basis of the ongoing investigations.

All simulations are carried out using the finite element program ANSYS®, the elastoplastic material model library multiPlas [10] for ANSYS and the software for stochastic analysis ANSYS optiSLang® [9].

3. NONLINEAR FINITE ELEMENT MODEL

For the nonlinear simulations a 3D model of the dam and the foundation is created. The model has a width of 768 m, a length of 515 m and a height of 218 m. The FE model is shown in Fig. 1.

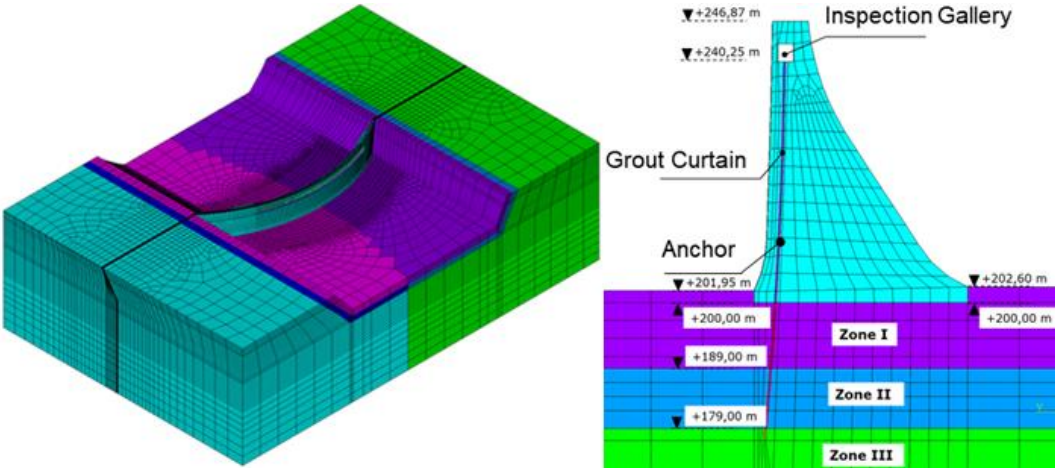

Fig. 1
3D FE-model of the dam and the dam section

The subsoil model is based on the data in [2], [3] and [5]. In total, three zones of different permeability in the vertical direction are considered (see Figure 2). Clay slate is found on the right slope according to [2]. On the left slope, greywacke with clay slate interlinings are found.

A grout curtain is installed and extends to a depth of +177.00 m a.s.l. in the region of the clay ridge and on both sides of the clay ridge to a depth of +191.00 m a.s.l.. 104 anchors stabilize the dam in the middle area. Each anchor contains 34 strands. The cross-sectional area of each strand is 150 mm². The anchor force is 4500 kN/anchor. 52 anchors reach into a depth of +167.0 m and 52 into +172.0 m. The grout length of the anchor for transmitting forces into the rock is 10 m each.

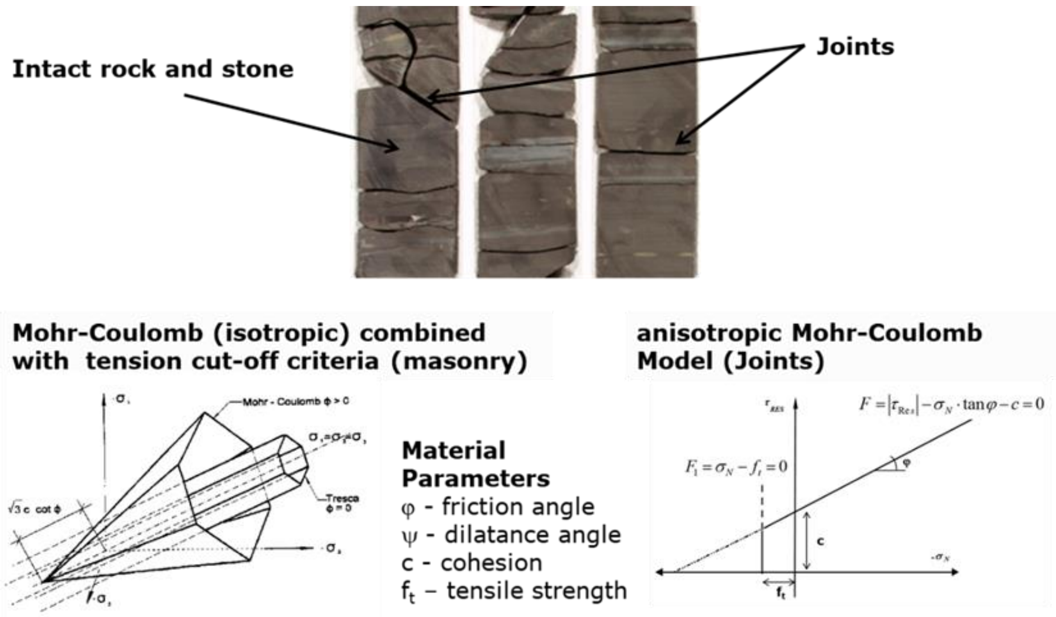

Fig. 2
Constitutive models used for the masonry dam, the intact rock and the joints

The nonlinear behavior of the masonry and the fissured rock subsoil is simulated using isotropic and anisotropic elastoplastic Mohr-Coulomb material models with tensile stress limitation. The position and orientation of the separating surface layers are also considered in the constitutive models. Virtual horizontal separation surfaces are taken in account to allow for stress free openings in vertical direction. Material parameters of the final calibration of the model can be found in Table 2. Fig. 2 illustrates the constitutive models used for the masonry dam, the intact rock and the joints. The final material properties from the calibrations are summarized in Table 2.

The boundary conditions are defined to prohibit the model to move in normal direction to the rock boundaries. The load history is taken into account in all load case combinations (LS) according to the composition in Table 1. The individual loads are multiplied by the corresponding partial safety factors from [1].

Table 1
Load steps of the nonlinear simulation

Loadstep	Action
LS1	Deadweight foundation (Initial Stress State)
LS2	Deadweight dam
LS3	Hydrostatic water pressure for defined water level
LS4	Hydrostatic water pressure at the level of anchor pre-stressing (241,605 m NN)
LS5	Anchor activation
LS6	Anchor pre-stressing
LS7	Hydrostatic water pressure for defined water level
LS8 f.	Additional varying loads according to Eurocode [1]

Non-stationary thermal finite element calculations are carried out for the determination of the temperature stresses in the dam. The external temperatures in the Hessen region are extracted from [7]. The water temperatures are taken into account in the thermal calculations as a function of time and water depth according to temperature data available at BAW (Federal Waterways Engineering and Research Institute).The 3D pore water pressure fields are calculated with a transient thermal analysis using a temperature-flow analogy.

4. MODEL CALIBRATION AND VERIFICATION

In order to increase the realistic proximity of the simulation model and thus to achieve a high quality of the stability tests, the simulation model is calibrated with deformation measurements of the dam. The measured deformation points are shown in Figure 3. Furthermore, pore water pressure and temperature measurements are to verify the hydraulic and thermal analyses.

Parameter identifications and sensitivity analyses are done to determine the dependencies between the model/material parameters and the response variables/measurements to be calibrated.

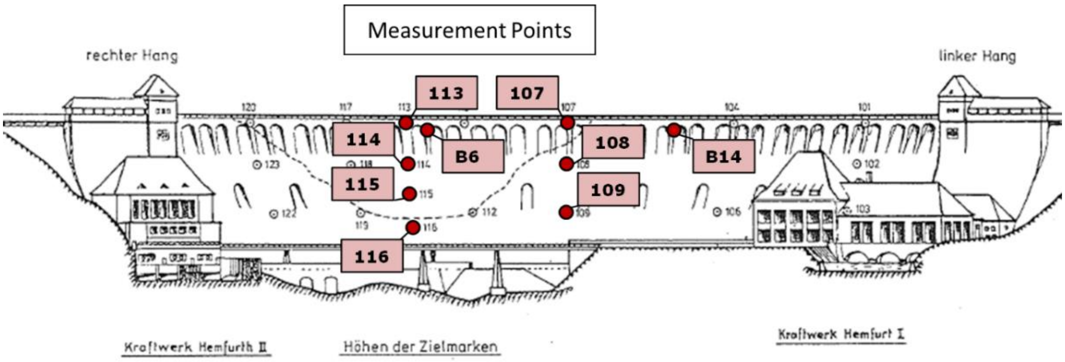

Fig. 3
Displacement measurement points used for calibration

The sensitivity analysis is carried out by means of variations-based correlation analysis in ANSYS optiSLang® [9]. All material parameters are varied as scattering inputs of the sensitivity analysis. The response variables are the radial relative displacements at the measurement points from Figure 3. 200 parameter combinations (designs) are calculated for the sensitivity analysis. Latin Hypercube sampling available in ANSYS optiSLang® [9] is used for sampling the 200 designs. In each design, a nonlinear load history calculation is simulated with the following load steps for calibration (LSC):

- LSC1 Activation of the dead weight in the foundation (Initial stress state)
- LSC2 Activation of the dead weight of the dam
- LSC3 Hydrostatic Water Pressure at 229,02 masl
- LSC4 Hydrostatic water pressure at minimum water level (220,00 masl)
- LSC5 Hydrostatic water pressure at maximum water level (244,95 masl)

The dam is simulated in the sensitivity analysis and model calibration without anchors and restoration measures, because the measured values of the deformation measurements originate from the time before the rehabilitation and the installation of the pre-stressed anchor.

The relevant input parameters (CoP values as a bar histogram) for the maximum water level (244.95 masl) and the minimum water level (220.00 masl) are calculated for each measuring point and the associated dependencies (anthill plots of the relevant input parameters vs. deformation). The CoP values are prognosis parameters and indicate how much the variance of the observed response variable (deformation at the measuring point) can be explained by the variation (or variation) of the respective input variable. Unimportant input parameters (whose scatterings are not correlated with the spread of the response variable) are automatically filtered out by ANSYS optiSLang® [9]. As the sensitivity analysis shows, the stiffnesses of the subsoil and of the masonry of the dam can be calibrated in particular by means of the deformation measurement values for the observed / measured water levels. It is also plausible that the stiffness of the masonry has a greater influence on the higher measuring points, whereas the deformation on the MP 116 is almost exclusively determined by the foundation stiffness. Fig. 5 shows the calculated and measured deformations. The black line indicates the measured values, gray lines indicate the spread of all designs and red is the best design Nr.186, which is determined by optimization and shows a very good agreement with the measured deformation values. As a result of the model calibration, a simulation model is developed which can easily and reasonably reconstruct the available measurements with regard to the deformations, temperatures and pore water pressures.

Reference temperature	°C	10	8

5. STOCHASTIC ANALYSIS

Based on the experiences gathered from the stability studies and stochastic analysis from [11] new assessment criteria and more elaborated reliability analyses are carried out using the calibrated FE model.

The motivation for the stochastic analysis results from several questions. For example, a stochastic analysis can be used to circumvent contradictions arising from the use of partial safety factors in nonlinear analyses, where questions arise from whether it should be determined by a load-side increase or by a reduction of the resistance. Both approaches aren't without doubt possible in connection with nonlinear analyzes.

By means of a stochastic analysis, failure probabilities can also be determined in the case of nonlinear analyses when introducing load and resistance-side scatterings. This procedure is included in Eurocode EN 1990:2002 (Annex B and C). In a recent and ongoing cooperation between the BAW (Federal Waterways Engineering and Research Institute) and Dynardo, the example of this dam is worked out, including further fundamental investigations, to develop a procedure for practical projects.

The stochastic analysis consists of the following steps.

- Definition of the scattering of the input parameters.
- Generating the samples in ANSYS optiSLang® [9], various methods (Monte Carlo, Latin Hypercube, Directional Sampling, FORM, ...) are available for this purpose.
- Definition of evaluation criteria, e.g. Displacements in the abutment, Displacement gradients in the abutment, tilt safety - position of the resultant, sliding safety - principal shear strain, pressure failure -

principal normal strain and risk of fracture in the grouting zone - max. plastic vertical strain, etc.

- Performing nonlinear analyses of all necessary designs defined by the sampling method.
- Evaluation and determination of the probability of failure

5.1. RESULTS OF THE STOCHASTIC ANALYSIS

In this investigation two reliability analyses by means of probabilities of failure are carried out. To determine the exceedance probabilities, an adaptive response surface method (ARSM) was used in combination with the First Order Reliability Method (FORM). For each reliability analysis, more than 600 designs were calculated in individual (here three) iteration steps. With each iteration step, new designs are created that are closer to the limit state. The approximation quality of the generated response surfaces is 99%.

The total displacement V (nodal mean value at the abutment) is used as the evaluation criteria. For the derivation of the limit values, limit load analyses were carried out (due to load increase and due to resistance reduction). Two threshold levels were derived for the rating criterion V, which are V_1 = 0.05 m (near system failure) and V_2 = 0.03 m (transition to non-linear system behavior)

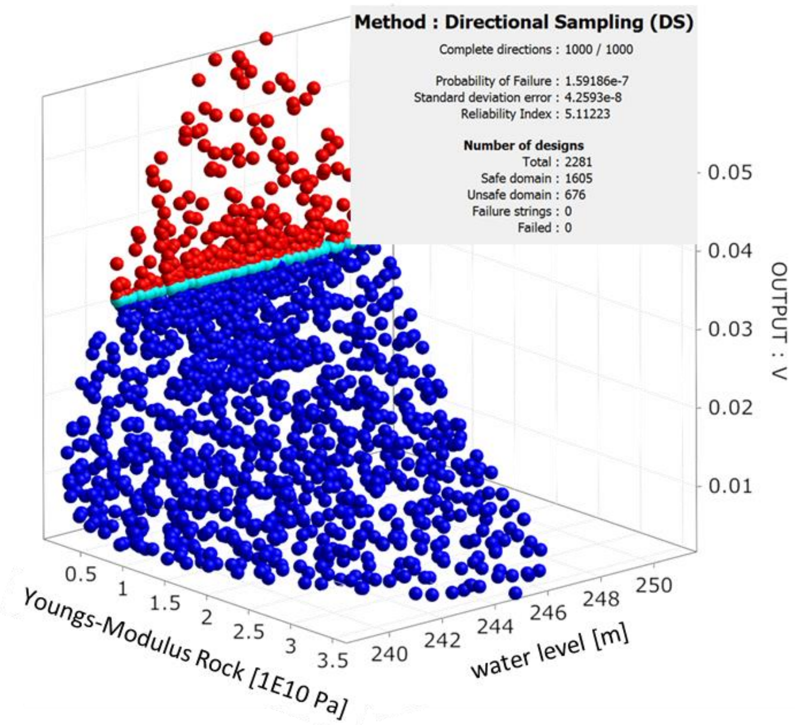

Fig. 7
Reliability analysis V_2, All Design points in the space of the most important parameters; red dots: V > 0.03 m; blue dots: below the limit of 0.03 m

The exceedance probability of the reliability analysis for the limit value of V_1 = 0.05 m gives a $P_{f(V\_1)} = 1.59 * 10^{-13}$; which corresponds to a reliability index $\beta_{(V\_1)} = 7.29$. The result of the reliability analysis for the limit value V_2 = 0.03 m is shown in Fig. 7. The determined exceedance probability is $P_{f(V\_2)} = 1.59*10^{-7}$; this corresponds to a reliability index $\beta_{(V\_2)} = 5.11$

As a result of the analyses, it can be stated that both probabilities are below the value of $P_f = 10^{-5}$, corresponding to reliability indexes above $\beta = 4.27$ (Reference period of 100 years). Thus, by using probabilistic analyses and procedures described in the report, a sufficient stability of the Eder dam can be confirmed and the safety margins beyond are quantified.

In addition to the calculation of the probability of failure, the influencing parameters which are decisive for the distribution of the response variable can be output both qualitatively and quantitatively in ANSYS optiSLang® [9]. This allows statements to be made as to which stray input variables (loads, resistances) are relevant for the failure of the dam.

6. ACKNOWLEDGEMENTS

The financial and technical support by BAW (Federal Waterways Engineering and Research Institute) is gratefully acknowledged.

SUMMARY

The analysis of failure probabilities is an important element of risk assessment in dam management. This investigation is illustrating probability of failure calculations of the Eder dam, an old gravity dam in Germany, by means of a parameterized and fully nonlinear 3D-finite element model of the dam and the foundation. The model is calibrated based on measurements (thermal, hydraulic and mechanical) with the software optiSLang®. Therefore, sensitivity analysis with stochastic latin hypercube sampling is performed using a total of 200 designs (parameter combinations) with varying material parameters of the dam and the foundation. For the stochastic analysis of the dam, distribution functions for all relevant effects and resistances, e.g. flood events, are defined. After all, the evaluation of the stochastic analysis is done again with optiSLang®, which is capable to directly yield the failure probability P_f for the specified assessment criteria. Additionally, input parameters influencing the failure probability the most can be indicated quantitatively and qualitatively. Two reliability analyses by means of probabilities of failure are carried out. To determine the exceedance probabilities, an adaptive response surface method (ARSM) was used in combination with the First Order Reliability Method (FORM) with several hundred simulations each. As a result of the analyses, it can be stated that both failure probabilities are below the value of $P_f = 10^{-5}$, corresponding to reliability indexes above $\beta = 4.27$ (Reference period of 100 years). Thus, by using probabilistic analyses and procedures described in the report, a sufficient stability of the Eder dam can be confirmed and the safety margins beyond are quantified.

CHALLENGES OF DAMS CONTRUCTION AND MANAGEMENT IN INDONESIA

Tri HARTANTO
Geologist of Dam Safety Units, MINISTRY OF PUBLIC WORKS AND HOUSING REPUBLIC OF INDONESIA

INDONESIA

Indonesian Archipelago, which is situated in tropical zone, doesn't benefit much its climatic condition from the hydrological point of view. With existence of dry season and rainy season, the rainfall depth is only concentrated in certain months of the year (mostly on November, December, January and February), thereby varying from region to region and from island to island. Such as situation has caused people to look for means of storing up as much as possible water for future use in the dry season when rain is scarce or if it's of not non-existent. One answer to this problem is the construction of dams capable of storing up water in large quantities.

Ministry of Public Works and Housing, who responsible for infrastructure, will construct 65 dams across the region, From 2013 until 2019. It will provide totally 6.5 billion m^3 reservoir and irrigated 460,382 Ha and in 2022, it expected that all of 65 dams, will be finished. From 65 dams, 49 are new dams, the other 16 dams still on going. All of them are were owned by the government with 6.5 billion m^3 reservoir capacity, not included of those from all other dam stakeholders. So for next 5 years later, Indonesia will have over 270 large dams accros the nation.

This paper will attempt to present some issues and solution regarding to challenges of dams construction and management in Indonesia.

Keywords : land acquitition, human resources, Indonesia

CONCLUSION

As a tropical country and largest archipelago which has abundant water potential, Indonesia plan to build more dam in the future. Building a dam, is the same as we build a dangerous structures. Therefore, Indonesia needs a lot of competent dam engineers to escort this plan to be done. Unfortunately, increasing the number of dams in Indonesia is unbalance with the availability of competent human resources in dam engineering.

Nevertheless, the government realized, they need some breakthrough to solve this issues. Some breakthrough among them is to conduct training and continuously based on the need.

In terms of non-technical issues, land acquisition, handling social impact and budget provision for dam construction must be solve immediately. All those factors should be organized very well, government as a leader, cooperate with other stakeholder and communities with more normative and human approach.

Abstract:

The Analysis of dam-reservoir-foundation coupled system is a complicated problem due to mutual interaction between reservoir water, rock foundation and concrete dam. In order to design earthquake resistant dams, it is essential to have accurate and reliable analysis procedures to predict the dam response. In this paper, KOYNA concrete gravity dam subjected to four different normalized ground motion excitations was investigated as a typical case study. A 2-D Finite Element model of the dam was constructed using ANSYS computer code to simulate dam-reservoir-foundation coupled system. The reservoir water domain is represented as incompressible and inviscous fluid continuum having infinite length in the upstream direction. The foundation rock is represented as a viscoelastic half space considering both its mass and flexibility. Both the mass concrete and foundation rock are assumed to have homogenous, isotropic, linearly elastic properties. Seismic dam responses are expressed in terms of dam deformations, dam stresses, spectral displacements and accelerations, hydrodynamic pressure, natural frequency and response time history. Obtained results confirm that El-Centro earthquake caused the minimum displacement and stresses while Aqaba-EW earthquake resulted in maximum displacements and stresses. Spectral results confirm the significant effect of dam natural period on its seismic behavior.

Introduction

Concrete dams are very important structures, regarding to requirements for continuous service during their life time, and catastrophic effects in cases of dam failure. Therefore, the safety of these structures should be investigated quite critically by logical and precise methods. The fluid-structure-foundation interaction is one of the main factors that affect dam behavior during earthquake excitations. The analysis of dam-reservoir-foundation coupled system is much more complicated than that of the structure alone. For a dam-reservoir-foundation system, the earthquake response is significantly influenced by the interaction of the dam with the impounded water and with the underlying foundation region, thus increasing the requirements for the analysis procedure to be used, and complicating what would otherwise have been considered a routine finite element analysis of a concrete cross-section.

State of Art

The seismic behavior of concrete gravity dams under strong ground motion was investigated by numerous researchers. Chopra (1967) conducted a study on the determination of the effects of foundation-structure interaction on the seismic response. Das Gupta and Chopra (1977) presented a procedure to produce a complex valued, frequency dependent stiffness matrix for the surface of a dam base which is supporting the structure. Chopra and Chakrabarti (1981) introduced a general procedure for analysis of the response of concrete gravity dams including the dynamic effects of impounded water and flexible foundation rock, to the transverse (horizontal) and vertical components of earthquake ground motion. Fenves and Chopra (1984) developed a semi analytical-numerical procedure to analyze the earthquake response of concrete gravity dams. Effect of reservoir-foundation interaction was the subject of a study conducted by Dominguez et al (1990). A boundary integral technique was proposed for the investigation of the response of dam-reservoir-sediment-foundation systems subjected to ground acceleration. Bougacha et al. (1993) introduced a technique based on the Finite Element Method for the analysis of wave generation in a layered, fluid filled poro-elastic media to consider the sediments. Bhattacharjee and Leger (1994) conducted a study on the two dimensional static fracture behavior of dams. Smeared crack models were developed from a nonlinear fracture mechanics point of view that can simulate the tensile and shear softening of the plain concrete. The static fracture behavior of a dam subjected to an incremental increase of the reservoir water level was also investigated by Bhattacharjee et al. (1995). A rotating smeared crack model was considered in the nonlinear finite element analyses. The uplift pressure occurring inside the smeared crack bands was taken into account by effective porosity concept. Ghanaat (2004) introduced an assessment approach that utilized linear time history analyses. The potential failure mechanisms of concrete gravity, buttress and arch dams were discussed and taken into consideration at the performance evaluation approach. Javanmardi et al. (2005) developed a theoretical method to determine the water pressure variations along a tensile crack during dynamic response. The results of the proposed model were compared with experimental test results. Arabshahi and Lotfi (2008) conducted a study on the natural vibration mechanisms due to damage at the dam foundation interface. Zeidan (2013) used *ANSYS* code to investigate the interaction of reservoir water-dam structure. Yucel (2013) evaluated the hydrodynamic pressures, dam-reservoir-foundation rock interactions and reservoir bottom absorption. Zeidan (2014) analyzed the problem of dam-reservoir-foundation seismic response on concrete gravity dams numerically using *ANSYS* code. Her results showed that simulation of foundation in dam-reservoir interaction problems significantly affects the seismic response of concrete gravity dams especially in case of mass rock foundation.

Although the dam-reservoir-foundation interaction has been highlighted via many authors, the dam-reservoir-foundation coupled system is a very complicated phenomena and further studies on foundation simulation on seismic response of concrete gravity dams including foundation-structure interaction is required. The objective of the present study is to assess the impact of key parameters which affect the static and dynamic behavior of concrete gravity dams. A 2-D Finite Element model is employed using ANSYS program. *KOYNA* dam subjected to the S00E component of EL-Centro earthquake is investigated as a typical case of study. The dam is represented as a finite element system, the fluid domain, as a continuum of infinite length in the upstream direction and the foundation rock region as a viscoelastic half-plane. Static, modal and time history analyses are considered in the dynamic simulation. In the static and dynamic analyses, the foundation is simulated considering foundation flexibility. The dam concrete, foundation rock and reservoir water are assumed to have homogeneous, isotropic, linear and elastic properties. Reservoir water is assumed to be incompressible and inviscous fluid. The dam-reservoir-foundation coupled system is idealized as shown in Figure 1.

Governing Equations and Boundary Condtions

Governing equation of wave propagation through fluid is represented in both the Eulerian and Lagrangian methods. The governing fluid-structure system equation is solved using wave propagation through the fluid by assuming linear compressibility and inviscousity. The wave propagation equation through acoustic fluid is as follows (Chopra and Chakrabarti 1981):

$$\nabla p^2 = \frac{1}{c_2}\frac{\partial^2 p}{\partial t^2} = \frac{\rho}{k}\frac{\partial^2 p}{\partial t^2} \quad \text{………………………… (1)}$$

Where c= (k/ρ) ½ ………………….…….…... (2)

In which p is the pressure function, c is the acoustic wave speed, ρ is the fluid density and k is the fluid compressibility. If the fluid would be incompressible, equation (1) would take the following form:

$$\nabla p^2 = 0 \quad \text{………………………………………. (3)}$$

Reservoir upstream boundary (Γ_R)

With the vibration of the dam, volumetric hydrodynamic pressure waves are created in the reservoir and propagate toward the upstream, if the length of the reservoir is assumed to be infinity, then these waves would approach to vanish. It should be noted that the length of reservoir is assumed as a finite length, L, in numerical modeling. Hence, an artificial boundary is applied to simulate effect of infinite reservoir. This boundary is modeled based on the Sommerfeld boundary as

$$\frac{\partial p}{\partial n}(x, y, z) = -\frac{1}{c}\left(\frac{\partial p}{\partial t}\right)(x, y, z) \text{……….……….…. (4)}$$

Reservoir bottom (Γ_B)

According to the rigidity of the reservoir bottom, by assuming the horizontal movement of the earth, the pressure gradient is neglected.

$$\frac{\partial \mathrm{p}}{\partial \mathrm{n}}(\mathrm{x}, \mathrm{y}, \mathrm{z}) = 0 \quad \text{………………….……………..… (5)}$$

Reservoir free surface (Γ_F)

By neglecting the effects of surface waves, the governing boundary condition is as follow:

$$p(x, y, z) = 0 \text{ ……………………………….....… (6)}$$

Fluid-structure interface (Γ_I)

In the common boundary between the reservoir and the dam body, an interaction between these two occurs which the result of inertia force is caused by the movement of the dam body. Hence, the applied pressure on the reservoir face caused by the inertial force is as follow;

$$\boldsymbol{\frac{\partial p}{\partial n}(x, y, z) = -\rho . \ddot{u}_n(x, y, z)} \text{ ……………..……..... (7)}$$

In which ρ is the density of fluid and $\ddot{u}_n$ is the structure's acceleration vector in the direction normal to the common boundary of the fluid and structure.

Foundation region boundary conditions

The nodes on edges A and B at the end of the foundation region are assumed to be constrained in the vertical direction, while it is free in the horizontal direction. The nodes at the horizontal line at the base (edge C) of the foundation region are assumed to be constrained in both vertical and horizontal directions. The nodes at the interface between the dam body and foundation are coupled in the vertical and horizontal directions. The same coupling is applied at the interface between the reservoir and foundation (Refer to Figure 1).

Coupled Dam-Reservoir-Foundation System FEM Modeling

In the present study, the standard finite element technique is adopted utilizing Galerkin's method in which the structure displacement vector is discretized as (Zienkiewicz 1991).

$$u = N_u \, \bar{u} \quad \ldots\ldots\ldots\ldots (8)$$

And the fluid is similarly discretized as

$$p = N_p \, \bar{p} \quad \ldots\ldots\ldots\ldots (9)$$

Where u and p are the nodal parameters of each field and N_u and N_p are appropriate shape functions. The standard finite element technique is adopted utilizing Galerkin's method in which the discrete equation of the concrete dam and the rock foundation dynamic responses reads.

$$\mathrm{M}\ddot{u} + C\dot{u} + K\bar{u} - Q\bar{p} + f = 0 \quad \ldots\ldots\ldots\ldots (10)$$

$$\int_{\Gamma 1} N_u^T \, np \, d\Gamma = \left(\int_{\Gamma 1} N_u^T \, nN_P d\Gamma \right) \bar{P} = Q \, \bar{P} \quad \ldots\ldots (11)$$

In which $[M], [C]$ and $[K]$ are mass, damping and stiffness matrices of the structure respectively. $\bar{u}$, $\dot{u}$ and $\ddot{u}$ are displacement, velocity and acceleration vectors respectively. In the above n is the direction vector of the normal to the interface. Standard Galerkin's discretization applied to the fluid equation and its boundary equations leads to:

$$\mathrm{S}\ddot{u} + \acute{C}\dot{p} + H\bar{p} - Q^T\ddot{p} + q = 0 \quad \ldots\ldots\ldots\ldots (12)$$

in which [S], $[\acute{C}]$,[H] and $\boldsymbol{q}$ are pseudo fluid mass matrix, pseudo fluid damping matrix, pseudo fluid stiffness matrix and prescribed flux vector respectively, Q is a transformation matrix which transforms the acceleration of structure to fluid pressure and also transforms the hydrodynamic pressure into applied loads on the structure to simulate fluid structure interaction.

$$S = -\int_{\Omega} N_P^T \frac{1}{C^2} N_P \, d\Omega + \int_{\Gamma 3} N_P^T \frac{1}{g} N_P \, d\Omega \quad \ldots\ldots\ldots\ldots (13)$$

$$\acute{C} = \int_{\Gamma 4} N_P^T \frac{1}{C^2} N_P \, d\Omega \quad \ldots\ldots\ldots\ldots (14)$$

$$\mathrm{H} = \int_{\Omega} \nabla N^T \, \nabla N \, d\Omega \quad \ldots\ldots\ldots\ldots (15)$$

The coupled equation of the dam – reservoir - foundation system subjected to earthquake ground motion can be presented as follows (Zeidan 2014):

$$\begin{bmatrix} \mathrm{M} & 0 \\ \mathrm{Q^T} & \mathrm{S} \end{bmatrix} \begin{Bmatrix} \ddot{\mathrm{u}} \\ \ddot{\mathrm{p}} \end{Bmatrix} + \begin{bmatrix} \mathrm{C} & 0 \\ 0 & \tilde{\mathrm{C}} \end{bmatrix} \begin{Bmatrix} \dot{\mathrm{u}} \\ \dot{\mathrm{p}} \end{Bmatrix} + \begin{bmatrix} \mathrm{K} & -\mathrm{Q} \\ 0 & \mathrm{H} \end{bmatrix} \begin{Bmatrix} \mathrm{u} \\ \mathrm{p} \end{Bmatrix} = \begin{bmatrix} \mathrm{M.I.}\ddot{\mathrm{u}}_{\mathrm{g}}(\mathrm{t}) \\ -\rho\mathrm{Q^T.I.}\ddot{\mathrm{u}}_{\mathrm{g}}(\mathrm{t}) \end{bmatrix} \quad \ldots (16)$$

Case of Study KOYNA Dam

The *KOYNA* Dam, situated in the Maharashtra State, India, is part of the *KOYNA* Hydroelectric Project, which aims to supply water to western Maharashtra as well as hydropower to the neighboring areas. It is located on the *KOYNA* River, approximately 120 miles SSE of Bombay. The existing *KOYNA* Dam, completed in 1963, is a rubble concrete gravity dam of 853 length and 103 m height. The reservoir has a capacity of 2780×10^{6} m3. Figure 2 shows a schematic model for KOYNA dam (Huang 2011), along with its reservoir and foundation.

Results of Seismic Analysis (Case of Full Reservoir)

The effect of foundation stiffness on dam horizontal displacements, vertical displacements and normal stress for case of full reservoir is presented in Figure 3. Obtained results show that dam displacements and stresses are very sensitive to variation in foundation stiffness up to E_F/E_C ratio equals 2.0. For ratios of E_F/E_C greater than 2.0, no significant effect on dam displacements and stresses is noticed. Figure 4 shows hydrodynamic pressure distribution on dam upstream face at various times during El-Centro earthquake. The figure shows that the hydrodynamic pressure distribution is almost linear at the top 25% of reservoir depth. For the lower 75% of reservoir depth it shows nonlinear trend. Moreover, the shape of the nonlinear part of the hydrodynamic pressure distribution at different times has no specific trend. Furthermore, the maximum observed hydrodynamic pressure occurs at T=0.02 sec. If it is approximated as linear trend it might be about 6% to 9% of the hydrostatic pressure. From the design point of view, the observed hydrodynamic pressure can be accounted for by increasing the hydrostatic pressure by say 15-25% over the entire height of the dam.

Figures 5 and 6 show time history for dam displacement, stresses and hydrodynamic pressure for ratios of E_F/E_C equal 0.5, 1.5, 5 and fixed base case. Obtained results indicates that the maximum horizontal dam crest displacement decreases as the foundation stiffness increases. The time history for horizontal displacement at different heights on upstream face show that all points move in phase indicating essentially that the first mode dominates the response. Figure shows that in case of full reservoir there are tensile stresses at the heel. This already occurred in 1967 when *KOYNA* dam subjected to *KOYNA* earthquake and a damage was observed in the actual dam due to tensile stresses at *KOYNA* dam heel. This tensile stresses leaded to a cracks between the dam body at heel and the rock foundation (Hunjie, 2011). **Fehler! Verweisquelle konnte nicht gefunden werden.** shows that the normal stresses at the toe are compression stresses at all times and that the behavior is not affected by foundation stiffness variation. But the compression stresses increase as the foundation stiffness increases. Moreover, the foundation stiffness has no significant effect on hydrodynamic pressure at reservoir base. The time history of displacements and stresses show that when the foundation stiffness is five time that the dam concrete, the assumption of fixed base is acceptable.

Effect of Ground Motion Excitation

To study the effect of different ground motion excitations on the seismic behavior of dam-reservoir-foundation coupled system, four earthquakes are utilized. These are EL-Centro-S00E components, Taft-N21E component, Aqaba-NS component and Aqaba-EW component. While EL-Centro and Taft earthquakes represent severe and moderate earthquakes, respectively, Aqaba earthquake occurred in the Gulf of Aqaba, Egypt, and represent a minor to moderate earthquake. To have a common base for comparison of the dam behavior under different earthquakes, all ground motions were normalized to have the same peak acceleration of EL-Centro. Table 1. Shows values of peak accelerations and the factor of normalization for each earthquake. Table 2. Shows the effect of four earthquakes; on *KOYNA* dam displacements and stresses. Obtained results show that EL-Centro earthquake-S00E component caused the minimum displacements and stresses, while Aqaba-EW earthquake resulted in maximum displacements and stresses. Figure 7. Shows spectral displacements and accelerations for the four earthquakes. It is clear that dam natural period has significant effect on dam seismic behavior. Natural period for *KOYNA* dam for first mode of vibration equals 0.38 sec. It is noticed that Aqaba-EW earthquake has the maximum and EL-Centro has the minimum spectral displacement and acceleration.

Conclusions

Based on the results presented in this study, the following conclusions can be drawn:

1. Foundation stiffness affects modal properties and an increase from E_F/E_C = 0.50 to 5 leads to significant decrease in natural period. For EL-Centro earthquake-S00E component, when E_F/E_C ratio changed from 0.50 to 5.0 a significant difference in displacement and acceleration occurred. This difference explain the effect of foundation stiffness on seismic behavior of the dam.
2. For static and seismic analysis, foundation stiffness has a pronounced effect on dam displacements and normal stresses up to E_F/E_C = 2.0. Up to this value foundation stiffness shouldn't be ignored in dam simulation and analysis especially if foundation stiffness less than two times dam concrete stiffness. When E_F/E_C equals 5.00, it is recommend to assume fixed base to simplify the problem.
3. Ground motion variation affects dam seismic response, although the different ground motions have the same peak acceleration. This difference is dependent on the frequency content of earthquake and the dynamic characteristics of the dam.

1. INTRODUCTION

Scour of rock foundations and spillways pose a significant concern for the safe and reliability operation of dams across the world. The February 2017 events at the Oroville Dam spillways in California, USA are a prime example. Knowledge regarding the mechanics of rock mass break-up resulting from hydraulic loading is still limited and has largely been deduced from scaled laboratory models and testing. This is due, in part, to the challenge of making direct observations of the rock scouring process during spill events from actual dam and spillway sites.

Due to these challenges, nearly all studies on rock erodibility have focused on laboratory testing using simplified rock block geometries (i.e., rectangular/cubic blocks) under idealized flow conditions [1-14]. Extrapolation of the findings of such studies to field conditions can be challenging given the highly irregular 3D geologic structure often encountered at specific sites which, as many rock mechanics practitioners are aware, significantly influences block/rock slope stability.

Accordingly, a research study was undertaken to develop a high-resolution data set from both field and laboratory settings on the erodibility of 3D (non-cubic) rock blocks [15]. This paper presents first-of-a-kind observations made in real-time leading up to the removal of an instrumented rock block in a prototype unlined spillway channel at a dam site in Northern California.

2. SITE DESCRIPTION AND INSTRUMENTATION

Collection of real-time data on 3D rock block erodibility from a prototype setting has several challenges related to selection of a site that is readily accessible, that spills regularly and that has erosion actively occurring. Additionally, instrumentation would need to withstand variable climatic conditions as well as hydraulics loads associated with spill events to allow capture of data.

The basic concept for the prototype set-up was to re-create rock blocks within a spillway channel from locations in the rock mass where blocks once existed but had subsequently been eroded. To do so, two instrumented artificial rock blocks were installed in an unlined rock spillway channel at a dam site in Northern California. The dam is located in the Sierra Mountain Range and founded on hard, blocky granodiorite rock. The spillway consists of a concrete ogee control section that discharges onto rock just downstream (Fig. 1). Ten radial gates are present, three of which are larger and have an invert at a slightly lower elevation. The capacity of the spillway with all gates open is 1,161 m^3/s and the maximum flow experienced to date was 968 m^3/s in January 1997. Typically, the spillway discharges on an annual basis in the winter and spring months associated with rain on snow events or runoff from snowmelt in the Sierra.

Scour of the granodiorite rock within the spillway has generally be observed throughout the almost 100-year lifespan of the structure, with the first documented instance in the early 1940's. Based on aerial photography, approximately 185,000 m^3 (the equivalent of 75 Olympic swimming pools) of material has been eroded from the spillway channel (Fig. 2). Despite several large flows through the spillway, catastrophic erosion has not been witnessed, but rather scour appears to occur more gradually.

Given the propensity for regular spill events and historic erosion of the spillway, the site provided an excellent opportunity to collect real-time scour data from a prototype setting. As mentioned above, two artificial, instrumented blocks were installed within the spillway channel. The blocks were cast into existing block molds, which are locations were a rock block once existed but has subsequently been eroded (Fig. 3). Block 1 was installed below the upper (small) spillway gates, while Block 2 was installed below the lower (large) spillway gates.

Fig. 1
Small discharge (approximately 14 m^3/s) through gated spillway control section.

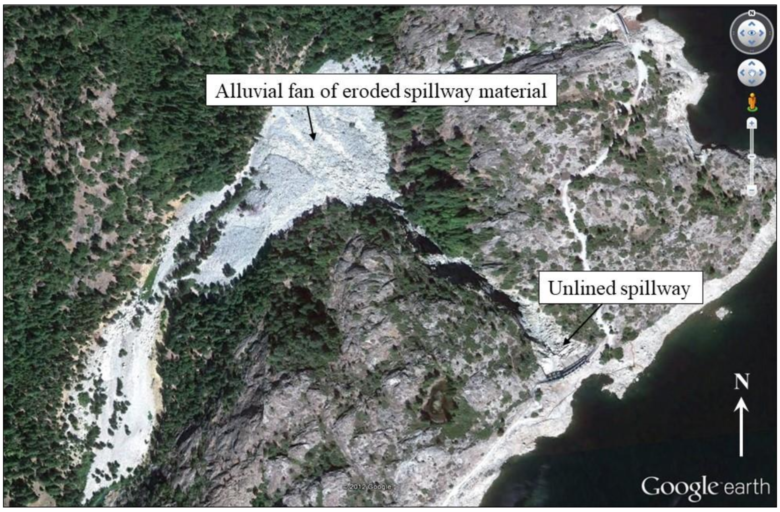

Fig. 2.
Aerial photo of unlined spillway channel. Volume of eroded spillway rock material is estimated to be approximately 185,000 m^3.

Fig. 3
Location of artificial rock blocks in unlined spillway channel [16].

Both blocks were tetrahedral (4-sided), which is the most basic non-cubic block geometry but also the most likely removable block geometry from a rock mass [17]. The blocks were located close to the spillway gates where flow could still be relatively characterized as 2D channel flow, before becoming more complex further downstream. This was done to facilitate comparison with physical hydraulic model testing done on 3D tetrahedral blocks in a flume channel as another facet of this research study.

The blocks were fabricated out of concrete and instrumented with pressure and displacement sensors on each of the block faces (Fig. 4). This was done to allow measurement of hydrodynamic forces applied to the block during spill events and track block movements precursory to removal. Sensor cables were run through waterproof conduit to a datalogger located above the spillway crest. Measurements were captured at a frequency of 100 Hz to obtain high resolution data sets for hydrodynamic pressure and displacement.

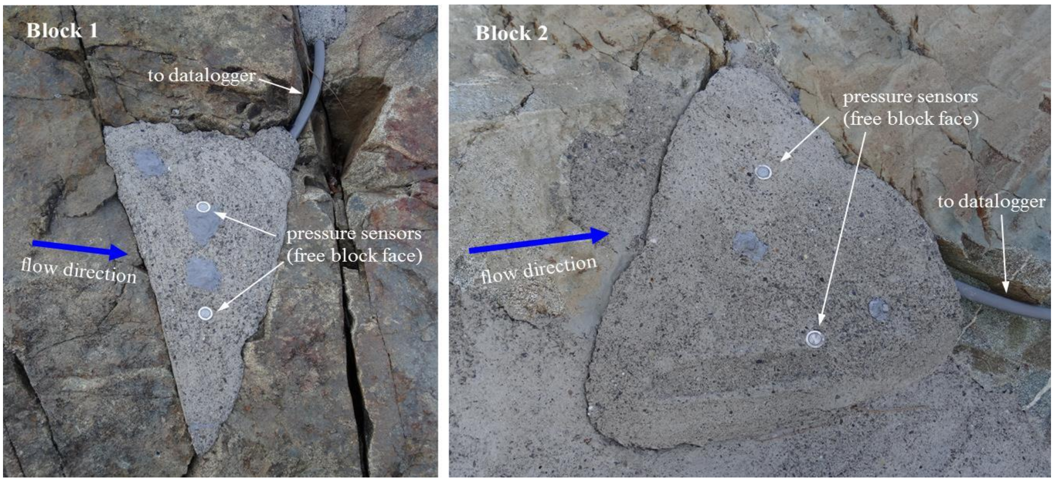

Fig. 4
Artificial rock blocks, as constructed. Note displacement sensors are on block faces within the rock mass and subsequently not shown [16].

3. MARCH 2016 SPILL EVENT

Block 1 was installed in November 2012, while the Block 2 was installed the following year in November 2013. Subsequent drought conditions in California, however, lead to no significant spill events that impacted the blocks. It wasn't until March 2016, when a peak discharge of 126 m^3/s resulted in the removal of Block 2 from below the low-level spillway gates. During the afternoon of March 5, 2016 discharge from the spillway began through the low-level outlet gates and at approximately midnight flow through the upper-level gates commenced. The peak discharge occurred around 6 am the following morning. Flow through the upper-level gates terminated on the morning of March 7 around 5 am, while flow continued to spill from the low-level gates for more than a week after the peak flow occurred. The outflow hydrograph for the event in shown in Fig. 5, while observations of the spill event are shown in Fig. 6.

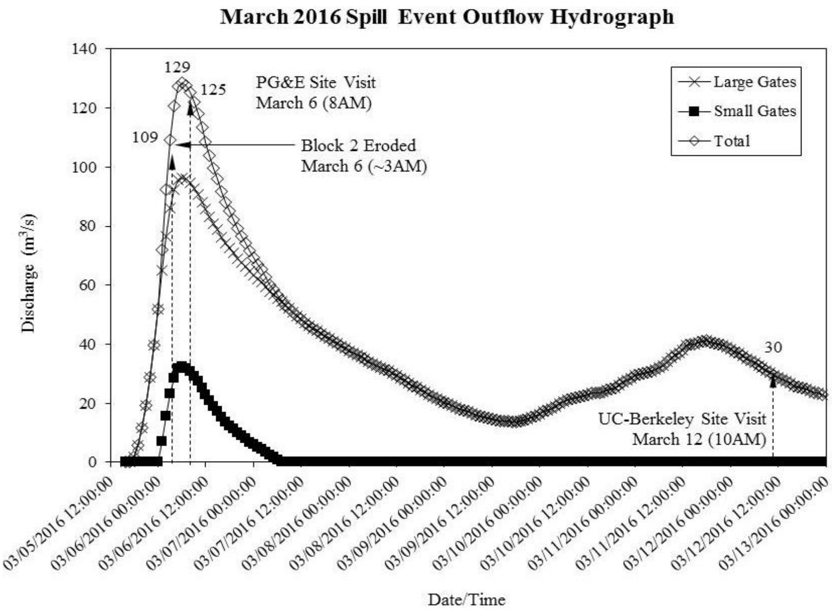

Fig. 5
Outflow hydrograph from March 2016 spill event.

Fig. 6
Discharge on March 6, 8 am (125 m^3/s (left), March 12, 10 am (30 m^3/s) (right).

Analysis of displacement data recorded for Block 2 indicated the block was eroded from its mold at approximately 3 am on March 6 during the rising limb of the outflow hydrograph at a discharge of 109 m^3/s (Fig. 5). After the initial wetting of the block by spillway flows, displacements occurred gradually (at the sub-millimeter scale) until the block was removed (Fig. 7). Prior to removal, the total magnitude of uplift was relatively minor (less than 3 mm) during the approximately 9 hr period when the block was submerged. Some anomalous spikes are observed in the displacement magnitude data, however, review of individual data from each of the displacement sensors suggests that these spikes are erroneous and potentially related to temporary sensor malfunction (likely due to the turbulent flow environment).

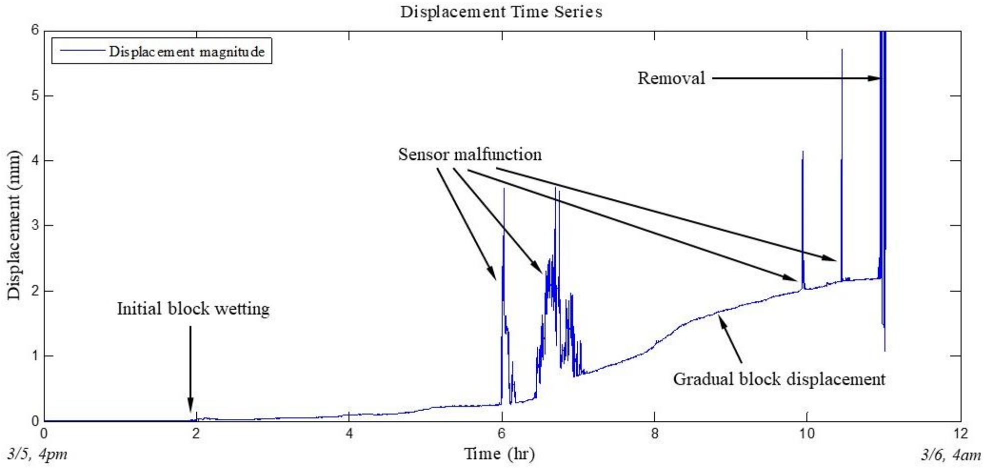

Fig. 7
Displacement magnitude time series leading up to block removal.

Hydrodynamic pressures measured on each of the block faces were used to calculate the active resultant force vector (**R**) applied to the block associated with the hydraulic loading from the spillway discharge [16]. Instantaneous measurements were averaged and plotted on a whole sphere, limit equilibrium stereonet in 2 hour increments leading up to removal of the block (Fig. 8). Note that the final resultant vector was calculated at 2:19 am on March 6, corresponding to last measurements obtained prior to failure of the pressure sensors.

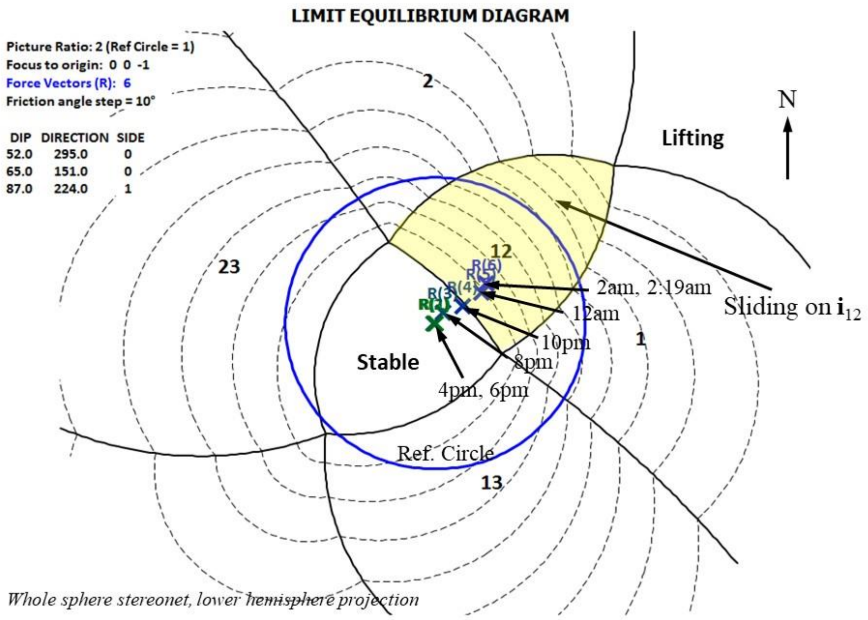

Fig. 8
Limit equilibrium stereonet for 3D stability of Block 2 showing average active resultant force vector (**R**) leading up to removal.

The limit equilibrium stereonet presents a graphical solution for 3D stability of the block. The different regions, delineated by the solid black lines, correspond to the different potential kinematic failure modes of the block (e.g., “2” = 1- plane sliding on joint 2, “13” = 2-plane sliding on joints 1 and 3). The dashed lines correspond to contours (10 deg. increments) of the required friction angle on the joint planes to maintain the block at equilibrium. Initially (at 4 pm), the active resultant force vector (**R**) plots within the “stable” region at the center of the stereonet as loading is only due to the self weight of the block. As the block experiences additional loading from hydraulic forces from the spillway flow, **R** rotates outwards away from the “stable” region into region “12” corresponding to the kinematic mode of sliding on joints 1 and 2. Accordingly, the likely failure mode in which the block was eroded was 2-plane sliding on joints 1 and 2.

Flow conditions (velocity and turbulence intensity) in the proximity of Block 2 were assessed using recorded video of the spill event. Particle Image Velocimetry (PIV) software was used to track turbulence structures within the flow field overtime to estimate the instantaneous velocity at the flow surface (Fig. 9). A simplistic free online code, Tracker [18], was used for the analysis. More robust codes are available but are often reserved for more controlled laboratory settings. An existing high-resolution LiDAR point cloud of the spillway was used to spatially scale spillway features in the video used in PIV analysis.

Video for PIV analysis was taken at a discharge of 30 m^3/s during a site visit on March 12. From the video a mean flow velocity, u = 10.3 m/s and turbulence intensity, T_u = 19 % were calculated. Turbulence intensity values compared well with those determined from pressure sensor measurements on the free surface face of the block. Although no video was available during the time the block was removed, the PIV results provided guidance on estimation of flow characteristics at the time of block erosion.

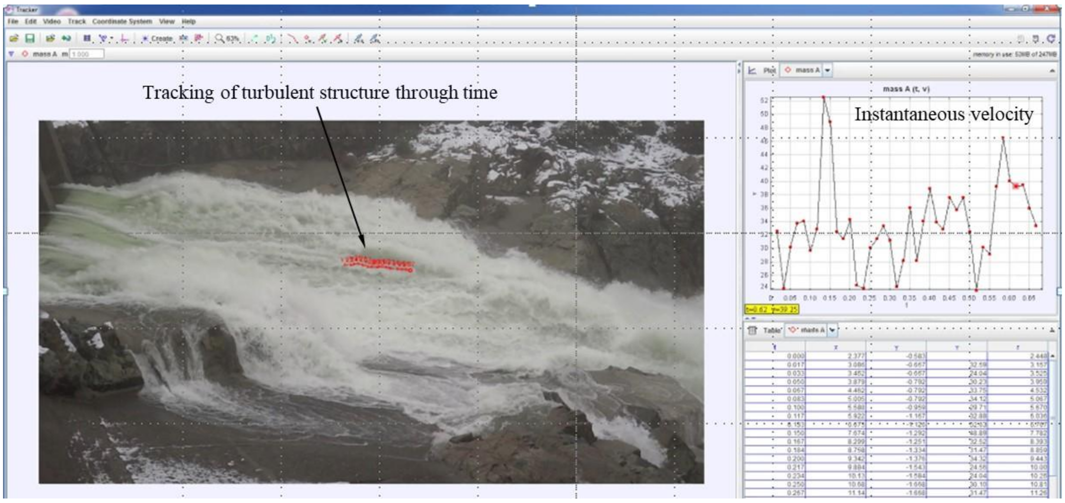

Fig. 9
Screen capture of particle tracking during March 2016 spill event.

4. DISCUSSION AND CONCLUSIONS

The instrumentation of two artificial rock blocks within an unlined spillway channel provided first-of-a-kind, high resolution insight into the rock scour process in a prototype setting. The observations and measurements recorded from the March 2016 spill event that resulted in removal of one of the instrumented blocks allowed assessment of applied hydrodynamic loads and subsequent block response precursory to failure.

The gradual displacement of the block from it's mold even under highly turbulent flow conditions agrees with other measurements made on 3D block response from laboratory flume experiments [16]. In these experiments, block kinematics (related to the orientation of the bounding joint planes on the block with respect to the flow direction) played a significant factor in the observed block response. Blocks with limited kinematic resistance to movement exhibited gradual displacement prior to removal whereas blocks with higher kinematic resistance showed a more dynamic response with larger, impulse-type movements. The distinction between low and high kinematic resistance is thought to occur when the active resultant force vector (**R**) must be rotated outwards by more than approximately 60 deg. from it's initial vertical orientation (due to the self weight of the block). Block geometries requiring rotation of **R** less than 60 deg. are considered to have a low kinematic resistance [16]. At the field site, the rotation of **R** required for instability of Block 2 (assuming a friction angle on joints1 and 2 equal to 20 deg.) is 58 deg., suggesting Block 2 has a low kinematic resistance.

Other near-prototype laboratory experiments on 3D block response using a simplified cubic block geometry showed block response was highly dynamic when subject to loading from turbulent jet impact (e.g., [11,12]). In light of the observations from the field study presented herein and the laboratory results presented by [16], this response can be expected given the minimum rotation of **R** required for uplift of the cubic block in the above experiments would be approximately 110 deg. (assuming a joint friction angle of 20 deg.). Accordingly extrapolating data obtained from idealized block geometries for analysis of rock scour for sites with highly irregular 3D geologic structure can be challenging.

A framework based on block theory principles [19] has been developed in order to assess 3D rock block erodibility. This has been shown to reasonably predicted block erodibility thresholds obtained from the laboratory flume experiments on 3D tetrahedral blocks [16] as well as in the back calculation of the erodibility threshold of instrumented field block presented herein [20]. Accordingly, this framework can allow practitioners to incorporate site-specific 3D geologic structure into analysis rock erodibility.

SUMMARY

Scour of rock foundations and spillways during normal and extreme flood events poses an important concern for dam safety. The challenge of making direct observations during a spill event has limited the understanding of the mechanisms driving the break-up of the rock mass when subject to hydrodynamic loading. Historically, methods for scour prediction have been derived from scaled laboratory studies often using simplified rock geometries and flow hydraulics. We present real-time observations of block removal captured using an instrumented block during a flood event in an unlined rock spillway of a dam in northern California. Particle image velocimetry (PIV) from digital video footage provides information on flow characteristics near the time of removal, while pressure and displacement sensors installed on the block faces provide measurements of hydrodynamic loads and block displacement leading up to failure/removal.

1. INTRODUCTION[1, 2]

Roller compacted concrete dam (RCC) construction, including preparation of RCC materials, construction procedures and testing during construction is put into the framework of quality concepts. When put into this framework, the designer and contractor can see the integrated nature of both design and construction processes to achieve project quality objectives that result in safe and cost effective dam construction.

Quality concepts, particularly quality assurance (QA) and quality control (QC) are defined as follows:

Quality assurance (QA) is a program covering activities necessary to provide quality in work, and to ensure that activities that require good quality are being performed effectively. QA specifies actions necessary to provide enough confidence that the project will satisfy the given requirements as established in e.g. design criteria and performance specifications.

Quality control (QC) is the specific implementation of the QA program and includes the monitoring and evaluation of processes and outcome against the requirements and specifications. QC has to facilitate the immediate application of actions to the outcome, thus, allowing the engineer to exert direct influence on the outcome.

The Quality Control system for RCC dams comprised the following main activities:

- Control of production process by inspection of the equipment and material
- Control by testing and inspection of the properties of the RCC constituents
- Control of fresh RCC sampling and testing
- Control of hardened concrete by testing samples and statistical conformity analysis

This paper is concerned with the relationship between the specification of RCC, construction procedures, the properties of RCC and how quality control is used in RCC dams during construction.

2. QUALITY CONTROL OF MATERIALS [1, 2, 3]

The primary objectives of performing RCC mix designs for a dam project are to evaluate the uniformity, compactability, workability, and economic issues of the likely RCC mix components and proportions. These objectives are evaluated relative to the RCC unit weight and strength requirements.

Commonly, RCC mix design is comprised of four main components: aggregate, cementitious materials (pozzolan and cement), water and admixture. The selection, proportioning, and quality of each of these components effect on the RCC quality. Key aspects of each of these components on the quality of the final concrete product are discussed below.

2.1. AGGREGATE

The selection of an appropriate aggregate for RCC production is probably the single most important factor in any RCC project. Aggregate is the one component in RCC that potentially has the greatest variability and impact on quality. Ideally, a suitable RCC aggregate will have the following characteristics:

- Compactable to high density
- High specific gravity
- High Strength
- Suitable gradation to prevent segregation
- Excellent durability/soundness

Aggregate is normally derived from local sources to avoid the considerable cost attached to transport. Some sources will yield aggregate of high quality, which conforms to national or international standards. Specification of processes and RCC mixtures can overcome such defects and produce adequate RCC. Where the aggregate source is known to be of good quality, the specification can be based on published standards such as ACI 221 or ASTM C-33. Table 1 and figure 1 show QC tests for aggregate in RCC dams and aggregate production in stone crusher.

Table 1
QC tests for aggregate in RCC dams

Quarry or borrow pit		
Petrography	Specific weight	Sulphides
Compressive strength	Absorption	Chloride
Soundness	Alkali-aggregate reactivity	Organic matter
Abrasion resistance	Sulphates	Mica, Clay
Product streams		
Grading	Particle shape	
Before loading into batch plant bins		
Grading	Absorption	
Moisture content	Temperature	

In RCC dam, the physical properties of the source area were measured in the design phase. Tests were carried out to determine rock types, strengths, grading, particle shapes, freeze-thaw resistance, abrasion resistance, specific gravity, water absorption, moisture content and the content of impurities. The chemical soundness of the rock was also investigated and includes tests for alkali-silica reaction (ASR), sulphate resistance and others. Some of these tests are carried out during construction to ensure that the source material and the aggregate produced conform to the design assumptions as embodied in the specifications. Test frequencies will depend on the consistency of the source. Table 3 shows QC chart of aggregate production.

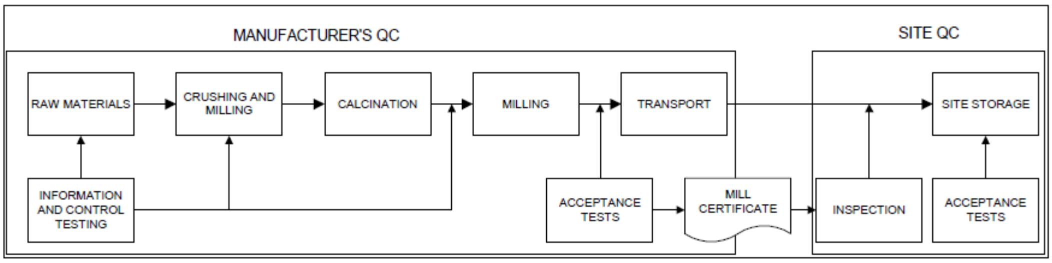
Fig. 1
Aggregate production in stone crusher (Uma Oya project-Sri Lanka)

2.2. CEMENTITIOUS MATERIALS

In RCC dams the cement used in concrete determined according to ASTM C150. This determination is based on environmental, materials and structures conditions. For mass concrete, as in the case of RCC Dams, cements with low heat generation -Type 2 or pozzolanic should be used. For cementitious materials, most important is the control of uniformity, which can vary considerably due to heterogeneous sources or caused by the grinding process.

The rate of cement consumption can be very high for RCC dams and the turnover of on-site storage can be rapid. Considerable reliance has to be placed on the manufacturer’s certificates. In the early phases of construction, it may be prudent to arrange for comprehensive testing of the cement at frequent intervals until there is full confidence in the manufacturer’s test results. After that, physical tests should be carried out periodically. The tests that can realistically be performed at site are related to setting time and temperature. Table 2 shows QC chart of cementitious material.

Table 2
Quality control chart of cementitious material



2.3. ADMIXTURES

A number of chemical admixtures are available to improve the properties of fresh concrete and RCC. Admixtures commonly used in RCC and concrete are set retarders and water reducing/workability enhancing chemicals and air-entraining agents. Admixtures are available that combine more than one of these properties.

For RCC dams, the effects of admixtures have to be tested with the various RCC mixes. These tests are typical setting times and workability (VeBe test). Poor or undesirable results can arise with particular products because of incompatibility with cement or pozzolan and with some types of aggregates and may arise with seasonal variations in air temperature. These cases require a change of type or brand of admixture. Such tests should be carried out periodically throughout the construction period.

2.4. WATER

Water quality for RCC mixing should satisfy an appropriate standard with respect to the content of contaminants. Potable water is preferred for RCC as it has been filtered for contaminants. When potable water is not available, tests should be made with the precise source of construction water to validate the mix design and RCC properties. Any source of water may be used if the 7 and 28-day strengths of 5-cm cubic mortar specimens be at least 90 percent of the index mortar made using distilled water according to ASTM C109. Besides, the setting time of the test paste shall not be 60 min shorter or 90 min longer than that of the check paste made using distilled water according to ASTM C191.

3. BATCHING PLANT AND MIXING OPERATION [1, 2]

For RCC dams, the batching plant and mixing operations have an important impact on the in-place properties of the RCC. Table 3 shows quality control activates for batching plant and mixing operations.

When the batching plant is operating, the amount of all constituent materials including cement, and each size group of aggregate, water and admixtures shall be continuously controlled. A daily (24 hour basis) report shall be prepared indicating the type, source, and quantity (actual and SSD basis) of cement, each size group of aggregate, admixture, and water used during each shift of plant operation, based on plant production records. The report shall show the required mix proportions per cubic meter for each mix design, and the average proportions for each mix calculated from the totals used during each shift.

Table 3
Quality Control activates for batching plant and mixing operations

Activity	Frequency
Mixer efficiency tests	At start-up, monthly and changes in material sources
Mixing times	Each batch
Workability	Each batch to hourly (with RCC)
Verification of preventive maintenance	To follow the maintenance schedule
Cleaning and maintenance	Daily

4. QUALITY CONTROL PLAN DURING CONSTRUCTION [1, 4, 5]

4.1. QUALITY CONTROL TESTS DURING CONSTRUCTION

During construction, all of QC tests should be performed according technical specification in specified frequency. Table 4 shows typical quality control tests for RCC dams.

4.2. PLACEMENT

For RCC dams, important factors shall be considered for placement of the RCC include Transportation; RCC placement temperature; Segregation; Timing; Lift joint conditions and Bedding mortar.

Transportation: RCC may be transported from the batching plant to the point of the placement by several means as a function of distance, rate of placement and environmental factors. The method of transport may affect the workability of the RCC and may cause segregation. Transportation and handling equipment should not only have the required capacity but also be capable of being adapted to different mixes and should be designed to minimize segregation. Checks are required to ensure that the method of RCC transport will not adversely affect the fresh RCC properties such as may be induced by drying, wetting or segregation. Maintenance of transport vehicles and conveyor belts has to be carried out and verified. This includes daily maintenance, which entails cleaning off accumulated concrete on the delivery system as well as mechanical maintenance. Figure 2 shows conveyor system for transporting the RCC.

Table 4

Typical Quality Control Tests for RCC dam

Material tested	Test procedure	Test Standard[2]	Frequency[3]
Cement	Physical and chemical properties	ASTM C150	Manufacturer's certificate or pre-qualification
Pozzolan	Physical and chemical properties	ASTM C618	Manufacturer's certificate or pre-qualification
Admixture		ASTM C494 ASTM C128	Manufacturer's certificate
Aggregates	Relative Density And Absorption	ASTM C127 ASTM C128	One per month or 50 000 m^3
Aggregates	Flat and elongated particles	BS812	One per month or 50 000 m^3
Aggregates	Los Angeles Abrasion	ASTM C131	One per month or 50 000 m^3
Aggregates	Gradation	ASTM C117 ASTM C136	One per shift or One per day
Aggregates	Moisture content	ASTM C566 ASTM C70	Before each shift or as required
RCC	Workability	ASTM C1040	500 m^3 or as required
RCC	Gradation	ASTM C117 ASTM C 136	1000 m^3 or as required
RCC	Fresh density	ASTM C1040	1000 m^3 or as required
RCC	Oven-dry Moisture content	ASTM C566	1000 m^3 or as required
RCC	Temperature	ASTM C1064	100 m^3 or as required
RCC	Variability of Mixing procedures	ASTM C172, C1078, C1079 or special	Two per month or 25 000 m^3
RCC	Compressive Strength	ASTM C1176 or tamper	Two per day or 1000 m^3
RCC	Tensile strength (direct and/or indirect)	Special or ASTM C496	One per day or 2000 m^3
RCC	Elastic modulus	ASTM C469	One per day or 2000 m^3

Fig. 2

Conveyor systems for transporting the RCC (Javeh Dam-Iran)

RCC Placement Temperature: The placement temperature of the RCC is an important consideration relative to the potential for surface and mass gradient cracking in the gravity dam construction. In hot weather, for reducing of RCC temperature, aggregate cooling shall be accomplished by several methods. These methods include mining and processing the aggregate in colder seasons, shading stockpiles from direct sunlight and evaporative cooling of aggregates in the stockpiles. Some reduction in the placement temperature of the RCC can be achieved by cooling the mix water. Under cold weather, heating of mixing water and protection of RCC exposed surface shall be considered. Under the most extreme weather conditions, the RCC placement tasks are stopped.

Segregation: Segregation of RCC during transport and placement shall be controlled by employing means and methods similar to those used in transporting and placing conventional concrete. For this propose the gradation of aggregate, time of mixing in batching plant, transporting system of RCC and concreting equipment should be controlled. Figure 3 shows segregation of RCC.

Fig. 3

Segregation of RCC and effect of segregation on lift surface

Timing: Time limitations are commonly prescribed to keep the RCC from setting before final spreading and compaction. In RCC dams the following time limits for handling, transporting and compacting the RCC:

- Maximum time from plant to spreading on the fill is 45 minutes;
- Compaction starts within 15 minutes of spreading;

• Maximum elapsed time from introduction of water to the mix and final compaction is 60 minutes.

Lift Joint Conditions: The thickness of the layer shall not exceed 300 mm, and shall be aggressively cleaned before applying bedding mortar and placing next layer. Good lift joint conditions are a vital component of good RCC construction. The underlying goal is to place subsequent RCC lifts before the underlying lift has set, allowing the lifts to bond to each other. Cleaning shall include removal of all loose material, cement paste, fine particles, still and current waters, snow, ice, oil and grease and other detrimental materials. In particular, the surfaces of joints shall be kept free of dust at all times. All horizontal joints shall be prepared for the next lift by removing mortar coating, laitance, or other contaminants by water jet or other approved methods. After this initial preparation, the surface shall be kept damp until receiving the bedding mortar application prior to the next RCC placement.

Bedding Mortar: A lift surface is considered a "cold joint" if the surface is damaged by weather or equipment, frozen, Cold joint treatment consists of thorough cleaning of the surface and placement of a layer of bedding mix concrete (bedding mortar) immediately prior to placement of the successive RCC lift. Not more than 15 minutes shall have elapsed after spreading the bedding mortar when RCC is spread on it. Figure 4 shows cleaning of lift Surface and spreading of bedding mortar.

Fig. 4
Cleaning of Surface and spreading of bedding mortar (Uma Oya Project)

4.3. COMPACTION AND VERIFICATION

Compaction is generally viewed as one of the most important elements in RCC Construction. During construction of the RCC, adequate compaction will have one of the most profound impacts on the quality of the finished RCC dam.

In RCC dams, the in-place compaction and water content of the RCC in the lifts are tested using nuclear gauges in accordance with ASTM C1040 and ASTM D1557. The testing shall be performed frequently; Acceptance criteria for in-place density of the RCC require no test less than 98 percent of required compaction. The variation of moisture outside minus 5% and plus 5% of the optimum moisture content shall require aggregate moisture contents testing and control of water contents at the batch plant. Re-compaction of the RCC shall not be allowed beyond 45 minutes from the batching time of the mix placed at the failing location. Figure 5 shows RCC construction and compaction testing.

Fig. 5
RCC construction and density testing (Javeh Dam-Iran)

5. POST CONSTRUCTION QUALITY CONTROL ACTIVITIES [2, 4, 5]

As with conventional concrete, RCC must be kept continuously moist for the prescribed curing period. Because RCC is dryer than conventional concrete, surfaces tend to dry more rapidly during warm weather. In such conditions, considerable effort will be required to maintain a uniformly moist surface. After compaction of RCC, the curing activates shall be started. Curing activates shall be done according to air condition and weather temperature in summer or winter. Figure 8 shows curing of RCC lift surface.

In RCC Dams, Samples of RCC can be obtained from coring in order to determine the in situ properties. This provides the best evidence of concrete performance by providing samples for strength and density determination, for viewing the density matrix from top to bottom of the lifts, and for identifying lift joint bond or lack of bond. Generally, coring is performed upon completion of the RCC structure. Figure 6 shows Curing of RCC lift surface and Core of RCC.

Fig. 6
Curing of RCC lift surface and Core of RCC- length 3m (Uma Oya Project)

6. CONCLUSION

There are some conclusions in the following:

• RCC mix design is comprised of four main components: aggregate, cementitious materials (pozzolan and cement), water and admixture. The quality of each components effect on the RCC quality

• For RCC dams, the batching plant and mixing operations have an important impact on the in-place properties of the RCC. When the batching plant is operating, the amount of all constituent materials shall be controlled.

• During construction, all of QC tests should be performed according technical specification in specified frequency.

• For RCC dams, important factors shall be considered for placement of the RCC include Transportation; RCC placement temperature; Segregation; Timing; Lift joint conditions and Bedding mortar.

• During construction of the RCC adequate compaction will have one of the most profound impacts on the quality of the finished RCC dam.

• After compaction of RCC lift, curing activates shall be done according to air condition and weather temperature in summer or winter.

SUMMARY

The purpose of RCC quality control is to maintain uniformity of all constituents and operations entering into the final product. Thus, quality assurance and quality control (QA/QC) systems for RCC dams need to be

established in the preconstruction phase and rigorously continued during the dam construction. In this paper, quality control of RCC dams during construction are discussed along with corresponding quality control (QC) programs, QC tests and acceptance criteria.

Le but du contrôle de qualité RCC est de maintenir l'uniformité de tous les constituants et opérations entrant dans le produit final. Ainsi, des systèmes d'assurance qualité et de contrôle de la qualité (AQ / CQ) pour les barrages des RCC doivent être mis en place dans la phase de pré construction et rigoureusement poursuivis pendant la construction du barrage. Dans cet article, le contrôle de qualité des barrages RCC pendant la construction est discuté avec les programmes de contrôle de qualité (QC), les tests de CQ et les critères d'acceptation correspondants.

AN EVALUATION SYSTEM OF HYDROPOWER SUSTAINABLE DEVELOPMENT

Chunna LIU

National Research Center for Hydropower Sustainable Development
CHINA INSTITUTE OF WATER RESOURCES AND HYDROPOWER RESEARCH

CHINA

The 13th Five-Year "hydropower development planning (2016-2020)" clearly stated that we must "Make the development of hydropower an important strategic measure of energy supply side structural reforms, so as to ensure energy security and promote the construction of ecological civilization. Sustainable hydropower is an effective way by which to comprehensively understand the social, economic and ecological benefits of hydropower, comprehensively measure the benefits and impacts of hydropower, and coordinate hydropower development and watershed/regional development.

As China's administrative department of energy industry, the State Energy Bureau attaches great importance to the long-term development of hydropower. It has proposed that the concept of sustainable hydropower being established through the innovation of ideas, so as to solve practical problems in the development and management of hydropower industry. The global greenhouse gas emission reduction and China's demand for the prevention and control of smog have given China a new connotation of sustainable hydropower development. China has drawn lessons from international experience, and established a sustainable technology evaluation method for hydropower in China, which is consistent with international standards, in line with the national energy development strategy, and of great significance for promoting sustainable development of the hydropower industry, thereby achieving national emission reduction targets, and promoting the development of green power.

Hydropower development, while generating enormous social benefits, also has an important impact on local immigrants, society and ecological environment. Xie Qingsheng (2013) pointed out that large-scale hydropower development has resulted in the situation of "reservoirs of rivers and rivers, ecological fragmentation, interest group formation and overall inefficiency" of some of the main tributaries in the upper reaches of the Yangtze River. China's sustainable hydropower is different from the green hydropower of Switzerland and the low-impact hydropower of the United States.

In order to assess and provide guidance on the protection of the ecological environment during the construction of hydropower projects, the Swiss Federal Institute of Water Science and Technology (EAWAG) proposed the certification procedures and standards for green hydropower stations in operation in 2001. The US proposed the implementation of a low-impact hydropower station certification system. German International Cooperation (GIZ) compiled a handbook of watershed ecosystems in hydropower development. In 2000, the World Commission on Dams (WCD), a joint initiative of the World Conservation Union (IUCN) and the World Bank (WB) published a paper entitled Dams and Development - The New Decision Framework and Development: A New Framework for Decision-Making)". The International Commission for the Protection of the Danube River (ICPDR) explicitly sets forth the development of sustainable hydropower in the "Sustainable Hydropower Development in the Danube Basin Guiding Principles".

At present, the relevant evaluation of hydropower projects in China mainly focuses on the planning, preparatory stage and implementation stages, while the operational stage is relatively inadequate, especially in terms of environment and immigration. Relevant policies, standards and norms concerning planning, preparation, implementation and operation of hydropower station, are issued to identify stakeholders in China. Sustainable development issues should be addressed, and specific recommendations and supporting policies should be given to promote the sustainable development of hydropower.

China's large and medium-sized hydropower project, has led the local economy, improved the environment, and enrich the social responsibility of immigration. Subsequent research on hydropower development sustainability evaluation has to be combined with other systems, such as negative listing system and ecological compensation system to improve the ecological environmental benefits of hydropower projects. And it’s helpful to treat immigration in addition to reservoir anti-poverty policies as well as engineering benefit sharing mechanisms.

The issue of sustainable development of hydropower in China is not only a policy issue, but also a technical issue. Many problems occurred in the process of hydropower development, which affected its positive development and system in the status and in turn. In the future, we must seize the opportunity of power system reform and study-related supporting policies regarding sustainable development of hydropower from the aspects of finance, taxation, electricity price and financial subsidies. We must also establish an incentive mechanism to alleviate the contradictions between local governments and businesses, and achieve a win-win situation.

1. INTRODUCTION

At the simplest level, risks associated with dam protection gates can be classified into two headings, namely Hard and Soft. Hard risks are those that have defining factors and a great deal of statistical data. They include machinery failure, power failure and storm events. They are generally quantifiable, analytical and can be stated within statistical limits.

Soft risks are often people-related and include factors which are difficult to analyse. They include, without limit, ethos and culture, leadership and incentives, communications, human psychology, change and complexity. Such risks are often difficult to identify and quantify. As Engineers, do we under-estimate these risks because we are naturally disposed towards analysis and it is easier to operate where numbers are available?

This paper explores the source of soft risks and attempts to learn lessons by reference to previous studies into fields such as finance, corporate governance and accident investigations. As such, it explores "Human Factors" relating to individuals, groups and organisations. In case there is any doubt as to the need to explore the non-technical issues, we quote below an extract from the Oroville Investigation into the failure of the spillway:

"The fact that this incident happened to the owner of the tallest dam in the United States, under regulation of a federal agency, with repeated evaluation by reputable outside consultants, in a state with a leading dam safety regulatory program, is a wake-up call for everyone involved in dam safety."

2. HOW PREVALENT ARE SOFT RISKS?

In order to make an immediate case as to the importance of soft risks reference is made to a number of areas, starting with accident investigations. The United Kingdom's Health and Safety Executive (HSE) in their evidence to a parliamentary science and technology committee previously stated that:

"It has been estimated that 90% of all workplace accidents have a human error as a cause"

Indeed, human error was cited as a significant constituent in many of the notorious industrial accidents, which have led to subsequent independent enquiries. The following examples are quoted as examples of incidents/accidents with a strong human influence:

Accident, Industry and Date	Consequences	Human Contribution
Three Mile Island, Nuclear Industry 1979	Serious damage to core of nuclear reactor	Operators failed to diagnose a stuck open valve due to poor design of control panel, distraction of 100 alarms activating and inadequate operator training. Maintenance failures had occurred before, but no steps had been taken to prevent them recurring.

Kings Cross Fire Transport Sector 1987	A fire at this underground station in London killed 31 people.	A discarded cigarette probably set fire to grease and rubbish underneath one of the escalators. Organisational changes had resulted in poor escalator cleaning. The investigation pointed to poor fire training and a culture that viewed fires as inevitable.
Space Shuttle Challenger Aerospace 1986	An explosion shortly after lift-off killed all seven astronauts on board	An O-Ring seal on one of the solid rocket boosters split after take-off releasing a jet of ignited fuel. Inadequate response to internal warnings about the faulty seal design. Decision to go for launch in very cold conditions. Decision making result of conflicting scheduling/safety goals, mindset and effects of fatigue.
Total IT failure for British Airways 2017	All flights grounded knock-on costs from stranded passengers and planes "in the wrong place".	According to BA, caused by an employee who disconnected a power supply which created a surge when re-connected. Employee was "not authorized to do what he did"
Virgin Galactic crash 2014	Co-pilot unlocked braking system too early	The National Transportation Safety Board determined the cause of the breakup of SpaceShipTwo was Scaled Composite's failure to consider and protect against human error and the co-pilot's premature unlocking of the spaceship's feather system as a result of time pressure and vibration and loads that he had not recently experienced.

Hawaii false missile alert. Hawaii Emergency Management Agency 2018	Panic and fear as the following text alert was issued to residents of Hawaii: “BALLISTIC MISSILE THREAT INBOUND TO HAWAII. SEEK IMMEDIATE SHELTER. THIS IS NOT A DRILL.”	The incident occurred when a supervisor gave the arriving day-shift workers a spontaneous drill, according to a Federal Communications Commission report. The supervisor posed as a military official and played a message that warned workers of a fake threat and included the phrase “exercise,” three times, as well as “this is not a drill,” language that would be used during a real alert. The employee who issued the missile alert claimed he hadn't heard the portion of the message that repeatedly declared it was an "exercise" because a co-worker had placed the call on speakerphone partway into the message.

In the case of commercial corporate crises, several investigations have been made into the reasons behind the failure of large institutions, that were otherwise seen as healthy immediately prior to their problems. In a study of such cases undertaken by the Cass Business School, named “Roads to Ruin”, the authors looked at a number of major financial risk events, their origins, impact and implications.

The report investigated “over twenty” corporate crises often involving major international brands (who are named in the report but not important for the purposes of this paper) whose pre-crisis assets were collectively worth about $6 Trillion. The report noted that:

> *“The organisations themselves were badly affected by the outcomes. Seven companies collapsed under the strain, in 11 cases the chairman and/or CEO lost their jobs. In 16 cases the company and/or executives suffered financial penalties. Personal reputations were destroyed; Four executives went to prison”.*

The CASS report noted numerous underlying types of weakness which they distilled into key risk areas including the soft risks of:

- Inadequate ethos, culture and behaviour;
- Poor leadership and inappropriate incentives;
- Poor internal communication, including getting information to the top;
- Change and complexity;
- Reputation

Staying with the financial sector, Anthony Hilton a highly respected City Editor is quoted as saying:

“ Risk systems tend to be numbers-based, and cover potential hazards or current operations. They can cover hard data, technical know-how, systems and strategies. What they don’t do is handle soft issue such as management style, employee motivation, shared values and corporate culture. They are hopeless at behavioural issues. So for that matter are male only boards….

….The trouble with accounting performance measurement and risk control – and indeed the teaching of business schools – is that they treat companies as if they are mechanical. They assume broadly that they are machines which, for a certain level of inputs, will deliver a predictable level of output. But the greater truth, particularly in the modern era where talent is the big differentiator, is that companies are collections of people, and they are as much biological as mechanical”.

Although the above quote was written in the context of financial risk it resonates at the anecdotal level with personal experiences. For “financial accounting performance measurement” could we substitute “engineering reliability studies”?

3. WHAT ARE THE “HUMAN FACTORS”?

Before making further progress, it is worth reviewing what are generally considered to be “human factors” and which are the root cause of many so-called soft risks.

It should also be recognized that cultural differences throughout the World make it difficult to be too universal in our observations. Most of the research drawn upon herein relates to Western civilisations.

3.1. WHY ARE HUMAN FACTORS IMPORTANT?

Estimates suggest that Human Factors are the primary cause of between 60% and 85% of incidents. They emerge because machinery and systems are:

- Designed by humans
- Built by humans
- Programmed by humans
- Tested by humans
- Commissioned by humans
- Operated by humans
- Modified by humans
- Maintained by humans
- Decommissioned by humans
- Disposed of by humans

3.2. HUMANS AS INDIVIDUALS

Human beings are very complex and no two of us are alike. The variability in our capabilities is marked and yet most tasks assume they are being undertaken by a standardised, competent person. In reality each of us is more or less competent from one day to another.

In addition, we tend to over-estimate our own competence usually thinking we are above average. This phenomenon has been given the name "illusory superiority". In a recent survey, rating how good a car driver they were, most people gave themselves a score of seven out of ten having been told that average was five. In another study 32% of employees in a software company ranked themselves above 19 out of 20 of their colleagues.

It is interesting to note that a common reason given for introducing computers and artificial intelligence into financial processes, is that the computers make better decisions than humans.

In respect of human errors, industrial psychologists sometimes use the terms "slips", "lapses" and mistakes. The general definition being that:

- A slip is a failure to undertake the task correctly. It could be performing the task too soon or late. Or it could mean omitting to perform a step.
- A lapse is a failure to carry out an action, perhaps one task in a series of tasks. For example the omission of steps in maintenance has been cited as a substantial cause of nuclear power plant incidents.
- A mistake involves doing something wrong that we believe to be right (there is still the problem of a deliberate error or (violation"). These tend to be of two categories knowledge based or rules based.

Such human slips, lapses and mistakes come about for lots of reasons.

3.2.1. Attention

People have a limited attention span which has been estimated to be about twenty minutes before fatigue sets in and errors are more likely to occur.

Regular tasks become habit forming so that when repeated often enough they become automatic responses rather than reasoned decisions. By way of an example, in a historic study of automatic train protection on the UK network the following was observed in respect of train driver behavior:

> *The automatic warning system installed on passenger trains in the UK is an example of a system that was not designed with the limitations of human attention in mind. It is a device fitted in the train cab, based on the new obsolete mechanical system of signaling that used to signal either STOP or PROCEED. It sounds a bell when a clear (green) signal is passed and a buzzer when caution or danger is signaled. If the buzzer is not acknowledged by a press of the button, then the train begins to automatically*

stop. In commuter traffic, most signals will be at "caution" aspect, and given the frequency of signals (spaced 1 km apart), most drivers will face two signals per minute. Given the tendency for the attentional system to automate highly repetitive behavior, many drivers lose focus on the reasons for carrying out this repetitive task, and act in reflex whenever the buzzer sounds. The end result is that drivers often hear the buzzer and press the button reflexively without actively thinking about train speed and location.

3.2.2. Perception

Perception relates to how we interpret information from our senses. A particular problem is that people are often required to interpret information rather than receive it directly. The interpretation of the information is a source of error and hence risk.

3.2.3. Memory

People's short-term memory has a limited capacity. Tests have shown that we can typically hold only seven individual items at a time in our memories.

3.2.4. Logical Reasoning

Humans are not always good at logical reasoning. During the Three-Mile Island nuclear accident, two valves which should have been open were blocked shut. The operators incorrectly deduced that they were in fact open because of an illogical assumption about the instrument panel.

3.2.5. Situation Context

Having identified individual failings in human beings, we should also recognize that our performance in any particular situation is greatly affected by the context we are working in. If we are tired, we will not perform so well and may also work poorly within teams.

We will all have seen people who perform badly when trying to answer a question on a TV quiz show, the answer to which they know but cannot recall under the pressure of the situation.

3.3. HUMANS IN SMALL GROUPS

Over recent decades the principle of building winning teams has become an axiom that few people dispute. The belief that working in teams makes us more creative and successful has become one from which there is little dissent. And yet the Harvard Business Review recently identified a list of problems associated with people working in teams, which included:

- The absence of a team identity such that there is a conflict between team and personal goals. Here individuals are described as being self-centred or half-hearted.
- Difficulty in making decisions because of rigid adherence to individual positions
- Poor communications including silence from some members and constant talking from others. Perhaps personality clashes.
- Inability to resolve conflicts, perhaps because of heightened tensions or perhaps stubbornness
- Lack of creativity prevents seeing problems as opportunities
- “Groupthink” where the team is not open to discussing new alternatives but has a fixed view of a situation into which the members “buy in”
- Ineffective leadership, perhaps by failing to convey a vision or failing to delegate.

3.4. HUMANS IN LARGE ORGANISATIONS

The difference between small teams and large organisations is that the team may have little interaction with their senior management within a large organization. This presents new sets of problems that may lead to risks.

Principal among these risks is the establishment of a culture which may not be appropriate for the organisation as a whole. Frequently this can be driven by inappropriate incentives. For instance, a large oil refining company rewarded their staff if no accidents had been reported over a period. Rather than report minor incidents there was a culture of not reporting them to avoid losing their reward. And so was lost valuable opportunities to identify ways of improving safety. Here is a good example of poor communications and the wrong incentives.

The culture of an organisation is significantly set by its reward systems. Do the compliant get promoted do the dissenters get moved on? Does the Board of Directors want to know?

Much evidence exists that reward systems are a strong indicator of the health of a safety culture. Where employees are rewarded for achieving no accidents, then no accidents are reported. Where they are punished for causing accidents, they will be hidden, or acts will be denied.

What levels of training are available to front-line staff?

4. THE EVIDENCE THAT SOFT RISKS AFFECT DAMS?

In the recent report on the Oroville dam spillway failure, there are a number of references to problems at the human level, including complacency, bureaucracy and an inadequate safety culture. For instance the report notes:

- the California Department of Water Resources, was "significantly overconfident and complacent about the integrity of its State Water Project civil infrastructure, including dams."
- "insular organization which inhibited accessing industry knowledge and developing needed technical expertise."
- an "insular organization which inhibited accessing industry knowledge and developing needed technical expertise." Within the department, the engineering division clashed with the operations and maintenance staff, resulting in a "lack of mutual respect," it found.

Andrew Brazier reports that upon reviewing the prevalence of Human Error in the US forces:

> "*Further to this, 20% of defects are missed by inspectors who are specifically looking for them and the U.S. Strategic Air Command claim that 16% of all critical events are made worse by human intervention.*

5. APPLYING SOFT RISK LESSONS TO THE PROTECTION OF DAMS

The application of systems and procedures aimed to reduce soft risks, requires commitment from the top. Without an understanding of the issues raised there will be little chance of addressing them. The values inherent in the proposals herein must be communicated from the top and demonstrated by main board actions.

Once the main board is united, they need to get the safety culture right. In general, this needs:

- A single, responsible person at the top for dam safety issues.
- A balanced board, both for skills and gender.
- The avoidance of incentives for the lack of recorded incidents and accidents, since this encourages non-disclosure. Rather the encouragement and celebration of opportunities to learn from experience.
- The non-punishment of mistakes.
- The encouragement of an open, honest and respectful dialogue between work colleagues without dependence on where they are placed in the organization hierarchy. It is important that incidents can be investigated and reported upon without putting a career at risk.
- The regular look for new and better ways of doing things.

- The encouragement of external collaboration, whether with expert consultants or shared experiences with other organisations similar to your own.

Once the culture is right, then:

- Simplify tasks as far as practicable. Design jobs so that the work entailed is less complex. For instance, a shaft containing eight discs has only one way to disassemble them but over 40,000 ways of putting them back together!
- Continually train staff. Make sure they understand the why as well as the what within their jobs. Many human interventions during a crisis only make matters worse
- Try to organize instrumentation so that it presents information and not just data, this reduces the degree of interpretation required of staff.
- Remember that soft risks can be present in the supply chain. Do suppliers share the same safety culture?

6. CONCLUSIONS

The presence of soft risks and the need to control them does not in any way diminish the importance of reliability analysis relating to hard risks. The need is to find ways of addressing and minimizing both.

This paper has explored at a high-level the frailties and quirks of the human condition and shown how these can be embraced in a way that can reduce risk and thereby improve safety.

Finally, in case the reader is still not convinced, here is a direct quote from the official report into the Oroville dam spillway failure:

"The fact that this incident happened to the owner of the tallest dam in the United States, under regulation of a federal agency, with repeated evaluation by reputable outside consultants, in a state with a leading dam safety regulatory program, is a wake-up call for everyone involved in dam safety."

HYDRAULIC ASSESSMENT OF TUNNELS

Balkrishna Shankar CHAVAN,

Scientist-D, Central Water and Power Research Station, Pune

India

1. INTRODUCTION

A river diversion tunnel is used to divert river water during construction of a project. Once construction is over, diversion tunnel is plugged before initiating storage of water consequently tunnel part becomes redundant. No universally accepted standards are available for design of temporary structures like coffer dams and diversion tunnels. Tunnel construction has high costs and usually adopted when other solutions are unfeasible. Length of tunnel is kept minimum as possible. To minimize the project cost, part of diversion tunnel can be reused for depletion of reservoir storage. There are instances where part of river diversion tunnels have been used as depletion tunnel after construction of dam is completed. In India projects such as Yamuna, Doyang, Nagarjunsagar, Salal have successfully used the concept of multipurpose tunnel for diversion of river flow and depletion of reservoir. Hydraulic design associated with such tunnels has to function satisfactorily for high discharge at low head during construction and also high head low discharge during operation period of project. Present paper describes hydraulic problems associated with design of diversion cum depletion tunnel. Methodology adopted to arrive at solutions for design parameters in selecting flood flow, tunnel flow capacity during diversion as well as depletion, transitions in shape, energy dissipater at tunnel exit and smooth return of flow to river downstream of the structure.

1.1. NEED FOR DIVERSION OF WATER

Urban centers are providing job opportunities, educational facilities and better living, because of which people migrate to cities. The rate of population growth of metropolitan and urban cities of India is unprecedented. Mumbai being the capital city of the state of Maharashtra is also the commercial and financial capital of the country. Actual growth of city and forecast is shown in Figure. 1.

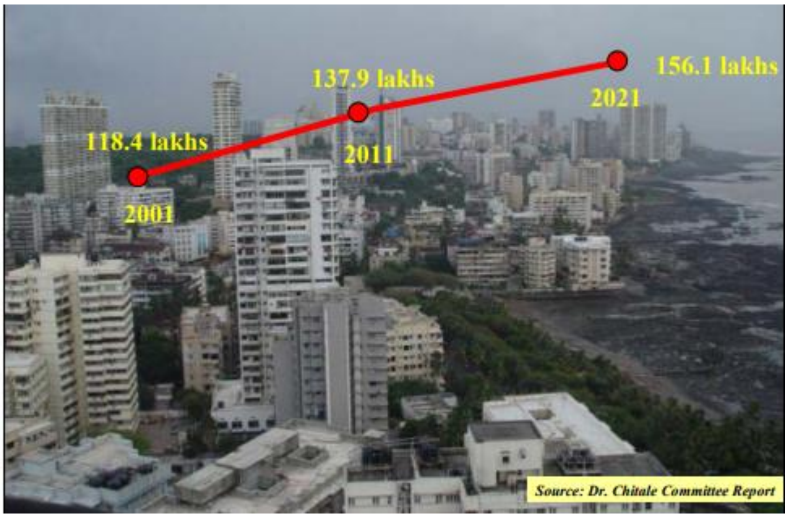

Figure 1: Population Growth of Mumbai City

1.2.

To meet increased demand of water of Mumbai urban agglomerate, a proposal of interlinking Damanganga and Panjal rivers is proposed.

The link envisages transfer of balance available water at the proposed Bhugad reservoir across Damanganga river and at the proposed Khargihill reservoir across Vagh river, a tributary of Damanganga river, in Damanganga basin for augmentation of water supply to Greater Mumbai to meet its domestic and industrial water requirements in the near future. The Bhugad and Khargihill reservoirs (proposed by NWDA) and Pinjal reservoir (proposed by Government of Maharashtra across Pinjal river, a tributary of Vaitarna river) are proposed to be connected through pressure tunnels. The purpose is to make the combined water from Bhugad and Khargihill reservoirs to reach Pinjal reservoir from where further arrangements for transmitting the water to Greater Mumbai will be made by Municipal Corporation of Greater Mumbai (MCGM) and Mumbai Metropolitan Region Development Authority (MMRDA)[6].

The salient details of Damanganga-Pinjal link project are briefly described below:

- A 826.60 m long composite dam is proposed on Damanganga river near village Bhugad in Peint taluka of Nasik district of Maharashtra State and very near to border of Valsad district of Gujarat. The FRL, of the dam fixed on the basis of detailed Surveys & Investigations at 163.87 m. The gross and live storage capacities of the storages are 426.39 Mm3 and 400.00 M m3 respectively. The maximum height of dam is 68.63 metres.
- A 16.85 km long Bhugad-Khargihill link tunnel with 5.0 m diameter connecting Bhugad and Khargihill reservoirs below their minimum draw down levels (MDDLs)is proposed.
- A 572.80 m long composite dam across river Vagh at Khargihill site near village Behadpada in MokhadaTaluka of Thane district of Maharashtra State is proposed. The FRL, of the dam fixed on the basis of detailed Surveys & Investigations at 154.52 m. The gross and live storage capacities have been fixed as 460.79 Mm^3 & 420.50 Mm^3 respectively. The maximum height of dam shall be 75.62m.
- A 25.70 km long Khargihill-Pinjal link tunnel with 5.25 m diameter connecting Khargihill and Pinjal reservoirs below their MDDLs.
- A 681 m long Pinjal dam on river Pinjal (tributary of Vaitarna river) near village Khidse in Jawhar taluka of Thane district has been proposed by Govt.of Maharashtra. The FRL, have been fixed on the basis of detailed Surveys & Investigations by Government of Maharashtra as 141.00 m. The gross and live

storage capacities have been fixed as 413.57 Mm^3 and 401.55 Mm^3 respectively.

The divertable water yield to Mumbai city at Pinjal dam site at 75% dependability (as fixed by Government of Maharashtra) is 332 Mm^3. Thus, a combined release of 43.84 cumecs of water i.e. 3741MLD will be diverted through Pinjal reservoir. Figure 2 shows typical layout of linking Damangaga and Pinjal rivers.

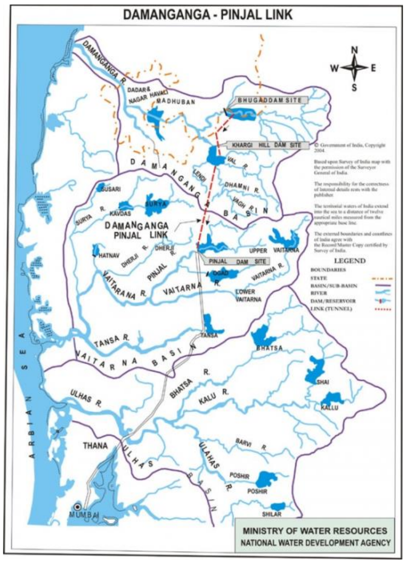

Figure 2: Linking Damanganga and Pinjal rivers

1.3.

The Beas-Sutlej link is 37.25 km long of which 25.45 km is tunnel through difficult rock formations. The capacity of the tunnel is 254.70 cumec. The main storage on Satluj is at Bhakra, while that on Beas is at Pong. A diversion dam at Pandoh, 140 km upstream of Pong, enables diversion of water from Beas to Bhakra reservoir and generates 165 MW of power. Bhakra system provides irrigation to 26.3 lakh ha. of new area besides stabilization of existing irrigation of 9 lakh ha. The aggregate generation capacity of power on Bhakra Nangal Project is 1,354 MW. Beas-Satluj link in combination with the Indira Gandhi Nahar Project is a example of how the large inter basin transfers brought about all round socio-economic growth with overall enhancement in the ecology and environment of the region.

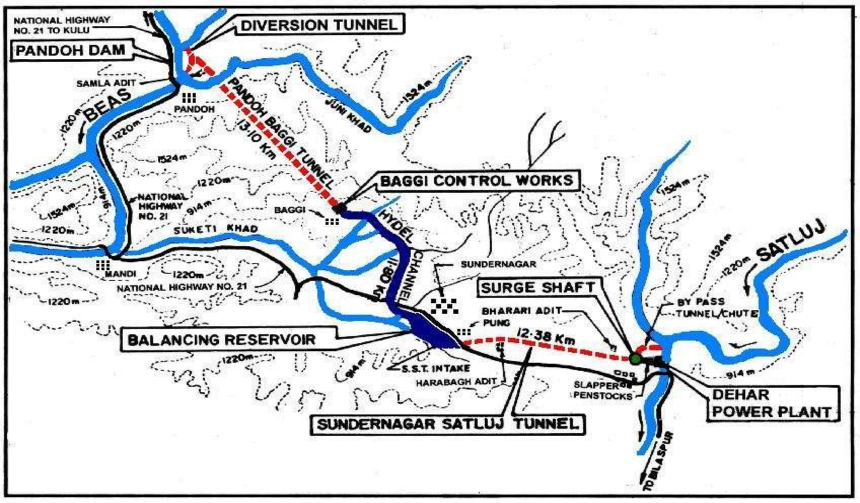

Figure 3: Tunnel for inter linking Beas and Satluj rivers

In addition to transferring water from deficit region, diversion tunnels are used to divert water during construction of dam. The scheme of this type of diversion is characterized by the completion of the diversion tunnel and two coffer dams (upstream and downstream) that will dry the area, in which, it is intend to carry out the dam construction. Tunnels are commonly used to convey water from its source to demand area. Even though costly, compared to surface hydraulic structures, depending upon geological features of the surrounding hills. Complicated geological conditions and extraordinary geological occurrences such as intra-thrust zones, very wide shear zones, geothermal zones of high temperature, cold/hot water springs, water charged rock masses, intrusions, fault planes, etc. should preferably be avoided. Sound, homogeneous isotropic and solid rock formations are the most suitable for tunnelling work. However, in the Himalayan region, such conditions are rather rare compared to the hills of peninsular India. This is because the Himalayan geological formations are mostly sedimentary in nature whereas the peninsular upland of the country is of igneous nature. Hence, geological investigations have to be carried out in detail before a tunnel alignment is finalized. The river diversion tunnel has the function to drain the bypass flow, and may have several sections. However, the sections most frequently used are circular and horseshoe. The choice and design of the type of section employed is related to the final design of the diversion tunnel in relation to its integration or not in the definitive structure. The diversion of the river through tunnels can be held in free surface or pressure flow.

2.

Main components of a water conveyance system for diversion of river water consist of the following components:

1. Intake structure
2. Water conducting system (Tunnel) comprising of control structures.
3. Outflow structure, which joins river flow downstream

2.1. INTAKE STRUCTURE ENTRANCE

An intake is provided at the mouth of a water conveyance system for a diversion of river flow.

It is designed with the following points:

1. There should be smooth entry of water in to the tunnel as water enters from the reservoir behind a dam or the pool behind a barrage into the tunnel.
2. There should not be any formation of vortices that could draw air into the water conducting system.
3. There should be minimum entry of sediment into the water conducting system.
4. Floating material should not enter the water conducting system.

Inlet structure: Inlet transition facilitates the flow acceleration, ensuring the transition from subcritical flow which is established upstream in the reservoir created by the construction of the cofferdam or, in some cases, the channel connecting the bed to the frame, to supercritical flow that occurs in the diversion tunnel. The implementation of this structure aims to promote sufficient air to the flow, so that it develops a pressure equal to atmospheric pressure along the tunnel. This avoids the possibility of reaching pressures near the water vapour pressure, reducing the risk of cavitations phenomena in the diversion tunnel and hence its erosion. Regarding installation of the inlet structure it may be implemented directly on the ground or resort to auxiliary concrete that supports it above the ground level.

For smooth entry of water in to the tunnel, generally following elliptical equation is used

$$\frac{x^2}{D^2} + \frac{y^2}{0.33D^2} = 1 \tag{1}$$

In the inlet structure design it is important to proceed to the analysis of flow velocities that are practiced within and upstream the structure. To this end, the ratio of the velocity flow in the control structure and velocity flow upstream the structure must be in a range of 2 to 5. The inlet separation. In order to drain maximum water sometimes no curve is provided to bottom surface of tunnel which is in touch with invert of approach channel. The flow separation may occur in the transition river section with irregular section for the tunnel section, usually circular or horseshoe sections.

3. GEOMETRIC DESIGN

Sections usually adopted for tunnels are covered in IS 4880 (Part III, Hydraulic design) -2000[1].

The functional requirements are defined in a broad sense. Design requirements include all hydraulic and geometric, ancillary and environmental, logistics, and maintenance requirements and limitations.

3.1. TUNNEL DIMENSIONS

should be decided on the basis of economic studies so as to obtain a most economical section. The following should be taken into account:

Discharge passing through the tunnel flowing partial full is given by:

$$Q = \frac{2}{3} B C_d \sqrt{2g} H^{\frac{2}{3}} \tag{2}$$

Where Q= Discharge passing through the tunnel in m^3/s

B= Width of tunnel in m

C_d= Coefficient of discharge

g= Acceleration due to gravity

H= Net head in m

Velocity in tunnel, computed by Manning's equation

$$V = \frac{1}{n} R^{\frac{2}{3}} S^{\frac{1}{2}} \quad (3)$$

Where V= Velocity of water in the tunnel in m/s

n= Coefficient of rugocity for unlined tunnels may range from 0.04 to .06

R= Hydraulic radius in m, for sections other than circular R = 4

S= Longitudinal slope

3.2. HEAD LOSS

- Following losses may be expected for flow in diversion Tunnel:

- Head loss in approach channel, if tunnel is located away from reservoir
- Head loss at intake entrance

$$h_e = k_e \frac{V}{2g}^2 \quad (4)$$

Where

h_e , K_e are head loss and loss coefficient s respectively

K_e = 0.16 for square bell mouth entrance

= 0.03 for circular bell mouth

= 0.1 for gate wall rounded corners

Head loss due to gradual contraction

$$h_e = K_e \left(\frac{V_2{}^2}{2g} - \frac{V_1{}^2}{2g} \right) \quad (5)$$

Here K_e =0.10

Other losses as at bends, transitions, etc.

Head loss due to tunnel friction, calculated with the help of Darcy Weisbach resistance equation:

$$Head\ loss = h_f = \frac{fLV^2}{2gD}$$

Where

h_f = Head loss in m

f = Friction factor

L = Length of stretch

3.3. ESTIMATION OF FRICTION FACTOR

Implicit equation for estimation of friction factor was given by Colbrook in 1939

$$\frac{1}{\sqrt{f}} = -2log\left[\frac{\frac{e}{D}}{3.7} + \frac{2.51}{Re\sqrt{f}}\right] \qquad (6)$$

This equation needs iterative steps for its solution. Many investigators (some of them are listed in Annexure A) proposed approximate solution in form of explicit equation. Two power explicit equation given by the author (2017) Chavan is very convenient :

$$f = \frac{0.0075\left(\frac{(4000)^{0.05}}{R_e}\right)}{0.25+\left(\frac{4000}{R_e}\right)^5} + \frac{20}{R_e} \qquad (7)$$

Where f = Friction factor

R_e = Reynolds Number given by

$$R_e = \frac{\rho DV}{\mu} \qquad (8)$$

μ = Coefficient of Dynamic viscosity

Exit head loss is

$$h_e = k_e \frac{V}{2g}^2 \qquad (9)$$

Discharging capacity- Discharge passing through the tunnel flowing full is computed backwardly, using known head loss, known conditions in which tunnel is being operated i.e. Reynolds number, and friction factor curves for operation characteristics of particular tunnel are prepared.

Based on the above losses, the diameter of the tunnel has to be fixed, such that it results in an overall economy. This is because if the diameter of a tunnel is increased, for example, the friction losses reduces

The tunnel diameter determined as a result of economic studies should be examined from practical considerations, such as space requirements for the excavating equipment and the section may be modified if necessary, based on the above considerations. A minimum height of 2 m is necessary. For mechanized handling of excavated material a minimum section of 2.5m x 2.5 m is required.

Approach Channel for diversion tunnel- The dimensions and alignment of the excavated approach channel upstream from the river to the tunnel and of the discharge channel to convey the water back to the river downstream are determined by the hydraulic design requirements and the stable slopes for the material excavated

4. THE TUNNEL SLOPE, LENGTH

The tunnel longitudinal slope, S, has no typical value as it depends on the geometry of the river and the valley but generally is of the order of the riverbed slope at the site. The effect of the slope is to add LxS to H. Therefore, if the slope increases, the discharge capacity of the tunnel increases and the required cofferdam height decreases. When S is significantly different from the average value assumed, the effect on the cofferdam height estimated from guides in this study should be accounted for. A circular diameter (D) of the tunnel is used to represent and compute the tunnel cross-sectional area available for the flow. In the case of the horseshoe section, the equivalent circular section should be employed. L depends on the extent of the site needed to remain dry and is typically a few tens of meters more than the base width of the dam. It is generally greater for embankment dams than for concrete dams. In any given project, L is fairly fixed and is not subject to optimization here. In the optimization attempt, D and H are inter-related and vary together. Greater H requires smaller D and vice versa.Longer tunnels are generally associated with smaller optimum diameter- $D_{optimum}$ regardless of Q and W and the support type. When the tunnel is very long, an overly large tunnel must be avoided and heightening of the cofferdam should be examined instead. It is prudent that some who follow the tradition of determining D only by Q and W often overlook the simple fact of dependency of $D_{optimum}$ on L.

Reservoir depletion tunnel comprises three sub-structures: Inlet Structure, Tunnel body and Outlet Structure. Section of a depletion tunnel studied at Central Water and Power Research Station is shown in Figure 4

5. TUNNELS

Tunnels need to be designed and constructed in an efficient manner for the best performance. The Bureau of Indian Standards code IS: 4880-1976 “Code of practice for design of tunnels conveying water” (Parts 1 to 4)[1] provides guidelines for design of a tunnel under various situations. The following are the salient points.

5.1. TUNNEL LAYOUT

The first aspect that needs to be decided for a tunnel is the alignment, that is, the route layout of the tunnel in plan. Figure 5 shows the possible alignment for the tunnel water conveyance system for a diversion of water through tunnel. The inlet structure geometry must be hydrodynamic, both in plan and in longitudinal profile to avoid flow separation. The flow separation may occur in the transition river section with irregular section for the tunnel section, usually circular or horseshoe sections

The layout is usually governed by the geological features of the surrounding hills. Complicated geological conditions and extraordinary geological occurrences such as intra-thrust zones, very wide shear zones, geothermal zones of high temperature, cold/hot water springs, water charged rock masses, intrusions, fault planes, etc. should preferably be avoided. Sound, homogeneous isotropic and solid rock formations are the most suitable for tunnelling work. However, in the Himalayan region, such conditions are rather rare compared to the hills of peninsular India. This is because the Himalayan geological formations are mostly sedimentary in nature whereas the peninsular upland of the country is of igneous nature. Hence, geological investigations have to be carried out in detail before a tunnel alignment is finalized.

5.2. TUNNEL BODY

The flow in a river diversion tunnel should occur in supercritical scheme to provide quick acceleration required by deploying of upstream structure. In the river diversion tunnel design it should be noted that in the river diversion through this structure, the flow depth should progress to uniform depth. Thus, it is necessary to define under which conditions the flow is to proceed along the diversion tunnel. Therefore, it is possible to conclude the existence of hydraulic jumps inside the tunnel and determine its location. Studying the flow conditions inside the tunnel consists of analyzing the flow depths along the tunnel by defining the backwater curves. Thus, it is important to trace the backwater curves for diversion tunnel with the goal of establishment the various flow depths along the structure allowing the flow classification.

Flow conditions in tunnel: The occurrence of hydraulic jumps inside the river diversion tunnel can cause structural problems. By establishing the different depths inside the tunnel, it is possible to determine the amount of total movement inside it and the hydraulic jump position. Knowing the flow depths is very important in the study of the river diversion tunnel, so it is imperative to establish backwater curves inside the tunnel. This computation is based on the Bernoulli's theorem.

Free surface flow: In most cases, flow takes place in free surface and should not exceed 70% of the tunnel capacity. When deploying a river diversion with pressure flow, it must be ensured that the structure's altimetry track allow the respective domes to always be situated below the isometric line to avoid depressions that may cause structural and hydraulic inconvenient. The study of flow through the tunnel is hampered by the tunnel geometry. The tunnel cross section assumes generally circular or horseshoe geometry. In case of using a river diversion tunnel is possible to convert it in the bottom discharge of the final structure. This approach has advantages, especially in project costs.

The location of diversion tunnel or tunnels is affected by topography, abutment foundation conditions, hydraulic requirements, and economy of construction. Except for some high-head dams, it usually is economical to place an outlet tunnel near stream elevation and use it for diversion during construction. A tunnel should be located far enough into the abutment to obtain adequate cover for the character of rock encountered, and the tunnel alignment must meet the hydraulic requirements. The most economical location to pass around or under the dam and meet the foregoing requirements should be selected. An alternate plan used for some deep reservoirs has a high-level intake at the head of an inclined tunnel connecting with a tunnel through the abutment near river level. After serving its purpose of diversion during construction, the low-level tunnel is plugged at the upstream side of the intersection and the inclined tunnel and downstream portion of the low-level tunnel with a connecting curved transition from the permanent outlet. This plan may be economical and satisfactory under special conditions where the reservoir is very deep, the minimum water surface is high, and rock foundation is adequate. Because of the difficult foundation and structural problems involved in this type of construction, thorough foundation investigations and comparative studies should be made and this plan should not be selected without full analysis of its practicability and economy. The advantage of the high-level intakes for a very deep reservoir is the lower intake structure and lower head on intake gates, resulting in a less expensive intake structure. Disadvantages of this type of outlet are: cost of the inclined tunnel, difficulty of obtaining an adequate foundation for the intake structure, and the difficulty of excavation for and the complexity of the transition structure at the junction of the inclined tunnel with the low-level tunnel. Particular care should be taken to obtain high quality concrete, smooth gradual curves, and good alignment at the junction. If the intake structure is located directly over the low-level tunnel, there should be an ample thickness of good, sound rock between the intake base and the tunnel to transmit the foundation loads to the main rock mass. Sometimes conditions may be favourable for locating the intake far enough to one side of the low-level tunnel to simplify the problem of supporting the intake structure. For some high dams, outlet works separate from diversion facilities and located much higher than the river channel may be suitable. In such cases, overall economy may result from use of separate high-level outlets and use of the downstream portion of the diversion tunnel as part of the spillway outlet.

5.3. NUMBER AND SIZE OF TUNNELS

The proper selection of number and size of diversion tunnels depends on hydraulic requirements, the maximum size of tunnel which it is practicable to drive in the rock encountered, operating flexibility, and economy of construction. In some instances it may be necessary to limit the size of tunnel in yielding rock to prevent excessive movement in the surrounding rock. Generally the larger the tunnel within practicable driving limits, the more economical it is per unit flow capacity. Also, the approach and discharge channels and the intake structure usually are more economical for fewer tunnels because the reduced width results in less channel excavation and a narrower intake structure. However, if it is necessary to use two parallel gates in each larger tunnel and only one in the smaller, the intake structure may not be reduced and economy may not be affected by use of larger tunnels. The most economical number of tunnels which will meet the other requirements should be used. A single tunnel is used when, as is frequently the case, the required diameter to handle the entire discharge is not over 20 ft to 25 ft. In order to provide reasonable operating flexibility, a total of not less than two service gates should be provided in the outlet works. In some cases, this requirement may influence the number of tunnels. Detailed design and construction procedures for tunnels are provided in EM 1110-2-2901, A Tunnels and Shafts in Rock[4].

5.4. INFLUENCE OF DOWNSTREAM LEVELS FOR DIVERSION TUNNELS

When dimensioning the river diversion tunnel it is important to study the influence of the downstream level into the flow conditions inside the tunnel, once it may not be guaranteed that the establishment of the uniform system within the diversion tunnel ensures that free surface flow occurs along its entire length. In order to proceed with the study of the downstream level influence, it is necessary to analyze the altimetry placement of diversion tunnel. Submerged flow considerably reduces the discharging capacity of the tunnel. A first stage begins by analyzing the total momentum inside the tunnel, comparing it with the natural bed total momentum. In the case of the natural bed total momentum overcome the values obtained in the tunnel, the hydraulic jump occurs inside the tunnel. Thus it is possible to determine the existence of hydraulic jump, and if there is, proceeding to its location. The occurrence of a hydraulic jump inside the diversion tunnel involves a correction of the upstream altimetry position. The calculation of the flow depths by defining curves backwater enables the calculation of the total momentum into the river diversion enabling comparison with the total momentum in the natural bed and the location of the hydraulic jump.

5.5. MULTIPLE DIVERSION TUNNELS

For at least two reasons, the designer may choose multiple (mostly twin) tunnels to carry a large design flood: (I) large cross-section needed to divert large flood is associated with specific problems such as higher tunnel stability risks and expensive support measures, need for more complicated excavation or support equipment, and more risks brought about for the abutments specially when the overburden or the rock quality is not sufficient; (ii) the design flood may not happen during construction and the discharge in a great majority of construction days is much below the design flood. Therefore, twin tunnels may be constructed, one to carry the usual low and average discharges another with a higher invert elevation to carry the additional part of the design flood. When the second one is constructed sufficiently higher than the first, it may be mostly used as access road tunnel between upstream and downstream parts of the dam during construction, a double arch 180m high concrete dam under construction in southwest of Iran). The designer may choose to apply support but avoid RC lining in the second tunnel.

6. TUNNEL EXIT

It is also essential to design the entry and exit points of the tunnel very carefully. Where the tunnel emerges out of the hill slope, a structure in the form of an arch is usually provided, which is called the portal. Since at this point the water leaves the tunnel, it is prone to hydraulic head loss and erosion. Proper transition shape has to be provided to keep the loss minimum and to avoid cavitations. The length and slope of the transition depends upon the velocity and flow conditions prevailing in the tunnel, economics, construction limitations, etc. It is generally preferred that a hydraulic model study is conducted to arrive at an efficient but economic transition. tunnel. When a circular tunnel flowing partly full empties into a chute, the transition from the tunnel section to one with a flat bottom may be made in the open channel downstream from the tunnel portal or it may be made within the tunnel so that the bottom will be flat at the portal section. Ordinarily, the transition should be made by gradually decreasing the circular quadrants from full radius at the upstream end of the transition to zero at the downstream end. For usual installations the length of the transition can be related to the exit velocity. An empirical rule which may be used to design a satisfactory transition for velocities up to 6 m/s is as follows:

$$\tan\alpha = \frac{1}{F} \qquad (10)$$

Where L = length of transition in m, v = exit velocity in m/s, and D = tunnel diameter in m

6.1. Outlet Structure

The return diverted flow, through the river diversion, can be made through direct connection to the river or by deploying outlet structure. The deployment of the restitution structure may have two objectives, the dissipation of excess energy or the recovery of part of the kinetic energy. The need to implant a restitution structure is associated with the fact that the flow in the tunnel that is supercritical or if the downstream section of the tunnel is elevated compared to the river bottom, hindering establishment subcritical conditions in the restitution area. The outlet structure can match the deployment of a transition structure or deployment of stilling basin. Diversion tunnel discharge can be led to directly in to river depending upon gradient of river. To avoid bank erosion some form of bank protection is provided. In case of depletion tunnel exits, where high velocity may occur, energy dissipation arrangement has to be provided as shown in fig: 6.It works well as part jet is lifted to 35^0 splitting and spreading before plunging in to river pool.

7. COST ANALYSIS

Following are the main factors affecting overall cost of the tunnel

a)Capital investment

b) Cost of equipments

c) Interest charges on capital cost of tunnel,

d) Annual maintenance charges,

e) Whether lined or unlined and

f) Cost of gates and their hoists.

8. TUNNEL INSPECTION AND MAINTENANCE

Inspection of tunnel and its maintenance takes an important role in sustainable functioning of the tunnel. Inspection is carried out at lean water levels. Sometime tunnel has to be closed down. As such very little time is available for inspection as compared to other types of tunnels.Another hurdle for inspection of hydraulic tunnels is remoteness.

Cavitations: - Design shall be such that negative pressures are avoided. Cavitation observed at Sardar Sarovar tunnel is shown in Figure 4.

Figure 4. Prototype photograph showing exposed reinforcement inside Tunnel due to cavitations

Closing of river diversion: For diversion tunnels, it is necessary to close the flow through diversion tunnel to start filling the dam or divert the tributary flow through definitive structures that are completed. The temporary diversion closure can be permanent or temporary (Pinheiro, 2002). In temporary closure, it is common to use a gate. For permanent closing it is implanted a concrete plug inside the diversion structure. The planned temporary diversion closure must be programmed according to a study of local flow conditions and the closing of the river coincide with the dry season. The type of diversion structure influences naturally provisional closing. In the case of the structure consist of two diversion tunnels it is possible to make the closing of one of the tunnels continuing the flow to be diverted by other tunnel (ICOLD, 1986)[5].

SUMMARY

Increasing urban population and the pace of industrial and other developments led to increase in water demand. Many of metropolitan and urban cities are facing acute shortage of water for domestic and industrial purposes To reduce the stress on water supply infrastructure, existing water sources are utilized to fullest and new sources are continuously added to augment the water supply. Major problems in design of tunnel for water flow are flow conditions in approach to tunnels, in tunnel and downstream of tunnel. Even though art of tunneling is very old and well documented, new challenges in design and construction in difficult situations are added over the years. In this paper various hydraulic aspects related to tunnel interlinking rivers are described. Major head loss in tunnel flow is due to friction. Detailed information on investigation by various researchers related to friction factor is attached in Annexure A.

Key Words: Discharge, Diversion Tunnel, Explicit Equation, Friction Factor

OPERATIONAL MODES MONITORING FOR PREVENTION OF FAILURE OF DAMS WITHIN THE DESIGN ENVELOPE

DND HARTFORD and SJ RIGBEY.

Dam Safety, BC HYDRO

CANADA

1. INTRODUCTION

For the purpose of promoting debate and discussion this paper introduces two important and difficult questions concerning surveillance and monitoring arise for dam owners that pursue or are interested in pursuing risk-informed dam safety management. The questions, in no particular order because they are related are:

1. To what extent should dam owners rely on risk assessment to guide their surveillance activities? and,
2. Which approach to risk assessment should they use?

Everyone involved in dam safety management is involved in risk management to some degree. This is regardless of whether or not some type of risk assessment is practiced in their country or if they favour risk assessment over established deterministic practices. Further, and again regardless of the approach (deterministic or probabilistic), all dam safety management activities depend to a significant degree on reliable monitoring data and surveillance reports for their integrity. The data and surveillance reports reflect the performance of the dam in its operational mode, where the operational mode refers to any condition of combination of the conditions of containment of the stored volume and passage of flows through and around the dam that the dam has experienced or is intended to experience during its operating life. This definition of operational mode corresponds to that used in the nuclear and other industries [1]. The operational modes of the dam as a whole are derived from the operational modes of its subsystems, components and parts and the activities, or modus operandi, involved in achieving the overall operational functions. Some form of monitoring and surveillance of the operational modes of the dam and its sub-systems, components and parts provide the starting point for a dam safety analysis, regardless of its form or the level of detail [2], [3]

According to the US Bureau of Reclamation (p.17): *"Many times, weaknesses or deficiencies can be identified from changes in the behavior of the structure, foundation, abutments, or seepage.", …*, *"Any unusual behavior, regardless of how seemingly insignificant, should be identified and recorded because any unusual condition may be the forewarning of a newly developing unsafe condition."*

Monitoring of structural and functional behaviour under normal operating conditions covers the spectrum from visual identification of structural or functional distress (visually observable deformation, overtopping), through visual identification of precursors of physical distress (increased seepage), to detection of actual distress or its precursors via instruments and other technologies. Typically, the monitoring activity is embodied in the broader surveillance process that involves assessing the integrity of the recorded data, interpreting this data and transforming it into meaningful information that then informs safety management actions. Surveillance, which transforms monitoring data into engineering information provides essential analytical and interpretative elements of real-time dam safety assessment.

The notion of basing a surveillance program on monitoring the operational modes of a dam system and its components is not obviously aligned with the notion of focusing the surveillance process on detection of early development of significant failure modes as set out in ICOLD Bulletins 138 and 158 [4], [5]. This is because the latter implies that the effort should be directed at "significant" failure modes that can be identified prior to the establishment of a surveillance program (or prior to re-configuration of an existing program), whereas the former operational modes monitoring approach which is deterministic, does not impose any restrictions or make assumptions about how failures or incidents might develop either physically or temporally.

This paper is underpinned by an unparalleled 25 years of pioneering experience as a dam owner in developing and advancing capability in risk-informed dam safety management while simultaneously maintaining and improving a robust surveillance program as part of a comprehensive dam safety management system. Periodic critical re-assessment of our performance in both of these areas of the dam safety program, which includes independent external audits of the program every 5 years, leads to the question as to whether the dam safety program should revolve around the results of analysis of failure modes in a portfolio risk management process as suggested by some, or maintain and advance the current approach of focusing first on monitoring and surveillance of the operational performance of the dams on an individual basis.

2. THE "AXIS" OF A DAM SAFETY MANAGEMENT PROGRAM

ICOLD Bulletin 154 [6] provides a general process for managing the safety of dams during the operational phase of the life-cycle (Figure 1). This framework and variations of it have a proven track record of effectiveness in managing the risks from dams over many years.

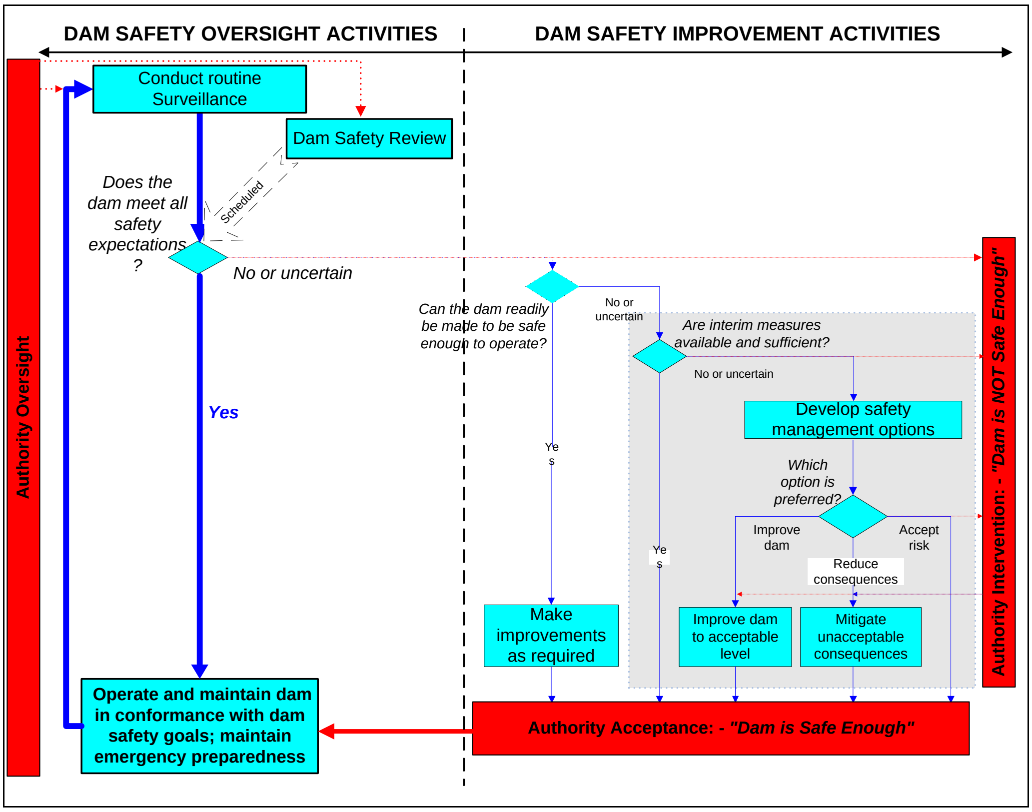

Figure 1. Dam Safety Management Process (ICOLD, 2017)

The effective implementation of the activities shown on the left side of the framework is essential for real-time dam safety management, demanding diligent attention by the dam owner. As such, these ongoing activities under normal operational conditions can be considered to form the axis of a dam safety management program that all other dam safety activities depend on in some way. The importance of diligence and thoroughness in conducting these activities cannot be overstated as investigations into dam failures and incidents invariably point to weakness in implementation of these activities together with other factors such as management and organisational weakness, human error and the likes. For example, the Independent Forensic Report on the Oroville Dam Spillway incident found weakness in the three activities together with significant management and organisational factors and professional practice concerns.

ICOLD Bulletin 154 does not provide detailed treatment of the activities that are carried out in these implementation steps, referring instead to other ICOLD

Bulletins such as Bulletins 118 [8], 138 and 158 on Surveillance. Emergency preparedness typically involves external agencies in the country where the dam is situated and as such is not dealt with in specific detail by ICOLD.

2.1 CONDUCT ROUTINE SURVEILLANCE

A general framework for what is intended by "conduct routine surveillance" is summarised in ICOLD Bulletins 118 and 158 as illustrated in Figure 2 from ICOLD Bulletin 158 [5] which was taken directly from ICOLD Bulletin 118 [8],

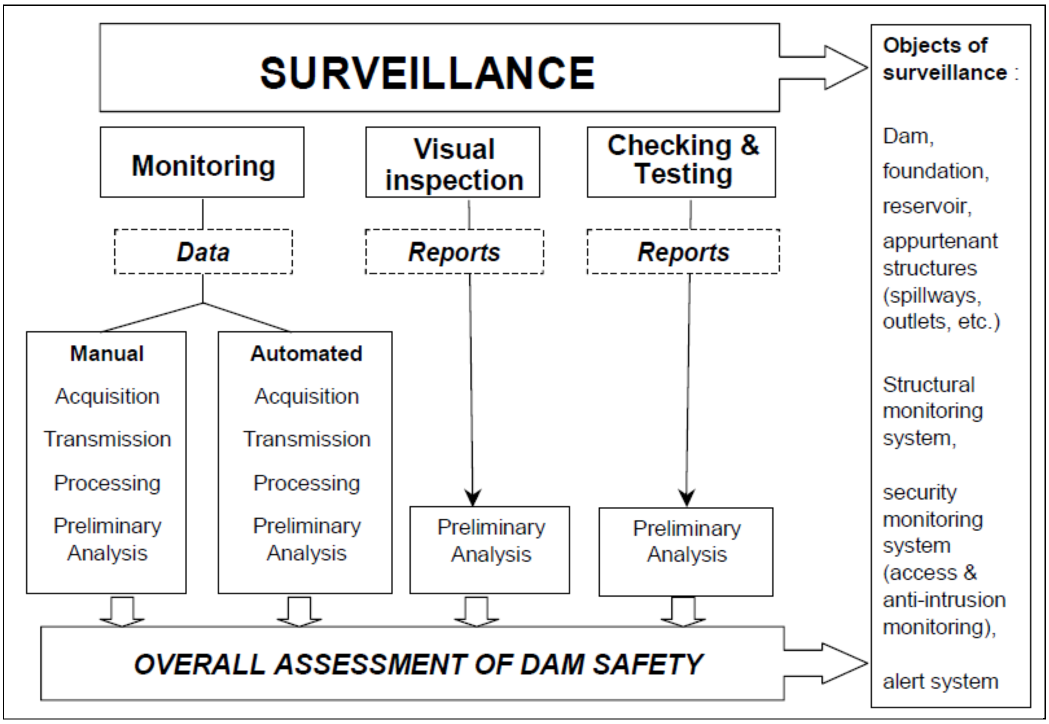

Figure 2. Framework for Surveillance (ICOLD B 118 and B 158)

The definition and intended meanings of the terms failure mode require clarification in Bulletin 158 for instance by referring to ICOLD Bulletin 130 on Risk Assessment [9]. Bulletin 158 refers to the objective of early detection of significant failure modes and some sample potential failure modes of interest provided. These failure modes are clearly defined at a very high level in the dam system similar to the hazards and failure modes framework illustrated in Figure 21 of Bulletin 154. However, the manifestation of such adverse performance characteristics may occur late in the failure process, or be difficult to ascertain such as in the case with seepage, where differentiating between "normal seepage" and "failure inducing seepage" can be exceptionally difficult. Bulletin 158 is unclear with respect to what is meant by a failure mod;, what constitutes significant; and how failure modes can be detected. However, it does provide clear advice on some of the behavioural features of significance to be considered in visual inspections and significant parameters to be monitored by instrumentation.

3. OPERATIONAL MODES AND FAILURE MODES

At the outset, it is important to be clear as to the definition of a “Mode”, be it an operational mode or a failure mode by focusing first on the common use of the term mode:

Mode: A state, condition, way of doing things (modus operandi), manner in which something occurs.

- Common uses include “flight safe” mode; mode of transport (aircraft, car, railway, etc.)

Mode of operation: A mode in which the operational states or objectives of the system manifest themselves.

- In the context of dams, water retention and water conveyance are operational modes; at a more detailed level, the operational modes of a spillway gate system include a) dormant mode (during the dry season); in-service mode (closed to retain water or open to pass flows); and ready mode (just prior to initiation of gate movement).

Failure Mode: The manner in which an element or component fails to achieve its operation (design) objective.

- In the context of spillways, failure modes of a spillway gate include unintended closed state and unintended open state.

Any owner, regardless of degree of sophistication can understand the operational modes of a dam being retention and conveyance when set out in terms of commonly understood terminology.

With reference to well established experience in the nuclear industry, as well as first-hand experience of operational incidents at dams and reflecting on the Oroville Dam Spillway incident where the incident could not be attributed to a specific cause, it is proposed that attempting to define failure modes as sequences of events from initial cause to system end state should be avoided. Referring to the Fault Tree Handbook (Page II-1) [10] (Nuclear Regulatory Commission, 1981): *“For systems that exhibit any degree of complexity (i.e., for most systems), attempts to identify all possible system hazards or all possible component failure modes-both singly and in combination-:-become simply impossible”.* Concerning inductive techniques overall, such as Failure Modes Analysis and Event Tree Analysis, the Fault Tree Handbook points out that “*due to constraints such as time, money and experienced staff, exhaustiveness in the analysis is a luxury that we cannot afford*”. Thus, not only will it be impossible to capture all possible failure sequences in an inductive analysis, it will typically not be possible to include all identified possible failure sequences in the analysis. Therefore if one defines failure modes as sequences of events from initiation to failure, one should not be surprised if a failure sequence that was not identified in the analysis occurs.

Given that one can reasonably exclude defining failure modes in terms of the sequence of events between initiation and ultimate failure on the grounds that it is impossible for all but trivial systems, one must also accept that failure modes are not uniquely defined, [10], [11]. Rather, failure modes are a matter of the perspective at which the analysis is conducted. System level failure modes are different to parts level failure modes. This has hugely important implications for monitoring and surveillance as these activities are directed at detecting changes in performance of some feature of the dam be it at the system level as is the case with visual inspections of dam (e.g. deformation of the dam body), or tests of functionality of parts (e.g. measuring friction in a trunnion bearing).

The concept of system level and parts level failure modes is illustrated in Figure 3, which also illustrates the relationships between cause-mode-effect for one module of the spillway sub-system, specifically the gate which is further resolved to its component parts.

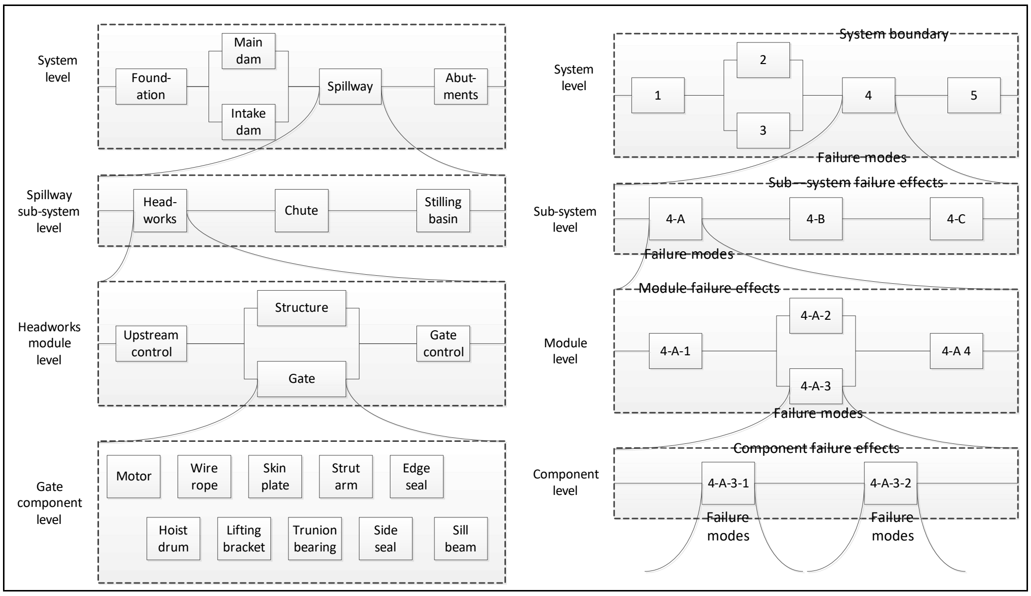

Figure 3. Systems, parts and “cause – mode – effect” relationships

Note, all features at the component level are not shown due to space limitations, and each component can be further resolved into the elements that comprise each component.

At some point, it becomes necessary to ask the question: “To what extent should the system be resolved?” We suggest that the answer is that as a general principle resolution should be to the level at which maintenance and testing can be carried out. This then defines the level in the system at which the monitoring and surveillance effort should be directed because this is the level at which the operational failure risk is managed. Thus, the answers to the questions as to what should be monitored and tested emerge directly from the practicability of establishing and maintaining the operational integrity of the various features of the dam system be it at the component level (or even further down to the elemental level, such as motor windings), or at the system level, or somewhere in between.

Thus, beginning with the operational modes of water retention and water conveyance, and progressively resolving these system operational modes into their constitutive functional modes, it is possible to determine the overall operational integrity of the dam system and to establish that the dam is functionally safe. This can all be achieved on the basis of operationality without consideration of failure modes.

3.1 Derivation of Failure Modes

Failure modes can be derived directly from the operational modes of the system and its resolved parts. Figure 4 illustrates a spillway gate at the headworks module level comprising 10 components, and a functional analysis diagram that illustrates the operational modes of the various components in a self-explanatory way.

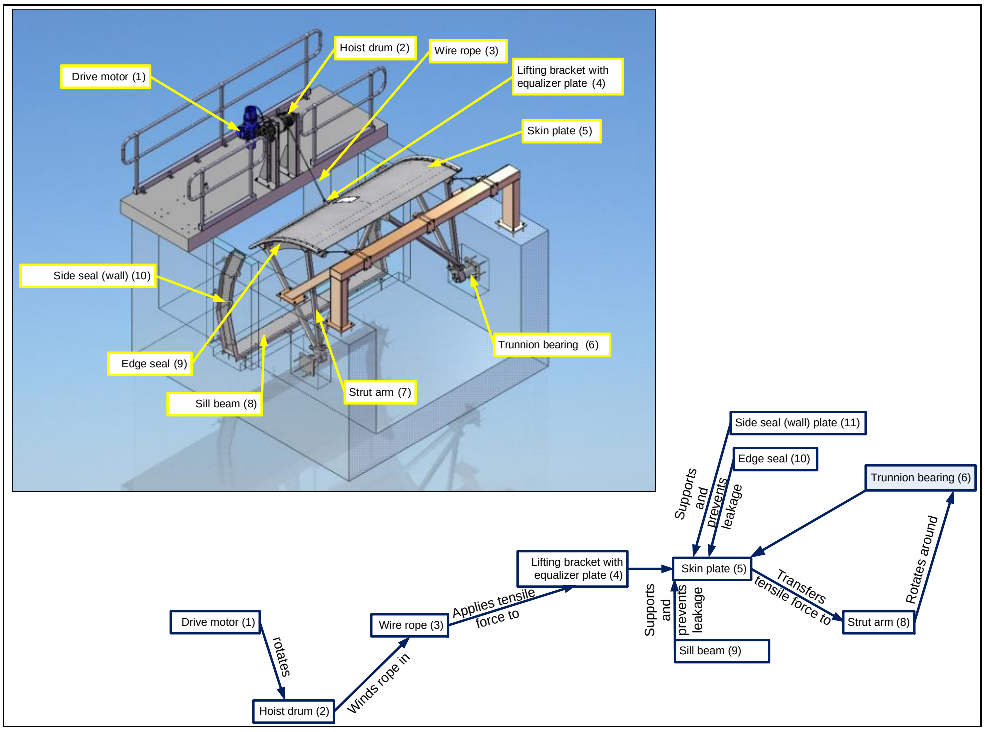

Figure 4. Component level Functional Analysis Diagram of a spillway gate

The function of the motor is to rotate the hoist drum and the failure mode of the motor is loss of rotation, with the effect that the hoist drum does not move. Functionality of the entire gate module is lost as a result and the obvious dam safety management action in the surveillance process is to verify that the motor does indeed rotate as intended during the inspection and testing process. The failure modes of the various components of the spillway gate module can then be derived by taking the compliment of the operational mode of the component. Thus, if the operational modes of the components (or higher levels of the system) are known, then the operational failure modes can be derived directly.

The derivation of failure modes from operational modes is of **crucial** importance, because it contributes greatly to overcoming the problem of a failure modes analysis (of any type) not having the analytical power to reveal the modes. In Failure Modes and Effects Analysis (and its variants), the analysis depends heavily on the ability and expertise of the analyst for finding all necessary modes. [12]

3.2 Operational modes based or failure modes based surveillance?

None of the above provides direct answers to the questions that motivated this paper:

1. To what extent should dam owners rely on risk assessment to guide their surveillance activities? And,
2. Which approach to risk assessment should they use and to what extent?

But then, perhaps these are the wrong questions from the perspective of dam safety assurance, where the overriding objective is to demonstrate that the dam and its various subsystems, modules and components are functioning properly and are available to be brought into service as required. Of course, the definitions of what constitutes an "operational mode" and a "failure mode" are vitally important. It is a somewhat straightforward matter if failure modes are derived from operational modes, although it must be recognised that this derivation is not "cut and dried", as the operational function may not be achieved exactly as intended. Rather than considering failure modes in dam surveillance as forming the basis of real-time dam safety assessment, we suggest that it is more appropriate to consider operational modes as the basis of surveillance for risk management and failure modes as being derived from the loss of the operational modes and from design knowledge. This also means that from a dam surveillance perspective, the effort should be focused on the performance attribute that can be determined in the most efficient and effective way. This said, visual (and now remote via drones etc.) inspections, monitoring and testing all target deviations from the expected performance state of the dam and it various sub-systems, one of which is the failed state (in principle there can be unexpected performance states that are not failed states). Thus, understanding of and focus on the operational modes of a dam, which can be assessed continually in time if necessary, thereby providing the capacity to capture functional and non-functional (failed) states all of which can be validated and verified objectively, provide the foundational basis of a robust dam safety assurance program.

3.3 A ROLE FOR PROBABILITY?

All of the above can and should be achieved in terms of deterministic analysis as there should be no uncertainty in how the designer intended the dam and its constitutive parts to function. This design intent raises the question as to whether or not there is a role for probabilistic assessment of the significance of operational and non-operational (failure) modes, noting that the definition of a failure mode as a sequence of events from initiation to complete failure is unrealistic as explained above.

Given the deterministic nature of the process of setting out the operational functionalities of a dam system and for determining the failure cause – failure mode – failure effect relationships in terms of the intent of the design, any identifiable deviations from the design intent are also determined deterministically; specifically all not intended states are those that do not conform to the design intent. This means that any use of probability pertains to consideration as to whether or not the failure mode is considered to be “significant” or “critical” to safety.

The Fault Tree Handbook [10] provides useful advice as follows: “*In FMEA (and its variants) we can identify, with reasonable certainty, those component failures having "non-critical" effects, but the number of possible component failure modes that can realistically be considered is limited. Conservatism dictates that unspecified failure modes and questionable effects be deemed "critical".* This observation points to a limited, if any, role if any for screening out failure modes on the basis of probability.

4. CONCLUSIONS

On the basis of the above, we conclude that surveillance of **the operational modes** of a dam in the sense of visual inspections, monitoring, and testing provide the foundation of an effective dam safety management process. These activities can be carried out at various levels of refinement where the most fundamental elements are available to and implementable by all dam owners regardless of their institutional strength and sophistication. We observe that “screening out” of failure sequences on the basis of actual or perceived probability should not be attempted for a complex system such as a dam. This is because the number of possible combinations and interdependencies of functions and functional variances rises exponentially with the size of the system. The number of possible combinations of unfavourable events is correspondingly as large as the probability of any one of them occurring is small. The probability of at least one combination of pernicious events actually happening can be significant.

1. INTRODUCTION

Slit-type energy dissipaters (STED) change the trajectories of nappes by using specific flip buckets to make the flow contract transversely and extend longitudinally. The energy of flow is greatly dissipated in this progress and then the erosion of downstream channel caused by the nappe can be relieved. Because of its advantage of efficient energy dissipation effect, STED has been widely used in hydraulic projects of high water head, large discharge, and narrow river valley. The energy dissipation problems of many large scale hydraulic projects in China, such as, Longyangxia dam, Ertan dam, Shuibuya dam, and Geheyan dam are successfully solved by the application of STEDs.

From the aspects of energy dissipation effect and structure safety, the water surface in the channel, the characteristics of pressure and cavitation, the shape of the nappe, and the scouring effect of downstream riverbed of STED have been studied theoretically and experimentally. Zhang and Wu (1989), Dai and Yu (1992) observed the movement and extension features of the nappe experimentally, proposed estimated formulas for the water line in contraction section and the distance of the nappe. Wu et al. empirically provided the conversion conditions of the nappe forms, and experimentally investigated the behavior of the flow choking. The estimated formulas for nappe maximum width and its location of slit-type flip buckets were presented by Liu et al. Huang et al. developed a method to calculate the dynamic water pressure in the contraction section of STED.

Ippen (1943) put forward the ideal shock wave theory based on the mechanical principle, proposed the basic equations of shock wave, then the main theoretical foundation of the contraction type energy dissipaters was laid. Ippen's formulas was then simplified by Hager et al. (1987) and Liu et al. (1999) Ippen's theory following several assumptions: (1) the deflection angle of flow is small; (2) the friction of side wall is negligible; (3) the pressure distribution along the depth of the water conforms to the hydrostatic pressure distribution regularity. However, the flow regime in the STED no longer satisfies the assumptions, for the rather sharp deflection angle, and the narrow width of the surface. So Ippen's formulas would result in large deviation, and need to be modified for the application in STED.

As a special hydraulic phenomenon, the water wing caused by the shock waves in the contraction section of STED may bring about harmfulness to the stability of the bank and the safety of the downstream buildings. However, the harmful effects caused by water wings has been hardly attached enough importance. In hydraulics prototype observation of Geheyan project, it was found that, the water wing caused by the STED diffused transversely, scoured the side bank slope. And the operation of the upper outlet on both side was then limited. The results of model test of Shiubuya project confirmed that, part of the water detached from the main flow from side outlet, and scoured the river bank. Hence it is necessary to carry out special study on the formation mechanism and movement features of the shock waves and the water wings.

In the present study, physical model experiments and theoretical analysis were conducted to reveal the internal relation of the shock wave and the movement characteristics of the water wing. And then the estimation formula for calculating the shockwave - water wings spread area was proposed, based on the experimental data combined with theoretical derivation.

2. EXPERIMENTAL SET-UP AND METHODOLOGY

The experiment model consisted of a water tank, a sloping flume, a STED structure, and a downstream pool, as shown in Figure 1. The high pressure water tank is 10 meters high and provided adequate flow with enough water head. The flow was delivered by a Plexiglas-made sloping flume into the STED structure. The sloping flume is 3.2 m long, 0.2 m wide and 2 m high. A radial gate was set near the downstream end of the flume to adjust the Froude number of the flow in the STED contraction section.

The main geometric parameters of a STED are the length of the contraction section L, the bucket angels α, and the widths before and after the contraction section B and b, as shown in Figure 1. Then, b/B is the contraction ratio.

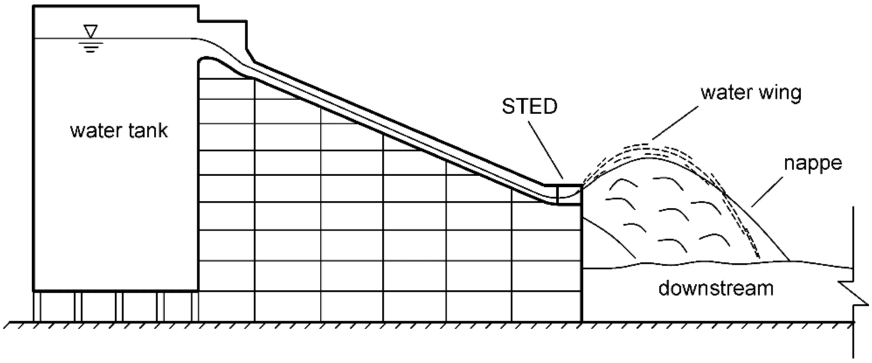

Fig. 1
Experimental set-up

Nine STED models (made of Plexiglas) with various bucket angels (α= 0°; 5°; 10°) and contraction ratios (b /B = 0.20; 0.25; 0.30) were studied. The length of the STED contraction sections was 0.5m. Table 1 summarized the geometric characteristics of the models. The models were systematically tested for approach flow *Fr* at the entrance of contraction section ranging from 4.10 to 5.95.

Table 1
Geometric parameters of the STED models

Cases	α (°)	b/B	θ (°)
M1	0.00	0.20	9.35
M2	0.00	0.25	10.00
M3	0.00	0.30	10.65
M4	5.00	0.20	9.35
M5	5.00	0.25	10.00
M6	5.00	0.30	10.65
M7	10.00	0.20	9.35
M8	10.00	0.25	10.00
M9	10.00	0.30	10.65

The form of the shock wave, the shape and the trajectory of the water wing were observed with high-speed photography. The measuring device for the measurement of the water wing was set in the downstream pool. A rectangular collector was in-house designed to measure the rain strength distribution in the downstream pool and the rainfall caused by the transversely spreading of water wing was analyzed.

3. FLOW REGIME OBSERVATION

3.1. FLOW REGIMES IN CONTRACTION SECTION

As demonstrated in Figure 2, the flow upstream of the STED remained in an open channel condition, with a flat free surface and hydrostatic pressure distribution. Then due to the effects of the side wall contraction, the flow contracted transversely and extended longitudinally when passing through the STED. Figure 3 shows that, the shock waves on both side collided at the center line. The water surface profile no longer remained flat along the contraction section.

The flow in the contraction section was affected by two factors, upstream of the shock wave intersection, i.e. the friction effect caused by the roughness of the side wall and the turbulence inertia effect caused by large vortex. Considering the distance from the inlet of the contraction section to the shock wave intersection point is rather short, the friction effects that caused by the small vortex in the boundary layer of the flow could be ignored. On the other hand, the force acted on the contracted side walls that caused by the inertial impact of the high-speed incoming flow would bring about rapid shock waves (a special form of hydraulic jump). After the shock waves intersected, the turbulence kept growing. As the side walls contracted continuously, the flow depth increased and the velocity decreased, then the inertial effects of the flow reduced accordingly. Large vortexes in the flow constantly split into small vortexes, due to the limitation of the side walls. As a result, large vortexes and small vortexes coexisted in the flow, whereas the turbulence inertia effects caused by large vortexes still played a dominant role in this section.

Upstream of the shock wave intersection, the water-surface curve near the center line of the STED raised slowly, while the water-surface curves near the side wall raised rapidly. The cross section of the flow presented an ‘U’ shape. Downstream of the shock waves intersection, the water-surface curves near the side wall kept rising, while the water-surface curve near the center line raised sharply, and got above of that near the side wall, due to the collision of the shock wave flow. A ‘W’ shaped cross section of the flow appeared. Moreover, part of the water detached from the main flow, then ejected out in the form of scattering, with high inclined initial velocity above the main flow. That was how the water wings formed.

Fig. 2
Overall flow regime in STED

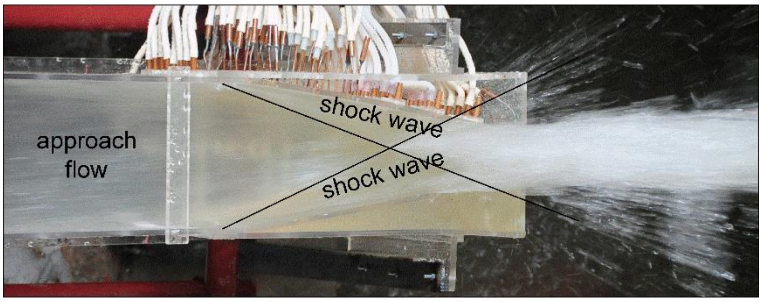

Fig. 3
Flow regime in the contraction section

3.2. NAPPE FORMS

The flow separated into three parts after it left the edge of the STED, i.e. nappe, fin, and water wing. Among these parts, the nappe was formed by the longitudinally extended main flow; the fin was a very thin nappe moved downstream along a straight line trajectory, formed by the flow beneath the main flow under high pressure, which contained negligible quantity of discharge and might hardly cause damage to the buildings; the water wing was caused by the collision of the shock waves, might bring about harmfulness to the stability of the bank and the safety of the buildings downstream.

4. SHOCK WAVES

The shape of the shock wave is the key factor that affects the operation of STED. Ippen proposed the basic formula of shock wave (Eq.1), based on static water pressure assumption.

$$\sin\beta = \frac{1}{Fr}\sqrt{\frac{1}{2}\frac{h_2}{h_1}\left(1+\frac{h_2}{h_1}\right)} \tag{1}$$

Where, β is the angle of the shock wave, h_1 and h_2 are the depth upstream and downstream of the shock wave respectively; Fr is the Froude number of the incoming flow.

Ippen's formula was then simplified by Hager et al. (1994) and Liu et al. (1999) According to Ippen's theory, there are also two formulas,

$$\frac{h_1}{h_2} = \frac{\mathrm{tg}\varphi}{\mathrm{tg}\beta} \tag{2}$$

Hence,

$$\frac{v_1}{v_2} = \frac{\cos\varphi}{\cos\beta} \tag{3}$$

Where, φ is the angle of the shock wave to the side wall, v_1 and v_2 are the velocity upstream and downstream of the shock wave respectively. According to energy conservation assumption,

$$\sin\varphi = \frac{h_1}{h_2}\frac{v_1}{v_2}\sin\beta \tag{4}$$

Combining Eqs. (1), (4), and (5), the following equation was obtained,

$$h_1 + \frac{v_1^2}{2g} = h_2 + \frac{v_2^2}{2g} = H \tag{5}$$

Eq. (6), could be expanded in Taylor's series, with higher-order small components ignored,

$$\sin\varphi = \frac{1}{Fr}\sqrt{\frac{1}{2}\left(\frac{h_1}{h_2}+1\right)\frac{H-h_1}{H-h_2}} \tag{6}$$

Further ignoring one-order small components, a new shock wave simplified formula then derived,

$$\sin\varphi - \frac{1}{Fr} = \frac{1}{2Fr}\left(\frac{\Delta h}{H-h_2} - \frac{\Delta h}{2h_2}\right) \tag{7}$$

Further ignoring one-order small components, a new shock wave simplified formula then derived,

$$\sin\varphi = \frac{1}{Fr} \tag{8}$$

Then, the angle of the shock wave could be simply expressed as

$$\varphi = \arcsin\frac{1}{Fr} \tag{9}$$

However, the flow regime in the STED no longer satisfies the static water pressure assumption, for the rather sharp deflection angle, and the narrow width of the surface. So Eq. (9) would result in large deviation, and need to be modified for the application in STED.

It was assumed that,

$$\gamma = c \cdot \arcsin\frac{1}{Fr} \tag{10}$$

Where, γ is the angle between the shock wave and the side wall; c is a correction coefficient, which depends on the geometric coefficient of the STED, and the incoming flow regime.

Assuming that influencing factors include the bucket angel α, the deflection angle of the side wall θ, and the Froude number of the incoming flow Fr. The results of the orthogonal simulation analysis indicated that, only the deflection angle of the side wall θ, and the Froude number of the incoming flow Fr have significant influences on the coefficient c.

The relationship between the coefficient c and the Froude number of the incoming flow Fr for different deflection angles θ were plotted in Figure 4.

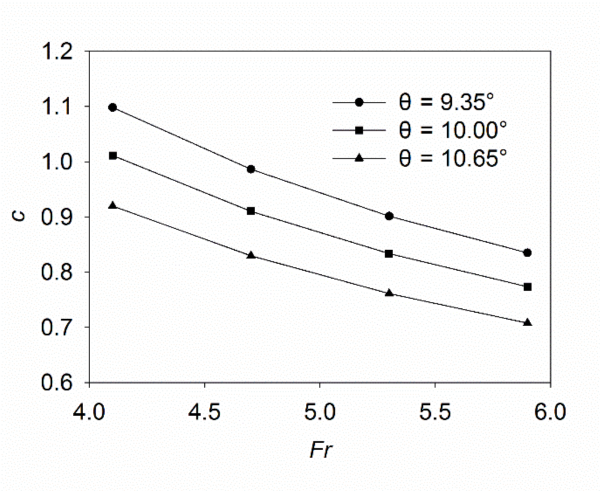

Fig. 4
Relationship between the coefficient c and the Froude number of the incoming flow Fr

According to the results of the least-squares method, c can be calculated as

$$c = \frac{Fr^{0.336} - 0.929}{1.580 - 5.141\theta} \tag{11}$$

As a conclusion, the angle of the shock wave

$$\beta = \theta + \frac{Fr^{0.336} - 0.929}{1.580 - 5.141\theta} \cdot \arcsin\frac{1}{Fr} \tag{12}$$

Eq. (12) is applicable to the STED with the deflection angle $9° \leqslant \theta \leqslant 12°$ and the Froude number of the incoming flow $4.45 \leqslant Fr \leqslant 5.57$. According to the accuracy test, the calculation results obtained with Eq. (12) are accurate enough to calculate the angle of the shock wave, for the maximum relative error is 0.27% and the average relative error is 0.15%, compared with experimental results.

5. WATER WING IMPACT SCOPE ESTIMATION

Caused by the intersection and collision of the shock waves, part of the water detached from the main flow, and formed the direct source of the water wing. Part of the water wing ejected toward downstream direction or feed into the main flow. This would not cause damage to the bank or the buildings downstream and it was called harmless water wing. Another part of the water wing ejected scattering toward downstream at a certain angle and might lead to continuous rainfall shock to the buildings in a certain area downstream, called harmful water wing. Therefore, estimating the scope of the water wing was of great significance.

Coordinate origin O was set at the bottom of the contraction section inlet. The height of the STED bottom from downstream water surface was denoted as z. The shock waves collided at C point, caused the water wing ejected out with a maximum angle α, then fell to downstream on both sides of the main nappe, with a drop point of D. L_{OC} was defined as the longitudinal distance of the shock waves collision point; L_{CD} was the longitudinal distance between C and D; L_M was the longitudinal distance between Point D and the origin; T_M was defined as the transversal distance from the center line. Hence, the scope of the water wing could be estimated from the values of L_M and T_M.

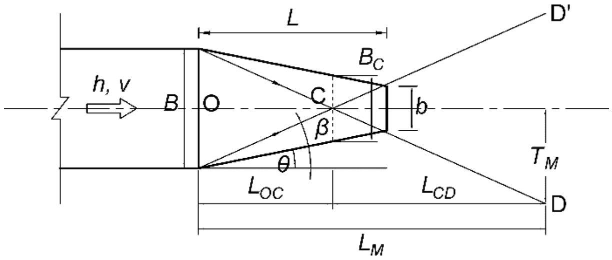

Fig. 5
Sketch of the shock waves and the water wing

According to the geometry relationships,

$$L_{OC} = \frac{B}{2} \cdot cot\beta \tag{13}$$

$$L_M = L_{OC} + L_{CD} \tag{14}$$

$$T_M = L_{CD} \cdot tan\beta \tag{15}$$

The shape of the water wing could be regarded as a trajectory of projectile motion. So L_{CD} could be calculated based on the projectile motion theory.

$$L_{CD} = \frac{v_C \cdot \cos\gamma \cos\beta}{g} \left(\sin\gamma + \sqrt{v_C^2 \cdot \sin^2\gamma \cos^2\beta + 2g\left(z + h_C\right)} \right) \tag{16}$$

Where, v_C, γ, and h_C are the velocity, the angle of departure, and the depth at the shock waves collision point C respectively; g is the gravitational acceleration. Therefore, the value of v_C, h_C, and γ need to be determined.

The value of v_C could be calculated based on Ippen's theory. The velocity after the shock wave was determined by the angle of the shock wave.

$$v_C = v \frac{cos\beta}{cos(\beta - \theta)} \tag{17}$$

Where, v is the velocity of the incoming flow before the shock waves.

The depth at the shock waves collision point could be got from continuity equation,

$$vhB = v_C h_C B_C \tag{18}$$

Where, BC is the width of the contraction section at the shock waves collision point.

Then,

$$h_C = \frac{vhB}{v_C B_C} = \frac{h \cdot cos(\beta - \theta)}{cos\beta(1 - tan\theta \cdot cot\beta)} \tag{19}$$

According to the experimental results (as demonstrated in Figure 6), the water surface along the central line could be approximately expressed as the shape of a parabolic function,

$$y = px^2 + h \tag{20}$$

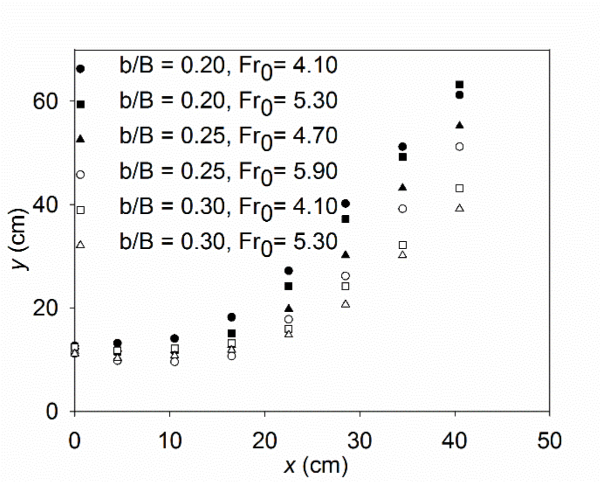

Fig. 6
Water surface along the central line for various conditions

As defined above, the coordinate of the collision point C was (L_{OC} , h_C). So

$$p = \frac{h_C - h}{L_{OC}^{2}} \tag{21}$$

Substituted into Eq. 20, then the parabolic function turned out to be

$$y = \frac{h_C - h}{L_{OC}^{2}} x^2 + h \tag{22}$$

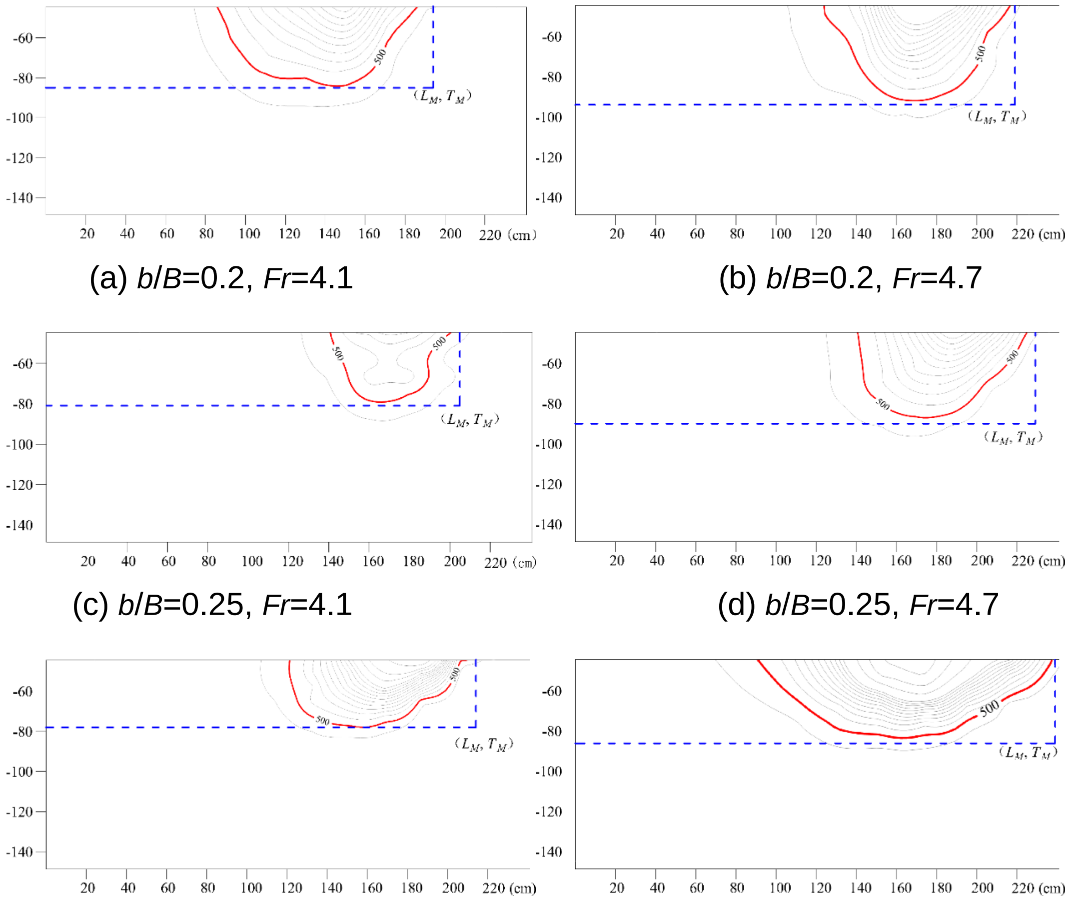
From the derivative of Eq. 22 at C (L_{OC} , h_C), the slope at the collision point was obtained,

$$\tan\gamma = \frac{2(h_C - h)}{L_{OC}} \tag{23}$$

Therefore,

$$\gamma = \arctan\frac{2(h_C - h)}{L_{OC}} \tag{24}$$

To validate Eq. (14), and (15), the calculation results L_M and T_M were compared to the experimentally determined area of the rainfall caused by water wing in Figure 7 under different conditions, as listed in Table 2. Furthermore, due to the difficulty of defining the boundary of the water wing, the typical rainfall intensity contour of 500 mm/h was defined for the analysis of the rainfall intensity rainfall area and its distribution characteristics. Table 2 summarized the calculation errors for water wing areas under different conditions.



(a) b/B=0.2, Fr=4.1 (b) b/B=0.2, Fr=4.7

(c) b/B=0.25, Fr=4.1 (d) b/B=0.25, Fr=4.7

(e) b/B=0.3, Fr=4.1 (f) b/B=0.3, Fr=4.7

Fig. 7
Comparison of the experimental water wing area and the calculation results for various conditions

According to Figure 7, the typical rainfall intensity contour of 500mm/h were just accurately covered by the calculation results L_M and T_M obtained with Eq. (14), and (15). The maximum relative error of L_M is 4.4% and the average relative error of which is 3.0%; the maximum relative error of T_M is 4.7% and the average relative error of which is 2.6%. So they are accurate enough to estimate the area of the water wings.

SUMMARY

Slit-type energy dissipater (STED) as an efficient device to dissipate energy of flow, is widely used in hydraulic projects of high water head, large discharge, and narrow river valley. However, the water wing caused by the shock waves in the contraction section of STED, may bring about harmful effects, which has been hardly attached enough importance. This paper revealed the internal relation of the shock waves and the water wing in STED through physical model experiments and theoretical analysis. Simplified formulas to calculate the shock wave angle and the water wing area were theoretically derived, which were demonstrated to be accurate enough to estimate the scope of the water wings.

1. INTRODUCTION

The Finite Element Method is a good choice for solving wave propagation through bounded and unbounded elatodynamic problems. In the finite element method for unbounded problems such as seismic wave propagation through the soil, a closed boundary must be considered for the foundation so the geometry of the model which has a significant effect on the response changes.

In simplified dynamic analyses of structures, it is normally assumed that the structure is fixed at the ground level and subjected to a base motion [1, 2]. The base motion represents the ground motion anticipated at the proposed site and is influenced by the nature and extent of the soil deposit at the site. In addition, the presence of the structure could also influence this base motion. This mutual influence of the structure and the foundation on their responses is commonly referred to as soil-structure interaction. When the response at the base of the structure is essentially identical to that with no structure present, there is no interaction between the soil and the structure. On the other hand, when the response at the base is significantly different for the two cases, strong interaction exists between the soil and the structure. For cases where the interaction is strong, the soil and structure systems should be analyzed together using a coupled system. For cases where the interaction is insignificant, the soil and structure systems can be uncoupled and each analyzed separately.

Very little work has been done regarding the seismic response of dams on flexible foundations. Most of the research has been directed toward the analysis of dams on rigid foundations.Finn and Khanas [3] also evaluated the response of an earth dam on a flexible foundation using the finite element method of analysis. Their results indicated strong dependence of the response on the ratio of the fundamental periods of the dam and the foundation layer.Finn and Reimerg [4] considered the interaction problem between the dam and the underlying foundation layer. They analyzed both the coupled and the uncoupled dam-foundation systems and showed significant differences in the response depending on the period of the systems compared to the fundamental period of the base input motion.

Chopra et al. [5] by considering dam as an assemblage of two-dimensional finite elements, and the foundation as an elastic half space, determined the dynamic properties of earth dams including foundation interaction effects. Their results indicate that foundation interaction may have significant influence on the frequencies and mode shapes of vibration of earth dams and the influence of foundation interaction depends significantly on the geometry of the earth dam cross-section, being relatively more important for dams with flatter side slopes. Among the geotechnical software, Quad4 and Plaxis can be used to seismic analysis of the dam-foundation model considering foundation-structure interaction. Quad4 is a dynamic, time-domain, equivalent linear two dimensional computer program to evaluate the seismic response of soil structures. Plaxis with dynamic module can be used to model advanced constitutive behaviors for the simulation of the non linear, time dependent and anisotropic behavior of soils and/or rock.

In this study dynamic analysis of Mijaran earth dam (Iran) considering dam-foundation interaction, under Manjil earthquake (after scaling to a_{max} =0.28g), as input motion, carried out by Plaxis. In order to study the effect of the dam height and foundation width in the finite element model, on the calculated earthquake responses, several dam-foundation coupled models have been solved with Plaxis. In addition, dam heights and the foundation width affect on the displacement of the dam. In order to measure displacement of dam, we have used a nonlinear energy operator (NLEO). In this research, NLEO has been defined as a function of both dam heights and the foundation width. We minimize the cost function using PSO algorithm.

Soil-structure interaction (SSI) is an important issue,especially for stiff and massive structures constructed on the relative soft ground, which may alter the dynamic characteristics of the structural response significantly.

Thus, the interaction effects should be accounted for in the dynamic analysis of all soil-structure-system, particularly in severe soil conditions. The SSI system has two characteristic differences from the general structural dynamic system. These are the unbounded nature of the soil and the non-linear characteristics of the soil medium.

The radiation of the energy towards infinity, leading to the so called radiation damping, is the most prominent characteristic in an unbounded soil, which is not relevant in a bounded medium. Various studies and contributions have appeared in the literature regarding the effects of SSI on the dynamic seismic response of buildings (Ben et al.,2000). [6]

This paper is organized as follows: The Mijaran earth dam properties are described in Section 2. Section 3 presents the the numerical modeling for the dynamic analyses. The theoretical foundation of NLEO and PSO have been presented in Section 4. The performanceevaluation of the proposed method are provided in Section 5. Section 6 summarizes our conclusions.

2. METHODS

2.1. DEFINITION OF PROJECT

Mijaran earth dam, which is under construction, is located 20 km north east of Ramsar-Iran. It is constructed on the route of the Nesa River to supply agricultural and drinking water. It’s height is 60 m from the foundation and with crest length of 186 m. Fig. 1 shows typical cross section of the dam-foundation coupled model. The dam site is located in Alborz seismic zone where active periods have been observed. One of the most important earthquakes that occurred in this area, was the 1990 Manjil earthquake, with Mb=7.3 and Ms=7.7.

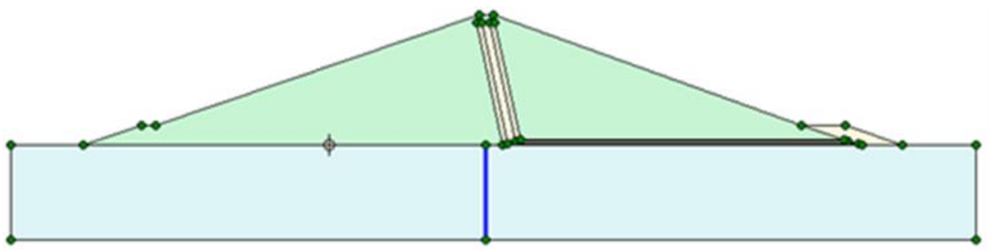

Fig. 1
Typical section of the dam-foundation coupled model

2.2. DYNAMIC ANALYSIS

The numerical modeling for the dynamic analyses has been performed using the Plaxis program, which are based on finite element method. Fig. 2 shows the geometry of the dam-foundation coupled model of the Mijaran earth dam. Dynamic analyses were performed for the end of construction stage using the elasto-plastic Mohr-Coulomb model for material nonlinear behavior. Material properties of dam body and foundation have been presented in Table 1. In order to absorb the increments of stresses on the boundaries caused by dynamic loading, absorbent boundaries has been used. For accurate representation of wave transmitted in the model, the element sizes should be selected small enough to satisfy the following criteria expressed by Kuhlemeyer & Lysmer [7]:

$$\lambda \leq \frac{\Delta l}{10} \qquad [1]$$

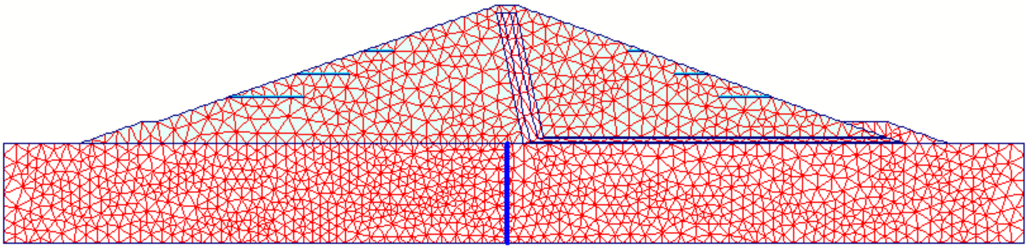

Fig. 2
. model of dam-foundation and its elements

where λ is the wave length associated with the highest frequency component that contains appreciable energy and Δl is the length of element. Considering to these criteria, the element size have been selected as fine as possible.

Table 1
Material properties of the Mijaran earth dam

Type of material	γ (KN/m**3**)	C (KPa)	φ	E (MPa)	υ
Dam body	21.5	27	23	215	0.3
foundation	21.5	1	42	270	0.3
Drain material	20.5	1	42	345	0.25

It should be mentioned that shear modulus, G has been modified according to effective mean stress (σ_0) as

$$G = G_i \sqrt{\frac{\sigma_0}{\sigma_{0i}}}$$

Small viscous damping is added for dam body. This damper was given by Rayleigh damping: the damping factors were assumed 0.005 for the first and second natural periods.
Earthquake response analyses were carried out for Manjil earthquake. The acceleration time histories of the Manjil Earthquake as shown in Fig. 3, were

normalized to a maximum acceleration of *0.28g* which has been considered inaccordance with Maximum Design Level (MDL).

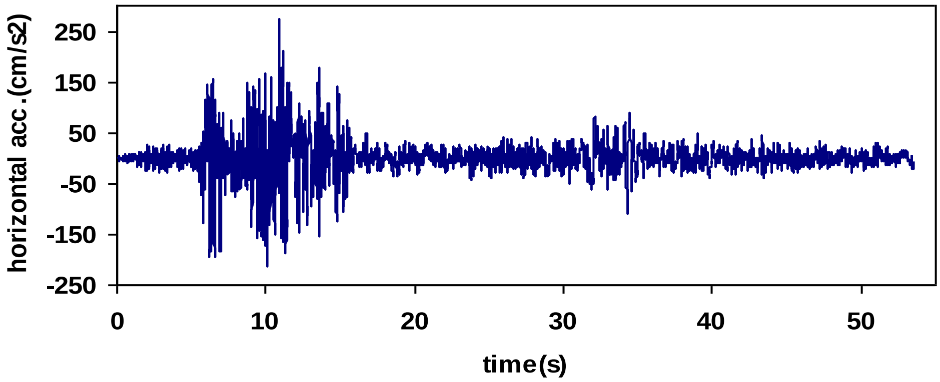

Fig. 3
Normalized horizontal component time history of Manjil earthquake

2.3. NLEO

Teager proposed (as presented in [4]) a simple NonLinear Energy Operator (NLEO) ψ_d given here in its discrete form as

$\psi_{\mathbf{d}}[x(n)] = x^2(n) - x(n-1)\,x(n+1)$

By using simulated signals, Kaiser [4] analyzed this operator and found that it can detect frequency and amplitude of these signals. One of its key properties for a pure tone can be summarized by the rule

$$Q_d(n) = \psi_d[A\,Cos\,(\omega_0\,n+\theta)] = A^2\,Sin^2\,\omega_0 \qquad [3]$$

The proven can be expressed as:

$$Q_d(n) = \psi_d[A\cos(\omega_0 n+\theta)] = A^2\cos^2(\omega_0 n+\theta) - A\cos(\omega_0(n-1)+\theta) *$$

$$A\cos(\omega_0(n+1)+\theta) = \frac{A^2}{2}[1+\cos(2\omega_0 n+2\theta)] - \frac{A^2}{2}\cos(2\omega_0 n+2\theta) - \qquad [4]$$

$$\frac{A^2}{2}\cos(2\omega_0) = \frac{A^2}{2} - \frac{A^2}{2}\cos(2\omega_0) = \frac{A^2}{2}[1-\cos(2\omega_0)], 1-\cos(2\omega_0) = 2\sin^2\omega_0$$

$$\Rightarrow Q_d(n) = \psi_d[A\cos(\omega_0 n+\theta)] = \frac{A^2}{2} * 2\sin^2\omega_0 = A^2\sin^2\omega_0$$

For ω_0 much less than the sampling frequency, $Q_d(n) = A^2\,\omega_0{}^2 = cte$. Therefore, The output of NLEO is proportional to multiplication of instantaneous amplitude and frequency of the input signal.

With the above motivation, Kaiser **[4]** used the second order differential equation governing the simple harmonic motion and the energy (sum of the kinetic and potential energies) required to generate the motion, to introduce a continuous-time counterpart of the NLEO,

$$\psi_C[x(t)] = (x'(t))^2 - x(t)x''(t)$$

The instantaneous energy, E_0, of an undamped oscillator is constant and is proportional to the output of ***(3)*** **[4].**

$$\psi_C[x(t)] = A^2{\omega_0}^2 \quad \propto \quad E_0 = \frac{m}{2}A^2{\omega_0}^2$$

where $x(t) = ACos(\omega_0 t + \theta)$ with $\omega_0 = \sqrt{(k/m)}$ is the displacement of the oscillator and ***k*** is the spring constant and *m* is the mass. Kaiser gave an interpretation of **(4)** as the amount of energy required to generate a sinusoid. Unlike the classical mean-square error *(mse)* definition of energy, this definition depends not only on the amplitude but also on the frequency of the sinusoid. To illustrate this difference, consider two sinusoids with frequencies of 1 Hz and 1 kHz but with the same amplitude. It is clear that *mse* energy will be the same for both sinusoids, while **(4)** suggests different amounts of energy requirement to generate these two signals. The latter relates the energy to the physics of generating a sinusoid of a given frequency ***[5].*** As such, we will refer to the output of the NLEO **(4)** as the frequency weighted energy (FWE).

2.4. PSO

The basic operational principle of the particle swarm is reminiscent of the behavior of a group of a flock of birds or school of fishes or the social behavior of a group of people [8]. Each individual flies in the search space with a velocity which is dynamically adjusted according to its own flying experience and its companions' flying experience, instead of using evolutionary operators to manipulate the individuals like in other evolutionary computational algorithms. Each individual is considered as a volume-less particle (a point) in the N-dimensional search space. At time step t, the *i*th particle is represented as $X_i(t) = (x_{i1}(t), x_{i2}(t), ..., x_{iN}(t))$. The set of positions of *m* particles in a' multidimensional space is identified as $X = \{X_1, ..., X_j, ..., X_{l.}, ..., X_m\}$. The best previous position (the position giving the best fitness value) of the *i*th particle is recorded and represented as $P_i(t) = (p_{i1}, p_{i2}, ..., p_{iN})$ .The index of the best particle among all the particles in the population (global model) is represented by the symbol *g.* The index of the best particle among all the particles in a defined topological neighborhood (local model) is represented by the index subscript *l*. The rate of the position (velocity) for particle *i* at the time step *t* is represented as $V_i(t) = (v_{i1}(t), v_{i2}(t), .. v_{iN}(t))$. The particle variables are manipulated according to the following equation (global model [9]):

$$v_{in}(t) = w_i * v_{in}(t-1) + c_1 * rand1() * \\ (p_{in} - x_{in}(t-1)) + c_2 * rand2() * (p_{gn} - x_{in}(t-1))$$

where *n* is the dimension $(1 \le n \le N)$, c_1 and c_2 are positives constants, $rand1()$ and $rand2()$ are two random functions in the range [0,1], and w is the inertia weight. For the neighborhood (*lbest*) model, the only change is to substitute p_{1n} for p_{gn} in equation for velocity. This equation in the global model is used to calculate a particle's new velocity according to its previous velocity and the distance of its current position from its own best experience *(pbest)* and the group's best experience *(gbest).* The local model calculation is identical, except that the neighborhood's best experience is used instead of the group's best experience.

The constants c_1 and c_2 in above equation represent the weighting of the stochastic acceleration terms that pull each particle toward *pbest* and *gbest* positions. Thus, adjustment of these constants changes the amount of 'tension' in the system. Low values allow particles to roam far from target regions before tugged back, while high values result in abrupt movement toward, or past, target regions.

The inertia weight w controls the impact of the previous histories of velocities on the current velocity, thus influencing the trade-off between global (wide-ranging) and local (nearby) exploration abilities of the 'flying points'. By linearly decreasing the inertia weight from a relatively large value to a small value through the course of the PSO run (total number of generations prior termination), the PSO tends to have more global search ability at the beginning of the run while having more local search ability near the end of the run [10].

3. RESULTS

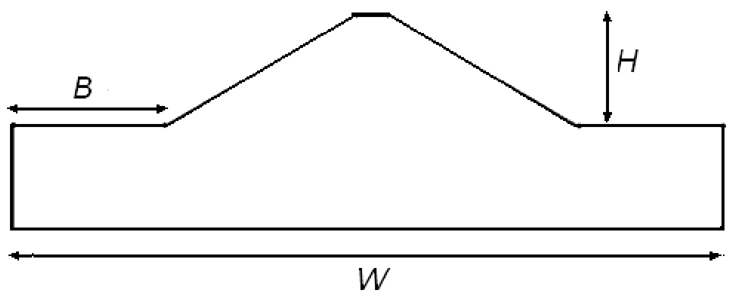
In order to evaluate the effects of dam height (*H*) and width of the foundation (*W*) on the finite element solution, some experiments had been carried out in the finite element model [9] (See Table 2). On the basis of experiments, it had been found that lateral extent must be selected less than twice the dam height in the finite element model. In this work an energy fitness function has been defined so that horizontal displacement time history at the dam crest in the finite element model on the earthquake response be minimized. The fitness function has been considered as a function of *B/H* ratio and we minimize the cost function using PSO algorithm.

In this experiment, the following PSO parameters are used:

Population size: 30; Weight_{max}=1; Weight_{min}=0.4; C1 =C2 =2; Dimension=2; Iteration: 1000. *B* and *H* parameters change between 50-200 and 30-90, respectively. The PSO algorithm were implemented using MATLAB from Math Works. In this experiment, by using the PSO algorithm the *B/H* ratio should be equal to 1.29.

TABLE 2
Desired Dam Heights Lateral Extents And Foundation Width

Model Number	H (m)	B (m)	W (m)
1	30	50	303
2	30	100	403
3	30	200	603
4	60	50	498
5	60	100	598
6	60	200	798
7	90	50	669
8	90	100	769
9	90	200	969



4. CONCLUSION

In this study, dynamic analysis of Mijaran earth dam (Iran) considering dam-foundation coupled model with various foundation widths and dam heights under horizontal component of Manjil earthquake has been performed using the Plaxis program. In the previous work, *B/H* ratio has been adjusted experimentally. But, in this research it has been found optimally using PSO algorithm. Several experiments has been carried out and the results shown the efficiency of the proposed idea.

ABSTRACT

Geotechnical monitoring is an important issue of design, construction and sustainable operation of embankment dams. Two most important categories of geotechnical monitoring by instrumentation are the measurement of pressure and displacement. In many instances of measurement technologies, these two physical parameters help each other to measure a quantity of them. Besides the displacement of soil mass is a source of inconsistent total pressure data. This issue is a challenging matter in geotechnical monitoring of embankment structures, which experience a considerable displacement during construction or consolidation phases.

In case of rotation of a total pressure cell without knowledge of the final inclination, correction of measured values through the theoretical assumptions is either impossible or not completely reliable.

This paper describes an innovative outcome of a project for developing a new measuring instrument, which can solve the above-mentioned problem, increase the reliability of monitoring data and reduce the errors and the costs of instrumentation. The important critical success factor of this measuring system is an optimal mechanical and electrical integration of an inclination sensor and a pressure insert in a tight heavy-duty housing. This type of total pressure cell is capable to measure the inclination in two axes up to 90°.

1. LITERATURE REVIEW

1.1. SOURCE OF ERRORS; HOW CHALLENGING THE MATTER IS?

A total pressure cell installed in the body of an earth-fill, e.g. in the clay core of an embankment dam, must be capable to measure the total stress in a special direction. In many instances, the position of pressure cell changes continuously due to the development of displacements and functionally changes the value of measured pressure. This is the most important reason for the inconsistent total pressure data and uncertainty of monitoring results of embankment structures. This uncertainty can cause some misunderstanding of pressure data and related pressure ratios – such as Arching Ratio - and following mistakes of monitoring.

The rotation of the total pressure cells in the soil material during compaction of an embankment is very likely. Therefore, the analysis of pressure data in an embankment without knowledge of final inclination of the pressure cell is a challenging matter, which sometimes causes resign form installation of total pressure cell.

For reviewing the literature of researches and studies, it would be very helpful starting with the GIN (Geotechnical Instrumentation News) which included an article by Ali Mirghasemi about total pressure cells of Karkheh dam in the 46th episode and subsequently discussions in the next episode. The exchange of ideas mentioned as below about no consistent total pressure data is being still discussed among the manufacturers, geotechnical institutes and consulting companies. The conclusion of Mr. Dunnicliff for this very interesting theme is generally accepted for principle of stress monitoring in embankment dams.

" A total of 102 clusters, each of five earth pressure cells, have been installed to determine the total stresses in the embankment – a total of 510 cells. This number is about half of total number of instruments installed in the dam. No consistent data was achieved from the earth pressure cells. " Ali Asghar Mirghasemi, Assistant Professor, University of Tehran; GIN March 2006 [Ref. 1]

" In summary, measurement of total stress in an embankment is extremely difficult and should not be done unless absolutely necessary and, if necessary, particular care must be given to installation details. " Elmo DiBiagio, Norwegian Geotechnical Institute (NGI); GIN June 2006 [Ref. 2]

" My experiences with free field total pressure cells have also been disappointing and the cost of their installation in the clay core of a dam is not justified, in my opinion. The results are rarely reliable. " P. Erik Mikkelsen, Geoengineering & Instrumentation, Geometron Inc.; GIN June 2006 [Ref. 2]

" My experience is, and that of many authors at ICOLD Congresses and other Conferences seems to be, that it is very difficult to interpret and rely on the readings from earth pressure cells installed in embankment dams, especially rockfill dams. Many investigators have spent time and money installing such cells, but have, in general, found the measurements of little value. There are examples of pressure cells giving valuable readings when the cells are installed on a structural interface, but not inside the dam body. " John Dunnicliff; GIN June 2006 [Ref. 2]

The conclusion of Mr. Dunnicliff, especially mentioning on a solid subsurface, implicates the rotation of total pressure cells as a main source of inconsistent data inside the embankment. Until that time, there were a number of tries to reduce the local initial rotation of total pressure cells, which happens during the earth filling of first layers. However, there are no documented tests attempting to measure the rotation of total pressure cell precise and long-term.

There are wide ranges of studies, which have focused on stress-strain status in embankment projects especially for the verification of monitoring results or numerical back analysis by the instrumentation. These researches have addressed many uncertainties and generally mentioned to the rotation of cells.

As a similar study which has already implicated this inconsistent total pressure data, there is a research on the stress status of Taham dam in Iran. The difference between the numerical modeling and instrumentation data for total normal pressure are shown in figure 1.

Normally if a total pressure cell in an embankment rotates, the measured values are less than vertical stress at the point of measurement. For a better imagination of rotation, two displacement profile of Taham dam, shown in fig. 2, are helpful. In this dam, it is expected to face a rotation of total pressure cells under these large displacement conditions.

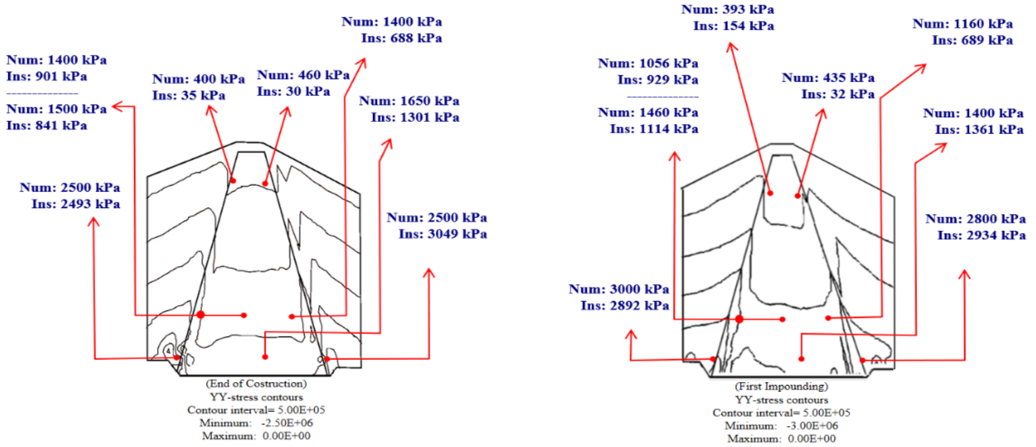

Fig. 1. Total normal pressure before and after impounding of Taham dam reservoir; Numerical analysis: Num. / Total pressure data: Ins. [Ref. 3]

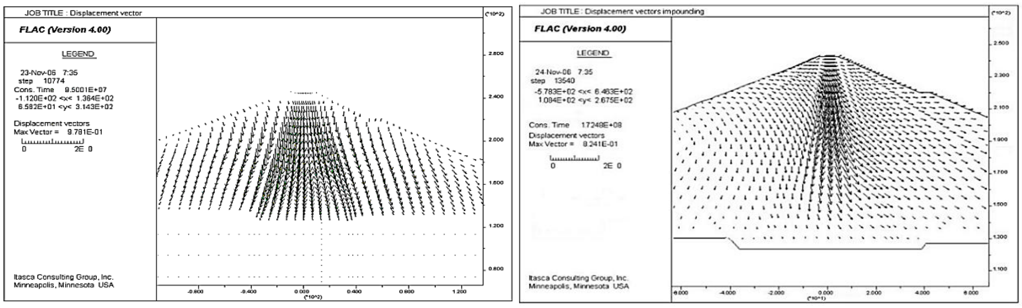

Fig. 2. Numerical Modeling of displacement vectors of Taham dam; [Ref. 3]

As shown in the figure 1, there is a considerable difference between numerical model (Num.) and instrumentation (Ins.). The best compatibility of the pressure data with the calculated values belongs to the lowest level of installation. This level of installation is located in the bottom of the clay core only 30 cm above the roller compacted concrete (Fig. 3). It is very likely that the rotation of total pressure cells in this level is very negligible (remember the conclusion of Mr. Dunnicliff: "the structural interface").

Fig. 3. A) Interface of RCC and clay core; Excavated installation banks [Ref. 3]

There are many discussions about some other technical source of errors, in spite of the rotation, which would be mentioned very briefly. For a better understanding of these technical difficulties, a review of the components of a total pressure cell is unavoidable.

The Total Pressure Cell (TPC) consists of one or two active pressure cushion(s), hydraulic oil tube, and housing for diaphragm-type insert as well as hydraulic/pneumatic compensation valve (Fig. 4). The grooved pressure cushions are expressly mentioned as Active Pressure Cushion (or Pad), which cause a quite uniform deformation of pressure cushion (Fig. 5).

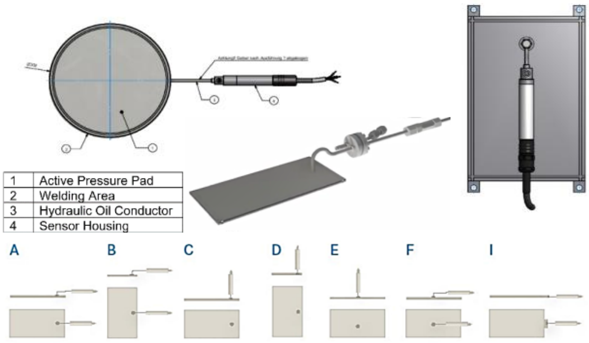

Fig. 4. Total Pressure Cells; Variations of electrical and hydraulic/pneumatic sensor, circular and rectangular, sensor housing connections

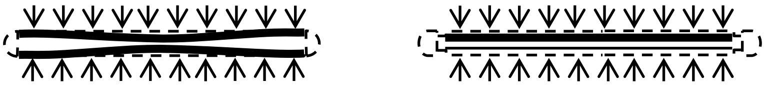

Fig. 5. Deformation of welded edge and grooved edge pressure cushions under uniform pressure in fine soil materials

The unqualified mechanical and electrical components are the prior source of errors and inconsistency of data respectively. Each mechanical component of an instrument as well as electrical components is involved in the final precision.

The assembly of cells and the insert in an appropriate housing are all-over important. A thigh housing with one-tenth millimeter tolerance or a slim housing prone to the deformation can reduce the precision tens of percent. In a similar manner the electrical components are enough sensitive to cause the errors.

1.2. SOURCE OF ERRORS; HOW HELPFUL THE CONVENTIONAL SOLUTIONS ARE?

There are some methods, which try to overcome these uncertainties either by some technical considerations during manufacturing, installation or by some recalculating of measured stress values.

First, some special changes in material and configurations of sensors, e.g. reducing drift and creep effects, the heavy-duty housings for inserts, short length hydraulic oil tubes, circular ventilation oil filling, grooving the loading pads, etc. would be listing as important achievements of manufacturers for overcoming the technological sources of errors (Fig. 6). However, they do not definitely warrant an on-site consistent measurement of total pressure.

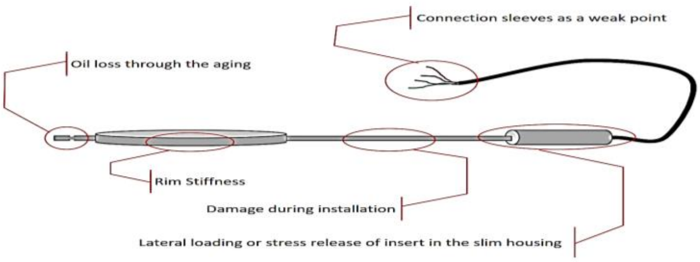

Fig. 6. Total Pressure Cell, Some sources of manufacturing errors

Second, the technical considerations during installation on site for positioning, installation, material filling and compaction don't guarantee in any case a steady fixed direction of installed pressure cells. These methods generally try to make a same compaction conditions around the total pressure cell for preventing local rotation and short-term local arch-action.

On the other hand, the theoretic recalculations are based on many assumptions. There are some methods, which are a combination of both practical and theoretical methods for reducing the negative physical effects and increasing the accuracy of theoretical calculations. These methods have certainly some limitations and disadvantages.

The conventional theoretical solutions, applicable considerations for installation and technological achievements of manufacturers are generally limited to the mechanical aspects of instrument and don't present any solution for overcoming the measuring errors due to the long-term rotation. Consequently, the theoretical, technological and technical solutions for inconsistent pressure date in an embankment under a large displacement conditions are effective for reducing the sources of short-term errors.

It is to be noticed that there is a considerable quantity of embankment structures, especially embankment dams, in which projects the designer has preferred to resign the stress monitoring by total pressure cells. The current technical and academic literatures implicate that this attitude is becoming rapidly as an accepted design method of instrumentation of embankment structures. In that case the only remaining solution for approximating the pressure ratios is evaluating a pressure value by the average density of overburden materials regardless of unequal layer compaction and arching phenomenon.

2. SOLUTIONS

2.1. CONVENTIONAL SOLUTIONS; CLUSTER CELLS WITHOUT EXCAVATION OF AN INSTALLATION BANK

The non-uniform compaction of installation area causes a short-term local arching and additional rotation on pressure cells. The most known practical method for overcoming this rotation is embedding the cell by spreading soil without excavation an installation bank. The compaction of soil in the bank by using a lightweight roller results lower stiffness at the embedded sections than surrounding fill.

In case of embedding the cell without excavation, using heavy machines for compaction of first soil spreading is possible (Fig. 7). The installation of total pressure cell in the large embankment projects through this method for overcoming the short-term local arching and initial rotation is quite accepted everywhere. However, these phenomena can cause an inconsistent pressure data during the filling of first overburden layers, which is negligible compared to the full-scale pressure and displacement. It would be very careless to account the short-term non-uniform compaction, which would be adjusted during the construction time for long-term source of error.

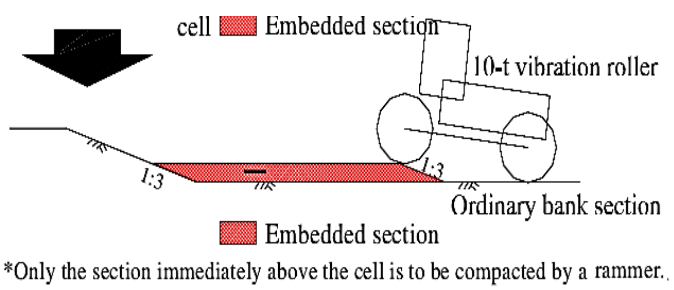

Fig. 7. Embedding cell by spreading soil; Minamiaiki dam (Ref. 4)

As a combination of practical and theoretical method, the installation of a cluster of cells makes the recalculation of the rotation possible. In this method, the pressure cells are installed with maximum possible compaction ratio and minimum disturbance of surrounding fill in a cluster form up to five directions. In figure 8, the arrangement of embedded total pressure cells in a cluster of five cells is shown.

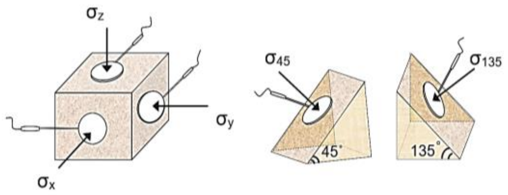

Fig. 8. The angles of embedded total pressure cells in a cluster of five cells.

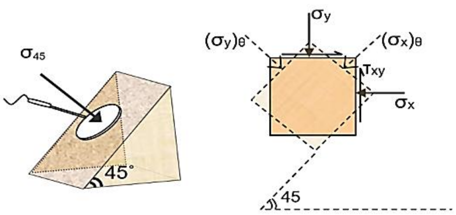
Since the total pressure cells in one cluster are close enough to each other and adjust equally with the soil mass deformation quite all of them, an equal change of installation angle – the rotation - of whole pressure cells is expectable. Therefore, they can be considered as stresses in different directions for a single point in the embankment. The evaluation of stress ratio (normal stress to lateral stress; σ_{max} and σ_{min}) and the angel of pressure cushions (θ) is possible by theoretic recalculating of pressure data. For this reason, the Plain Strain formulation of strength of materials is used (fig. 9).



$$\sigma_1 = \sigma_{max} = \frac{\sigma_x+\sigma_y}{2} + \sqrt{\left(\frac{\sigma_x-\sigma_y}{2}\right)^2 + \tau^2_{xy}}$$

$$\sigma_3 = \sigma_{min} = \frac{\sigma_x+\sigma_y}{2} - \sqrt{\left(\frac{\sigma_x-\sigma_y}{2}\right)^2 + \tau^2_{xy}}$$

$$(\sigma_x)_\theta = \sigma_x \cos^2\theta + \sigma_y \sin^2\theta + 2\,\tau_{xy} \sin\theta \cos\theta$$

$$(\sigma_y)_\theta = \sigma_x \sin^2\theta + \sigma_y \cos^2\theta - 2\,\tau_{xy} \sin\theta \cos\theta$$

Fig. 9. The normal stresses on the rotated element recorded by the cell embedded 45°

With knowledge of stress ratios form the installed pressure cells and using the pole method of Mohr circle, finding the direction of pressure cushion is possible. Any straight line drawn from the pole will intersect the Mohr circle at a point that represents the state of stress on a plane inclined at the same orientation (parallel) in space as that line (figure 10).

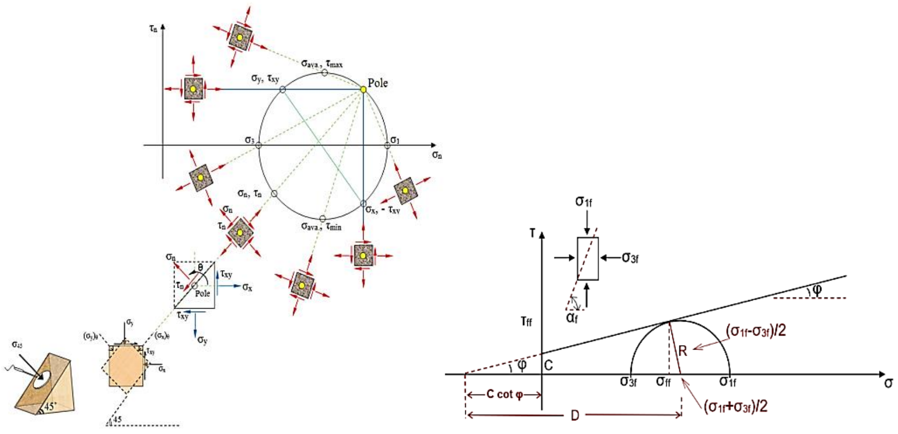


Fig. 10. Mohr circle and Mohr-Coulomb failure envelope for a cohesive soil; Mohr's circle for plane stress and plane strain conditions

2.2. THE EFFECTIVE SOLUTION; MEASURING THE INCLINATION OF PRESSURE PAD

The idea behind the new instrument for measuring the rotation of total pressure cells was very simple. However, there were many limitations to develop this simple idea. One of these limitations, which play a big role in the final product, is the geometry of instrument. The first comment for this idea was to combine a total pressure cell with a building inclinometer (fig. 11). In spite of that the selected inclination sensor for the first idea is very accurate, but the geometry of the product was not appropriate for installation in an embankment.

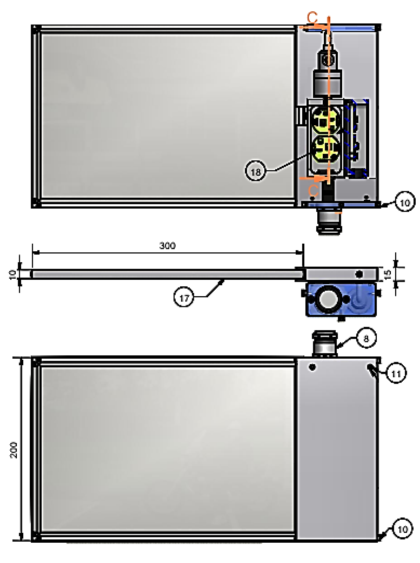

Fig. 11. The first idea for combination of pressure cell with biaxial inclinometer

The final comment on the idea was an integrated on-board sensor in the available standard heavy-duty housing of pressure insert. The standard available Glötzl heavy-duty housing and its mechanical components present an optimum ratio with active pressure pad. Therefore, the maximum dimensions of the electronic board were limited to 44x14 mm (LxW). The sensor which should be printed on the board can only place in a half-round space with maximum 3,5 mm height (fig. 12).

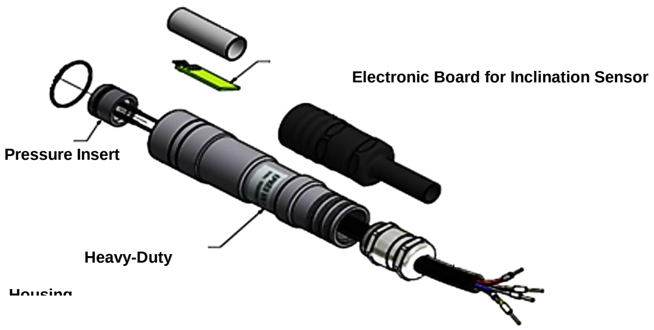

Fig. 12. Integrating an on-board inclination sensor in the standard Glötzl heavy-duty housing

Thank the rapid rise of electronic technologies, there are numerous types of reduced size inclination sensors available on the market. To make a decision for selecting an appropriate precise sensor, which is convenient for a thin electronic board, the significant approaches were dimension of sensor, precision and reproducibility, long-term stability, mechanical shock capacity, temperature sensitivity and price of final product.

The last factor is very decisive. The final price of this product depending on the precision of the sensor should not be expensive and possibly limited to the reasonable value of 30 percent of total pressure cell. On the other hand, the reasonable precision for measuring the rotation of a total pressure cells in an embankment dam are considerably less than a building inclinometer. Therefore, between wide ranges of sensors the MEMS-Sensor appears to be appropriate for the reason. The technical specifications of selected biaxial sensor are as follows.

- Measuring range: ± 30° and ± 90°
- Measuring accuracy and Resolution: 1 mm / m and 0.06 mm/m
- Mechanical drop shock: 1 m onto a concrete surface
- Temperature operating range / sensitivity: -40°…+125° / 0.01 % /°C

The next step for actualizing the idea was data measurement with available hand-held readout units. The output signals of the selected sensor are measured in two axes by Glötzl NMA09 and converted to the sinus values (fig. 13).

Two most important advantages of this development are sealing and dimensions. The dimensions are limited to the above-mentioned size and could be assembled in whole measuring instruments which include the housing. For example, the settlement gauges, load cells and borehole camera modules. For this reason, it is important to fix the housing with special brackets for preventing any waggle effect.

Fig. 13. Glötzl hand-held readout unit for inclination sensors connected to the MEMS

Since the total pressure cells in a cluster of cells are close to each other, it is enough to equip a total pressure cell with the inclination sensor and making it as reference instrument. For this reason, the total pressure cells equipped with biaxial inclinometer are characterized as Reference Pressure Cell (RPC).

As already mentioned there is no limitation for integrating a biaxial inclination sensor in the housing of whole pressure sensors. Therefore, Glötzl GmbH has developed a new generation of settlement gauges and load cells which are capable to measure the inclination. This possibility helps the engineers to achieve a better understanding of stress status and load distributions in the structures.

SUMMARY

The installation of reference pressure cells in an embankment enables the engineers to recalculate the normal pressure and verified pressure ratios.

Glötzl GmbH has achieved the success by focusing on mechanical and electrical components of a total pressure cell and trying to find an optimal solution for measuring the rotation of total pressure cells. A Reference Pressure-, Load- or Settlement Cell could be used in various type of projects which need to measure the pressure and the displacement.

An accurate measurement of rotation of total pressure cells installed in an embankment is a grate possibility for geotechnical monitoring for overcoming the uncertainties of stress monitoring. The arching (Ar.) and pore water pressure ratio

(Ru) are the critical relationships which are calculated through the knowledge of normal total pressure. It is possible if the rotation of total pressure cell is clear.

1. INTRODUCTION

The performance assessment of embankment dams in respect to main deterioration mechanisms is the major challenge for managers in charge of their security. However, the risk score of dams in Indonesia is moderate until high risk because rarely equipped monitoring instrument and vegetation are often present. To cope with them, the dam owners/managers have first to identify the specific status indicator linked with vegetation and behavior dam based on monitoring instrument.

There was a common belief among communities when damage to embankment dams and dam safety issues associated with tree and woody vegetation penetrations of embankment dams happened, people often immediately assumed that it happened due to lack of maintenance by the dam owners, dam safety regulator and engineers. However, during the Research Needs Workshop on Plant and Animal Impacts on Earthen Dams, a collaboration event between the Federal Emergency Management Agency (FEMA) and the Association of State Dam Safety Officials (ASDSO) in November 1999, they highlighted the realization that damage to earthen dams resulting from plant and animal penetrations was indeed a significant dam safety issue.

Tree and woody vegetation penetrations of earthen dams have been demonstrated to be the causes of serious structural deterioration and distress that can result in failure of earthen dams (FEMA 2005). The workshop itself brought together technical resources of dam owners, engineers, state and federal regulators, wildlife managers, foresters, and members of academia with expertise in their areas. They agreed that trees and woody vegetation should be removed because they can delay safety inspections also interfere with safe operation, or even leads to dam failure. Until this day, the engineers and dam safety experts were still debating on what kind of method should be used to prevent or control tree growth efficiently. However, they all are agreed that a healthy, dense stand of low-growing grass on earthen dams is a desirable condition and should be encouraged. Therefore removal of trees and other woody vegetation in the embankment area is required.

On the other hand, this removal (of trees and other woody vegetation) action will raise the social issue in communities. Dam safety regulators and inspectors, engineers, and consultants soon will be confronted with the grassroots resistance. This resistance is often associated with sentimental, cultural, ecological, legal, and financial issues. A fundamental understanding, technical knowledge and proper assessment of potential detrimental impacts of trees and woody vegetation growth on the safety of embankment dams are necessary to address these issues.

2. PROBLEM CAUSED BY TREE AND WOODY VEGETATION IN THE EMBANKMENT AREA

Trees and woody vegetation are considered dangerous to grow in the embankment area. The problems caused by tree and woody vegetation growth are: uprooted trees that produce large voids and reduced freeboard; reduced the maintaining stability, the decaying roots create seepage paths and internal erosion problems, interfering the dam safety monitoring, inspection and maintenance for seepage, cracking, sinkholes, slumping, settlement, deflection, and other signs of stress. There is also another problem related to safety dam, they are: hindering desirable vegetative cover and causing embankment erosion, obstructing emergency spillway capacity, clogging embankment underdrain systems, cracking, uplifting or displacing concrete structures and other facilities, inducing local turbulence and scouring around trees in emergency spillways and during overtopping, providing cover for burrowing animals, loosening compacted soil, allowing roots to wedge into open joints and cracks in foundation rock along abutment groins and toe of embankment, which leads increasing piping and leakage potential.

Many misconceptions and common myths regarding trees and woody vegetation spread and have been accepted by many people without any scientific explanation. These myths and misconceptions relative to plant physiology have originated from old, traditional and uneducated interpretations of observations associated with tree growth and tree root development. Not all myths are wrong, however, if we relate with the growth of trees and woody vegetation in embankment area, some of these myths need to be dispelled so that a new level of understanding about the impacts of trees and woody vegetation on earthen dams can be properly developed.

The root systems consist of two primary components that are the root ball and the lateral transport root system. Tree and woody vegetation roots have a primary function of providing oxygen, nutrients, and water to the plant, they also provide stability for the plant. The root ball which is typically directly below the trunk of the tree provides vertical support while the lateral transport roots provide lateral support for the tree. The root systems that were growing on dam embankment slopes will typically be asymmetrical because of the need for the tree to be stabilized in the sloping embankment soil mass. The lateral transport roots will typically be better developed on the uphill side of the tree than on the downhill side of the tree. Dr Kim D. Coder at the University of Georgia conducted many extensive studies and research on tree growth and tree root development requirements and characteristics. He developed data from these studies and research programs that relate tree trunk size to root ball diameter and lateral transport root system diameter. To relate the research data from Dr Coder, the author compiled a comparative list of soil properties for various soils that have been found in earthen dam embankments. The ranges given in the data presented in Table 1 below are associated with soil in a loose condition and soil in a compacted state that might be required in the construction or remediation of an earthen dam.

Table 1. Summary of typical soil parameter

Soil Type	Specific Gravity	Void Ratio	Porosity (%)	Dry Density, pcf	Permeability, cm/sec
Sand	2.62 to 2.66	0.40 to 0.90	30 to 45	90 to 115	0.01 to 0.0001
Silt	2.60 to 2.68	0.50 to 1.20	35 to 55	75 to 110	0.001 to 0.00001
Clay	2.66 to 2.72	0.60 to 1.40	40 to 60	70 to 105	0.0001 to 0.0000001

Source: FEMA 534, 2005

As shown in the tabulated summary of typical soil parameters, the continual tree root development cannot occur in soils that are well compacted. One of the best methods of controlling tree and woody vegetation growth on new earthen dams and existing earthen dams where remediation requires placement of additional embankment fill soil is to compact the embankment fill soils to a high stage of compaction. Increased compaction of embankment fill soils reduces the air void content and limits the quantity of surface water that can infiltrate into the embankment slope. However, a good ground cover of grasses can be established in well-compacted soils since the depth of grass root penetration is minimal and the surficial soils will typically sustain the shallow grass root penetration.

The initiation of the tree and woody vegetation development on the downstream slope starts soil moisture uptake cycle with the goal that the line of immersion and the leakage line may never totally develop and intercept the downstream slope. In any case, one must comprehend that as the tree and woody vegetation development proceeds compacted soils of the dam embankment are relaxed continuously by the penetration of major tree and woody vegetation roots. Besides, trees that might seem healthy to an untrained inspector might be an unhealthy sample and have a premature death leaving penetrating root frameworks to rot inside the dam embankment. Moreover, soil supplements in the compacted soil embankment of an earthen dam may not be adequate for improvement of growth beyond which the tree can't be properly maintained without premature death. Notwithstanding the reason, trees and woody vegetation do die and stop to take-up soil moisture that they previously used. This change in soil moisture uptake will influence the zone of air circulation, the zone of saturation, and the area of the leakage line (seepage) near the dead trees and woody vegetation.

When an earthen dam embankment impregnated with many trees and woody vegetation penetrations, routine and even major maintenance activities will likely not be enough to regain the original design lifespan of the dam. At this time in the life of an earthen dam, previously identifiable maintenance problem has become serious dam performance and dam safety issues. Restoration through an engineered dam remediation design and remediation construction is typically required to bring the dam to acceptable standards congener to dam safety requirements. Figure 1 illustrates some of the problems and dam safety issues which can be created by a non-maintained tree and woody vegetation growth in what has been termed by the author as the 'Mid-Life Crisis' of an earthen dam.

Seepage flow might rise out of root ball holes of blowdowns (uprooted trees) since they are no longer using soil moisture and the seepage line has adjusted upward toward the surface of the slope. Expulsion of developing trees by woodcutters decreases the soil moisture take-up of the removed trees along these lines additionally adjusting the area of the seepage line closer to the downstream slope. Root balls and root systems of trees situated at and past the toe of the downstream bank slope end up immersed by the balanced seepage line. Since trees cannot survive through prolonged submergence of their significant root systems, these trees will end up unhealthy and die to leave decaying root balls and root systems as serious penetrations in the earthen dam. Root ball pits staying from blowdowns (uprooted trees), and their relationship to the seepage line create conditions worse to potential slope failure of the embankment dam. Restoring the earthen dam showed in Fig. 1 to a protected condition cannot be brought through periodic maintenance.

3. ASSESSING THE PERFORMANCE OF AN EMBANKMENT DAM

Evaluating the performance of an embankment dam consists in looking for and assessing all the weakness factors which contribute to the damage. It allows appreciating, at a given moment, the fitness of a hydraulic structure to fulfil the functions for which it was designed and so its level of safety. This assessment will help managers and owners to take the best decisions for carrying out the required maintenance works to secure the safety of their structures. Thus, the managers responsible for the safety of dams' demand methods and tools that they can use to perform detailed diagnostics of their structures then assess their status and performance.

The Authors choose to use knowledge-based systems in this paper due to their interest in performance assessment, especially for complex systems such as dams, as they can reproduce the reasoning of an expert and consider data of various origins and types (visual observations, design-visualisation data, monitoring data, resulting from models). The works cited above focused on the case of dams (i) equipped with monitoring instruments providing the information required to assess their performance with respect to deterioration mechanisms such as internal erosion; (ii) equipped with a drainage system, one of the components ensuring the safety of these structures. However, certain dams such as embankment dams have specific characteristics on which we intend to focus on.

In this paper, the Authors use the models of Curt et al. (2010) and Curt (2013) which are adapted to assess the performance of embankment dams equipped with drainage systems and monitoring instruments for both the "embankment" part and the foundation of the structure, as our basis. This approach analyzes the models to perform until they reached their limits in comparison with the application, then propose modifications and adaptations to take these limits into account. Figure 1 shows the hierarchical model for assessing the performance of an embankment dam with respect to deterioration by internal erosion (Curt et al., 2010), and the limits of this model.

These assessment models have a three-level hierarchical structure: (i) status indicators; these are the input data of the model; (ii) the performance of functions; and (iii) the performance of the component regarding the internal erosion mechanism. The status indicators are formalized data. Different data are used by the engineer to perform an assessment: monitoring data if the dam is equipped with instruments, visual observations, design and construction data and calculation data. It is important to formalize them, to obtain the robust measurement, repeatable and reproducible, however, it is also great to use them in combination. Therefore, a formalization grid is used, based on: the name of the status indicator, its definition, the scale of measurement and the associated references giving the anchoring points on the scale and which allow describing the different possible statuses of the indicator, the spatial characteristics specifying the part of the dam to be analyzed and the temporal characteristics indicating the time step for measuring the indicator and the analysis of the trend presented by this measure (Curt et al., 2010).

The paper proposes using a second assessment scale for all the indicators: an ordinal scale characterized by the ordering of categories as a function of an intensity criterion linked to a scale of intervals that allows working on continuous numerical magnitudes (Fig. 2).

Fig. 2 Scale of the double assessment chosen for assessing the performance of dams

To build our model, we conserve this general structure according to three levels:

- status indicator,
- performance of functions and
- the performance of the component.

The limits of these existing models with respect to the dams dealt with happened because they were developed for embankment dams equipped with drainage systems and monitoring devices. This observation leads us to propose three changes. As shown in Fig. 3, the performance of the embankment of a dam regarding the mechanism of deterioration by internal erosion is evaluated using three function performances: the sealing function, the drainage function and the self-filtration function.

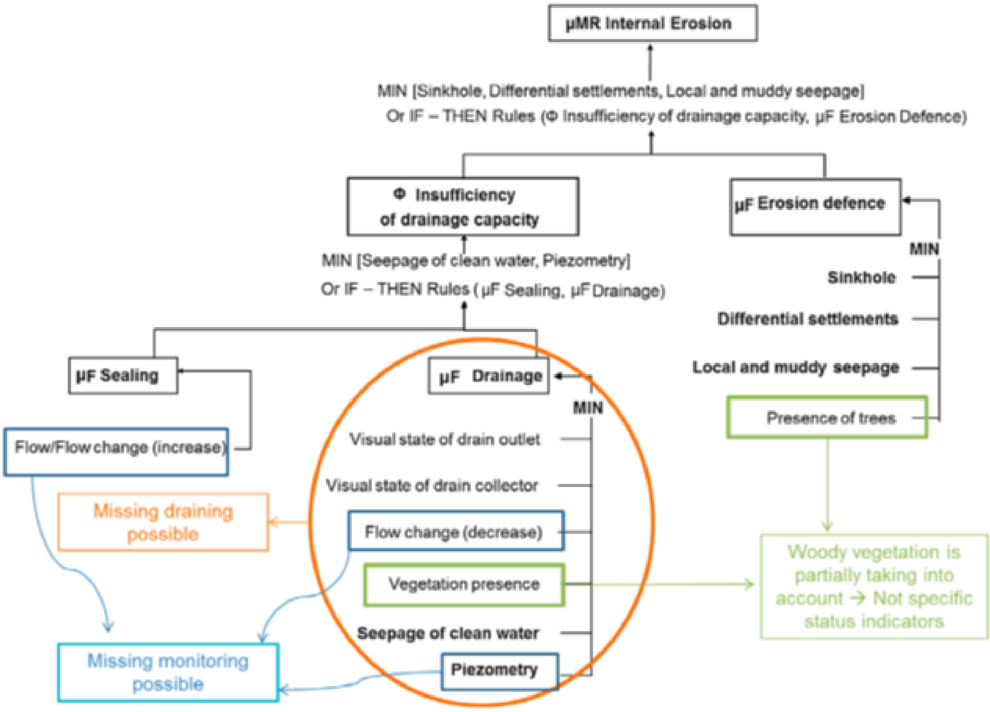

Fig.3 Hierarchical model for assessing an embankment dam built using homogenous fill equipped with a drain and monitoring instruments [μ = performance; Φ = phenomenon] (Bambara et al., 2016)

The performance of the drainage function cannot be evaluated if the structure is not equipped with a drainage system. The structure of the model must be changed to offset this problem. Each of the performances is evaluated based on status indicators stemming in part from monitoring data: “increased flow rate”, “piezometer”, etc. However, this type of information is not readily available for the certain structures we wish to study, thus the aim is to propose other information possibly available to experts, notably design and construction data. In addition, the small embankment dams studied here are often, or have been, subject to a lack of maintenance that has led to abundant woody vegetation on or at the edges of the embankments. The existing models consider woody vegetation only for assessing the performance of the drainage function and the self-filtration function using a single status indicator termed “presence of woody vegetation”. Indeed, they consider only the assessment of the performance of embankment dams regarding the mechanism of deterioration by internal erosion by suffusion. It is important to characterize this vegetation in greater detail by developing specific status indicators that allow assessing the potential for internal erosion of an earth fill hydraulic structure due to the state of the woody vegetation present on the dam (level of decomposition of root systems of dead trees, etc.). Furthermore, the presence of vegetation leads to another improvement to the models: the components assessed are, as for the existing models, however, the embankment–foundation interface must be considered specifically in the case of a dam that has no drainage system, as this can be a preferential location for the installation of woody roots.

The following steps are aimed at proposing methods to respond to these three main constraints: possible absence of a drainage system, possible absence of monitoring data and presence of woody vegetation.

For specific indicator, we used the safety assessment techniques (Functional Analysis – FA – and Failure Mode and Effects Analysis – FMEA) to identify the indicators specific to woody vegetation by focusing on the external element "woody vegetation". The FA is carried out in two steps. An external FA makes it possible, initially, to identify the function(s) that the structure must have regarding external constraints, in this case woody vegetation. An internal FA is then performed. It leads to the identification of different functions resulting from the relations between each component of the structure and the external environment.

Following the FA, an FMEA is used to identify the failure modes, their effects and possible causes for each component, and the indicators of the causes and effects of the failures of the different components. This inductive method systematically considers each component of the structure, one after the other. In our case, the failure mode considered is internal erosion linked to the presence of vegetation. The experts use the formalizations on examples of real cases and express their agreement/disagreement regarding the formalizations. The indicators are modified if necessary. The starting point comprises the indicators listed in the FMEA tables. The objective of the sessions is to describe these indicators to ensure their robustness for application. However, it is difficult to assess certain status indicators when there are no known instrumental methods and if visual observation is impossible, since the element to be assessed is inaccessible, as is the case of the status indicator "Degree of decomposition of the woody stump or roots of an individual1". Thus, an indirect chemical measure by NIRS (Near Infrared Spectrometry) has been developed (Bambara et al., 2013) and a formalization for this indicator based on the results of the chemical measurement proposed.

4. IDENTIFICATION, FORMALIZATION AND AGGREGATION OF STATUS INDICATORS SPECIFIC TO WOODY VEGETATION

The specific status indicators were identified to assess the performance of embankment dams. These status indicators were identified using an FMEA. Table 2 is the identification of specific indicators for woody vegetation. For the assessment of the sealing function ("Type of root structure of individuals") and one in the assessment of the drainage function ("Visual condition of the environment of the drainage blanket outlet"). In Table 2, present the formalization grid for assessing the indicator "Diameter of tree trunk from" with the scoring scale of Figure 2. Knowing that diameter of tree trunk is depend of root systems grow as a tree ages, an individual with a stump having a large diameter leads to assuming a tap root system. Thus, the indicator "tree trunk diameter per individual" transposes the measure of the taproot diameter. It is important to know this parameter to predict the impact in terms of the global increase in dam permeability during root system.

The status indicator “Diameter of tree trunk of individuals” provides a global root characterization next to the profile analyzed. Indeed, the different types of root structure of individuals can act on the internal erosion mechanism to varying degrees during woody root. Thus, individuals with a long horizontal type root structure with the potential for crossing the embankment dam from downstream to upstream would be particularly serious. The taproot would likely form a pipe through the embankment (depends on the material), hence the importance of having an assessment of the status indicator “Degree of decomposition of the taproot or woody roots of an individual”. The status indicator “Visual condition of the environment of the drainage blanket outlet” is appreciated by the “Tree trunk of individuals” present at the outlet of the drainage blanket. Thus, it has the same references as the status indicator “Diameter of individuals”. The status indicators specific to woody vegetation are aggregated according to functional logic. Their successive combinations permit obtaining the propensity to flows within the embankment dam due to the presence of vegetation (Figure 4). This “block” will be used for assessing the performance of the function. The summary of methodology for building embankment dam performance assessment models is shown Fig.5.

		Performance of diameter tree trunk										
		0	1	2	3	4	5	6	7	8	9	10
Performance of internal erosion	0	0	0	0	0	0	1	2	2	8	9	10
	1	0	1	1	2	2	2	3	3	8	9	10

5. CASE STUDY

The study area is the biggest dam in Indonesia, named Juanda dam at Jatiluhur. The location is100 kilometers east of the city of Jakarta, Indonesia. The Juanda dam is a multipurpose dam, it is a rockfill-type dam with inclined clay core, and it height is 96 meters. The total storage reservoir capacity of more than 2.5 billion cubic meters and crest length is 1220 meters. It was constructed during the period of 1957 - 1967. The operation of Juanda (Jatiluhur) multipurpose dam was firstly managed by the Jatiluhur Development Project under the Department of Public Works and Electric Power up to the year of 1970 and since then the dam has been operated under the management of Jasa Tirta II Public Corporation.

Based on the results of the latest visual inspection, on the downstream slope of Juanda Dam is not found any hard trees. The downstream part of the dam body is covered by grass as a protector from rain water splashing, also serves as an indicator when there is a wet area on the downstream slope. In Fig. 6 looks a hard tree, all of which is in the original land, and there is no visible hard tree growing on the dam body (embankment).

1. BACKGROUND

Since the late 1990's in the U.S.A. there has been a technological revolution in rock fissure grouting practices, primarily as a result of the technical and dam safety challenges which have typified the dam remediation market. This revolution has been well documented in numerous papers at the New Orleans Grouting Conferences [1] [2], at the Honolulu Grouting Conference [3], in USSD publications and conferences, and in more recent textbooks [4] [5]. Final confirmation is provided in the USACE's new Grouting Manual [6], which is a radical overhaul of the prior version (1984).

An observer of the huge remedial grouting projects at Mississinewa, IN, Clearwater, MO, Center Hill, TN, Boone Dam, TN, East Branch Dam, PA, and Wolf Creek, KY as examples, cannot fail to note the sophistication (and the curious similarities) of the means, methods and materials each contractor has used. It is equally clear that owners and designers are now producing specifications that consistently reflect modern practices, instead of recycling contract documents ("boiler plate") that are inconsistent and awkward amalga of the old and the new.

The authors are involved in different contractual and oversight roles in a large number of remedial grouting projects for dams. We have noted over the

* INJECTION RÉPARATEUR DES FONDATONS DE BARRRAGES EN REMBLAI EXISTANTES: LEÇONS APPRISES (ET IGNORÉES)

last few years that certain “lessons learned” during the revolution have not been fully or correctly applied, or have indeed been ignored. If left unchecked, these regressions will have the effect of reducing the quality and reliability of the finished product, and will increase the prospects of contractual disputes.

The following topics focus on practical issues associated with the execution of the works, and so exclude reference to design-related issues such as the number and spacing of grout lines; drill hole spacing and orientation; upstage versus downstage; or grouting control principles.

2. LESSONS LEARNED

2.1. DRILLING TECHNIQUES FOR OVERBURDEN AND ROCK

Most remedial grouting projects will involve drilling and casing through overburden and/or embankment fill so that standpipes can be placed to permit safe access to the rock drilling activities therebelow. In essence, neither compressed air nor water is considered acceptable for fear of compromising the integrity or safety of the embankment [7]. This explains the widespread use of the rotary vibratory method (“sonic drilling”) and dry, double-head duplex, wherein an inner auger is advanced simultaneously with the outer casing. In both cases, minimal amounts of water are introduced to facilitate progress. Every care should be taken to prevent “cleaning water” used on the working platform from escaping down and around the casing (or standpipe once it has been installed).

It is one of the oldest debates in the drilling and grouting industry: percussion versus rotary methods and air flush versus water flush. Past practice has been dictated by the capabilities of the drilling industry: given that air flush is not permissible for rock fissure grouting, or when drilling in karstic limestone formations under existing embankments, much traditional work was done by rotary drilling, either coring or “blind,” using water flush.

Rotary percussion drilling, especially of the Down-the-Hole (DTH) variety, has distinct advantages over rotary drilling in terms of speed and deviation control, but was always synonymous with the use of air flush. The practice of some contractors to “mist” the air with water is totally misguided, as this actually reduces the chances of drilling a clean hole, not improves them. The best of all worlds arrived in 1995 in the form of the water activated (and flushed) DTH (WDTH) [8]. This tool has been the staple of the better resourced grouting contractors since it was first successfully demonstrated at the McCook Quarry Trial (Chicago, IL) in 2001 and consistently provides high quality holes for grouting.

2.2. DESIGN AND TESTING OF GROUT MIXES

One of the major changes in rock grouting technology in recent years has been the increased level of understanding, and almost universal application of multi-component, balanced, stable grouts. Gone, thankfully, are the days of highly unstable, high water content “neat” mixes wherein the only concession to sophistication would be the (unnecessary) addition of superplasticizer and/or a handful of dry bentonite. The dynamic stability of a particulate grout (“pressure filtration coefficient”) is a fundamental control over its ability to penetrate fissures, and is at least equally as important as its grain size and apparent viscosity. Thus, contemporary HMG’s (“High Mobility Grouts”) can be regarded as “high performance” in that they maximize the injection potential value from every grout hole, instead of simply prematurely clogging up the fissures a very short, and uneconomic distance from the borehole wall.

Acceptable grouts should have minimal bleed (< 2%,), and low pressure filtration coefficient (a value of 0.06 min-1/2 is suitable for most cases). Reflecting current “Apparent Lugeon Theory” practice for controlling injection, dominant now in N. America, these grouts can be manufactured in the field to provide mixes with discrete Marsh Cone ranges, e.g., 35; 45; 60 seconds; and infinite. Bear in mind that Marsh Cone readings over about 60 seconds are imprecise measurements, and other measures such as a Flow Cone or Shear Vane might be required, especially for the “closer” mix. The Baroid Mud Balance, for measuring grout specific gravity, and hence checking water:cement ratio, is a particularly simple, cheap and accurate tool, and stands in sharp contrast to the systematic use of grout cubes as a QC/QA tool: practically useless in rock fissure grouting applications. The true goals of a remedial grouting program should be permeability and seepage reduction, and not production of the highest strength grout cubes possible.

2.3. PLACEMENT AND SEALING OF STANDPIPES AND MPSP’S

This is a process the quality of which is frequently overlooked, even though it is absolutely fundamental to the safe grouting of existing embankment dam foundations.

The USACE Engineering Regulation [7] provides significant discussion on the potential for hydraulic fracturing while backfilling drill holes through embankments. This has led, in some quarters, to the development of specification provisions that require that grouting of standpipes installed through an embankment be performed in stages. A concern over hydraulic fracturing has also led to specifications that require water testing and grouting be performed under very low pressures or under gravity head. The following is a quote from the current version of the Regulation.

“For borings that penetrate zones with low confining stress it is possible to induce hydraulic fracturing from the gravity pressure. When grouting borings in these locations or if significant grout losses are observed, the grout backfilling should be done in stages allowing the grout to set between stages."

This statement in the Regulation, together with concerns regarding embankment hydraulic fracturing, have resulted in grouting specifications that limit backfilling of the annular space outside of a standpipe ("casing grout") to heights of only 10-15 m above the water table. Such requirements are extremely expensive to implement as they require that a drill rig and crew be kept on standby for days for each standpipe installed. Stage grouting of the standpipe annular space also results in the risk of grouting the drill casing into the embankment if the casing is not pulled far enough, or for the embankment to collapse around the standpipe when the casing is pulled above the grout level.

Such staged requirements might be an affordable conservative approachwhen drilling a limited number of borings for investigation or installing instrumentation. However, in the case where grouting is being performed as a pretreatment for future cutoff wall construction, these requirements are considered to be nonsensical by the authors. The grouting program in these cases is an investigation and treatment program in advance of performing much larger and riskier excavations through the embankment. In the case where a slurry-supported trench is being considered for the cutoff wall construction, this large excavation will be uncased. It seems logical that if a zone of the embankment were prone to hydraulic fracturing under gravity head, the Engineer would want to determine this during the grouting program where only small diameter holes are being drilled, the fluid being used is self-hardening and the fluid quantity is limited and can be easily controlled. If these zones of low confining pressure are not discovered and treated by the grouting program in advance of the cutoff wall construction, the continuous slurry filled panel or trench will most certainly "discover" this zone of weakness. The surface area and volume of non-hardening bentonite slurry in a typical panel excavation is orders of magnitude greater than the surface area and annular space volume around a typical drill hole. Furthermore, if a hydraulic fracturing event does occur during panel wall excavation resulting in slurry loss, the specified procedure is to add slurry to maintain the trench full (i.e. maintain the pressure the caused the fracture to propagate). It seems obvious that the more cautious and prudent approach is to identify any weak zones during the course of the drilling and grouting program and to systematically treat the identified weak zones by compaction grouting or other means prior to excavating uncased higher risk elements through the dam embankment.

Counter to grouting standpipes in stages, some recent grouting programs have elected to limit the amount of annulus standpipe grout used during installation, as a predetermined multiple of theoretical annulus volumes. In these cases, the standpipe annulus was being grouted through the bottom of the standpipe under gravity head. This approach poses several concerns in regards to the effectiveness of grout treatment and more importantly in regards to dam safety. First, the act of prematurely halting the addition of grout into a formation that is readily accepting the grout is counter to the very goals of the grouting program. Second, not continuing to provide grout during the standpipe installation allows for potential incomplete filling of the hole annulus, as the annulus grout is lost to the formation. This situation lends to defects or incomplete filling of the annulus. These defects can permit direct connection of embankment materials to the foundation and/or connection of grouting fluids up into the embankment during the drilling and grouting operations at lower depths. Both situations are serious dam safety issues.

Arguments for the cessation of annulus grout include avoiding potential hydrofracture of soft embankment or foundation soils above the bedrock. However, it should be noted that most standpipes are drilled and installed into the top of rock immediately below the embankment. This zone of rock is often the most permeable and the zone of rock that most likely led to the need for the remediation being conducted. It is much more likely that any grout take during standpipe installation is flowing into the bedrock or weathered features of the rock (or an alluvium layer remnant immediately above rock) rather than into embankment materials. Bedrock that is being treated during standpipe installation should be viewed as part of the treatment program and should be grouted to refusal just as any other standard grout stage.

In order to adequately backfill and install standpipes, the designer has two options. The first option is to backfill the entire annulus in one complete operation, adding grout as needed and maintaining a continuous head of grout in the annulus at all times until the grout comes to surface and remains at the surface. The second option is recommended for areas of suspected weak embankment soils or zones in which the designer wishes to avoid potential hydrofacture. This option involves the use of Multi-Port Sleeve Pipe (MPSP) with a barrier bag that is inflated with grout at the embankment/foundation interface. The barrier bag hydraulically separates the embankment from the bedrock foundation with the use of a barrier bag. (Figure 1).

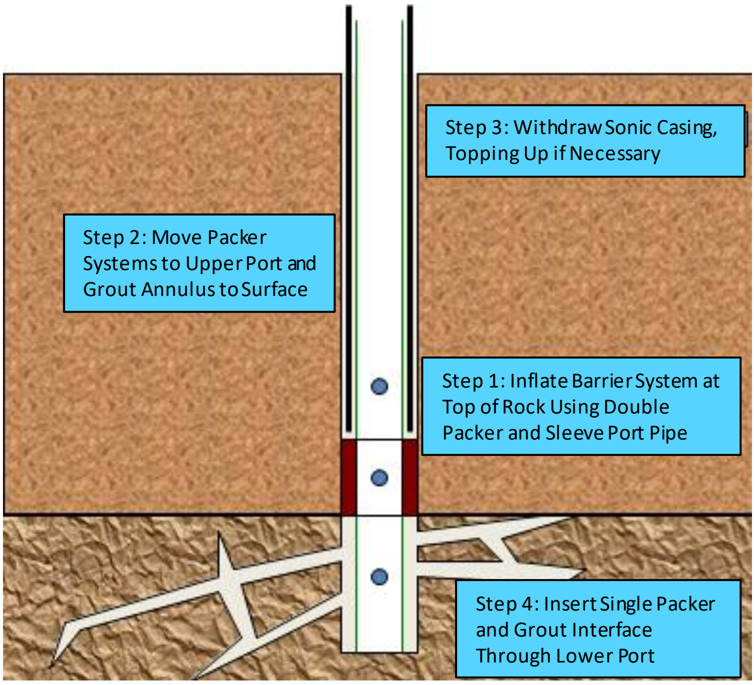

Fig. 1
Separation of embankment and foundation

The annulus can then be filled through a port in the standpipe above the barrier bag, while the critical interface and bedrock immediately below the bag can be treated and evaluated as a separate grouting stage. Either option involves the continuous and uninterrupted backfilling of the hole annulus within the embankment to the top of the hole. Use of the barrier bag to separate and isolate the embankment from the foundation is the only method that verifies that hydrofracturing of the embankment is not occurring. Grout coming to the surface around the outside of a standpipe that was incompletely filled during installation is not evidence of hydrofracturing: it is evidence that the installation method is inappropriate and has created a dam safety concern.

On a similar note, use of very low excess pressures or even gravity head during water testing and grouting due to fears of hydraulic fracturing in advance of cutoff wall construction is misguided. Again, if a zone of the embankment or gouge within rock defects is susceptible to fracture or erosion under low pressures, then one needs to know this prior to excavating the cutoff wall. On one recent project, the allowable water pressures during testing were so low that the headloss through the delivery pipe was not exceeded when flow started and zones with zero water take subsequently consumed very large quantities of grout during pressure grouting. If these zones had not been grouted under pressure due to the low or zero water take and had been backfilled in stages in accordance with the requirements above, then a future large slurry loss during cutoff wall excavation would have been the inevitable result.

2.4. DATA MANAGEMENT SYSTEM (DMS)

It is now common practice for an Owner to insist that the contractor collects, presents and stores all his construction data in real time in some form of an automated DMS (Data Management System). We have found that the contractors are often overwhelmed (initially at least) by the needs, scale and seriousness of such a system. This must not be permitted by the Owner to occur: a fully compliant DMS must be up and running before production work commences. From the technical viewpoint alone, it is integral to controlling and analyzing the treatment in real time, and informing all interested parties on the progress and effectiveness of the work (e.g., via Trend Analyses). It is therefore the only true basis for determining when the work is actually complete or if further work (e.g., higher order holes) is required, and where.

The Contractor’s DMS must be controlled by a suitably qualified grouting engineer (not just an IT specialist). There must be a similarly-equipped, dedicated and experienced engineer on the Owner’s side. All parties must have simultaneous access to all the information generated during the works.

2.5. REFUSAL AND CLOSURE

Each and every stage of every grout hole must be brought to a true and proper "refusal" in accordance with Apparent Lugeon Theory. This means that the maximum specified pressure has been held over a certain period (say 5 minutes) at a certain maximum flow rate (typically 1-3 liters per minute, depending on the project's residual permeability goals and the nature of the rock mass). "Closure," on the other hand, is when a section of the curtain has been judged to have been completed with a degree of certainty that the subsequent verification test holes will indeed confirm that the target residual permeability has been achieved. A proper judgment of closure depends on a holistic analysis of all available and relevant information, such as drilling logs, water tests, optical televiewer logs, grout take analyses and dam instrument response.

Lax refusal criteria will result in incompletely and inefficiently grouted stages. These can also lead to partially grouted fractures resulting in a high residual permeability. Given the limited number of fracture intersections by grout holes and given that the cost of drilling a new hole or holes is likely the most expensive operation in typical foundation grouting programs, each and every hole should be viewed as an opportunity to reduce the bedrock permeability and should be grouted to the fullest extent possible.

Many designers may view the additional time to grout to a low refusal flow criterion as unnecessary and expensive. To the contrary, the last volumes of grout injected during the final refusal of a grout stage can be some of the most important time and effort spent to achieve closure, especially if the time spent reduces the number of additional holes to complete what the prior holes and stages were not able to compete. Designers should consider the costs of drilling additional holes as well as the implications in regards to dam safety (especially for holes that need to be drilled and installed through embankments) when setting refusal flow criteria. Additional time grouting to low refusal criteria will help to reduce the number of additional holes to be added, drilled, water pressure tested, and grouted. All of these operations come with some measured amount of risk involving dam safety, so a reduction in the number of instances that these operations are performed should be viewed as an improvement.

One of the gifts we accept from the use of stable grouts (i.e., those grouts with minimal bleed and pressure filtration) is that they maintain a relatively constant rheology during their period of injection: they do not allow water to be squeezed out of the mix, into fissures, when under pressure. Thus, a grout with constant rheology (i.e., like water has) can thus be regarded as not only a fissure filler, but also a test fluid. This allows us to calculate an Apparent Lugeon Value during the initital grouting of any stage, calculated in the same way as a Water (True) Lugeon Value, but corrected by a factor being Marsh time (grout) / Marsh time (water).

Grout curtains should always be grouted to a target True Lugeon Value (residual permeability). Individual stages should be brought towards refusal by observing and controlling the Apparent Lugeon value, subject to the final "refusal" flow rate. Grout curtains should not be brought to closure based solely on

Apparent Lugeon Values, however, as the authors have observed on a major recent project in the Pacific North West. Water testing of the final hole series and verification holes should always be performed to prove the residual permeability of the treated rock mass.

2.6. ALLOWABLE SAFE INJECTION PRESSURES

A prime rule in any remediation is "First – Do No Harm," and this is a logical and proper dictum to which the authors fully subscribe. However, the whole issue of safe rock grouting pressures under existing dams has reached levels of hysteria, especially in uninformed and inexperienced circles. Bearing in mind that a) a dam foundation is a 3D structure, b) contemporary computer-aided grouting control and recording systems provide essentially continuous real-time pressure/rate of injection data for each stage, and c) QA/QC programs are generally now quite sophisticated, then the authors believe that the highest safe injection pressures should be used, for both economic and technical reasons. "Rules of Thumb" (e.g., 1 psi/foot) can be discarded provided proper and progressive testing is conducted, and all processes are carefully controlled and monitored during injection.

2.7. JOINT INSTRUMENTATION MONITORING PLANS AND LONG-TERM PERFORMANCE MONITORING

It is normally the case that the dam to be remediated will already have some amount of instrumentation in its body and in its foundation. (It is usually the case that the results of this instrumentation will have highlighted the actual need for remediation, in concert with visual observations.) Further instrumentation should be added just before or during the grouting, to target specific "problem areas," or simply to ensure a broad coverage without data gaps. The result is a plethora of instruments, typically now configured to provide data in real time.

It is essential for Dam Safety Assurance during construction that the Owner and the Contractor partner to collect, study and act upon these data in real time, regardless of whose contractual responsibility or liability it may be to do so. The most efficient strategy is to create, prior to construction having commenced, a Joint Instrumentation Monitoring Plan (JIMP). This will identify which instruments are to be read, by whom, and at what frequency. The JIMP will also provide Threshold and Action Level guidance for each instrument, and identify courses of action when these levels are reached.

We also note that a JIMP is implemented most effectively when the Owner and the Contractor can view the data while being physically in a joint "Mission Control" facility. In this way, the impact of the Contractor's work on the dam and its foundation can be seen in real time, and acted upon accordingly when necessary.

We consistently observe that after the curtain or cutoff has been built, little attention is paid to continuing to use the in-situ instrumentation to monitor the long-term efficiency of the cutoff. Even less attention is devoted to publishing such data so that the dam remediation community can have the benefit of a successful (or unsuccessful) case history. Such long-term monitoring is the responsibility of the Owner, and this should be regarded by them as an essential cost outlay – perhaps as part of the routine O&M budget.

3. CLOSURE

It has become very easy to become an "instant" expert, or an "internet" expert, whereupon a great deal of information on any given subject matter can be quickly accessed. However, experience is not so quickly or so easily gained, and its value in a specialty engineering process such as grouting cannot be overstated. The authors' opinions expressed in this paper reflect their respective experiences, and they have done so in the hope that the opinions will leaven the bread of the internet expert thrown into the midst of a major dam remediation project involving drilling and grouting, both processes previously inexperienced.

SUMMARY

There has been a technological revolution in rock grouting for dam remediation projects in the U.S. stretching back almost 20 years. This has been extensively described in many conferences and publications, and has resulted in a very high level of technical competence and project performance. However, the authors have observed that many "lessons learned" in that period have not been universally applied or, in some cases, have been ignored. This paper reaffirms may of the practical lessons learned in many grouting processes, including:

- Drilling techniques for overburden and rock,
- Design and testing of grout mixes,
- Placement and sealing of standpipes and MPSP's,
- Data management systems,
- Refusal and closure,
- Allowable safe injection pressures,
- Joint instrumentation monitoring plans, and long-term performance monitoring.

Depuis près de 20 ans se déroule une révolution technologique en ce qui concerne l'injection du rocher pour les projets de réhabilitation des barrages aux États-Unis. Ce sujet a été largement traité à plusieurs conférences et dans maintes publications, et en est résulté une amélioration considérable des compétences techniques et de la performance des projets. Cependant, les auteurs considèrent que les « leçons apprises » n'ont pas toutes été considérées, et dans certains cas, ont été ignorées. Cet article réitère plusieurs des meilleurs pratiques dans les processus d'injection, incluant :

- Techniques de forage pour le mort-terrain et le roc,
- Conception et essais de mélanges de coulis,
- Emplacement et étanchéité des conduits,
- Système de gestion des données
- Refus et fermeture
- Pressions d'injection admissibles et sécuritaires
- Programme de suivi de l'injection et suivi à long terme du comportement

SEEPAGE CUTOFFS FOR DAMS AND LEVEES: LESSONS LEARNED FROM 40 YEARS OF REMEDIAL CONSTRUCTION IN NORTH AMERICA *

Donald A. Bruce

President, GEOSYSTEMS, L.P.

U.S.A.

1. INTRODUCTION

The National Inventory of Dams (NID) has listed over 84,000 dams in the United States which meet its criteria for inclusion [1], namely:

1. High hazard classification - loss of one human life is likely if the dam fails.
2. Significant hazard classification - possible loss of human life and likely significant property or environmental destruction.
3. Low hazard classification - no probable loss of human life and low economic and/or environmental losses, but the dam:
   - equals or exceeds 25 feet in height and exceeds 15 acre-feet in storage;
   - equals or exceeds 50 acre-feet storage and exceeds 5 feet in height.

Almost 14,000 dams meet Criterion 1. Only 4% (3,075) are federally owned, and these mainly date from the earlier third of the Twentieth Century. Over 87% of the total are primarily classified as earth embankments, while no other category exceeds 3% of the total. The main primary purposes are recreation (35%), flood control (17%), fire protection in stock/small fish ponds (15%) and irrigation (10%), while less than 3% generate power. Many structures are multipurpose. Figure 1 summarizes their completion dates: about 50% were

* MURS PARAFOUILLES POUR DES BARRAGES ET DES LEVÉES : LES LEÇONS ONT APPRIS DE 40 ANS DE CONSTRUCTION RÉPARATRICE EN AMÉRIQUE DU NORD

completed between 1950 and 1979, while the median age in the year 2018 is about 67 years.

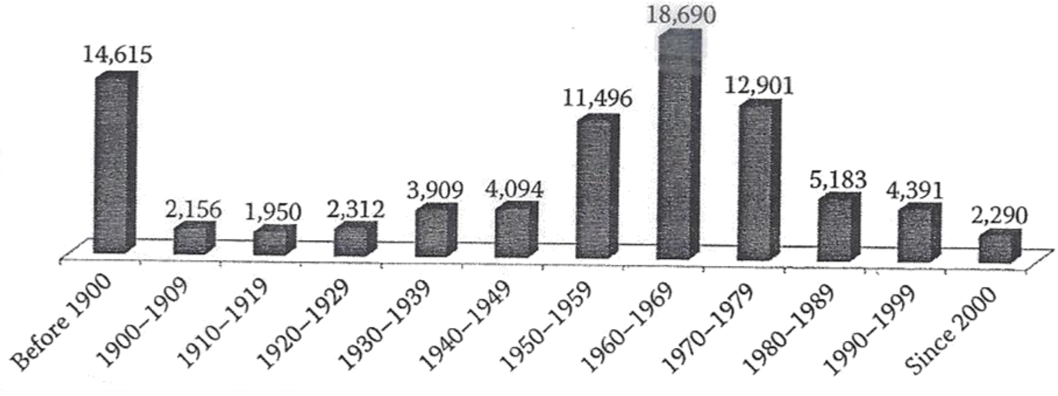

Fig 1
U.S. dams by completion date. (From National Inventory of Dams, CorpsMAP, http://nid.usace.army.mil, 2010.)

Whereas it may be calculated from the National Inventory of Dams [2] that the cumulative "end-to-end" length of all the U.S. dams is around 18,000 miles, preliminary estimates put the cumulative length of levees in the U.S. at over 120,000 miles. Only about 14% of this total may be regarded as federal, and considered by Halpin [3] as "robust." The balance includes municipal, local and agricultural structures often featuring little engineering design, patchwork construction and minimal periodic maintenance, since they were traditionally regarded as "simple" structures.

Certain design assumptions and construction techniques used in the dams and levees built prior to, say, 1960, would not be acceptable today, and have left behind fundamental flaws in some structures. Appropriate filter criteria for embankments and uplift/sliding issues in concrete dams are two obvious design related examples, while old approaches to rock surface preparation and foundation treatment would also fall into the unacceptable category. In addition, there are two overriding geological considerations which directly influence the serviceability, reliability, and performance of the dam and levee system. These considerations are (i) the presence of carbonate and evaporite formations, and (ii) the potential for seismic activity.

Focusing on point (i), there is a huge swath of karstic limestones and dolomites which outcrops from Pennsylvania to Alabama, while it is estimated [4] that evaporites underlie about 40% of the contiguous 48 states. These potentially soluable and erodible foundation conditions underlie many of the major river basins, such as the Mississippi-Missouri basin, and the Tennessee and Ohio River Valley systems – and, of course, the aging dams built thereon.

Beginning with the first Wolf Creek Dam KY remediation in 1975, one can tabulate 27 major cutoff walls which have been built through and under the existing embankment dams, to counteract increasing seepage trends, and the erosional dangers these seepages pose to dam and foundation alike. This paper presents the lessons learned from these projects.

2. SUMMARY OF CASE HISTORIES (1975-2017)

A recent review [5] provides details of 27 major remedial cutoffs using "excavate and replace" methods, as opposed to "mix in place" methods [6]. These projects are listed in Figure 2 which also shows the principal construction method and Specialty Contractor. One project remains in progress (East Branch Dam, PA), while three others are foreseen to commence in 2018, including two in Tennessee and the second phase of Herbert Hoover Dike, FL. Details of construction methods and cutoff material design are provided in older texts (such as [7]), while many of the more recent case histories referred to in Figure 2 are summarized more recently in reference [6]). Several different methods of constructing cutoffs have been successfully and safely utilized on these projects, including the use of clamshells, hydromills and large diameter rotary drills. The choice of method is primarily dictated by the geotechnical conditions, the depth of the cutoff, dam safety considerations, and the traditional preferences of the respective Specialty Contractors.

3. LESSONS LEARNED

3.1. DESIGN CONSIDERATIONS

3.1.1 Geological and Geotechnical Site Characterization

The following observations are provided, for brevity and clarity, in bullet form. Some readers may find certain lessons to be self-evident and not worthy of consideration. However, each topic has its roots in situations personally observed by the author and, in his opinion, each merits inclusion.

- Before designing a new program of investigation, very carefully reexamine existing, historical information (e.g., grouting programs, original site investigation data, construction photos, as-built drawings), and dam performance data, especially "signs of distress" (sinkholes, seepages, depressions, erratic piezometer readings, etc.). The work product is a basic but robust hydrogeological model.
- The intensity of the new investigation must reflect the variability of the ground conditions as interpreted from the preexisting hydrogeological model (but will be, practically, governed by budget and access, and the project risks).
- Drill holes must extend over the entire length and depth of a foreseen cutoff. Their location should reflect what is suspected to be the main risk areas identified in the preexisting hydrogeological model.

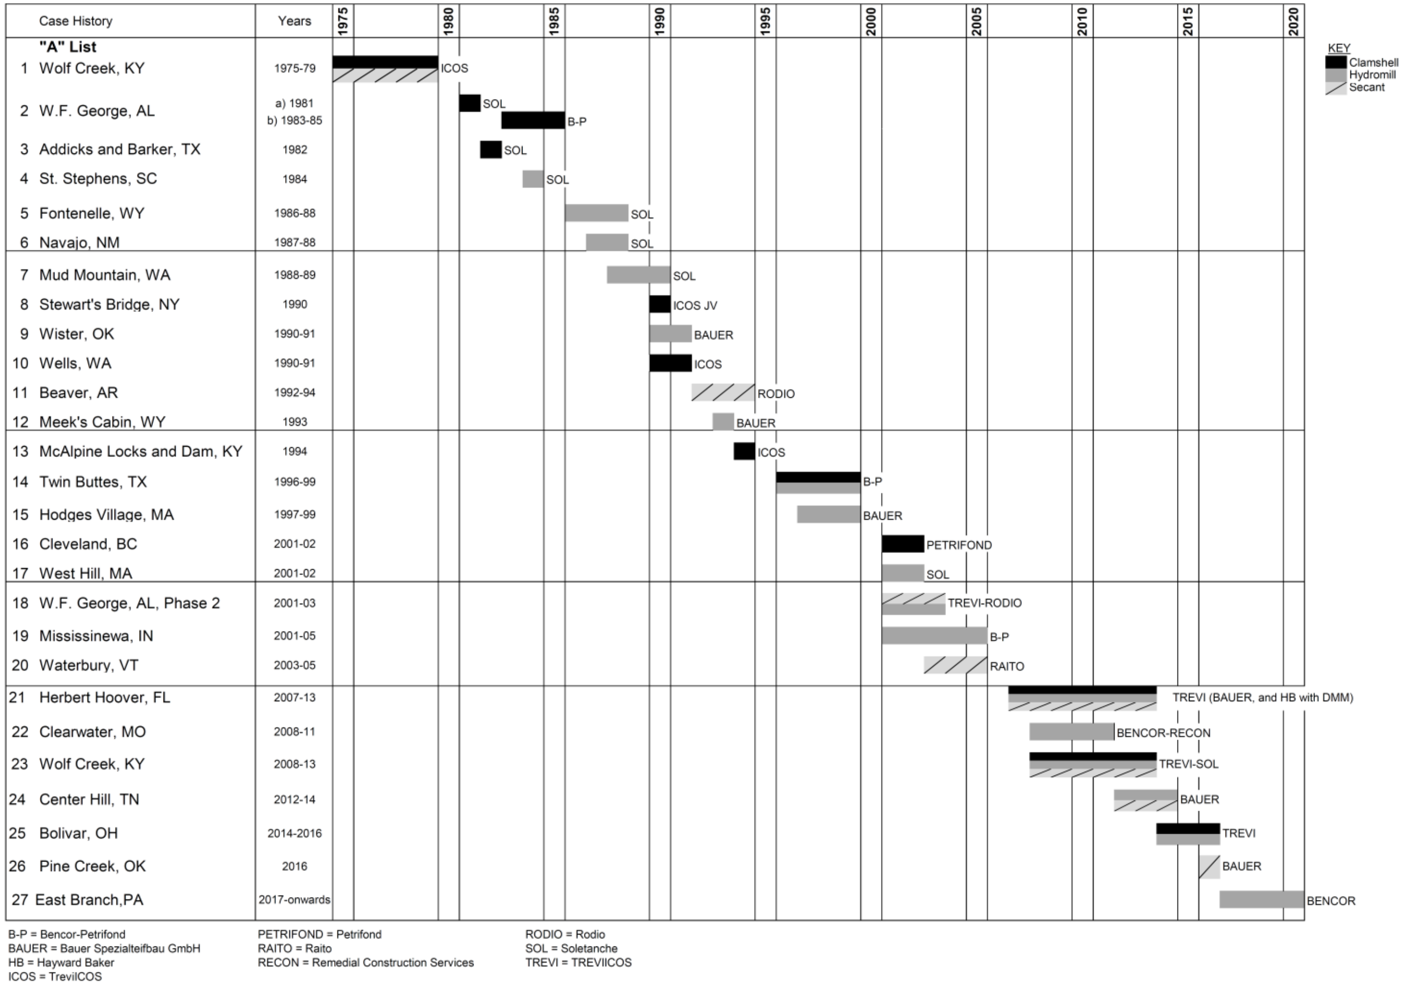

Fig 2
List of remedial cutoffs for dams showing principal construction method and specialty contractor.

- The investigatory program must inform the design of the cutoff, and produce information essential for bidders to select their construction methods, estimate productivities, and evaluate construction risks.
- All investigations must be conducted in accordance with prevailing standards of care for drilling in dams/levees, and for environmental protection.
- Even the investigatory program may require a certain enhanced level of instrumentation monitoring during its implementation.

3.1.2 Geotechnical Reports

- Many different types of Reports can be produced on a project including:
  - Geotechnical Data Report (GDR),
  - Geotechnical Interpretive Report (GIR),
  - Geotechnical Baseline Report (GBR),
  - Geotechnical Design Basis Report (GDBR).
- It is essential that at least the GDR, GIR and GDBR are shared with all bidders, in full. GBR's are relatively uncommon outside the tunneling industry, and have very well-defined contractual and legal significance. The goals of these Reports, considered together, must:
  - allow development and understanding of an accurate hydrogeological model,
  - permit the Engineer-of-Record to design a responsive cutoff,
  - ensure that all bidders are on a "level playing field" when preparing their submittals,
  - clearly identify areas of particular geotechnical construction or performance risk,
  - permit the implementation of an appropriate geotechnical plan to monitor conditions before, during and after construction.

3.1.3 General Principles of Cutoff Wall Design

- Plan Location: A cutoff is typically located on the centerline of the embankment (for access reasons), or on upstream slope (to save footage and to ensure tie-in to sloping cores).
- Length: Determined by flow analysis to ensure minimal "end around" seepage. Most cutoffs actually tie-in to existing concrete structures, such as spillways or powerhouses. Their far end typically is determined by the geology and topography of the site (i.e., width of abutment).
- Width: The minimum continuous width (typically 0.3 to 0.6 m) should primarily be determined by the depth of the wall, the variability of the geology, the composition of the wall, and its performance requirements. Note that a cutoff wall does not have to be perfectly vertical to satisfy its design function: it can "ripple" provided the minimum inter-element overlap thickness is satisfied.
- Depth: The terminal elevation of the toe must be chosen to reflect the geological conditions and the design concept of the wall:
  - a "full depth" cutoff into effectively impermeable rock; or

- a "partial depth" (or "floating") cutoff, to reduce (not eliminate) seepage and/or to prevent internal erosion. Such walls are often constructed through previously installed grout curtains (minimum 2 rows), intended to investigate the ground, pretreat voids to prevent sudden slurry loss; and grout to say < 3 Lu the rock mass under and around the wall in "clean fissure" conditions. This is the concept of the "composite wall" [6].

- Material Properties:
  - In-situ permeability (especially at joints) must be established, and verified. It is typically ≤ 10^{-8} m/s for materials, but 1 Lu for joints (i.e., approximately 1 x 10^{-7} m/s).
  - Strength and deformability must reflect the project conditions (e.g., plastic concrete vs structural concrete). All materials must be non-erodible in service.
  - Homogeneity must be emphasized, e.g., no inclusions of native ground or bentonite slurry, no segregation of the backfill, no contamination of the joints (or the toe) with slurry.
  - Durability/chemical compatibility must be addressed, but is typically not a problem.

3.1.4 Risk and Performance Considerations

- In dam safety considerations, Risk = Probability x Consequence.
- Risk is to be assessed in Potential Failure Mode Analysis sessions (PFMA).
- The individual PFM's, appropriately prioritized, must drive the remedial requirements and the instrumentation requirements.
- The performance of the cutoff and the existing structure must be measured during construction, and after construction. Specific project goals must be set and verified, e.g.:
  - reduction in seepage,
  - acceptable piezometric performance,
  - elimination of other "signs of distress" (e.g., settlements, sinkholes, muddy flows, boils).
- The evaluation of risk may dictate the sequencing and prioritization of the work and the permissible remedial techniques.

3.1.5 Durability of Walls

- The actual backfill materials must be durable. This will be proved by laboratory testing ("pinhole erosion"), quality of construction, and conditions of curing and service.
- There may be some evidence of cracking in old diaphragm walls, but the case is not proven. Newer walls have intense in-situ verification and superior long-term performance monitoring.
- Desiccation cracking may be a concern in embankments where the upper part may be above water level for most of its service life. However, the typical cross-sectional shape of an embankment is favorable (i.e., very broad).

3.2. CONSTRUCTION

- Each Contractor has its own particular mentality and preferences for means and methods, as well as for equipment. Each project's construction details must therefore be evaluated on this basis, with the prime concern being the safety of the dam during construction.
- A proper, stable, working platform (concreted if possible) is essential for a host of reasons, ranging from personnel safety to enhancing productivity.
- Some cutoff walls involve extensive pregrouting such as in the "Composite Wall" concept [6]. Such grouting must be conducted by an experienced and knowledgeable Contractor who may not necessarily be the same business entity as the cutoff wall Contractor. Insufficient or ineffective grouting may create dire problems to subsequent cutoff wall quality and schedule.
- "Technique Demonstration Areas" – thoroughly assessed – are invariably of great value to all the project's stakeholders.
- Time is well spent up front in building high quality, weatherproofed bentonite and concrete storage and batching facilities, and maintenance shops.
- Development of mix designs and their approval by the Owner should not be allowed to negatively impact schedule and should be given high priority during the site mobilization phase.
- All preconstruction permits, etc., must be in place prior to site mobilization.
- Ensure that all equipment is maintained regularly, and that all instrumentation is frequently recalibrated (if necessary).
- Individual cutoff wall elements, be they diaphragm wall panels, or secant piles, should be sized to minimize the number of inter-element joints, consistent, however, with dam safety concerns.

3.3. QA/QC AND VERIFICATION

- Details must be linked directly to the design intent and the project specifications, regulatory requirements, and to the actual construction techniques adopted by the Contractor.
- Key elements promoting success include:
  - Clear and complete contract specifications and drawings;
  - Appropriate organizational structure and qualified personnel;
  - Good communication protocols;
  - Cooperation from all parties (Owner, Engineers and Contractors);
  - Diligent implementation of the Quality Plan.
- A comprehensive, formal Quality Control Implementation Plan is essential, and the effort needed for the drafting and implementation of this Plan should not be underestimated by the Contractor. This project-specific plan must address, as a minimum:
  - Site organization charts showing responsibilities, lines of communication and levels of authority of project personnel from all stakeholders;

- Setting out methods and tolerances;
- Bentonite slurry properties, production and testing;
- Wall verticality and panel overlap (by at least 2 independent methods);
- Wall tolerances;
- Joint cleanliness criteria;
- Concrete materials, batching, placement and testing;
- Coring and in-situ permeability testing (and the use of an Optical Televiewer);
- Management and communication of data and records (real time, and archived);
- The development and implementation of a Joint Instrumentation Monitoring Plan (JIMP), between the Owner and Contractor.

- While an essential element of the Quality Plan is timely and accurate transmittal of information, the Plan must be developed and managed by an Engineer or Geologist, and not an IT Specialist in Data Management Systems.

3.4. Instrumentation and Performance Monitoring

- Prime types are piezometers, settlement gages, inclinometers, seismographs and weirs.
- Data loggers ("trolls") can detect suspended sediments, change in pH, and temperature in seepages. Real time data transmission is preferable.
- Instrumentation adequacy must be audited, and supplemented if necessary, well in advance of construction ("baselining").
- Location, intensity, and responsibility <u>during</u> construction must be governed by the JIMP.
- Monitoring must be continued after construction, with clear guidelines for identifying and acting upon Threshold and Action Levels.
- Long-term performance trends should be published in the technical community.

3.5. Development of Contract Documents and Contractual Arrangements

- Performance-based specifications are optimal, and the fundamental performance goals must be clearly and consistently stated.
- Partnering must be implemented rigorously, and with total commitment at all levels in each stakeholder.

- Contractual risks must be allocated fairly, with the Owner being responsible for the site conditions and for the potential impacts and benefits of any previous remediations (e.g., by pregrouting) on the project. Risks to the Owner can be managed in many ways:
  - Ensure all available site-specific data are made available at bid stage;
  - Engage an appropriately qualified, experienced and resourced Design Engineer and Board of Consultants;
  - Clearly define respective roles, responsibilities, and duties, especially for site inspection staff;
  - Select a "Best Value" as opposed to "Low Bid" basis for Contractor selection;
  - Insist on a "Partnering" environment;
  - Select a qualified and experienced Contractor with appropriate human and mechanical resources;
  - Encourage the bidders, via Performance Specifications, to bring their own ideas and expertise to the project;
  - Ensure modifications are issued quickly, and be sympathetic to requests for bid extensions;
  - Allow budget for adequate short- and long-term instrumentation.
- There must be realistic expectations, such as that:
  - The project will satisfy the design intent;
  - The project will be designed and built to the current state of practice and to appropriate referenceable standards of care;
  - Project schedule is actually attainable (especially in "tight" projects with multiple trades);
  - The work will not cause damage or detriment to adjacent preexisting structures;
  - Claims are inevitable, and must be evaluated strictly on merit (often not the case when Construction Managers operating on very small margins are involved).
- The principles of "Early Contractor Involvement" should be applied whenever feasible, and especially on particularly challenging projects, technically or schedule-wise.

SUMMARY

Twenty-seven case histories of major remedial cutoff walls have been reviewed. These cutoffs (excavate and replace methods only) have been installed through existing embankment dams and deep into usually karstic conditions to counteract the dangers to dam safety created by escalating seepage rates and velocities. “Lessons learned” are presented relating to design considerations, construction, QA/QC, instrumentation and development of contract documents.

Vingt-sept études de cas de réhabilitation de grande envergure des parois moulée ont été vérifiés. Ces parois (excavation et méthodes de remplacement seulement) ont été installées à travers des barrages en remblai existants et en profondeur en milieu karstique afin de contrer les risques en lien avec la sécurité des barrages créé par l’augmentation des taux et des vitesses des infiltrations. Les « leçons apprises » présentées concernent la conception, la construction, l’assurance qualité et contrôle de la qualité, l’instrumentation et la rédaction des documents contractuels.

THE SEEPAGE ANALYSIS OF THE EMBANKMENT DAMS OF A FLOOD RETENTION BASIN IN POLAND

Burcu ERSOY, Ronald HASELSTEINER

Hydraulic Engineering Department, BJÖRNSEN CONSULTING ENGINEERS

GERMANY

1. INTRODUCTION

All kind of embankment fill dams are faced with seepage body during impoundment and during operation. Therefore, seepage control plays an important role at the design stage to prevent uplift pressures, instability of the downstream slope, piping through the embankment and/or foundation and potential suffusion and erosion processes. In order to guarantee safe seepage conditions for the anticipated load cases, the seepage control design should comprise sealings, dam body specifications, special drainage elements, and their characteristics.

The paper provides the main information and results of the seepage and stability analysis of a case study and aspects considering potential suffusion and erosion processes.

2. PROJECT OVERVIEW – CASE STUDY

A dry/green flood retention reservoir is under construction in Poland since 2013. The project includes embankment dams (head, right and left dam). The lengths of all embankments show approx. 22 km. The reservoir volume is 180 Mio. m³ with a perspective to be enlarged to 300 Mio. m³. The maximum height of the embankment dams is over 11 m in the area of head dam. The maximum water level is specified at a level of 195.2 m a.s.l. and the crest elevation is defined at 197.5 m showing a freeboard of 2.3 m. A selected section of the dam (head dam) is given in Fig. 1. Within specified sections the sand-gravel material was selected as main dam fill material. Gravel material is used as filter material and the seepage control function is provided by a geosynthetic clay liner (GCL). In addition, gravel columns have been placed within the foundation area where weak formations are located beneath the future dam body.

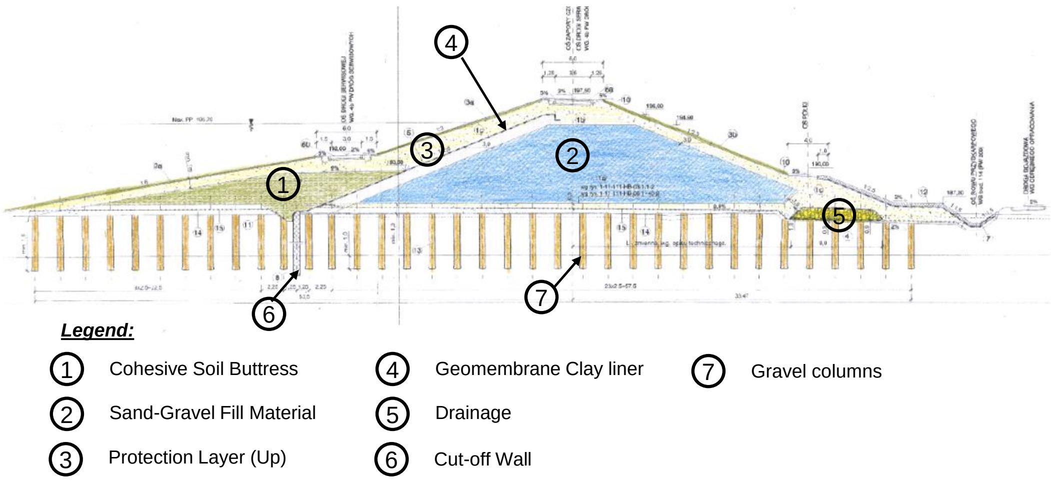

Fig. 1

3. SEEPAGE AND STABILITY ANALYSES

3.1. PREPARATION OF THE FINITE ELEMENT MODEL AND BOUNDARY CONDITIONS

The finite element model (FEM) is defined as a mathematical simulation of a real physical process. For the FEM a typical dam cross section with a height of 11 meters was considered (Fig. 1). The model size (width) was defined in consideration of the dam height. As minimum size two times the dam height to up- and downstream were defined so that the model boundaries are not influencing the seepage conditions within the dam. This approach results in a model width of 172 m. The modelled underground depth was selected also with a minimum of two times the dam height. The maximum water level is applied at 195.20 m a.s.l. which is 8.7 m above the upstream ground surface level. The geological formation consisting of a clay layer, sand-gravel, and London clay layers are integrated in the model. The thicknesses are established as 6 m, 7 m, and 7 m for clay layer, sand-gravel and London clay, respectively. The thickness and depth of the cut-off wall are applied with 60 cm and up to 13 m respectively. The thickness and depth of gravel columns are assumed as 80 cm and 9 m respectively. The distance between the gravel columns is assumed as 2 m (center to center) so that in total 33 gravel columns are considered in the model section. For a better possibility of evaluation the reference coordinate system used the origin (x, y) = (0, 0) at the upstream dam toe. The final view of the numerical model that used in seepage analysis is given in Fig. 2.

To determine the seepage flow – steady state conditions were considered – through the embankment body, a FEM requires the definition of boundary conditions. Three hydraulic boundary conditions are applied for the numerical model as follows:

- 'Constant head' → Upstream face → at a height of 195.20 masl (water level with 8.7 m above the terrain surface) → dark blue in Fig. 2
- 'Constant head'→ Downstream face → the maximum water level that is at a height of -0.44 m → blue downstream line in Fig. 2
- 'Seepage exit', 'Total flux type' → Potential seepage exit areas along the downstream slope → the ground water flow as 0 m^3/s → red line in Fig. 2

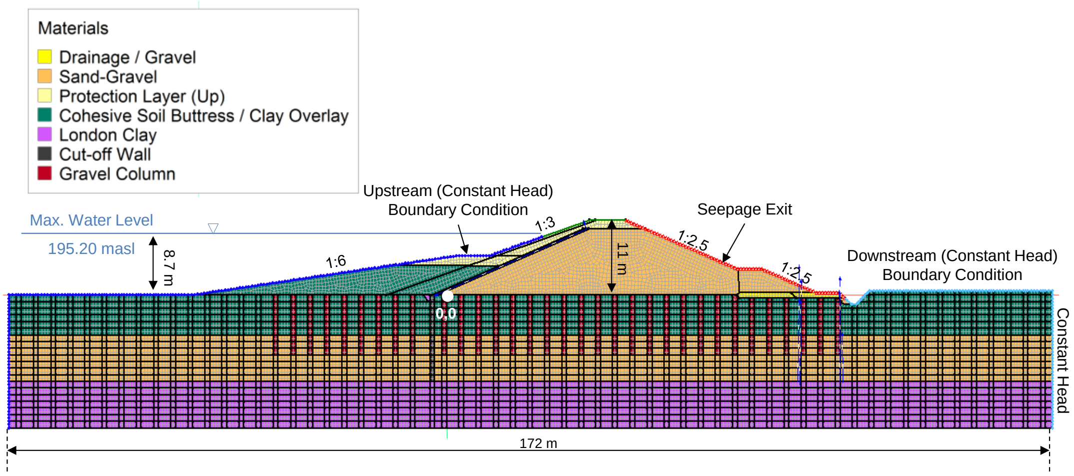

Fig. 2
Finite element model for the seepage analysis

3.2. DEFINITION/DETERMINATION OF THE GEO-HYDRAULIC AND SHEAR STRENGTH PARAMETERS

The next step in developing a numerical model is to assign materials to the regions as defined in the numerical model before. The geo-hydraulic and shear strength parameters are the key parameters for seepage and stability analyses. To assign reliable inputs to the numerical model, geo-hydraulic parameters are implemented that are included in different books and papers, e.g., in Haselsteiner (2007) [8] and the referenced literature sources. In Haselsteiner (2007) [8] the geo-hydraulic parameters are compiled from 17 different literature sources. The compiled geo-hydraulic parameters are categorized in accordance with typical embankment dam zones such as gravel drain, gravel fill used for the dam body and underground, sand material, surface sealing and alluvial clay/loam.

'Saturated only' option was selected for the steady state seepage analysis and for the material shear behavior, the 'Mohr-Coulomb' model was selected. The geo-hydraulic and shear strength parameters that are implemented to the numerical model are given in Table 1.

Table 1
Geo-hydraulic and shear strength parameters for the zones of the embankment dam

				geo-hydraulic			*shear strength*		
No	Type	Name	Color of Zone in Model	Permeability k_S [m/s]	Anisotropy $A=k_y/k_x$ [-]	Saturated Volumetric Water Content [-]	Unit Weight γ [kN/m³]	Cohesion c' [kPa]	Friction Angle φ' [°]
1	Embankment Zone	Cohesive Soil Buttress		10^{-9}	0.5	0.325	19	4	31.0
2		Sand-Gravel		10^{-3}	0.5	0.225	17	0	37.5
3		Protection Layer (Up)		10^{-3}	0.5	0.200	17	7	31.0

10		London Clay		10^{-11}	0.5	0.325	20	5	28.0

3.3. DESIGN SITUATIONS AND LOAD CASES

The design, construction and operation of a dam with a reservoir need to be developed in consideration of its long-term performance that is affected by boundary conditions such as reservoir water level, traffic loads, performance of the dam zones, climate impacts, etc. Therefore, corresponding design situations and load cases need to be defined during the design stage especially for the seepage and stability analyses.

Load cases consist of a set of conditions that are taken into consideration in the dam safety analysis. For the analyses, the “Deutsches Institut für Normung e.V.” [1], [2], [3] and DWA [4] codes are considered which regulate dam engineering aspects. The load cases and the revision of guidelines are given in Table 2. Seven load cases are considered within the seepage and stability analyses. The load cases showing unsteady seepage, e.g., for rapid drawdown conditions,and operation earthquake conditions are not taken into consideration for the analyses since they were considered irrelevant.

In addition to the load cases, four design conditions were considered for the numerical model to evaluate the long-term performance of the designed sealing (geo-synthetic clay liner + cut-off wall) and soil treatment systems, e g., gravel columns as given in

Table 2

Different load cases (design situations) for seepage and stability analyses according to DIN (adapted after DWA, 2015)

No.	Con-sidered		Design Situations according DWA M-522/2015 adapted according EC 7	Load Case according to DIN 19700-10,-11,-12	Loads		Resistance Dam status/situation

Open Sealing without Gravel Column	OS-GC							

3.4. RESULTS AND INTERPRETATION OF SEEPAGE ANALYSIS

The 2D steady state seepage analysis is performed by using SEEP/W software program that is a part of GeoStudio 2016 software package. As a result of 28 seepage analyses considering the different design situations and load cases, following results are obtained.

Generally, the differences obtained for the different dam/design conditions (FS, OS, with/without GC) regarding total head and pore water pressure are not substantial. Therefore, the application of sand-gravel columns does not worsen the seepage situation critically. But also does not show a benefit in consideration of the performance of the embankment dam.

The comparison of the results for the different design/dam conditions and for selected load cases are given in Fig. 3. The load cases LCT1, LCA1, LCA2a and LCA2b are selected in order to compare the design/dam conditions. In general, the results of the seepage line and pressure head reflect the same trends as theoretically expected.

For the load cases LCA2a “Malfunction of the sealing” and LCA2b “Malfunction of drain”, the drain capacity is not enough to drain the dam body. In addition, an unfiltered exit is the result that may lead to backward erosion.

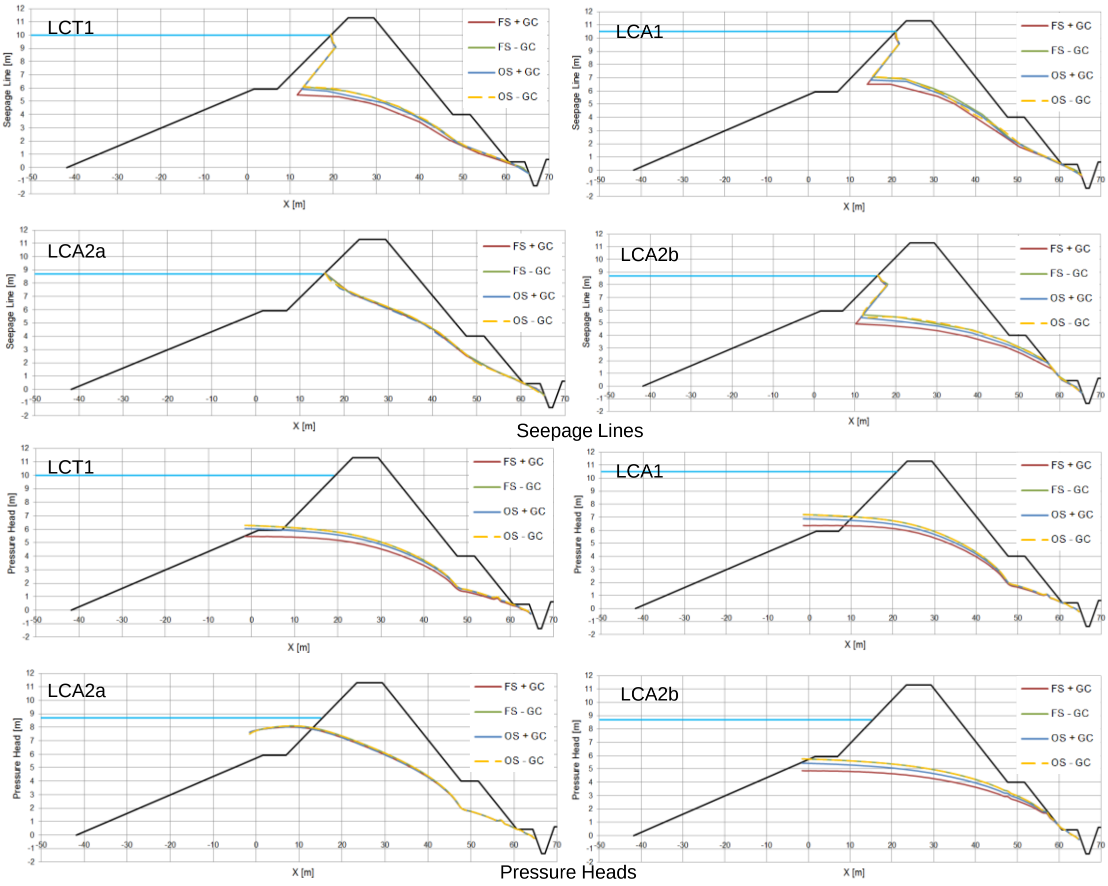

Fig. 3
The comparison of different load cases and design situations in form of on line of seepage and pressure head

The sealing of the actual design does not reach to the crest level. Therefore, a considerable seepage flow may occur within the unsaturated zone, bypassing the sealing in the crest area. Especially, for high water levels this shows an adverse effect.

The gravel columns show a minor effect on the underground seepage conditions. The gravel columns do not show a practical effect when the sealing system is not working, anyway, or the “open sealing situation” is established in the model. The gravel columns increase the seepage flow amount, pressure head and seepage line when the sealing system is working in full sealing (FS) conditions.

3.5. RESULTS AND INTERPRETATION OF THE STABILITY ANALYSIS

The slope stability analysis is performed by applying the limit equilibrium analysis (LEA) method in order to determine the factor of safety (FoS) only for the downstream embankment slope (using SLOPE/W software, GeoStudio 2016). The FoS values are obtained only for the sliding slope stability considering the downstream slope. Results are presented in Table 4.

The required FoS ([1], [2], [3], [5]) are relatively below the calculated values. In addition, thanks to the conservative dam design and flat slopes in respect to the limited height of the embankment the static stability is not a matter of concern. The FoS range show up to 30 % safety margin.

Table 4
FoS Evaluation of the Downstream Embankment Slope Slip Stability

	Load Cases

4. HYDRODYNAMIC SOIL DEFORMATION PROCESSES

Fell & Fry [6], [7] developed a process dependent approach for assessing erosion and suffusion processes. The consideration of more assessment steps in order to obtain a full risk assessment approach also in consideration of important aspects such as system identification, detection, measures, etc. [9] supports of a better understanding and more detailed risk assessment.

Beneath the assessment steps (initiation, development, continuation, breaching), which are directly addressing the particle transport, the pre- and post-phases need to be investigated and assessed as well. For the assessment it is also important to localize the transport processes. Within this localization step erosion paths shall be defined which are strongly depending on the dam design and the underground situation. In total three erosion paths are identified as dam body erosion path (DB EP), underground erosion path 1 (UB EP 1) and underground erosion path 2 (UB EP 2). Along the erosion paths different sorts of processes (A to E) are evident which are also checked within the main four phases of the erosion and suffusion assessment (see Fig. 4).

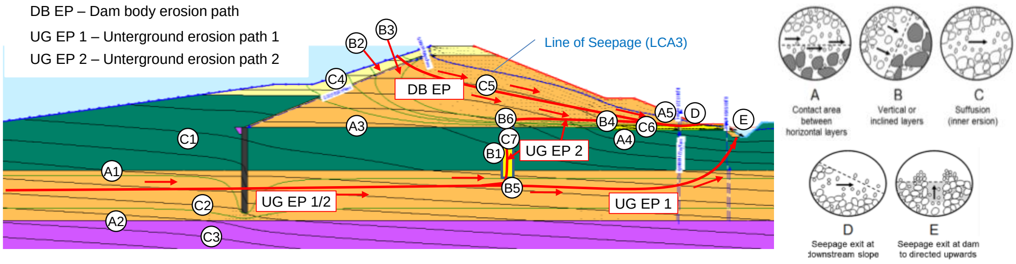

Fig. 4

Defined erosion paths within the embankment dam section

The continuation of erosion shall be assessed by mean hydraulic gradients derived from the seepage analysis. The definitions of the hydraulic head difference and the flow path length are shown in Fig. 5.

The determined hydraulic gradients are given in Table 5. The critical gradient for the present sand-gravels should be approx. i_c = 0.20 to 0.40. For finer sands this can decrease to i_c = 0.15 and for silts to i_c = 0.10 or even less. For the dam body erosion path the material shows the firstly mentioned gradients. However, the gradients within the dam body (Table 5) are generally small $i < 0.20$, except for load case LCA3 where it reaches a value of $i = 0.30$. Thus, for reaching the crest water level also backward erosion may continue since hydraulic forces are strong enough. For the other load cases the erosion through the dam body should not be a problem due to low gradients.

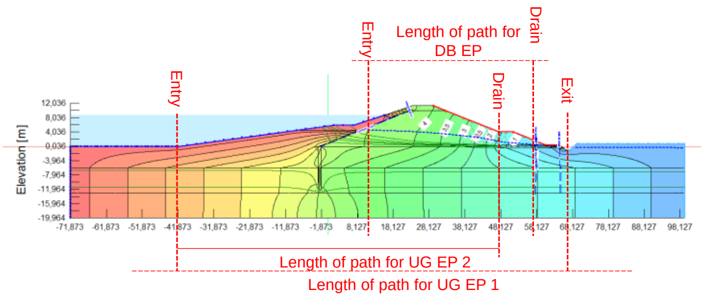

Fig. 5

Determination of the Hydraulic Head difference and Flow Path length using the Total Head results of the Seepage Analysis (here: LCP1, OS - GC)

For the crest water level (LCA3) the hydraulic gradients are strong enough to continue the erosion process through the dam body. This is a result of the seepage control design which does not meet the requirements to European codes and guidelines, especially German design philosophy. Processes within the underground are also considered to be not critical thanks to the protective clay layer and the conservative dam design.

Table 5
Hydraulic and critical gradients for the analyzed load cases and design situations

Erosion path	LCP1	LCT1	LCT3	LCA1	LCA2a	LCA2b	LCA3	Design/dam condition
	Load Cases							
	Mean actual hydraulic gradients i [-]							
Critical hydraulic gradient for sand-gravels i_c = 0.20 to 0.40 (Brandl & Hofmann, 2006)								
Dam body	0.08	0.12	0.02	0.13	0.16	0.09	0.30	OS without GC
Underground 1	0.08	0.09	0.05	0.10	0.08	0.08	0.10	OS without GC
Underground 2	0.09	0.10	0.04	0.12	0.09	0.09	0.12	OS with GC

Suffusion plays a minor role, but as a result of checking selected suffusion criteria some of the applied sand-gravels in the dam fill as well as in the underground might be susceptible to suffusion.

The applied monitoring concept for a 22 km long dam is not able to contribute to an effective detection of potential erosion processes. Intervention measures to stop the erosion through the dam body, once it occurs during accidental load cases, are difficult to realize. Due to the cohesionless fill material in the dam body breaching should proceed relatively fast.

Following recommendations were given. The sealing should be extended to the crest elevation. The drain should be redesigned and extended to be connected to the drainage ditch. The gravel columns do not show a critical negative effect on the design and the dam behavior in respect to erosion and suffusion risks but, therefore, can be spared.

5. CONCLUSION

The dam shows an unsatisfactory seepage behavior resulting in an unfiltered seepage exit which is the first phase to backward erosion. This risk is mainly present for the dam body, which shows a design which does not comply with modern dam design criteria and modern dam safety philosophy. Therefore, the application of an additional sealing or drainage element and redesign of the downstream toe drain are considered to be required. The static stability of the downstream slope is not of concern thanks to the applied flat slope. Erosion risks are mainly related to the embankment dam body. Within the underground erosion risks are tolerable.

SUMMARY

The seepage control concept that comprises sealing, dam body and drainage elements in order to guarantee safe seepage conditions for the anticipated load cases should be developed where remarkable seepage conditions are expected through the dam body. As long as the seepage conditions are not controlled and hydraulic gradients occur, erosion may occur in form of backward erosion in the underground/subsoil and along all contact borders/interfaces of different materials in the dam body.

The paper presents the seepage and stability analyses of a case study to emphases the importance of seepage control design and the assessment of hydrodynamic soil deformation process. Based on the analyses' results, recommendations and conclusions are presented to overcome and to improve the specific drawbacks and inherent risks of the present dam design.

1. INTRODUCTION

Using cement grouting to improve bedrock water tightness is quite common and there are numerous examples of its application to the engineering of dam-foundation improvement. Evaluation methods of the effectiveness and quality of grouting include analysis of drilling data, water pressure testing results, grouting records and monitoring data. Evaluations may be performed on an on-going basis concurrent with grouting, near the end of grouting, or after the completion of grouting [1]. Currently, in-situ water pressure testing over discrete zones in the foundation provides an excellent method for verification of the effectiveness of the grouting program. However, in some particular cases the Lugeon target is hard to achieve in spite of intensive grouting. Areas of abnormally high or low grout takes in comparison to the Lugeon values are identified. For such cases performance evaluations should be based on the general grouting objectives [2]. Post-construction monitoring of seepage from foundation drains and collecting galleries can indicate whether the grouting program has satisfied design seepage requirements. This paper addresses the question by discussing methods one might use to evaluate the adequacy and progress of grouting and items one might choose to consider in evaluating the performance of grouting.

2. GURA APELOR DAM

Gura Apelor dam is a clay core rockfill dam 168 m high, that provides a 230 mil. m^3 storage for the 335 MW Retezat power plant. It is the tallest dam in Romania. The crest length is 480 m and total fill volume is 11.2 mil. m^3. The core is moderate thick, 64 m at the dam base. The grouting and inspection gallery is located along the clay core – foundation rock contact, in the mid axis of the core. A second gallery is provided downstream of the grouting gallery, inside the downstream filter, in order to collect the water seepage escaped through the clay core or percolating the grout curtain.

The spillway is located at the right abutment. It is a free flow weir followed by a rapid channel and a 10m diameter tunnel. The end is a flip bucket leading to downstream river bed. The bottom outlet and mid height outlet are also in the right abutment and connected with spillway tunnel.

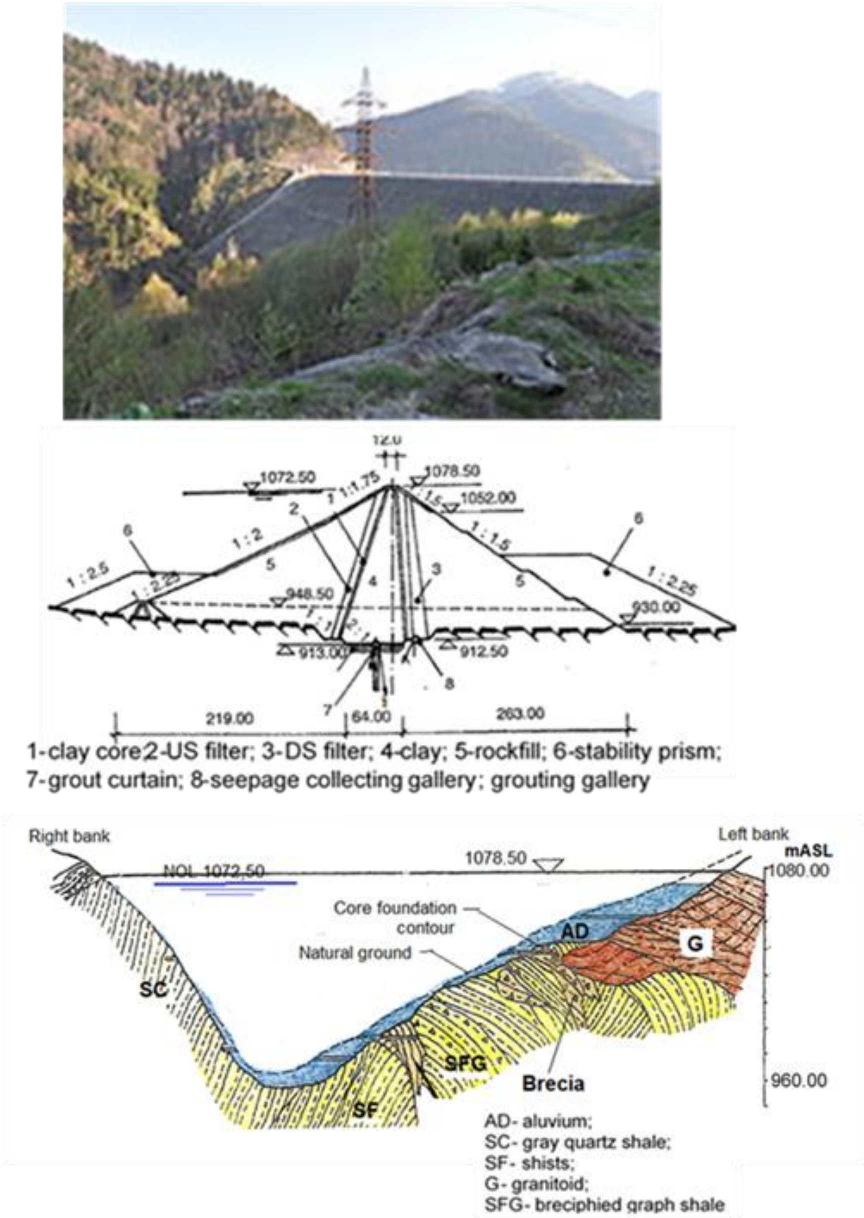

Fig.1

Gura Apelor Dam – cross section, geology and downstream view

The foundation rock is made up of a complex of crystal shale and granite gneiss. The right slope, the river bed and the left slope below 950 mASL consist in gray quartz shale with greenish chlorine-sericitous bands. The left slope above elevation 950 mASL up to elevation 1,030 mASL is made up of tectonised, breciphied graph shale. Above the 1030 mASL the right bank is made of granitoid rock mass. Water permeability tests performed in investigation drillings pointed out important absorptions on the left slope, particularly in the tectonised area between the granite and the breciphied shale.

3. FOUNDATION WATERTIGHTENING

In order to avoid the seepage along the discontinuities in the upper part of the rock foundation the entire base width of the core was grouted to a depth of 6 to 12 m to form a grout platform, or a grout bulb (fig. 2). The grout curtain was designed based on lugeon values and consists in two rows of grouting holes, with a depth of 60 … 80 m, performed from the grouting gallery. On the right abutment, on the dam valley and on the lower half of the left abutment the grout curtain achieved the required technical conditions. On the upper part of the left abutment, above the elevation 985 mASL the control drillings have shown very large water absorptions. Areas of abnormally high or low grout takes in comparison to the Lugeon values were identified for further analysis. The grouting records for these abnormal zones were reviewed carefully along with the pressure testing and grouting records from adjacent holes.

The difficulties encountered during the grouting process due to complex geological conditions has imposed the temporary stopping of the grout curtain performance. Consequently, the reservoir water level was severely restricted. The apparent inability of the traditional grouting practices to provide a watertighteness barrier of acceptable efficiency and durability led to the idea of replacing the grout curtain with a concrete wall. The attempt was abandoned bearing in mind that the average cost of a concrete wall is many times that of a grouted cut-off, and that there was currently a shortfall in contractor capacity to construct the former,

After 10 years of studies and analyses it was decided to complete the grout curtain. A campaign of high quality drilling, permeability testing and grouting was first conducted. The decision was supported by the fact that grouting equipment, methods and contracting procedures have evolved over the last decade and the engineers can now design, build and verify the performance of permanent grouted seepage barriers for dam structures.

The extension and completion of the grout curtain performed in the first stage was differentiated according to rock mass characteristics (see fig. 2). For the schist zone, between 960 and 1021mASL elevations, along a length of 146 m, groutings for the bulb underneath the core foundation, 15 m deep were firstly provided. The grout curtain itself, with a depth of 35 m, consists in three rows of grouting drillings disposed at 0.5 m in between and 2m along the curtain. For the brecia zone, with a length of 23.3 m, between elevations 1021 and 1028 mASL, bulb grouting and grout curtain with a depth of 35 m encountered some anomalies. In some places the grout take was quite large in spite of low Lugeon values. For the granitoid zone, with a length of 150 m, between elevations 1028 and 1078.50 mASL, the grout curtain consists in three rows of grouting drillings, with a depth of 55 m for the ones performed from the grouting gallery and with a depth of 70 m for drillings performed from the platform.

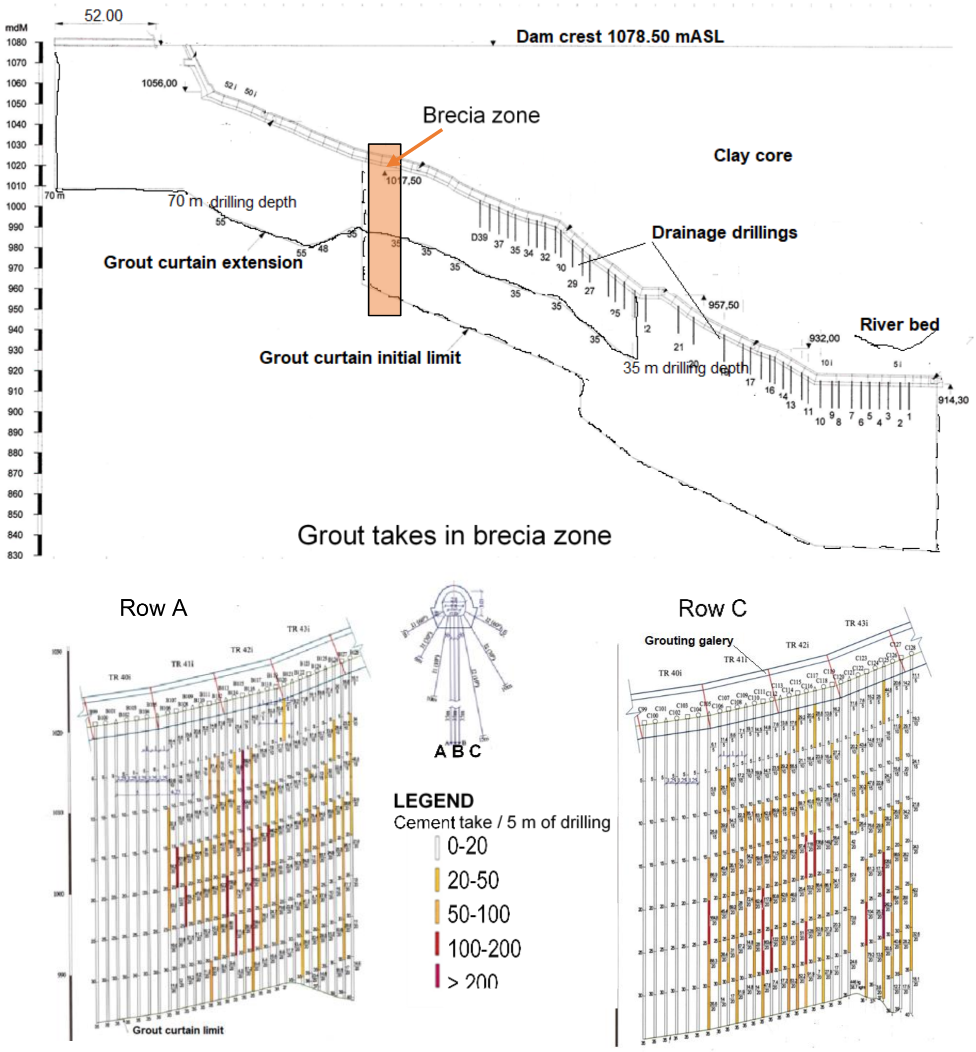

Fig. 2.
The extension and completion of the grout curtain performed in the first stage

3. GROUT CURTAIN EFFICIENCY BASED ON LUGEON VALUES

At the end of the process the criteria based on Lugeon specific absorption [3], [4], [5] were partly fulfilled: some 60% in the case of Romanian standard and ICOLD recommendations and up to 80% in the case of FST criteria.

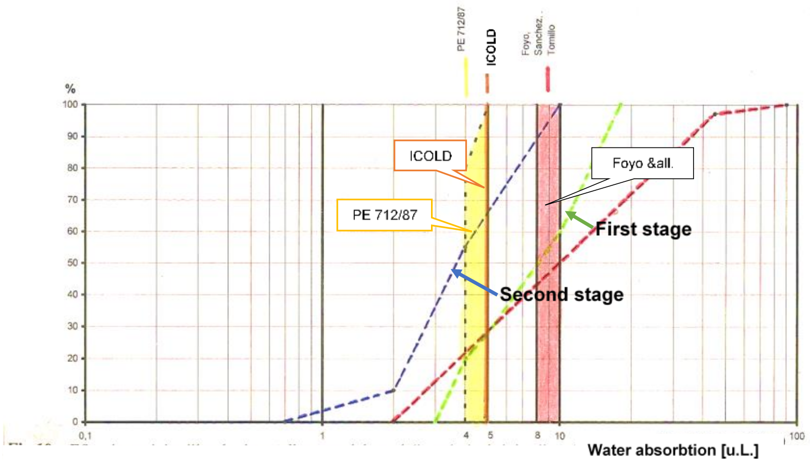

Fig.3
Grout curtain efficiency in terms of water absorption

In spite of intensive grouting the Lugeon target was not achieved. The brecia zone and the breciphied graph shale zone were areas of abnormally high or low grout takes in comparison to the Lugeon values are identified (see fig. 2). Consequently, performance evaluations were based on the general grouting objectives. Monitoring of seepage from foundation drains and collecting galleries was the criterion that indicates whether the grouting program has satisfied design seepage requirements.

4. GROUT CURTAIN EFFICIENCY BASED ON SEEPAGE MONITORING

4.1. MONITORING SYSTEM

Gura Apelor dam is provided with an extensive monitoring system, that allow the record of pore water pressures in the core and inside the rock mass, of the seepage flows, of the strains, of the fill settlements, of the rock displacements, of the joint movement, of the dam body movements. For the grout curtain efficiency, the relevant measurements are the interstitial water pressures in the rock foundation, upstream and downstream of the grout curtain, and the seepage collected in the seepage collecting gallery (fig.4). The interstitial water pressures are measured by manometers that equipped the drainage drillings performed from the grouting gallery. The seepage is collected by provided windows in the collecting gallery and by drainage drillings performed from the same gallery. Concrete diaphragms separate defined zones along the seepage collecting gallery in order to localize the potential large seepage sources.

A drainage gallery was provided in the left abutment, with a length of 100 m, between elevations 996 and 1000 mASL. It is connected to the drainage collecting gallery. The purpose was to avoid the buildup of large interstitial pressure inside the rock mass thus endangering the slope stability. As it will be seen, the gallery has an adverse effect, increasing the total seepage attributed to lack of imperviousness of the foundation.

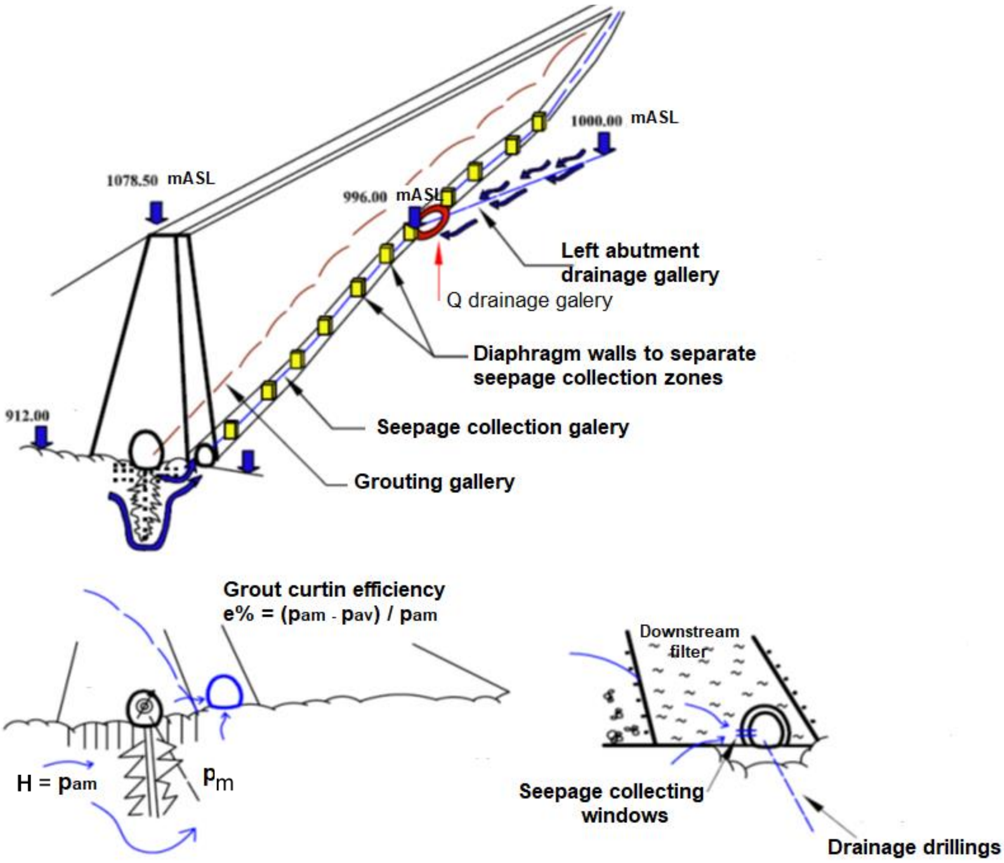

Fig. 4.
Monitoring system for grout curtain efficiency

4.2. MONITORING DATA

Evaluation of the grout curtain efficiency was based on three monitoring values:

- The measured pressures upstream and downstream the grout curtain. The characteristic value was the efficiency defined as $e\% = 100 (H – p_m) / H$, were H is the water column corresponding to water level in the reservoir and p_m is the pressure at the manometer, expressed as meters of water column. At the 1030 mASL reservoir elevation, the efficiency was above 80% on the average, except two local zones where the efficiency was 65 … 70% (fig.5).
- The seepage flows in the seepage collecting gallery, differentiated into seepage through gallery windows and seepage in drainage drillings.

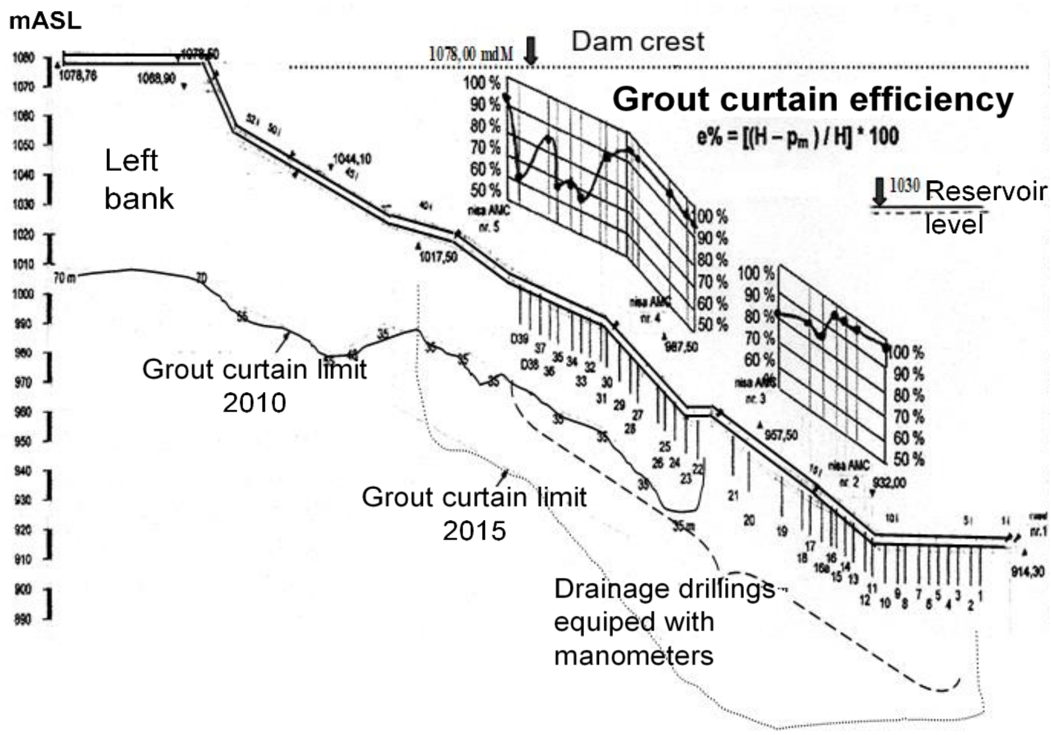

Fig.5.
Grout curtain efficiency in terms of pressure drop

- Total seepage collected at the final weir at the end of the collecting gallery (fig. 6). The total seepage has shown significant decrease i.e. for the same reservoir water level,1010 mASL, the seepage has decreased from 52 l/s before the grout curtain extension to 23 l/s.

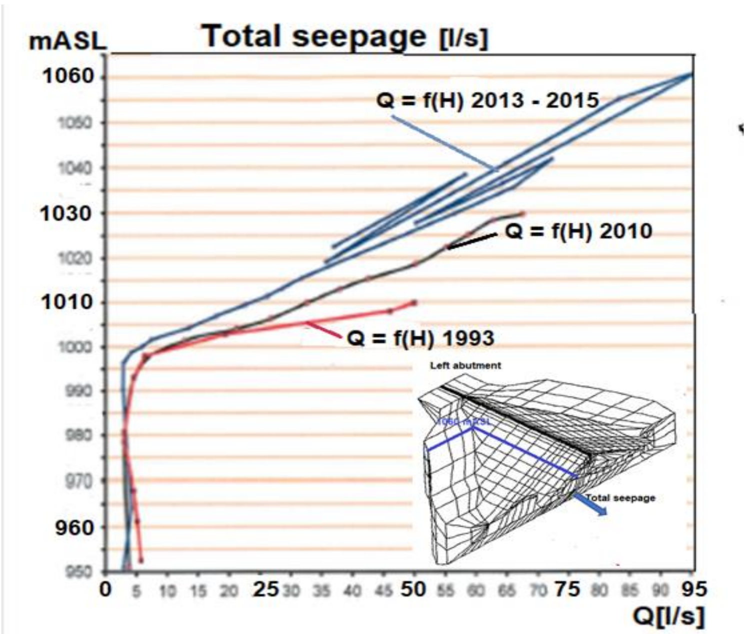

Fig. 6.
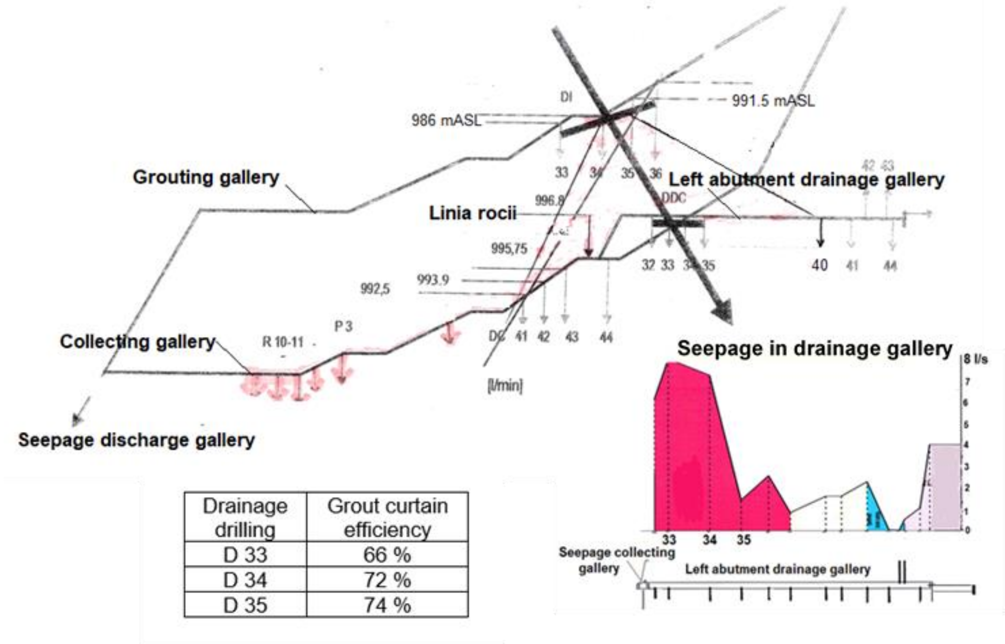
Total seepage versus reservoir water level

4.3. EFFECTS OF THE LEFT ABUTMENT DRAINAGE GALLERY

The analysis of the seepage distribution shows that up to 40% of the total seepage is the contribution of the left abutment seepage gallery. The gallery induces a defavorable behavior, increasing the infiltration gradients from the reservoir towards the left bank and consequently the seepage flows. There are gaps and fissured rock zones at the outer surface of the lining and thus the gallery is actually a large diameter drain with a length of 100 m (fig.7). In spite of filling grouting performed from the gallery and decreasing the number of drainage drillings from 32 to 14, the drainage effect is still very active.



Drainage drilling	Grout curtain efficiency
D 33	66 %
D 34	72 %
D 35	74 %

Fig. 7.
The seepage contribution of the left abutment drainage gallery

The seepage collected along the left abutment drainage gallery is mainly taken over by the collecting gallery and creates a false image of the seepage pattern corresponding to a more permeable zone in the grout curtain.

The same phenomenon has been revealed by the numerical modeling of the seepage. A 3 D finite element model for dam foundation system was built providing the background for deciding the extent of foundation treatment required to satisfy design and safety criteria and its efficiency (fig. 8). The numerical model was calibrated based on the monitoring data corresponding to a reservoir level of 1030 mASL and was used to predict the dam behavior for reservoir elevation 1050 mASL and normal operation level. The extension of the grout curtain limit from 35 m to 60 m do not improve significantly the seepage control, the reduction being less than 10%. The left bank drainage gallery was included in the model by special boundary conditions. The results underline the need for a retreatment of the drainage gallery.

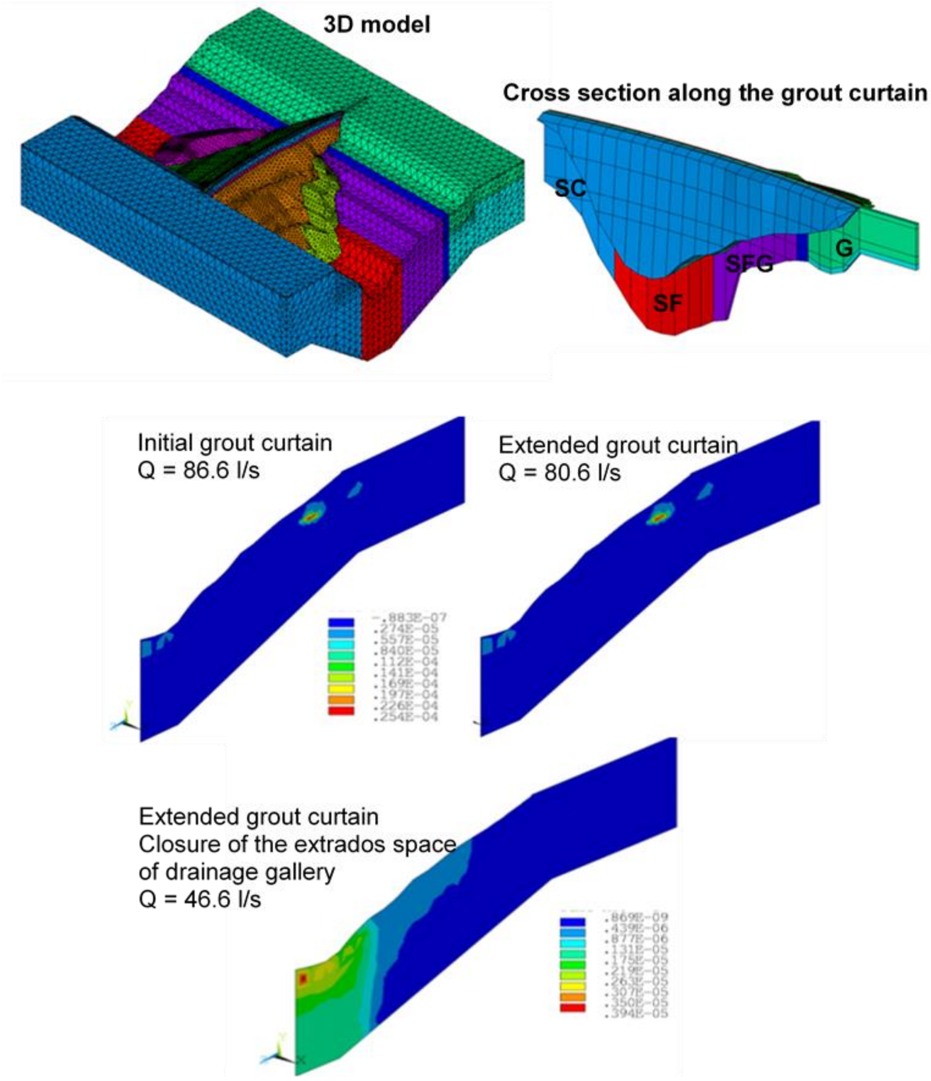


Fig. 8.
Finite element model to predict the grout curtain parameters

5. CONCLUDING REMARKS

The grouting program conducted for Gura Apelor dam has revealed that in some particular cases the Lugeon target is hard to achieve in spite of intensive grouting. For such cases performance evaluations should be based on the general grouting objectives. Monitoring of seepage from foundation drains and collecting galleries can indicate whether the grouting program has satisfied design seepage requirements.

The drainage galleries performed inside the abutment rock of the dam induces a defavorable behavior, increasing the infiltration gradients and consequently the seepage flows. Such galleries are to be avoided unless there is a real risk to build up large interstitial pressure inside the rock mass of a slender abutment endangering its stability.

6. SUMMARY

The difficulties encountered during the grouting process on the left abutment of Gura Apelor dam due to complex geological conditions has imposed the stopping of the grout curtain performance on the last upper quarter of the dam height. Consequently, the reservoir water level was severely restricted. After 10 years of studies and analyses it was decided to complete the grout curtain by the same grouting process but using high performance equipment. Up to now, the reservoir level was raised in stages above the previous restricted level, up to some 12 m below the normal operation level. The closely monitoring seepage phenomena pointed out that the imperviousness of the left abutment was successfully achieved.

1. GENERAL SITUATION OF THE DAM

The dam is a homogenous embankment dam with length of 2222m and maximum height of 24m. The elevation of dam crest is 28.72m. The normal water storage level is 21.16m, and the design flood water level is 25.92m. Dam body is filled by four types of compaction, such as heavy roller compaction, light roller compaction, roller compaction in the water and compaction manually. The bedrock is overburdened by Quaternary alluvial and diluvial layer, which includes three permeable layer composed by sand and gravel and two impervious layer composed by clay. Seepage control prevention measures of the dam include cut-off wall in section from 0+700 to 1+250 (extended deeply to the bedrock) and jet grouting in the section from 1+250 to 1+750 (extended to the first imperious layer). The maximum thickness of overburden layer is 42m. The axial geological formation of the dam is shown in Fig. 1.

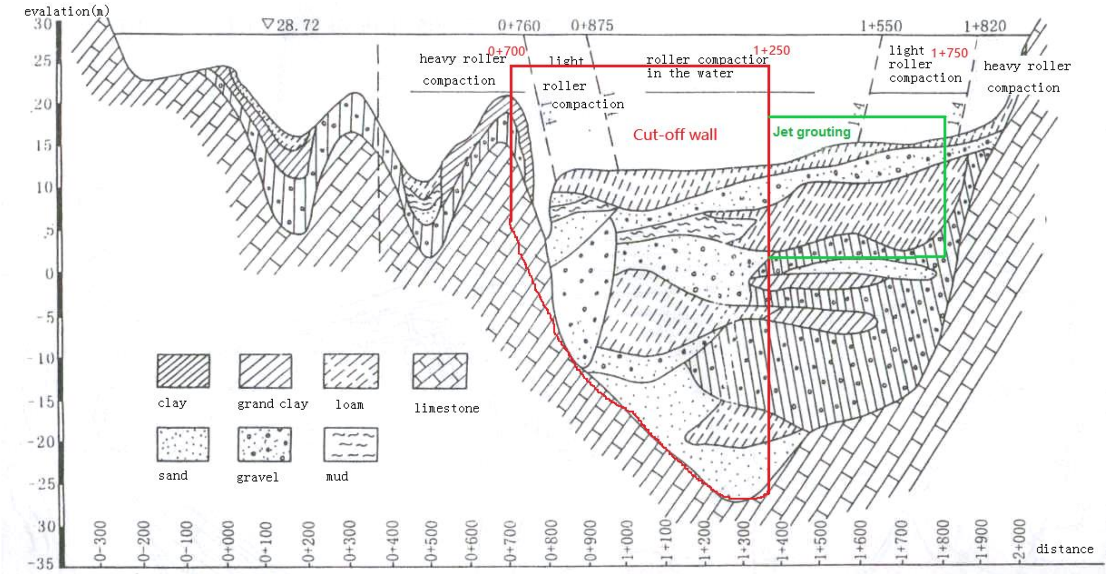

Fig.1
Theaxial-section geological formation of the dam

2. THE LAYOUT OF SEEPAGE OBSERVATION POINTS

Seepage observation points are distributed in the cross sections of 0+500, 0+850, 1+130, 1+300 and 1+650(mark B). Observation points of dam body and foundation are distributed in front and back of seepage control measures. Some standpipes are used to monitor the groundwater level also (mark S). There are five seepage discharge observation points in the sections of 1+020 (L1), 1+250 (L2), 1+280 (L3), 1+450 (L4) and 1+650 (L5). The observation layout is shown in Fig. 2 and Fig. 3.

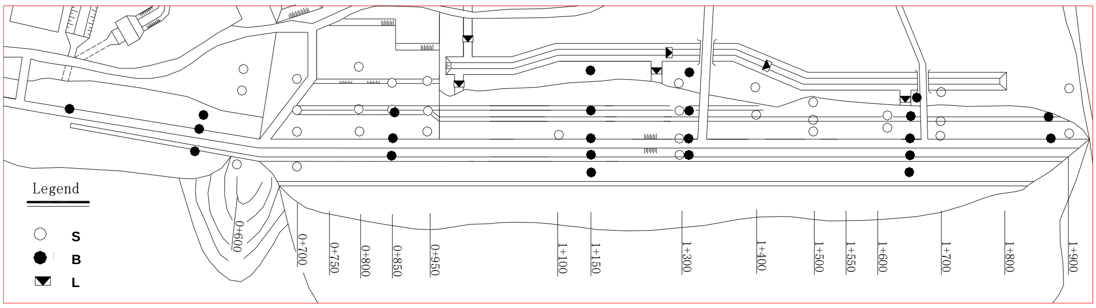

Fig. 2
The plane distribution of seepage observation points

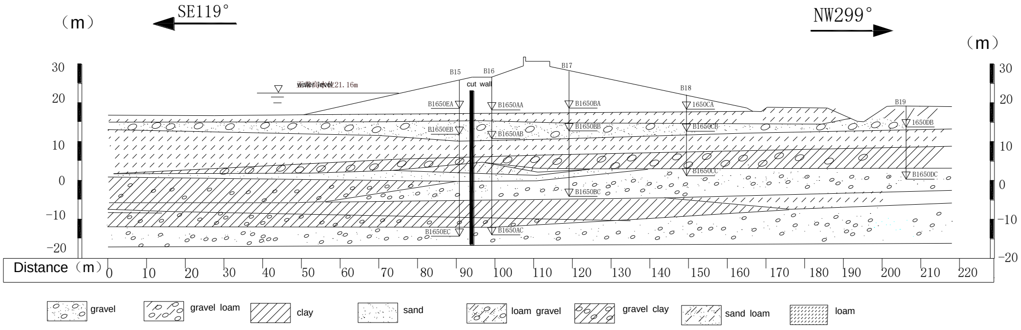

Fig.3
The cross-section distribution (1+650) of seepageobservation points

3. EVALUATION OF SEEPAGE CONTROL EFFECT

The seepage pressure hydrograph of dam foundation are shown in Fig.4-Fig7 and the co-efficient between seepage pressures with water level are shown in Table 1.It can be concluded that:

(1) Two dam foundation observation points B0850AB and B0850BB of section 0+850 are located at the back of cut-off wall, and their average potential percent reduce about 75% compared with water level and their seepage pressures have a poor correlation with water level. The measure points B1130AB and B1130AC of section 1+130 are located in the first and third permeable layers at the back of cut-off wall, and their potentials reduce about 72% and 60% respectively compared with water level. These two phenomena mentioned above indicate that the cut-off wall has a significant anti-seepage effect.

(2) B1300AB, B1300BB and B1300CB of section 1+300 located in the same permeable layer, their potentials are almost same, reducing 50% compared with water level and their seepage pressures have a poor correlation with water level. There is small loss of water head and high permeability of dam foundation, which means that the joint area of cut-off wall and jet grouting shows a weaker anti-seepage effect.

(3) B1650AB and B1650AC of section 1+650 located in the first and third permeable layers at the back of cut-off wall, and their potentials reduce about 30% and 40% respectively compared with water level. Besides, the correlation coefficient between their seepage pressures with water level approximate or even exceed 0.9. Section 1+650 shows a more significant correlation with water level compared with other sections on both sides. As a result, jet grouting at this area has a poor anti-seepage effect.

In addition, after cut-off wall set up in 2001, 60% total seepage discharge in the sections of 1+020 (L1) is reduced, whereas seepage discharge of number L3 in the section of 1+280 and number L4 in the section of 1+450 show little difference. This proves lower efficient of seepage prevention for jet grouting than cut-off wall and leakage happens in the right abutment of dam foundation.

Grouting is to fill in the pores or holes of the dam body or foundation materials by thin mixture of sand, water, and cement or lime, which aims to make the materials denser and form an impervious barrier in dam. Grouting (include jet grouting) is with advantages as little investment and short construction period. But as its anti-seepage effect is significantly influenced by the condition of the soil layer and the anti-seepage thickness is not uniform, grouting is only suitable for the low water head embankment dam.

Cut-off wall is a technique used to build reinforced concrete walls in dam body or foundation. The technique presents a higher safety and reliability in deep overlying strata. Although the investment of cut-off wall is high, but its integrity is good and anti-seepage effect is remarkable, which makes it more applicable.

Therefore, as shown in the case, for an embankment dam with a deep gravel foundation, cut-off wall is more efficient of seepage prevention than jet grouting.

4. CONCLUSION

Anti-seepage effect of jet grouting is significantly influenced by the condition of the soil layer and it is only suitable for the low water head embankment dam. Cut-off wall presents a higher safety and reliability in aspects of foundations' cutoff in deep overlying strata and it is more applicable. As shown in the case, for an embankment dam with a deep gravel foundation, cut-off wall is more efficient of seepage prevention than jet grouting.

SUMMARY

An embankment is with 30-40m depth of gravel and loams layer. Jet grouting and concrete cut-off wall were implemented in different foundation location for seepage control. Dam seepage observation points were distributed in dam foundation. Seepage-control effect is evaluated by long-term data analysis of dam foundation. Anti-seepage effect of jet grouting is significantly influenced by the condition of the soil layer and it is only suitable for the low water head embankment dam. Cut-off wall presents a higher safety and reliability in aspects of foundations' cutoff in deep overlying strata and it is more applicable. As shown in the case, for an embankment dam with a deep gravel foundation, cut-off wall is more efficient of seepage prevention than jet grouting.

1. INTRODUCTION

Hydro Tasmania is the State-owned generation company for the island of Tasmania, Australia. Hydro Tasmania's power system includes 55 large dams, 30 hydropower stations and two major wind farms and has a total installed capacity of over 2000 MW of hydropower and 300 MW of wind.

Hydro Tasmania's portfolio of dams is ageing, with more than 30 of the dams now more than 50 years old. As a result there has been increased effort to understand the risks associated with this ageing portfolio of dams. Hydro Tasmania has had an active dam safety program since the early 1970s. This program was initially structured around dam surveillance activities; however, in the past two decades risk assessment has become the framework for the program. A full portfolio risk assessment was completed in 2006, which forms the basis for risk-based decision making in relation to dam management.

Hydro Tasmania's dam portfolio consists of a number of different types of dams including a total of 12 concrete gravity dams, ranging in height from 6 m to 49 m.

The portfolio risk assessment, along with an instrumentation monitoring review, resulted in the following findings associated with the concrete dams:

- A key failure mode was overturning or sliding during a flood event, and a key contributing factor to this failure mode was the build-up of uplift pressures under the dam.
- Larger dams were generally designed with a drainage gallery and foundation drain holes to reduce uplift; however, the foundation drain holes were generally of smaller diameter than the industry best practice of 75 mm or more.
- The majority of dams did not include any direct monitoring of uplift and relied on measurement of seepage from drain holes as an indicator of their effectiveness.

A key risk identified was the unknown uplift pressures under the concrete gravity dams, which directly influence stability due to both sliding and overturning. This heightened risk was due to the lack of uplift monitoring, the fact that foundation drains were a smaller diameter than current best practice and the lack of consistent foundation drain cleaning/maintenance since construction.

Based on the outcomes of the portfolio risk assessment and monitoring review, recommendations were made to upgrade both the foundation drainage and the monitoring of uplift at a number of Hydro Tasmania's large concrete gravity dams. The upgrade program of works included:

- Installing piezometers.
- Measuring pressures within the foundation prior to drain cleaning.
- Cleaning of the drains and in some cases increasing the diameter of the drainage holes.
- Ongoing measurement of uplift pressures following drain cleaning.
- Ensure that there was a link between O&M manuals for the dams and the uplift monitoring.

A similar program was also undertaken on Hydro Tasmania's concrete arch dams that range in height from 42 m to 140 m. To demonstrate this program of works, two case studies are provided of the upgrade works undertaken with respect to reduction and monitoring of uplift pressures.

2. TREVALLYN DAM CASE STUDY

2.1. BACKGROUND

Trevallyn Dam is a straight concrete gravity dam that impounds Lake Trevallyn located near the city of Launceston in the north of Tasmania. It is rated as an extreme hazard/consequence category dam. The dam is 33 m high, has a crest length of 178 m and was completed in 1955. It is cast in 15 blocks of up to 15 m in width and it straddles a fault zone which passes diagonally under the dam at its deepest point. Within the dam there is an internal gallery which gives access to the foundation drainage facilities as well as to the control valve for the low level outlets. A two-level free overflow ogee spillway occupies the central 131 m of the crest. Fig. 1 provides a plan and long section of the dam that also shows the location of the drainage gallery and foundation drains.

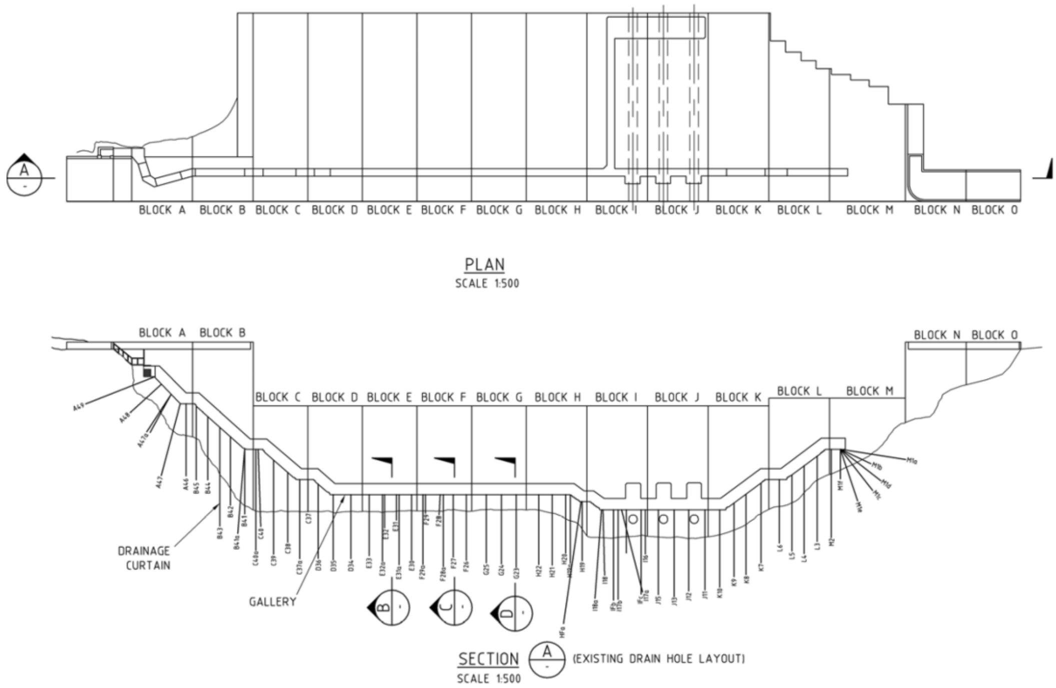

Fig. 1
Trevallyn Dam – Plan and long section

Recommendations were made to upgrade the foundation drainage system by installing new 75 mm diameter drainage holes between each of the existing 50 mm diameter drainage holes. Piezometers were also recommended to be installed at a number of locations across the dam to provide ongoing monitoring of uplift pressures.

The geology of the dam site is dolerite rock with the dominant joint orientation being sub-vertical resulting in columnar sections of rock under the dam. Both the piezometers and the drain holes were therefore orientated in the downstream direction in order to intercept the dominant rock joints.

Piezometer installation was undertaken prior to the foundation drainage upgrade and the uplift pressure monitoring data was reviewed after the works had been completed.

2.2. PIEZOMETER INSTALLATION

Piezometers were installed to monitor the uplift pressure under the dam as shown in Fig. 2. Alternative blocks were selected in order to provide a good coverage of monitoring at an economical price.

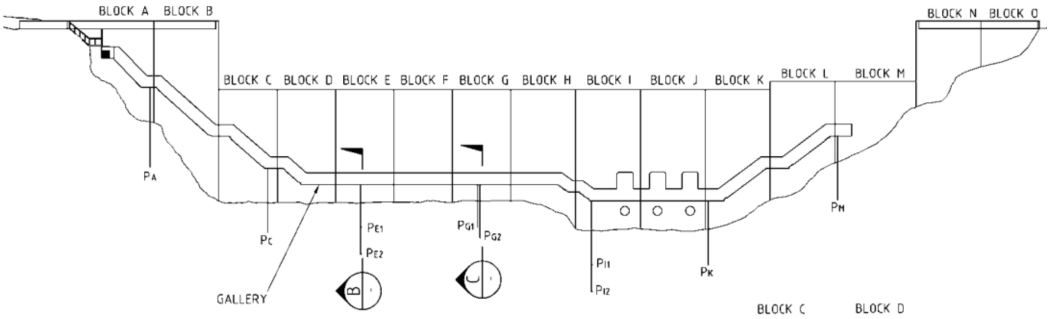

Fig. 2
Trevallyn Dam – Proposed piezometer locations

The following process was followed for the installation of piezometers:

- Holes for piezometers were core drilled and the core was immediately logged by an engineering geologist.
- A dam engineer reviewed the draft core log and provided a mark-up log to indicate the location for the piezometer with the aim of locating the response zone for the piezometer within jointed rock that would be expected to convey seepage and uplift pressures.
- The piezometer was then installed by the instrumentation contractor.

Continuous supervision and logging of the core drilling was a significant portion of the overall cost of the uplift drainage and monitoring upgrade. The supervision and logging was critical to the success of the piezometer installation and this investment was considered necessary in order to have confidence in the monitoring results obtained from the installed piezometers. If this supervision work was not undertaken, there could have been some capital cost savings; however, this would have led to a lack of certainty as to whether the piezometers had been installed in sections of massive rock that would not have exhibited any uplift pressures.

An example of a marked up borehole log that indicated the required position of a piezometer and its response zone is given in Fig. 3. In this example two piezometers were installed in a single hole, with both located in an area that was expected to convey uplift pressures.

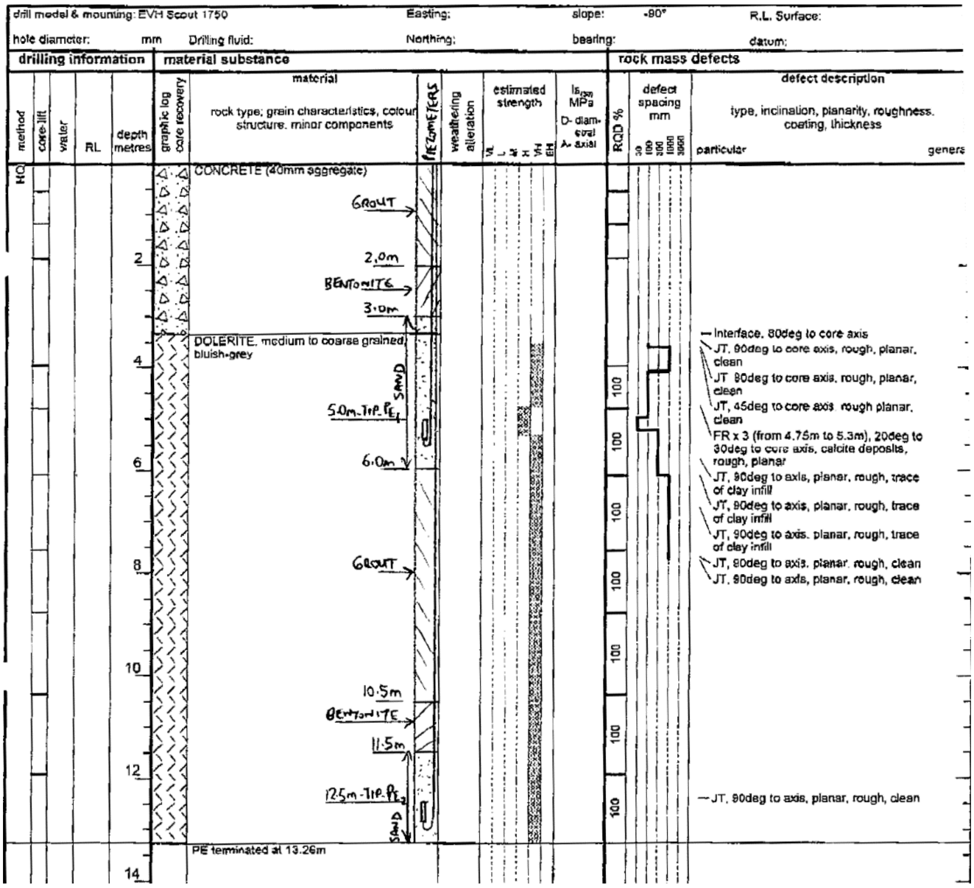

Fig. 3
Trevallyn Dam – Example borehole log showing nominated piezometer location (Pe1 and Pe2)

2.3. REVIEW OF MONITORING DATA

Data collected from the piezometers was reviewed in November 2007 after the piezometer installation and drainage upgrade works had been completed. As background to this review, it should be noted that piezometers were installed and commissioned over the period March–April 2007 and new foundation drainage holes (75 mm diameter) were drilled over the period June/July 2007. The existing foundation drainage holes (50 mm diameter) were flushed with high-pressure water in late July 2007.

An example piezometer plot is provided in Fig. 4. This was for piezometer Pe2 that is the lower piezometer shown in E block in Fig. 2 and Fig. 3. A summary of the findings from this review are given below:

- Prior to drainage hole drilling/flushing, the uplift pressure was measured as near the top of the drainage holes (e.g. at the level of the gallery).

This is below the design assumption of 2/3 reduction of the difference between headwater pressure and tailwater pressure at the line of the drains and therefore indicated that the original foundation drainage was behaving satisfactorily.

- During drainage hole drilling/flushing, the uplift pressures measured by the piezometers reduced by approximately 5 m. This was attributed to the flushing process that resulted in the standing water in the drainage holes being air-lifted out of the holes for a short period. The holes subsequently filled up with water again.
- As a result of the foundation drainage upgrade, it can be observed that the measured uplift pressures have reduced by approximately 0.3 m head from RL 108 to RL 107.7. This could be attributed to the increased drainage efficiency provided by the larger diameter drains.

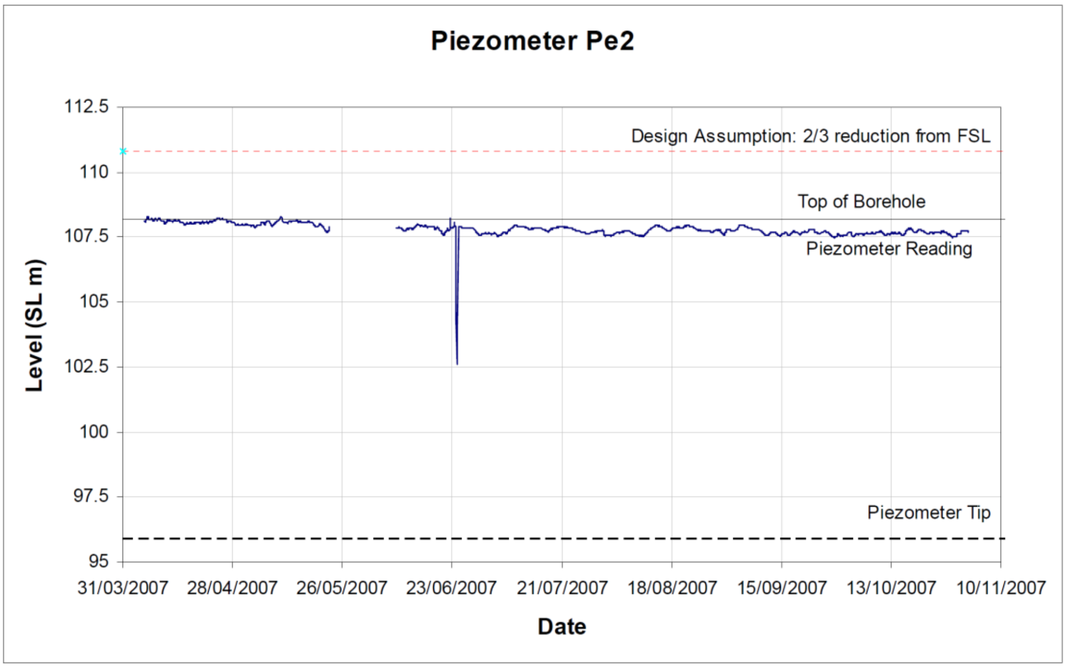

Fig. 4
Trevallyn Dam – Example piezometer plot (Piezometer Pe2)

Other piezometers also generally indicated a similar small reduction in uplift pressures following the installation of new foundation drainage and flushing of the existing foundation drains.

While it could be concluded that the foundation drainage has had minimal effect on uplift pressures, it should be noted that the key failure mode is overturning and sliding during a flood event and it is expected that the larger drainage capacity will be more critical during flood events. As such events are rare, further review and analysis is required to confirm that the upgraded foundation drainage works are adequate to reduce uplift pressures to an acceptable level. In addition, with the installation of piezometers, there is now greater certainty in relation to the uplift pressures under this dam.

3. CLARK DAM CASE STUDY

3.1. BACKGROUND

Clark Dam is a 67 m high concrete arch gravity dam that impounds Lake King William in the central highlands of Tasmania. Initial construction was completed in 1951 and raising was undertaken in 1964.

As part of the program of works, 12 piezometers were installed from the gallery at locations across the dam in 2011–12. Fig. 5 provides a plan and long section of the dam that also shows the location of the drainage gallery and piezometers.

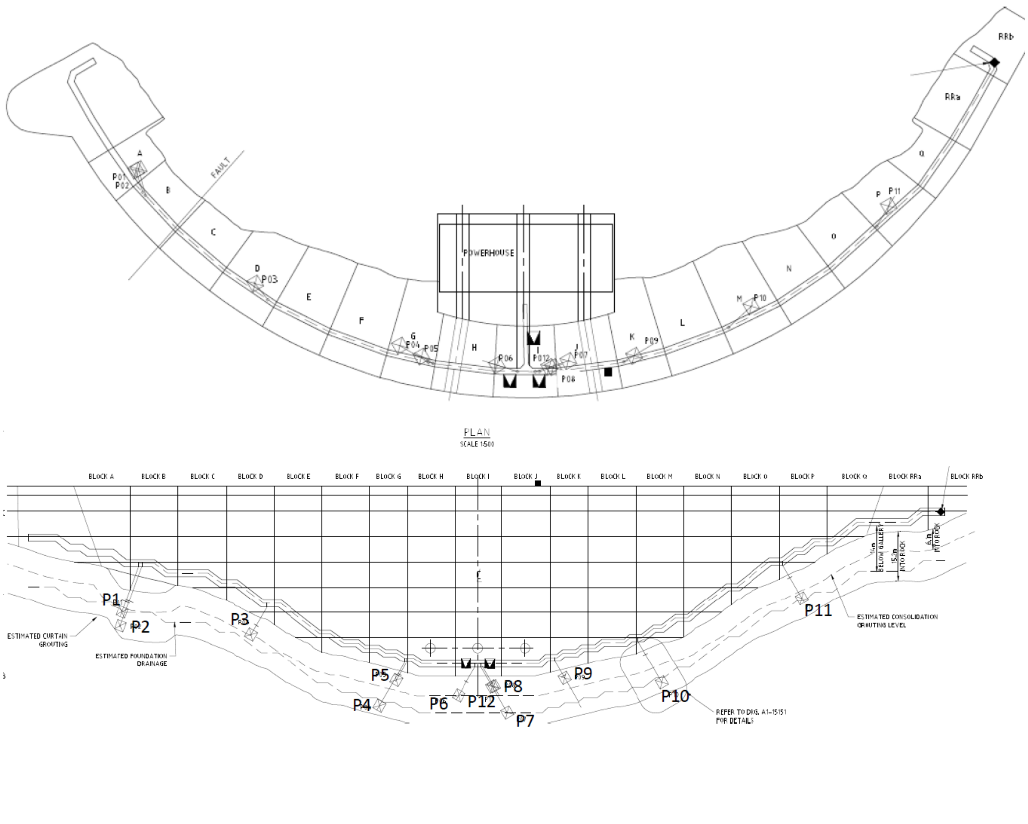

Fig. 5
Clark Dam – Plan and long section

After the piezometers were installed, 95 new drainage holes were drilled from the gallery into the foundation to improve the drainage efficiency. The new drains were 75 mm diameter compared to the existing drain size of 32 mm.

3.2. REVIEW OF MONITORING DATA

A detailed review of the effectiveness of the foundation drainage upgrade was undertaken by monitoring the piezometric pressure before and after the new drainage holes had been drilled. The results of this assessment are provided in Table 1.

Table 1
Clark Dam – Review of foundation drainage effect on piezometric pressure

Piezo	Block	Piezo Level (S.L) (m)	Foundation Level (S.L) (m)	Pressure prior to drain drilling S.L. (m) *2	Pressure after completion of drain drilling S.L. (m) *2	Foundation S.L. Pressure Reduction (%)	% of Reservoir Head Before *2	% of Reservoir Head After *2
P01	B	676.9	680.9	146.01	140	4.1%	37.7%	35.9%
P02	B	672.7	681	197.9	160.1	19.1%	46.2%	37.2%
P03	D	670.1	673.5	214.1	100.1	53.2%	47.1%	21.9%
P04 *1	G	648.3	658.3	583.8	617.9	-5.8%	87.1%	88.1%
P05 *1	G	656.1	658.4	84.6	81.8	3.3%	14.3%	13.1%
P06	I	651.4	656.3	81.8	83.7	-2.3%	12.8%	12.5%
P07	I	646.2	655.7	375.1	330.5	11.9%	54.5%	46.1%
P12	I	654.1	655.7	63.4	64.3	-1.4%	10.4%	10.1%
P08	I	654.2	655.8	77.8	86.2	-10.8%	12.8%	13.5%
P09	K	656.7	657.9	48.5	48.7	-0.4%	8.3%	7.9%
P10	M	655.4	664.6	297.5	170.4	42.7%	49.7%	27.2%
P11	P	681.1	687.5	123.2	110.5	10.3%	35.6%	29.5%

Table 1 indicates that drilling the new drainage holes resulted in an average pressure reduction across the dam of 10%, or 2.5 m of head. The maximum pressure reduction achieved was 53.2%, equating to 11.6 m head relieved from piezometer P03. It is noted that piezometer P04 pressure increased 1% of previous reservoir depth after the works; however, this piezometer had some installation issues that required removal and subsequent re-insertion which may have increased the pressure slightly.

4. CONCLUSIONS

This paper has outlined the process and reasoning behind upgrade of foundation drainage for Hydro Tasmania’s concrete dams.

An important part of the process undertaken was the measurement of foundation pressures before and after foundation drain upgrades/maintenance to quantify the state before and after and the impact of the drainage.

An upgraded drain size of 75 mm was adopted in both case studies with varying results. The foundation drainage upgrade at Clark Dam was noted to be more effective than at Trevallyn Dam. This could be due to the smaller initial drain size at Clark Dam (32 mm diameter) compared to Trevallyn Dam (50 mm diameter) or drain cleaning at Clark Dam being less frequent previously than at Trevallyn Dam.

The data provided in this paper is considered to be of value to the wider dam engineering industry.

Abstract: Ultra high arch dam has higher stress level and requirements in integrity, safety and durability on concrete dam body, it also requires that the dam concrete must have higher strength, impermeability, frost resistance and crack resistance. The low heat Portland cement (P·LH) with high belite content studied for ultra-high arch dam concrete, can effectively reduce the adiabatic temperature rise and improve the crack resistance of the concrete. According to the law of strength and hydration heat influenced by cement compound compositions, suitable content of four major minerals, say, C_2S, C_3S, C_3A, C_4AF and surface area in P•LH cement, was determined, and the relevant standards have been formulated. The concrete applied with P.LH cement standard is characterized as lower water consumption, high strength in late age, lower adiabatic temperature and complicated impermeability. P.LH concrete has been used in Wudongde and Baihetan 300m ultra-high arch dam. The current control results tested have been proven that P.LH concrete quality can meet the technical requirements with Max.temperature within

design limit without temperature crack occurred.

Key words: P·LH cement, dam concrete, temperature control and crack resistance, duration of forms removal, rinsing duration, ultra high arch dam

0. GENERAL

With increase of ultra arch dams constructed or being constructed in China, the dam height is beyond global record, such as Xiaowan(294.5m), Xiluodu(285.5m), the first cascade of Jinping(305m) and Baihetan(289m) together with Wudongde(270m)[1]. As thin dam body with high stress, compressive strength and durability of concrete, relevantly smaller cementitious ratio and larger unit usage of cementitious material on concrete will cause self-constriction of concrete and temperature shrinkage, and big self-constriction, temperature control and crack resistance are critical. “Moderate heat Portland cement (P·MH) + 35% I fly ash” as cementitious material was generally used in most of 300m high arch dams in China. Although concrete performance can meet the design requirement, the temperature control measures and management have reach current technical limit, and the safe factor can only be greater than 1.8 even in strict accurate management. The temperature crack will occur while careless in the process of implementation, which is harmful to structure safety and impermeability worse to influence the construction duration and investment directly. Therefore, high attention shall be paid to temperature crack resistance of concrete. From the view of the material, it is necessary to research a kind of special low heat Portland cement(P.LH) to own the characteristics of temperature risen slowly, small temperature rise and high performance of complicated crack resistance.

P.LH cement study was started in the regional position in Three Gorges Project, afterwards it has been used in diversion tunnel, flood discharge tunnel and absorption basin in Xiangjiaba, Xiluodu, Wudongde and Baihetan projects. Referring to dam characteristics and tech requirement of Wudongde and Baihetan, further systematic test study and proven consultation[2][3] on P.LH cement have been implemented in the aspects of structure safety, material feature, temperature crack resistance, construction tech and long-term feature. Final decision has been made P.LH concrete will be applied in the two 300m ultra arch dam.

1. SUMMARY OF P.LH CEMENT DEVELOPMENT

C_2S is main component in P.LH cement, which was used in Hoover dam in 30's last century. After Hoover dam completed, concrete strength has increased slowly[4][5]. C_2S content in Hoover dam is 46%[4] and US national standards ASTM C150 specified the C_2S content should be over 40%[7]. As lower early strength, difficult production and high cost, P.LH cement was no longer produced and applied in US after 50's and ASTM IV was only remained in US standard list[8].

C_2S is functioned as lower hydration heat, less water consumption, high step-up strength in late age and well durability, which has incomparable superiority in comparison with C_3S. There are two difficulties existed in traditional calcing process while high C_2S content cement produced, one is how to remain stability of β-C_2S crystal type to prevent transformation to γ-C_2S basically without hydration activation, the other is how to excite C_2S hydration activation to avoid lower early strength in normal ambient temperature, for instance, 7d strength is only 7MPa in accordance with US standard ASTM IV. Breakthrough of high C_2S cement research and production in China were made to realize industrial production and large-scale application with $C_2S \geq 40\%$ as dominant mineral. Chinese standard *Moderate Heat Portland Cement, Low Heat Portland Cement and Low Heat Portland Slag Cement* [9](GB 200-2003) was published to specify 7d strength of P.LH cement shall be not less than 13MPa.

In the early study and research, consideration has only been taken how to realize higher C_2S content in P.LH. With high C_3A but lower MgO content, P.LH cement was milled finer such that the complicated crack resistance performance would not get obviously different while compared with concrete mixed with P.MH cement[16][17]. It is necessary to optimize P.LH research on the current basis to meet the requirement of ultra arch dam .

2. P.LH CEMENT CHARACTERISTICS APPLIED FOR ULTRA ARCH DAM

The match of clinker's mineral composition, physical performance and overall performance of P.LH cement applied shall be optimized in ultra-high dam .

While C_2S is over 40%, C_3S will be increased properly to ensure that total quantity of silicate mineral is greater than 75% to guarantee a certain early strength. Simultaneously a certain flux mineral(C_3A and C_4AF) shall be existed. In consideration of durability, properly increase C_4AF and decrease C_3A in P.LH cement. Therefore the law of cement strength and hydration influenced by silicate and flux mineral were researched systematically. Finally it is to ascertain that the available C_3S is 30%~40% and C_2S is 40%~50%. The optimum C_3A is specified under 4% and C_4AF is in the scope of 15%~19%.

A certain chemical shrinkage occurs to cause concrete self-constriction by cement hydration which is seriously critical in low cementitious ratio concrete. The crack risk will easily incur if volume shrinkage and procedure of temperature decrease overlap together. P.MH cement with 3.5%~5.0% MgO was adopted in the Three Gorges Project to improve crack resistance such that the shrinkage can be compensated effectively with well result and concrete was in micro expansion mode while temperature decreased[18]. In the research of P.LH cement, concrete test in low MgO has ever been conducted and it is resulted that concrete volume constriction became bigger. While other restraints unchanged, concrete volume constriction with P.LH in low MgO obviously became smaller and presented micro expansion. In accordance with relevant research result, concrete volume mixed with P.LH cement in 4.67% MgO is in micro expansion mode [13], but negative influence to cement strength becomes great while MgO over 5%[14]. Thus MgO in P.LH cement clinker shall be in the scope of 4.0%~5.0%.

The compressive strength and hydration heat are affected seriously by cement fineness(Fig.1) referring to a great deal of research result. The finer the cement is, the larger the surface area will be, the faster the hydration reacts, the quicker the concrete condenses and hardens to cause high 28d compressive strength and more 3d early hydration heat. Simultaneously not only will the cement cost and water be increased, and more constricted, but also more energy will be needed while milled more finely. The research by the US Bureau of Reclamation indicates concrete frost resistance will become worse while cement was milled finely[14]. The relationship between cement surface area and RCC frost resistance by Chinese scholars makes clear it is helpful to improve concrete frost resistance while cement surface area reduced[15]. Surface area of the special P.LH cement applied in ultra arch dam shall be within 340m^2/kg in overall consideration of the influence to cement strength and hydration heat, etc.

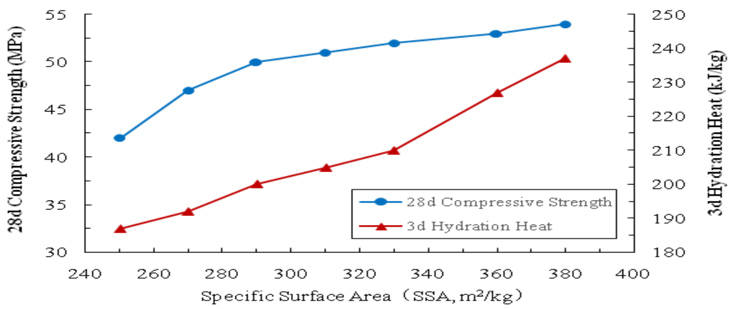

Fig. 1 Effect of specific surface area on compression strength and hydration heat of low heat Portland cement

In accordance with the research above, the mineral composition and chemical components to produce special P.LH cement in ultra arch dam are shown in Table 1, meanwhile quality acceptance items and index have been put forward in Table 2 to control the quality and stability. For this reason, CTG enterprise standard *Technical Requirement and Test of Low Heat Portland Cement Applied in Arch Dam* (Q/CTG 13—2015) was formulated in Table 2.

Table 1 Composition requirements of specific P.LH used for ultra-high arch dams

Se. No	Mineral composition & chemical component	P•LH requirement in ultra high arch dam(%)	Se. No	Mineral composition & chemical component	P•LH requirement in ultra high arc dam(%)
1	C_3S	30~40	4	C_4AF	15~19
2	C_2S	40~50	5	f-CaO	≤0.8
3	C_3A	≤4			

Table 2 Quality requirements of specific P.LH used for ultra-high arch dams

No.	Items		P·LH in Q/CTG13 **Index**	No.	Items		P·LH in Q/CTG13 **Index**
1	SSA5(m^2/kg)		≤340	6	Soundless		qualified

		Final set(h)	≤12			28d	≤300
5	Loss on ignition(%)		≤3.0				

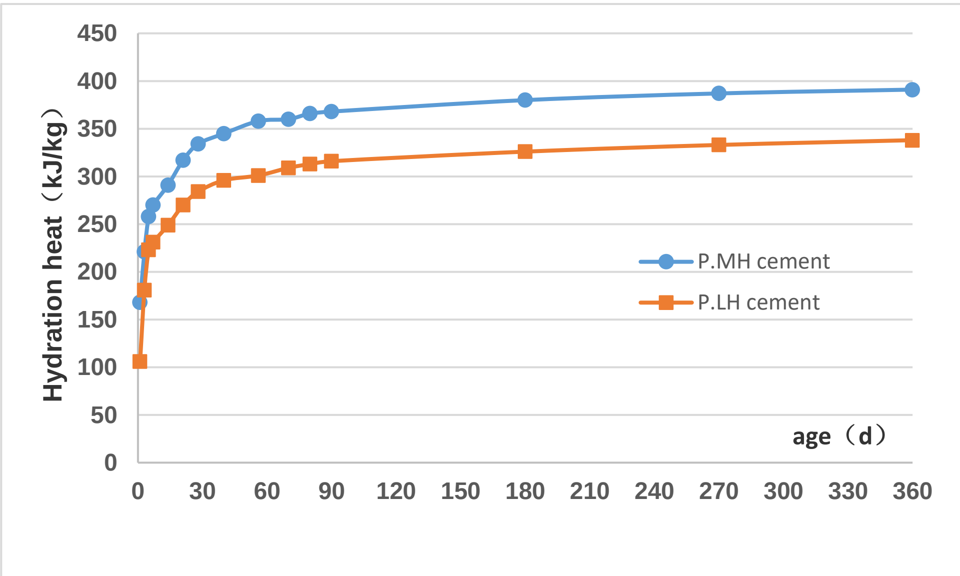

Fig.2 Development of hydration heat of P.LH and P.MH

The comparison of long-term hydration heat has been tested and the result is that P.LH cement has such characteristics of slow hydration release, small peak heat release ratio, low early hydration and lower later-aged hydration than P.MH cement, which the hydration heat of 1d, 3d, 7d, 28d and 360d is only 63%, 82%, 84%, 85% and 86% of the same age. Fig.2 is the developing law of hydration heat between P.MH and P.LH cement.

After many time of industrial production, control point and key parameter were specified during the overall production procedure, and accurate quality management system of P.LH production from quality control and mixture of raw material, calcing and milling of clinker have been established, which mass production have been realized in many cement factories in China.

3. P.LH CONCRETE CHARACTERISTICS OF ULTRA ARCH DAM

In order to ascertain P.LH cement performance, systematical comparison tests have been implemented between P.MH and P.LH cement relying on Wudongde and Baihetan ultra arch dam projects. The research shows that P.LH concrete have such following characteristics of slow early-aged strength and temperature rise developed, high later-aged strength and lower final temperature rise. The concrete mix ratio and performance test of batching mass between P.MH and P.LH are compared in Table 3 while $C_{180}40$ concrete taken from Baihetan ultra arch dam. The test result shows that major parameters are nearly the same, but only early-aged duration has 2h delay and final-aged duration has 7h delay.

The compressive strength and splitting tensile are shown in Table 4 and $C_{180}40$ concrete changing law of the compressive strength are shown in Fig.3.

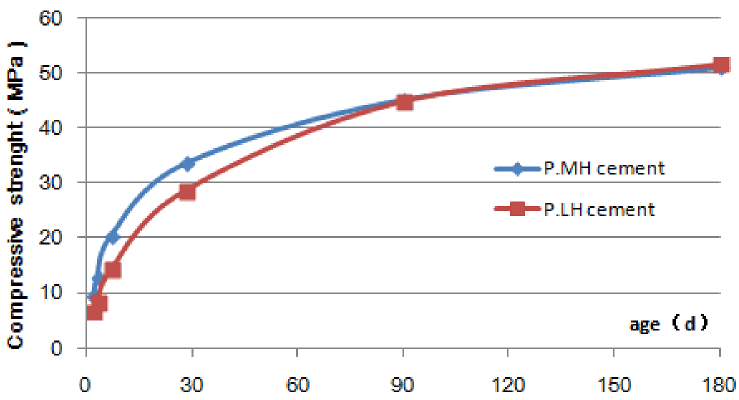

Fig.3 Compressive strength of $C_{180}40$ concrete

Table 3 Mix proportion and fresh properties of $C_{180}40$ concrete

Cement type	Water consumption/ (kg/m^3)	cementitious ratio	Fly ash(/%)	Sand(/%)	Admixture(/%)		Slump/mm	Air content(/%)	Consolidation age/(h:min)	
					Water reducer	Air entraining agent			Initial	Final
P.MH	82	0.42	35	23	0.60	0.048	46	5.1	9:11	13:54
P.LH	82	0.42	35	23	0.60	0.065	47	4.8	11:07	20:40

Table 4 Compressive strength and splitting tensile strength of $C_{180}40$ concrete

Cement type	Compressive strength(MPa)						Splitting strength(MPa)					
	2d	3d	7d	28d	90d	180d	2d	3d	7d	28d	90d	180d
P.MH	9.4	12.7	20.4	33.5	45.1	50.9	0.73	1.05	1.55	2.17	3.08	3.50
P.LH	6.6	8.3	14.3	28.6	44.9	51.6	0.56	0.75	1.19	2.13	3.01	3.58

Both can meet the design requirement and P.LH compressive strength ahead of 28d is lower than P.MH concrete, the compressive strength is nearly the same at 90d, but 180d compressive strength is greater than P.MH concrete.The increase magnitude of P.LH concrete strength in later age is greater than P.MH.

The ultimate tensile strain and static compressive modulus of elasticity of $C_{180}40$ concrete are shown in Table 5, which are nearly the same as changing law lasted and compressive strength.

Table 5 Ultimate tensile strain and static compressive modulus of elasticity of $C_{180}40$ concrete

Cement type	Ultimate tensile strain /($\times10^{-6}$)				Compressive modulus of elasticity/(GPa)					
	7d	28d	90d	180d	2d	3d	7d	28d	90d	180d
P.MH	72	96	118	121	23.4	26.7	31.4	35.6	39.2	42.5
P.LH	65	93	120	122	21.2	23.1	29.3	35.5	42.7	44.6

The time-lasted difference curve of adiabatic temperature rise are shown in Fig.4. The result is that 28d adiabatic temperature rise as same strength and cementitious ratio level of P.LH concrete is lower than the one of P.MH concrete, and the difference at 2d age is 5.0□ then to reduce gradually, so is 2.6□ at 28d age which indicates heat of P.LH concrete in early age release slowly with low adiabatic temperature rise to benefit control concrete Max.temperature effectively.

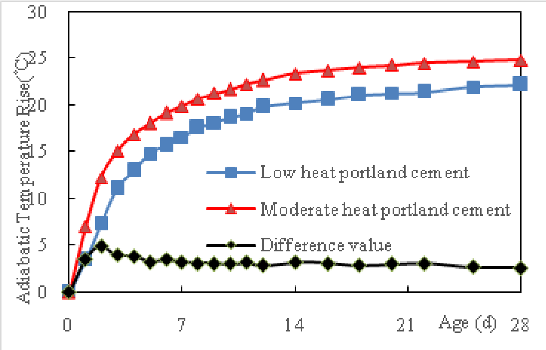

Fig.4 Adiabatic temperature rise of $C_{180}40$ concrete

The frost resistance and impermeability both are nearly the same which can reach $F_{90}300$ and $W_{90}15$ respectively with large margin.

P.LH concrete strength, deformation and durability have been tested in Wudongde and Baihetan site sample, the features and developing law mentioned-above in research stage have been witnessed in consistency with test result to meet the design requirements.

4. P.LH CONCRETE CONSTRUCTED IN ULTRA ARCH DAM

Concrete placement in Wudongde and Baihetan arch dam was started on March 16, 2017 and April 12, 2017 respectively, the stable construction process has been formed in these two 300m high arch dam.

4.1 Concrete transportation, pave and vibration

The concrete is transported dumper and poured by chute through cable crane. After concrete poured, concrete will be leveled immediately and vibrated , and manual vibrator will be used in partial corner and reinforcement steel area. In accordance with the site P.LH concrete application, it is well for workability, easy vibration with tiny aggregate segregation and bleed in these two dam, and it is tight from site core sample with high quality.

4.2 Rinse time

The optimum principle is to completely rinse cream in the placement area, tiny expose raw sand and wash cleanly in 32h~36h after pouring. The standard rinsed on transverse joint is in cream rinsed completely, micro exposition of coarse sand and cleanliness generally 10d after cast. The optimum rinse time of P.MH concrete is 16~20h after pouring, the optimum rinse time of P.LH concrete is 14~16h delay while compared with P.MH concrete.

4.3 Time of forms removal

Time of forms removal have been test at 26h, 30h, 38h, 42h and 48h after concrete cast, it is ascertain that the time of forms removal is 42h~48h to guarantee smooth appearance. The time of forms removal for P.MH concrete is 24h after cast, the time of forms removal for P.LH concrete is 18h~48h delay while compared with P.MH concrete.

4.4 Construction time-schedule

Although the rinse time and forms removal are a bit lag 2d after poured, there is no influence to the construction time-schedule even if 1d~2d delay as 7d~10d is required for the next concrete placement preparation which is in the construction time interval. As the rinse to the transverse joint is later, it is witnessed the application of P.LH concrete makes no influence to the construction time-schedule in comparison with the application of P.MH concrete.

5. TEMPERATURE CONTROL EFFECTS OF P.LH DAM CONCRETE

In the procedure of P.LH concrete construction, the intelligent temperature system, such as pre-cooled concrete, intelligent water supply and surface heat preservation are applied.

The secondary air-cooling plus mixing with ice are used in batching system of concrete and the concrete temperature at outlet of the batching system will be adjusted dynamically in accordance with the ambient and concrete temperature poured. Simultaneously, full close heat preservation dumper are adopted for transportation to improve efficiency and accelerate concrete pouring so as to reduce temperature recovery during transportation.

The layer covering time in concrete placement shall be controlled within 4h to decrease temperature recovery, and 2cm thick canvas quilt for heat preservation shall cover to prevent the concrete from temperature flowed backward and air-dry of the surface aggregate. 2h before concrete pouring, mist will sprayed to decrease temperature while temperature in the concrete pouring area in sunshine is over 23□(or greater than 28□ without sunshine). After concrete finished, mist spray shall be continued for curing and it will be changed to spun spray for curing to form flowing water film. In transverse joint and upstream and downstream surface, flower pipe is adopted for curing. 4cm thick urethane foam is coat over the upstream surface and 3cm thick polystyrene extrusion plate is pasted over the downstream surface for annual heat preservation.

In order to guarantee the temperature less than the presettings during water cooling, the Max. temperature will be preset as 2□ according to Max. Temperature to adjust water temperature and flow, and 0.5□/d temperature decrease shall be controlled after the temperature reaches peak value. The temperature control principle is small temperature difference and early cooling. The cooling pipe is always full of water after pipeline laid in the concrete placement area, and the cooling water will be changed into intelligent cooling water control system directly after concrete finished.

The result measured shows: it takes 5~10 days to the Max. value in low temperature season. it takes 4~8 days to the Max.value in high temperature season. The average temperature of concrete in the placement area shall be controlled in 24.1□~26.4□ which is lower than 27□ designed as the Max. allowable temperature.There is no temperature crack fund till now.

It is known from the site practice that the Max. temperature of concrete can be more easily controll while adoption of P.LH concrete and the temperature control measures maybe be still optimized.

6. CONCLUSION

From current quality data checked in site, well effect applied of P.LH concrete has been got.

(1) P.LH concrete applied in these two arch dams has meet the requirements specified in CTG enterprise standard with stable quality.

(2) The mixing ratio of 4 grade concrete with unit water consumption is only 79kg/m^3~83kg/m^3.

(3) The concrete mix can fulfill the construction specifications, and site core test of concrete strength, ultimate extension and durability is in consistency with design requirements.

(4) The core sample has tight appearance, smooth distribution of aggregate without visible layer joints with construction quality controlled.

(5) The concrete Max. temperature has been controlled in the allowable scope designed without temperature crack and with sufficient safe margin till now to show that P.LH concrete is stronger for crack resistance.

(6) It is still required to grasp the law and mechanism of P.LH concrete, accumulate more experience and adjust temperature control measure if available to make it better for P.LH concrete to apply.

1. INTRODUCTION

The US Army Corps of Engineers (USACE) in the USA is, amongst others, responsible for the surveilling and maintaining of dams. One of these structures is the Center Hill Dam in Tennessee, built in the 1940ies as a combination of a concrete gravity dam and a connected embankment dam. The structure is used for flood control of the Caney Fork River up to the town of Nashville and to generate electricity with a associated power station.

The subsoil mainly consists of karstified limestone. The karstification resulted in water conductivity below the dam soon after the filling. Several grouting measures were not able lastingly sealing these permeabilities. At the beginning of this century, not only damp spots occurred at the embankment dam but also major sinkholes opened up at the left abutment.

Subsequent examinations led to the decision to install a permanent concrete cutoff wall as a sealing-barrier in the until then coreless embankment dam and to permanently tie this cutoff wall to the existing concrete gravity dam. Due to dam safety reasons, an encasement wall for temporary use was specified to prevent uncontrolled trench collapse in case of sudden slurry loss into undetected voids during execution of the cutoff wall. Within this encasement wall, the permanent barrier wall was installed.

Beginning in 2011, BAUER Foundations Corp. (BFC) was tasked by the USACE with the installation of a seepage barrier/cutoff wall at the Center Hill Dam Foundation Remediation project.

Fig. 1 Site overview 2014 – Slurry Plant, BG 50 Drill-rig and MC128 with BC50 Hydrocutter

The executed features of work include the installation of two walls. The first wall, an encasement wall, extends vertically through the clayey embankment and is embedded into the underlying bedrock to provide embankment stability during the construction of the second wall, the barrier wall. The encasement wall is constructed of overlapping panels outstanding 2.25 m wide and up to 64 m deep. The second wall is the seepage barrier and provides a continuous wall, nominally 0.6 m wide, consisting as well of overlapping panels. The barrier wall extends through the concrete encasement wall into the underlying bedrock and is up to 93 m deep. BAUER BC40 and BC50 hydrocutters (Fig. 1) mounted on BAUER MC96 and MC128 foundation cranes were used to perform the majority of the works. Excavations were performed using bentonite slurry (encasement wall) and water (barrier wall) as supporting fluid and concrete was poured with the tremie method. Adding to the challenges, the project had to be executed in an environmentally sensitive area.

2. GEOLOGY AT THE DAM

Based on the Geotechnical Baseline Report (USACE 2011), the right rim of the Caney Fork River is characterized by a steep rock slope, while the left rim rises more gently about 70 m from the riverbed to the crest of the earthen embankment. The earthen embankment section of the dam wraps around the left end of the concrete dam assembled by twenty-nine monoliths and extents about 260 m at the crest to its end at the intersection with the left rim. The earthen embankment consists of compacted fill made of impervious silty clay and clayey silts.

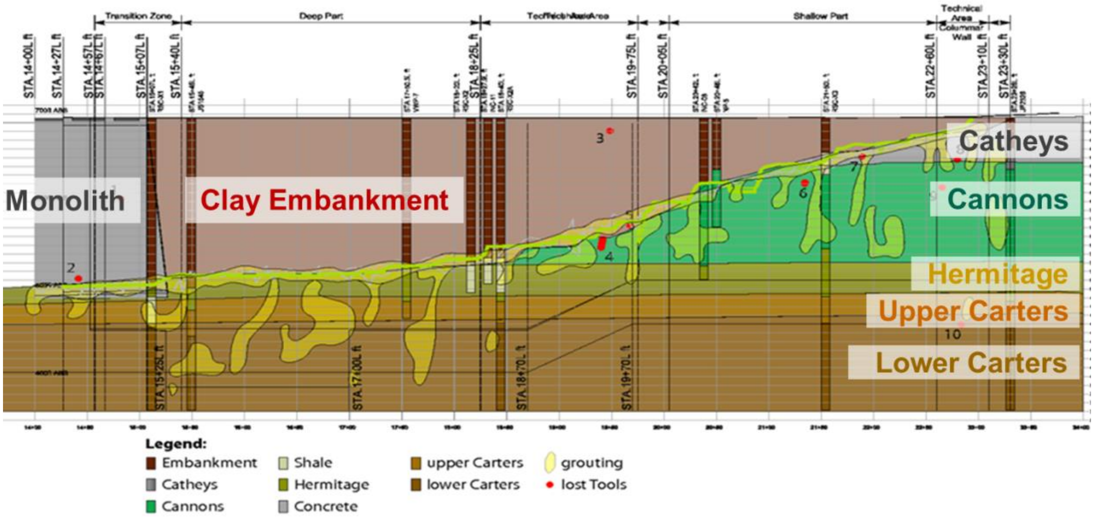

Fig. 2 Geological profile in the wall alignment including areas of high grout takes (upstream view)

The embankment was constructed directly on the existing overburden after topsoil was stripped. The alluvium is underlain by the flat lying Catheys, Cannon and Hermitage formations, with the Hermitage being underlain by the non-daylighting Carters and Lebanon formations (Fig. 2). The Cannon formation is massive bedded, all other formations are thin bedded or medium to thin bedded. The unconfined compressive strength of the rock was up to 220 MPa in the Cannons with formation averages ranging between 50 and 190 MPa.

Physical evidence of karst is visible throughout the site including disappearing streams, sinkholes, caves and extensive solution features. Bedding planes and vertical fractures have the potential to form interconnected systems of open features. These systems are especially threatening if they reach the embankment, creating piping features in the soil rock interface and potentially causing an erosion failure of the embankment.

3. PRIOR REMEDIATIONS

A grout curtain was installed during the original construction of the dam. Later, after several potentially unsafe conditions were detected in the late 1970's, a further grout curtain was installed about 3 m downstream of the embankment centerline through the embankment into the bedrock from 1982-1984. Finally, in order to reduce seepage through the bedrock and in order to allow for a safe

Barrier Wall construction, grout curtains were installed 3.6 m upstream and downstream of the wall alignment from 2009 to 2010.

4. REMEDIATION BY A CONCRETE BARRIER WALL

4.1. ENCASEMENT WALL FOR DAM SAFETY

Trenches excavated during barrier wall construction had the potential to intersect open solution features and connect the slurry-filled trench with the reservoir or the tail water and in this way cause a sudden and substantial loss of fluid. Apart from the environmental impact, such a fluid loss could destabilize the excavation trench and therefore put the dam embankment at risk. To address such a risk, an encasement wall was built that extends from the crest of the dam down to a minimum of 0.6 m into the foundation bedrock. In this configuration, the encasement wall would support the embankment by bearing earth and water pressure in the event of trench fluid loss, protecting both the embankment and the excavation equipment. The encasement wall was installed using three different approaches ().

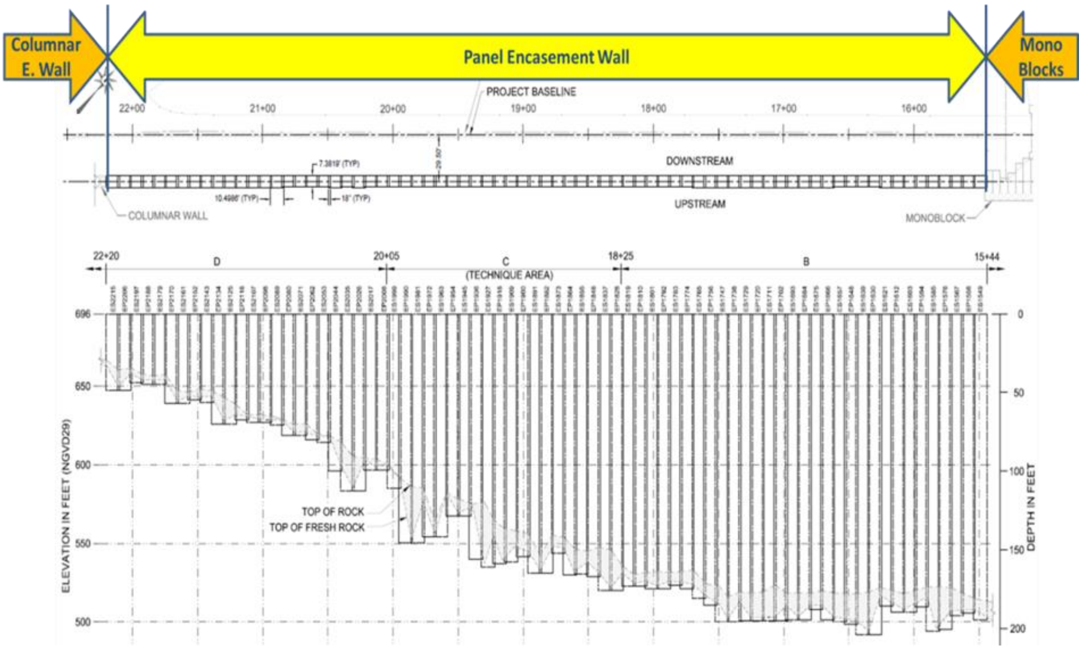

Fig. 3 As build Encasement wall panel layout.

4.2. Columnar Encasement Wall

In the shallow section at the left rim, about 36 m long, the encasement wall was specified and designed as a columnar wall consisting of 2.3 m diameter and up to 11 m deep unreinforced concrete columns. The columns were excavated under dry conditions using fully cased Kelly drilling by a BAUER BG 50, the most powerful rotary drilling rig made by BAUER at the time, capable of delivering a maximum torque of 468 kNm.

4.3. Mono Blocks

In order to tie-into the existing concrete dam monolith at the upstream face, the barrier wall runs parallel to the existing dam for approximately 14 m, which resulted in a section of the encasement wall in close proximity to the sloped upstream side of the concrete dam. This creates a wedge of embankment soil between the barrier wall and the existing dam. BFC decided to fully replace this wedge of soil with a special encasement wall. This was achieved by a series of seven, 2 m wide, 5.5 to 8.2 m long and up to about 60 m deep multi-bite panels called mono blocks, which touch each other along the long side (Fig. 4).

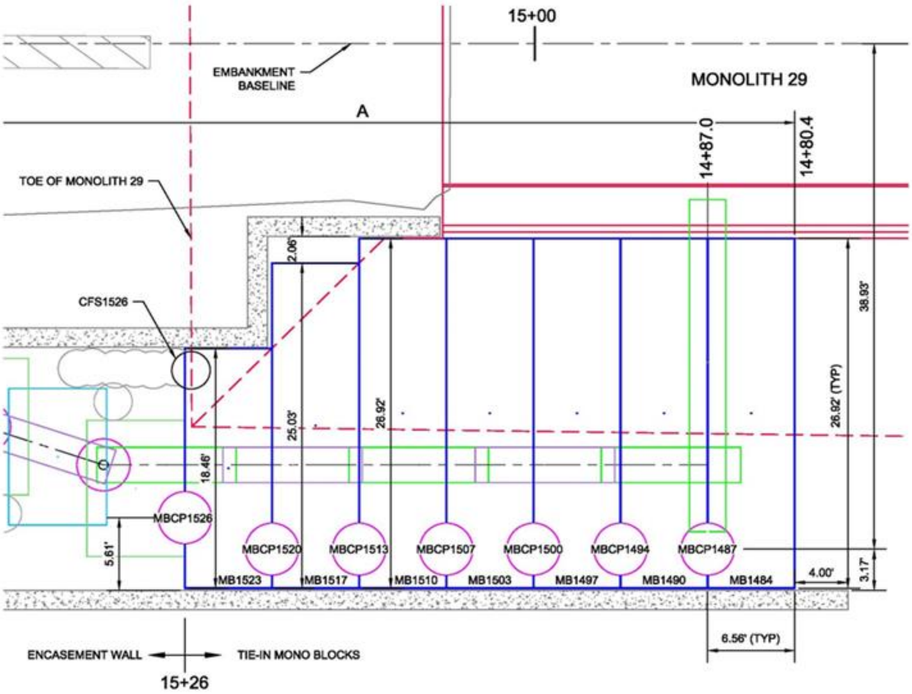

Fig. 4 Layout of Mono blocks

4.4. PANEL ENCASEMENT WALL

The 210 m long main section of the encasement wall was excavated in 3.2 m long panels reaching depths of over 60 m (). Each primary panel was pre-excavated using a hydraulic grab mounted on the MC 96. After pre-excavation of the secondary panels by the onsite available BG50, the element was fully excavated using a BC 50 hydrocutter mounted on a BAUER MC 128 foundation crane. All excavations were performed under bentonite slurry-support. Concrete was placed via two tremie pipes per panel.

The technical specifications (USACE 2011) [2] called for tolerances of 0.25% maximum panel verticality deviation, maximum six degrees panel rotation (twist) and a minimum 0.15 m overlap between primary and secondary panels throughout the full width and depth of the wall. To achieve these goals the cutter needs to be steered, which requires both precise information about the actual position of the tool with respect to design and steering capabilities.

5. BARRIER WALL INSTALLTION

5.1. COLUMNAR BARRIER WALL

BFC's design consisted of twelve 1.22 m diameter primary columns up to 57.3 m deep, and eleven 1.37 m diameter secondary columns up to 56.7 M deep. Downhole water hammers, Wassara W150 and W200, in conjunction with a Klemm KR 806-4 drilling rig were used to drill the pilot holes. All but two pilot holes (maximum verticality 0.35%) achieved the verticality tolerance of 0.25%. Due to the active steering during drilling by means of a bent sub, a piece of drill string with a slight angle to put the hammer at an angle to the borehole axis, the maximum deviations out of plumb were observed above final depth. After final excavation, the pilot holes were tremie-grouted with flowable fill.

BFC used rock augers and drilling buckets, both equipped with stingers (extended pilot bits) to follow the pilot hole, to excavate the columns. Drilling was performed dry at the top and under water at depth with the BG 50. One tremie pipe was used to place the concrete. Geometry surveys were performed using BAUER's proprietary Drilling Inclination System (DIS) and the Koden and SoniCaliper methods with the Koden data being used as as-built data set. Two secondary elements had to be reamed to a diameter of 1.45 m to meet the 0.61 x 0.15 m overlap requirement at all investigated 1.5 m depth intervals.

5.2. Panel Barrier Wall

In their proposal, BFC followed the specifications [2] and proposed a hybrid wall configuration (primary columns and secondary diaphragm wall panels). The columns in the USACE plan were designed to provide additional wall thickness at the panel overlaps due to USACE concerns that the required vertical and rotational accuracies would be difficult to achieve at more than 90 m depth. However, based on the ability of the BAUER hydrocutter to excavate the hard rock and maintain excellent verticality as demonstrated at the panel encasement wall, BFC made a value engineering cost proposal (VECP) to eliminate the columns (red circles in Fig. 5) without increasing the nominal overlap between the barrier wall panels. The government accepted the VECP.

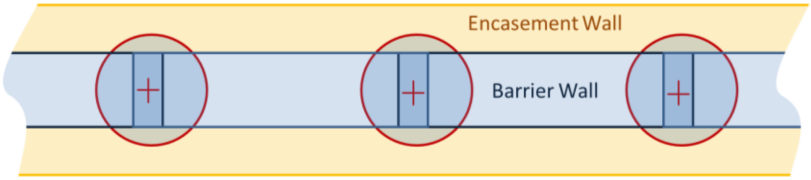

Fig. 5 Hybrid wall as specified

The barrier wall was excavated through the encasement wall concrete into the foundation rock to depths between 44 m and 93 m using two BAUER Hydrocutter. Water was used as trench support and transport fluid. Concrete was again placed using two tremie pipes. Cores and borehole images showed that the use of water as fluid in conjunction with a rigorous joint cleaning procedure allowed for an excellent bond between the primary and secondary panels.

6. TIE-IN CONNECTION TO THE CONCRETE DAM

6.3. Task to connect to the Concrete Dam

Specified was to construct a positive, continuous, full height, water-tight, connection between the encasement/barrier wall and the concrete dam [2]. The tie-in had to accommodate the sloping surface of the concrete monoliths providing a seal along the monolith to prevent floodwaters from circumventing the joint seal with the monolith. A minimum embedment of six (6) inches and a maximum embedment not exceeding four (4) feet had to be met.

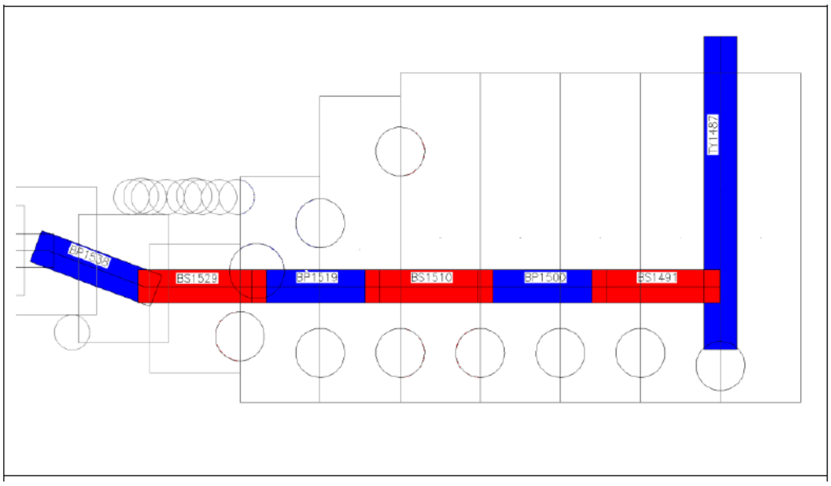

Fig. 6 Layout of barrier wall panels along the monolith 29 with perpendicular tie-in-panel element TY1487.

After installation of the special encasement wall mono blocks adjacent to each other at the upstream side of the existent concrete dam (see chapter 4.3), the joints between individual mono blocks were closed by closing piles to assure the specified function of the encasement wall.

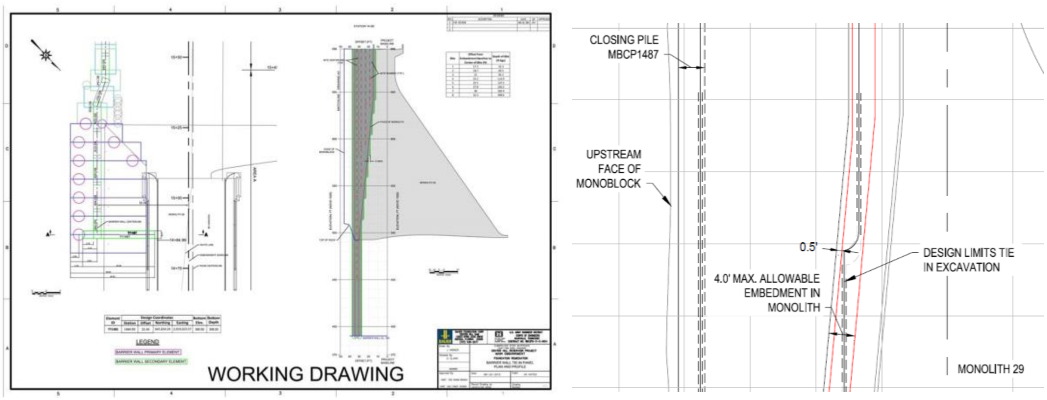

Fig. 7 Tie-in detailed design by BAUER

During the installation of the mono blocks (MB) and mono block closing piles (MBCP) construction data and quality control data had been examined and after acceptance the elements excavated and concreted. Based on these construction and quality control data and the barrier wall construction practices as proven during the installation of other elements in the main barrier wall earlier accepted to be sufficient, permission was granted to install the six typical barrier wall panels (Fig. 6) in the area along the concrete dam for the following reasons:

- All mono blocks and mono block closing piles excavations have held bentonite slurry or water without appreciable fluid loss during their construction.
- Video footage taken in mono block closing pile excavations of the mono block-to-mono block joints, and the rotated cutter panel-to-mono block joints indicate relatively tight joints between adjacent elements.

- Data from verification boring indicate homogeneous concrete from top to bottom, and a clean concrete-to-rock contact.

Only the tie-in element TY1487 was constructed differently.

The tie-in element TY1487 perpendicular to the concrete dam (Fig. 6) was installed as a primary element with a trench cutter using several bites. The first bite was furthest away from the concrete monolith and was cut to the foundation level of the concrete dam. The cutter was controlled lowered to defined depths cutting into the concrete of the monolith. Guidance was assured by the standard cutter guide frame at the top. After cutting the other bites from top to down into the monolith, finally at the position of the first bite, the cutter was lowered and excavated to the specified final depth. Due to this sequencing, the cleaning of the bottom of the element TY1487 was assured.

SUMMARY

The risks associated with failure of Center Hill Dam were significant and urgent which prompted the USACE to address this risk producing a remediation program of unprecedented scope with stringent specification requirements. Execution of the remediation provided many lessons learned for the USACE and BFC and the project achieved great technical success.

In spite of strict specification requirements, BFC met or exceeded the required plans and specifications with a value engineering approach that also resulted in significant cost savings to the government. BFC was able to achieve this using innovative techniques and equipment for diaphragm wall construction that allows for extremely accurate excavations in very challenging geologic conditions.

It was observed that for the steered hydrocutter excavation the maximum deviations out of plumb – like the maximum panel rotations – typically occur well above final excavation depth since corrections are made during drilling or excavation. The maximum deviation is not a function of depth but the system-inherent result of survey accuracy and steering capabilities. For this reason, the verticality tolerance for deep cut-off walls installed with steerable techniques should be specified as an absolute value similar to rotation and not as a percentage of depth.

The challenging tie-in connection to monolith 29 of the existent concrete dam executed successfully proved, that such connections are feasible. Connecting perpendicular was required due the highway running across the dam. Contractor detailed designed and execution achieved the specified task.

1. INTRODUCTION

To address problematic seepage from existing dams, a grouting method can be applied to the deteriorated core layers without reducing the reservoir's water level. Remediation grouting for sealing of aging embankment dam cores has been known as effective, however, no standardization is at present and publication of case histories are rare. Applying remediation grouting directly to the embankment is technically challenging. For remediation grouting of dam core layers, the main purpose should be the improvement of core impermeability. Therefore, it is not desirable to use pressure-type grouting methods such as jet grouting, vibro-type compaction grouting, rock-mass pressure grouting, etc.

For remedial grouting of embankment dam cores, a different design concept is required comparing to typical dam foundation or coffer dam grouting. It should satisfy the opposite conditions, which are the prevention of hydraulic fracturing as well as the maximization of filling of voids and deteriorated areas [1-3].

In this paper, low pressure remediation grouting techniques applied for two large dams over past 10 years are analyzed in detail. More extended case histories can be referred to the reference authored by Park and Oh [4].

Both dams in this study are central core-type fill dams. Technical descriptions of each dam's seepage-related problems are provided. In practice, the deteriorated areas of the clay core layers are not uniformly distributed; rather, the deteriorated areas are randomly distributed, which complicates grouting designs and requires flexibility in the application of the grouting technique. Therefore, the grouting specifications for each case history vary depending on the characteristics of their respective core materials, voids, and degrees of deterioration.

The study of each dam remediation informs empirical guideline for the recommended permeation grouting methods, including grout mix, injection period per stage, injection rate, and maximum fluid pressure to prevent hydraulic fracturing. This empirical guideline for successful low-pressure permeation grouting constitute the primary contribution of this study, and the guideline can be applied to substantially improve a dam's core layer permeability and efficacy as a water barrier.

2. DAM INCIDENTS

After apparent incidents derived from deteriorated clay cores, carefully designed remediation grouting technique was applied for two earth-cored embankment dams (WM and AG dam) in Korea. Table 1 shows basic dimension, construction period, brief incident description, initial measures, and final remediation by permeation grouting scheme. Fig. 1 shows typical cross-sections of the dams.

Table 1
Case study dam specifications, observed deterioration, and remediation measures

Dam	WM	AG
Construction period	1985.12–1993.06	1968.08–1971.12
Reservoir capacity (million m^3)	135	18
H (m)	55	32.5
L (m)	407	223.5
Hazard type	Exposed event 1998.04–10: Three sinkholes found near crest, excessive leakage	Exposed event 1985.06: Wet zone found on the downstream slope; 2003.07: Downstream slope-sliding after intensive rainfall
Initial remediation	2000.05–08 Partial compaction grouting (L80m)	1986.07–1989.05: General grouting 4 times; 2003.08–10: Emergency slope protection
Ultimate remediation	2003.04–09: Permeation grouting	2004.05–10: Permeation grouting

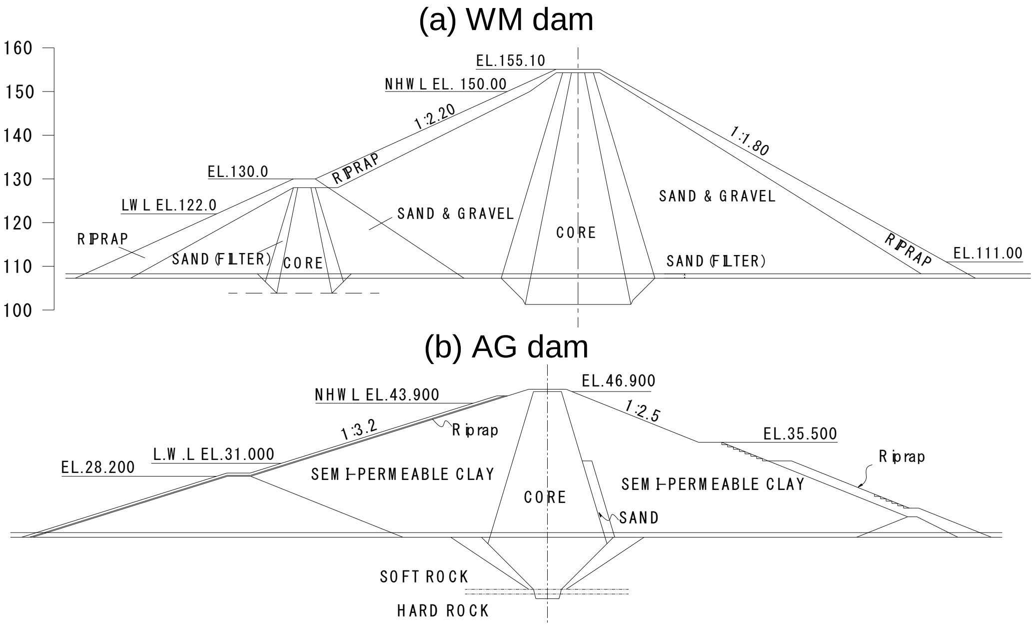

Fig. 1
Typical cross-sections of dams in this study

WM dam is a 55-m-high earth-cored rockfill dam that exhibited distinct deterioration in the form of three sinkholes near the dam crest which were observed over six months during normal dam operation (Fig. 2). Before any remediation, the dam seepage measured at the downstream toe increased up to approximately 2340 m^3/day at normal high water level (NHWL) (EL: 150.0 m). After an in-depth diagnosis, an initial remediation measure was applied by compaction grouting on 80 m out of the dam crest's total 407 m [5]. After compaction grouting, the total seepage was reduced to 860 m^3/day near NHWL. However, two and a half years later, seepage had increased to up to 1007 m^3/day and another in-depth diagnosis revealed diversified flow paths within the embankment, which required remediation to be applied over the whole length of the dam. The final remediation was conducted using low-pressure permeation grouting.

Fig. 2
WM dam sinkhole incidents

AG dam also showed distinct symptoms of core deterioration after first impoundment. The dam embankment's earthfill had very low stiffness and the core material contained a relatively large proportion of sandy soil with fine-grained soils. Various areas of wet zones were found on the downstream surface and general grouting was performed four times. After common grouting applications, heavy rainfall in 2003 induced significant downstream slope-sliding (Fig. 3). After implementing immediate emergency measures to rehabilitate the slope, permanent remediation was undertaken with low-pressure permeation grouting.

Fig. 3
AG dam incident: downstream slope-sliding (2003)

3. REMEDIAL GROUTING

WM and AG dams exhibited distinct incidents such as sinkholes, slope-sliding, excessive seepage, etc. The common feature among all dams was the degraded impermeability of their core layers, and the degrees of deterioration were largely inhomogeneous and anisotropic. Therefore, site-specific remediation grouting designs and applications were essential. Initial remedial grouting design conditions were carefully arranged according to the pilot grouting test results. Additional findings obtained through additional trial tests were applied to correct the initial grouting design conditions. Specific criteria for maximum fluid pressure, grouting duration, and refusal were determined to prevent hydraulic fracturing and grout penetration into filter layers.

Table 2 and Fig. 4 show a typical procedure and a sequence of remedial permeation grouting, respectively. Two rows of grouting holes were spaced 2 m from each other in the dam axis direction and 1 m from each other in the stream direction. The grouting sequence was conducted by interpolation with each incremental grouting spaced at least 8 m from the preceding one. For the remedial grouting of AG dam, three rows of grouting holes were partially drilled, considering a relatively higher degree of core deterioration.

Table 2
Typical permeation grouting procedure for core layer remediation

Sequence	Procedure
Pilot hole drilling	NX-sized no-water boring, accompanied by core sampling, standard penetration test (SPT), and in-situ permeability test
↓	
Pilot hole grouting	Upward grouting (1 stage : 5 m) Grout mix ratio and grout materials follow specified injection pattern

Downstream row sequence: U4 → U1 → U7 → U2 → U5 → U3 → U6

Fig. 4
Remedial grouting sequence applied to WM dam

Table 3 summarizes the specific designs of the low-pressure permeation remedial grouting techniques applied to each of the dam. In Table 3, details of the empirically proven technical specifications are addressed, including maximum grout fluid pressure, grouting duration, initial grout mix ratio, grout mix change condition, refusal criteria for every stage, fluid pressure change condition, and additive ratio. As a main grout material, either ordinary Portland cement (OPC) or micro-cement (MC) was used depending on the groutability, void ratio of the core material, and the degree of core material degradation. For WM dam remediation, two different criteria between those associated with OPC and MC were applied, depending on the type of cement material.

Although different grouting designs were applied, Table 3 reveals a common guideline that should be applied to the maximum grout fluid pressure to avoid hydraulic fracturing in remedial permeation grouting. In these empirical applications, a maximum fluid pressure of 2 × 10 kPa/m × depth (m) × 0.75 was proposed. The equation can be interpreted as that the maximum fluid pressure is approximately 75% of the hydraulic fracturing pressure at the given depth, with a minimum pressure of 10 kPa per unit depth. Therefore, the maximum fluid pressure increases with depth, limited to 100 to 500 kPa depending on the dam height.

The grouting injection duration per meter in depth varied depending on the depth; in general, the grouting duration was determined to be 8 to 40 minutes for grouting depths of less than 40 m. The commonly applied injection fluid rate was 5 to 20 L/min, and the initial grout mix ratio for core layers was mostly 1:3 or 1:2, as a mass of cement relative to that of water. The grout mix ratio gradually varied up to 1:1 depending on the in-situ condition. The grout mix change criteria during grouting were applied differently depending on the in-situ conditions of the dams; however, in all cases, the flow rate was an important factor in considering changes to the cement-to-water ratio. In some cases, the grout mix ratio was kept constant, and the fluid pressure and grouting duration were adjusted accordingly.

The grouting refusal criteria for every 5-m stage was selected primarily to limit the maximum injection quantity in liters. The fluid pressure change conditions varied a lot for each dam; however, a common approach was to set the pressure value in conjunction with the flow rate (*l*/min) condition at each depth as shown in Table 3.

More detail information regarding remedial permeation grouting can be referred to Park and Oh [4].

Table 3
Design and application details of permeation grouting for dam core remediation

Dam	WM		AG
	OPC	MC	
Max. fluid pressure (kgf/cm2)	2~5	2~5	1~4
Grouting duration (min/m) (DS: downstage; US: upstage)	Varied from 8 min for z ≤ 10 m to 40 min for z > 40 m	Varied from 8 min for z ≤ 10 m to 40 min for z > 40 m	Varied from 5 min for z ≤10 m to 45 min for z > 45 m
Initial grout mix ratio (C : W)	1:4.5 for z ≤ 20m, 1:3 for z > 20m	1:2 for core embankment 1:1 for rock foundation	1:2 for core embankment 1:1 for rock foundation
Grout mix change condition	(1st) when flow rate > 15 *l*/min: C:W=1:3 for z ≤ 20m after 5–10 min, C:W=1:2 for z > 20m after 10 min (2nd) when flow rate > 10 *l*/min: C:W=1:2 for z ≤ 20m after 5 min, C:W=1:1 for z > 20m after 10 min (3rd) when flow rate > 8 l/min: C:W=1:1 for z ≤ 20m after 3–5 min, keep C:W=1:1 for z > 20m	Keep C:W=1:2 constantly	(1st) when flow rate > 55 *l*/min for 5 min at 1 kgf/cm^2: C:W=1:1 for core embankment, C:W=1:0.8 for rock foundation (2nd) when flow rate ≤ 10 *l*/min at the max fluid pressure: C:W=1:3 for core embankment, C:W=1:2 for rock foundation
Grouting stop condition for every stage (5m)	After injection, 800–1,000 *l* maximum	Without duration consideration, 1,000 *l* maximum for core, 2,000 l maximum for rock foundation	800–1,000 *l* maximum for core, 1,000–1,200 *l* maximum for rock foundation
Fluid pressure change condition	Stop injection when there is no flow rate decrease, re-inject after not less than 4 hrs; keep approximately 3 min at least when incremental fluid pressure increase	Keep low pressure when flow rate > 20 l /min at low pressure; stop injection when there is no more flow rate decrease and re-inject after 4 hrs; keep approximately 3 min at least when incremental fluid pressure increase	Increase fluid pressure when flow rate ≤ 10 *l*/min for 5 min at each pressure stage; maintain the pressure when flow rate is 10–55 *l*/min for 5 min at each fluid pressure increase; decrease fluid pressure when flow rate > 55 *l*/min for 5 min at each fluid pressure increase; keep approximately 3 min at least when incremental fluid pressure increase

Note, z = depth from the dam crest, OPC = ordinary Portland cement, MC = micro-cement

Table 4 shows the results of dam core layer remediation by low-pressure permeation grouting for the dams in this study. Both dams that exhibited distinct dam incidents during operation were remediated over the entire crest length of the dams. The grouting depth reached to the bottom of the foundation rock mass.

The majority of the grout material was MC; however, OPC was also used in WM dam, which had sinkholes and granular cores. To stabilize the grout holes and mitigate bleeding during remedial grouting, up to 5% bentonite was added to the mix, and this addition was found to be effective.

The average amount of cement used per meter (kg/m) was 39–40 kg/m for AG and WM dams, which showed distinct incidents. The average grouting quantity was varied from 18–24 *l*/min for WM and AG dams.

Table 4
Results of dam core remediation by permeation grouting

Dam	WM	AG
Total grout length (m)	16,932	11,131
Total grout quantity (m^3)	1,544	825
Total cement quantity (kg)	690,493 OPC: 94,170 MC: 596,323 Bentonite: 30,718	437,362 MC: 424,139 Bentonite: 13,223
Avg. grout quantity (*l*/m)	91.2	74.2
Avg. flow quantity (*l*/min)	23.9	18.2
Avg. cement quantity (kg/m)	40	39
Avg. cement quantity (kg/min)	11	9.7
Mixer RPM (min)	800	1,600
Remarks	Total length of dam remediated; two grouting rows; mainly MC, partially OPC, and bentonite 5% added for core grouting, no bentonite for rock foundation	Total length of dam remediated; two or three grouting rows; MC used, bentonite 5% added for core grouting, no bentonite for rock foundation

4. VALIDATION

Because the remedial grouting state is not visible underground, the remediation work is not easily validated quantitatively. However, a limited validation can be attained by visual inspection of the surface, checkhole drilling and sampling, analysis of the sampled core's reaction to chemical indicator spray, in-situ permeability testing, analyses of grout quantities and total seepage rate change at the dam toe, and electrical resistivity surveys.

Table 5 shows the results of the remedial grouting validation. Visual inspection during checkhole drilling and sampling for WM dam showed a good core sample recovery. For AG dam, which exhibited distinct wet zones on the downstream surfaces, visual inspection after grouting showed the dry state of the previously wet surface soils. Chemical indicator reaction tests were performed on checkhole core samples using Phenolphthalein spray. It was observed that the area penetrated by the grout milk turned red after application of the Phenolphthalein spray, indicating a good filling of soil voids.

Based on in-situ permeability measurements during the checkhole drilling process, all dams showed less core layer permeability after remedial grouting. The maximum permeability coefficient before remediation of approximately 10^{-4} cm/s was reduced down to approximately 10^{-5} cm/s.

The seepage rate measured at the center of the downstream toe after remediation grouting decreased remarkably for WM and AG dams, indicating successful permeation remedial grouting.

Electrical resistivity surveys were conducted. Overall, after remediation, uniformly increasing patterns of resistivity distribution were found as depth increases.

All of the validation findings support the effectiveness of remedial permeation grouting for the dams in this study. Remediation grouting of dam cores is demonstrated using a low-pressure permeation grouting technique that effectively remediates deteriorated core layers. The empirical case studies in this paper are believed to offer an important reference for hazard mitigation technology in a wide range of aging dam rehabilitation projects.

Table 5
Validation of the effect of remediation grouting

Dam	WM	AG
Visual inspection and borehole investigation	Good checkhole core recovery condition	Previously wet zones on the downstream surface become dry
Chemical indicator reaction	Confirmed indicator reaction to grouted core sample using Phenolphthalein spray	Confirmed indicator reaction to grouted core sample using Phenolphthalein spray
Permeability (cm/s)	Before, k ~ 10^{-4} max → After 10^{-5} max	Before, k ~ 10^{-4} max → After 10^{-5} max
Average flow rate (*l*/min) or grout quantity (kg/m)	24 *l*/min for general holes → 28 *l*/min for check holes	18.8 *l*/min for general holes → 14.5 *l*/min for check holes
Seepage rate (Q) (m^3/day)	For reservoir water level = EL:147 m, Q = 640 m^3/day after 1st remediation by compaction grouting → Q = 4.1 m^3/day after 2nd remediation by permeation grouting	Leakage decreased remarkably after remediation, as measured by a temporary flowpipe-type device

SUMMARY

As empirical guidelines for the two dams, permeation grouting of two- or three-rows layout was successful with a grout column spacing of 2m in dam axis direction and 1m in stream direction on the crest. Remedial grouting sequence at least 8m spacing in an interpolation method was accompanied. Main grout material was composed of ordinary Portland cement and micro-cement. Bentonite mix with a mixture less than 5% mass quantity was effective as an additive material. Empirically proven recipe of permeation remedial grouting encompasses the maximum fluid pressure (kPa) given as 2 × 10 (kPa/m) × depth (m) × 0.75.

Seepage rate measured on the center of downstream toe after remediation grouting remarkably decreased for WM and AG dam, which indicated the successful effect of permeation remedial grouting.

Empirical case study in this paper is believed to be an important hazard mitigation technology in the field of aging dam rehabilitation project.

ABSTRACT:

Rivers play an important and life-sustaining role in human societies and provide many critical advantages to human civilizations such as water transport, habitat, economical support, transportation, etc. Degradation of rivers due to the natural occurrences such as flooding or human's interferences like constructions would inevitably lead to undesired environmental and economical situations. Therefore, river engineers have always attempted to monitor the river/coast interactions and control the potential failures which might take place in rivers. Erosion and sedimentation are two key parameters which need to be closely monitored in rivers in order to prevent unfavorable consequences. In this study, internal erosion as one of the main mechanisms for the river degradation and bank erosion has been experimentally investigated and the effect of the groundwater flow velocity and sediment discharge on the internal erosion was evaluated. The results of extensive experimentations showed that the parameters such as the length of internal erosion in sandy layer, hydraulic gradient, sediment transport parameters, and Reynolds number are significantly influenced by river bank slope. Also, an empirical correlation was proposed to predict the length of internal erosion. Results of the present study were found to be in good agreement with the previous measured data and other empirical equations.

Key Words: Internal Erosion, River Bank Slope, Alluvial Layer Slope, Experimental model

1. INTRODUCTION

Rivers are continuously changing. This concept is understood by the people who have settled near rivers for decades or engaged in agricultural activities nearby. Their memories usually involve local motions and gradual or sudden changes in rivers. One of the main sources of sediment is the bank erosion which is significant in the development of floodplain and management of water resources due to its influence on the characteristics of river channels. Bank erosion also induces extensive damages to adjacent lands and buildings [1]. Investigation of channels around the United States of America indicated that bank erosion is an important source of sediment load at most of the rivers [2]. However, channel width is one of the most effective parameters for describing the characteristics of natural channels and rivers as well as their morphology [3]. The larger the river width, the higher the bank erosion rate would become. On the other hand, bank erosion will result in the loss of adjacent fertile agricultural lands; also, it will cause millions of dollars of damages each year [4]. Studies have shown that riverbank sediments constitute about 30 to 80 percent of the total sediment load of the watershed. These sediments are usually a result of the loss of soil pore pressure as well as confining pressure during water surface lowering after a rainfall [5]. Erosion due to seepage flow is one of the causes of river bank erosion. In addition to entering a considerable amount of sediment directly into the river, this type of erosion also causes internal erosion of the river's surrounding layers and mass failure of the upper layers. Important parameters contributing to the formation of this erosion are listed below:

1- Flow exchange between the river and aquifers will loosen the surrounding layer materials; hence, sediments are washed to the river by groundwater flows from the aquifer.

2- Floods cause fluctuations in surface water level. When the water level rises, some flows enter the surrounding layers, and when the peak flood is passed the back waters from surrounding layers will cause internal erosion.

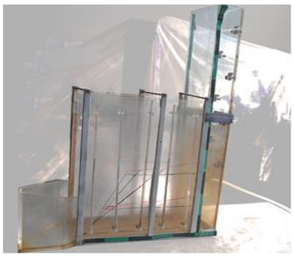
Many engineers believe seepage force causes the changes in soil particles and decreases particle resistance against the erosive forces. Seepage force is one of the reasons for internal erosion. When seepage flow has been seen in the soil, not only it's uplift force decreases the effective stress in the soil, but also seepage force from the hydraulic gradient and consequently, the water velocity in the soil is applied to the particles. Howard et.al. experimented the effect of seepage on sand erosion. They showed that different hydraulic conductivities and the river bank layering has been caused seepage forces and moving soil particles. Internal erosion is a complicated factor of the river morphologic changes [6]. Hagerti did many of studies and field investigations that resulted in the existence of a permeable layer between fine-graded and cohesive layers as being the main reason for the internal erosion. This layer drains water and removes sediments from the river bank and promotes internal erosion. Initiation of the internal erosion depends on the hydraulic gradient. On the other hand, when the rainfall goes into all soil regions, hydraulic conductivity between soil particles has been decreased, and it causes a reduction in vertical flow velocity and enlargement in lateral flow velocity [7, 8]. Furthermore, buried pipelines or reservoirs can also engender internal erosion in addition to the rainfall infiltration or lateral seepage. Fox et al. accomplished field and experimental investigations to develop a sediment transport model for measuring internal erosion and river bank failure [9]. They continued their studies and experiments to see the effect of lateral subsurface flow on bank slope stability. Experiments were conducted on 26, 36, 45, 60 and 90 degrees' bank slopes. They revealed that they were not able to predict the failure in banks with slope angles less than 45 degrees [10]. Chu-Agor et al. simulated vertical banks in their experimental model and investigated the effect of undermining due to seepage on the elimination of water pore pressure caused by sapping [11]. They did their research for a better understanding of internal erosion in a three-dimensional model, and they limited the number of variables [12]. The researchers investigated the effect of changes in statistical analysis on the bank failure in their three-dimensional model [11,13, 14, 15,16]. Rostami Pour et al. investigated internal erosion as an important parameter in bank erosion and instability in the micro model. Results showed that the particle size of the sand layer and bank height have a significant influence on the critical hydraulic gradient for the initiation of the erosion and erosion rate [17]. Salamat et al. did the experiments and found the probable parameters for erosion near river structures. Results displayed the effectiveness of particle size and changes in gradient on the formation of the internal erosion near the structures [18].

Most researchers have studied the internal erosion in vertical banks with horizontal alluvial layers, and influence of the bank slope and layers have not been considered, simultaneously. Also, in most researches, the relationship between the erosion depth and other parameters were not stated. Therefore, these parameters are experimentally evaluated in this study and attempted to find the relationship between these parameters by getting the ideas from an experimental model which was designed by Fox et al. The aim of this study was to simulate a part of the river bank in a laboratory flume to investigate erosion depth and particles' Reynolds number changes considering the bank slope as well as alluvial layers' slope.

2. EXPERIMENTAL STUDIES

2.1. EXPERIMENTAL EQUIPMENT

The experimental reservoir built in Laboratory was applied to investigate erosion depth and Reynolds number changes of the particles for different bank slopes. In this regard, experimental Plexiglas reservoir with dimensions of 50 cm length, 20 cm width, and 50 cm height was used (Fig.1). The reservoir was divided into two sections for water and materials, and these two sections are connected with a perforated Plexiglas plate having holes of 1 mm diameter. Length, width, and height of the water reservoir were 10, 20 and 100 cm, respectively. Input and output valves were put on the reservoir to manage the water depth. As shown in Fig.1, the end of the reservoir tried to mimic the channel form and the direction of the water and sediment. Additionally, the discharge from the sandy layer was measured in this section.



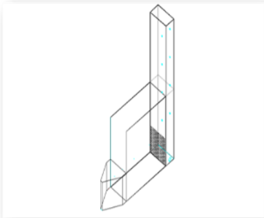


Fig. 1
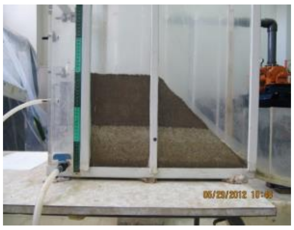
Schematic view of the laboratory flume

The experiments were conducted in two stages. First, nine experiments with three uniform gradation ranges of 0.4-0.8, 0.8-1.2 and 1.2-2.0 mm and three bank slopes of 1:1, 1.5:1 and 2:1 for horizontal alluvial layers were performed. The second stage was done with the three mentioned gradations and bank slopes with a 5-degree slope for the alluvial layers. In other words, eighteen experiments were designed and carried out in the same situation in this study. For a summary, the results of experiments with gradation range of 1.2-2.0 mm will be presented.

Generally, the sandy river banks with alluvial materials are usually surrounded by non-alluvial materials above and below the sandy layers. So, the model includes three layers of material: clay, sand and mixed soil with a moisture content of 20% as a surface layer with a thickness of 5, 10 and 15 cm respectively. Also, a timber with the same dimensions of the surface layer was used to provide a uniform load distribution for simulating the river bank, and its weight is equal to the weight of a 20 cm soil. All the steps were repeated for three different bank slopes. For the second phase, all of the layers were inclined at 5-degree (Fig. 2).



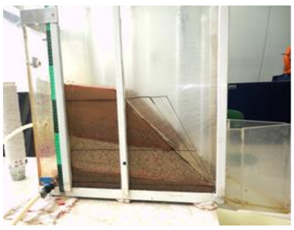


Fig. 2
A view of the laboratory flume, horizontal and steep alluvial layers

Then water enters the reservoir and penetrates into the sample. Based on initial experiments the erosion in the sandy layer has been observed in heights more than 15 cm; therefore, the water level in the reservoir was constant at first (15cm), and it was added every 30 minutes by 2 cm to see and measure the possible changes. When the water level was lower than the sandy layer bed, no significant erosion was seen; while, when the water head was more than 15 cm it caused a critical hydraulic gradient in the sandy layer. However, these values were different for various gradations. The experiment continued until the surface layer was cracked and collapsed.

Measured parameters during the tests included time, water level, output discharge from the sandy layer, the weight of the removed sediments and the depth of erosion. In every step, discharge was measured by using specified volume containers at a specific time; since the maximum compaction was considered in the other two layers and seepage was negligible; so, the measured discharge was for the sandy layer. The sediments were collected and weighted by using specified volume containers during the specific time. Also, erosion depth was measured with a scaled ruler with a precision of mm.

2.2. Dimensional analysis and determination of dimensionless parameters

The purpose of the dimensional analysis is to specify effective parameters on the phenomenon under study and to determine the dimensionless relations. There are a large number of parameters affecting these phenomena; so, it is not possible to develop a specific mathematical relation for the analysis of the problem. Therefore, dimensional analysis is used to present dimensionless parameters. Effective parameters are as follows:

$$f\ \ (h, d_{50}, \rho, \rho_s, g, \mu, q_s, L, d, \theta, \alpha, t, t_{max}) = 0 \quad [1]$$

In the Buckingham π theorem, dimensionless groups (π) are selected, and after some calculations, dimensionless relations are established based on the obtained dimensionless groups. Some dimensionless ratios are also established between some parameters.

$$f\ \ \left(\frac{\mu}{\rho d\sqrt{gd}}, \frac{q_s}{\sqrt{gd^3}}, \frac{d}{L}, \frac{\rho}{\rho_s}, \frac{t}{t_{max}}, \frac{h}{L}, \theta, \alpha\right) = 0 \quad [2]$$

The first one is Reynolds Number of the porous media. The critical Reynolds Number states that the water flow between the particles changes from laminar flow to turbulent flow has been shown in the range of 1 to 12. However, Reynolds numbers would be considered equal to or less than one as a laminar flow [19]. The second one is sediment transport parameter, and sediment discharge is considered cumulative. The third one (d^*) is the dimensionless length of internal erosion.

3. RESULTS AND DISCUSSION

As mentioned before, flow discharge, gradient, and internal erosion length were measured for different water levels, and the results are presented in graphs. Hydraulic gradient was calculated by dividing water level by the sample length minus the internal erosion length. The actual velocity was calculated by dividing the average velocity by the porosity coefficient.

3.1. DIFFERENT RIVER BANK AND ALLUVIAL LAYER SLOPES

The dimensionless erosion length (d^*) over dimensionless time (t^*) is shown in Figures 3 and 4 to see the effect of different bank slopes on the erosion length in the alluvial layer.

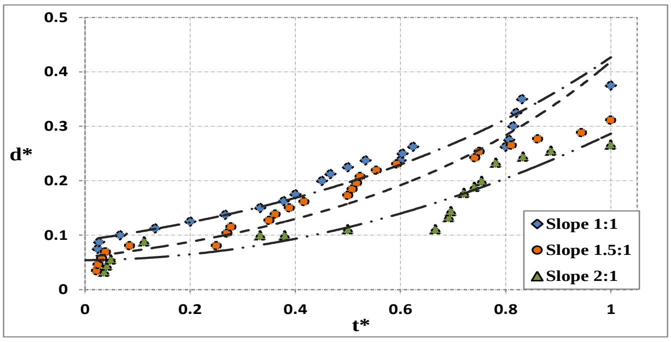

Fig. 3
Changes of d^* and t^* for gradation range of 1.2-2.0 mm for horizontal layers

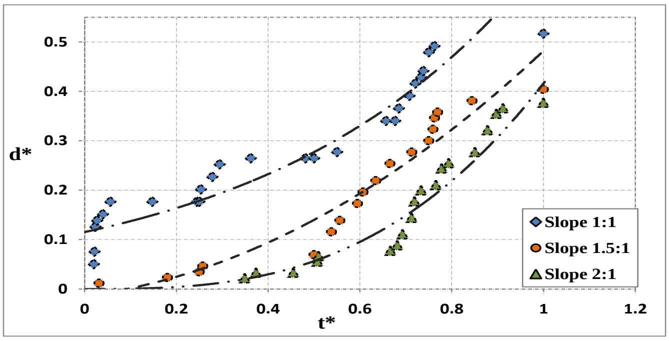

Fig. 4
Changes of d^* and t^* for gradation range of 1.2-2.0 mm for steep layers

It could be seen that by increasing the river bank slope, internal erosion in the horizontal sandy layer has been decreased. The reason might be explained that when the water level in the reservoir rises, the seepage flow through a sample has been increased and it causes growth in discharge and erosion in the layer. Since the sand particles are uniform and don't have any cohesiveness, the sandy layer is washed out through a seepage flow by passing the time. However, when the river bank slope increases, there is more amount of load from the river bank; so, the force doesn't allow to have more undermining. As it can be seen in figure 6, similar trends are observed for steep layers. Figures 5 and 6 show examples of the bank slope effect on the hydraulic gradient over time. Hydraulic gradient calculated by dividing the difference between water levels and the sample length.

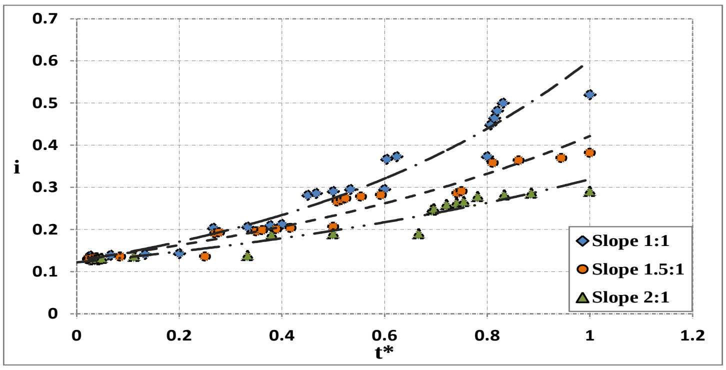

Fig. 5

Changes of the hydraulic gradient and t^* in gradation range of 1.2-2.0 mm for horizontal layers

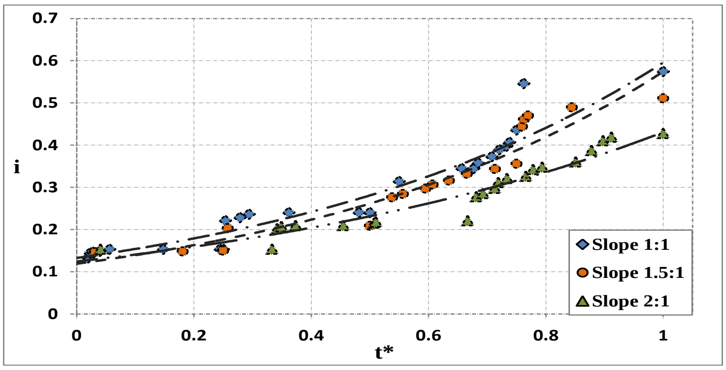

Fig. 6

Changes of the hydraulic gradient and t^* in gradation range of 1.2-2.0 mm for steep layers

Comparison of the hydraulic gradients for different bank slopes, at the same time, shows that by increasing the bank slope, hydraulic gradient is decreased. As mentioned in the previous section, when the bank slope is increased, internal erosion length is decreased; Therefore, according to hydraulic gradient formula, by reducing the internal erosion length, the hydraulic gradient is diminished. The outcomes of the experiments display that the hydraulic gradient for three bank slopes has an increasing trend over time. The reason is attributed to the higher effect of increased water level in the reservoir than the increased internal erosion length in the sandy layer. To investigate the effect of river bank slope on the particles Reynolds Number, Figures 7 and 8 are presented for various time intervals and considering different layer slopes.

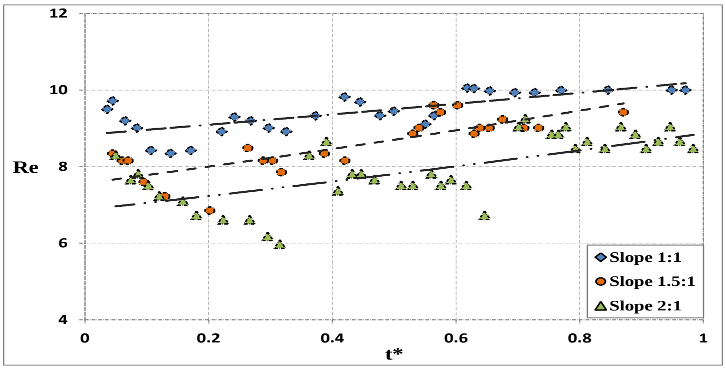

Fig. 7
Changes of Reynolds number and t* for gradation range of 1.2-2.0 mm for horizontal layers

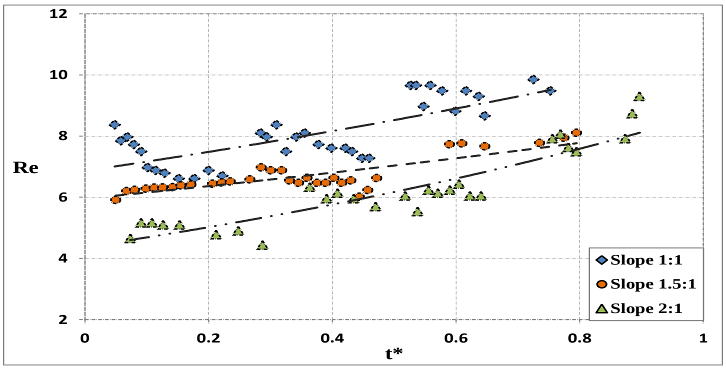

Fig. 8
Changes of Reynolds number and t* for gradation range of 1.2-2.0 mm for steep layers

The results indicated that in a specific time interval, by reducing the bank slope, the Reynolds Number is increased. This trend is observed for all the slopes. The reason might be explained with Darcy Law; also, based on Darcy's Low when the hydraulic gradient increases, water flow velocity is also increased. On the other hand, there is a direct relation between Reynolds Number and flow velocity, and the fluid density and viscosity coefficient and particle diameter are constant for each gradation; Therefore, Reynolds Number is also increased. The application range of Darcy's Law is extended to Reynolds Numbers ranging from 1 to 10. For higher Reynolds Numbers, the linear state of the seepage law will gradually change [20]. Figures 9 and 10 show cumulative sediment transport parameter curves versus dimensionless time for three different sediment gradations at three different river bank slopes. q_s^* is dependent upon sediment transport rate per unit width (q_s), sediment particle size (d), a relative density of the particles (S) and gravity acceleration. In the results of each gradation, sediment discharge per unit width was the only variable parameter.

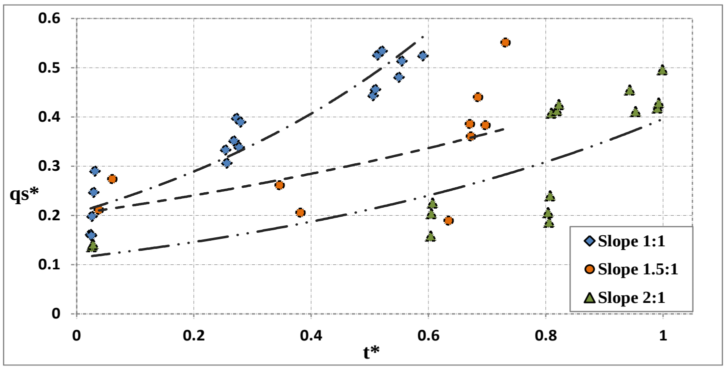

Fig. 9

Changes in q_s^* and t^* in gradation range of 1.2-2.0 mm for horizontal layers

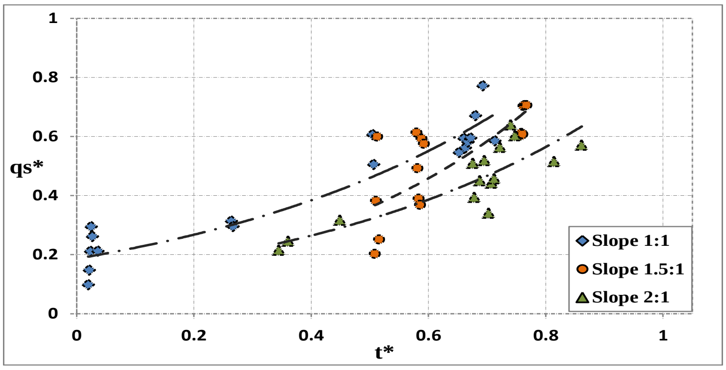

Fig. 10

Changes in q_s^* and t^* in gradation range of 1.2-2.0 mm for steep layers

The figures display that cumulative sediment transport parameter is increased over time for three different bank slopes and three different gradations. The reason is over the natural course of time, Reynolds Number and actual water velocity in the porous media has been raised and it causes the enlargement in cumulative sediments. As mentioned in the previous section, by increasing the river bank slope, internal erosion of the sandy layer is diminished, and thus, the cumulative weight of the sediments is also declined.

3.2. Empirical Relationships for Estimating the Internal Erosion Length in the Alluvial Layer

According to the dimensional analysis, dimensionless equation of d^* can be written in different experimental conditions by considering the dependent parameter of d^* as a function of the independent parameters of R_e, i, $\tan\theta$ and $\tan\alpha$. Previous studies were conducted in porous media where flow was surrounded by particles. Fluid viscosity is an effective parameter in porous media, and Reynolds number is the parameter controlling fluid motion in the porous media. Considering the least error and highest correlation between observed and calculated values, the following equation is presented for estimation of d^*value when Darcy's Law is applied. In this equation, R^2 is calculated 0.94, and its application range is proposed as Re<10.

$$d^* = 0.2\ \left(1+\frac{1}{\tan\theta}\right)^{0.82}\left(1+tan\left(\frac{\pi}{4}-\alpha\right)\right)^{1.15}(Re)^{0.47}(i)^{1.62} \qquad [3]$$

Figure 11 shows the observed values, d^* versus computed ones when Darcy Law applies, derived from Equation 3. The outcome displays that most of the data lie in the error range of ±25% indicating the appropriate accuracy of the equation.

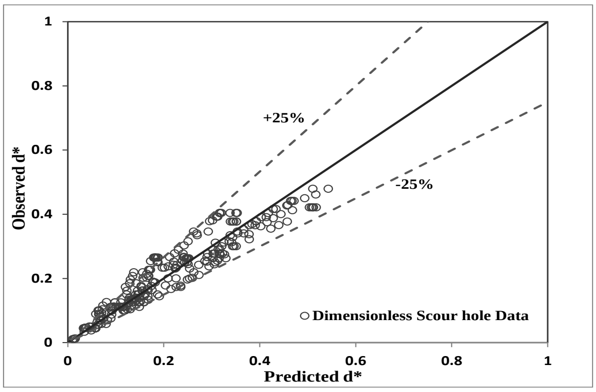

Fig. 11
Comparison of the observed and calculated values

4. CONCLUSIONS

Considering the importance of internal erosion in alluvial rivers, in this project, an experimental study has been carried out to better understand the effect of the bank slope, and alluvial layers slope of the rivers on the internal erosion and output discharge, and experimental results were compared. The results show that, by increasing the bank slope, for both horizontal and steep alluvial layers, the dimensionless internal erosion through the alluvial layer had been decreased. Also, initiation of the internal erosion in the sandy layer with a mild slope occurs more quickly than other slopes, and this issue confirms the role of the load from river bank. It is worth mentioning that by increasing the bank slope, hydraulic gradient, the Reynolds Number and cumulative sediment transport parameters are diminished. The results of this study suggest that the sediment transport parameter is directly related to the slope of the alluvial layer and by increasing the removed sediments from the sandy layer, length of the erosion hole due to undermining is move forward.

DESIGN OF DEEP SOIL MIXING WALLS AND THEIR ADVANTAGES OVER CONVENTIONAL SEALING FOR EMBANKMENT DAMS

Daniel KERRES; Ronald HASELSTEINER

Hydraulic Engineering Department, BJOERNSEN CONSULTING ENGINEERS

GERMANY

1. INTRODUCTION

1.1. GENERAL

Reconstruction of embankment dams plays a major role in contemporary flood protection projects in Germany. Many old embankment dams are too low and an increase of the height of the dam by earthmoving techniques is difficult in concern of available space. Furthermore, the dam body is often in a poor condition. A lot of embankment dams and dikes/levees show woody vegetation, in some cases this vegetation is nature protected. In order to reconstruct the dam body, static sealing elements are usually the only effective solution.

In general, sheet piles are used as a static sealing element, although they are quite expensive. Unconventional solutions exist like different types of earth concrete walls. Usually earth concrete walls are cost-effective and can be realized even in case of limited space. The selection of a construction method that fits best to the project’s boundary conditions can grant a high potential for savings. Therefore, the construction method for implementing static sealing elements should be assessed in detail during the early planning process (preliminary / final design).

1.2. PROJECT AREA

The project area is located on the Neckar River in the southwest of Germany. The length of the river is 362.3 km and the project area is approximately at river kilometer 215 from its mouth. An embankment dam protects the hinterland against flooding. The embankment dam was upgraded and partly rebuilt after a major flood occurred in 1980/81, so the structure of the dam body is partly inhomogeneous. Furthermore, there is no existing floodplain. The embankment dam is directly along the riverbed.

The Neckar River valley is densely populated and intensively agriculturally and industrially utilized (Fig. 1). Hence, the damage potential with the floodplains and hinterland is quite high.

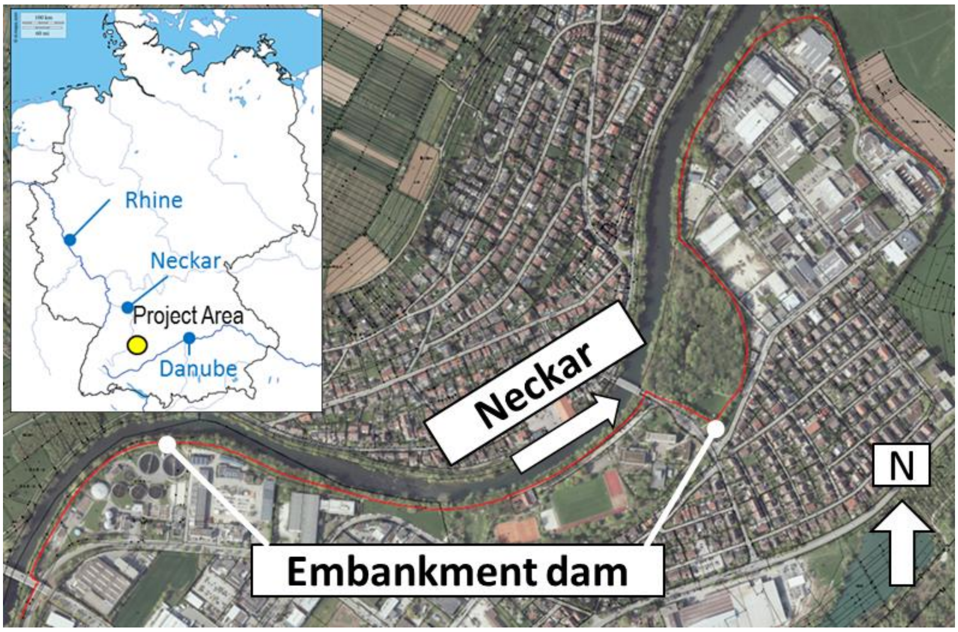

Fig. 1
Project area

Current hydraulic flooding analysis came to the result that the height of the existing embankment dams is partly not sufficient to protect the embankment hinterland from flooding. Furthermore, the existing embankment dam is not stable according to German standards (DIN 19712 [1], DWA M-507 [2], etc.). The standards do not allow woody vegetation on and close to the dam body in general. Nevertheless, many large trees developed on and close to the dam body in the project area (Fig. 2). Nature protection laws dictate that the trees must not to be removed. Thus, the strengthening of the embankment dam can only be realized by the installation of static sealing elements as discussed before.

Fig. 2

2. MODELLING

2.3. SOFTWARE TOOLS

In the case study presented in this paper the analyses for the design of static sealing elements were done with a software package developed by GGU (German: Gesellschaft für Grundbau und Umwelttechnik mbH). This software determines the deformation of the construction in consideration of the bedding modulus of the surrounding ground. This bedding modulus is not a real soil parameter. The parameter acts as a spring rate in order to model the interaction between structure and soil. The value of the bedding modulus is depending on the depth of the embedment, etc. The value for the bedding modulus needs to be selected on empirical basis.

The design of sealing elements must comply with several European and German standards as well as technical guidelines (Eurocode 2 [3], EAB [4], EAU [5], etc.). In order to carry out the required analyses, various specifications of the static system need to be defined.

The structure of the system as well as boundary conditions, load cases and material parameters will be discussed within the next sections.

2.4. BOUNDARY CONDITIONS

Load cases were defined corresponding to the specifications of DIN 19712 [1], DWA M-522 [6], Eurocode 1 [7], DIN 19702 [8], etc. They consider different conditions. In addition to standard load conditions such as water level, traffic load, earth pressure and dead load, the load case ”tree failure” is also considered in form of a geometric slope failure criterion. The load case is considered e.g. in the German technical standard for waterways MSD [9].

The mentioned technical standard recommends a reduction of statically required slope inclination. Two different failure modes need to be distinguished. In one case, a tree located on the downstream slope falls, in the other case a tree located on the downstream slope falls. For the tree located on the downstream slope a so-called minimum cross section is defined in MSD [9], which shall be considered for the special load case (Fig. 3). MSD [9] is prepared for embankment dams along waterways with permanent water level, so that trees within the upstream area are not considered, as it is required for levees [13].

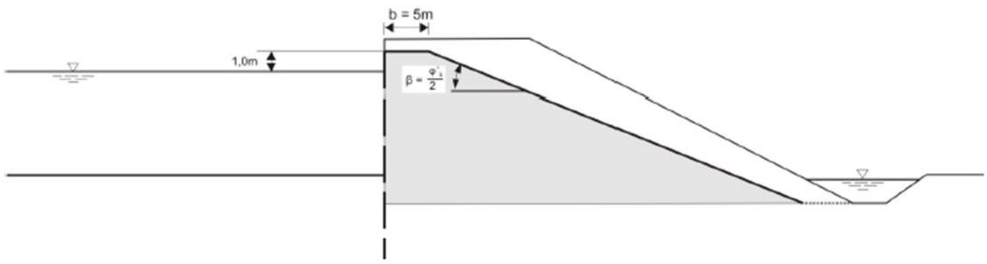

Fig. 3
Minimum statically required cross section according to the load case “tree failure” defined in MSD [9]

Usually trees located at the hinterland or on the downstream slope of an embankment dam are not endangered by flood and a loss of shear strength of the rooted soil area but by strong winds. The coincidence of a flood and storm is quite unlikely to occur. Storm events are preceding flood events. Therefore, the decisive load case for flood embankments and levees is usually the failure of a tree, which is located at or on the upstream slope and which is induced by a loss of shear strength of the rooted area. In consequence, the static sealing element has to be designed as a “free standing” wall which covers a vertical height span. This span can embrace the entire upstream dam shoulder reaching down to the foundation. For the case study, the static function of the sealing element is designed for this total loss of the upstream slope, which is justified by missing foreland, steep slope inclination, and strong flow velocities during flood that might lead to erosion process. The height of the dam crest and the downstream slope was not reduced.

Another boundary condition that has to be set is reflected by the groundwater situation. The software package of GGU allows selecting two different methods. The first method assumes a linear hydrostatic pore water pressure on both sides of the sealing. It is a simplified and conservative approach, since the pore water pressure is usually overestimated. More realistic pore water pressures can be achieved by the second method, which determines the pore water pressure, based utilizing a FEM analysis based on the theory of potentials. For the second approach the geohydraulic parameters for all soils and materials, such as permeability coefficients, effective pore content, etc. need to be available. Hence, the second approach is likely to produce results that are more realistic. The input parameters were defined by laboratory testing. It was applied for the case study.

In order to guarantee the serviceability of the future dam structure the deformation for the decisive load case was limited to L/100 (L = length of the sealing element). The length is defined as the vertical height of the sealing element.

3. DESIGN ASPECTS

3.5. GENERALS

The entire length of the existing embankment dam section in the project area is approximately 2.7 km. 2.05 km of the embankment dam shall be strengthened by placing a static sealing element. A length of 0.8 km shall be fit with an earth concrete wall realized by the so-called mixed-in-place (MIP) wall.

The MIP method destroys the actual the grain structure of the soil in situ and mixes the soil with a cement suspension. The method was developed by the company BAUER. Fig. 4 shows a schematic illustration of the method. This method uses generally three auger drillings which are rotating in opposite directions. The wall itself is established by the pilgrim step method so that each lamella is overlapped by new stitches at least once.

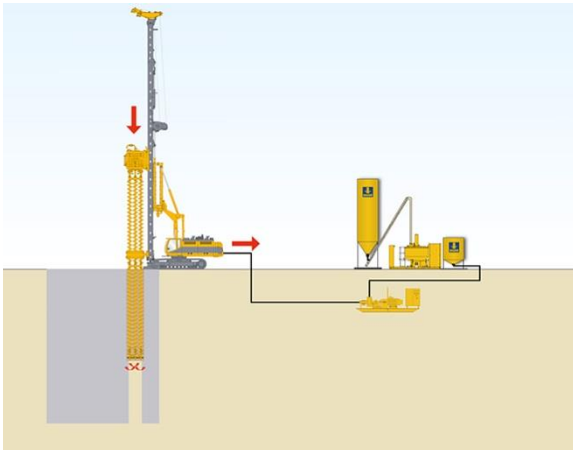

Fig. 4
Schematic illustration of the MIP method (Source: BAUER Spezialtiefbau GmbH)

By placing steel sheet piles into the suspension ditch, the MIP wall can bear loads due to the arching effect utilizing only compressive strength of cement bounded materials.

3.6. DESIGN CROSS-SECTION

The complete embankment dam construction lot was divided into different sections. For each of section a design cross-section was prepared. Fig. 5 shows geotechnical design cross section for the decisive load case “tree failure” which is allocated to the permanent design situation “BS-P” according to DIN 19712 and EC 7.

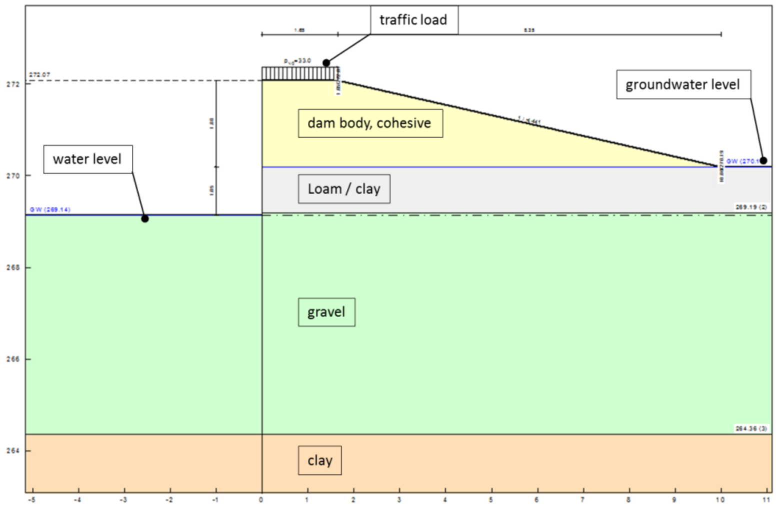

Fig. 5
Geotechnical design cross section for the load case “tree failure” (BS-P)

The height of the considered levee cross section is approximately 2.0 meters. A minimum freeboard of 0.5 m was applied. The embankment slope downstream is not that steep in this design cross-section. It is V:H = 1:4.4. The groundwater level was assumed to reach the ground surface level downstream and a selected rapid drawdown water level upstream.

3.7. CHARACTERISTIC SOIL PARAMETER

In order to carry out the required analyses for design, characteristic soil have to be selected. Table 1 gives an overview of the given characteristic values for the soil layers according to the laboratory tests.

Table 1
Characteristic soil parameters

Soil type							
	γ [kn/m³]	γ' [kn/m³]	φ [°]	c [kN/m²]	k [m/s]	δ_a [-]	δp [-]
dam fill, cohesive	19	9	25	5	$1 \cdot 10^{-8}$	0.667	-0.667
loam / clay	19	11	30	0	$1 \cdot 10^{-8}$	0.667	-0.667
gravel	18	10	35	0	$1 \cdot 10^{-4}$	0.667	-0.667
clay	18	10	35	0	$1 \cdot 10^{-8}$	0.667	-0.667

Specific weights, friction angles, cohesion and permeability coefficient were determined. The angle of wall friction between sealing and soil can be assumed according to EAB [4] or DIN 4085 [10] (Table 2).

Table 2
Assumptions for the friction angle between sealing and soil

wall texture	according to EAB	according to DIN 4085
teethed wall	$\delta_k = \varphi'_k$	$\delta_k = \varphi'_k$
rough wall	$\varphi'_k \leq 30°$: $\delta_k \leq \varphi'_k - 2{,}5°$ $\varphi'_k \geq 30°$: $\delta_k \leq 27{,}5°$	$\delta_k \leq 2/3\varphi'_k$
less rough wall	$\delta_k \leq 1/2\varphi'_k$	$\delta_k \leq 1/2\varphi'_k$
smooth	$\delta_k = 0$	$\delta_k = 0$

Due to the construction method of a MIP wall a rough wall characteristic can be assumed, so the friction angle was set to $\delta_k = 2/3\varphi$.

Furthermore, the bedding modulus has to be defined. For this, Weißenbach & Hettler [11] provide reference values depending on the level of mobilization of the earth pressure. Reference values are given for cohesive (Table 3) and non-cohesive soil (Table 4).

Table 3
Reference values for the bedding modulus for cohesive soil according to Weißenbach & Hettler [11]

level of mobilization	bulk density		
	loose	medium	dense
mob $E_{ph,k}$: $E_{ph,k}$ = 25 %	15.0 MN/m³	30.0 MN/m³	60.0 MN/m³
mob $E_{ph,k}$: $E_{ph,k}$ = 37,5 %	3.0 MN/m³	6.0 MN/m³	12.0 MN/m³
mob $E_{ph,k}$: $E_{ph,k}$ = 50 %	1.2 MN/m³	2.5 MN/m³	5.0 MN/m³
mob $E_{ph,k}$: $E_{ph,k}$ = 75 %	0.5 MN/m³	1.0 MN/m³	2.0 MN/m³

Table 4
Reference values for the bedding modulus for non-cohesive soil according to Weißenbach & Hettler [11]

level of mobilization	bedding modulus
mob $E_{ph,k}$: $E_{ph,k}$ = 25 %	9.0 MN/m³
mob $E_{ph,k}$: $E_{ph,k}$ = 37,5 %	5.0 MN/m³
mob $E_{ph,k}$: $E_{ph,k}$ = 50 %	3 MN/m³
mob $E_{ph,k}$: $E_{ph,k}$ = 75 %	2 MN/m³

Bedding modulus and the level of mobilization are interacting so the bedding modulus has to be determined iteratively.

For simplifying the calculation, the bedding modulus can be assumed constant over one soil layer, at least if the embedment depth is small [4]. Furthermore, the MIP wall may only reach down to the gravel layer in order to establish groundwater flow windows (Figure 5).

In addition, the compressive strength of the MIP wall needs to be defined. The compressive strength depends on the soil structure, the content of cement, water, bentonite, etc. According to Witt [12] a characteristic compressive strength of UCS = 5 N/mm² is a reasonable value for earth concrete structures. In DWA (2005) [15] further case studies are mentioned applying less strong mixings with a compressive strength from 0.3 to 1.2 N/mm².

3.8. ANALYSES

The applied software the deformation and moment curve for the indicated system, and it determines the necessary embedment depth. Based on these results a type of steel sheet pile can be selected which meets the requirements for the internal stability and the development of the arching effect.

When selecting the type of the steel sheet pile the dimensions are dictated by the width of the drilling augers, which is, e.g., 370 mm for the smallest rig of BAUER equipment. The steel sheet piles may therefore be maximum 310 mm wide in consideration of at least 30 mm concrete cover. Further, the distance of each sheet pile need to be defined which may vary between 1.0 to 5.0 m in general, mainly depending on the height of the dam (= failure height) and the existing geotechnical conditions.

4. RESULTS

Fig. 6 shows the results of the analysis with the software of GGU, e.g. the moments, shear forces, and the deformation along the MIP wall.

The comparison of different alternatives shows that a wall depth of 7.5 m and a distance between the steel sheet piles of 2.7 m leads to the least amount of steel per meter levees (Table 5). When the embedment depth is reduced or increased, the amount of steel increases. As a result, the MIP wall does not have to be embedded in the impermeable soil layer and the aquifer is sealed so that the groundwater exchange is guaranteed also for normal flow conditions.

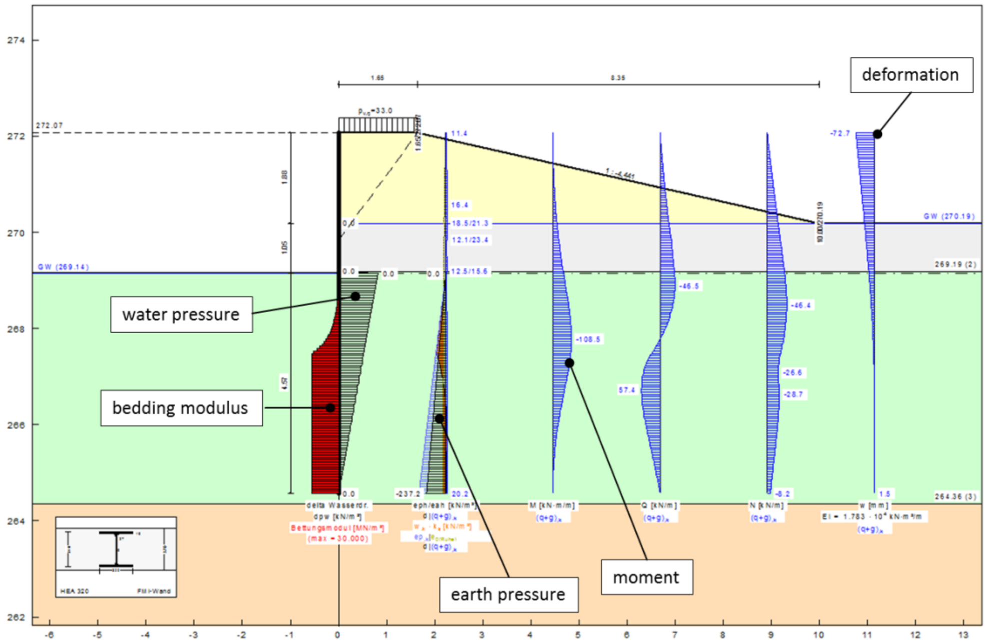

Fig. 6
Results for the design cross-section with an wall depth of 7.5 m and a distance between the steel sheet piles of 2.7 m

Table 5
Required amount of steel for different embedment depths and distances between the steel sheet piles

sheet pile	compressive strength ($f_{c,k}$)	groundwater flow window	depth [m]	distance [m]	amount of steel [t/m]	comment
HEA 320	5	yes	6.5	1.0	not determined	deformation too high, bigger profile or less distance is not possible
HEA 280	5	yes	7.0	1.2	0.45	
HEA 300	5	yes	7.0	1.7	0.37	
HEA 320	5	yes	7.0	2.1	0,32	
HEA 320	**5**	**yes**	**7.5**	**2.7**	**0.27**	
HEA 300	5	yes	7.5	2.2	0.3	
HEA 320	5	no	8.0	2.7	0.29	
GU 15N	5	no	8.5	-	1.7	
AZ 12-700	**5**	**no**	**8**	**-**	**1.09**	
-		yes	7	-	-	embedment depth too low

5. CONCLUSION

Earth concrete walls, installed by different methods such as MIP method, are an equivalent alternative to sheet pile walls; both are able to bear static loads. For the described case study groundwater flow windows needed to remain in the underground so that the embedment depth was predefined by this special environmental constraint.

Several design specifications need to be established. The referred German technical standards and guidelines offer practicable hints and suggestions. By using an accredited software program, the MIP walls can be treated like a cut-off wall regarding the design method and the design analysis.

The paper provided an indication of required design alternatives that were considered during the design process. By varying the embedment depth and the distance between the steel sheet piles, an optimum economic solution could be defined which shows the least material consumptions, mainly regarding steel.

1. INTRODUCTION

With a maximum height above foundation of 179 m and a fill volume of 84 hm³, the Ataturk dam on the Euphrates River in Turkey creates a reservoir with about 49 km³ storage capacity [1], feeds two hydropower plants with a combined capacity of 2.6 GW and offers command over an extensive irrigation area in Southeast Anatolia. A sequence of carbonate sediments – limestone, marl, dolomite – forms the foundation of the Ataturk dam. Exploratory drilling and especially galleries identified important karstification and, in consequence, the design included an extensive grout curtain (1.2 km² area) and provided drainage systems for the spillway and the powerhouse. Nevertheless, with the variation in hydrogeological properties and complexity of the hydrogeological regime in a folded and faulted rock mass, substantial uncertainty in the prediction of the development of seepage and uplift had to be admitted.

To contain the risks potentially associated with this uncertainty, a hydrogeological monitoring system was installed and, concurrent with the progress of construction of the grout curtain and with reservoir filling, the collected data were evaluated for implications related to the performance of the curtain and the building of uplift pressures [2]. Already when river diversion raised the upstream levels, a conspicuous hydrogeological phenomenon materialized: at substantial depth under the dam high artesian pressure developed in karstic rock, potentially affecting the stability of the foundation.

Options for remedial action were studied but their implementation met with technical and economical constraints. Eventually, a balance of grouting and drainage works, which produced an acceptable performance of the foundation, and an observational approach intended to manage the risks associated with conceivable but unpredictable long term effects in the deep underground of the dam was adopted. The contribution explains the concepts applied, summarizes observations obtained and the conclusion resulting for future handling of the hydrogeological problem.

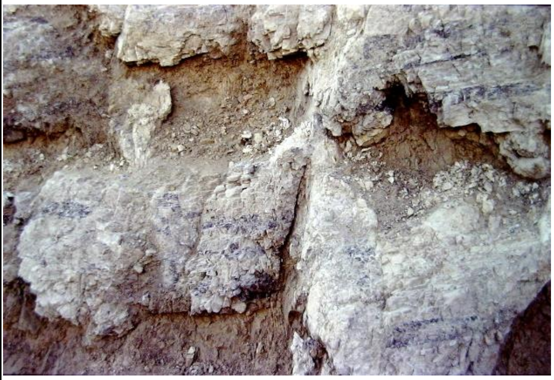
2. GEOLOGICAL AND HYDROGEOLOGICAL CONDITIONS

The dam rests on a sequence of marls, limestone and dolomite, dating from the Cretaceous, as listed in Table 1.

Table 1
Litho-Stratigraphy
Ltihostratigraphie

	Formation	Lithology	Thickness	Karst
	Bozova Formation	Marly Limestone	200-300m	modest or absent
	Sayindere Formation (Plaketli Lst.)	Stratified limestone, marl, chert	100-250m	significant, primarily related with faults
	Karabogaz Fm.	Chert, bituminous limestone	50-100m	locally important
	Karababa Formation	Dolomite, dolomitic limestone	100-150m	caves, cellular and sugary solution
		Chert, bitum. lst.	50m	aquitard
		Dolomitic limestone	>100m	significant

With the loss of calcium carbonate, the limestone of the Sayindere Formation partially became erodible, the dolomites of the Karababa Formation locally had converted into flowable sand or developed a highly porous cellular structure (Figure 1).



Sayindere Platy Limestone

Karababa cellular dolomite

Figure 1
Karstification in Sayindere and Karababa Formations
Karstification des Formations de Sayindere et de Karababa

A major anticline obliquely crosses the dam axis on the left abutment and raises the upper part of the Karababa Formation to the surface. Downstream of the dam, the Bozova Fault brings the Cretaceous carbonates in contact with clastic sediments of Tertiary age

(Figure 2). A number of minor faults crosses the grout curtain and has promoted the development of karst conduits.

Carte géologique du site du barrage

3. HYDROGEOLOGICAL OBSERVATIONS

After river diversion, springs showed up in the former riverbed, discharging about 1 m³/s. The chemical composition and isotope content of the spring water differed significantly from the Euphrates river water, the elevated temperature suggested deep circulation in a karst system. With rising water levels upstream of the cofferdam, the deep piezometers displayed

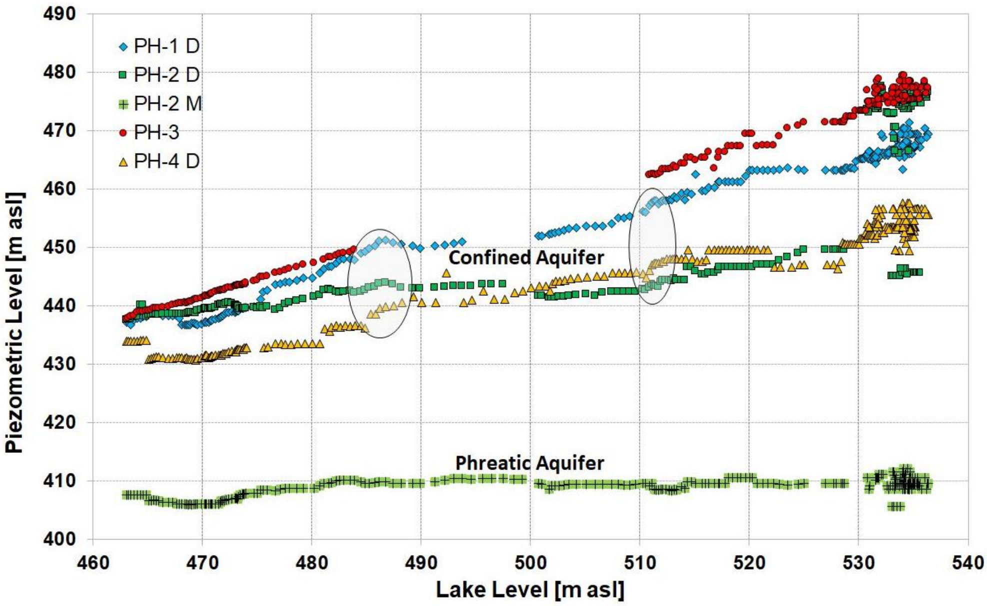

Figure 3
Samples of piezometer response (Location PH 1, 2, 3 see Fig.6)
Exemples des réactions des piézomètres (Location PH 1, 2, 3 voir Fig.6)

a confined response in the lower Karababa Formation, with the intercalated horizon of bituminous limestone acting as aquitard. In response to the upstream water levels, the piezometric head became notably artesian. Already in 1990, river water had replaced the karst water in the deep, confined aquifer. This condition implied recharge from the future reservoir area close to the dam site. Reservoir filling started end of 1989 and Figure 3 illustrates the piezometric response in the deep aquifer. Piezometer PH-2M is completed in the upper Karababa Formation at 120m depth, the other instruments sit below the bituminous layer at around 200 m depth. Although the tectonic faults cut through this layer, the latter continues to act as an efficient aquitard, maintaining a head difference of up to 70 m, reaching an artesian level of about 100 m above the valley floor downstream of the dam. However, the two ellipses in Figure 3 mark events when the response of the deep piezometers changes synchronously, evidencing a change in the hydrogeologic regime, most probably due to the opening of a new drainage path. The observations have the following consequences for the dam: (1) the magnitude of the uplift pressure raises concerns in respect of the hydraulic stability of the valley floor downstream of the dam, (2) the performance of the aquitard is not guaranteed, more important fracturing is conceivable and may raise seepage and concurrent erosion of karst affected domains. Figure 4 illustrates the importance of the piezometric head downstream of the dam.

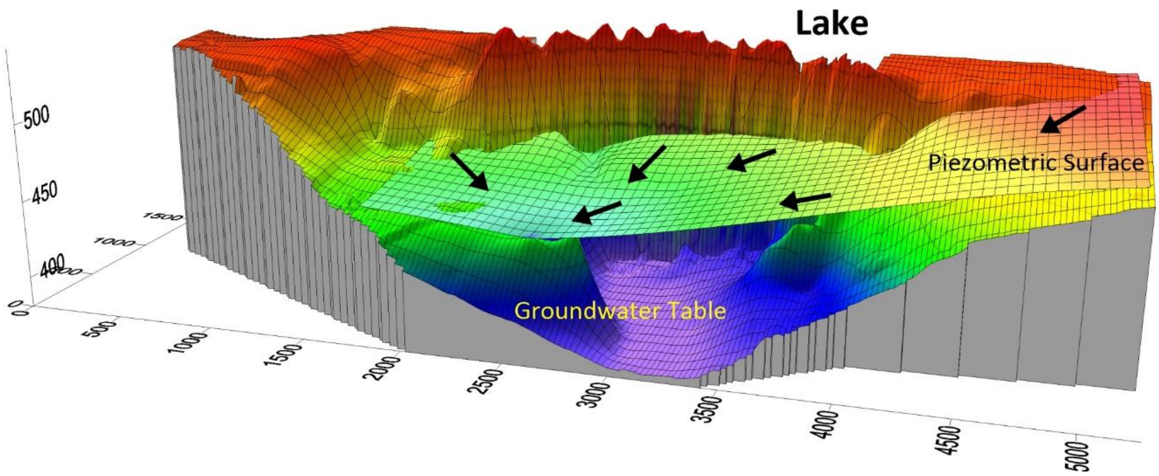

Fig. 4
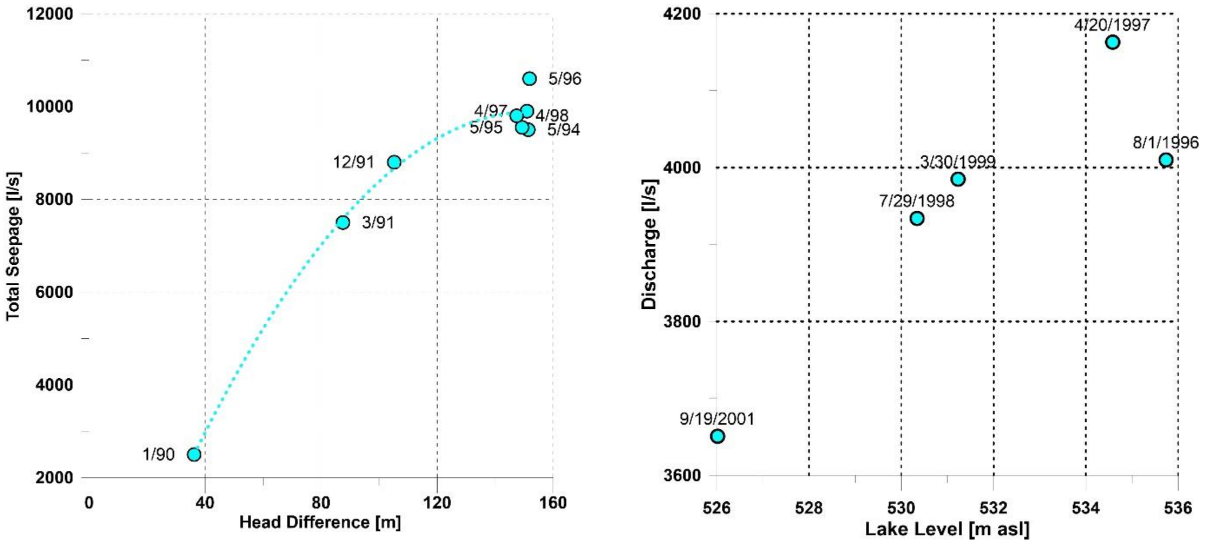
3D models of groundwater table and piezometric surface downstream of Ataturk grout curtain
Modèles 3D de la nappe phréatique et de la surface piézométrique en aval du voile d'injection

Monitoring of total reservoir seepage is a difficult undertaking. The powerplant has to be shut down for sufficient time to approach steady state and this has trans-border implications. A further complication materialized when the Birecik dam raised the tailwater to the toe of the Ataturk dam. For these reasons, no measurements were taken after 1998. To obtain the value corresponding to reservoir seepage, several other components had to be accounted for, partially poorly defined, and in consequence, a significant error has to be allowed for the data presented in Figure 5. Nevertheless, the data indicate a favorable effect of the complementary grouting works performed after the start of reservoir filling and they also imply a fairly stable performance of the curtain over the period covered by the measurements. Figure 5 also shows the discharge recorded at the drainage galleries driven at the spillway in the left valley flank and in the right valley flank behind the powerhouse and farther downstream. The excavation of these galleries started during the initial stage of reservoir filling in 1990 and was completed at the beginning of 1993. The measurements in these galleries are not very accurate and this circumstance may account for the low value reported for 1996.



Total Seepage in riverbed Seepage collected by drain galleries

Discharge measurements

Mesures des eaux de drainage

4. ORIGINAL DESIGN AND AMENDMENTS

The design had allocated generous quantities for the grout curtain and these sufficed to handle also the additional geological problems encountered during construction. The design had provided particular precautions for the foundation of the core, with blanket grouting from the surface, a main grouting gallery and an additional control gallery with fan grouting under the core [1, 2, 3]. The design included extensive drainage systems for the powerhouse [4] and for the spillway. A dense network of piezometers allowed monitoring of the efficiency of the grout curtain and the development of uplift in the foundation of the dam and at the appurtenant

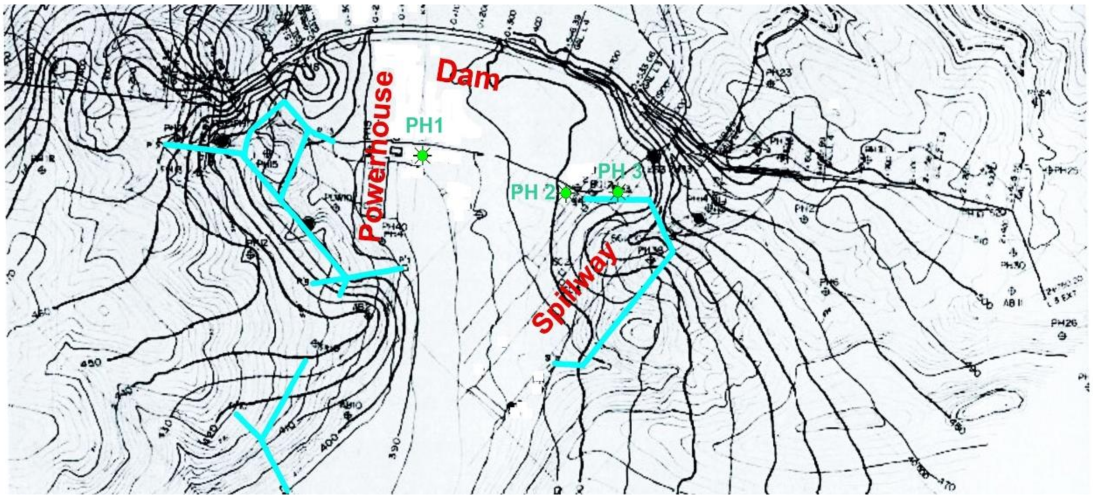

Fig. 6

Dam site, contours for phreatic aquifer, location of drainage galleries in the valley flanks

Site du barrage,

. Contours de la nappe phréatique, emplacement des galeries de drainage dans les appuis

structures. The piezometric records, complemented by tracer tests, guided the works on the grout curtain and also alerted on piezometric hazards rising at the spillway, the powerhouse and in the deep, confined aquifer.

As verified by hydrogeological model simulation, deepening the grout curtain within technical viability promised to reduce reservoir seepage by up to 30%. This effect was not justifiable from an economical point of view. Considering the uncertainty regarding the recharge to the deep aquifer, constraining the seepage at higher levels in the foundation could even risk producing higher loads on the deep aquifer. These considerations led to the decision to implement additional drainage works in both valley flanks and to adopt an observational approach for the deep aquifer. Figure 6 shows the alignments of the drainage galleries, which were constructed in the valley flanks.

After 12 years of safety monitoring, hydrogeological investigations and complementary works on the curtain, the drainage system and the instrumentation, a set of criteria for future action was defined [5], distinguishing three levels of increasing hazard. Level 3, the worst-case scenario, would prompt declaration of an Alarm and immediate start of contingency action under the following conditions:

- If the drainage gallery discharge increases by 20% or if the trend is of the order of 10% per month
- For the curtain and deep aquifer piezometers 20% abrupt change, or 10% persistent monthly trend for an Alarm. For the deep aquifer, these criteria would also apply for a loss of piezometric head because such drop would indicate serious hydrofracturing or erosion of the confining layer.
- An Alarm should be declared if the seepage water in the observation pits, the dam site springs or drainage galleries becomes turbid, indicating erosion of the foundation or the core.
- An Alarm should be given if a sinkhole develops in the vicinity of the dam or the structures
- An Alarm must be declared if the admissible uplift at the powerhouse or the spillway chute is reached or exceeded.

With the data provided by the monitoring system, timely remedial action can be taken and the hazards linked to the karst can confidently be contained.

ACKNOWLEDGEMENTS

Out of the large number of professionals participating in the implementation of the monumental project, a few are mentioned because of their specific support to the installation of the monitoring system and contribution to the geological and hydrogeological investigations: E. Basmaci, A. Öktem, E. Önhon, J. D. Andrey. Credit also has to go to the auxiliary staff who over the years conscientiously collected the wealth of monitoring data.

[5] Ataturk Engineers Joint Venture: Hydrogeological Situation at the dam site. Monitoring report. Update October 2001

SUMMARY

The designer of the Ataturk project had provided an extensive treatment for the karstic conditions at the dam site. Nevertheless, with the variation in hydrogeological properties and complexity of the hydrogeological regime in a folded and faulted rock mass, substantial uncertainty in the prediction of the development of seepage and uplift had to be admitted. To contain the risks potentially associated with this uncertainty, a hydrogeological monitoring system was installed and, concurrent with the progress of construction of the grout curtain and with the reservoir filling, the collected data were evaluated for implications related to the performance of the curtain and the building of uplift pressures. The development of high artesian head in a confined aquifer presented a particular problem. Further extension of the grout curtain met with economical and technical constraints and, in consequence, the drainage system had to be strengthened.

In this way, the construction activities for the treatment of the foundation were progressively optimized and the method for managing the risks associated with the complex conditions was developed.

RÉSUMÉ

Les auteurs du projet pour le "Barrage Atatürk" avaient d'emblée prévu un important traitement des fondations karstiques du site. La variété et la complexité du régime hydrogéologique dans un massif plissé discontinu, nécessitaient d'envisager de substantielles incertitudes dans la prédiction et le développement des filtrations et des conditions de sous-pression. Pour y pallier, un vaste système d'observations hydrogéologiques a été mis en place et, durant les travaux pour le voile d'injections ainsi que pendant le remplissage du réservoir, les résultats des mesures d'infiltrations et de sous-pressions ont été évalués et pris en compte. Le développement de forte pressions artésiennes dans un aquifère confiné a représenté un problème particulier car l'extension du rideau d'injections rencontrait des difficultés techniques et financières et il a fallu renforcer le système de drainage.

Cela a permis l'optimisation des dispositions constructives et a grandement contribué à contrôler les risques associés à une fondation complexe.

Introduction

Chitgar (Persian Gulf Martyrs) Artificial Lake of Tehran was recently developed for recreational purposes and has significantly changed the landscape of the Iran's Capital. Design and Construction of the lake involved many technical challenges. Shortage of water supply from the nearby river, a four-month impounding constraint and significant surficial evaporation made water tightening at the reservoir bed and the surface of the upstream earth fill dam inevitable. Several solutions were initially considered for the purpose of water tightening among which use of clay blanket, concrete protection layer, injection in alluvium, protective hydraulic asphalt and finally Geomembrane were notable. After carrying out comprehensive technical and economic studies and also considering the time frame of construction, use of Geo-synthetic material was ultimately selected as the best option. In this paper, challenges and lessons learned during construction and installation of Geomembrane for the 130 hectare Chitgar Lake were discussed. Authors hope that information provided herein can be used and applied to many similar projects and help toward improving technical knowledge and successful completion of large scale water tightening projects around the world.

1. Chitgar Lake and City of Tehran

Chitgar Lake was developed with the objectives of improving on recreational, commercial, environmental attractions of the Tehran City. The Lake is located in West side of Tehran near the Chitgar National Park and also in vicinity of the Alborz Mountain Range. These nearby natural features have dramatically improved the scenic beauty and landscape of the area.

Figure 1 Areal View of Chitgar Lake located West of Tehran City

In General, the Lake Project consists of three main components which are illustrated in Figure 2.
A: Diversion Dam
B: Water Conveyance from Kan River to the Lake
C: Rock-fill/Earth-fill Dyke/Dam and Reservoir

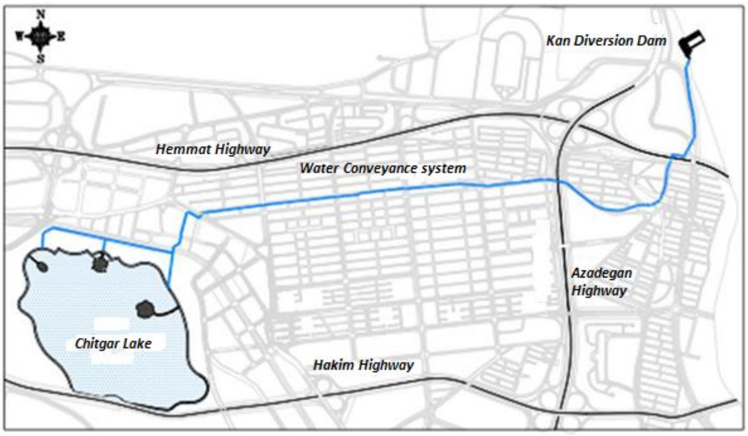

Figure 2. Different components of Chitgar Lake Project (Diversion Dam (Top Right), Water Conveyance and Reservoir)

Kan Diversion Dam is a concrete structure built on the seasonal Kan River at a 7km distance to the Lake in order to increase the level of river water and divert it toward the Lake.

The 7-km Water Conveyance from the Kan River to the Lake is composed of a 3.5km concrete channel (1.5mx1.1m) and 3.5km of GRP Pipes with varying diameters from 600mm to 1200mm. The conveyance was designed to have a maximum discharge capacity of 1.2m^3/s.

The Lake Reservoir spread over a 132 hectare area with a storage capacity of 6.9 million cubic meter was the primary component of the project. The Lake has three artificial islands with a total area of 3 hectares within it. By considering the topography of the area and the required depth and geometry for the Lake, a 10.5 m high and 735 long earth-fill dam plus a perimeter dyke with a total length of 4km were constructed.

2. Necessity of Water tightening for Chitgar Lake

Total allowance for the Lake annual inflow is about 5 million cubic meters while 2.2 million cubic meter is the estimated annual loss through surface evaporation.
In order to identify the soil layer underneath the Lake and estimate the amount of water seepage, investigation bore holes were drilled initially on a 400x400 grid and later on refined to 200x200 and 100x100 grids over the Lake's area. Based on the permeability test results at the depth of 2m, the permeability and seepage potential for the reservoir bed area were listed as given in Table 1. Following assumptions have been used to determine the permeability parameters provided in the table:

- Darcy formula (Q=k.i.A) was used for calculation of discharge. ("k" value varies over different areas)
- Depth of reservoir was considered between 4m and 10m with an average depth of 7m.
- Depth of fine-material alluvium layer of reservoir was assumed 4m.
- Hydraulic gradient was considered 1.75. (i.e. 7/4=1.75)
- Area of the reservoir is roughly equal to132 hectares

Table 1. Summary of Estimated Seepage Rate for the Reservoir Based on Permeability Test Results

Annual Seepage	Seepage Rate (m^3/s)	Reservoir Area	Average Permeability	Permeability Range (cm/s)
0.72	0.023	24.4	4.06×10^{-6}	$10^{-6} – 10^{-5}$
1.61	0.051	5.4	4.10×10^{-5}	$10^{-5} – 10^{-4}$
74.35	2.36	32.4	3.15×10^{-4}	$10^{-4} – 10^{-3}$
905.95	28.73	37.8	3.29×10^{-3}	$10^{-3} – 10^{-2}$
983	**31.16**	**100**	1.35×10^{-3}	**Total**

Calculated seepage rate based on the above assumption and parameters was $31.16m^3/s$. With the assumption of full reservoir, this leads to an annual seepage rate of approximately 1 billion cubic meters. This suggested that water tightening and through insulation for the reservoir was essential for the Chitgar Lake Project.

Due to the significant depth of alluvium (more than 100m), water tightening underneath the dam body and the perimeter dyke was impractical and the only feasible option was continuous interconnection of the water tightening membrane over the entire area of the reservoir and extending to upstream face of the dam. This solution provides many advantages compared to other possible remedies such as elimination of dam foundation water tightening activity, seepage-free dam body resulting in size reduction of the dam's core and finally ease of construction.

3. Lake Water tightening Alternatives

3.1. Water tightening using Clay Blanket

One method for the purpose of reservoir water tightening is to use Clay Blanket. As common practice, in order to have a functional clay blanket with a permeability rate of 1×10^{-7} and less, materials with following specifications should be used: 50% passing rate through No. 200 Filter, a minimum 20% clay material, above 20% Plasticity Index (PI) and above 30% Liquidity Index (LL) Index.

Overall, due to the poor condition of reservoir fine-grain material and unavailability of suitable material in proximity of the project which lead to undesirable seepage, the option of Clay Blanket was rejected. Another disadvantage of the use of Clay Blanket was the possibility of plant growth on the surface which can contribute to pollution of the Lake and have negative environmental impact.

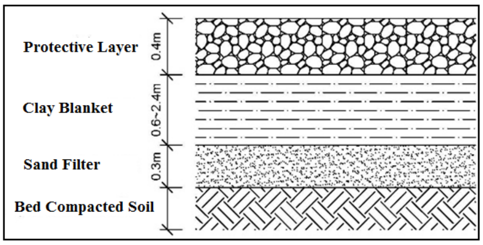

Figure 3. Section Details for Clay Blanket Option

3.2. Water tightening using Impervious Concrete Layer

Use of impervious concrete layer for large reservoirs such as Chitgar Lake's is not common due to the significant size and importance and functional requirements of the Lake. From the geotechnical perspective, impervious concrete layer should be placed on the alluvium with a concrete thickness of about 30cm plus uniform thermal reinforcement and water-tight joints every 12 to 15 meters.

Due to the high cost and relatively lengthy implementation time, the impervious concrete layer was not considered as a suitable option when compared to other feasible options.

3.3. Water tightening using Injection in Alluvium Layer

In principle, injection in alluvium is very rarely used where no other option is available. This method requires heavy research before implementation and is often very costly and time consuming. In addition, injection in fine-grain material would result in rupture and fracture of soil due to hydraulic pressure of injection which is highly undesirable.

For Chitgar Lake, considering the type of soil material, permeability and fine material amount, use of high Belin cement grout injection to achieve allowable permeability (even with injection holes distanced at 75cm) was not feasible. Furthermore, injection using chemicals like Resin and Polyurethane and other stable and unstable materials considering their permeability, even by using 50cm apart injection holes deemed not suitable to achieve the target permeability. Even if this method was somehow technically feasible, due to the large size of the Lake, the projected cost and implementation time makes it impractical within the given time-frame of the project as it required nearly 2.5 million injection holes over the entire Lake area.

3.4. Water tightening using Asphalt Concrete

Another suggested method for water tightening of the Lake was use of Asphalt Concrete with the details shown in Figure 4. In this method, after soil improvements and implementation of the base layer, asphalt concrete with a total thickness of 10cm placed in two 5cm layers is used. Gravel size for this type of concrete is not to exceed 12.6mm according to the ICOLD's Bulletin 114. About 7 to 8 percent bitumen may be used with a porosity of less than 4% to result in a permeability factor of 1×10^{-8} to 1×10^{-9} cm/s. The bitumen has a penetration rate of 80-100 based on ASTM D5-D946 for asphalt concrete. As top finish, a 10mm thick layer of bitumen mastic layer will be placed on top of the asphalt concrete to improve water tightening and provide physical protection.

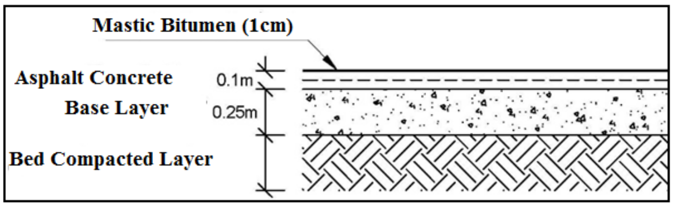

Figure 4. Section Details for Asphalt Concrete Option

With assumption of average reservoir head of 7m and permeability of about 1×10^{-8} cm/s for asphalt concrete, the annual seepage from the reservoir was estimated 300,000 m^3 for an intact concrete layer. By considering the possibility of cracking in the asphalt layer the estimated annual loss will be doubled to a total of 600,000 m^3/year.

3.5. Water tightening using Geomembrane

Use of Geomembrane was another alternative for water tightening of the Chitgar Lake. The Geomembrane consists of three layers of Geo synthetic material: a Geomembrane layer protected by two layers of Geo textile on top and bottom. Use of Geomembrane has many advantages as follows:

- very low permeability rate to reduce the reservoir seepage
- sufficient flexibility to allow placement on alluvium with minimum base preparation
- a continuous impervious layer extending from the lake to the upstream surface of the earth-fill dam
- ease and high pace of installation process

The main weakness of Geomembrane is its vulnerability to possible physical damage which can be mitigated by soil placement on top of the Geomembrane; however this remedy makes it very difficult to locate and fix the possible damaged area during operation and maintenance.

In this method after soil improvement is complete, the bottom Geotextile layer is placed at the reservoir bed. Then the main Water tightening Geomembrane layer is placed on top of Geotextile layer and once the top Geotextile layer surface is placed over the Geomembrane, the top surface is covered with a protective soil/rock layer.

The Geotextile layers are provided to protect the Geomembrane against physical damage as well as to provide shear resistance which is critical on the slopes. Due to sensitivity of installation process, extra care and quality control is required for the Geomembrane water tightening procedure.

The top protective layer is made of available alluvium material of higher one inch and with a thickness of 15cm to 20cm with the use of manual non-vibration compactor. Main reason to use the large size material in to avoid a fine-grain layer suitable for growth of plants during the operation period while other benefits are listed below:

- protection against wrinkle effect of Geomembrane due to thermal expansion
- protection against uplift of Geomembrane during extreme wind under empty reservoir condition
- protection against physical damage and act of vandalism

Assuming a 7m reservoir head and a permeability factor of 1×10^{-12} cm/s for the 1.5mm thick Geomembrane, the expected annual seepage from the Lake will be around 2000 m^3.

3.6. Finding the Best Solution by Comparison between Water tightening Alternatives

Considering the above figures about the Lake, Water tightening option using the Clay Blanket was eliminated and comparison between Geomembrane and Asphalt Concrete indicated that the Geomembrane option is the most cost-effective solution for the Lake. Another distinctive advantage of Geomembrane is the pace of installation which is much higher for the cold seasons compared to the Asphalt Concrete. Furthermore, reliability of asphalt concrete is of concern as many implemented hydraulic asphalt concrete did not fully meet the expectations for water tightening performance. Ultimately the Geomembrane protection was selected as the preferred water tightening option for the Chitgar Lake.

4. Geomembrane Installation and Quality Control

4.1. Implementation of Water tightening Layer on Chitgar Lake Bed

Water tightening layer for bed of the lake consists of a Geomembrane layer protected by two layers of Geo textile on top and bottom as shown in Figure 5 covered with a protective coarse material layer.

Figure 5. Preparation and Installation Stages for Water tightening of the Chitgar Lake bed

The Specifications for the Geomembrane and Geotextile used in Chitgar Lake bed are provided in the Tables 2.

Table 2. Geomembrane Specifications used in the lake bed

Description	Spec.	Reference
Thickness	1.5 mm	ASTM D5199
Density	0.940 gr/cm^3	ASTM D1505/D792
Tensile strength	:(type IV	ASTM D6693
Yield strength	$\geq$ 22 KN/m	
Break strength	$\geq$ 40 KN/m	
Elongation at Yield	$\geq$ 12%	
Elongation at break	$\geq$ 700% type IV)	ASTM D6693
Tear resistance	$\geq$ 187 N	ASTM D1004
Puncture resistance	$\geq$ 408 N	ASTM D4833
Carbon Content	2-3%	ASTM D4218
Standard Oxidation Induction Time	100 min	ASTM D3895 – 5885
Resistance against crack propagation(SCR)	300h	ASTM D5397
Oven Aging (Hp) After 90 Days	80% of Oxidation Induction Time	ASTM D5885
Resistance against UV radiation After 1600 hours	50% of Oxidation Induction Time	ASTM D5885

Table 3. Geotextile Specifications used in the lake bed

Geotextile Type	400 gr	Reference
Weight per meter square	$\geq$ 400 gr	ASTM D5261

Elongation	$\geq$ 50%	ASTM D4632
Resistance against Rupture	$\geq$ 0.51	ASTM D4533
Resistance against puncture	$\geq$ 0.62	ASTM D4833

4.2. Implementation of Water tightening Layer on Upstream Slope of Chitgar Dam and Perimeter Dykes

The main water tightening member of the dam and perimeter dykes is the Geomembrane protected by Geotextile layers. The recommendations of ICOLD Bulletin 135 were used as reference for installation of Geo-synthetic material and associated details as follows:

A) Base Layer: To provide a smooth and suitable surface for installation of Geomembrane, first the coarse aggregates and small rocks from the face of the dam were removed and then a 5cm-thick shotcrete was placed on the dam after grading and trimming.
B) Protective Bottom Geotextile: To ensure the Geomembrane is protected against physical damage and also to provide adequate friction at the base, a 500g/m^2 Geotextile was used underneath the Geomembrane layer. The GT 12a standards was used for quality control of this protective layer.
C) Impervious Geomembrane Layer: For the Geomembrane layer on the dam's slope and on top of Geotextile layer, the HDPE type Geomembrane conforming to GM13 standards was used. The specification for the Geomembrane is as follows:
   - Thickness: 2.5 mm (ASTM D5199)
   - Density: 0.94 gr/cm^3 (ASTM D792, ASTM D1505)
   - Tensile strength $\geq$ 37 KN/m (ASTM D6693)
   - Elongation at break $\geq$ 700 % (ASTM D6693)
   - Tear resistance $\geq$ 311 N (ASTM D1004)
   - Puncture resistance $\geq$ 800 N (ASTM D4833)

D) Top Protective Geo-Textile: The Top Geotextile layer is to protect the Geomembrane during installation and particularly during placement of upper protective soil/rock fill layer. This layer is placed on top of the Geomembrane and is free to move in order to prevent possible stress transfer from the top layer to the Geomembrane.

Table 3. Geotextile Specifications used in the Dam Body and Perimeter Dykes

Parameter	Geotextile Type		Standard
	700 gr	500 gr	
Weight per square meter	≥700gr	≥500gr	ASTM D5261
Tensile Strength	KN ≥ ≥ 2.00 KN 1.46	KN ≥ ≥ 1.64 KN 1.33	ASTM D4632
Elongation	≥50%	≥50%	ASTM D4632
Resistance against Rupture	KN ≥ ≥ 0.89 KN 0.46	KN ≥ ≥ 0.64 KN 0.51	ASTM D533
Resistance against puncture	KN ≥ ≥ 0.89 KN 0.46	KN ≥ ≥ 0.64 KN 0.51	ASTM D833

E) Upper Protective Finish Layer: The upper protective layer on top of the Geotextile layer consists of a 10cm-thick plain concrete layer with a compressive strength of 16 MPa containing Polymer Acrylic additive. This layer was placed from Elevation 1266m to 1268.5m and underneath the riprap and Mallon work. The details of this protective layer are shown in Figure 6. This detail was kept for the entire architectural features and includes a 5cm concrete layer with Polymer additives.

F) Dam Crest and dyke Details at connection point to the upstream protective layer: At the upstream edge of dam and dyke crest, the impervious Geomembrane is placed and supported in a trench. The crest along dam's width is covered by appropriate finishing layer. In order to protect the accessible surface of the upstream face, a 10cm thick shotcrete layer is placed covered by riprap and crushed rock. This protective layer extends to the crest level and is fixed within the walkway concrete.

G) Connection Details of the upstream face of dam and dyke to the reservoir impervious layer: The Geomembrane layer is present both at the bed of reservoir and underneath the upstream face of the earth fill dam; however their sub-layer details are different. A concrete bump (hunched concrete zone) was used at the connection point of the Geomembrane as shown in Figure 6. The concrete bump is 1.5m-wide plain concrete with a compressive strength of 16 MPa.

4.3. Quality Control

4.3.1. Short-term Tests

Sampling from the on-site materials was carried out and the measured data was sent to the Laboratory according to GM13 and GT12a for Geomembrane and Geotextile respectively. Prior to installation of each role of Geomembrane and Geo-Textile, laboratory tests were done and results were sent to the Owner's Engineers for approval. One sample every 9 role of Geomembrane and one sample every 7 role of Geotextile were sent to the Labs for testing. After installation, verification on welding process is done. In Table 4 the results for concrete strength placed at the Lake are provided. Table 5 and Table 6 show the results for weld tests and Geotextile strength tests.

Table 4. Geotextile and Geomembrane sampling Specifications used in the Dam Body and Perimeter Dykes

No.	Description	Total samples	Rejected Samples	Accepted samples
1	Geomembrane	206	11	195
2	Geotextile	410	154	256

MD: Machine Direction, TD: Transverse Direction

4.3.2. Long-term Tests

From every Geomembrane material that was used, two samples were sent to SAGEOS Laboratory in the country of Canada to perform long-term resistance tests against UV radiation and also Oven

Aging. In the process the short-term tests results obtained from Iranian Lab were also verified. Followings test were conducted on the samples:

- Oven Aging for a duration of 90 days
- Resistance Test against UV radiation
- Stress Crack Resistance (SCR)
- Geomembrane Joints Welds

Test results were as follows:

- The Oxidation time reduction amounts from HP-OIT test after over aging were within the acceptable range. The reduction rate was also verified in the 90-Day test.
- The Oxidation time reduction amounts from HP-OIT test after continuous UV radiation were within the acceptable range.
- The procedure for OIT testing for a particular product made by Rowad Company had a direct impact on the obtained results. The difference between the results obtained from in-country and oversea testing Labs (on the over aging results) were mainly due to variation in testing procedures.
- Results obtained from Stress Crack Resistance test from Iranian and Canadian Labs were in complete agreement.

5. Construction Difficulties

Installation of the Water tightening layer for the Lake had its specific challenges and difficulties some of which are listed below:

- Harsh Weather Condition (wind storm and cold weather) during installation of Geomembrane
- Difficulties for Iranian manufactures to supply Geotextile conforming to GT12A standards
- Most Iranian Manufactures failed to provide products certificates
- Foreign Purchase and Import difficulties due to the Sanctions against Iranian Government
- Timeliness for customs clearance and release of products to do standard tests on materials
- Gradual impounding concurrent with the construction to meet the project deadline
- Limited access to different regions of the lake to avoid possible machinery damage to the installed Geomembrane
- Timeliness of quality control process for the membrane
- Fluctuations of exchange rate and associated complications to finalize the price from receipt of Performa to time of approval and budget availability

6. Concluding Remarks

The artificial Chitgar Lake project has significantly contributed to improvement of landscape, environmental and public recreation of Tehran City. Due to limitations on impounding time and also high evaporation rate during summer, the use of Geomembranes was selected as the preferred method among other researched alternatives for Water tightening of the reservoir at the Chitgar Lake. The project faced many challenges in supply and installation of the Geomembrane impervious layer. Since the use of Geomembrane was not common in Iran, finding local manufacturers and test labs specialized in quality control of such products was extremely difficult. In addition, the fluctuations of currency exchange rate during construction made it difficult to order and purchase the products.

Fortunately in spite all the commercial complications and construction difficulties, the project was executed according to plan while fulfilling all the quality control requirements. Considering the time constraint and duration of the project and the direct impact of the Lake Water tightening activity situated on the critical path of the schedule, the client decided to use both Iranian and Foreign Geomembrane products. Therefore the Geomembranes were supplied by four different manufacturers one of which was Iranian. For the quality control, Sageous Test Lab, a Canadian Company along with an Iranian Test Lab was selected.

To this date, according to the monitored operation of the Lake there has been no report or evidence of seepage through the installed Water tightening layer which indicates success of this insulation method for the Chitgar Lake. This project has set records in use and installation of Geo-synthetic materials for an artificial Lake in Iran and also the Middle East Region. Installation of nearly 133 hectares of Geomembrane and 265 hectares of Geotextile while fulfilling latest standards of practice requirements was a great achievement for the Engineering industry and the project has proven to successfully serve the nature, residents and tourists of the Iran’s Capital.

1. INTRODUCTION

Grouting in dam foundation is known as a process of injection the fluids by which openings are sealed off so as to minimize seepage and leakage, to strengthen and stabilize rock foundation for the purpose of filling micro and macro features such as joints, fractures, fissures, bedding planes, cavities, or other openings. There are different techniques used to provide impermeability requirement for dam foundation. Control of foundation seepage beneath dam structures can be provided by cutoff trench, sheet piling, slurry trench, diaphragm wall, upstream blanket and grouting curtain [1]. Powell and Morgenstern [2] evaluates the efficiency of seepage control techniques with quantitative data. Fell et al [3] introduce the general requirements to help control seepage, internal erosion and piping mechanics for embankments dams in detail. Some researchers investigated the effectiveness of grout curtain by using in-situ tests and laboratory-scale physical models [4, 5, 6]. World practice indicates that grouting curtain is one of the most effective and widely used techniques to help control foundation seepage beneath dam structures.

In the design standard of USBR for foundation grouting of embankment dams, the dam grouting is categorized into three groups: curtain grouting, blanket grouting and stitch grouting [7]. Curtain grouting is known as the most common method of foundation seepage reduction used beneath dam structures. This standard states that curtain grouting consists of drilling holes into the bedrock at some regular spacing along a line or lines parallel to the dam axis. The curtain is located at normal position to the seepage flow direction. Blanket or consolidation grouting is commonly used to provide a firm foundation, to reduce seepage within the near-surface foundation bedrock, to reduce seepage from the embankment into the foundation when fractured rock exists at the foundation contact [7]. It helps to reduce the likelihood of internal erosion of the embankment materials into the foundation. Stitch grouting is performed along faults, shear zones or discontinuities exposed on the foundation surface to reduce potential for seepage along these discrete features.

This study introduces design experience on grout curtains of thirty-two embankment dams constructed in Turkey. The depth of grout curtains ranges from 25 to 60 m for the moderate height dams. Table 1 gives the list of dams and their physical properties. Dams considered for this study were selected from different regions of Turkey and their heights from river basin range from 44 to 87 m. Their construction was completed between 1984 and 2013. They were designed for different purposes such as irrigation, energy, flood control, domestic water and industrial use. Their total reservoir capacity changes within a wide range of 12 to 2 120 hm^3.

2. MATERIALS AND METHODS

Grout curtain was firstly used in United States to control seepage in rock masses under and around dam structures in the 1890's [8]. At the beginning, long term behavior of many curtains has not been provided, especially in formations including soluble or erodible materials. However, effective and durable grout curtains have been formed since the mid-1970's using a new design perspective and considering different grout materials. Use of positive cut-offs such as slurry trench and diaphragm wall increased after 1980 [9]. In the past decade, there have significantly been advancements on grout curtain concepts and grouting industry. Especially new developments on real-time monitoring of flow rate and pressure of pumped grout result to more effective and durable grout curtains.

There are generally three separate techniques, which are used for forming grout curtain in engineering sector. These are jet-grouting, high-mobility grouting, and compaction grouting. In jet-grouting technique a cementitious material known as grout is injected into poor rocks or soils with high velocity and high pressure to form soilcete, which is composed of mixture of soil and grout materials. In high-mobility technique the cementitious grout material is pressurized into the pores and structural features of the underlying soil to form the grout and soil to binding. Its performance is directly related with the size of the pores or void spaces of the underlying soil material. This type of grouting provides an increase on strength properties and a decrease on permeability. Compaction grouting is another technique which use low viscosity grout to displace and densify loose soils. Its use in dam site provides stabilization of large void spaces known as sinkholes. Some scientists have explained these techniques more detail in their research [10]. All three installation techniques mentioned above is commonly used to simply prevent seepage from occurring under water retaining structures, especially for dams.

The depth of grout curtain is a critical issue for performance of dam structures. It is clear that depth for primary holes are based on the geology and permeability of foundation materials and also regional groundwater conditions. In USBR standard, it can extend to a depth below the surface of the rock equal to about 0.5 to 1.0 times the reservoir head, which lies above the surface of the rock [7]. However, an empirical criterion is generally used as guideline which are based on practice ($D= 0.3333xH + C$). In this formula D is depth of grout curtain, H is the height of the dam (the final head of water) and C is a coefficient ranging from 7.5 to 22.5 in m. The Indian Standard [11] introduced guidelines for the design of grout curtain as similar of USBR formula ($D= 0.667xH + 8$). In this empirical formula D and H are the depth of curtain and the head of the reservoir of water given in m, respectively. In Switzerland it is observed that the average of the depth of the curtains grout is stated as 66.7 percent of height of the dam [12] In Sweden, specified deep of grout curtain was depended to the head of the reservoir water at the dam. If height of dam is less than 30 m, the depth of curtain can be selected between 20-30 m. However, its height is greater than 30 m it can be taken between one-third ad two-third of the head of water in reservoir [13]. In Turkey dam engineers consider the simple USBR formula for designing the grout curtains of dams.

3. ANALYSES

In this study thirty-two existing dams are considered and a back analysis was performed for all dams to relieve Turkish experience on the formation of grout curtains of dams. For each dam structural height and water head in the reservoir were determined and more detail geological inspection was performed on the planning report to exactly determine the geological formation, in which grout curtain is installed. Then the depth of curtain was determined from the design sections with inclusion of revised ones. The research on rough data indicates that most of grout curtains was installed by high mobility technique. There are also some examples constructed by other techniques. For example, slurry trench technique was adopted in construction of some parts of curtain for Aslantas dam, which is a 95 m height dams located on Ceyhan River. The diaphragm wall technique was utilized to install the curtain of Tahtali dam, which is a 55 m height dam for providing domestic water of Izmir province in West Turkey.

Table 2 introduces the structural heights and depths of grout curtains with the geological formations, in which curtains were installed, for all dams considered for study. The structural heights of dams, which range from 50 to100 m, average 72.6 m for all dams. The depths of curtains are between 25 and 60 m and their average is 41.6 m. The type of rock units, in which curtains are emplaced, have different characteristics when considered their strength and permeability. There are limestone, clayey limestone, marl, and their alternation as soluble sedimentary rocks in foundation. Claystone, sandstone, siltstone, ophiolite series, agglomerate and conglomerate can be separated as non-soluble sedimentary rocks. The igneous rocks in foundations of dams considered for this study can be classified as andesite, basalt, brecciated tuff, diorite, granite, granodiorite, meta-granite, monzonite, peridotite, rhyolite, serpentinite, syenite, syenite porphyry and tuff. Chlorite schist, gneiss, quartzite, meta-quartzite, marble, mica-schist and schist are the metamorphic rocks seen in the foundation of dams considered for this study (table 2).

In this study the empirical relationship between the depth of grout curtain and water head in the reservoir was criticized as based on the Turkish practice. For this purpose, a back analysis was performed by means of the simple USBR equation. In this simple equation the depth of curtain is directly related by the height of the dam (the final head of water) additionally with the C-coefficient ranging from 7.5 to 22.5 in m. As based on this equation a C-coefficient was calculated for each dam. Table 3 introduces actual depth of curtain and structural height of dam and the calculated C-coefficient for each dams. This table also includes the exceedance ratio for some cases. It means just the deviation percentage from upper limit for C-Coefficient. There are six dams that their depths exceed the upper limit of C-Coefficient given for the equation. Three of them have too much exceedance ratio. There is no any calculated value which is less than lower limit of C-Coefficient (table 3). If exceedance ratio is represented by (-), it means no exceedance on upper and lower limits.

Table 2. Depth of grouting curtains and rock type in which curtain is emplaced

Dam No	Dam Name	Structural Height (m)	Depth of Curtain (m)	Rock units, in which curtain is emplaced
1	Aslantas	95	45	Claystone-sandstone
2	Bakacak	65	40	Brecciated tuff
3	Batman	85	60	Limestone-clayey limestone-marl
4	Cat	78	37	Schist, quartzite
5	Catalan	82	50	Claystone-sandstone
6	Caybogazi	78	40	Claystone-sandstone-siltstone
7	Demirdoven	67	45	Rhyolite, tuff
8	Egrekkaya	100	50	Andesite
9	Erzincan	81	45	ophiolite series
10	Gazibey	58	34	Basalt
11	Godet	93	43	Tuff schist, radiolaritic schist
12	Goksu	53	33	Limestone, clayey limestone, claystone
13	Guldurcek	68	40	Tuff-agglomerate, andesite
14	Havran	80	65	Alternation of limestone, claystone and sandstone
15	Kapulukaya	61	41	Granodiorite
16	Karadere	90	50	Serpentinite
17	Karaova	64	35	Conglomerate, schist
18	Kirklareli	72	42	Meta-granite
19	Kockopru	74	33	Agglomerate, basalt, mix of clay, sand and gravel
20	Koruluk	54	35	Tuff, breccia, agglomerate
21	Madra	97	55	Andesite, agglomerate
22	Manyas	91	40	Chlorite schist, meta-quartzite, marble
23	Mursal	58	39	Syenite, syenite porphyry, monzonite, granite
24	Polat	54	38	Diorite, grana-diorite, peridotite
25	Sarımehmet	62	35	Limestone
26	Sıddıklı	53	28	Limestone, sandstone, conglomerate
27	Suat Ugurlu	51	25	Basalt, agglomerate, tuff, breccia
28	Topcam	62	30	Gneiss
29	Tahtali	55	60	Weathered schist and alluvial soil
30	Umurbey	74	40	Andesite, agglomerate, tuff, siltstone, claystone, sandstone
31	Yaylakavak	89	43	Gneiss, mica-schist
32	Zeyrek	80	35	Limestone, schist, diabase

4. RESULTS AND DISCUSSION

In Turkish design practice, it is a common way to design grout curtain by the simple USBR equation for the dams. For this study thirty-two dams having a height between 50 and 100 m were considered. This study indicates that there are some extreme cases when design engineers consider a curtain, in which soluble rocks are emplaced. The extreme examples can be defined as Tahtali, Batman and Havran dams. The cutoff structure of the Tahtali dam was installed in weathered metamorphic rocks and alluvial soil by diaphragm wall. Therefore, its depth is control by thickness of alluvial soil. However, second and third dams were constructed on limestone, clayey limestone, marl, sandstone and their alternation. For the grout curtains of Batman and Havran Dams, exceedance ratios are 43.6 and 73.3 percent, respectively. It means that the cost of curtain has high percentage of total structure for these dams. Their expenditures on grout injection could be decreased by means a detail and more sophisticated geotechnical investigation for these dams.

Table 3. Actual depths, calculated c-values and exceedance ratio for the dams considered for this study

Dam		Structural Height (m)	Depth of Actual Curtain (m)	D = C + 0.3333xH (m)		
No	Name			0.333H* (m)	C-value** (m)	Exceedance ratio (%)
1	Aslantas	95	45	30.7	14.3	-

32	Zeyrek	80	35	26.0	9.0	-

(*) one-third of hydraulic height
(**) C-Values (7.5-22.5 m)

Sarımehmet, Sıddıklı and Goksu dams are good cases even if their gout curtains were emplaced into limestone and its alternation. Because their C-coefficients range between 11 and 16 m. The curtain of Suat Ugurlu dams, which is emplaced in basalt, agglomerate, tuff and breccia has lowest C-coefficient for this study. The performance of curtain is currently high, although there are complex geological units in dam foundation and abutments. Therefore, it means that a good engineering service has been spent for designing of this element of Suat Ugurlu Dam.

Fig.1 shows the relationship of curtain depth with water head in reservoir for three separate series. This figure indicates that the relationship between two parameters are very changeable for soluble sedimentary rocks (red color). There is a more acceptable relationship between curtain depth and water head in reservoir for the series including igneous and metamorphic rocks as based on the cases considered for this study (blue color). The series about non soluble sedimentary rocks conforms the relationship belonging to igneous and metamorphic rocks (green color).

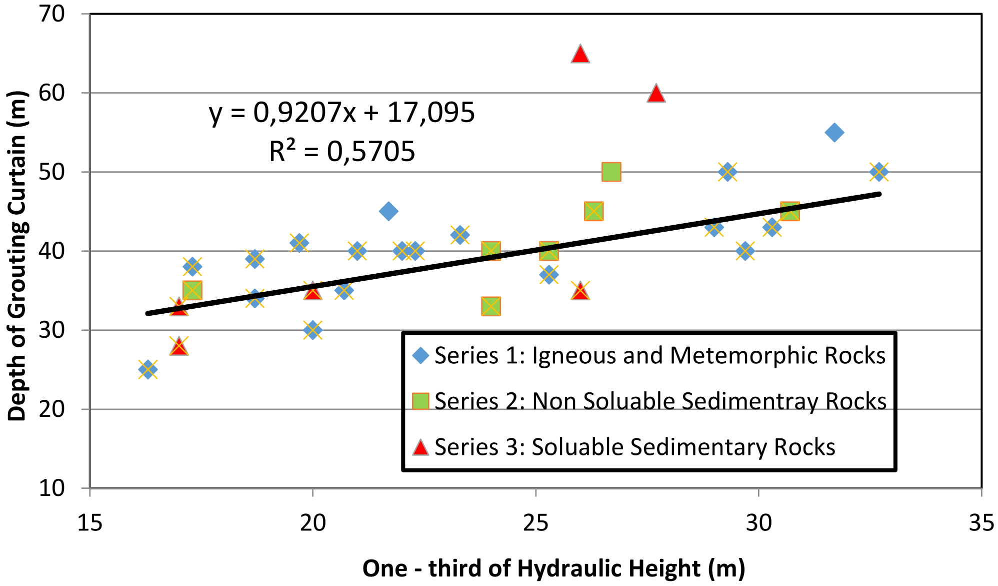

Fig. 1. Direct relationship between gout curtain and hydraulic height for three different series

A simple equation is suggested to relate depth of grout curtain and hydraulic height for non-soluble sedimentary, igneous and metamorphic rocks for the dams having a structural height of 50 and 100 m (eq.1).

$$D = 0.307x\ H + C_c \qquad [1]$$

in which

D= Depth of grout curtain
H= head in reservoir water
Cc = corrected coefficient for grout curtain (averages to 17.01)

Table 4 summarize this study based on thirty-two projects considered for this study. The numbers of projects, range of curtain depths, range and average of C-coefficient are introduced in this table according to rock units, in which curtains are emplaced. This table indicates that range of C-coefficient for soluble sedimentary rock is too wide when compared with the cases in non-soluble sedimentary, igneous and metamorphic rocks. The percent of projects having the exceeded C-coefficients is also high for soluble sedimentary rocks. Author states that this table can be used as a guideline for designing the grout curtains in all rock units with exception of soluble sedimentary rocks. It should be notified that It can be used for the design of grout curtains of embankment dams having a hydraulic height of 50 m to 100m.

Table 4. Depth of grouting curtains as based on rock types

Number of projects considered for this study	Range of curtain depth (m)	Range of C-value (m)	Average of C-value (m)	Exceeded C-value		Rock units, in which curtain is emplaced
				Number of projects	Percent of projects (%)	
6	28-65	9.0-39.0	20.4	2	33.3	Limestone, clayey limestone, marl, and their alternation
7	33-50	9.0-23.3	16.2	1	14.3	Claystone, sandstone, siltstone, ophiolite series, agglomerate, conglomerate
19	25-67	8.0-23.3	15.4	2	10.5	Tuff, brecciated tuff, schist, quartzite, andesite rhyolite, basalt, granodiorite, serpentinite, meta-granite, chlorite schist, meta-quartzite, marble, syenite, syenite porphyry, monzonite, granite, diorite, grana-diorite, peridotite, gneiss, mica-schist

5. CONCLUSIONS

Turkey has more than 1 250 large dams with different types. The most of them were constructed in embankment type. The thirty-two large dams having a good performance on impermeability of foundation materials were selected for this study. This study indicates that there is a good experience in designing of grout curtains of embankment dams in Turkey and concludes as follows:

- The simple USBR equation is generally used in designing of grout curtain for all foundation materials in Turkey. The equation suggested in this study confirms that one mentioned above for the dams having a height between 50 and 100 m. However, its use for soluble sedimentary rocks is questionable.
- In soluble sedimentary rocks such as limestone, clayey limestone, marl and their alternations the performance of grout curtains depends on nature of material, in which curtain is installed. Detail and more sophisticated geotechnical investigation should be made for this type of dam sites.

Spaces, cavities or holes should be found before designing of curtain and an extended program should be realized for a dam site having soluble sedimentary rocks.

- Table 4 given in this study can be used as a guideline for designing the grout curtains in rock units with exception of soluble sedimentary rocks.
- This study has been realized for only dams having a height of 50 to 100 m. Further study or studies can be performed for the dams having a height less than 50 m and more than 100 m.

SUMMARY

Dam designers believe the fact that grouting curtain is one of most effective techniques used to control seepage and leakage quantity under embankment dams. The efficiency of a grout curtain is directly related with its depth. The empirical equations have been developed to explain the relationships between dam height and curtain depth, and then adapted as design criteria in specifications. In this study a back analysis was performed on grout curtain activities of thirty-two embankment dams, which pose a height of 50 to 100 m in Turkey. The foundation units of these dams are completely igneous and metamorphic rocks and their sedimentary products. The dams having soluble rock units were also considered for this study. The results of this study show that the Turkish design practice for grout curtains of embankment dams generally conform the USBR's approximation for the dams having a height of 50 to 100 m from foundations. A new empirical equation relating depth of grout curtain with hydraulic height of dam and a guideline on depth of grout curtains as based on rock types are suggested for the dam having moderate height as based on the Turkish practice.

1. SUMMERY

The earth-rock joint area is generally existed in some earth dams, such as the combination area of dam body with concrete dam, Spillway, dam culvert and other structures. The soil in these areas is susceptible to infiltration failure due to seepage and soil properties, and this kind of damage phenomenon will further affect the distribution of uplift pressure in earth-rock contact surface. In order to study the transformation of the uplift pressure distribution, a contact scouring experiment which is based on the normal stress controlling by the pressure of contact surface is proposed in this paper. The experiment can simulate the seepage failure of soil-rock joint area and reveal the basic law of stress, seepage and soil loss. Based on the experimental results, a mathematical model of contact mechanical state of contact area is established, and the seepage failure in the contact area is simulated using finite element. In conclusions, the evolution

process of the uplift pressure/pore water pressure in the contact area of soil and stone is simulated while taking in to account the aging factors.

1. INTRODUCTION

This paper concerns about the assessment of the hydraulic behavior of a 50 m height zoned dam used for industry water supply, located in Alentejo region, in Portugal. The original draining system of the embankment is composed of a sub-vertical filter, located downstream of the central core, and by a drainage blanket placed over the foundation, in the deeper area of the valley, which, in turn, discharges to a downstream drainage toe. After first filling of the reservoir, resurgences and artesian pressures in the terrain at downstream of the dam body were identified in the left bank. Following that abnormal behavior, the reservoir water level was restricted, and an inverted filter was built over the affected area, to limit occurrence of internal erosion and heave. Additionally, to monitor the hydraulic behavior of the dam and of the inverted filter, several piezometers and a few flowmeters were installed.

Based on the monitoring data (piezometers, flowmeters and reservoir water level) recorded in the last 30 years, a artificial neural network (ANN) model was established for the hydraulic behavior prediction of the zoned dam. The results of this study show that ANN models can be a useful tool for the prediction of the flow rate measured in the flowmeters.

2. SAFETY OF ZONED DAMS

Dams are water-retaining structures that are built to provide water for human consumption, irrigating, generating hydroelectric power and use in industrial processes. They are critical structures for the continuation of life and providing public safety. Statistics from the International Commission on Large Dams (ICOLD) [1,2] reveals that embankment dams represent the most common dam construction type, totalizing about 3/4 of all the existing dams, and, of those, 88% are earthfill dams and 12% are rock-fill dams. Zoned dams account with about 53% of the world population of embankment dams. The most common zoning profiles are zoned earthfill (36%), zoned earth and rock-fill (9%), and central core earth and rock-fill (8%). The main failure modes associated with these type of structures are caused by overtopping (due to inadequate spillway capacity or malfunction of gates), by piping, and by slope instability. Failure modes by piping and overtopping together are responsible, in similar importance, for more than 92% of the total failures [3].

Embankment dam failure and accident statistics [3] show clearly that high average frequencies of failure are associated with dams using profile types without zoning and with inherently poor control of seepage and pressures in the embankment and foundation. On the contrary, embankment dams with downstream rock-fill zones have a particularly low incidence of failure, mainly because they are less likely to progress to breaching if piping erosion initiates compared with dams with earthfill materials in the downstream zones.

In some case studies of zoned dams, leaks appeared at downstream of the embankment, meaning that they bypassed the dam's internal drainage system. Typically, these pathologies appear during first filling or during the first years of exploration of the reservoir. These incidents are usually associated to an inadequate treatment of the foundation, or due to the presence of pervious soil formations or interconnected cracks in a rock formation, not detected during geological prospection of the construction site.

In this paper, we describe the history of a zoned dam, built in the 80s, in which leaks appeared at downstream of the dam during first filling. The remedial actions to overcome the abnormal hydraulic behavior of the foundation are also indicated. Finally, we use a neural network, considering as input parameters the reservoir level and piezometric data, to predict the flowrates measured in a flowmeter located near the leakage area.

3. CASE STUDY

3.1. DAM DESCRIPTION

Figure 1 shows a satellite view of the dam in concern. It is a zoned earthfill dam located in the south center region of Portugal, in particular, in Setúbal district, in Alentejo. The dam crest, following a curve in the longitudinal axis, has an extension close to 2700 m, and a maximum height above foundation of about 52 m (45 m above streambed). The completion of the dam dates the year 1980, and the current dam owner is APA (*Agência Portuguesa do Ambiente*). The dam's reservoir aims mainly the supply of water to industry. The reservoir has an effective storage of 27000 ML.

Fig. 1
Satellite view of the dam (source: Google maps)

Figure 2 shows the typical cross section of the embankment. The crest is defined at level 70 m above sea level and the normal water level (NWL) of the reservoir was initially established from design at 68.3 m. The upstream shell of the embankment has a slope of 1(V):3(H), whereas the downstream shell has a slope of 1(V):2.4(H). The core is made of selected weathered schist materials and has a slope of 2(V):1(H) and 2.5(V):1(H) at the upstream and downstream sides, respectively. The internal drainage system is composed by sub-vertical filter/drains, located at downstream and upstream of the impervious core, a horizontal drainage blanket, located in the downstream shell and above the foundation, and a downstream toe drain, below level 41.5 m.

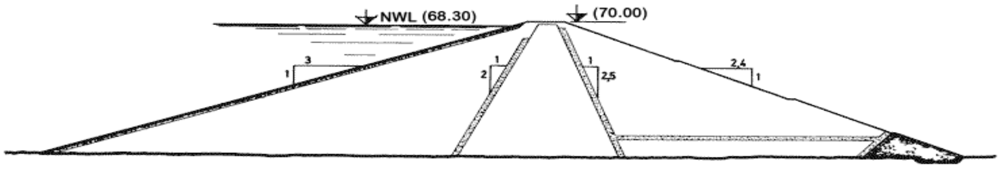

Fig. 2
Cross sectional profile of the embankment of the dam

The dam has a siphon type spillway, located on the left bank, and a bottom outlet, composed by a conduit, under the embankment (in the deepest zone of the valley).

The geological setting for the embankment is characterized by metamorphic rock formations mainly of schist and greywacke. Preparation works involved slush-grouting of the core trench and removal of superficial deposits beneath the shell zones.

3.2. THE MONITORING SYSTEM OF THE DAM

The initial monitoring system of the dam was composed of survey points, to measure vertical displacements of the embankment, inclinometers, to measure the horizontal displacements in the embankment, hydraulic piezometers in the embankment and foundation, to measure pore pressure, and a flowmeter located in the bottom of the valley, to assess the seepage water through the embankment and foundation. Figure 3(a) represents the majority of those monitoring devices.

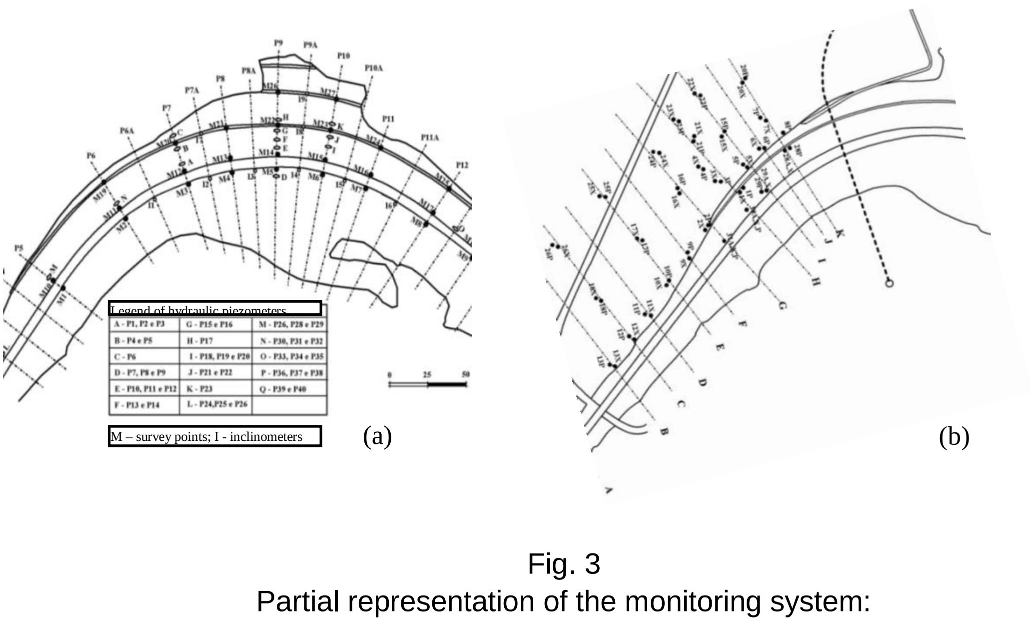

Fig. 3
Partial representation of the monitoring system:
(a) Initial monitoring system; (b) Piezometers installed in the left bank after abnormal hydraulic behaviour of the foundation

Deficient hydraulic behavior of the dam foundation occurred short after first filling of the dam reservoir. In particular, high pore pressures formed in the natural terrain downstream of the embankment, mainly, at the left bank side. Artesian pressures installed in the natural terrain, and, thus, to improve the safety conditions and the monitoring system, an inverted blanket filter and an installation of additional 66 piezometers at downstream of the dam were conducted, respectively. Figure3 (b) shows the location of the majority of these piezometers. In addition, to measure the seepage water collected by the inverted blanket filters a set of flowmeters was installed. In this paper, we evaluate the usefulness of neural network models to predict the hydraulic behavior of such complex dam site. In particular, we correlate the monitoring data from one of the additional piezometers with the data from the closest flowmeter, and confirm that the prediction from the neural network is more accurate than that from a simple linear correlation.

3.3. DATA EVALUATED WITH THE NEURAL NETWORK MODELS

The data used in the model corresponds to a period between March 2003 and August 2017, resulting in more than 120 observations per variable. The time evolution of the reservoir water level, the uplift pressure in the P30, P31 and P17 piezometers (in profile E, shown in Fig 3(b)), and the seepage in the drain MC4 are presented in Fig. 4. The samples were collected every month. Among the different loads acting on dams, it is usual to distinguish, as the most important ones for structures in normal operation, the hydrostatic pressure variation, Fig. 4. Missing data resulted from lack of inspections.

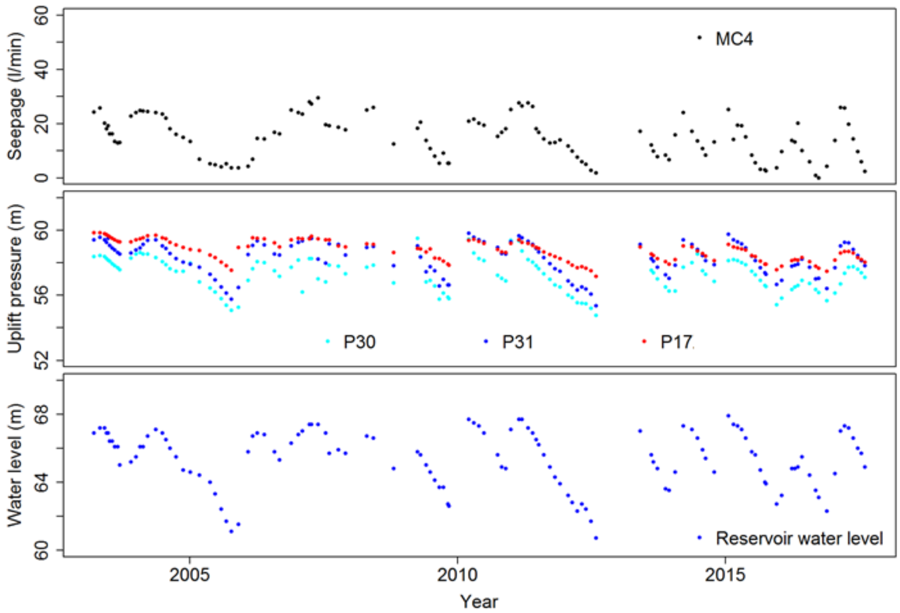

Fig. 4
Seepage, uplitf pressure and water level measured between 2003 and 2017

3.4. TRADITIONAL ANALYSIS BASED ON MULTIPLE LINEAR REGRESSION MODELS

The structural response of, for instance, the seepage in any point of the dam, is strongly related to the corresponding variation in the water level in the reservoir. The observations presented in Fig. 3 will be used for the computation of the models presented in this work.

In this case study, the multiple linear regression (MLR) model with the best performance for the seepage of the MC4 drain $y^{MLR,MC4}$ was obtained as the sum of the hydrostatic pressure term $\beta_1 \times h$ (where h is the reservoir water level height), the uplift pressure terms in the upstream zone $\beta_2 \times P31$ and the uplift pressure terms in the downstream zone $\beta_3 \times P17$ e to represent the effect of the head loss variation along the dam and its foundation. The time effect did not seem to have a significant importance in the period examined by this study. The regression coefficients of the quantitative models obtained are $\beta_1 = 1.09$, $\beta_2 = -3.05$ and $\beta_3 = 2.4$, with k=-257.8; being the MLR model represented trough the following equation:

$$y^{MLR,MC4} = \beta_1 \times h + \beta_2 \times P31 + \beta_3 \times P17 + k$$

the residuals were obtained through the difference between the observed seepage and the corresponding predicted value obtained through the MLR model.

4. METHODOLOGY FOR SEEPAGE CONTROL

4.5. INTRODUCTION

Seepage measurement devices are installed at the downstream of the dam to measure the amounts of seepage through, around, or under dams. Drain outlets are commonly used as seepage measurement points. The rate of flow is measured either individually in each drain or for a combination of drains grouped by specific zones of the foundation and, in this case, it will also include the infiltrated water through the dam body.

Modelling the hydraulic behaviour of dam foundations is a non-linear problem and a very complex task, mainly because of the discontinuities of the foundation mass and the lack of information concerning the hydraulic properties of foundation mass and the discontinuities characteristics.

As referred before, in order to study the application of the neural network technique in the seepage control of case study, drain MC4 was selected. This measurement point is located at downstream of the embankment (in profile E, Figure 3(b)) and collects the water in the vicinity, from the inverted filter placed above the natural terrain. The reservoir water level and the pressures measured in the P31 and P17 were considered as inputs for the ANN model.

4.6. Theoretical concepts - Artificial neural network model

Artificial Neural Networks are computational methods inspired on the efficiency of the brain process (Patterson, 1996). The increasing interest for that area derives from the learning ability of these models, which relate the variables without imposing relationships among them. For the creation of these models, it is necessary to define the architecture of the neural networks and to go through a training process with examples (the monitoring data).

Multilayer Perceptron networks have units arranged in layers. The first layer receives the inputs and the last layer produces the outputs. The middle layers have no connection with the external world, and are called hidden layers. A unit is an operator with inputs and outputs, associated with a transfer function, interconnected by synaptic connections.

Each unit in one layer is connected to every unit on the next layer. The information is constantly "feed forward" from one layer to the next.

Multilayer Perceptrons learn by an iterative process, adjusting the weights so as to be able to correctly learn the training data and hence, after the testing phase, to predict unknown data. Fig. 5 illustrates a generic example of a Multilayer Perceptron neural network, with an input layer having input parameters, one hidden layer, *I*, with *Q* processing elements and an output layer, *L*, with *M* outputs.

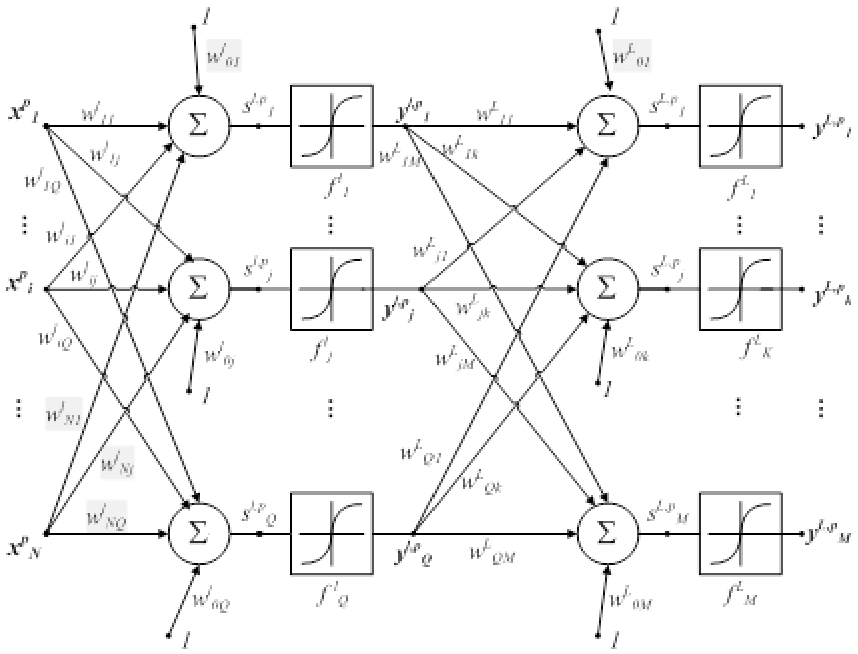

Fig. 5
Multilayer Perceptron neural network designations

The parameters have the following meaning:

x_i^p - input network i, from pattern p;
P - number of patterns;
L - output layer;
l - hidden layer;
N - number of inputs in input layer;
Q - number of processing elements in the hidden layer;
M - number of processing elements in the output layer;
w_{ij}^l - synoptic weight between input network i from layer $l-1$ at processing element j from layer l;
$s_j^{l,p}$ - activation value at processing element j from layer l, from pattern p;
f_j^l - activation function at processing element j from layer l.
$y_i^{l,p}$ - output unit i, from layer l, from pattern p;

First, the neural networks were trained with a small number of processing elements in the hidden layer and the performance over the training set was determined. Then, the procedure was repeated with one more processing unit in the hidden layer and the performance was again calculated. After a sufficient number of architectures were trained, the best architecture was chosen.

4.7. APPLICATION AND RESULTS

The ANN model used in this case study consists of an input layer with 3 input parameters (the reservoir water level and the uplift pressures measures in the piezometer P31 and P17), an output layer (to represent the seepage measured in the MC4) and one hidden layer. Every neuron in the network is fully connected with each neuron of the next layer. A hyperbolic tangent transfer function has been chosen to be the activation function for the hidden layer and the linear function for the output layer. The generalized backpropagation delta learning rule algorithm was used in the training process. The chosen network architecture has shown the best results, considering all the tested networks, from 3 until 30 neurons, at the hidden layer. To find the optimum result, 5 initializations of random weights and a maximum of 5000 iterations were performed on each ANN architecture.

Figure 7 shows the evolution of the seepage at the drain MC4 (black color), and the predicted values from the MLR model (green color) and the ANN model (red color).

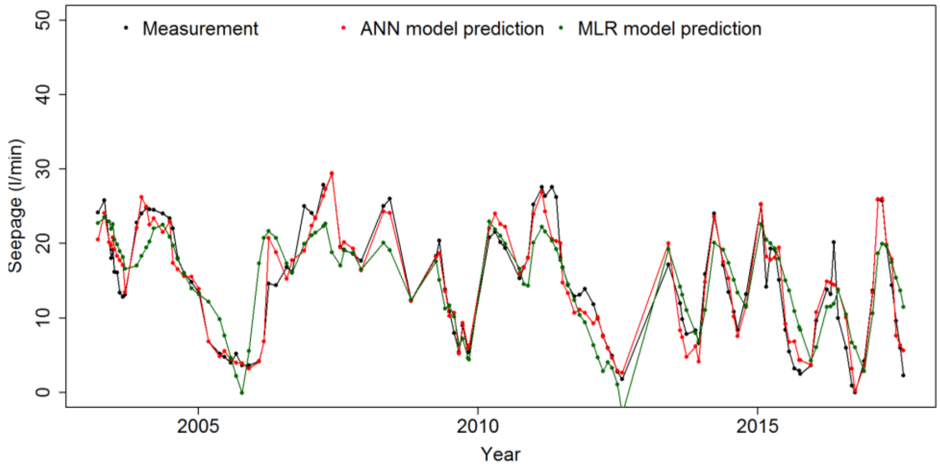

Fig. 6
Measurements, ANN prediction and QI prediction along time

The good fit shown by the models can be seen by comparing observations with the values predicted by the models (Figures 6 and 7) and by the analysis of Table 1, where the values of the maximum residual and the values of the standard deviation of the residuals, σ, for the MLR and the ANN models are presented.

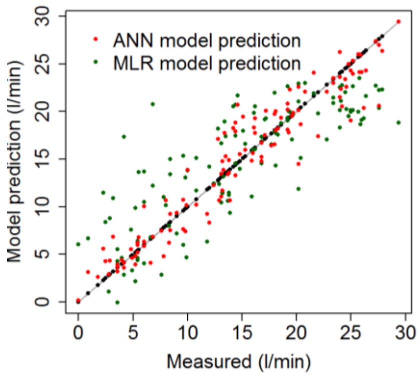

Fig. 7
Model predictions vs measurements

Table 1
Performance parameters for the MLR and the ANN models

Model	Max residual (l/min)	σ of the residual (l/min)
MLR	13.9	4.5
ANN	7.0	2.2

5. FINAL REMARKS

After identification of the main inputs and outputs for the neural network models and after establishing the methodologies for the learning and generalization procedures, the Multilayer Perceptron neural networks may become a new useful tool to support the safety control of seepage in zoned dams.

In this study, the achieved performance of neural network models to predict the flow rate in drain MC4 was very good when compared with traditional multiple linear regression models. Despite the good results presented for MC4, it is necessary to carry out further studies including the results obtained from other individual drains, and it is not dispensable a global evaluation of the dam safety on the basis of a comprehensive analysis of the various observed parameters. Finally, it is always wise to carry out the safety evaluation simultaneously with various models rather than with just one model.

ACKNOWLEDGEMENTS

We would like to thank APA - Portuguese Environment Agency (dam owner) by given us permission to publish the dam monitoring data results.

SUMMARY

This paper concerns about the assessment of the hydraulic behavior of a 50 m height zoned dam used for industry water supply, located in Alentejo region, in Portugal. The original draining system of the embankment is composed of a sub-vertical filter, located downstream of the central core, and by a drainage blanket placed over the foundation, in the deeper area of the valley, which, in turn, discharges to a downstream drainage toe.

In this study, the achieved performance of neural network models to predict the flow rate in a drain was very good when compared with traditional multiple linear regression models. Despite the good results presented, it is necessary to carry out further studies including the results obtained from other individual drains, and it is not dispensable a global evaluation of the dam safety on the basis of a comprehensive analysis of the various observed parameters. Finally, it is always wise to carry out the safety evaluation simultaneously with various models rather than with just one model.

1. INTRODUCTION

Application of geomembrane as the upstream impervious layer of dams, especially of Roller Compacted Concrete Dams, has been increasing worldwide due to its better performance and easier process.

A reinforced concrete slab was in the design phase supposed to be used for waterproofing of dam but within construction phase, it was changed to geomembrane due to some technical and economic reasons.

In this paper, the upstream impervious layer of Kahir dam is described. According to special regional conditions and to prevent any construction stop caused by implementation of waterproofing system, a unique method carried out.

Finally, combination of three methods used in upstream part of the dam including exposed geomembrane in lower levels, geomembrane covered with precast panels in middle part and geomembrane attached to the precast panels (known as Winchester method) in upper levels.

Kahir dam is the first concrete dam of Iran which uses geomembrane as the waterproofing element and at the moment, the design and construction method have been finalized and the abovementioned system is under construction.

2. PROJECT SALIENT FEATURES

Kahir RCC dam is the first Faced Symmetrical Hardfill Dam (FSHD) of Iran (Fig. 1). The dam is located in southeastern part of Iran, Siatan & Balouchestan province, in a hot climate. The main project information is as below [1]:

Type of dam	Gravity dam, FSHD type
Dam height	54.5 m
Crest width	5 m
Crest length	382 m
Spillway length	120 m
Reservoir volume	314 MCM
RCC volume	485.000 m^3
CVC volume	179.000 m^3
Total concrete volume	664.000 m^3
Diversion system	6 m diam. tunnel with a length of 283 m, upstream and downstream cofferdam

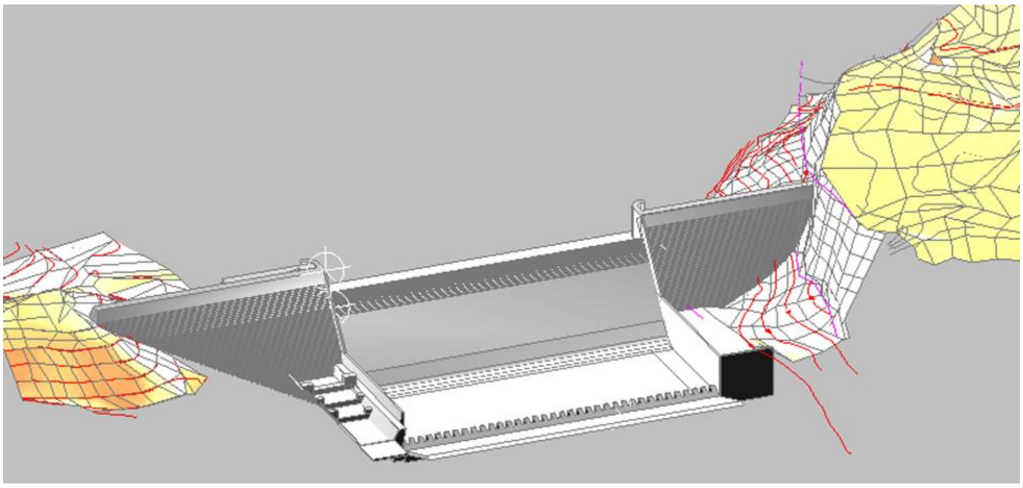

Fig. 1
3-D View of Kahir FSHD

3. MAIN DESIGN OF DAM WATERPROOFING SYSTEM

According to the contract drawings, waterproofing of the dam should be done by a 60 cm-thick reinforced concrete layer. This layer should be implemented after completion of dam body to lessen the tensions on concrete layer induced by settlement. The concrete impervious layer was to start from plinth concrete at the bottom part to the top as shown in Fig. 2:

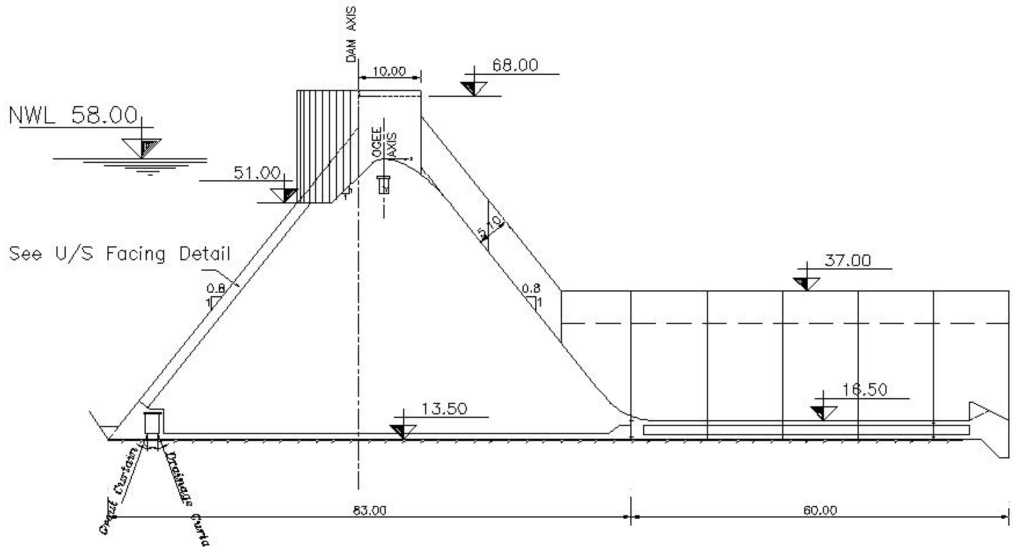

Fig. 2
Dam Section in Spillway

4. GEOMEMBRANE IMPERVIOUS SYSTEM DESCRIPTION

On the one hand, concrete impervious layer of main design should be implemented after the completion of dam body, which increases the time of project and on the other hand, geomembrane is technically more flexible than concrete and eliminates concerns about concrete cracking. For this purpose, a work group named Kahir Dam Waterproofing Design Review Team was formed and after lots of technical meetings, the impervious layer was changed to geomembrane. Eventually, geomembrane waterproofing system was designed as mentioned below (Fig. 3 & 4):

- Expose part from elevation +16 to +42 (bottom outlet level) which is always under water after first impounding. Using geocomposite including a 3 mm PVC geomembrane and 500 gr/m^2 geotextile attached together. Moreover, a 1000 gr/m^2 geotextile over it as a protective layer.
- Covered part with precast concrete panels over geocomposite from elevation +45 to +50. Similar to expose part, geocomposite have been

used with 1000 gr/m^2 geotextile over it to protect from probable damages of precast panels placed later on. However, extra 500 gr/m^2 geotextile layer used under the geocomposite in order to prevent puncturing.

- Winchester part (geocomposite attached to precast concrete panels) [2]. The impervious element of this part is a 2.5 mm geomembrane and 200 gr/m^2 geotextile attached to concrete panels.
- At the end, after implementation of all geocomposites, the two berms in elevations +42 and +50 are filled with concrete. These two berms have been designed to support the harness system of cover segments.

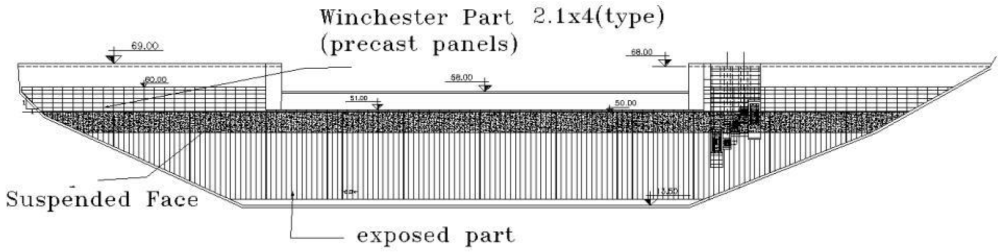

Fig. 3
Geomembrane Impervious System

In items below, the design details and construction method of each part are explained:

4.1. ELEVATION +16 TO +42

After first impounding, up to level +42 is always immersed; therefore, there is no need to have a permanent protection layer over geomembrane. Geomembrane is attached to the plinth concrete in lower parts and vertically to the dam body in every 6 m intervals as well. Plinth concrete is waterproof itself and geomembrane is fastened to plinth concrete by batten strips. There are two drainage pipes in each 12 m of upstream face to collect the probable leakage and lead it to the drainage gallery. The drainage system is designed in a way that the leakage of every 12 m is separately discharged into the gallery.

4.2. ELEVATION +45 TO +50

This part of dam body is above the lower bottom outlet. Since this elevation may sometimes be above water level, the geocomposite needs to be protected. It was supposed to perform Winchester method to seal this part like as upper levels; however due to the time-consuming procurement process, dam body construction reached to this level and the sealing system was inevitably changed to concrete-panel covered geocomposite (CPCG). In this method, without any significant interruption on construction of upper levels, geocomposite layer is installed and precast concrete panels are thereafter placed on it. It is noteworthy that concrete-panel cover layer's stability and harness system were analyzed.

Being in critical path, geocomposite in elevation of +45 to +50 was implemented first. Lower part can independently be installed; but the upper part should be installed after completion of CPCG in middle part.

4.3. ELEVATION +53 TO +60

Winchester method is used in this part; i.e. precast concrete panels overlaid with geocomposite layer are used as formwork. In this method precast concrete panels stability has been considered as well.

Fig. 4
Berms of Elev.+42 & +50, Dam U/S View

Similar combinational method including Winchester method in upper part and exposed method in lower part (backfilled later on) has been utilized in Rizzanese RCC dam in France [3], [4].

5. IMPERVIOUS SYSTEM DESIGN

As previously mentioned, Kahir dam waterproofing system is specific. Additional to the design of conventional elements -like as stability of exposed geomembrane against uplift induced by wind [5] and stability of Winchester panels and connection anchors- stability analysis of the middle part cover segments, harness system including harness rebars and reinforced concrete berms have been performed. High seismic risk of the region was of great concern. Design loads were considered as below (Fig. 5):

- Weight of concrete cover segments
- Hydrostatic and hydrodynamic loads
- Inertial loads activated by seismic acceleration
- Inertial impact of dam body on concrete cover
- Wind uplift

Although design of different elements has basically been done, the results have been compared to main references; e.g. the number of anchors per unit surface has been calculated less than common construction experiences; therefore the number of steel anchor area has been replaced by the typical quantity mentioned by E. K. Schrader [6].

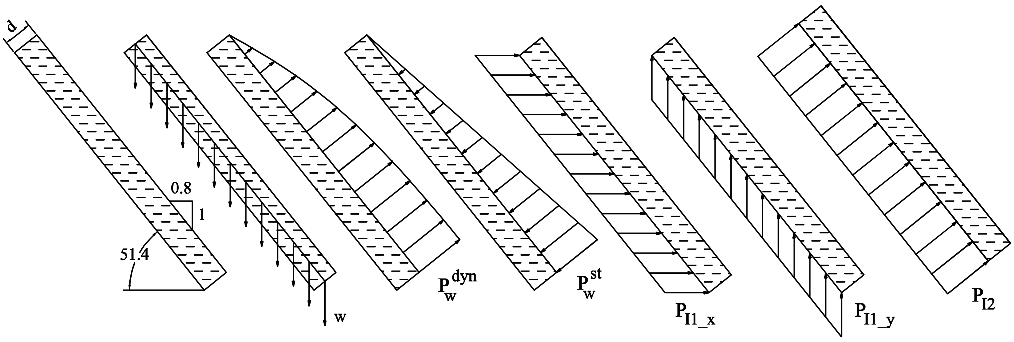

Fig. 5
Schematic Design Loads

Upper and lower harness concrete blocks have been modeled in ANSYS with 4-node plane elements (PLANE42). Some schematic diagrams of this analysis have been shown in Fig. 6.

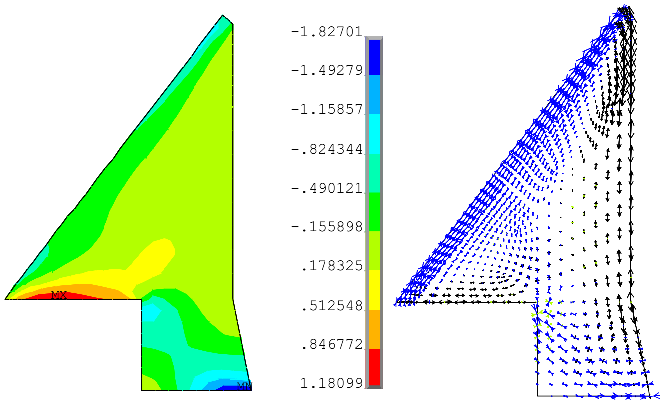

Fig. 6
Horizontal Stress Contour And Normal Stress Direction of Lower Block

Also, installation method of concrete panels in Winchester part has been modeled by SAP2000 as demonstrated in Fig. 7.

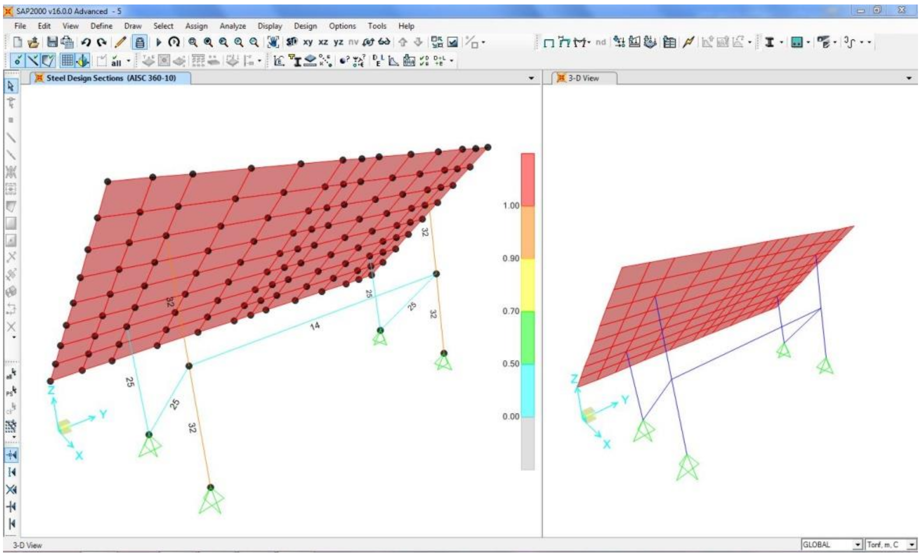

Fig. 7
SAP2000 Model for Installation Method of Winchester Panels

6. CONCLUSION

Based on studies [7], utilizing PVC geomembrane system instead of concrete slab as the impermeable element of Kahir dam has had these advantages:

- From technical aspect; watertightening with geomembrane has better results than upstream concrete slab and brings about higher level of certainty.
- From time aspect; using geomembrane shorten the duration of the project due to simultaneous construction of dam body and impermeable system. However implementing upstream concrete slab should be done after completion of dam body and foundation settlements.
- From cost aspect; both concrete slab and geomembrane system have almost had the same expenditure in this project but as mentioned before, the shorter the time of construction, the less the costs of project.

1. INTRODUCTION

The upper dam of Cheongpyeong Pumped Storage Power Plant is an old dam constructed in 1980, which is approximately 35 years ago. A water-collecting wall and a measuring device were installed in the downstream area of the dam structure in order to observe the seepage of water passing through the dam structure. However, the leakage could not be determined with the measuring device except during the period of localized heavy rain and summer season. It can be assumed that the water passing through the dam structure did not stay in the seepage water-collecting wall but flowed to other places.

Various field surveys were executed in order to determine the path of the water passing through the dam, which found a variety of paths of the seepage passing through the seepage water-collecting wall and the peripheral ground. This study intended to describe the survey and analysis processes designed to determine the cause of performance degradation of the facility for measuring the seepage in old dams.

2. CURRENT STATUS OF SEEPAGE MEASURING FACILITY

2.1. DAM STATUS

The Upper Dam is CCRD (Center core Rockfill Dam) which is a type of fill dam; the impervious core zone is installed in the center of the dam structure, the peripheral area is filled with rocks, and the seepage water-collecting wall is constructed in the downstream area of the dam structure. (Fig.1, Table 1)

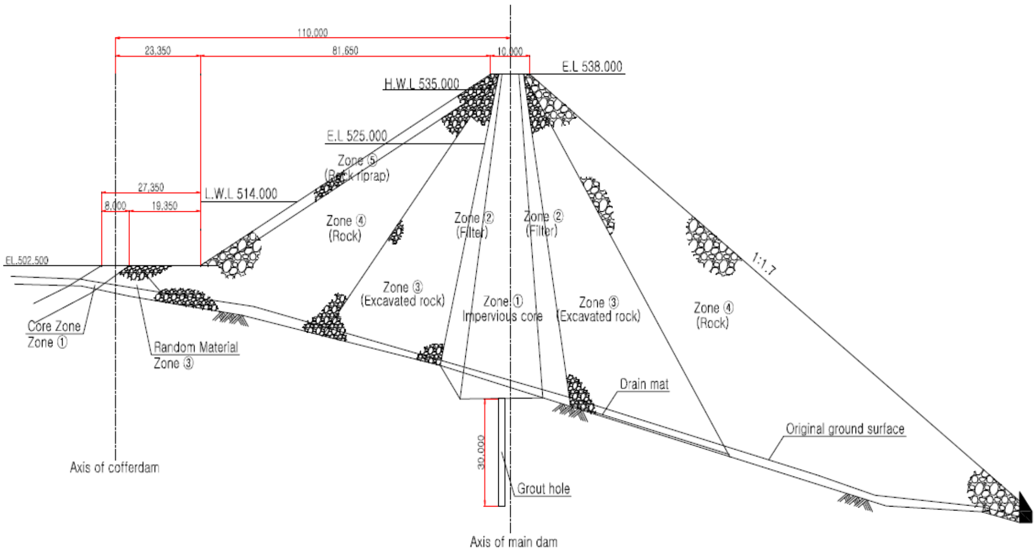

Fig. 1
Sectional Diagram of Upper Dam

Table 1
Specification of Upper Dam

Type	-	Center Core Rockfill Dam (CCRD)
Dam Crest	m	EL. 538.0
Length	m	290.0
Height	m	62.0
Dam Crest Width	m	10.0
Dam Volume	m^3	1,072,600
Inclination of Upstream Slope	-	1:2.3
Inclination of Downstream Slope	-	1:1.7

2.2. CURRENT STATUS OF SEEPAGE MEASURING FACILITY

The seepage measuring facility is composed of a water-collecting wall (Fig. 2) made of a concrete retaining wall (96m in length, 10m in maximum height) and a measuring room for measuring the collected water in the downstream area of the dam. (Fig. 3, Fig. 4)

Fig. 2
Water-collecting Wall

Fig. 3
Appearance of Seepage Measuring Room

Fig. 4
Inside Seepage Measuring Room

3. FIELD INVESTIGATION

3.1. OVERVIEW

Naked eye investigation, test pit investigation, concrete strength measurement, boring investigation, and Lugeon test were performed to determine the cause of failure of the seepage measurement facility.

3.2. NAKED EYE INVESTIGATION

The concrete of the water-collecting wall has been deteriorated and damages such as local breakage and peeling were found. However, the overall condition was acceptable and did not appear to have functional problems.

The seepage measurement facility using V-notch was constructed by using concrete and stainless steel, and the conditions of all four screen facilities installed inside were acceptable, and it is deemed that the facility has not lost its functionality completely as it maintained consistent water level even after pumping for a long time in the upstream area of the water-collecting wall.

3.3. TEST PIT INVESTIGATION

The test pit investigation was carried out at two points at the corners of both banks where it was expected that the influence of the groundwater level on the excavation would be low and the construction of the water wall would be easy to check as the height of the locations are relatively high among the sections where water-collecting walls are installed (Fig. 5).

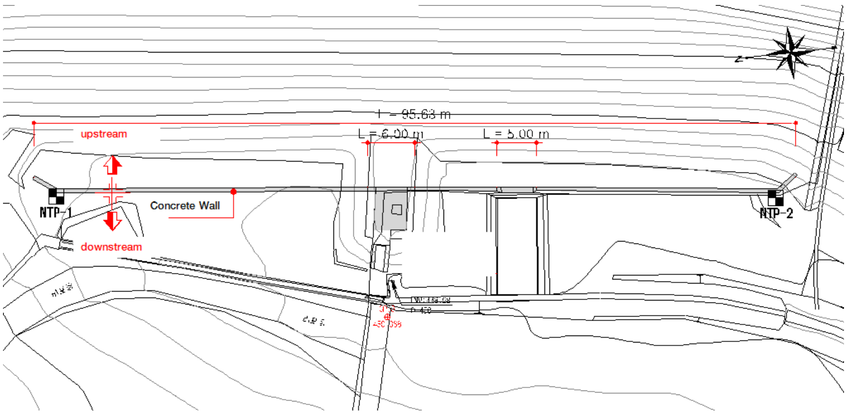

Fig. 5
Position of Test Pit Investigation

The NPT-1 test pit investigation was conducted at the corners of the water-collecting wall in the right bank of the dam. The groundwater was flowing into the excavation surface from 4.5m below the surface and the excavation could continue down to 4.8m below the surface. The mixture of buried layers (silty gravel layer mixed with sand) and boulder stones was distributed down to 1.5m below the surface of the ground. Concrete water-collecting wall (3m high) is installed at the bottom of the buried layer. There was no damage or leakage such as cracks and breakage on the concrete of the collecting wall, indicating the condition of construction is generally acceptable. However, the groundwater leaked from the contact area between the foundation concrete of the collecting wall and the bedrock (Fig. 6)

Fig. 6
Result of NPT-1 Test Pit Excavation

The NPT-2 test pit investigation was conducted at the corners of the water-collecting wall in the left bank of the dam. The groundwater was flowing into the excavation surface from 3.5 m below the surface and the excavation could continue down to 4 m below the surface. In addition, the bedrock was not found within the excavated depth, and the mixture of buried layer (silty gravel layer mixed with sand) and boulder stones was distributed in the downstream area of the water-collecting wall. There was no damage or leakage such as cracks and breakage on the concrete of the collecting wall, indicating the condition of construction is generally acceptable (Fig. 7)

Fig. 7
Result of NPT-2 Test Pit Excavation

3.4. Measuring Concrete Strength

The concrete strength was measured by using the Schmidt hammer and performed on the collecting wall and the measuring room. As a result of measuring the strength of the collecting wall and the lower spots of the wall in the positions NPT-1 and NPT-2 where the test pit investigation was conducted, the average uniaxial compressive strength was 19.6 ~ 19.7MPa, and the compressive strength compensated based on the age coefficient was estimated at 12.3 ~ 12.4 Mpa.

The concrete strength of the seepage measuring room was measured in one place inside the measuring room. The average uniaxial compressive strength was 23.1MPa and the compressive strength compensated based on the age coefficient was estimated at 18.3 Mpa.

3.5. Boring Investigation

The boring investigation was carried out at eight positions selected to determine the stratigraphical composition of the lower area of the collecting wall. The depth was determined based on the extent to which the bearing stratum is confirmed and the casing was gradually insderted down to the bottom of the weathering soil and the standard penetration test was performed at the same time in order to prevent the collapse of the pore wall during boring. As a result of the study, the water-collecting wall is distributed around the depth of 4.4 ~ 10m and is normal or acceptable as TCR was 50 ~ 100% and RQD was 50 ~ 100%.

The foundation the water-collecting wall was in contact with the soft rock layer which had a broad development of cracks and joints being. The soft rock layer was distributed in the lower area of the collecting wall in the depth of 5.4 ~ 9m and was relatively acceptable as TCR was 22 ~ 100% and RQD was 0 ~ 48%

Hard rocks were distributed in the lower side of the soft rock layer and they were relatively acceptable as TCR was 83 ~ 100% and RQD was 25 ~ 100% (Fig. 8).

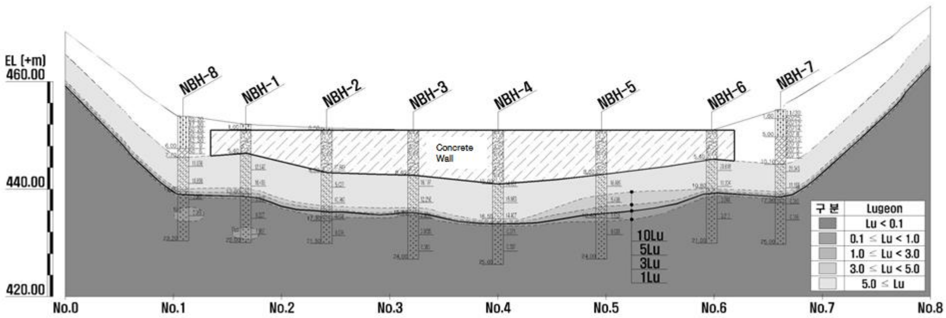

Fig. 8
Boring Investigation & Lugeon Map

3.6. Lugeon Test

A Lugeon test was conducted within the borehole to determine the permeability of the water-collecting wall and the ground, and some sections of the collecting wall and the soft rock layer showed 3Lu or higher permeability and the hard rock section showed less than 3Lu in all sections (Fig 8). It was assumed then the main speepage pathway of the water-collecting wall is the soft rock layer.

4. ANALYSIS OF SEEPAGE PATH

4.1. Longitudinal Seepage Path

The major seepage path is the 3Lu or more permeable stratum formed around the water-collecting wall, and this stratum is distributed in the thickness of 6.1 ~ 8.0m in the lower side of the water-collecting wall (a) and in the left side (b) and right side (c) of the water-collecting wall (Fig. 9) in the width of 19.0 ~ 25.2m.

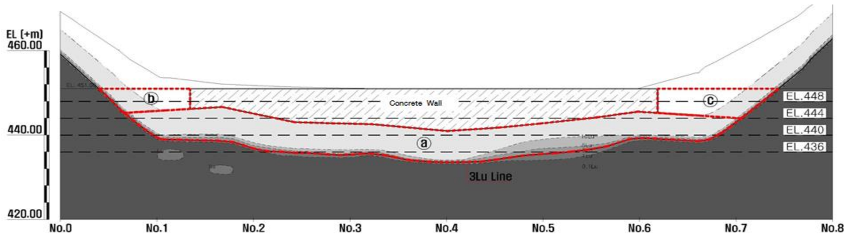

Fig. 9
Longitudinal Map Showing Seepage Path

4.2. PLANAR SEEPAGE PATH

As a result of analyzing planar seepage path at EL. 448m, the seepage pathway greater than 3Lu is distributed in the width of 133.8m, and the area blocked by the water-collecting wall is 95.9m in the center and 16.3m on the left side and 21.6m on the right side of the water-collecting wall. As the water-collecting wall does not completely block the permeable layer, the groundwater can flow in by making a detour around both ends. (Fig. 10)

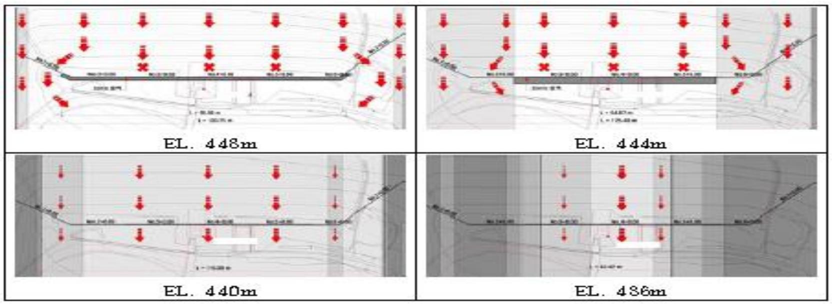

Fig. 10
Floor Plan Showing Seepage Path

At EL. 444m, the seepage pathway greater than 3Lu is distributed in the width of 125.4m, and the area blocked by the water-collecting wall is 64.9m in the center and 29.4m on the left side and 31.1m on the right side of the water-collecting wall. As the water-collecting wall does not completely block the permeable layer, the groundwater can flow in by making a detour around both ends.

At EL. 440m, the seepage pathway greater than 3Lu is distributed in the width of 115.4m. The seepage pathway between 3 ~ 5Lu accounted for 16.2% of the entire seepage pathway and that over 5Lu, 83.8%. It is confirmed that no section at this position is blocked by the water-collecting wall.

At EL. 436m, the seepage pathway greater than 3Lu is distributed in the width of 42.4m. The seepage pathway between 3 ~ 5Lu accounted for 50.8% and that over 5Lu, 49.2%. It is confirmed that no section at this position is blocked by the water-collecting wall.

5. CONCLUSION

As a result of several investigations which were conducted to identify the cause for functional degradation of seepage measuring facility, the water passing through the dam flew in various paths instead of being collected in the water-collecting wall, and the tracking of seepage path resulted in following conclusions.

First, the foundation of the water-collecting wall is located above the soft rock layer which is the bedrock. The quality of this soft rock layer is poor with the developments of cracks and joints and this layer displays 3Lu or greater permeabilty in all sections, which identifies the soft rock layer as the major seepage pathway.

Second, the investigation found the leakage of groundwater noticeable by the naked eye in the contact area between the concrete of the foundation of the water-collecting wall and the bedrock and identified the leakage in the contact area as another major cause.

Third, the condition of the concrete of the collecting wall was relatively acceptable. However, the Lugeon test showed that the lugeon value exceeded 3Lu in some sections and it is deemed that the leakage occurs through the wall as well.

We introduced and shared the methods and processes for analyzing the causes of functional degradation of the seepage measurement facility that can occur in dams as above and hope this helps the securing of the stability of the dam in operation.

ACKNOWLEDGEMENTS

The authors would like to express their gratitude for the extensive cooperation provided by Cheongpyeong Pumped Storage Power Plant.

SUMMARY

This study intends to find out the possibility of recovering the original function of the dam by analyzing the cause of functional degradation of the seepage measurement facility that may occur in old dams. The dam concerned is the upper dam of Cheongpyeong Pumped Storage Power Plant constructed in 1980, which is approximately 35 years ago, and it was not possible to measure the leakage except during the period of localized heavy rain as the water was not collected in the seepage measuring facility installed in the downstream area of the dam

Various field investigations were conducted to determine the cause of functional degradation of the seepage measuring facility. According to the result of naked eye investigation, the measuring facility did not have significant problems in carrying out its functions. Two points on both banks of the collecting wall were excavated to confirm the groundwater leakage around the water-collecting wall and it confirmed the leakage of groundwater in the foundation of the collecting wall in the right bank area of the dam. The result of strength measurement to confirm the soundness of the concrete of the collecting wall indicated that the condition of the wall is acceptable. In addition, a boring investigation was carried out to determine the geology of the foundation ground, and the Lugeon test, which was conducted to determine the permeability through the collecting wall and foundation soil, showed the sections with high lugeon values.

The comprehensive analysis of the investigation results showed various paths through which the leaking water flowed instead of being collected in the collecting wall and came to the following conclusions. First, the foundation of the water-collecting wall is located above the soft rock layer which is the bedrock. The quality of this soft rock layer is poor with the developments of cracks and joints and this layer displays 3Lu or greater permeabilty in all sections, which identifies the soft rock layer as the major seepage pathway. Second, the investigation found the leakage of groundwater noticeable by the naked eye in the contact area between the concrete of the foundation of the water-collecting wall and the bedrock and identified the leakage in the contact area as another major cause. Third, the condition of the concrete of the collecting wall was relatively acceptable. However, the Lugeon test showed that the lugeon value

exceeded 3Lu in some sections and it is deemed that the leakage occurs through the wall as well.

This study could identify various flow paths which deteriorate the function of the seepage measuring facility, and it is necessary to examine a way to recover the intended function of the facility by eliminating such abnormal flows in future studies.

1. INTRODUCTION

Mae Ngad Somboon Chon Dam is located in Mae Tang District Chiang Mai Province in the Northern part of Thailand. The project was initiated under His Majesty King Bhumiphol Adulyadej, originally proposed as multipurpose reservoir for irrigation, Water supply, hydro power and flood control. Construction period was 8 years, started in 1977 and was completed in 1985. Dam details and hydrology condition are as follows. Catchment area 1,281 square-kilometer, Average annual inflow 406 million-cubic meter Maximum reservoir storage 325 million-cubic meter, +398.000 m.-M.S.L. Normal reservoir storage 265 million-cubic meter, +396.500 m.-M.S.L. Dead storage 20 million-cubic meter, +360.500 m.-M.S.L. Dam height 59.00 meter (69.00 meter above bottom of cutoff trench) Dam crest width 9.00 meter (+404.000 m-M.S.L.), Dam length 1,950.00 meter Upstream slope 1:3, Downstream slope 1:2.5, Zone type dam Service spillway, Gate spillway capacity 1,035.00 cubic meter per second Emergency spillway, Earth spillway capacity 535.00 cubic meter per second River outlet 2,500 millimeter (I.D.), Right and Left irrigation outlet 800 millimeter (I.D.)

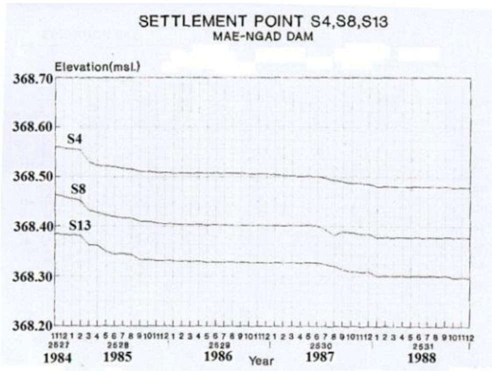
2. DAM INSTRUMENTATION AND DAM INVESTIGATION

During the end of construction, conventional dam instrumentation was installed in 1984 and started to measure manually in November. Dam instrumentation is as shown in Table.1.

Table.1 Dam instrumentation of Mae Ngad Somboon Chon (end of construction)

Dam Instrument			
1. Open end Stand pipe piezometer	18	4. Inclinometer	4
2. Surface settlement point	30	5. Observation well	21
3. Foundation settlement point	4	6. Reference Benchmark	6

Measured data from November 1984 to December 1988 is reported by Warathon[5] (1989). Settlement at Sta.0+180, depth section, is in Fig.2. In 2014, Region Irrigation office 1, Royal Irrigation Department (RID), improved dam instrument monitoring system by installation 50 vibration wire electric piezometers (Sta.0+180) (Fig.3), 3 Accelerometers, 2 Seismometers, 1 Seepage flow meter, 5 Observation wells with automatic water leveling sensor. Observation data are input to real-time monitoring system by specific time interval which can adjusted between 10 second to 1 minute. Output of real-time monitoring model display dam cross-section Sta.0+180 by numerical and color gradient display of pore pressure distribution. Dam investigation was done by collecting of large size sample (4 inch diameter) from dam crest to bottom of cutoff trench. Sample is trimed in laboratory for undisturbed sample for permeability test, triaxial test, and basic soil properties test (Fig. 4).



S.S.P	Degree of Consolidation (1984-1987)/(2014-2017)
S4	65.77%
S8	66.09%
S13	66. 36%

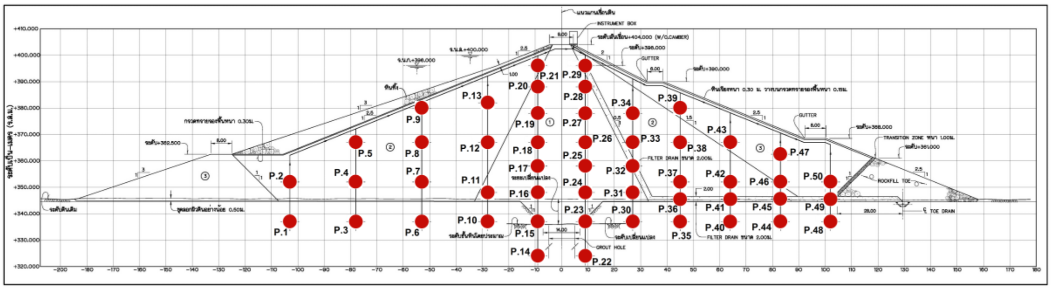

Fig. 3 Vibration wire electric piezometer at sta.0+180

Fig. 4 Dam investigation at Sta.0+180 (depth-section)

3. LONG TERM BEHAVIOR AND PERFORMANCE OF CORE ZONE AGAINST PORE PRESSURE DISTRIBUTION

Measured seepage behavior during period of 1984 to 1987 (before 66 percent degree of consolidation) are compared with recorded pore pressure distribution from 2014 to 2017 (approach 100 percent degree of consolidation) at Sta.0+180, depth section, as example shown in Fig. 5

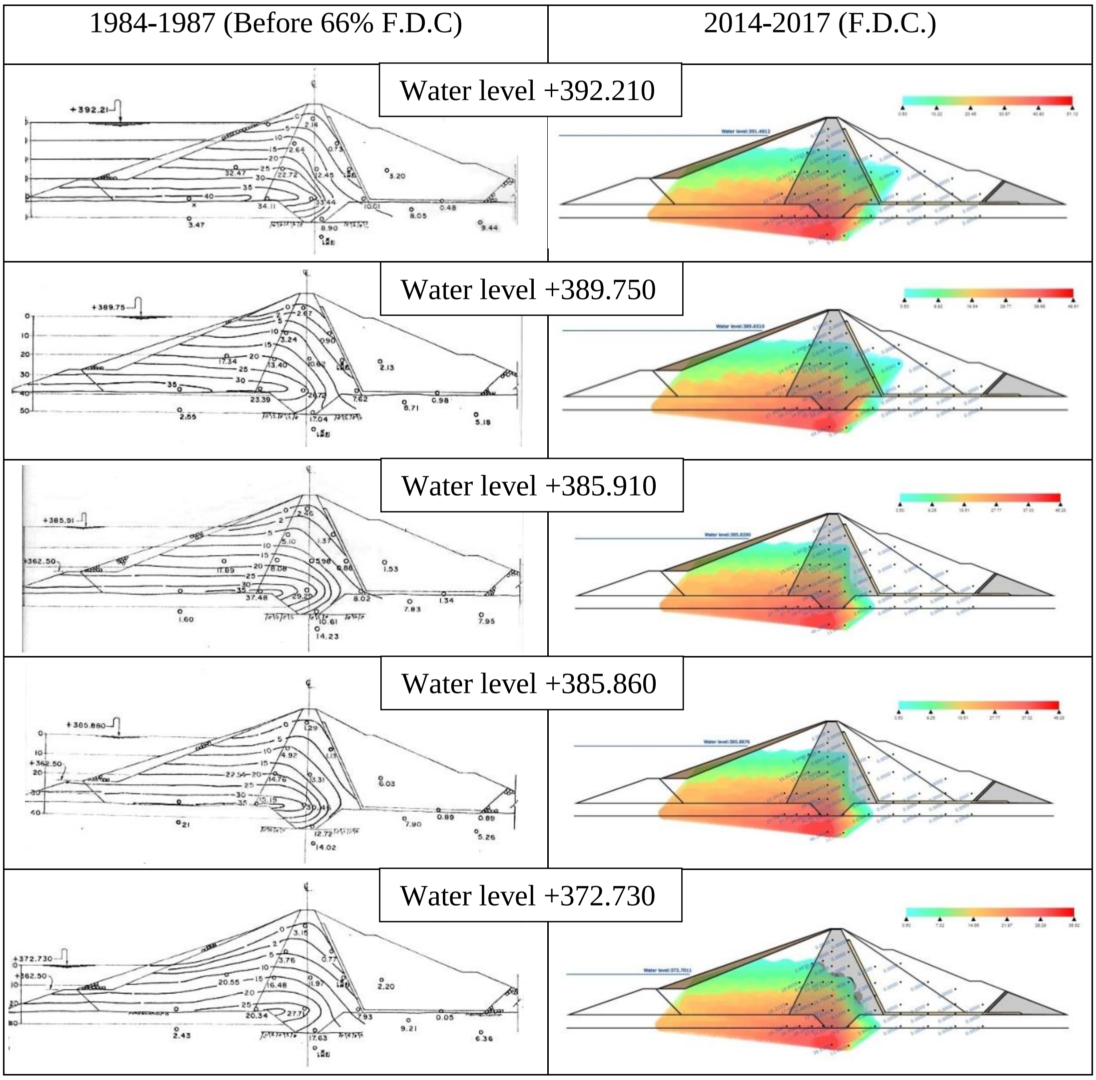

Fig. 5 Comparison between <2/3F.D.C. and F.D.C.

There are 5 seepage indicators proposed to assess core zone subjected to long term seepage pressure distribution as following.

1. Average upstream pore pressure of core zone
2. Average downstream pore pressure of core zone
3. Average seepage gradient of core zone
4. Average seepage velocity of core zone
5. Factor of safety against uplift of core zone

Long term behavior and performance of core zone against uplift distribution is proposed as comparison of indicators between seepage through core zone change from before two-thirds full degree of consolidation and full degree of consolidation under rule curve operation. Core layer seepage distribution a change is shown in Table2.

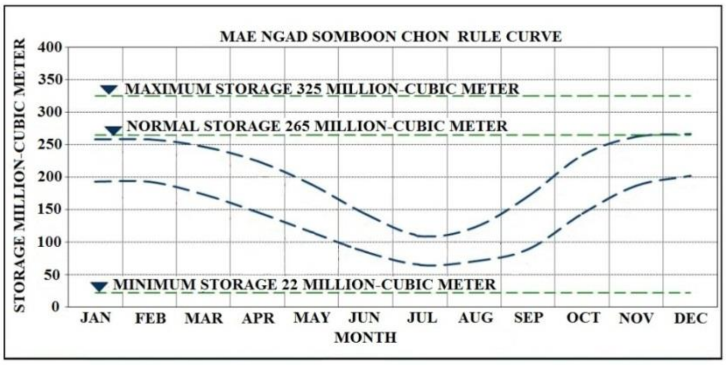

Fig. 6 Rule curve of Mae Ngad Somboon Chon Reservoir

Table2. Core layer comparison between <2/3F.D.C. and F.D.C.

Average	Contact clay $h_i \approx 0$	h_i=0.1	h_i=0.5	h_i=0.75
1.Pore Pressure U/S. core layer	reduce 77.72%	reduce 92.72%	reduce 92.37%	reduce 98.42%
2.Pore Pressure D/S. core layer	reduce 83.42%	reduce 99.05%	reduce 97.66%	reduce 172.26%
3.Seepage Gradient of core layer	reduce 61.40%	reduce 93.53%	reduce 91.60%	reduce 100.94%
4.Seepage Velocity of core layer	reduce 71.80%	reduce 95.63%	reduce 93.84%	reduce 100.50%
5.F.S. against uplift	increase 3.20 times	increase 13.76 times	increase 20.04 times	increase 294.15 times

Core zone investigation was done by dividing core height (H) into layers from bottom of cutoff trench. Core zone layer (i) is identified by height of considered core zone layer from bottom of cutoff trench (h) over core height (H), hi=h/H. Long term seepage performance index (L) of core layers is defined as lump conceptual for seepage indicator changes between first stage and stable stage compared with first stage.

$$L_{h_i} = a_{h_i} . b_{h_i} . c_{h_i} . d_{h_i} . e_{h_i} \quad [1]$$

Where,

a_{h_i}= average upstream pore pressure of core layer (i) change over first stage
b_{h_i}= average downstream pore pressure of core layer (i) change over first stage
c_{h_i}= average seepage gradient of core layer (i) change over first stage
d_{h_i} = average seepage velocity of core layer (i) change over first stage
e_{h_i} = factor of safety against uplift of core layer(i) change over first stage
H = height of core zone (m)
h = height of considered core zone layer from bottom of cutoff trench (m)

$$h_i = \frac{h}{Hi} \quad [2]$$

$$L_{avg_{h_i}} = -22273.739h_i^6 + 49838.747h_i^5 - 40452.909h_i^4 + 15444.748h_i^3 - 2925.149h_i^2 + 265.718h_i + 0.790 \quad , R^2 = 0.9967 \quad [3]$$

$$a_{avg_{h_i}} = -56.605h_i^6 + 156.448h_i^5 - 166.864h_i^4 + 87.455h_i^3 - 23.431h_i^2 + 2.962h_i + 0.793 \quad , R^2 = 0.995 \quad [4]$$

$$b_{avg_{h_i}} = 673.074h_i^6 - 1352.221h_i^5 + 990h_i^4 - 309.694h_i^3 + 33.616h_i^2 + 0.679h_i + 0.810 \quad , R^2 = 0.954 \quad [5]$$

$$c_{avg_{h_i}} = 305.093h_i^6 - 757.743h_i^5 + 723.474h_i^4 - 333.838h_i^3 + 76.548h_i^2 + 7.990h_i + 0.633 \quad , R^2 = 0.982 \quad [6]$$

$$d_{avg_{h_i}} = -233.363h_i^6 + 583.149h_i^5 - 560.129h_i^4 + 259.883h_i^3 - 59.786h_i^2 + 6.276h_i + 0.718 \quad , R^2 = 0.977 \quad [7]$$

$$e_{avg_{h_i}} = 37141.727h_i^6 - 57567.110h_i^5 + 30837.041h_i^4 - 5657.709h_i^3 - 277.879h_i^2 + 170.969h_i + 2.558 \quad , R^2 = 1.000 \quad [8]$$

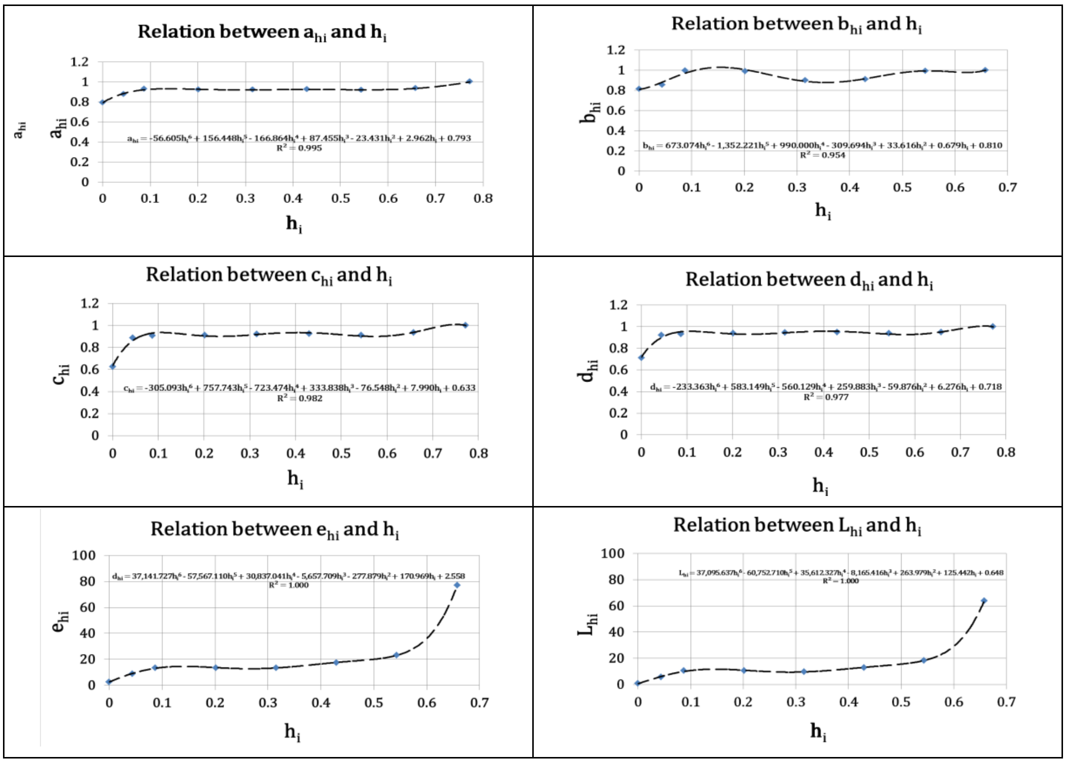

Fig. 7 Relation between $a_{h_i}, b_{h_i}, c_{h_i}, d_{h_i}, e_{h_i}, L_{h_i}$ and hi

Efficiency of core zone layer (i) can evaluated as, Efficiency of upstream pore pressure resistance = a_{h_i}.100, Efficiency of downstream pore pressure resistance = b_{h_i}.100, Efficiency of seepage gradient resistance = c_{h_i}.100, Efficiency of seepage velocity resistance = d_{h_i}.100. Seepage penetration resistance (S.P.R.) for long term is assumed as lump conceptual as resistance of core zone in reducing upstream pore pressure, downstream pore pressure, seepage gradient and seepage velocity.

$$\text{S.P.R.} = a_{h_i} \, . \, b_{h_i} . \, c_{h_i} . \, d_{h_i} . \qquad [9]$$

$$\text{S.P.R.} = -381.541h_i^6 + 842.326h_i^5 - 756.158h_i^4 + 354.974h_i^3 - 90.404h_i^2 + 11.201h_i + 0.284 \quad , \; R^2 = 0.999 \qquad [10]$$

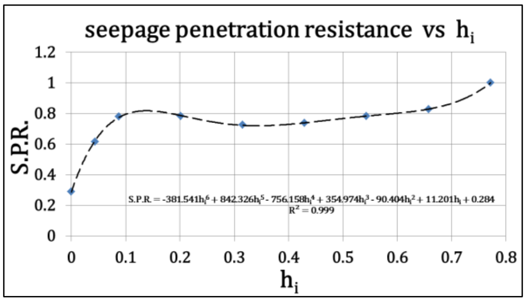

Fig. 8 Relation between S.P.R. and h_i

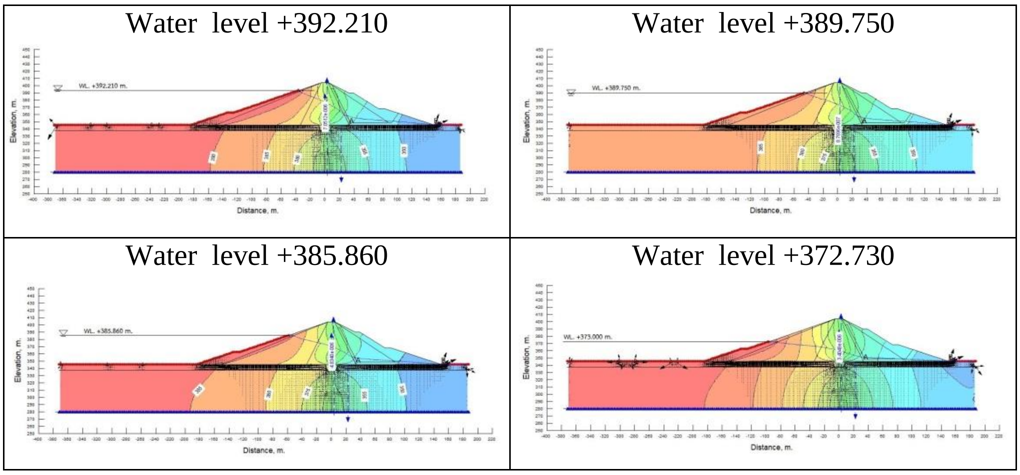

Fig. 9 Finite element seepage analysis

Eq. [3] to Eq. [10] and Fig.7 and Fig.8 show the long term behavior and performance of core layer from bottom of cutoff trench to top of core layer. Upstream core layer pore pressure is minimally decrease at bottom layer h_i = 0 and rapidly fall in $0 < h_i \leq 0.1$ from 79.30% (h_i = 0) to 92.72%(h_i = 0.1) then gradually reduce to 98.42% at h_i = 0.75. Downstream core layer pore pressure is minimally decrease at bottom layer h_i = 0 and rapidly falls in $0 < h_i \leq 0.1$ from 81.00% (h_i = 0) to 99.05 (h_i = 0.1) then gradually reduces to 107.23% at h_i = 0.75. Core layer seepage gradient is minimally decreased at bottom layer h_i = 0 and rapidly reduces in $0 < h_i \leq 0.1$ from 63.30% (h_i = 0) to 93.53 (h_i = 0.1) then slowly drops to 100.94% at h_i = 0.75. Core layer seepage velocity is minimum relaxation at bottom layer h_i = 0 and rapidly falls in $0 < h_i \leq 0.1$ from 71.80% (h_i = 0) to 95.63 (h_i = 0.1) then slowly drops to 100.50% at h_i = 0.75. Factor of safety against uplift of core layer is minimally increased at bottom layer h_i = 0 and rapidly rises in $0 < h_i \leq 0.1$ from 255.80% (h_i = 0) to 1,376.36% (h_i = 0.1) then slowly raises to 2,004.10% finally rapidly increases to 68,870.23% at h_i = 0.65.

Table4. Seepage distribution from $<\frac{2}{3}$ F.D.C. to F.D.C.

Part	h_i	q (m^3/sec/m)		Δq (%)
		<2/3 F.D.C	F.D.C.	
4^{th}	$0.5<h_i\leq0.75$	5.93×10^{-6}	1.68×10^{-7}	-97.17%
		(2.16%)	(2.94%)	
3^{rd}	$0.1<h_i\leq0.50$	5.12×10^{-5}	2.70×10^{-6}	-94.74%
		(70.42%)	(43.17%)	
2^{nd}	$0<h_i\leq0.10$	1.29×10^{-5}	2.09×10^{-6}	-83.70%
		(17.69%)	(36.61%)	
1^{st}	$h_i\approx0$	2.70×10^{-6}	7.62×10^{-7}	-71.80%
		(3.72%)	(13.32%)	
Total		7.27×10^{-5}	5.72×10^{-6}	-92.13%
		(100%)	(100%)	

The measured seepage data from 1984-1987 and 2014-2017 along with finite element seepage analysis result in Table.4 followed 4 parts of seepage penetration resistance. Long term seepage through core zone reduces by 92.13%. Seepage discharge almost penetrates the core zone in range $h_i \leq 0.5$ for short term 97.84% and long term 97.06% of average total seepage discharge. Core zone layers at $h_i > 0.5$ rapidly increased L and S.P.R. but seepage discharge for initial and final stage is 2.16% and 2.94% of average total seepage discharge, respectively. Core zone layers in $0.1< h_i \leq 0.5$ gradually raise L and S.P.R. however seepage discharge is mostly influence from average total seepage discharge for initial stage (<2/3F.D.C.) and final stage (F.D.C.) about 70.42% and 47.13%, consecutively. Layers in core zone $0< h_i \leq 0.1$ is rapidly increase L and S.P.R. but seepage discharge for initial and final stage is 17.69% and 36.61% in order. Contact clay layer (0.30meter from bottom of cutoff trench) at bottom of core zone hi ≈ 0 is minimum L and S.P.R. and minimum of seepage discharge reduction. Seepage discharge distribution dissipate to bottom layer $0.1< h_i \leq 0.5$, $0< h_i \leq 0.1$, $h_i \approx 0$ from initial stage 70.42%, 17.69%, 3.72% to final stage 47.13%, 36.61%, 13.32%, respectively. As part1 $h_i \approx 0$, contact clay layer has minimum reduction of seepage discharge 71.80%, maximum seepage discharge distribution from 3.72% to 13.32% or 3.58 times and minimum increase in factor of safety against uplift 255.80% exhibited boundary condition of core zone weak layer.

4. CONCLUSION

Long term performance index (L), Seepage penetration resistance (S.P.R.) represent an overview and inter-layers seepage through core zone layers changes between initial stage (before2/3 full degree of consolidation) and final stage (full degree of consolidation).

Significant seepage discharge penetrated core zone below middle height (hi ≤ 0.5) for initial stage 97.84% and final stage 97.06% of total average seepage discharge.

Minimal seepage discharge penetrated the core zone above middle height (hi > 0.5) for initial stage 2.16% and final stage 2.94% of total average seepage discharge, despite maximum reduction of upstream core layers pore pressure, downstream core layers pore pressure, core layers seepage gradient, core layers seepage velocity, and maximum increase factor of safety against uplift.

Long term seepage through core zone reduce 92.13%

Long term seepage discharge distribution tends to dissipate to bottom layers $0.1< h_i \leq 0.5$, $0< h_i \leq 0.1$, $h_i \approx 0$ from initial stage 70.42%, 17.69%, 3.72% to final stage 47.13%, 36.13%, 13.32% respectively.

Contact bottom core layer has boundary condition of weak layer from long term seepage behavior due to minimum reduction of seepage discharge 71.80%, maximum seepage discharge distribution (dissipate from upper core layers) from 3.72% to 13.32% or 3.58 times and minimum increase in factor of safety against uplift 255.80%.

5. RECOMMENDATION

Long term behavior and performance should not be used to design for safety factor but should benefit to additional safety factor.

Future research should extend to boundary condition affecting L, and S.P.R. such as shallow foundation against deep pervious foundation, various dam type, component, and efficiency of internal drainage system, foundation and abutment, reservoir operation, and the like.

Long term seepage performance index, L, and seepage penetration resistance, S.P.R., should benefit long term dam safety management alongside with visual inspection.

1. INTRODUCTION

1.1 BACKGROUND

Mea Thi Dam is located in Ban Thi district, Lamphun province in the northern part of Thailand as shown in Fig. 1. The construction of the dam was completed in 1987, for purpose to storing water for irrigation and water supply. The constructed dam is 25.60 m in height , 8 m in width and 437 m in length. The dam is maintained by, the Royal Irrigation Department (RID). Then in 2009, to increase the dam capacity up to 6.0 million cubic meters from 4.5 million cubic meters, 1 m parapet wall was constructed.

Furthermore, in 2012 seepage problem was encountered at the right abutment of the dam including embankment settlement. A hole of size 10 to 20 cm was observed in downstream at the connection zone between abutment and dam body as shown in Fig. 2.

The right side of the dam had water leakage with rate of as much as 60 liter/minute at the downstream along with the soil embankment subsidence. With all these problems encountered which would affect the dam efficiency and safety various solutions were mulled over and the appropriate one chosen as per suitability. To solve these problems without emptying the reservoir and avoiding any excavation works, cement and chemical grouting was proposed by Regional Irrigation Office 1 Chiang Mai province who supervised this project, to improve the foundation, control seepage and maintain stability of the dam. The general working areas to improve the dam condition were at the right abutment, dam embankment and the connection zone between embankment and abutment of the dam.

1.2 CHARACTERISTICS OF DAM

The general information characteristics of the dam is as below [1]

Dam length	437.00	Meter
Dam height	26.50	Meter
Dam crest width	8.00	Meter
Dam crest elevation	+419.00	Meter (M.S.L)
Maximum reservoir elevation	+417.00	Meter (M.S.L)
Retention water elevation	+416.00	Meter (M.S.L)
minimum reservoir elevation	+404.00	Meter (M.S.L)
bed level	+399.00	Meter (M.S.L)
Gross capacity reservoir	5.5	Million-cubic meter

Fig. 1 Location of Mae Thi Dam site, Lumphun province, Thailand
(https://www.google.co.th/maps/place/Thailand/)

Fig.2 Area of Water Leakage

2. GEOLOGY

2.1 GENERAL GEOLOGICAL CONDITIONS

Geological mapping of Geological Survey of Thailand, Geological Resources Department (DMR, 2007) identified the rocks in the reservoir area of Lumphun province and neighboring areas. It consists of sediments include gravel, sand, silt, clay and laterite of Quaternary time. Base rocks are Conglomerate, Sandstone, Shale, Slate and Chert of carboniferous period as shown in Fig. 3. [2]

2.2 GEOLOGICAL FOUNDATIONS AND SOIL CONDITION

The soil layer of embankment dam consists of mixture of silt with sand (ML) and sandy silt with gravel (ML). Borehole at the crest of the dam was conducted and stiff to very stiff cohesive soil was observed at depth of 0.00 - 15.00 m. The permeability ranged from medium to high (1.05×10^{-5} to 2.49×10^{-5} cm / sec.) The base of the dam consists of rock foundation extending from ground surface. It is characterized as Grayish-white colored sandstone, moderately weathered hard rock. The average permeability extended from low to moderate (1.09 - 3.46 Lugeon). [3]

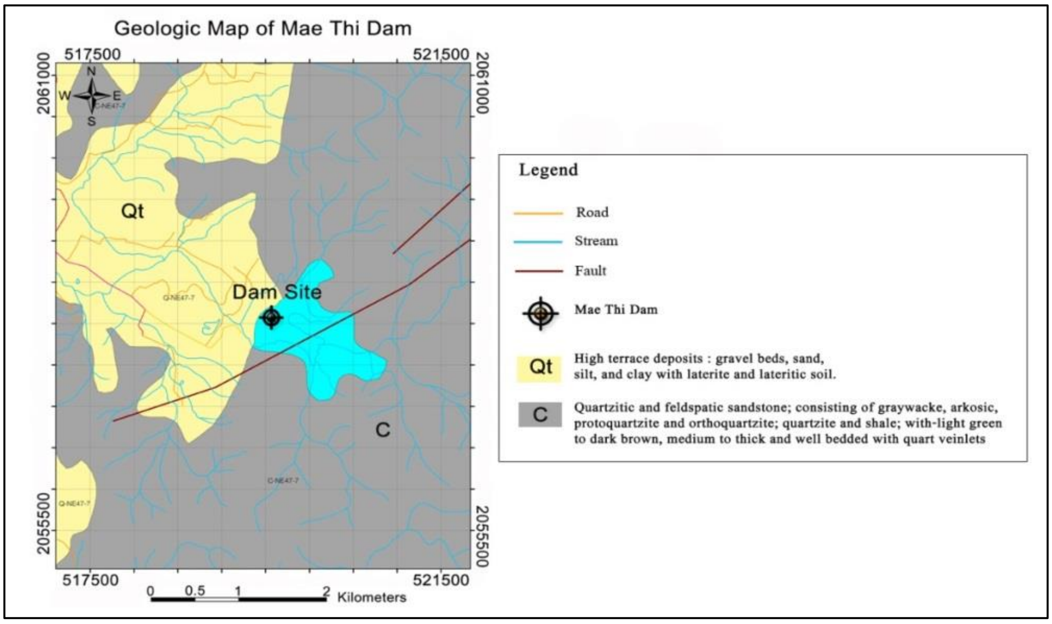

Fig. 3 Geologic Map of Mae Thi Dam Site (DMR, 2007)

3. METHODOLOGY

The main objective of this work was to improve ground condition of dam by carrying out cement and chemical grouting without excavation and emptying reservoir. The profile of grouting works conducted is shown Fig. 4 [3]. Other geotechnical works like the Standard Penetration Test (SPT), permeability tests of the soil, Lugeon Test in rock, drilling holes for cement and chemical grouting were carried out appropriately. Finally, after completion of work requirement quality and limit check was carried regarding the permeability, SPT and Rock Quality Designation (RQD).

3.1 CEMENT GROUTING

For rock foundation, high pressures cement grouting process with quick setting condition was applied. Whereas, for areas with high uplift pressure cement grouting was carried out in discrete steps allowing setting time for grout. Portland Cement Type 1 or Type 3 was used for cement grouting. The compound was used to improve the foundation in stages with varying ratio of cement and water of 1:10, 1:8, 1:6, 1:4, 1:3 and 1:2. Mortar was applied using varying pressure with depth with details given in Fig.5 At first hole was drilled to specified depth then permeability test using water pressure was carried out. Depending upon the permeability the grout mixture was selected as shown below.

Permeability	20	Lugeon	= Cement : Water	= 1:10
Permeability	20-50	Lugeon	= Cement : Water	= 1:8
Permeability	> 50	Lugeon	= Cement : Water	= 1:6

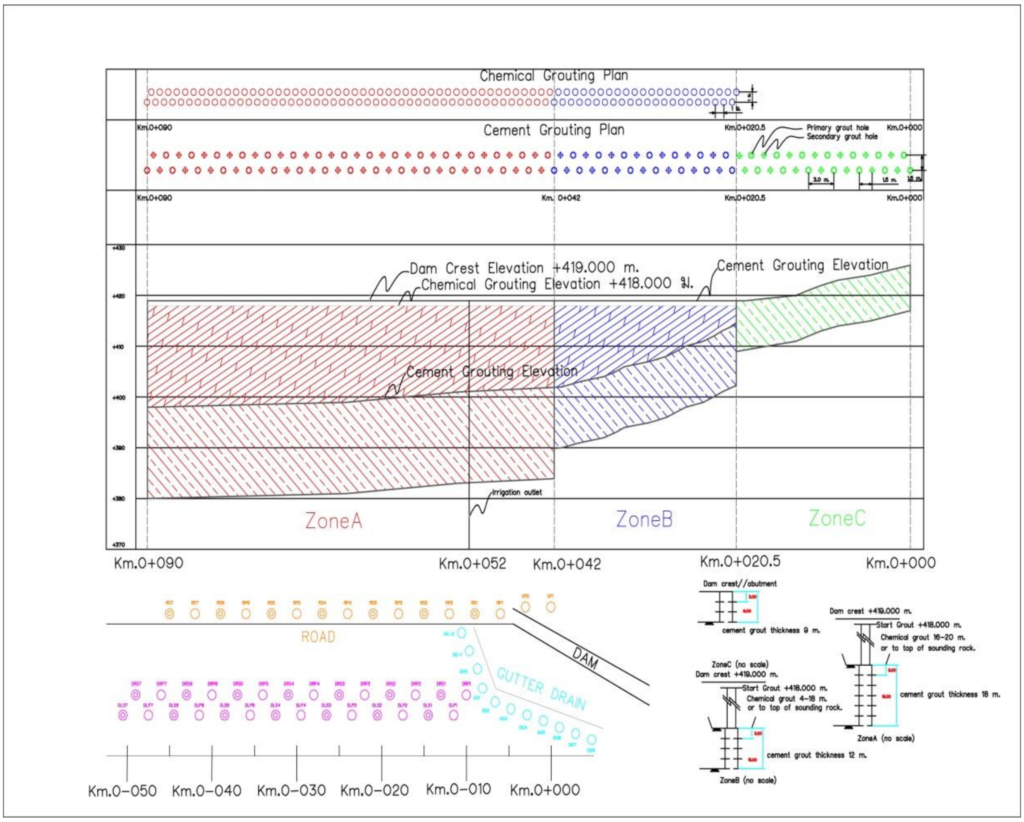

Fig. 4 Profile of Cement and Chemical Grouting Hole Conducted for Mae Thi Dam (Modified from Site plan No. RID1.GEOL. 153/2013)

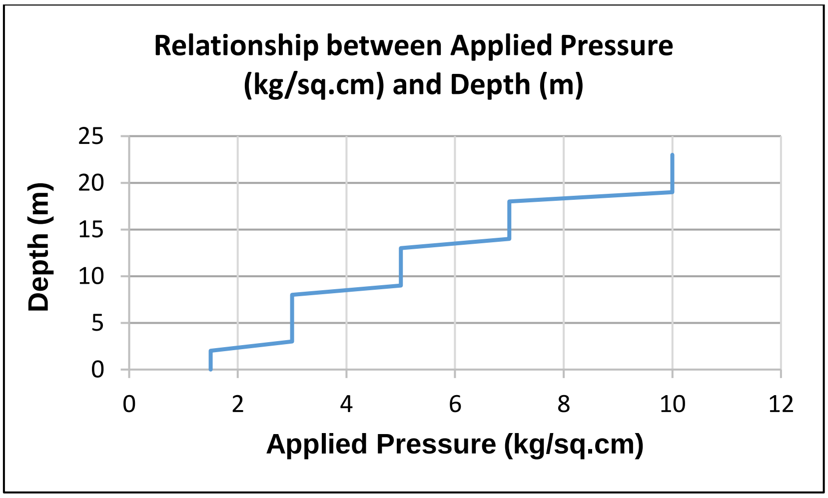

Fig.5 Pressure applied during cement grouting

3.2 CHEMICAL GROUTING

For chemical grouting in clay portion high pressure could not be applied during grouting thus, experiment was carried out to estimate the gel time of water (l), Silicate (l) and Bicarbonate (kg) mix as shown below in the lab. With reference to lab test, field mixture with varying gel time was determined and used accordingly.

The ratio of compound mixture from laboratory is as below

Water	:	Sodium silicate	:	Sodium Bicarbonate	Gel time
173 liters		25 liters		4 kg	2-3 hr.

The actual ratio of compound mixture in the field is as below

Water	:	Sodium silicate	:	Sodium bicarbonate	Gel time
150 liters		10 liters		2 kg	40 min.
115 liters		10 liters		2 kg	20 min.
110 liters		10 liters		2 kg	10 min.

As, due to high uplift pressure on upstream side, chemical grouting was conducted with application of pressure as given in Fig. 6 at the holes spaced at 6 m distance apart.

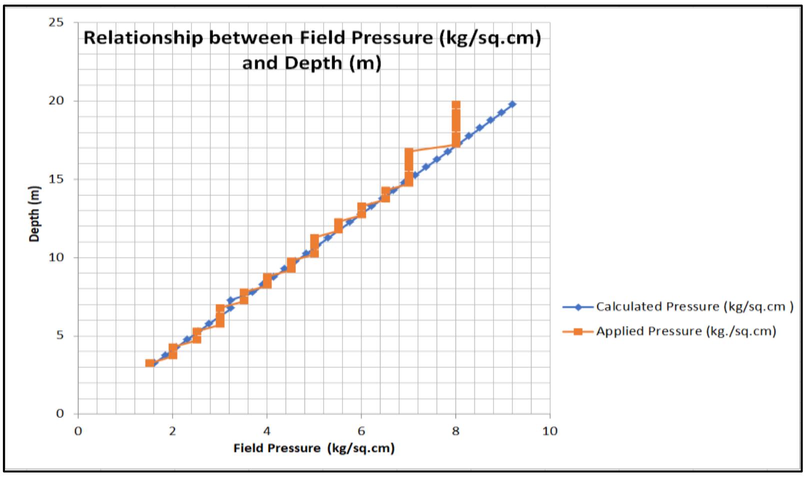

Fig. 6 Pressure applied during chemical grouting

4. WORKING PROCEDURE

The works were separated into Zone A, Zone B and Zone Cat connection zone between abutment and dam body, Gutting Drain and right abutment access road [4]. The profile of grouting hole depending upon the requirement conditions cement and chemical grouting were chosen accordingly as shown in Fig. 4. Chemical grouting was carried out in Zone A and Zone B while cement grouting was carried out in Zone B, C, connection zone between abutment and dam body, Gutting Drain and right abutment access road provided in Fig. 7.

Fig. 7 The working areas as A. Zone C, B. Zone A, B C. Gutting Drain, D. Connection Zone between Abutment and Dam Body, E. Gutting Drain and F. Right Abutment Access Road

5. ANALYSIS

SEEP/W program a finite element analysis of GEO-SLOPE Company [5] was used to calculate factor of safety against uplift of existing Mae Thi dam. The model of SEEP/W analysis of Mea Thi dam is shown in Fig. 8. The factor of safety (FS) calculation have been conducted for core zone separated into 8 layers for existing dam condition Then, it was compared with F.S. that was determined against uplift during chemical grouting for varying pressure from 1.5 to 8.00 kg/cm^2. The limited recommended factor of safety against uplift from USBR (2014) is 1.5. [6, 7]

Finally, graphical relationship between h_i and F.S. against uplift was plotted as shown in Fig. 9.

Where $$h_i = \frac{h}{Hi} \qquad [1]$$

H_i = height of core zone layer (m)
h = height of considered core zone layer from bottom of cutoff trench (m)

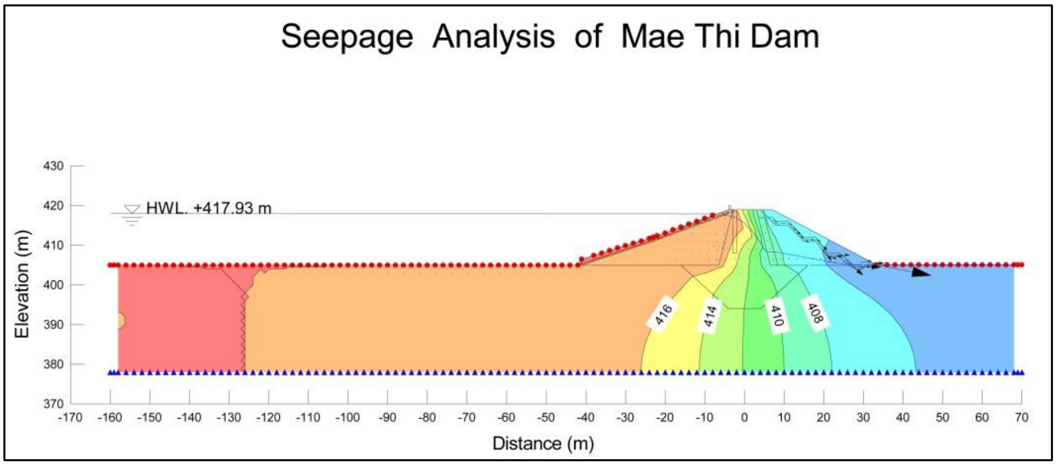

Fig. 8 SEEP/W model of Mae Thi dam, Lumphun province, Thailand

6. RESULTS

At normal reservoir storage condition of +416.00 m, for core layer $0< h_i \leq 0.5$ computed F.S. against for existing dam varied from 3.5 to 4.5 for h_i =0 and h_i =0.5 and was about 8 for h_i =0.75. Design Chemical grout pressure were in range of 1.5 t/m^2 (h_i =0.85) to 8.0 t/m^2 (h_i =0). The FS calculated for chemical grouting with pressure showed the values extending from 2.0 to 3.0, with was over the limiting value of stability against uplift of FS of 1.5 as show in Fig. 9. During chemical grouting, no embankment heave was measured from the surface settlement markers installed on the crest of dam. To increase the output efficiency of dam after increasing reservoir capacity under full storage condition, dam improvement was carried out to stop water seepage. Outcome cropping yield 10 square kilometers irrigation area are not affected from dam and foundation improvement. Agriculture production value about 2 million US Dollar/crop. The ground improvement works of Mea Thi dam were completed on June 2017. The present condition of still dam reservoir is shown in Fig. 10.

7. CONCLUSIONS

7.1 Ground Improvement of Mae Thi Dam without excavation and emptying reservoir by using chemical grouting showed the F.S. against uplift greater than the limiting value as per USBR standard.

7.2 The apply pressure of chemical grouting varied from 1.50-8.00 kg/cm2 in this project.

7.3 The water leakage through the soil embankment and rock foundation with full storage reservoir was within the prescribed limits. (Less than 5 Lugeon, 5.0x 10^{-7} cm^2)

7.4 Cement and chemical grouting without excavation and emptying reservoir saved time, cost and utilization excessive manpower or material mobilization without hampering the reservoir operation.

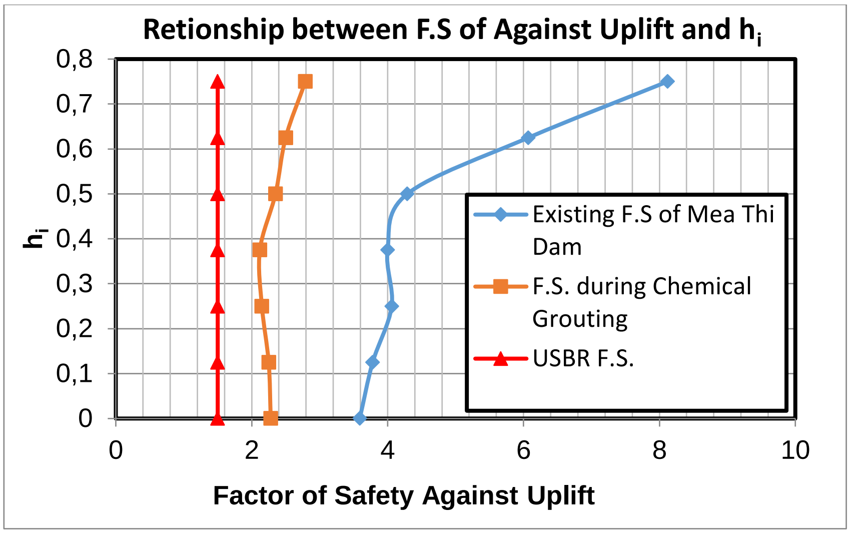

Fig. 9 Graph shown relation between F.S. against uplifts and h_i of Mae Thi dam

Fig. 10 Mae Thi Dam after completion of Ground Improvement

8. RECOMMENDATIONS

8.1 Dam and foundation seepage control improvement by cement-chemical grouting under storage condition should be controlled by F.S against uplift for not less than 2.0 along with measuring surface settlement to ensure the no excessive pressure is applied.

8.2 Grout pressure applied in the field should be gradually increased corresponding with gel setting time and chemical mixture. For Mea Thi core zone compound mixture of water (l), Silicate (l) and Bicarbonate (kg) was used in the ratio of 150:10:2 with the gel-setting time of 40 min., 115:10:2 with the gel-setting time of 20 min and 110: 10:20 mix with gel setting-time of maximum 10 min.

9. ACKNOWLEDGEMENT

Firstly, we would like to express our sincere gratitude and thanks to the Ministry of Agriculture and Cooperatives (MOAC) Thailand and Royal Irrigation Department (RID) for providing us necessary support and information to conduct this project. Also, we would like to appreciate all the colleagues of Chiangmai, RID and other people who are directly and indirectly involved to complete this project.

FOUNDATION TREATMENT CHALLENGES FOR EARTH AND ROCK FILL DAMS – CASE STUDY OF THE LEFT EMBANKMENT DAM ON ISIMBA (183MW) HYDRO POWER PROJECT, UGANDA.

Nicholas Agaba Rugaba, Assistant Project Manager, Uganda Electricity Generation Company Limited (UEGCL)

Co- Authors: Eng. Chad Silas Akita, Project Manager, UEGCL.

Eng. Isaac Arinaitwe, Chief Projects Officer, UEGCL.

Eng.Dr. Harrison Mutikanga, Chief Executive Officer, UEGCL

Introduction

Uganda will require 8,601MW by 2020, 14,670MW by 2025 and 41,738MW of electricity by 2040 as it works towards middle income status.[1] One of the strategies in the National Development Plans is to construct large hydropower plants and thermal power plants through public and private investments, and Isimba Hydro Power Project is being developed with debt financing to a tune of Five Hundred Million United States Dollars (USD 500m). The EPC Contractor is China International Electric and Water Corporation (CWE). The debt financing is provided by the China Export and Import Banks. For Isimba Hydro Power Project, the reservoir is retained by concrete structures and two earth-rock fill embankment dams on both sides of the concrete structures.

[1] Uganda's National Development Plan 2010-2015

Project Lay-out

The Isimba HPP structures are arranged in a polyline perpendicular to the flow of the river. The structures arranged along the dam axis, from left to right are the Left Embankment Dam section to connect the whole complex to the left bank, the Concrete Gravity Dam section GD1, Powerhouse, Spillways SP1 and SP2, the Concrete Gravity Dam section GD2 and the Right Embankment Dam section to connect the whole dam complex to the right bank . For the connection between the concrete structures and abutments as well as for the closures of the right river channel an earth-rock-fill dam type with central clay core was selected.[2] The lay-out of the embankment dams for Isimba HPP is shown in Figure 1 below.

Fig 1: Artistic Impression of Isimba Hydro Power Project (Adopted from EPC Contractor's Implementation Proposal, 2014)

[2] Isimba HPP Feasibility Study Report - Fitchner and Norplan , September 2012

Rationale for Adoption of Earth Rock-Fill Embankment Dams

Embankment dams are a crucial element for different infrastructure projects including hydropower dams for reservoir impounding (to create a “man-made lake”) for water that is used in power generation through the Electro-mechanical and Hydro-mechanical equipment in the plant. For Isimba HPP, the reservoir (retained by concrete structures and two earth-rock fill embankment dams on both sides of the concrete structures) was adopted both at feasibility design, basic design and currently at detailed design and construction stage.

Earth-rock fill embankment dams were preferred to other types of dams e.g. Roller Compacted Concrete dams. This is because of the vast availability of the rock fill and clay core material in the vicinity of the site, compared to the need for very distant transportation of pozzolanic or fly ash material for the Roller Compacted Concrete (RCC) dam. Furthermore, having reviewed test results from the laboratory investigations on the rock samples, it was established that a substantial part of the excavated material (from the foundation of the powerhouse and spillways) could be used for construction of the earth-rock fill dam without as much processing compared to a Roller Compacted Concrete (RCC) dam.

According to the International Committee on Large Dams(ICOLD), a “**dam**” can be defined as “An artificial barrier, together with appurtenant works, constructed for storage, or control of water, other liquids, or other liquid-borne material (excluding concrete/steel ring tanks reliant on hoop stress for structural stability).” The Left Embankment Dam is part of the appurtenant structures (spillways, power house, concrete gravity dams, right embankment dam etc.) that are used for retaining water and creation of a reservoir or man-made lake, to achieve desired head/ water levels for electricity generation through the electro mechanical and hydro mechanical structures. A rock-fill embankment dam is one composed largely of fragmented rock with an impervious core. The core is separated from the rock shells by a series of transition zones built of properly graded material. The rock-fill zones are compacted in layers 12 to 24 inches (300 mm to 600 mm) thick by heavy rubber-tired or steel-wheel vibratory rollers. A typical cross-section of an earth rock-fill embankment dam is illustrated in Figure 2 below.

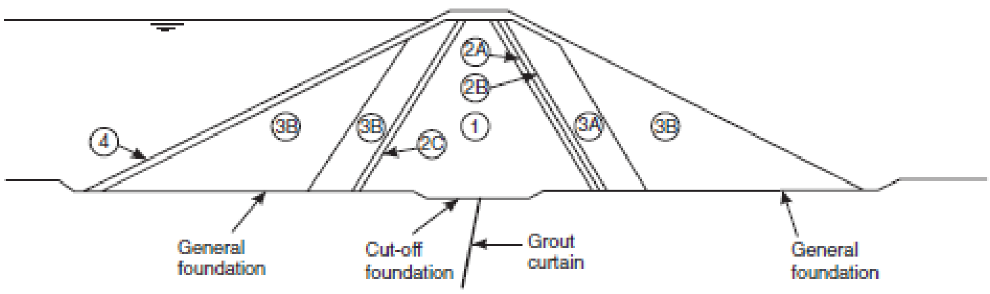

Figure 2: Typical Embankment Dam Section with Central Clay Core. (Key; 1 - Impermeable Clay core, 2 Filters/Transition Zones, 3 – Rock fill 4 – Rip Rap or Concrete face). Adopted from Robin Fell et al, 2005 (Geotechnical Engineering for Dams)

Foundation Treatment and Challenges

Geologic processes cause dam foundations to be much less than perfect for the construction of an embankment dam. Thus, foundation treatment is almost always required to improve a foundation to a suitable condition before a dam is constructed. Recognition of natural processes that damage foundations helps to formulate foundation treatment objectives. Such processes and their effects include; buried river channels, faulting, shearing, slope instability, solution cavities, potholes, benches, overhangs, steps, stress relief joints etc.[3] At the Isimba Hydro Power Plant, the right river channel had shear zones in the river bed that needed concreting and treatment. Foundation treatment is the utilization of ground improvement techniques so as to mitigate undesirable foundation concerns of

[3] Foundation Surface Treatment, Design Standard 13 USBR Manual

embankment dams namely, excessive seepage and possible piping; collapse of dry, low density abutment soils; and potentially liquefiable soils during earthquake shaking.[4] Seepage (percolation) is the slow movement of gravitational water through the soil or rock, as illustrated in Figure 3 below.

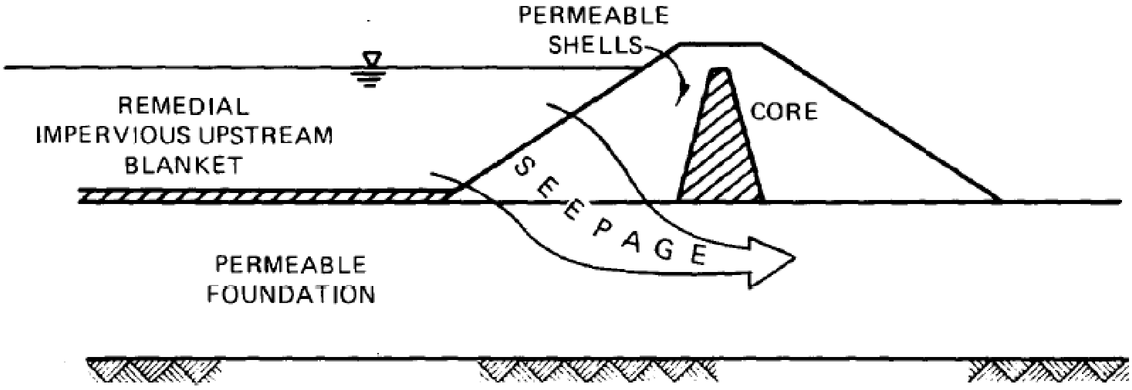

Figure 3: Possible seepage problem in embankment dam. (Adopted from USACE EM – 1110 – 2 – 1901 Seepage Analysis and Control.)

Piping is the washing of fines from soils/ rocks or fractures, dispersive soils. It involves the progressive removal of soil particles from a mass by percolating water, leading to the development of channels. Foundation treatment must therefore be adequate to satisfy the following criteria; minimum leakage, prevention of piping in the foundation, limited settlement and ensuring sufficient friction development between abutments and dam foundations to ensure stability against sliding.

The Left Embankment Dam foundation was also specified to comply with certain permeability parameters and also stability requirements. These include 1 Lugeon value for foundation permeability and dam stability under static and dynamic loading as per USACE EM – 1110 – 2 – 1902 guidelines. This called for robust

[4] Earth Manual Part 1

foundation treatment to ensure compliance to technical specifications and seepage control measures.

Seepage through a permeable foundation, similar to the weathered rock foundation at the Left Embankment Dam at Isimba HPP, can be reduced by constructing a low permeability cut off through the permeable material. There are various seepage cut-off approaches namely; cut-off trench filled with earth fill, slurry trench, concrete diaphragm wall, contiguous or intersecting bored piles, sheet pile wall, curtain grouting etc. The Left Embankment Dam at Isimba HPP adopted two main ground improvement methodologies as part of foundation treatment, i.e. grouting and construction of concrete cut-off wall, along the longitudinal axis of the dam. Grouting involves the injection under pressure of a liquid or suspension into the voids of a soil or rock mass or into voids between these materials and an existing structure. The injected grout must eventually form either a gel or a solid within the treated voids, or the grouting process must result in the deposition of suspended solids in these voids. The primary purposes of pressure grouting a soil or rock mass are to improve the strength and durability of the mass and/or to reduce the permeability of the mass. Prior to any grouting operation (trial or final), water pressure testing is done. Water pressure test is performed to measure the rate at which water can be forced into a hole under a specific pressure. It is from these water pressure tests, that lungeon values and thus indication of rock mass permeability are established. For the Left Embankment Dam at Isimba HPP, the water pressure testing and trial grouting operations indicated high permeability in the foundation material which was not being significantly reduced by the grouting during the trial phase. Trial grouting was done in the completely weathered and the highly weathered rock foundations. The trial grouting indicated high grout takes and high rock permeability. This thus influenced the decision to adopt utilization of both the concrete – cut off wall and curtain grouting as the seepage control measures for the weathered and sound rock foundations respectively.

CONCRETE CUT-OFF WALL

The concrete cut-off wall together with curtain grouting were thus adopted as the foundation treatment approach for the dam foundation to control under seepage and uplift pressures. The concrete cut-off wall was constructed using conventional concrete of Class C20. Concrete by its nature is too rigid and as the soil mass surrounding the concrete cut-off wall compresses under the weight of the embankment during its construction and the water load as the dam is filled, substantial loads will be shed onto the wall by negative skin friction. This can cause crushing of the wall and penetration of the wall into the dam fill. In this regard, the compressive strength of the concrete used for the cut-off wall should be able to with-stand these stresses associated with skin friction. The test results for the concrete cast for the concrete cut-off wall of the Left Embankment Dam of Isimba HPP range from 23MPA to 28MPA, as reviewed from the EPC Contractor's quality control reports and test results. The concrete cut off wall extends all through the weathered rock foundation and slightly penetrated the sound rock as shown in Figure 4. Whereas the Employer Requirements had not specifically specified the type of concrete to be used for the concrete cut-off wall, the Isimba Panel of Experts and other Dam Engineers recommended use of plastic concrete for the cut-off wall. This was rejected by the EPC Contractor despite numerous demands by the Employer. The site team could not trace literature and or international standards that specified use of plastic concrete for cut-off walls in foundation treatment.

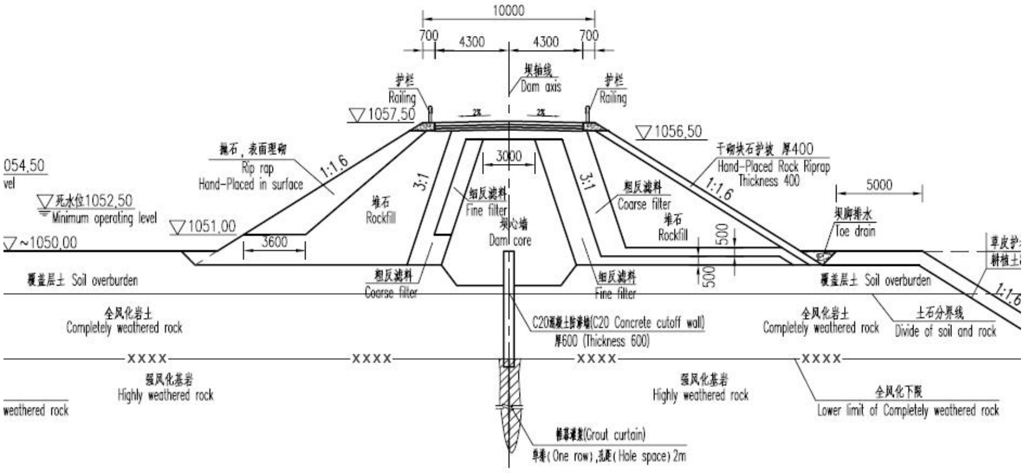

Fig 4: Cross- Section of Left Embankment Dam at Chainage D0+210, showing Concrete Cut-off wall below the central clay core, as part of foundation treatment works. (Adopted from the EPC Contractor's Volume IV of the Basic Design Report)

The concrete cut off wall was excavated in alternating panels with the panel supported by clay slurry. In some other countries or projects depending on availability and economic considerations, bentonite slurry is used to prevent the excavated trench from collapsing. Bentonite is a clay material composed principally of minerals of the montmorillonite group, characterized by high absorption and very large volume change with wetting. For the cut-off wall excavations on the Left Embankment Dam, clay slurry was used for trench support, however for the Right Bank cut-off wall excavations, a mixture of clay and bentonite was used. This was after Employer insisted on better trench support system. From the exposed sections of the cut-off wall on the left bank, it was noted that trench collapse had cause sections of the cut-off wall to have irregular surfaces.

The trench wall thickness was 500 mm, and it extends at least 500 mm into the engineering rock. The cut-off wall trench was excavated by use of percussion tools. Percussion tools and rock chisels are used where boulders, cobbles or other hard materials are encountered. The percussion tools are electricity or compressed air powered tools that operate by striking rapid blows unto the rock, thus break it up into smaller pieces. The broken pieces are removed by clamshell bucket. Clam-shells can also be used to excavate for the cut off wall trenches in soft rocks or foundations with gravely soils. When all the loose and broken up rocks are removed, concrete for the cut off wall is cast. For Isimba HPP, the cut off wall was excavated by use of a percussion hammer. During this excavation and chiseling of the rock and boulders, a lot of rock fragments were generated and these accumulated at the bottom of the slurry trench. To remove these rock fragments, airlift equipment was specified as part of the excavation method statement. However, the EPC Contractor used a bailer to remove the rock cuttings, excavation debris and contaminated slurry but it wasn't not suitable to do full cleaning of the bottom of the cut-off trench. As such, a lot of loose rock fragments would stay at the contact between the cut-off wall concrete and the engineering rock. The concrete wall was constructed by tremie pipe placement of concrete. The tremie concrete placement method uses a vertical or near vertical pipe, through which concrete is placed by gravity feed into the bentonite or clay-slurry-filled trench. The lower end of the pipe is kept immersed in the clay slurry/ bentonite slurry so that concrete rising from the bottom displaces the bentonite or clay slurry, thus limiting washing out of the cement content of the fresh concrete to the exposed upper surface. The upper end of the tremie pipe is kept above the trench level during the pour and is provided with a conical hopper for batch loading, or concrete may be pumped into the top of the tremie pipe. Concrete must be poured at a rate which avoids setting in the tremie. Admixtures may be used to control setting time, slump and workability. For the Left Embankment Dam at Isimba Hydro Power Project, admixtures like fly ash were added to improve the workability of the concrete and also minimize the heat generation in the concrete. Since the concrete is poured into the trench through tremie pipes and displaces the bentonite or clay slurry from the bottom of the excavation upward, the concrete must have a consistency such that it will flow under gravity and resist mixing with the bentonite or clay slurry. The steel tubing is inserted (and later removed) as a part of a construction joint to facilitate bonding of the concrete panels.

The concrete cut off wall for the Left Embankment Dam is not a reinforced concrete wall. Reinforced concrete walls may be justifiable for areas susceptible to high and frequent earthquake loading. The concrete for the cut off wall was tested for various parameters including slump, temperature, compressive strength, compressibility and permeability. ICOLD (1985) indicates that the permeability which can be achieved for cut off walls made of normal concrete are in the range of 10-9 to 10-10 m/ sec. The test results for the concrete cut off wall of the Left Embankment Dam indicate compressive strengths in the range of 23MPA and 28MPa above the design strength of 20MPA (C20). In addition to the compressive strength tests, the EPC Contractor conducted tests on the penetration resistance of the concrete according to ASTM Standard C803, and no water seepage was confirmed for the hardened concrete in the laboratory.

Curtain Grouting

The Left Embankment Dam adopted curtain grouting as a part of the foundation treatment works. Curtain grouting means grouting of rock in one or more lines of holes spaced to form a curtain barrier.[5] This method consists of drilling bore holes into the foundation bedrock at some regular spacing along a line or lines parallel to the dam axis and normal to the seepage flow direction. A bore hole is a hole of circular cross-section made in soil or rock.

According to Robin Fell et al (2005), since rock substance is generally almost impermeable, the permeability determined in the water pressure test represents an indication of the number, continuity and opening of the rock defects which intersect the wall of the borehole in the test section. Curtain grouting is designed to create

---

[5] Employer's Construction Specifications for Civil Works

a narrow barrier (or curtain) through an area of high permeability. It usually consists of a single row of grout holes which are drilled and grouted to the base of the permeable rock, or to such depths that acceptable hydraulic gradients are achieved. For large dams on rock foundations, dams on very permeable rock or where grouting is carried out in soil foundations, 3, 5 or even more lines of grout holes may be adopted. The Left Embankment Dam adopted curtain grouting mainly for dam foundations on sound rock or slightly weathered rock including below the cut off wall. A single line of grout holes was adopted since this was appropriate to achieve the specified permeability parameter/ Lugeon value of 1Lu. The holes were drilled and grouted in sequence to allow testing of the permeability of the foundation (by packer testing) before grouting and to allow a later check on the effectiveness of grouting from the amount of grout accepted by the foundation ("grout take"). Grout take is the measured quantity of grout injected into a unit volume of formation, or a unit length of grout hole. Grout is a mixture of cementitious or non-cementitious material, with or without aggregate, to which sufficient water or other fluid is added to produce a flowing consistency.

The grout holes / borehole were drilled using percussion drilling—a drilling technique that uses solid or hollow rods for cutting and crushing the rock by repeated blows. Percussion drilling methodology that was applied used hollow steel pipes that allow for rock core recovery to be utilized in the logging of the geological profile of the dam foundation along the dam axis. The employer specified drilling of boreholes by use of either percussion drilling method or rotary type diamond drilling. The EPC Contractor utilized the percussion drilling method since it is more economical. As argued by Fell et al (2005) grout holes should always be oriented and or inclined so as to intercept the major fractures in the rocks and as many discontinues in the rock foundation. The Employer Requirements for Isimba HPP further specified that check holes should be inclined too, to assess the effectiveness of the grouting works.

After the drilling of the boreholes, they are washed to remove any cuttings that may have clogged the rock fractures around the sides of the hole. The borehole is then water pressure tested to establish the rock mass permeability prior to grouting. Pressure testing is a method of testing the permeability of rock mass using water or grout pumped down hole under pressure. The water pressure test is carried out using pressure testing equipment, water and a packer. A packer—*in grouting*, is a device inserted into a hole in which grout or water is to be injected which acts to prevent return of the grout or water around the injection pipe. It is usually an expandable device actuated mechanically, hydraulically, or pneumatically. The results from the water pressure testing are indicated by a lugeon value. Lugeon is a measure of permeability defined by a pump-in test or pressure test, where one Lugeon unit is a water take of 1 L/min per meter of hole at a pressure of 10 bars. This implies that the rock permeability is that in one minute, one litre of water, will flow across a unit (1 metre) section of the rock, under a pressure load of 10 bars. These water pressure test results for the pressure testing prior to grouting are also recorded and submitted as part of the grouting records/ reports. Records of the drilling, grouting and water pressure tests, pressures, flow rates, the quantities used in the grouting operations and any other general records were kept and submitted to the Employer for review and information.

The curtain grouting was carried out sequentially to achieve a predetermined standard of water tightness in the foundation rock. This required the successive halving of the predetermined spacing of the grout holes. This is called the split spacing method with primary, secondary and tertiary holes. Split-spacing means the system of locating an additional grout hole approximately midway between two grout holes which have previously been drilled and grouted. Primary holes are the first series of holes to be drilled and grouted, usually at the maximum allowable spacing. Secondary holes are the second series of holes to be drilled and grouted, spaced midway between primary holes. The specifications for curtain groutug were also revised by the Emloyer on the advice of the Owner's Engineer. Whereas initially 1 Lugeon was specified as the limit for permeability, so as to save time and cost, and also optimize the grouting operations, 3-5 Lungeon was later adopted for the curtain grouting works. It was further indicted that industry best practice for grouting works, adopts permeability values in the range of 3-5 lungeon NOT the 1 Lungeon as had been specified by the project owner/ client.

Conclusion

All earth and rock-fill dams are subject to seepage through the embankment, foundation, and abutments. However, it is also evident from geological investigations and tests that compacted earth fill core materials has far less permeability ($< 10^{-8}$m/ s) compared to the permeability of rock foundations. As argued by Robin et al (2005), nearly all rock foundations have rock mass permeability greater than 1 Lugeon, and most rocks have permeability greater than 5 Lugeon. It is clear that most seepage occurs through the foundation not the embankment itself. However, seepage control is necessary to prevent excessive uplift pressures, sloughing of the downstream slope, piping through the embankment and foundation, and erosion of material by loss into open joints in the foundation and abutments.

The purpose of the project, i.e., long-term storage, flood control, etc., may impose limitations on the allowable quantity of seepage. Although the foundation is not actually designed, certain provisions for treatment are made in designs and specifications to ensure that the essential requirements are met. The foundation treatment for embankment dams requires an array of considerations that range from geological and geotechnical expertise to engineering judgment based on experience. A detailed foundation treatment program that include designs, technical specifications, construction and grouting procedures is critical to sound foundation treatment for dams to ensure dam stability and seepage control.

ABSTRACT
El Cajón Dam is located in a karst limestone geology; during the construction phase (1981-1985) the unusual Bathtub was implemented (no open end curtain in possible deep karst systems, [1]) and also the existence of randomly finding karstic caverns that had to be filled as part of the treatment (empty reservoir), this was presented to the International Community after the construction was finished. Years later (1995) the activities of injection through the Project known as "TRATI" were made known again, these were realized to extend the grout curtain and to remedy the increases in the filtration flows in the proximity of the Power House, on that occasion the project was already in operation and the karstic ducts that were present had water surges, and in some cases suction.

Currently The Third Remedial Grouting Campaign for Reinforcement of Impervious Curtain (2016-2017) is presented, again justified by the rise of filtration flows, this time identified in the left abutment of the dam and on the edge of the Bathtub on

---

[*] *Traduction en Français (en attente).*

the right side of the dam (together in the range of 200 L/s). The most important perforated drills presented surge pressure of up to 7 Bars, it is estimated that the anomalies found correspond to mostly vertical Tubular Karts, and permeably connected with the rock stratification planes themselves with dips between 15 ° and 35 ° related to the vertical oriented downstream. The solution implemented could not be equated to the first historical treatment due to the fact that there is a full reservoir and the entrainment of the cementitious mixtures to the exterior (sites downstream of the dam); nor could the unusual methods and materials of the second historic treatment be used because on this occasion there was no suction of the materials and the size of the filtration ducts intercepted by the perforations were less than 2 inches. Finally, as one of the treatments, the injection of concretes with maximum aggregate size of less than 1 inch was arranged, but the injection with the traditional Trailer Pumps was detrimental to the geological environment due to the fact that the "piston effect" [2] increased erosion deposits in the caverns; therefore, for the solution, selected size aggregates were pushed without using a concrete pump and intermittent mortar grout with smaller a size injection pump.

The sealing work on the left abutment had as a relevant factor, improving the contact surface between the concrete masses of the dam and the foundation rock with this treatment.

1. INTRODUCTION

El Cajón hydroelectric Project is located in the central zone of the Republic of Honduras. The dam site is located on the Comayagua river basin about 2 Km downstream from the junction of the Humuya and Sulaco rivers. The structure is a double curvature thin concrete arch dam, of 226 m high.

The foundation of the dam site is located on cretaceous thick limestone rock, the original construction had identified the presence of Karstic Phenomena located in the inside and outside of the bathtub grounding curtain. During the life of the project (around 33 years), the monitoring system has detected periodically changes in the followings parameters: infiltration flow and uplift. These variations have been attributed to process of dissolution and deposit erosion of such Karsts.

Over the past, few years one of the greatest anomalies was the increase in the flow of the "D-1" drain of the drainage system, in the left abutment of the dam, approximately between 106 and 135 m a.s.l. Initially in this drain, there was no infiltration, later between the years 2006 to 2015 an increase of approximate 20 l/s [3] was reported and some sediment drag (erosion). One of the tasks of the third reinforcement campaign was to seal this infiltration.

2. SEAL OF DRAIN “D1”

The initial activities of the project were the execution of grouting drills holes from the upper grouting gallery to the zone drain D1, at level 135 m a.s.l. obviously the execution of these grouting holes would damage the operative of the D1 drain, in case of communication of grouting fluids between both drains.

Due to this, grouting started in drain D1, with the purpose to seal the filtrations. Although later, it would be necessary to perform new drains to repair the drains curtain of the dam.

The first interventions failed, because the drain clogged and grouting mixtures were dragged into the G2 Gallery (located on the outside of the dam body, as shown in Fig. 1). Since then the D1 filtration moved to upper levels and G2 Gallery maintained a permanent filtration in the order of 20 l/s approximately.

Fig. 1
Panoramic View, left abutment

3. GROUTING MIXTURES

3.1. GENERAL

Most of the grouting of the project was done with mixtures that had a relation of between w/c 0.70 - 0.50 (see Table 1). Some cases required the use of mortars (sand/cement). But the grout curtain drill holes which had relation with the source of karsification or empty karst (erosioned), it was impossible to seal with these mixtures (each grouting was completed when a volume of grout was reached) and mixtures were dragged to the outside near the G2 Gallery (see filtration number 1 to 7, in Fig. 2).

Table 1
Conventional Mix used in Project

Mix Number	Proportion by Weight			
	Water	Cement	plasticizer	Sand
L-0	0.7	1	1	0
L-1	0.6	1	1	0
L-2	0.6	1	0	0
L-3	0.5	1	0.75	0
M0	0.6	1	1	0.25
M1	0.6	1	1	0.5
M2	0.6	1	1	0.75
M3	0.6	1	1	1
M4	0.6	1	2	1.5

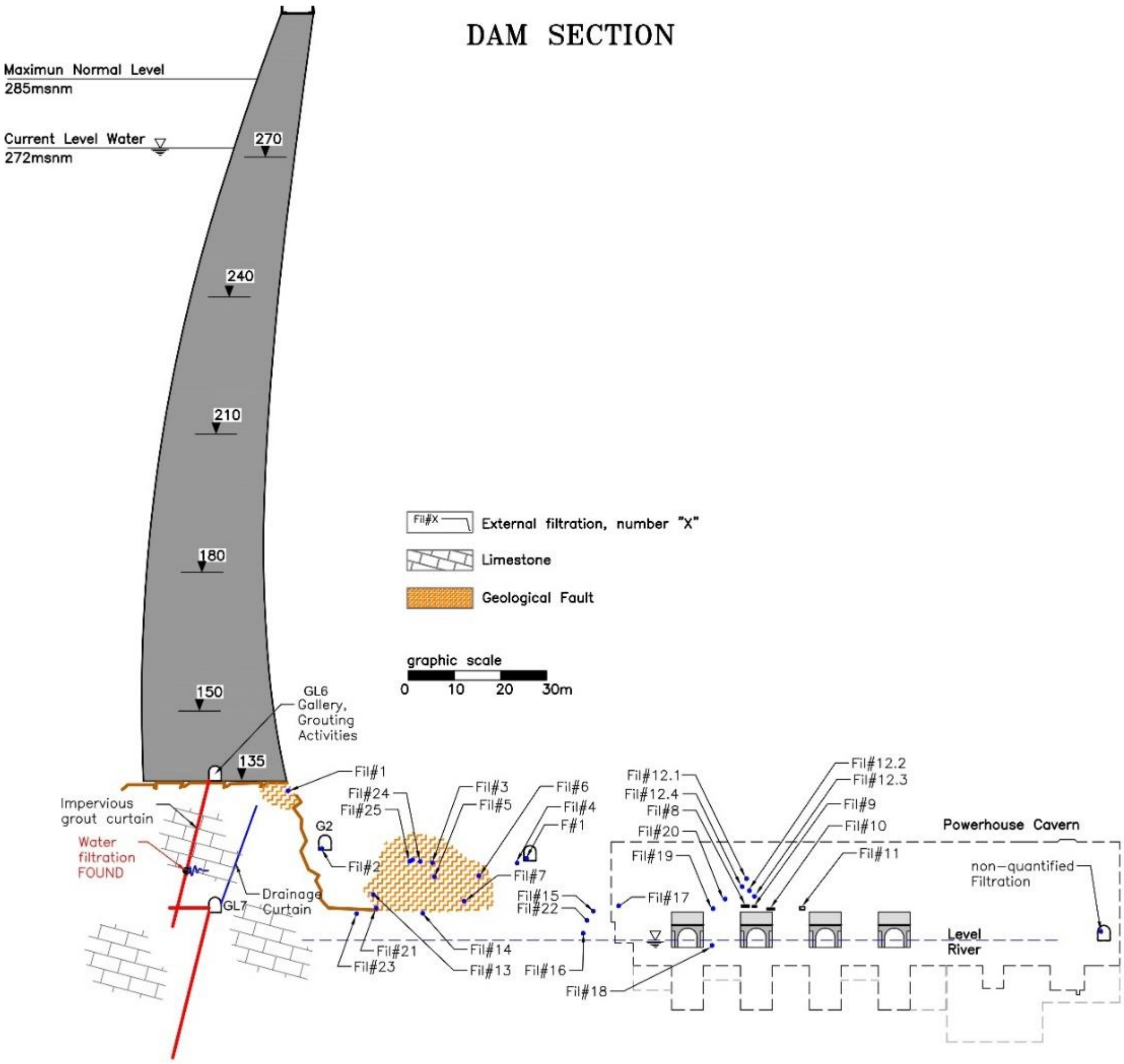

Fig. 2
Dam Section, new filtrations in site

3.2. UNUSUAL MIX

Subsequently, as one of the treatments, the injection of concretes with maximum aggregate size of less than 1 inch were arranged, but the grouting with the traditional Trailer Pumps was detrimental to the geological environment due to the fact that the "piston effect" [2] increased deposits erosion in caverns (see in Fig. 3 left, the erosion process identified in one of the infiltration).

After these activities, the Security Panel of the works (PSO), suggested to avoid the use of concrete pump and only use only traditional grouting pumps. It was recommended to use unusual low-density products for the grouting, such as the sawdust to minimize the drag out of the abutment.

The sawdust was injected to the drill holes in mixtures for water/bentonite (380L / 13.60kg), with a proportion sawdust/bentonite of 400% (by weight). Even in these cases the materials were not deposit in the source of karsification and were dragged to the exterior.

3.3. FINAL SOLUTION

For the final solution, selected size aggregates were pushed without using a concrete pump and intermittent traditional mix with grout or without aggregates was used (nominal size less than 1 inch), for details see Fig. 4.

At the beginning, of the process one part of the aggregate was pushed out to the exterior (see Fig. 3 right) similar to the other occasions but eventually the repetition of this procedure and the variation of the sizes in each grouting allowed to seal the karstic zone and eliminate the infiltration in the zone.

Fig. 3 [4]

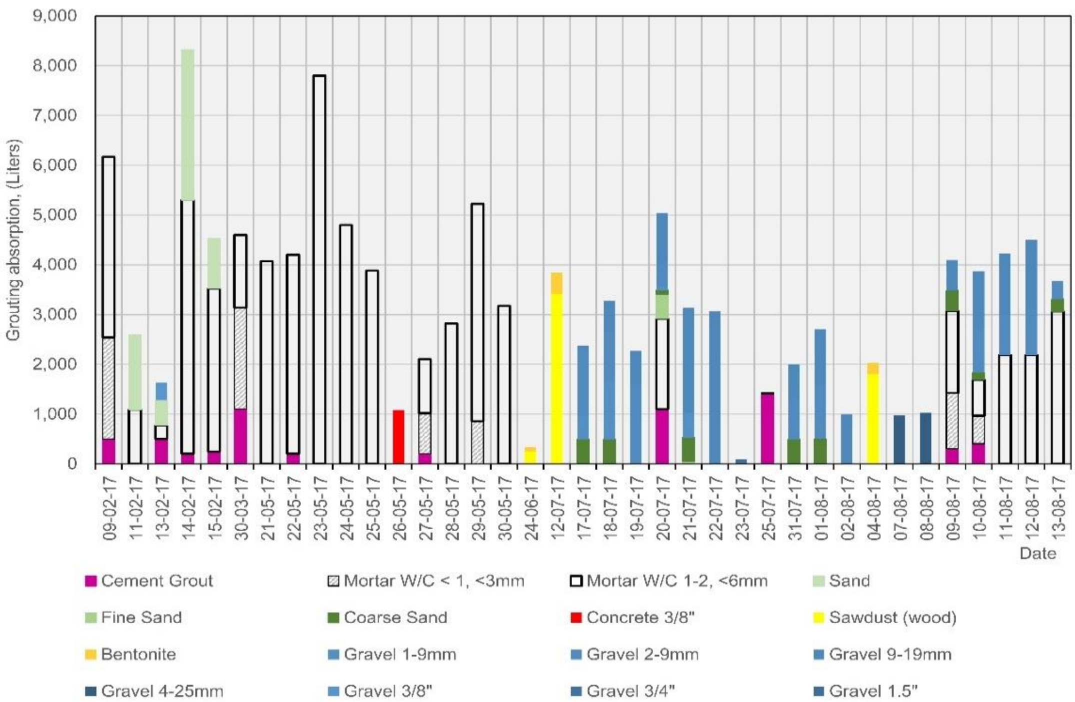

Fig. 4 [5]
Grouting absorption, elapsed time and mixes used. The terms “Gravel” and “Sand”, are utilized to indicate aggregates pushed with water, without cement.

4. CONCLUSIONS

The project experience taught the project participants the dangers of the piston effect" in the deposits of caverns and joints. This phenomenon is the propagation of hydraulic pressure at large distances [2], in the context of this project the distance can be measured between the site of injection (curtain drillings) and each one of the sites of infiltration which was present in the left abutment of the dam. The hydraulic pressure in the karst tubes was due to: operation (open / closed) of some or all of the infiltration sites (placing grout pipes with valves) and to the pumping cycle of the concrete pump.

The effect was manifested in the short term with the opening of new infiltration sites (the total infiltration flow maintained equal) and in the long term with the erosion process on the unconsolidated deposits in caverns and joints and finally in the increase of in the infiltration flow (see Fig. 5).

At the end of the Project, it was necessary to reactive the drainage curtain of the dam (damaged due to the loss of drain D1), with the drilling of new drain holes between level 106 and 135 m a.s.l.

Currently, the infiltration site originally sealed are inactive, even with the high reservoir level reached this year (2017) (maximum operation level of the powerhouse). Which are above the levels registered during the time of the repairs. (270 vs. 285 m a.s.l.).

1. INTRODUCTION

Nechranice Dam is located on the Ohře River in the North-West of the Czech Republic. The dam is the longest earth-fill dam in the Czech Republic and in Central Europe. The dam was presented to ICOLD Congress 2017 participants as one of the site visit locations.

This paper describes monitoring system and presents long-term data that has been collected since start of the dam operation.

2. DAM DESCRIPTION

Nechranice Dam is situated approximately in the middle of the Ohře River course being the fourth largest reservoir in the Czech Republic. The dam is 3280 metres long and 47,5 metres high. The dam volume is 9.5 million cubic metres [1]. It was constructed between the years 1961 and 1968. Last year the reservoir celebrated its 50 years anniversary since the dam first filling.

The reservoir covers the area of more than 13 km^2 with the capacity of 287 million m^3 – it provides 233 million m^3 of active storage and 52 million m^3 of flood storage. The main purpose of the dam is enhancing the flow to supply intakes for industry, power generation and maintaining the minimum water flow downstream of the dam.

Fig. 1: Nechranice Dam

The dam is situated in the geologically unfavorable environment of the brown coal mining area at the base of the Ore Mountains. The subsoil is composed of unconsolidated and partly consolidated sediments with the thickness up to 350 m. The overburden layers of clays and claystone are up to several dozen meters thick. The underlying beds consist of coal seams and sand saturated with artesian water.

The dam body is composed of a stabilizing part of local gravel sands and the central earth core of loess loams. The impervious earth core is tied to the subsoil loamy-concrete sealing curtain that extents to the maximum depth of 31 m below the foundation level. Due to the complex geological conditions, both the upstream and downstream slope is stabilized by surcharge embankments. The dam is up to 800 m wide at its toe. The slope of the upstream face is 1:2,1, while the slope of the downstream face is 1:1,75 (Fig. 2).

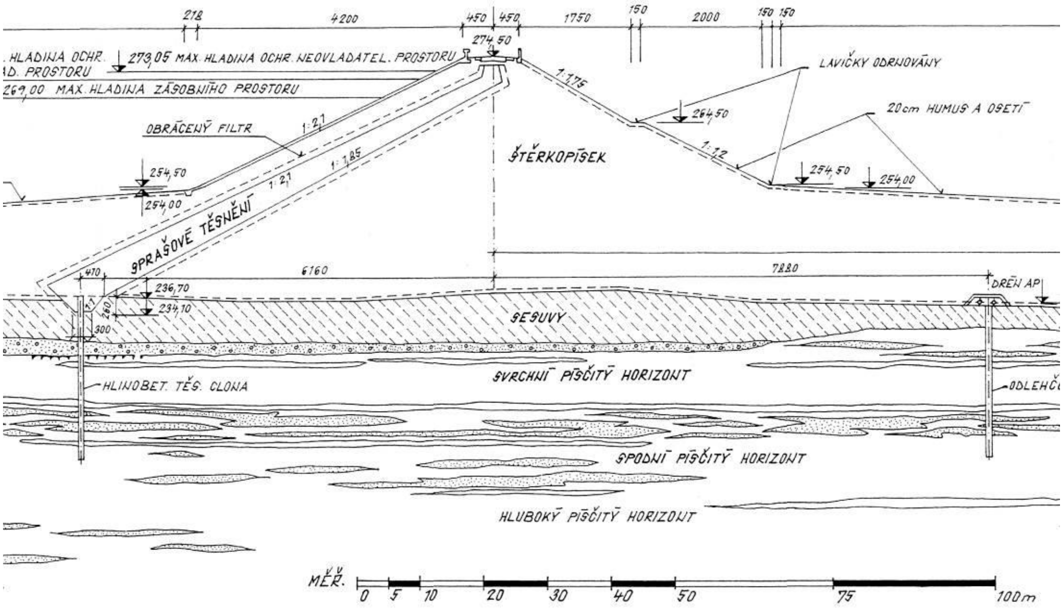

Fig. 2: Nechranice Dam cross-section

The bottom outlets and the hydropower plant are situated to the tower, which is located at the deepest point of the former riverbed near the upstream toe of the dam. The tower is 63,4 m high and its outer diameter is 20,4 m. The access to the tower is provided by the 475 m long tunnel that connects it with the downstream toe of the dam. The bottom half of the tunnel serves as a tailrace tunnel from the bottom outlets and the hydropower plant.

The largest flood since the construction of the dam occurred in March 1981. The dam attenuated the peak inflow of 650 $m^3.s^{-1}$, which is nearly the 1 in 50 year flow to the outflow of approximately 550 $m^3.s^{-1}$, which equals 1 in 20 year flood.

3. NECHRANICE DAM MONITORING

Due to the expected significant settlement of the dam, no inspection gallery or grouting gallery was designed. Instead, a network of geodetic surveying points, wells and piezometers was designed for the dam monitoring. The instrumentation comprised of a system of 82 piezometric boreholes, 53 levelling wells, 115 leveling points and lateral and 63 vertical movement monitoring points (Fig. 3).

A drain was designed at the downstream toe of the dam to collect water draining from some of the piezometric boreholes.

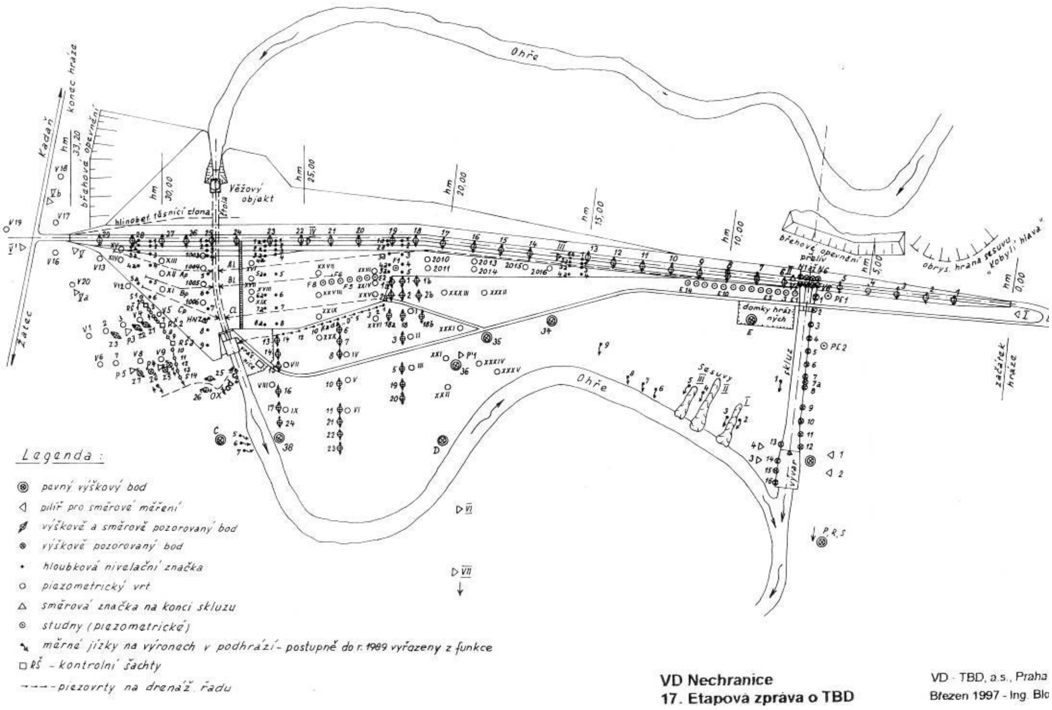

Fig. 3: Plan of the monitoring points

Some of the instrumentation is in operation since the construction of the dam, while other monitored points were added later in order to gather more detailed information at some locations.

The monitoring system comprises of the following:

- Levelling wells (Fig. 4): measure the vertical displacement at the dam foundations level. The wells are also used for the measurement of the water level in the wells providing information about the drawdown curve within the dam body.

Fig. 4: View into the levelling well

- Levelling points (Fig. 5) are used for measurements of vertical displacement.

Fig. 5: Levelling point

- Lateral and vertical movement monitoring points (Fig. 6) are used for measurements of the vertical as well as lateral displacements on the surface of downstream face of the dam.

Fig. 6: Lateral and vertical movement monitoring point

- Piezometric boreholes (Fig. 7) measure the piezometric pressure within the dam body. They are located in five cross-sections across the dam body. At some locations, two piezometric boreholes are present close to each other, reaching to different strata.

Fig. 7: Piezometric boreholes

- Piezometric sensors – are located inside the impervious core of the dam. Sensors are also located below the tower and below the communication tunnel. The measurements of the piezometric pressures are carried out four times per year.

Some of the piezometers at the downstream toe of the dam function also as relief wells. Once the water table reaches certain level it is collected conveyed out by the drain.

The measurements are carried out by the certified company Vodní díla TBD, a.s. Most of the monitoring is done annually fulfilling the Czech legislation requirements for the highest dam hazard classification rank.

4. RESULTS – LONG-TERM MONITORING DATA

4.1. DAM SEALING PERFORMANCE

Ground water table measured in the piezometers and levelling wells has been steady since the construction of the dam [2] allowing for slow changes according to the conditions at the site and water level in the reservoir. The ground water table is present relatively low within the dam body and does not reach the terrain on the downstream toe of the dam. The ground water levels in the dam body downstream of the dam sealing do not move significantly with the reservoir water level changes.

Fig. 8 shows comparison of the piezometric pressure in the four piezometric sensors located in the dam sealing at the dam foundation level over the the 50 years of the dam. The piezometric pressures relate to the water level in the reservoir. While the Sensor 1, located close to the upstream face of the dam sealing, reflects well the water level change, the other sensors react much slower. This applies particularly to Sensors 99 and 113, which are located close to the downstream face of the sealing.

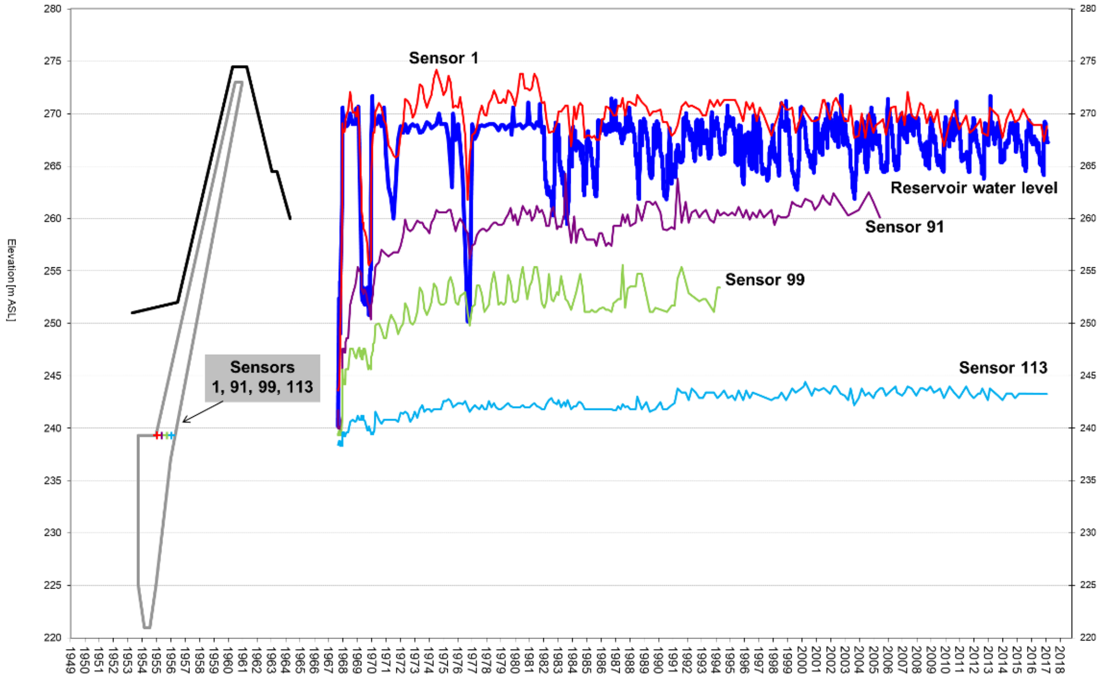

Fig. 8
Dam sealing performance since the dam construction (1967-2017)

The plot also shows that the pressure at sensors located in the dam sealing (91, 99 and 113) increased steadily for the first 7 years of the dam operation until they stabilized at values along which they oscillate since 1974. Sensor 99 and 91 stopped providing data at some point.

The reservoir water level curve shows the update of dam operation rules in 1979. Since then the dam outflow has been optimised and the reservoir storage has been used closer focus on the hydropower production as well as on the maintenance of minimum flow in the Ohře River downstream the dam.

In the period of May 1969 – May 1970, one year after the start of dam operation, the water level was lowered for testing purposes. Fig. 9 shows that the decrease of about 18 m affected the pressure particularly at the sensor 1 located close to the upstream face of the dam sealing. The other 3 sensors reacted to the reservoir water level to much lesser extent and with a delay.

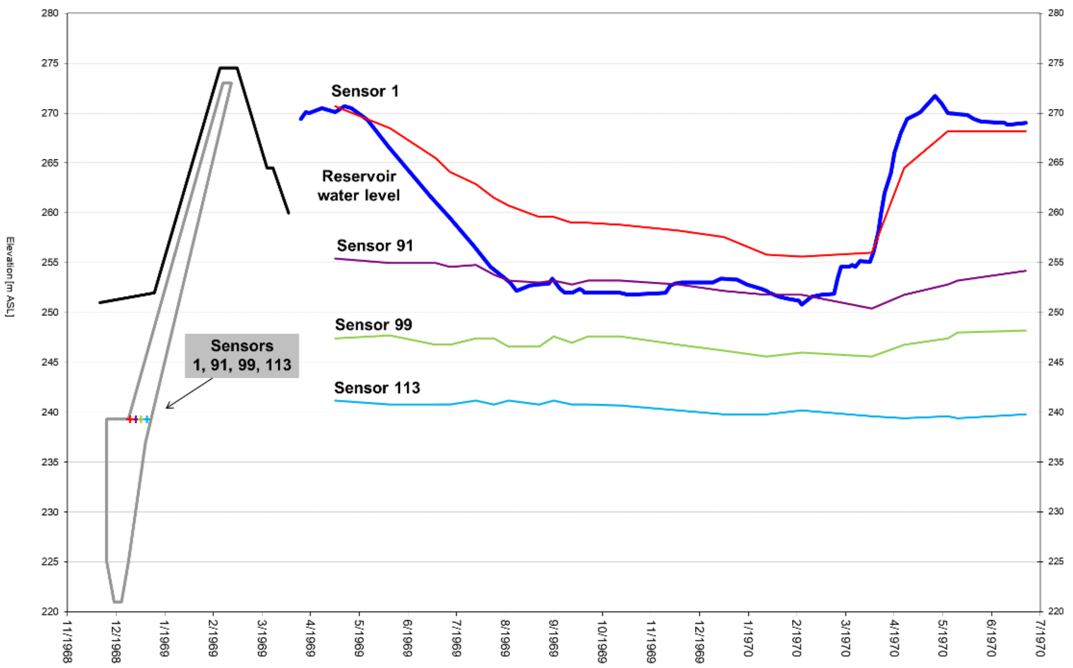

Fig. 9
Piezometric pressures at the dam sealing during the dam testing period (May 1969 – May 1970)

4.2. SETTLEMENT OF THE DAM

The settlement of the dam body has been continuous since the dam construction without any anomalies (Fig. 10). The highest settlement of the dam crest is located near the communication tunnel. At this point the settlement has steadily grown to the value of 550 mm in 2016.

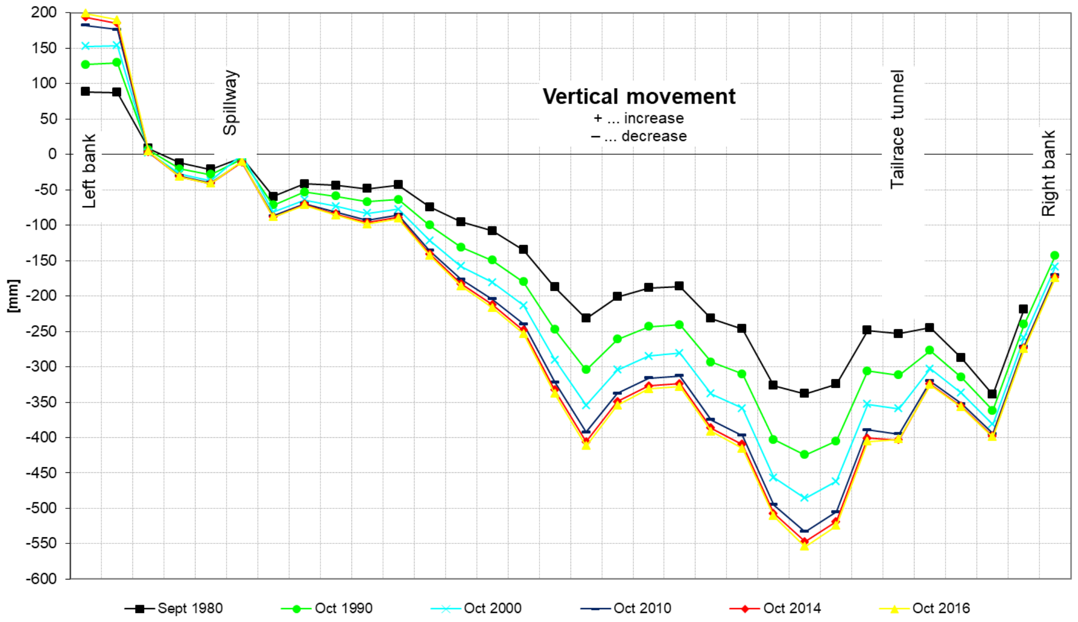

Fig. 10
Vertical movement of the dam crest

The settlement of the dam surface is related to the settlement of the foundation level [3].

The dam settlement was accounted for in the dam design. The dam crest was designed 0,5 m higher than its expected level after the settlement.

Fig. 11 shows the vertical movement of the communication tunnel. It shows that there has been no significant vertical movement since 1982.

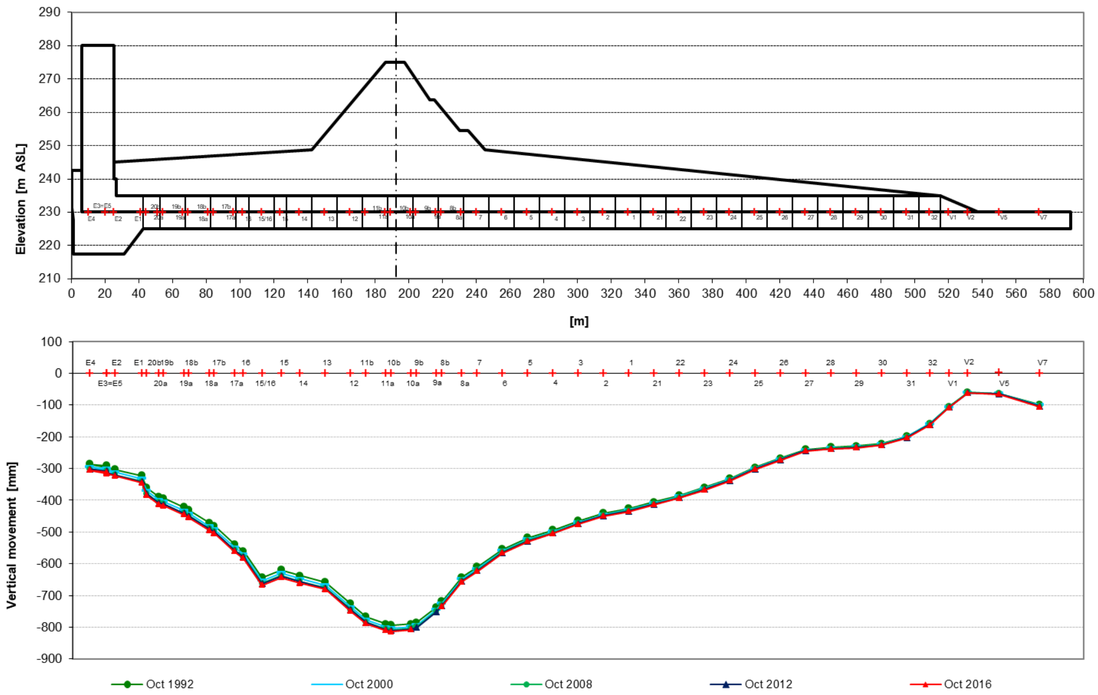

Fig. 11
Vertical movement of the communication tunnel

5. CONCUSIONS

Presented data show that the water table level is stable and no negative trends have been observed. Short-term movements are result of the specific meteorological conditions.

Settlement of the dam crest is continuous since the dam construction without any anomalies. The highest settlement of the dam crest is located near the communication tunnel. At this point the settlement has steadily grown to the value of 550 mm in 2016. Vertical movements along the communication tunnel show that there has been no significant vertical movement of this structure since 1982. Despite complicated geological conditions at the site, the monitoring has not registered any unexpected behavior.

5.1. ACKNOWLEDGEMENTS

We are grateful to Ing. Ondřej Švarc from Vodní díla TBD a.s. for kindly providing the complete set of the Nechranice Dam monitoring data.

SUMMARY

This paper presents Nechranice Dam long-term monitoring data that has been collected since start of dam operation in 1967. Nechranice Dam is located on the River Ohře in the North-West of the Czech Republic. The dam is the longest earth-fill dam in the Czech Republic and in Central Europe. The dam has the highest dam hazard classification rank as defined by the Czech legislation.

The Nechranice Dam monitoring system comprises of geodetic surveying points, wells and piezometers that monitor vertical and horizontal movements at the foundations level as well as on the face of the dam, piezometric pressures, water table elevation and amount of water drained.

The paper presents the piezometric pressures in the dam sealing at the foundation level over the 50-year long period of dam operation. The water table level is stable with no negative trends. Short-term movements are result of the specific meteorological conditions. Attention is then focused particularly on the one-year long period of significant reservoir water level decrease that occurred in 1969 - 1970.

Settlement of the dam crest is discussed. It shows continuous progress since the dam construction without any anomalies. The highest settlement of the dam crest is located near the communication tunnel and has steadily grown to the value of 550 mm in 2016.

Vertical movement along the communication tunnel is presented at the end of the paper. It shows that there has been no significant vertical movement of this structure since 1982.

Despite complicated geological conditions, the Nechranice Dam monitoring has not registered any unexpected behavior.

1. INTRODUCTION

The Arkun Dam and HEPP project is located on the Coruh River in the North East of Turkey. The main purpose is hydroelectric energy generation. Therefore, a main and an environmental powerplant were installed showing a capacity of total 237 MW. The Arkun project is owned by EnerjiSA which was formerly a joint venture of Verbund (Austria) and the Sabanci Group (Turkey) unless E.ON (Germany) took over the shares of Verbund in 2013.

The project was completed and started operation in 2014 after only approximately 5 years of construction. The project construction schedule and the project budget were kept in the range of early project assumptions. The good foundation and suitable dam fill material close to the dam location contributed to the positive project progress and completion.

The project consists of CFSGD, a 14 km long power tunnel, diversion works, a main and an environmental powerhouse as well as a gated spillway. A general layout is shown in Fig. 1. More details concerning the general layout of the project and details had been already published before [1] [2] [3].

Fig. 1
General layout of the project

2. GENERAL DAM AND FOUNDATION DESIGN

2.1. GENERAL DAM DESIGN

The Arkun dam is of CFSGD type including a rockfill part at the downstream slope. The dam design was prepared according to the corresponding ICOLD bulletin for CFRDs [4] and modern dam design criteria [5]. The design of the main dam was adapted to the special requirements imposed by using not free draining sand-gravel fill at the main dam embankment fill zones as discussed in [9] (see Fig. 2).

A parapet wall was placed at the crest. The upstream surface is covered by a concrete slab sealing which is connected via an articulated plinth to a cut-off wall (COW) which is reaching down to the bedrock which is located underneath a 70 m deep alluvial layer. The slopes are inclined by H:V = 1.0 : 1.6.

The spillway is designed for a PMF flood with a discharge of 4,701 m³/s. A gated spillway was placed at the right abutment integrating three bays close to the intake of the power tunnel. The power tunnel to the main powerhouse is approximately 14 km long with a diameter of 6.5 m. The tunnel shows a high pressure grouting pre-stressed concrete lining.

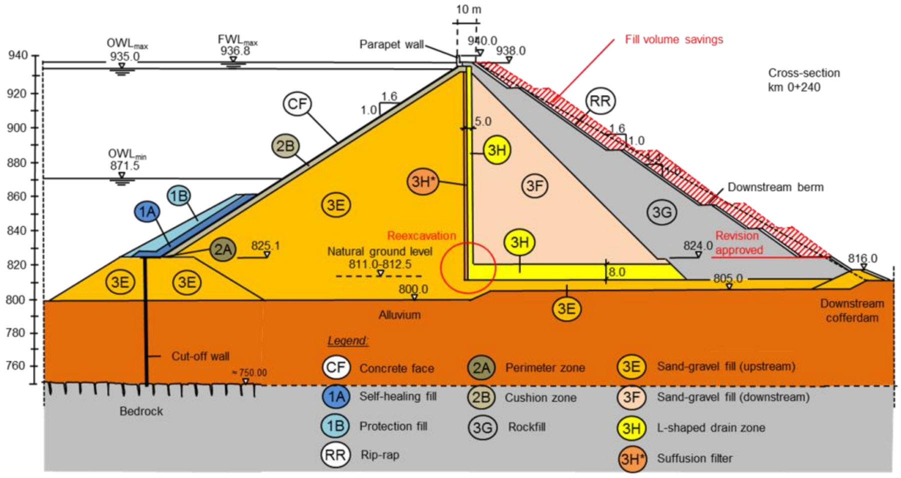

Fig. 2
Typical cross section of the Arkun CFSGD

The diversion tunnel is located on the left side of the dam. The diversion tunnel hosts the pressure tunnel to the environmental powerhouse. The penstock for the environmental powerhouse was constructed after the diversion tunnel was closed and plugged (Fig. 1) when the impoundment of the reservoir started.

2.2. SEALING AND SEEPAGE DESIGN

The Arkun Dam sealing and seepage design consists of an upstream barrier comprising a surface concrete slab sealing, an articulated plinth, and a cut-off wall. An L-shaped drain and a free draining rockfill zone (3G) shall guarantee a high safety level regarding the control of the seepage, also in consideration of critical failure of the upstream sealing barrier.

The drain (zone 3H) itself is protected by a suffusion filter (zone 3H*) in order to hinder small particles which are activated by suffusion processes within zone 3A. The sand-gravel material used for zone 3E was considered to be suffusive. The zoning concept of the dam is shown in Fig. 2.

2.3. FOUNDATION DESIGN

The dam body is placed on a 70 m deep alluvium layer. A stress-strain deformation analysis was performed in order to evaluate the deformation at critical project milestones such as end of construction and first impoundment **Fehler! Verweisquelle konnte nicht gefunden werden.**.

Particular focus was laid upon the stress-strain behaviour of the cut-off wall in order to assess the cracking potential induced by excessive tensile stresses. The testing results of local laboratories confirmed the design assumptions that intended to create an earth concrete mix with relatively low compressive strength and low stiffness in order to achieve similar deformation behaviour, as the surrounding alluvial material should show. Results of laboratories abroad and of local universities indicated a much stiffer and more brittle material behaviour. Relying on these later results serious cracking could not be excluded anymore, which initiated the Owner to check the impact of this potential cracking of the cut-off by a seepage analysis.

For the determination of the time dependent development of the cut-off wall concrete samples were taken from the ongoing concreting works and were tested after seven and 28 days and further selected periods. Two institutes came to the result that the elasticity modulus reached values exceeding 1,000 MPa after 28 days. One institute persisted to obtain values of approximately maximum 500 MPa also after 70 days after concreting. These contradictious results uncomforted the responsible parties so that further testing and analyses were performed.

Field investigations and the stress strain modelling were the basis for defining the future foundation level in form of the required excavation depth. The field testing results were also contradictious since geophysical investigations indicated a very loose degree of compaction of the alluvium to very large depths which would require extensive excavation works. Finally, an excavation of approximately five to ten meters underneath the dam footprint was realized in order to eliminate the layers showing a high deformation potential and organic particles.

3. APPLIED MODELS, PARAMETER AND ANALYSES

3.1. GENERAL

For the Arkun CFSGD a 2D stress-deformation were prepared using the Geoslope Sigma software package. For the seepage analysis the groundwater module of the Rocscience Slide program was used. The seepage model was further utilized in order to check seepage conditions for extreme load cases neglecting the sealing effect of the upstream barrier consisting of concrete face, articulated plinth and cut-off wall.

A limit equilibrium analysis was performed considering the shear stress behaviour derived from large scale triaxial testing performed in the Karlsruhe Institute of Technology (KIT) in Germany in order to optimize the downstream slope design and in order to check the stability also for extreme seepage conditions superposed with earthquake loads. For the LEA of the slopes the program Slide/Rocscience was applied.

3.2. FEM MODELS, INPUT PARAMETER AND ANALYSES

The seepage FE model is shown in Fig. 3. The finite element mesh was refined at critical structural objects such as the face slab and the articulated plinth as well as close to the cut-off wall and the L-shaped drain. Steady state conditions were investigated for different water levels and for different sealing and drain conditions which were combined to load cases (LC).

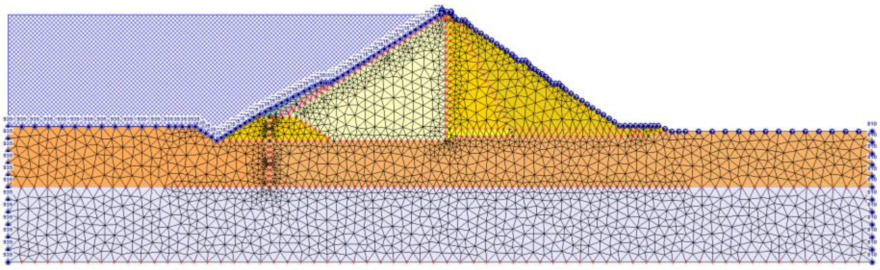

Fig. 3
FE mesh and model for the seepage analysis

For the steady state seepage analysis following parameters, e. g. permeability, were applied (Table 1). Table 1 includes the general Technical Specifications of the dam fill works.

Table 1
Technical specifications of the main dam fill materials **Fehler! Verweisquelle konnte nicht gefunden werden.**

			General Technical Specifications for the Fill works 1)6)							
No.	Name	Description	Passes [-]	Dry density 4) σ_d [g/cm³]	Max. grain size d_{max} [mm]	Layer thickness T [cm]	Elasticity modulus E [MPa]	Permeability k [m/s]	Water [l/m³]	Model "Set0" k-values [m/s]
1	1A 3)	Cohesionless fine grained soil	-	-	63	30	-	-	-	10^{-5}
2	1B 3)	Fill, protection material	-	-	400	60	-	-	-	10^{-4}
3	2A	Perimeter filter	8	2.0	40	40	-	-	-	Not modeled.
4	2B	Transition filter I	8	2.0	80	40	-	-	-	10^{-5}
5	3E	Upstream sand-gravel fill	12	2.5	400	60	200	10^{-4}	5)	10^{-4}
6	3F	Downstream sand-gravel fill	12	2.5	600	80	200	10^{-4}	5)	10^{-4}
7	3G	Downstream rockfill	12	2.2	600	80	80 2)	10^{-1} to 10^{-2}	250-500	10^{-1}
8	3H	L-shaped drain/filter	8	1.9	150	60	-	10^{-2}	-	$5\ 10^{-2}$
9	3H*	Suffusion filter	8	2.0	150	60	-	10^{-3}	-	10^{-3}
10	RR	Rip-rap	-	-	1,500	150	-	10^{-1}	-	Not modeled.

The FE mesh used for the stress-strain analysis (Sigma/W) is given in Fig. 4. The mesh had to be critically refined in the area of stiff objects such as the concrete slabs and the cut-off wall. In consideration of the laboratory test results particularly the deformation behaviour of the cut-off wall was of major interest. Hence, also observation points were accumulated there and where monitoring instruments were placed.

Thanks to the fact that construction already started when the models were prepared, calibration works could consider the actual construction stages and measurement results derived from inclinometers, settlement gauges and cells. This is a comfortable situation, which contributed to the reliability of the model. The stress-strain model was used mainly to investigate the dam conditions at the end of construction and the first impoundment stage. The deformation at the face slab and the plinth area as well as the stress conditions along the cut-off wall were of major interest.

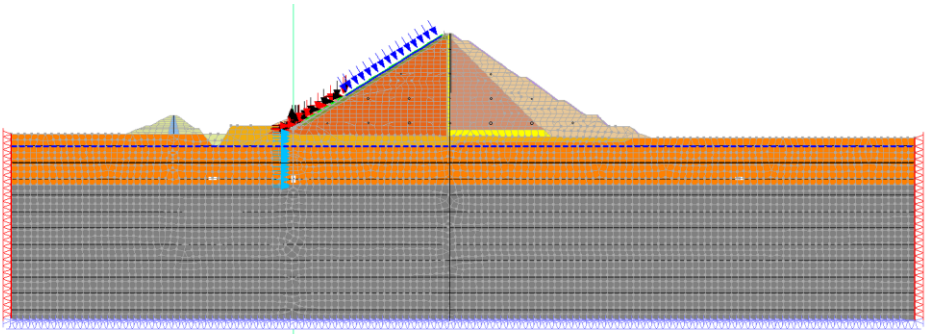

Fig. 4
FE mesh and model for the stress-strain analysis

The model considered 34 construction stages at the main dam before the impoundment was modeled by introducing the corresponding pore water pressures manually. The results of the steady state seepage analysis were considered. Table 2 includes the considered parameters for the stress-strain analysis.

Table 2
Applied parameters for the stress-strain model [2]

BCE preferred to apply an elastic-plastic material model rather than the linear-elastic models which were used before. Fundamental considerations concerning the deformation behaviour of rockfill and sand-gravel fill materials were considered as discussed in [4] [6] [7] [8]. Case studies with reference to principle rockfill characteristics are also included in [9] and [10]. Sand-gravel fill materials with a wide, uniform sieve curve tend to show very strong deformation characteristics which is confirmed by several benchmark projects [7].

For the elastic-plastic modeling constant elasticity moduli were considered as well as MC shear strength parameter. This approach is considered especially for the impoundment phase a priori too simplified but, nevertheless, lead to reasonable results, thanks to an accurate calibration of the model by comparison to the actual measurement data to reliable results (see chapter 4).

For the performed slope stability LEA following parameters (Table 3) were applied in order to consider a comprehensive shear-strength behaviour of the different applied materials. For the main fills (zones 3E, 3F, 3G) stress dependent shear curves were implemented which were derived from large scale triaxial tests performed in Germany, as aforementioned.

Table 3
Material parameters used for the LEA of the slope stability

No.	Zone	Name	Dry unit weight γ_d [kN/m³]	Saturated unit weight γ_S [kN/m³]	Wet unit weight γ_W [kN/m³]	Water content w [%]	Peak shear strength φ' [°]	Peak shear strength c' [kN/m²]	Residual shear strength φ_R [°]	Residual shear strength c_R [kN/m²]	Shear Type Type	Saturated permeability k_S [m/s]

4. RESULTS

4.1. SEEPAGE ANALYSIS

The seepage analysis showed that also for very unlikely, extreme load cases which consider the situation, that the complete concrete face and the cut-off were not working at all, the seepage is still controlled by the L-shaped drain and the rockfill zone (3G) so that no critical pore water pressures occur within downstream fill. This also emerges a positive effect on the slope stability of the downstream slope. In Fg. 5 the phreativ line of seepage is shown for selected load cases. For comparison also LC2 “Set 0” is included which shows the seepage conditions for complete functional sealing and drain elements.

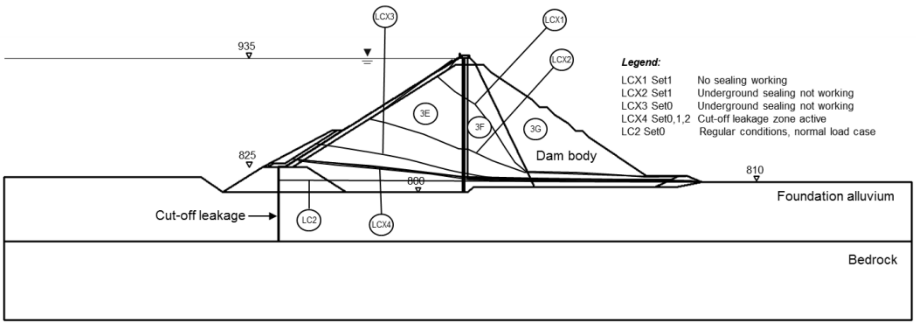

Fig. 5
Phreatic line of seepage of Arkun main dam for selected load cases [1]

Fig. 5 also illustrates that for extreme (unrealistic) load cases, e.g. LCX1 “No sealing working”, the draining zones are able to control the pore water pressure in the dam body and finally the phreativ line of seepage is controlled by the 3G rockfill zone. Thus, the danger of unfavorable pore water pressure conditions at the downstream slope are very unlikely to occur. The sliding stability of the downstream slope shows a sufficient factor of safety, in spite of a cmplete malfunction of the sealing. This proof was required to comfort all responsible parties due to ongoing discussions concerning the cut-off wall and slab behaviour during first impoundment.

4.2. LIMIT EQUILIBRIUM ANALYSIS

The strong characteristics of the rockfill and the sand-gravel fill material as well as the effective seepage control design resulted in quite confident safety factors considering the LEA for the sliding stability of both slopes (see Fig. 6).

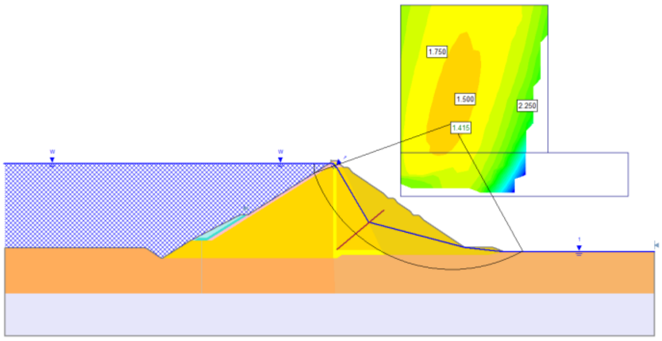

Fig. 6
Decisive sliding circle for the extreme load case 3C, FoS = 1.42

For example, for the extreme load case 3C “Normal operation water level/slab cracking/drain malfunction” (corrsponding to LCX1 of the seepage analysis) a factor of safety of FoS = 1.42 is obtained whilst the required safety factor is within the limit between 1.0 to 1.1 according to [5].

4.3. STRESS-STRAIN ANALYSIS

The stress-strain model predicted a total deformation of maximum approximately 75 cm located close to the dam foundation at the EoC stage which conforms to the expectations derived from benchmark projects which were founded on deep alluvium. The results were calibrated using the measurements results from settlement cells and settlement gauges. The obtained 0.5 % total deformation at EoC indicates an realistic value, although it is high in consideration of the relatively strong elasticity modulus which was achieved mainly for the sand-gravel fill materials.

For the first impoundment a horizonal deformation of the dam crest of 30 cm towards downstream was predicted which fitted quite well to the later measurments of the survey points. The articulated plinth showed total displacments of 45 cm. The alluvial foundation caused a triplication if this value.

The deformation of the cut-off resulted in stresses (> 5 MPa) which indicated a high likelihood of cracking of the cut-oof wall during first impoundment. The actual cut-off characteristics are considered to be too stiff.

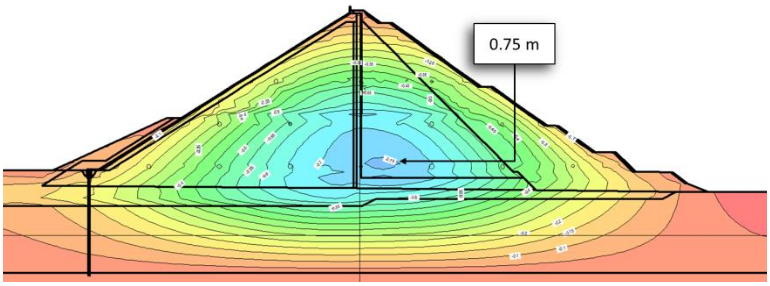

Fig. 7
Total displacements/deformations at the EoC stage

SUMMARY

The Arkun Dam and HEPP project is located in the North-east of Turkey on the Coruh River. The installed capacity comprises a main powerhouse with 225 MW and an environmental powerhouse with 12 MW. The main dam shows a height of 140 m and is of CFSGD type. The gated spillway is designed for a discharge of 4.701 m³/s. The energy tunnel which is connecting the reservoir with the main powerhouse is 14 km long with a diameter of 6.4 m. The project was commissioned in 2014.

The dam is founded on a deep alluvium layer within the V-shaped valley. The seepage of the concrete face sand-gravel fill dam (CFSGD) is controlled by the concrete face and the articulated plinth which is linked to the maximum 70 m deep two phase cut-off wall. During the construction a seepage analysis, a LEA slope stability analysis and a stress-strain analysis were performed in order to predict the dam's behaviour during construction, first impoundment and for the long-term perspective.

ABSTRACT

Tugu Dam is an earth fill dam located in Trenggalek district who has a problem with its foundation which is consists of a relatively thick deposit of pervious alluvium. When the dam foundation consists of a relatively thick deposit of pervious alluvium, the designer must decide whether to make a complete cut off wall (diaphragm wall) or allow a certain amount of under seepage to occur under controlled conditions.

To improve the earth fill dam with pervious foundation by cut off wall can be divided into three types: conventional concrete, slurry trench, and plastic concrete wall. Based on the many reasons, Tugu Dam could be proposed using Plastic Concrete Wall as a cut off wall.

Screen grouting under the cut off wall is considered to make sure the water seepage could be protected.

KEYWORDS

Earth Fill Dam, alluvium deposit, plastic concrete wall, screen grouting.

1. INTRODUCTION

Tugu Dam is a dam which is established to meet the requirements of irrigation water and influent. It was established on Keser River which has a river basin as wide as 43.06 km^2 with the length of the river is 9.3 km. Administratively, the dam is located in Nglinggis Village, Tugu Sub-district, Trenggalek Regency, East Java Province.

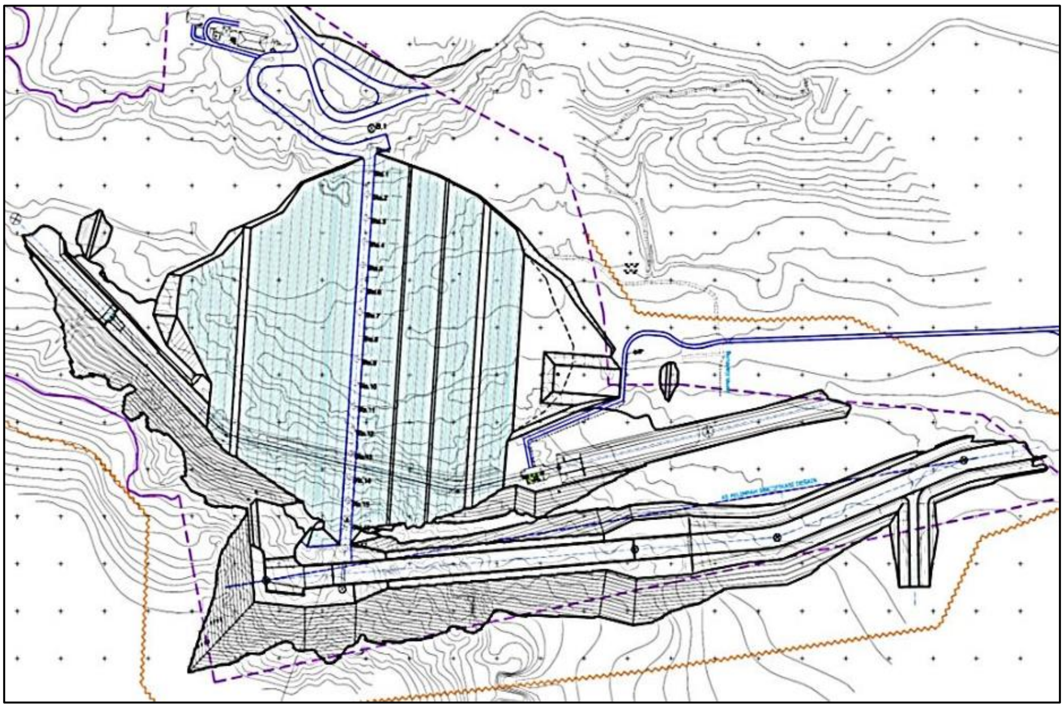

Figure 1. Layout of Tugu Dam

The design of seepage control is one of efforts in obtaining the dam safety and the water storage capacity. The seepage control through many ways is very necessary because there are many factors that have not been exactly known in the construction stage till the life time of the dam, such as:

a. The geological condition of the dam which is greatly various (not uniform) along the dam axis.
b. The incident of big earthquake and unpredictable weather.

c. A decrease in function of one or several efforts of seepage control in line with the age of the dam.

Principally, the efforts of seepage control on the dam foundation are divided into two categories, they are: by restraining the seepage (water barrier) and by controlling the drainage. The design of dam used a combination of the two efforts. The seepage control system on the dam body consists of divisions of embankment zone, blanket drain, and toe drain.

Meanwhile, on the foundation, water barrier, downstream drainage ditch, and relief well are made. Water barrier on the foundation can use a curtain grouting or use a slurry cutoff wall or diaphragm wall.

2. CUT OFF WALL OR DIAPHRAGM WALL

In the area of Tugu Dam, the condition of foundation along the axis is greatly various. The thicknesses of the alluvial deposit and weathering are greatly various starting from 5 meters up to 28 meters. If an excavation of cut off trench is conducted until it reaches the bedrock, this method is not economical. The repair of foundation on the alluvial deposit and the strongly weathered rock using the curtain grouting is also considered as ineffective.

This condition also considered the time function of construction and in line with the age of the dam, with the water head of 80 meters, the water pressure on the foundation will be very high. The effectiveness of material grouting for long term period will not be able to ensure the permeability level is maintained. Considering that the alluvial deposit and the strongly weathered rock are still porous enough, a special repair of foundation is needed using the cut off wall or the diaphragm wall.

The slurry cut off wall is a kind of cut off trench which is very effective in blocking the seepage from passing through the foundation of the dam. It is used if the repair using the methods of either the curtain grouting or the cut off trench which reaches the foundation layer of rock are not economical. The slurry cut off wall is made by digging a vertical narrow trench as wide as 0.8 – 1.6 meter, through the permeable foundation materials (alluvial layer, colluvium layer, or strongly weathered rock layer). The excavation of the hole of slurry cut off trench is conducted until reaching the layer of the bedrock which is relatively impermeable. Then, the trench is filled with the suspense of bentonite slurry in the water during the process of excavation. If necessary, slurry is continuously added during the excavation in order to maintain the slurry stage to keep constant in the surroundings of the top of hole/trench. It is necessary to prevent the collapse of the hole/the slurry trench.

The foundation treatment using the cut off wall aims to reduce the permeability of passing through the layer of porous deposit and to increase the length of equipotential line of the seepage from the reservoir. In the earthfilldam type, the cut off walls which can be used are:

a. Conventional concrete
b. Cement- bentonite slurry
c. Plastic concrete

For Tugu Dam, it is suggested to use the plastic concrete with a width of 80 or 160 cm. The maximum depth is 25-30 m and as long as 150 m (from Sta. 5 until Sta. 11).

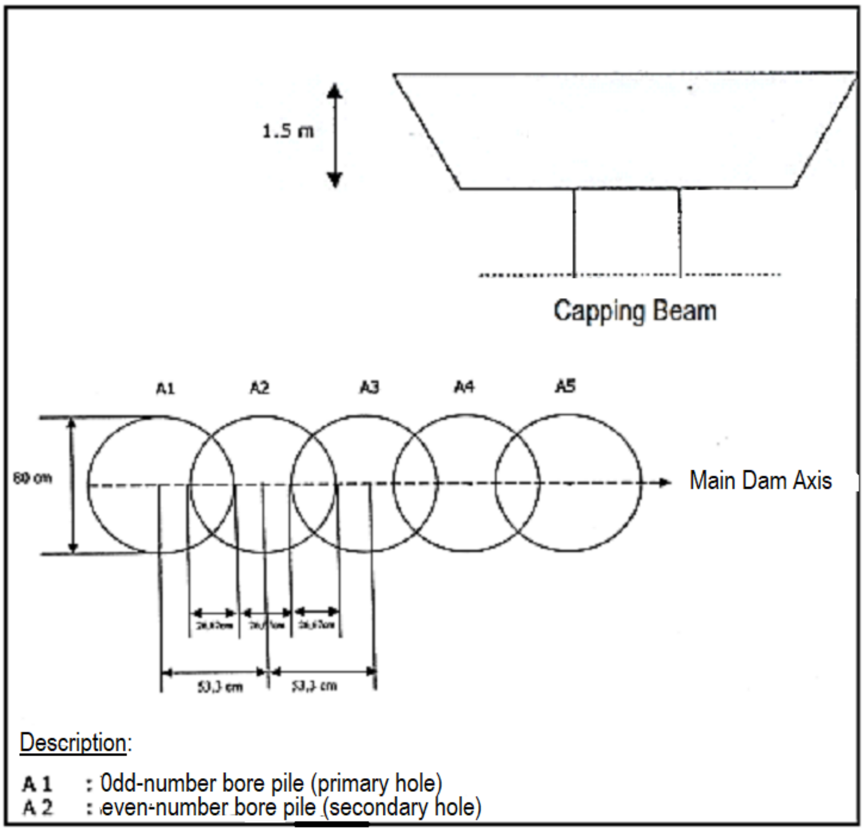

Figure 2. Lay Out of the Cut Off Wall with Bore Pile

3. TRIAL MIX OF PLASTIC CONCRETE

Trial mix of plastic concrete is necessary to be conducted in a laboratory using many varieties of material mix compositions. Several plastic concretes that are suggested are as follows:

Table 1. Trial Mix Composition of Plastic Concrete

Material	Unit	Trial Mix 1	Trial Mix 2	Trial Mix 3	Trial Mix 4	Trial Mix 5	Trial Mix 6
PC Type-1	Kg	185.0	143.6	143.6	185.0	185.0	185.0
Bentonite	Kg	100.0	22.30	36.6	100.0	100.0	100.0
Water	Liter	263.0	300.0	212.5	300.0	378.75	242.86
Coarse aggregate (coral)<2.5 cm	Kg	840.0	707.1	707.1	440.0	440.0	440.0
Fine aggregate (sand)	Kg	700.0	707.1	707.1	1,100.0	1,100.0	1,100.0

Table 2. Characteristics of Material for Diaphragm Wall (ICOLD Buletin 129, 2005)

Kind of Material	Strength (Mpa)	Permeability K (m/dt)	Deformability	Characteristic of Crack	Composition
Tremie concrete	30-50	10^{-12}	Rigid	Fragile	Cement+aggregate slump 20 cm w/c = 0,5-0,7
Plastic Concrete	1,0-3,0	10^{-9}	High	Durable against strain till 10% without any crack	Cement+aggregate +clay+bentonite w/c = 0,5
Slurry cement/bentonite	0,1-1,0	10^{-8}	Very high	212.5	Cement+bentonite w/c = 0,5

Bentonite slurry is made of bentonite slurry mixed with Portland cement type I or type II. The main function of slurry is to maintain the cement still in the suspense form until the initial set up. Cement is added after the bentonite slurry reaches a full hydration. The mixing of bentonite and cement with water is not allowed. The comparison between cement and water will influence the strength, deformability and permeability.

The compositions suggested by ICOLD (1985) for the mix of bentonite slurry-cement per m^3 are as follows:

- Cement: 80 up to 350 kg
- Bentonite: 30 up to 50 kg

According to *Xanthakos,* the percentages of the mix are as follows:

- Cement: 15-20%
- Bentonite: 2-4%
- Sand and gravel: 5-10%

The comparison between cement and water:

- For Portland cement, it is around 3.3:1 up to 5:1
- For cement of blast furnish cement (BLF) type, it is around 4:1 up to 10:1.

Cement has a bigger durability against the attack or the reaction of ground water that will dissolve the content of calcium carbonate within the cement. Then, each composition of the mix will be tested for the followings:

1. Compressive strength
2. Slump
3. Elasticity
4. Permeability

4. TRIALS OF CUT OFF WALL

The implementation of trial of the length and width dimensions, the amount of row of the bore pile, and the filed permeability test are necessary to be conducted first. They are necessary in order to know the effectiveness of the cut off wall.

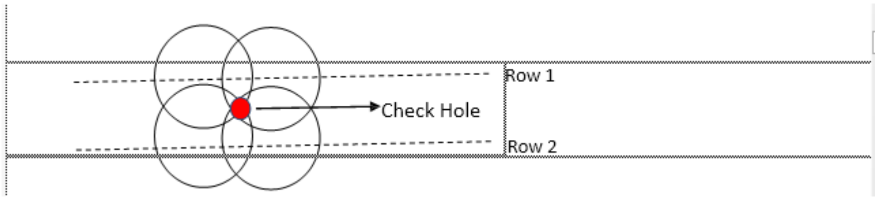
4.1. TRIAL 1

A cut off wall with a width of 80 cm is bored to make point A1 and point A2, then the points are filled with a selected trial mix. After that, the permeability is tested (check Hole) by being bored with rotary core drilling ϴ76 mm (dry drilling) and Lugeon test. The dry drilling is to prevent the occurrence of construction breakage of the plastic concrete. The coredrill test and Lugeon test are implemented in the overlap between two plastic concrete poles which have reached an age of 28 days. Pressure permeability test (packer test) uses the air packer as the screen. The water pressure is conducted using the pressure pump with a pressure variation of 1 kg/cm^2 up to 6 kg/cm^2.

If the result of the Trial 1 is not successful in reducing the targeted permeability score of the foundation, Trial 2 is necessary.

4.2. TRIAL 2

A cut off wall with a width of 2 x 80 cm or two rows of upstream and downstream bore piles are filled with the selected trial mix. Then, the permeability test (check hole) is conducted with the above similar pressure.



5. CURTAIN GROUTING UNDER THE CUT OFF WALL

The height of the dam is around 80 meter from the excavation base, meanwhile, the height of the cut off wall is only a maximum of 30 meter. Therefore, an analysis of seepage under the foundation of the dam is necessary to be conducted again. If the result of the analysis shows that the seepage on the foundation under the cut off wall still occurs, the implementation of curtain grouting work is necessary to be considered. Its implementation is by using the rotary machine of ϴ 76 mm <u>in the middle part of the row of the cut off wall</u>, by conducting a non coing drilling until penetrating the bedrock. After that, grouting cement is conducted in the part of the rock foundation, whereas, the hole on the cut off wall is plugged soon using the material of cement.

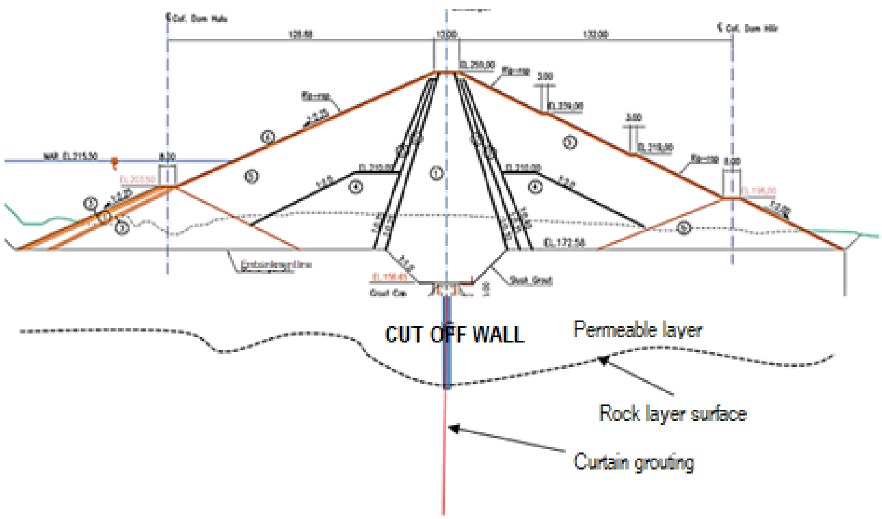


Figure 3. Curtain Grouting under the cut off wall

6. THE RELATION BETWEEN THE CUT OFF WALL AND THE CORE ZONE

For the cement-bentonite slurry cut off wall, a special attention must be paid on the connection between the cut off wall and the core in order that they are really joint. Although the decrease in the cement-bentonite is not too much after being hardened, but the compressibility will be different from the surrounding foundation materials. Therefore, an effort to prevent the occurrence of high-pressure concentration or low-pressure concentration is necessary. It is suggested to install a concrete slab above the rows of plastic concrete as wide as the area of the core zone foundation.

7. THE INSTALLATION OF INSTRUMENTS

The equipment of instrumentation is necessary for monitoring the condition of the foundation permeability. The suggested equipment are as follows:

a. Inclinometer and settlement gauge to monitor the deformation.
b. Piezometer which is set beside the upstream and the downstream of the cut off wall in order to monitor the efficiency of the cut off wall.

8. THE IMPLEMENTATION OF THE CONSTRUCTION

In the implementation of slurry trenching, commonly, a construction of berm is necessary to be established, as the work surface level as well as for increasing the stability of the work area slope. The placement of berm in a certain elevation is by considering the difference of gap height and utilized as the work berm or the foothold in the implementation of bore pile and casting works.

The cement-bentonite slurry will be hardened in several hours. A retarder can be used to retard the hardening as well as to increase the workability of the slurry. Before giving an agreement on the use of a kind of retarder, a designer should examine first the possibility of the presence of adverse effects on the long-term performance of the wall.

This such type of cut off wall has a round form and is deep, therefore, a tight controlling is necessary on the verticality, besides, the deviation in horizontal direction should be given a maximum limit on the percentage amount from the depth.

The volume of cement-bentonite slurry will be decreased during the early set up due to the loss of water and dewatering. Therefore, it is necessary to implement an extra casting height for the reserve of the volume loss. The top part of the cut off wall should be cut before implementing the concrete capping work or foundation concrete slab.

The excavation of cut off wall using the method of bore pile (hydraulic rotary drill) can be conducted continuously, by conducting a drilling in rotation with the primary hole series (odd-number bore pile) and then the holes are filled with cement-bentonite slurry and continued with the secondary hole bore pile (even-number bore pile).

STRENGTHENING AND SEALING OF GOMAL ZAM RCC ARCH-GRAVITY DAM FOUNDATION IN PAKISTAN

Eckhard SCHNÄCKER & Chongjiang DU

Lahmeyer International GmbH, TRACTEBEL ENGINEERING

GERMANY

1. INTRODUCTION

Gomal Zam Dam is situated at Khajuri Kach on Gomal River in South Waziristan Agency, Federally Administered Tribal Area, Pakistan. The dam's planned provision is to store water of rivers Gomal, Zhob and Wana Toi ensuring continuous water supply for irrigation and drinking purposes, flood control, and power generation.

The catchment area upstream of the dam site is 29,000 km². Thanks to the favourable topography of the wide-opening of Gomal Valley upstream of the dam, the 13.6-km long reservoir has a total storage capacity of approximately 1,100 mill. m³ and an active storage of 800 mill. m³ to irrigate an area of 66,000 ha of farmland. Moreover, the entire project area is located in an absolutely barren and desolate tribal area where there is no sign of habitation in need of compensation.

The main dam is an RCC arch-gravity structure of 133 m height from its low foundation level at El. 630.0 m and a crest length of 231 m with a crest width of 10 m at El. 763.0 m. The maximum width at base amounts to 78 m. A four-bay spillway of 17.5 m length is integrated in the central part of the dam, and a bottom outlet of 3.0 m in diameter with invert at El. 680.0 m is constructed to release sediment in front of the dam. Both sides of the dam are non-overflow dams. The power intake is located in the non-overflow dam on right bank to feed power water into the powerhouse, 320 m downstream of the dam on right river bank.

The project was implemented and is owned by WAPDA. The construction work was previously commenced in July 2002 on turnkey basis under an EPC contract, but unfortunately halted in October 2004. In June 2007, the work was resumed and completed in 2012. The initial reservoir impounding started from March 2011.

2. GEOLOGICAL CONDITIONS

The strata in the region are sedimentary rock of neritic to continental facies of Jurassic to Tertiary age. During early Cretaceous, this region was locally uplifted. In Palaeocene or Eocene period, it underwent an overthrusting and inversing movement. Afterwards, in the process of orogenic movement, it suffered further deformation. The formation is strongly folded and fractured due to action of principle compressive stress trending approximately E – W: Consequently folds and major geological discontinuities are striking S - N or SSW – NNE.

The dam foundation consists exclusively of Jurassic limestone with minor intercalation of thinly bedded calcareous marls, marls and fine-sandy claystone/shale. The strata form a wide spanned anticline generally striking perpendicular to the valley dipping with 30° to 70° gently to steeply towards upstream. Obviously, repeated internal folding has caused distinct to heavy tectonization of the thinly to medium bedded limestone.

The limestone is intensely tectonized, fractured and intersected by major faults and shear zones. Traces of faults F2, F3 and F13 are daylighting close to the main dam (Fig. 1), F2 and F3 of which in the right abutment are slightly curved striking approximately parallel to the river stream with a dip of 87° and 80° towards the river. Fault F13, a transpressional fault is striking sub-perpendicular to the river course with an downstream dip of 60° to 80°. Apart from these major faults many other faults and shear zones of minor persistence exist.

The significance of karst is disputed since direct signs of karstification such as open channels or cavities are rare and basically limited to particular faults. However several indirect signs such as increased permeabilities (8 LU to 90 LU) exist. Packer tests in the limestone at the dam site yielded Lugeon values of 50 LU above river level in average with minimum and maximum values of 40 LU and 90 LU, respectively.

Another indication for a high rock mass permeability is the groundwater level. At the dam site the water table is more or less stable at EL. 607 m to 608 m with seasonal variations of 1 m to 3 m. This is 27 m to 28 m below the river level.

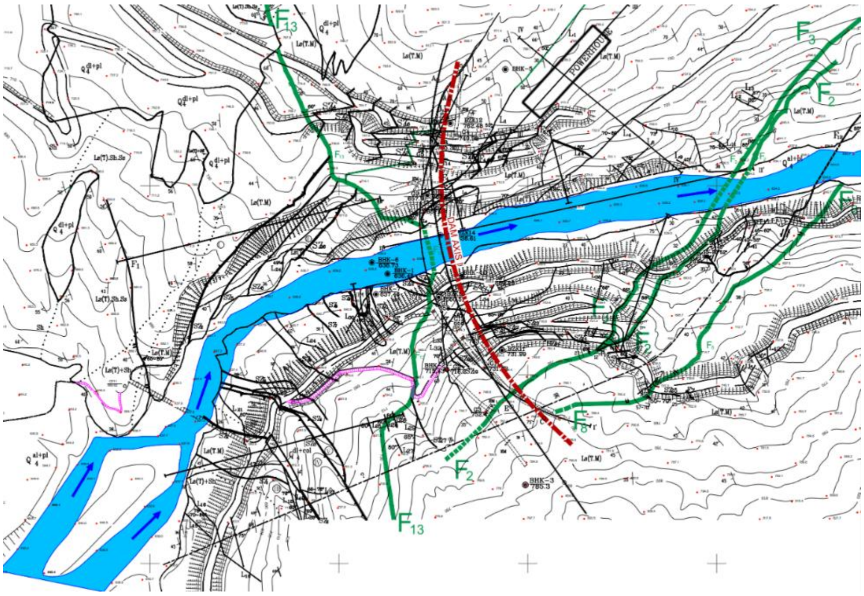

Fig. 1 Excerpt of the geological map at main dam site

3. SELECTION OF DAM AXIS AND TYPE

The river terrace in the confluence area of Khajuri Kach River to Gomal River is a broad unconfined valley with a vast basin. At its immediate downstream, the Gomal River is forced to pass through a narrow ravine named Khajuri gorge of 800 m length. From the topographical viewpoint, it is an ideal terrain to build a dam in the narrow valley which creates a gigantic reservoir for water storage.

At dam site the V-shaped gorge has a bottom width of approximately 25 to 40 m. The narrow canyon is slightly asymmetrical and has very steep flanks with an average slope of 75° and 65° for the left and right flank, respectively, while its upper flanks tend to slightly gentle with an average slope of 40° to 45°. The ratio of width to height of the dam is roughly -1.2:1. This topography is very favourable to an arch dam option. In fact, a double curvature arch dam of conventional concrete was proposed in feasibility studies [1].

Despite very promising conditions at first glance, aforementioned investigations revealed that the geological conditions and rock quality of the foundation leave much to be desired for a double curvature arch dam. The dam site itself lies in a deep gorge which cuts through a thick Jurassic limestone emerging among the shale. Probably through multiphase folding the limestone is intensely tectonized, fractured and intersected by major faults and shear zones, of which the faults F2, F3 and F13 have significant impact on the dam stability. The slightly curved F2 and F3 in the right abutment striking approximately parallel to the river stream with a dip of 87° and 80° towards the river are causing problems for the dam stability. Fault F13 striking roughly perpendicular to the river course and dipping steeply downstream had to be considered for the selection of dam type and setting up dam axis, since a deep depression on the right bank downstream of the dam, is limiting the possible dam location in downstream direction. Under these conditions, the double curvature arch dam cannot avoid being located across the F13, and its foundation will intersect the fault in each abutment.

Numerical analyses demonstrated that excessive tensile stresses could occur in the double curvature arch dam and thrust act on foundation in an unfavourable direction, so that it would be difficult to obtain an acceptable design satisfying both criterion of stress and criterion of the thrust direction. Preferably, the dam should be completely located downstream of the fault trace. For these reasons, a curved RCC gravity dam with a downstream slope of 1V : 0.7H applying a constant radius over the entire length was proposed for the EPC tendering. This dam can be fully seated downstream of the F13 fault.

During tendering, the dam type was further studied by the EPC Contractor and found that the topography and geology at dam site lends itself to the introduction of two curvatures to the dam axis and reduction of the downstream slope to 1V : 0.6H. Thus, an RCC arch-gravity (also referred to as gravity-arch) dam was developed without crossing the F13 fault, and the stresses in the dam can be adjusted to an acceptable level. This option can combine the advantages of RCC construction with the appreciable reduction in volume of RCC associated with the arch-gravity design concept, which is well suited to the conditions at Gomal Zam site. After weighing the pros and cons of each option, the RCC arch-gravity dam has finally been selected for construction, as shown in Fig. 2.

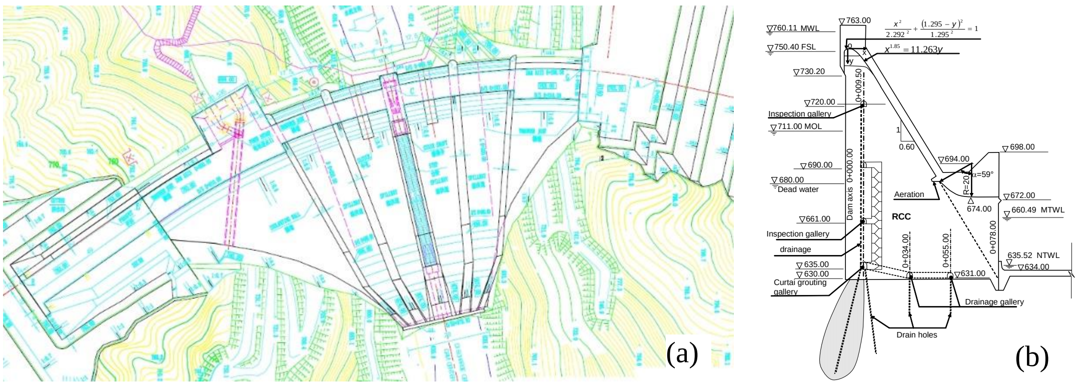

Fig. 2 (a) Layout and (b) cross section of Gomal Zam RCC arch-gravity dam

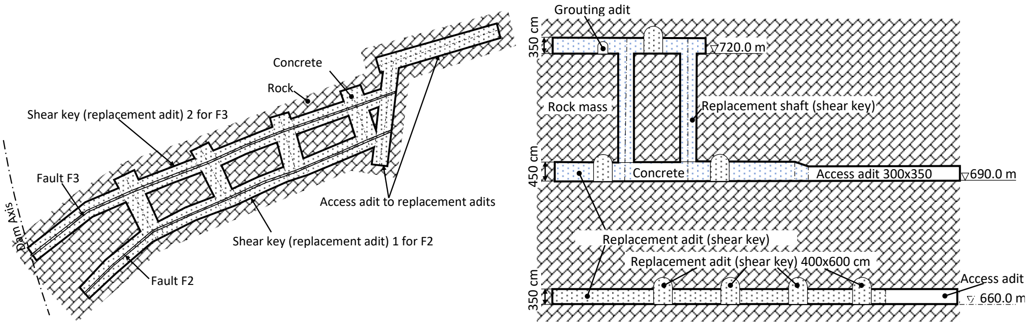
4. STRENGTHENING RIGHT ABUTMENT WITH CONCRETE SHEAR KEYS

As mentioned above, faults F2 and F3 in the right abutment may affect the stability of the right abutment against sliding. Geological investigation and excavation revealed that fault F2, striking almost parallel to the flow direction and dipping to the river bed at an angle of over 70°, cut through the whole right abutment. The faults have a width of 0.01 to 0.3 m locally up to 0.5 m, and an influence zone of 0.5 m locally 2.0 m thick. The faults have undulated face and are filled with greyish green, pale yellow, greyish black fault gauge, mylonite, breccia and calcite. The fill material is argillaceous cemented and squeezed firmly. The faults F2 and F3 cut the rock mass in the right abutment into prisms and wedges, jeopardizing the stability of the right abutment.

To improve the shear resistance of the faults F2 and F3 in right abutments, several measures were studied and found that the most desirable solution to secure and support the discontinuities is to use concrete shear keys. The shear keys (also named replacement adit) can effectively increase the shear strength of the faults. Furthermore, the seepage paths of groundwater along the faults can be cut off, and consequently, the infilling of the fault gauges is protected from deterioration [2]. Therefore, the stability of the dam and its foundation is ensured.



(a) (b)

Fig. 3 (a) Layout at El.660.0 m and (b) vertical section at Fault 2 of shear keys

At Gomal Zam dam, the shear keys in form of tunnel and shaft plugs were implemented. In this system the tunnels and shafts were excavated along the faults F2 and F3, and transverse connection tunnels were excavated between F2 and F3, forming the sub-vertical spatial grids. Then the tunnels and shafts were backfilled with concrete of C16 grade. As schematically shown in Fig. 3, the shear keys were accomplished at three levels of El. 660.0, 690.0 and 720.0 m. Between the shear keys at 690.0 and 720.0 m, two vertical shaft shear keys were implemented. In the original design, the vertical shaft shear keys were planned to be extended down to El.660.0 m. After excavation and re-evaluation of the actual conditions of the two faults and re-analysis of the dam stability [3], the two vertical shaft shear keys were cancelled.

5. SEALING THE FOUNDATION

5.1. FOUNDATION GROUTING

The physical characteristics of the natural rock mass are notably insufficient both in regard of the rock mechanical properties of the foundation, as well as with respect to the permeability or water tightness of the sub-surface. Therefore, rock mass treatment with consolidation grouting and curtain grouting was considered necessary, in the early stage already. Contact grouting was performed not only in the lower parts of the dam foundation, but also on the steep abutment slopes to provide a proper bond of the dam concrete to the rock.

The consolidation grouting was generally implemented for the entire dam footprint with extending to the areas 5 m upstream and 10 m downstream beyond the footprint. The holes were drilled vertical in river channel area and inclined on the abutments with a spacing of 3.0 x 3.0 m. High pressure was applied in the consolidation grouting to improve the grouting effectiveness. The purposes were among others (i) to improve the mechanical properties of foundation rock; (ii) to enhance the integrity and reduce deformation and differential settlement of rock mass; and (iii) to strengthen the existing stress-relief rock mass and fill the fissures, cracks and voids/cavities so as to reduce the permeability and seepage of rock mass. After the consolidation grouting of the rock mass, the permeability shall not exceed 5 LU, and the sonic velocity shall be at least 4160 m/s in shallow part and 4250 m/s in deep part, respectively. The deformation modulus shall not be less than 6 GPa for the river channel area, 5 GPa for the lower parts of the abutments and 3 GPa for the upper part.

In the river channel area, the consolidation grouting followed placement of 1 m thick concrete as surcharge. The grout holes were 76 mm diameter in a depth of 20 to 25 m into rock. The method of descending stage grouting with 5 m each was employed. The pressure was limited to 0.8 MPa for the top 5 m at beginning, while it was gradually increased with the depth to 2.5 MPa. The heave monitoring was conducted during grouting of the first stage holes, and soon found that the 0.8 MPa pressure for the top 5 m was too high, causing heave and cracking of the surcharge concrete. Then, the grouting for the top 5 m was divided into two stages of 2 m and 3 m. The pressure was adjusted to 0.2 MPa for the upper 2 m stage and 0.5 MPa for the lower 3 m stage. Additional consolidation grouting was carried out as the surcharge concrete raised to 4.0 m thickness, by which the grouting criteria above were satisfied.

The consolidation grouting for the abutments and placement of RCC dam was alternately carried out. For an RCC lift of 3 m (10 layers), grout holes were firstly drilled into the abutment rock. The grouting was conducted for the stages below the top 5 m and the pressure was gradually increased with the depth to 3.0 MPa. For the top 5 m stage, a PVC pipe was installed at hole entrance and lead up to the top of next RCC lift. After placement of the 3 m thick RCC lift, the top 5 m stage was grouted. Subsequently, the holes for the next 3 m lift were drilled. Although the consolidation grouting was conducted, the important lesson learnt from this procedure was that the drilling and grouting process of the 3 m high abutments needed at least 5 to 7 days, which forced the RCC placement for the 3m lift in a total 6 to 8 days or more, which considerably hold back the construction progress of the RCC dam. Moreover, grout was found to leak out of the rock surfaces during the grouting due to the high grouting pressure, which required immediately and effectively plugging or caulking.

The dam has a grouting/drainage gallery at El. 634.0 m near the dam heel and two control galleries at El. 675.0 and 720.0 m, respectively. Both sides of the galleries extended into rock in due lengths as grouting/drainage adits. On both sides of dam crest, the grouting/drainage adits were excavated. The galleries are accessible through a vertical stairway shaft in the middle pier of the dam, and from the downstream slopes. Two lines of grout curtains were implemented from the grouting/drainage gallery and adits. The main curtain grout holes are inclined arranged to the upstream with an angle of 5° to vertical in a spacing of 2.0 m, while the auxiliary curtain grout holes (also 2.0 m spacing) downstream of the main curtain are vertical. The hole depth is 74 m down into rock at dam bottom El. 634 m, decreased to 43 m at the crest level at El. 763.0 m. On downstream side of the grout curtains, a line of drainage holes of 110 mm diameter and 3.0 m spacing was drilled from the grouting/drainage gallery and adits inclined to downstream with an angle of 5° to vertical.

5.2. UPSTREAM BLANKET

The upstream cofferdam is a rock fill embankment of 41 m height and 82 m length at crest El. 676 m with an upstream sloping core, located at 85 m to the main dam axis. The cofferdam is 8 m wide at the top with 1V : 2.5H slope on upstream and 1V : 1.75H slope on the downstream surface. The thickness of the sloping clay core is 5 m at top and 17 m at bottom, protected by a layer of 0.4 m thick riprap and 0.6-m thick dry-stone pitching. Beneath the sloping core, a filter layer is placed which is inclined to upstream at an upper and lower slope of 1V : 1.7H and 1V : 1.5H, respectively. The cofferdam is seated on the rock foundation. Because the abutments are steep and the limestone rock mass is well developed in joints, fissures, the clay core is widened in the areas contiguous to the interfaces between the clay core and abutment flanks by 20% of its respective thickness at that level.

In order to additionally enhance the sealing effect of the dam foundation, the upstream cofferdam was utilized. The cofferdam was partially removed to a level below El. 670.0 m. After the space between the main dam and upstream cofferdam was filled and compacted with soil, an impervious blanket was placed on the filled soil from the upstream face of main dam extending to the sloping imperious clay core of the upstream cofferdam. The impervious blanket is established with clay/weathered shale and compacted layer by layer. The thickness of each layer is limited to 0.3 m as maximum, and the total thickness is not less than 2 m. In the area in front of the dam face, the thickness is increased to 4.0 m or more. The impervious blanket was completed prior to the initial reservoir impounding.

6. SEEPAGE THROUGH FOUNDATION AND FROM RESERVOIR

After completion of the RCC dam construction, the sub-contractor started the initial reservoir impounding on 29th March, 2011. Reservoir filling ran smoothly until 19/20th April, 2011 and the successive days. However, when reaching the reservoir water level El. 689.50 m, a large amount of seepage water flowed out of the existing drainage holes at right abutment into the drainage gallery at El. 634.0 m. The discharge of seepage water exceeded the installed capacity of the 3 pumps of 133.2 l/s, so that the galleries were flooded. The water level in the galleries/vertical shaft reached to their maximum at El. 643.88 m, i.e. 9.88 m above the invert level of the grouting gallery.

Fig. 4: New springs upstream of the Bailey bridge

Some 200 m to 300 m upstream of the Bailey bridge several new springs occurred on the left bank shortly after initial reservoir impounding, others experienced a sudden and drastic increase in discharge (Fig. 4). Four of these springs were perennial with little discharge all over the year [5]. Seepage water is percolating through open joints and fissures of the limestone. The total run-off of these springs in June/July 2011 was estimated to range between 0.05 m^3/s and

0.1 m³/s. At least two other leakage points (springs) in the vicinity of the Bailey bridge could be observed. The total discharge of all these springs was estimated to 1.2 m³/s.

Obviously, the quality and/or the dimensions of the grout curtain are responsible for the described seepage. Most likely, the seepage water bypasses the grout curtain vertically or laterally. The curtain might be either not deep, not long or not tight enough to prevent seepage. It could be even possible that seepage water directly passes the grout curtain through portions of increased permeability, using ungrouted open joints. The above statements basically concern the right bank.

At the left bank, the seepage paths may not even touch the actual grout curtain rather than be interrupted and stopped there. Reservoir water may seep into the limestone rock mass outcropping directly upstream of the dam. From there it may flow through joints and fissures, possibly also karst channels inside the rock mass following the general trend of the bedding. In the Bailey bridge area, some 2 km away, it eventually discharges at several springs.

With respect to the events happened during impounding, two potential problems exist. One of which pertains to the amount of seepage losses. The other is related to the forces exerted by the seepage. Loss of water through underground seepage may be of economic concern for the storage dam, but it will not adversely affect the safety of the dam at Gomal Zam. Main concern of the underground seepage is the stability of the dam and the downstream slopes.

The major purpose of the multiannual (carryover) storage reservoir is for irrigation. The average annual flow is 16 m³/s. If the seepage losses exceed 1.2 m³/s, or 7.5% of the natural flow, the losses are considered inacceptable. They may affect the irrigation of 66,000 ha of farmland.

7. ADDITIONAL SEALING MEASURES DURING RESERVOIR IMPOUNDING

In order to improve the existing grout curtain and to further reduce the permeability of the rock mass, additional grouting was carried out as immediate measure, by utilizing existing drainage holes in El. 634 m gallery. Aim of the grouting was to seal big seepage passages and to control the seepage flow into El. 634 m galleries in order to provide normal working conditions in the gallery. In the same time, this measure should enhance the thickness of the grout curtain and to improve its water tightness [6].

Since the permissible uplift pressure on the dam foundation behind the grout curtain is limited, the reactivation of the drainage system after completion of the additional grouting works had to be done in a timely manner as not to jeopardize the stability of the dam.

In order to reduce the seepage flow through the abutments, the existing grout curtain was extended and/or deepened at both river banks as shown in Fig. 5.

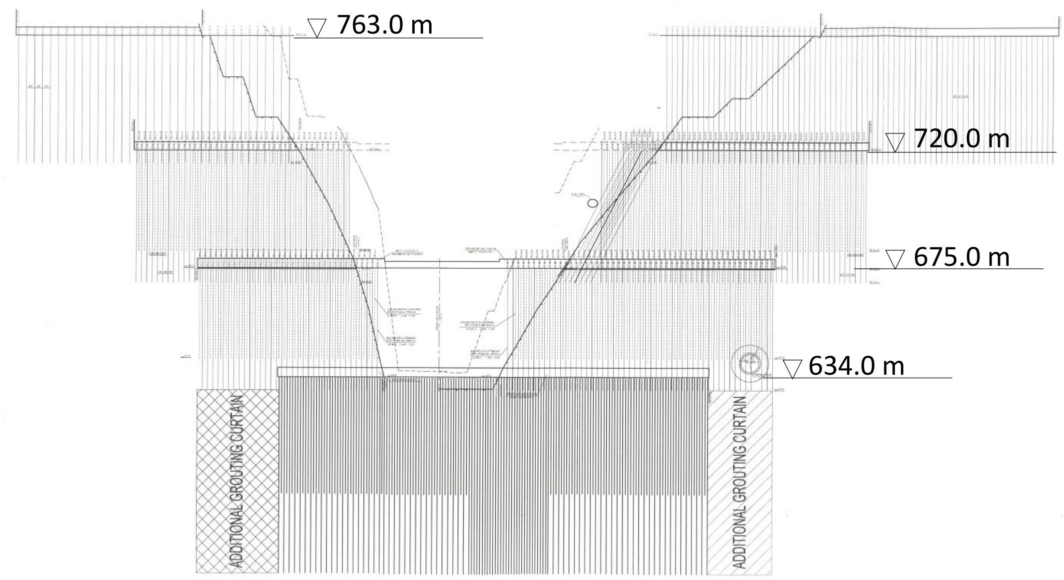


Fig. 5: Grout curtain along the main dam axis after extension

The initial gap between the right end of the EL. 675 m gallery and the right end of the El. 634 m gallery was closed down to EL. 560 m, similar to the curtain depth below EL. 634 m gallery. Initially the grout curtain drilled from the EL. 675 m gallery ended at EL. 629 m (primary holes) or EL. 641 m (secondary holes), respectively. Accordingly, in order to reduce seepage bypassing the left abutment, additional grouting from EL. 675 m grouting adit down to EL 560 m was carried out in left abutment.

The extension of the grout curtain consisting of a single row of grouting holes was drilled from EL. 675 m gallery. Space-splitting method was applied with a spacing of 8 m for primary holes, 4 m for secondary holes and 2 m for tertiary holes. Quality control criterion for the grout curtain was a Lugeon value of 5 LU [6].

8. REMAINING PROBLEMS AND FURTHER RECOMMENDATIONS

The above described sealing measures did not sufficiently solve the seepage problems inside the gallery on the right bank. Further extension of the grout curtain was carried out after completion of impounding. Details of the additional extension neither laterally nor vertically are known to us.

However, seepage on the left bank being in the order of 0.8 m^3/s to 1.0 m^3/s did not change considerably. These losses still constitute 5% to 6% of the mean natural discharge of the Gomal River. However, there appears to be a tendency of decreasing seepage discharge on the left bank downstream of the main dam.

Obviously, the measures taken so far are not sufficient to completely reduce the seepage to an acceptable level. Additional measures are required which could be as follows:

On either side of the Gomal River the permeable limestone complex striking sub-parallel to the dam axis is confined by impervious shales cropping out some 200 m upstream of the dam at the left bank. At the right bank the continuation of the shales upstream of the dam exists also. The exact distance between the dam axis and the impervious shales at the right bank is not known, but it could be in the range of 500 m. A detailed geological map of the upstream region showing the outcrops of shale unit up to El. 750 m does not exist.

The main dam together with the grout curtain is built on limestone striking sub-parallel to the dam axis at the footwall of the shales. A possible way to sealing both abutments could be to extend the grout curtain towards the impervious shales on either side:

Fig. 6: Exposures of limestone and shales at the left bank of the main dam

Left Bank: The grout curtain of the dam in the left abutment may be extended towards to the impervious shales situated some 200 m upstream of the dam axis (Fig. 6); it has to be studied in details if the thickness of the confining unit is sufficient and if the shales reach up to El. 760 m.

Right Bank: The right bank extension of the deep grout curtain towards the confining shales upstream of the dam axis is unknown. A rough field inspection indicated the distance between the dam axis and the shale unit to be in an order of 300 m to 500 m.

A more detailed field study and geological map is strongly recommended. The existing geological map is covering the immediate area of the main dam. It has to be extended on both banks to include the distribution of the shales

9. CONCLUDING REMARKS

Already in the early stage of investigations and construction, and later on in the second construction phase when the work was resumed in June 2007, the Consultant has repeatedly expressed his serious concerns regarding the unfavourable engineering geological conditions, and emphasized the need for additional investigation and an appropriate design. This was concerning the possible adverse effect of the faults F2, F3 and F13, as well as potential seepage problems due to the increased rock mass permeability regardless if it were caused by karst or mere tectonization.

The EPC contractor was reluctant to comply with the comments of the consultants. As far as the main dam and the appurtenant structures are concerned necessary measures have been successfully undertaken to ensure the general stability, i.e. concrete shear keys in alignment of fault F2 and F3, consolidation grouting, deep grout curtain and drainage curtain.

The seepage problem visible at the left bank downstream of the main dam involving losses between 5% and 7.5% of the mean natural discharge of the Gomal River has not been solved sufficiently until now. For contractual reasons the EPC contractor could not be persuaded to carry out appropriate sealing measures.

SUMMARY

Gomal Zam Dam, a multipurpose project in Pakistan, planned for irrigation and drinking water storage, flood control and power generation is an RCC arch-gravity structure of 133 m height, 231 m length, and 10 m top width. The dam foundation consists exclusively of limestone with minor intercalation of various marls. Due to repeated internal folding, the strata underwent distinct to heavy tectonization causing loosening of the rock mass and very high permeability. Major faults in the right abutment striking sub-parallel to the river, as well as the loosening of the highly tectonized limestone belong to the main engineering geological features jeopardizing the dam stability. Furthermore, the high permeability of rock mass with Lugeon values between 8 LU to 90 LU is causing considerable seepage problems through the foundation.

Treatment of the faults in the right abutment comprise the implementation of concrete shear keys with concrete filled shafts and tunnels at several levels. In order to improve and strengthen the jointed rock foundation, deep-extended consolidation grouting with high pressure was carried out over the entire footprint area. To seal the foundation and to prevent considerable seepage beneath the dam, a clay blanket was placed between the upstream face of the main dam towards the clay core of the upstream rock fill cofferdam. Last but not least a deep grout curtain starting from grouting galleries and adits was implemented.

Initial reservoir impounding started in March 2011. Shortly after commencement of impounding significant seepage into the lowest grouting gallery, as well as some 2 km downstream of the dam occurred. Mitigation measures regarding seepage into galleries included immediate grouting of existing drainage holes, reactivation of the drainage system in order not to jeopardize the stability of the dam and lateral extension of the deep grout curtain.

The Gomal Zam RCC arch-gravity dam was completed in 2012. Problems regarding the dam stability appear to be solved. Seepage downstream of the dam in the order of 5% to 7.5% of the natural discharge could not be reduced considerably.

Keywords: geological investigation, foundation treatment, reservoir watertightness, seepage, sealing work, grouting, upstream blanket

RÉSUMÉ

Le barrage de Gomal Zam, un projet polyvalent au Pakistan, prévu pour l'irrigation et le stockage de l'eau potable, le contrôle des inondations et la production d'électricité est un barrage–poids voute incurvé du type béton compacté au rouleau (BCR) de 133 m de hauteur, 231 m de longueur et 10 m de largeur en crête. Le barrage est uniquement fondé sur le calcaire avec intercalation mineure des marnes différentes. En raison du repliement interne répété, les strates ont subi une tectonisation distincte à forte, provoquant un ameublissement considérable du massif rocheux et une perméabilité très élevée. Des failles principales de l'appui rive droite, qui courent sub-parallèlement à la rivière, ainsi que la décompression du calcaire fortement tectonisé appartiennent aux principales éléments géologiques mettant en péril la stabilité du barrage. De plus, la forte perméabilité du massif rocheux avec des valeurs Lugeon comprises entre 8 LU et 90 LU provoque des problèmes d'infiltration considérables à travers la fondation.

Le traitement des failles dans l'appui rive droit comprenais la construction des clavettes de cisaillement en béton à plusieurs niveaux avec des puits et tunnels remplies de béton. Afin d'améliorer et de renforcer la fondation rocheuse, des injections de consolidation profonds à haute pression ont été réalisée sur toute la fondation de l'ouvrage. Pour améliorer l'étanchéité de la fondation et pour prévenir des pertes d'eau considérables sous le barrage, une couverture d'argile a été placée entre le parement amont du barrage vers le noyau d'argile du batardeau en enrochement amont. Enfin, un rideau d'étanchéité profond a été réalisé depuis quatre niveaux de galeries d'injection.

La mise en eau initiale du réservoir a débuté en mars 2011. Peu de temps après le début de la mise en eau dans la galerie de drainage la plus basse, ainsi que quelque 2 km en aval du barrage, de fortes fuites d'eau se sont produites. Les mesures immédiates pour contenir l'infiltration dans les tunnels comprenaient des injections de trous de drainage existants, puis la réactivation du système de drainage pour ne pas compromettre la stabilité du barrage, et enfin, l'extension latérale du rideau d'injections profond.

Le barrage Gomal Zam BCR a été achevé en 2012. Les problèmes d'infiltration concernant la stabilité du barrage ont été résolus. Cependant, les fuites d'eau en aval du barrage de l'ordre de 5% à 7,5% du débit naturel n'ont pas pu être significativement réduites.

1. INTRODUCTION

Bitumen emerged as a standard 20th century waterproofing material in civil and water engineering in the form of bituminous concrete, asphalt, and bituminous geomembrane.

For obtaining permission of opening a mine, a very stringent plan is asked by the authorities for containing pollution on site and to be sure that no pollution could impact very remote location in altitude or great North under polar circle.

2. GENERAL PRESENTATION OF BGM

The first applications of BGM were in France in 1975 near Grenoble and for potable water storage reservoirs in altitude around 2000 m in the Alps in Avoriaz.

The structure of BGM is multi-layered including mainly: a polyester geotextile providing the mechanical resistance and especially the high puncture resistance and a compound with an elastomeric bitumen providing the waterproofing properties and ensuring its longevity by impregnating totally the geotextile. The glass fleece provides the dimensional stability. The sand coating improves the resistance to UV. The anti-root film prevents puncturing from roots and vegetation. See Fig. 1.

Manufacturing is done under strict quality control procedures certified under an ISO 9002 quality assurance scheme, under a French ASQUAL certification and it is CE marked (European marked).

The factory located in the North of France operates with an ISO 14001 environmental certification.

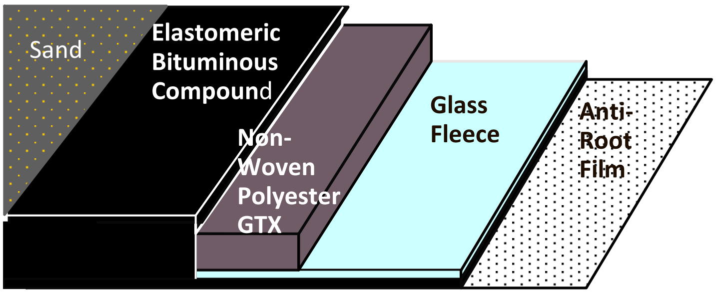

Fig. 1. Typical structure of a bituminous geomembrane

Some technical characteristics of BGM giving advantages for a use in hydraulic projects:

- Permeability at the same level of any other type of geomembrane, around 10^{-14} m/sec, Darcy law permanently at this level, (Laboratory IRSTEA, French Ministry of Agriculture, France).
- Easy to seal with rock and concrete structures, thus allowing to have the same permeability in any point of the lining. See Fig. 2.

Fig. 2. BGM connection to:

a) around HDPE pipe (Mongolia) b) concrete wall (UK)

- Highest mass per unit area giving an important resistance to lifting in windy regions. We can leave the BGM exposed (large economy) and we can install even under bad weather and very windy conditions.
- High puncture resistance. Tire-mounted vehicles and equipment even full loaded can run directly on top of the geomembrane traverse on top of the geomembrane during installation and maintenance. See Fig. 3.

Fig. 3. Tire mounted equipment traffic on top of the BGM

- BGM does not form wrinkles even in case of daily temperature variations. So, installation can take place at any time of the day, without interruption. Also, cover material can be placed on top of the geomembrane at any time of the day.
- The sand surfacing imparts a frictional surface to the geomembrane that reinforces the UV resistance of the bitumen. This face has a friction angle around 34° (values coming from tests ''Geosynthetic Friction by the Direct Shear Method ASTM D5321-02'' done by Sageos (Qc, Canada) and INSA (Lyon, Fr) and Precision lab (Anaheim, California, USA) daughter company of the US TRI lab and higher, depending of the material placed above it. Based on the above, designers can use slopes steeper than 2H: 1V at the upstream face of a dam or the banks of reservoir.
- BGM can store potable water. Proved by US international certificate NSF 61.
- BGM has a very high resistance to earthquake as demonstrated in the field (Milpo dam having supported an earthquake of a magnitude of 8.1 on the Richter scale and by tests done by TRI. in California for Los Angeles Department Water and Power Interface Friction Testing.
- The density is larger than 1 ton/m^3, so BGM can be installed under water. The seams under water can be done with a special mastic.
- The manufacturer supplies monitors for training local teams of installers on site.
- The quality of the total length of the seams can be controlled by manual or automatic ultra-sounds apparatus control. Which is recommended for control of the dam watertightness. See Fig. 4.

Fig. 4. Ultrasound equipment to test BGM welds

3. SOME CASE STUDY OF BGM IN HYDRAULIC CONSTRUCTION

In the cases mentioned here-under, all being in altitude (between 1.200 m and 4.800 m), BGM was chosen for one or some of the following reasons:

- High resistance to U.V.
- High resistance to puncturing (geotextile inside geomembrane) so, avoiding protection by geotextile underneath and above. In altitude as you have high speed wind with BGM there are only 1 geosynthetic to install at the place of 3 for thinner geomembrane.
- Highest unit mass means that you can install by wind more than 50 km/hour, with humidity therefore under some rain. Like this you can shorten significantly delays.
- Low cost of installation by local workforces as the manufacturer assumes the training of the installation personnel and you don't need special equipment for welding: only torch and bottles of propane gas.

3.1. In South America

3.1.1. Peru, Milpo tailings dam: a 30-m high earth and rock fill tailings dam in Cerro Lindo (See Fig. 5) to store polluted water.

Milpo is a Peruvian mining company headquartered in Lima.
At the Cerro Lindo mine, a 30-m high, earth and rockfill dam was built to store and control process water. The dam was built on a competent substratum reached through shallow excavations in natural soil. It is located at an altitude of approximately 2.000 m. in a region characterized by strong winds. This upstream face of the dam was waterproofed by means of a BGM. The upstream portion of the dam was built with compacted soil consisting of gravelly clay with a 1V/2H face slope. In the middle of the dam, a transition layer of 2 m wide and runs from the bottom to the crest of the dam. At the downstream toe, an infiltration-water collection box and monitoring wells were installed to allow a permanent control of watertightness.

Fig. 5. Cerro Lindo dam:
a) Typical cross section b) Work completed c) Dam in use after earthquake

3.1.2. Toromocho Copper Mine (Fig. 6), owned by the Chinese mining company Chinalco), lies at an altitude of around 4.600 m above mean sea level. Water was used throughout the production chain of the mine. The creation of the dam was used to contain water pollution. The water is then recycled.

Fig. 6. Toromocho Copper Mine

The choice of this BGM was done mainly as the installation could be done by local workers able to work at this altitude. They received locally a training by supplier monitor. The work was controlled permanently by the Lima subsidiary of the International consultant firm Amec.

The second reason of the choice was as the installation is possible in extreme weather conditions (rainfall, heavy wind at this altitude (BGM is the heaviest geomembrane per sqm (square meter), quick alternative of temperature during the day).

The third reason was because the membrane will be left exposed. BGM has the best resistance to UV due to the nature of bituminous and the protection by sand of the exposed face see test C.N.A.M – Centre des Arts et Metiers – National Testing Laboratories TEST No: 704-080-DMS/15.107.

3.1.3. In the copper mine Las Bambas, Chuspiri Dam, property of the Chinese company MMG, situated in more than 4.000 m of altitude between the provinces of Cotabambas and Grau, in Apurímac region, to 72 km of Cusco in Peru, Chuspiri Dam was built for the supply of water of the mine. See Fig. 7.

The project was developed by the MWH Engineering of Santiago, Chile. A geomembrane BGM of 4.0 mm of a unit mass of 4,85 kg/m^2 and of 4,8 mm and of a unit mass of 5,8 kg/m^2.

Fig. 7. Chuspiri dam:

a) Site overview b) Start of filling

3.2. In North America

3.2.1 Diavik Diamond Mine (Fig. 8)

The Diavik Diamond Mine is located at 300 kilometres northeast of Yellowknife, Northwest Territories of Canada on an island in the lake of Gras (water the purest in the world). DDMI is the operator of the project. DDMI is a wholly owned subsidiary of Rio Tinto, which is headquartered in London, England.

The choice of BGM was done due the extended period (10 months per year) when it was able to install BGM. January and February were excluded due to very low temperature met (-70°C).

On the same site, they would have been able to install only 4 or maximum 5 months per year.

Installation was completed by a local company based in Yellowknife, NWT, specializing in geomembrane installation in cold weather conditions. A & A retains the flexibility of BGM even when stored and unrolled at -40°C. No special precautions such as inside tunnels were required during welding, which was performed in the open air at -25°C and less till – 35°C.

The manufacturer monitor's presence was required by the international consultant (Golder Associates on their Vancouver and Yellowknife Canadian subsidiaries) to train A & A Technical employees (Native people: Inuit) and ensure that the installation work was done properly.

The second reason of the choice of BGM was the economy induced by the high puncture resistance by BGM comparing with HDPE. Initially, the design specified a 50-mm minus geomembrane bedding and cover material. Tests carried out on site showed that a 150-mm minus material could be used for bedding and cover without damage to the geomembrane. The 150-mm minus bedding material was compacted then the surface was raked by hand to remove the larger particles protruding above the surface. Cover material was dumped along the toe and pushed by a track loader approximately two-thirds up the slope. Cover material was then dumped along the crest and pushed by a track loader, down the slope over the geomembrane.

The use of relatively coarse bedding, cover materials and cushion materials (the cost for producing material on the site was very high) as well as the elimination of the need for a protective geotextile.

Fig. 8. Diavik grain size of the support and the cover

3.2.2 Bloom Lake, Iron Mine (Fig. 9)

Bloom Lake's mine is located approximately 9 miles southwest of Fermont, Quebec, Canada, being part of the southwest corner of the Trough Labrador iron mine.

Operations consist of an open pit mine comprising of a truck and shovel transportation system. A concentrator that utilizes single-stage crushing, an autogenously grinding mill and gravity separator is used to produce an iron concentrate. From the site, concentrate is transported by rail to a ship loading port in Pointe Noire, Quebec, Canada.

This BGM geomembrane was chosen due to:

- Excellent weathering resistance even when exposed.
- Installation in extreme weather conditions (rainfall, wind, cold temperature down -40°C).
- A wider range of materials to be used for the liner bedding and cover zones due to its high resistance to puncture and tearing.
- Installation by local installer after training by manufacturer monitor on site.

Fig. 9. Bloom Lake, anchorage at the toe of the dam

3.3. In Europe, in Finland and in Russia

3.3.1 Kiitilä Gold Mine (Finland) – Fig. 10

Construction is well underway on the Kiitilä mine in northern Finland, approximately 900 kilometres north of Helsinki and 40 kilometres from Kiitilä. The Kiitilä mine will feed 3,000 tons per day surface processing plant.

The Kiitilä Mine site lies within the Arctic Climatic Region (150 km north). Temperatures are cool with an average mean monthly temperature in July of 15°C and in January of -15°C. The mean annual air temperature at the site is approximately 0 °C. Snow falls in every winter month, although rain generally only occurs between May and October.

Fig. 10. Kiitilä site: general view

Dam walls are made from blasted rock with compound structure. This means that the main dam wall is made from maximum 600 mm diameter grain size blasted rock. The “wet” sides of the dam walls are made also from blasted rock (dam max. 300 mm grain size) and gravel (grain size 55 mm).

These layers are also compacted with an excavator equipped with a compacting plate.

BGM was chosen because:

- It can be installed directly over the prepared mineral sealing bottom layer instead of a layer of sand, and then geotextile and finally a polymeric liner. This provided a large cost saving because you don’t have to transport materials from outside the site and in the same time, you save many tons of CO_2.
- The low thermal expansion coefficient allows keeping the liner flattened directly on the mineral sealing layer like this, the combination of both moraine and BGM liner is always flat and in permanent contact of the glacial till support so, due to this intimate contact, the watertightness is assumed at 2 levels:
  - At the level of the geomembrane with a permeability of around 10^{-14} m/sec, that could be considered as an active barrier,

- At the level of the soil around 10^{-5} m/sec that could be considered as a passive barrier.

- It can be installed at very low temperatures such as -30˚C for the elastomeric grade of the BGM Liner.

3.3.1 Kupol Gold Mine (Siberia, Russia) – Fig. 11.

The Kupol deposit is in the Chukotka Autonomous Okrug. The total distance between the Kupol and Bilibino the nearest major city, is approximately 200 kilometres.

The climate of the region around the Kupol site is extremely severe, consisting of long and cold winters (8-8.5 months). The average annual temperature is -13°C, ranging from -58°C to 13°C.

BGM in this project has promoted the ease to be installed and welded in extreme weather conditions (rainfall, wind, cold temperatures down to -40°C) permitting to earn more than 1 year in the delay means 1 year of production of gold and the use of wider range of rough materials for the liner bedding and cover zones.

Fig. 11. Kupol Gold Mine (Siberia, Russia)

4. CONCLUSION

The BGM has been used successfully for over 35 years in hydraulics and in protection of Environment. BGM possesses high physical and mechanical properties allowing it to remain exposed and accept a support rougher than with any other type of geomembrane without any external geotextile for protecting it. Subgrade preparation for this liner is reduced to the minimum and the defect rate is low. This leads to wide savings of transport of materials coming from outside the construction site or to reduce the times of crushing thus to a reduction of the environmental impact of construction works.

Its installation is straightforward using propane torch welding and its high unit weight allows it to be installed in rough weather conditions with local installer trained by manufacturer’s monitor on site.

These other BGM installations were done at the satisfaction of international consultants (Golder Associates Lima, Vancouver and Yellowknife (NWT, Canada)) and the clients public client, Canadian Government, or private mine companies: Milpo in Peru, Rio Tinto in UK, Agnico-Eagle and Kinross from Canada on time and without any delay due to bad weather or strong winds either in altitude (4800m) or in very cold region, even inside polar circle.

At last, we would highlight that despite the large earthquake at the Cerro Lindo mine, the BGM maintained its core function of waterproofing and there were no defects of seepage because of this. The BGM has maintained the reservoir in the dam at full capacity for the past ten years and there has been no loss of activity at the mine due to seepage.

Furthermore, The City of Los Angeles Department of Water and Power (LADWP) was building two large concrete water reservoirs in Universal City, Los Angeles, California. Each reservoir is designed to hold over 210.000 m^3 of fresh water.

LADWP determined that the on-site soils beneath the east reservoir were only medium dense and could if saturated be subject to liquefaction during a strong earthquake and could settle a few inches. An order of magnitude that could lead to structural damage to the concrete reservoir and affect its integrity to remediate the liquefaction potential, LADWP engaged a remediation and mitigation program full seismic phenomenon.

The Precision lab (Anaheim, California, USA) conclusions/ BGM is not affected by the seismic induced shearing and will not be overstressed during a seismic event as the interface friction angle between the soils and the interfaces are in the same value of magnitude, the risk of slippage of the confined BGM is very low.

Installation is much less dependent on weather conditions. Due to the extended construction season of BGM, the completion of the geomembrane portion can be done in half the time of a HDPE solution. The reduced construction period means that the equipment used for the reservoir can be used earlier in mine construction. For investors, this could have the mine operation up and running much sooner, and the financial impact could be huge in mine activity.

1. INTRODUCTION

Controlling, measurement and estimation of the amount of water seepage through the body, foundation and abutments of embankment dams are of great importance [1]. Seepage in earth dams, according to their location, has two parts: seepage through dam body and through dam foundation. Using clay core, filters, and drains are the most common method for controlling the seepage through the earth dam body. To control the seepage through the dam foundation, there are several methods such as using permeation grouting, drainage under some parts of the dam, impervious blanket, and cut-off wall [2, 3, and 4].

Cut-off walls, in general, are constructed beneath the earth's surface to control horizontal flow of groundwater and contaminants. In cut-off wall construction in earth dam foundations, alluvium foundation materials will be removed and the gap will be refilled by good filler material such as drilling mud, rigid concrete or plastic concrete. Most commonly, cut-off walls are vertical and ideally penetrate down to a very low-permeable stratum, a clay or impervious bedrock, which forms a well-sealed base for the controlling the movement of groundwater in dam foundation [5,6]. Because of cut-off walls being influenced by the dam settlement due to its weight, horizontal and vertical displacement influenced during first impounding, and specially, condition such as earthquake, it is necessary to be designed in a way that the deformations due these conditions be the least possible and prevent cracking in the wall. In this regard, using plastic concrete for cut-off walls is one of the best solutions, since it has sufficient strength and flexibility to withstand static and seismic stresses and undergo seismic deformations along the surrounding soil [7].

In this paper, function of the plastic concrete cutoff wall in one of the zoned embankment dams in Iran, namely Silveh Dam, is evaluated by considering instrumentation measurements. In this regard, a performance index, k, has been introduced to evaluate the sealing performance of the water barrier cutoff wall system. For this purpose, related analyses have been performed on the measured pore pressure data obtained from pore pressure gauges located beneath the dam foundation at three different cross sections.

2. SITE AND THE DAM BODY CHARACTERISTICS

Silveh Dam is a recently constructed zoned earth dam located about 12 km Northwest of Piranshahr city in the Western Azerbaijan Province, Iran. Feasibility studies of dam construction on the Lavin-Chai river started in 1975 and Phase-I& II studies and geotechnical site investigations were completed in 2006 with more than 1353 meters of boring, by Abgeer Consulting Engineers. The studied dam body is placed on a wide valley which comprises a coarse-grained alluvial deposits with maximum of 65 m depth in right bank and limestone or schist rock in left bank, underlain by a layer of lightly metamorphosed limestone and shale with lenses of slate, metamorphic sandstones, and powdered layers of schist and mica schist. The dam body encompasses different zones, including a clay core and an impervious upstream blanket, upstream and downstream shells of coarse-grained gravelly sand, drain and filter [8, 9]. The capacity of the dam reservoir, at its normal water level (1573.5 m.a.s.l), is about 84 million cubic meters. With a crest level of 1579 m.a.s.l, the maximum height of the dam is approximately 89 meters from foundation and its crest length is near 720 meters. The maximum height section and the plan of the Silveh dam are shown in Fig. 2 and Fig. 3; respectively. Some Instruments are installed in the dam body and its foundation in order to monitor the behavior of the dam under different loadings, such as the dam body weight, embankment construction stages, dynamic and static pressures from the reservoir, effects of earthquake loading, and to determine the groundwater levels and the pore water pressure in the body and foundation of the dam. These instruments include electrical pore water pressure meters, inclinometers, earth pressure gauges, Casagrande piezometers, observation wells, earthquake accelerometer, V-notch, and surface settlement benchmarks. Fig. 4 shows the arrangement of the installed instruments in three sections of the dam. In this paper, measurements of pore water pressure have been studied over these three sections, namely 2-2, 5-5, and 7-7 [10]. The cutoff wall on the right abutment is a continuous barrette wall. In the river bed and left abutment, it is installed by the execution of the plastic concrete secant piles with the diameters of 1.2 and 1.0 meters and 45 meters maximum depth (Fig. 5) [11].

3. RECORDED PORE PRESSURES IN DAM FOUNDATION

As mentioned in part 2 of this paper and depicted in Fig. 4, two pairs of pore pressure measuring gauges are implemented in each cross section of the dam body to study the pore water pressure generations and dissipations through the dam foundation. In Fig. 6, the variation of the measured pore water versus time is depicted for the three studied cross sections of the dam along with the variation of the dam reservoir water elevation and dam body filling level. As illustrated in Fig. 6, in general, pore water pressure in each gauge has been increased by increasing the dam body elevation (during construction) and due to first impounding and then slightly approaches to the constant value. In addition, the recorded pore water pressures at downstream sides of the cross sections are greater than those for the upstream sides, which implies the suitable function of the cutoff wall system.

4. ANALYSIS ON THE CUTOFF WALL PERFORMANCE

To assess the workability of the cutoff wall, recorded pore water pressures at upstream and downstream sides in dam foundation are considered. In this regard, a performance index, *k*, has been defined as presented in Eq.[1]:

$$k = (U_{up} - U_{down}) / (W_r - Z_i) \qquad [1]$$

In which, U_{up} and U_{down} are the recorded pore water pressures by two semi-elevated pore pressure gauges placed at the upstream and downstream sides of the cutoff wall, respectively, and W_r and Z_i are the reservoir water and pore pressure gauges elevations, respectively [10, 12].

From Eq.[1], one can postulate that the more value the k gained, the more water head lost occurred due to the better performance of the cutoff wall to elongate the seeping stream lines.

Diagrams of the changes in *k* v.s time in three studied sections 2-2, 5-5 and 7-7 of the Silveh dam for 2 pairs of pore pressure gauges at each cross section are shown in Fig.7. Data presented in Fig. 7 shows that during dam body construction, *k* values show oscillations by time increasing which can be related to the simultaneous pore pressure generation and dissipation in dam foundation. The same pattern can be observed during first days of reservoir impounding. Anyhow, after reaching the dam body to its proposed maximum height and stopping the reservoir further impounding, *k* approaches to an almost constant value, which show the steady and controlled seepage through the dam foundation. Moreover, positive *k* values in all time ranges shows the pore pressure at upstream sides of the cutoff wall is always greater than the corresponding value at the downstream side (regarding Eq.1) and implies the suitable sealing performance of the cutoff wall.

5. CONCLUSION

In this paper, the sealing function of the executed cutoff wall water barrier system of an embankment dam in IRAN, namely Silveh dam, has been assessed by implementing instrument pore pressure data. For this purpose, at three different cross sections of the dam body and its foundation, recorded pore pressures at both upstream and downstream sides of the cutoff wall have been used to calculate a performance index, *k*.

The performance function is defined as the ratio of the pore pressure difference at upstream and downstream sides of the cutoff wall to the maximum possible hydrostatic pore pressure at the level of measuring. It actually gains larger values when the pore pressure difference at two sides of the cutoff wall increases, which means the cutoff wall, is working properly. Moreover, the trends of pore water generations and dissipations during dam body construction and first impounding imply the safe condition of the dam and steady seepage occurrence.

Analysis performed on the obtained instrument data from Silveh dam foundation shows that performance index of the dam is rationally great enough which means the suitable function of the constructed cutoff wall.

ACKNOWLEDGEMENTS

This research has been financially supported by “West Azarbayjan Regional Water Authority, Ministry of Energy of Iran” which is greatly acknowledged.

In addition, the second author would like to appreciate the “Niroo Research Institute, Ministry of Energy of Iran” to provide him the opportunity to contribute in this research.

FOUNDING AND SEALING LARGE DAMS ON VERY WEAK FOUNDATIONS

1. INTRODUCTION

Finding appropriate sites to build new storage dams particularly for potable water for drinking, domestic and industrial use, as well as to irrigate land for growing food although on the increase has not kept pace with the population growth across the globe. Engineers are now consistently being called upon to design and build dams at very marginal sites, while on the other hand dam design guidelines and construction quality requirements have been getting more rigorous particularly with regards to seismic and flood hazards.

ICOLD guidelines provide more than adequate basis for designing and building traditional dams be it arch, arch gravity, and gravity dams. Computational methodologies that are currently available do further provide a superior set of tools for the analysis and evaluation to verify the associated performance criteria for any type of conventional dam. The easier access of powerful analysis tools to the modern-day dam design engineer still require appropriate site specific parameters as input which require detailed site investigations specific to the marginal sites. It has also become more than necessary to apply "common sense engineering" to ensure appropriate dam type selection, layout and design.

Crucial lessons being learned on recent dam projects are not being adequately documented. If this is due to preservation of intellectual property rights or propriety design methods, then it is acceptable. But if it is due to liability issues related to poor engineering design or construction then it would raise integrity questions and should be avoided. The fundamental approach to data collection and interpretation of geological conditions of dam foundation has suffered greatly due to the lack of sufficiently allocated resources and time for site investigations with the pressure to deliver faster but not necessarily the economic and safer solutions. The "Why" question that should continue to persist in planning site investigation logically has been unintentionally taken away. Site investigations which used to be enhanced by local knowledge and experience are routinely being ignored or not attended to, mostly due to budgetary and time constraints imposed by the various stakeholders. A further trend is for stakeholders to persist with original concepts much longer than they should be, even when initial indications are that more economic and technically sound alternative solutions are available.

2. SUITABLE LARGE DAM TYPES FOR WEAK FOUNDATIONS

2.1. DAM TYPES

Traditionally rockfill dams with concrete spillways on one of the banks on competent rock has been preferred in general for weak foundations. Morning glory spillways have been a feasible but less preferred alternative for flood evacuation. Where rockfill is not available in sufficient quantities or quality, earthen embankments have been selected with similar arrangement for spillways and alternatives.

Engineers, in the recent past have begun to consider composite dams for very weak foundations. Composite dams provide a flexible rockfill dam for the geologically weaker parts including over active and inactive faults and fault zones. The relatively more competent part is set aside for providing a spillway section in conventional concrete or RCC after appropriate foundation strengthening treatment are undertaken, if required. Although there are several dams that have been designed and built and in operations currently no guidelines exist for engineering composite dams. This needs to be addressed by ICOLD at the earliest.

.

2.2. VERY WEAK FOUNDATIONS

Large dams have been built and will continue to be built on very weak foundations that are poor. Engineers who have conducted routine finite element analysis of large gravity dams on such foundations would have observed the following:

1. For embankment dams of similar height, the maximum foundations stresses are similar except for the stress bulb width.
2. A 1:1.5 upstream and downstream sloped rockfill dam imposes less foundation stresses than a flatter 1:2.0 sloped rockfill dam. This observation is very important as widening the width of an embankment dam with flatter slopes does not necessarily provide increased safety nor economy.
3. For the rockfill part of a composite dam the most steeper slopes that provide the required safety margins is adequate and thus must be selected. The foundation improvement will thus be required over a smaller foot-print and the cost savings can be used to provide treatment even deeper that is beneficial.
4. The incremental stresses imposed by even a large dam on the foundation decreases rapidly with depth, with minimal stress increase beyond depths exceeding 15 to 20% of the dam height. The most important zone for consolidation is thus the upper most foundation layers within this impacted depth.
5. RCC dam and/or spillway blocks on weaker foundations are also normally provided an upstream slope partially or for the full height of the dam.

In traditional dam construction, how consolidation grouting is undertaken still remains less effective as it is normally done after exposing the foundation but prior to commencing dam construction. For very week dam foundations such an approach is not beneficial particularly in zones where a concrete or RCC spillway section needs to be placed. In such areas, it would be more effective if a confining concrete or RCC cap layer, several meters in thickness be placed first and then followed with consolidation grouting. If this confining layer is in mass concrete pipes can be left in place to minimize subsequent drilling for consolidation grouting. Proper consolidation grouting enhances curtain grouting for sealing the foundation for water tightness. This also allows higher grouting pressure such as at the foundation-dam interface where it matters most. Such construction requirements should be put in place at the time of tender.

Irrespective of dam type, proper drainage downstream of the grout curtain is critical for the safety of the dam. Thus the placement of the grouting gallery is also of importance. Usually upstream of the grouting gallery the intent of the consolidation grouting is for both water tightness as well as for strengthening the foundation whereas on the downstream part more emphasis shall be on foundation strengthening. The curtain grout must follow a single axis through the composite dam to be most effective as well as for economic considerations.

2.3. BACKGROUND ON COMPOSITE DAMS

Incidentally most of the early dams, prior to the advent of concrete in early 1900s, were all of composite construction. It is now recognized that the masonry remains of the oldest dams known, the 5000 year old Jawa Dams in Jordan were the spillways. The oldest known continuously operating dam in the world is in South India, built 1800 years ago. It had a main stone masonry structure with earthen embankments on its flanks as its name in the local Tamil language Kallanai also implies. This dam was apparently rehabilitated in 1776 following a major flood by the then English rulers. Strangely one of the earthen spillways ever designed was for the ancient Maduru Oya dam in Sri Lanka. It was placed several kilometres from the main dam on a naturally occurring saddle. The dam was built in the 12th century, but may have never been completed although intact headworks were excavated downstream of the new dam and now saved for posterity.

Of the four RCC dams in Jordan that were built some twenty years ago and have been in operation, two at Wala and Mujib respectively are composite dams. Engineers could obtain additional information from available publications on RCC dam construction in Jordan. Grouting at Mujib dam has also been extensively addressed in several publications and in a text.

Other notable composite dams include the recently completed Neelum Jhelum diversion dam at Nauseri in Pakistan that has recently begun filling up for operation. The main boundary thrust fault crosses this composite dam. Some details of this dam briefly described in a publication by Engineer Khaliq Khan (2012) and other relevant information are available on the internet. After taking into consideration the Chi Chi earthquake damage to the Shih-Kang Dam in 1999, a composite dam was proposed and eventually provided at Nauseri instead of the concrete dam with a Clyde dam type slip joint that was provided in the tender design.

2.4. COMPOSITE DAMS OVER FAULTS AND FAULT ZONES

Fault movements in the footprint of a dam are the most critical seismic hazard for most dam types. If no other site can be selected, then a conservatively designed earth core rockfill dam would be the only solution (Wieland 2012).

Robert C. Lo and Yumei Wang (2012) in their Lessons Learned from Recent Earthquakes - Fault Displacement note Fault displacement caused significant structure damages in the Wenchuan earthquake. Fault displacements reported in the literature range from few metres to tens of metres.

The following is a relevant summary for composite dams from the Lessons Learned from Dam Incidents and Failures as reported by Richards:

- Seepage along penetrations through embankment parts of composite dams should be controlled using a filter diaphragm instead of anti-seep collars. A concrete encasement or cradle around or under conduit penetrations through earthen/rockfill embankments allow for better compaction of earthfill/rockfill.

- The first filling of a reservoir should be planned, controlled and monitored.
- Treatment of fractured foundation rock for embankment parts of composite dams is important to prevent internal erosion of embankment material that is in contact with the foundation.
- Stability of the dam foundation and other geologic features must be considered during composite dam design.
- The design engineer should be involved in the construction phase of composite dam projects.
- High and significant hazard rockfill parts of composite dams should have internal filter and seepage collection systems.
- External independent peer review of designs and decisions is an effective means of providing quality assurance and reducing the risk associated with design oversights and deficiencies.
- Local experience must be consulted and considered for composite dam solutions for better effectiveness and local compliance.
- PMF magnitude floods do occur. High and significant hazard dams should be designed to pass an appropriate design flood.
- Composite dams need an operable means of drawing down the reservoir.
- Access shall be provided and available at all times for the inspection and routine maintenance of gates and other mechanical systems at composite dams.
- Composite dams and grouting galleries located in areas of potential seismic activity need to be evaluated for liquefaction, cracking, potential fault offsets, deformations, and settlement due to seismic loads.
- Alkali-aggregate reactions (AAR) can cause serious concrete deterioration and other problems at concrete/RCC parts of composite dams.
- Most concrete/RCC parts of composite dam failures are the result of foundation stability problems.
- Concrete/RCC parts of composite dams founded on bedrock require detailed corroborating subsurface investigations and testing of rock properties.
- Outlet works and pressurized conduits in composite dams should be provided with a means for upstream closure.
- Composite dams built from or on loose granular soil can be susceptible to liquefaction of the foundation material.
- Settlement of rockfill parts of a composite dam can reduce freeboard and increase the risk for overtopping. Composite dams should be designed with allowances for settlement.
- For high and significant hazard composite dams, elements that are critical for the safe operation of the dam should all be engineered.
- As for the traditional dams, internal erosion can take decades to progress in composite dams.
- Karstic foundations are difficult to treat and can cause internal erosion issues and require special attention.

- Foundation approval should be documented by designers and geologists.
- Moisture content and compaction of fill material particularly at the interfaces of composite dam parts must be carefully monitored for acceptance during construction.
- Landslides around the rim of a reservoir can cause composite dam overtopping. The stability of the hillsides around the rim of the reservoir as well as the impact of potential slope failures should be addressed.
- The presence of weak zones in natural foundation materials must be evaluated at the time of design and treatment specified at time of tender.
- Brittle materials, such as asphalt and Portland cement concrete, should not be used as reservoir liners without high capacity filtered underdrains.
- Zones of permeable soil, such as old riverbed deposits in dam foundations, should be addressed.
- Grout curtains in a formation where potential seepage paths (joints, fractures, etc.) are filled with either erodible or soluble materials are not permanent and may require periodic maintenance grouting to remain effective.
- Conventional instrumentation may provide early detection of conditions within a composite dam that could lead to failure.
- Construction inspection is critical in assuring proper construction techniques and construction in conformance with approved plans and specifications.
- For concrete and RCC spillway blocks in a composite dam, weak features in rock foundations can be mitigated using concrete shear keys and dental concrete.
- Vertical seismic accelerations can be as high as the horizontal accelerations and this should be considered in the design.
- Reservoir sedimentation can increase destabilizing forces acting on a composite dam and have other detrimental effects that could contribute to a dam failure.
- Rockfill that may become loose following an earthquake should not be placed against a concrete or RCC section in a composite dam.
- Differences in the stiffness of structural materials as well as the foundation can lead to unforeseen stress concentrations particularly concrete/RCC part of a composite dam.

3. DAMS ON VERY WEAK FOUNDATIONS

3.5. SEISMIC CONSIDERATION OF COMPOSITE DAMS ON FAULTS

The rupture of the Chelungpu Fault, led to Shih-Kang dam axis being shortened by about 7 meters with vertical displacement of 9 m.

Activity of a fault was initially taken as “activated” if at least once in the past 10,000 years. An active seismic source is now defined as a fault that has ruptured within the last 35,000 years. However, this or any fault activity criterion is somewhat arbitrary by its very nature. There is no physical reason why a fault that has not moved during the last 35,000 years cannot move again. Case in point is the October 16, 1999 Magnitude 7.1 Hector Mine Earthquake.

Allen and Cluff (2000) note the following:

1. There is no standard definition of what constitutes an "active" fault, which reflects the geologic reality that all degrees of fault activity do, in fact, exist. Any distinction between active and inactive faults is necessarily arbitrary.
2. In worldwide practice, faults in dam foundations that are estimated to have ruptured on the average of once in every few thousand, or every few tens of thousands of years, have typically been considered worthy of engineering consideration.
3. At least some engineers appear to be gaining confidence that, with innovative new techniques, dams of virtually all types can be designed to accommodate moderate foundation fault displacements without major failure.
4. Owing to advances in the ability to obtain absolute ages on geologic materials, mainly through new geochemical techniques, degrees of fault activities can now be estimated far better than only a few years ago. A critical parameter in both probabilistic and deterministic assessments is long-term fault slip rate.
5. Field studies of faults in dam foundations demand the expertise of geologists trained and experienced in neotectonic studies. Classical geological maps, however competently done, often have only limited relevance to earthquake hazard assessments.
6. Seldom are adequate field exposures available in the dam footprint area itself to characterize fully the neotectonic environment of a proposed dam. It is virtually always necessary to carry out such studies, including trenching of suspect faults, throughout a much wider area than that of the dam footprint—typically extending over many tens of kilometers.
7. Seismologic studies of earthquakes in dam areas can play an important role in safety evaluations, particularly in establishing seismic shaking parameters such as maximum ground accelerations and velocities to be expected. But field geologic efforts are nevertheless critical in estimating the likelihood of surface fault rupture through a dam foundation. The abundance or absence of microearthquakes may have little relevance to the probability of large local earthquake associated with surface fault rupture.

.

S. Gangopadhyay (1993) also noted that many of the dam sites in India had various geological defects creating problems for the construction of the dam. Precise evaluation of these weaknesses of dam foundations at the investigation stage by engineering geological studies had helped cost-effective design and safe construction of the structures after adopting suitable corrective measures.

4. CONCLUSIONS

1. For composite dams, defensive design concepts must be applied until proper ICOLD guidelines become available.
2. Modelling rupture to estimate potential displacement at faults may be useful.
3. Use of elasto-plastic models for analysis of dams for strong earthquake or fault rupture.
4. In the absence of reliable fault displacements for the design earthquakes, flexible joints shall be provided in grouting galleries particularly over faults and fault zones.
5. Simple interface details are only required at the interface between Concrete/RCC and rockfill/clay parts even on a large composite dam.
6. Geological investigations are very crucial for composite dams.
7. Simple aspects of river geomorphology and topology would provide important clues to unexposed faults/fault zones.
8. New Guidelines for Composite dams must include interfaces details and how to handle potential fault displacements.

SUMMARY

KEY WORDS: Composite Dam, Foundation Treatment, Fault, Grouting Gallery

ICOLD guidelines developed over the past several decades form the basis for current design of large dams of all types. Routinely, such dams have been designed and built on foundations deemed sufficiently competent for the selected dam type, be it concrete, RCC, CFRD, AFRD, Geomembrane faced Rockfill, clay core rockfill, earth embankment, etc., However, over the past few decades dams are being designed and built on foundations that are marginal to poor at best as well as over faults and fault zones due to the increasing need to store water for

various needs. Since dams need flood evacuation capacity, spillway structures and headworks are normally placed on the more competent foundation part of the dam axis, which has given rise to composite dam design and construction. The flexible part of the dam usually comprises of central core rockfill construction. When such composite dams need to span over fault zones, particularly over extensional fault zones, structures such as grouting galleries need to be provided with sufficient flexibility for future likelihood of extension that may occur during an earthquake. However, assessing the allowance for such extensions remain to be more of guesswork. When composite dams are built in developing countries some additional allowance must also be provided as such countries cannot afford the loss of the dam even in the short term. This paper presents how this uncertainty can be adequately addressed. Further, observations on the design and construction of composite dams including interfacing of the flexible segment with the rigid segment are also presented. In addition, a case is presented for this issue to be addressed in greater detail to develop basic guidelines for use by Engineers in the future.

1. GENERAL

Many dykes and dams rest on alluvial deposits, which usually grade from fine-grained materials near the ground surface to coarse sediments with high permeability in the lower part of the strata. If dykes or levees do not have a cut-off wall fully penetrating the aquifer, underseepage may occur beneath the earth structure during high river levels. Such seepage may cause an excessive water pressure in the aquifer landside of the embankment dam. Most dangerous situations occur when high hydrostatic pressure acts on the upper low permeable soil layers and ground failure develops in the form of uncontrolled boils or uplift of the blanket.

The risk of dykes or dams failure increases not only with the magnitude of a flood but also with its duration. For instance, the peak period of flood waves along the Austrian section of the river Danube usually lasts one to three days, whereas its tributary, the river March/Morava (Austrian/Slovak border) frequently undergoes flood waves up to three or six weeks (Fig. 1).

After today´s practice the hydraulic failure due to underseepage may be prevented mainly by two permanent measures at the landside dyke or dam toe by

---

* *Systèmes de drainage de la decompression contre les défaillances hydrauliques dûes au manque de visibilité des digues et des levées*

installing pressure relief elements or by placing berms. Especially, relief drainages have proved very successful in Austria during the last excessive floods along the rivers Danube and Morava.

However, until now the design of relief drainage systems was based on rather insufficient basic principles, strong simplifications and idealizations. For the quantification of the discharge from relief columns only assumptions based on numerical models are in use. Therefore, various model tests were performed to study the of relief drainage behavior and quantify the water discharge.

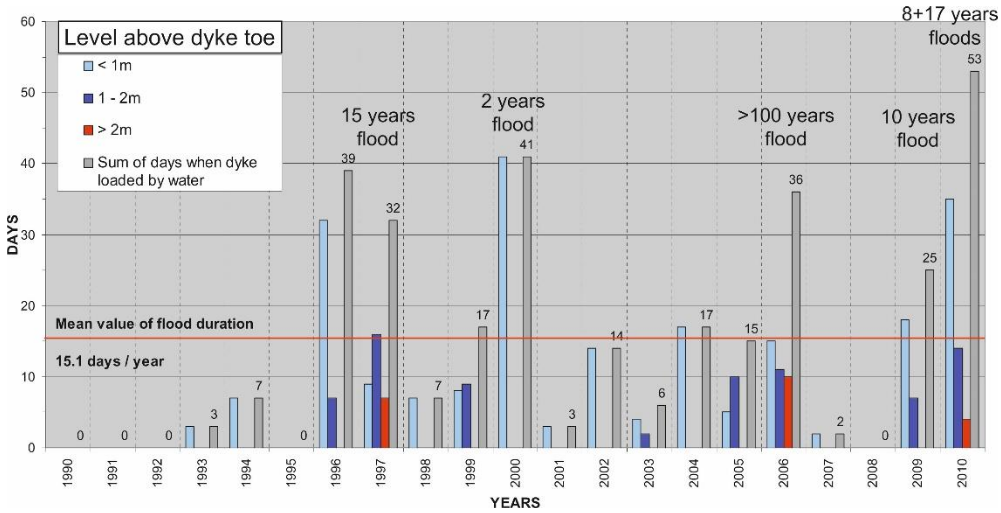

Fig. 1

Duration of floods along the River March dykes (Water level at Dürnkrut – Austria/Slovakia; adapted after via donau). Two floods within three weeks in 2010.

Durée des inondations le long des digues de la rivière March (Niveau d'eau à Dürnkrut – Austria/Slovakia; adapté après via donau). Deux inondations dans les trois semaines en 2010.

2. FAILURE MODES OF DYKES AND LEVEES

Knowledge of possible failure modes due to underseepage is an essential prerequisite, both for a reliable quality assessment of existing dykes and dams and for an optimised design of new ones. The simplified scheme of Fig. 2 illustrates the main failure mechanisms as observed in most cases.

Actually, it is often difficult to precisely determine the causes of a dyke failure. Statistical analyses show that overtopping and internal erosion are the most common failure modes. While many of these failure mechanisms occur relatively fast, the erosion by underseepage develops more inconspicuously. If a groundwater communication below the dyke is possible, the aquifer or the overlaying low permeable layer can be progressively eroded during hydraulic loading. Hydraulic failure is critical because there may not be any external evidence, mostly only soil boiling can be found.

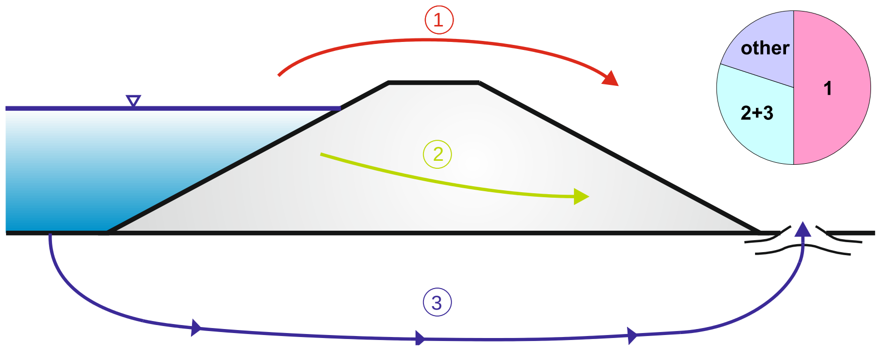

Fig. 2

Main failure modes of dykes: 1 = Overflowing, overtopping → Erosion failure, 2 = Seepage through dyke → Internal erosion, 3 = Underseepage → Internal erosion, Upheave, Ground failure

Principaux modes de défaillance des digues: 1 = Deversement sur le barrage → Erosion, 2 = Infiltration à travers la barrage → Erosion interne, 3 = Infiltration ci-dessous barrage → Erosion interne, Sous-Pression, Rupture ou sol

Due to this unpredictable behaviour hydraulic failure is frequently underestimated in practice and may occur in different forms (e.g. Eurocode 7; CEN 2004):

- By uplift (buoyancy). The pore-water pressure under the low-permeability blanket exceeds the overburden pressure.
- By heave. Upward seepage forces act against the weight of the soil, reducing the vertical effective stress to zero; soil particles are then lifted away by the vertical water flow. This ‘boiling’ dominates in silty-sandy soil, and is combined with internal erosion.
- By internal erosion. Soil particles are transported within a soil stratum or at the interface of soil strata. This may finally result in regressive erosion, leading to ground failure of the dyke, levee or dam.
- By piping. Failure by piping is a particular form of internal erosion, where erosion begins at the surface, and then regresses until a pipe-shaped discharge tunnel is formed. Failure occurs as soon as the water-side end of the eroded tunnel reaches the river bed or bottom of the reservoir. Frequently, several tunnels develop. This process may be induced or significantly promoted by animal activities, as field observations over many years have revealed.

Hydraulic failure may occur despite cut-off walls. If they are “imperfect” (i.e. with underseepage), groundwater communication below the dykes or levees (for environmental reasons) occurs and overpressure can develop beneath the landside blanket and the safety against a failure of the subsoil reduces significantly. The loss of stability is usually initiated by uncontrolled hydraulic rupture (uplift) of the blanket or by concentrated transport of fine particles (erosion, suffusion, piping) from the subgrade.

Hydraulic failure may reach several tens of meters away from dykes or dams, as experience has shown (Fig. 3). This could be observed even for low flood protection embankments with a relatively small hydraulic gradient. Soil boiling may create large volcanos (e.g. Fig. 4) that require urgent flood defense and stabilizing measures.

Fig. 3

3. FLOOD CONTROL MAESURES AGAINST HYDRAULIC FAILURE

Hydraulic failure as an effect of underseepage may be prevented mainly by two permanent measures landside of a dyke or flood protection dam by:

- Filling of berms, thus displacing the possible starting point of internal erosion or piping farther away from the structure, and decreasing the hydraulic gradient at this point. Such berms should be designed and constructed such that they work simultaneously as access ways/roads for quick and easy dam defence in the case of severe floods.
- Installing pressure relief drainage systems in form of trenches, relief stone columns or relief wells.

A filter stable berm compensates through its counterweight the hydrostatic pressure beneath the blanket (Fig. 5a) and prevents hydraulic failure by seepage or uplift, or by internal erosion and piping. When seepage through or beneath the dyke occurs, a free water outflow must be allowed; clogging would be counter-productive. Otherwise an excessive pore-water pressure could cause a failure.

In many cases, berms merely move the hydraulic problem farther away from the dyke, and retrogressive internal erosion may finally reach it in the long term (after several floods). Boiling and internal erosion have been observed up to 20 to 50 m away from dykes and dams (Fig. 3), even though they were only 3 to 6 m high. Moreover, wide berms are often not possible under confined space conditions; therefore relief drainages are preferred under these circumstances.

Pressure relief systems are high permeable linear or punctual drainage elements at the landside embankment toe (Fig. 5b). They connect the terrain surface with the aquifer and allow a controlled pressure relief during floods, while water freely discharges. To prevent the relief elements from clogging due to fine particles transport from subgrade, they must be wrapped into a geotextile.

Filter protection of berms is generally provided by the use of non-cohesive granular material (natural soil) that must fulfil the permeability criterion and the retention criterion. While two criteria are sufficient for granular filters, four criteria are required for geotextile filters (Giroud (2010), Heibaum et al. (2006)): the porosity criterion and the roughness criterion also have to be considered.

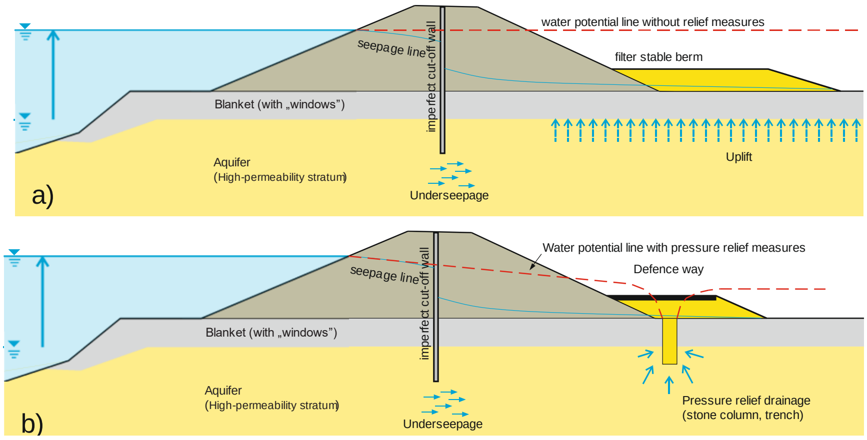

Fig. 5

Mesures permanentes contre les défaillances hydrauliques dûes à la sous-pénétration des dykes: a) berm b) Colonne de la decompression ou tranchées.

3.1. RELIEF TRENCHES

A pressure relief trench is a longitudinal drainage of coarse gravel fill material wrapped in a filter stable geotextile at the landside dyke toe. Wider trenches may consist of granular fill material with horizontally differing grain curves as separating two- or three-stage filters (also in the base). They usually do not penetrate into the permeable aquifer, but rest mostly on top of it. However, a hydraulic connection must always be ensured so that the pressure relief is possible. At the same time, the groundwater must freely discharge the relief drainage and is conducted within the trench or flows into the adjacent hinterland.

3.2. RELIEF STONE COLUMNS ("GRAVEL PILES")

Jacketed (coated) stone or gravel columns have been installed in Austria since 1992. This method has significant construction advantages over conventional drainage trenches in loose or soft soil.

Pressure relief columns are cylindrical relief elements at the landside dyke or dam toe, which penetrate through the low permeable blanket and embed into the high permeable ground layer (aquifer). They are made of high permeable fill material (rounded grains, clean: 16/32 mm; permeability factor: $k \geq 1 \times 10^{-2}$ m/s) that is wrapped with a nonwoven geotextile.

The common diameter of these “gravel piles” is about 60 cm to 70 cm, but it can be easily adapted to the required relief effect. The installation is carried out with a designed center-to-center distance by means of vibroflotation or modified auger drilling method (Fig.6).

4. EXPERIMENTAL AND NUMERICAL MODELLING OF RELIEF DRAINAGE BEHAVIOUR

The study of pressure relief behaviour and the estimation of discharge from relief drainages were based on a combined modelling by using experimental and numerical techniques. First, a small-scale (1:10) dam model on two-layer strata was used to analyse the influence of main geometric and hydraulic parameters on the relief behaviour of stone columns and trenches. The results of these tests were the basis for calibrating the numerical model and for the large-scale modelling (1:1 scale) as well. Furthermore, this gradual approach allowed parametric studies exceeding the limits of the small-scale model.

4.3. SMALL-SCALE MODELLING

The small-scale dam model represents a vertical cross-section of a dyke including the subgrade in a scale 1:10. The 25 cm high dam model is founded on two-layer strata (Fig. 7). Beneath the silty-clayey blanket ($k = 10^{-9}$ m/s) with a thickness of about 10 cm follows a homogenous aquifer layer of coarse sand with a thickness of about 18 cm. In addition, the dam has an imperfect cut-off wall (i.e. with underseepage), which slightly embeds into the aquifer.

The pressure beneath the blanket due to underseepage was measured by means of piezometers pipes in the longitudinal and transversal model axis. In addition to these measurements, also the discharge was quantified.

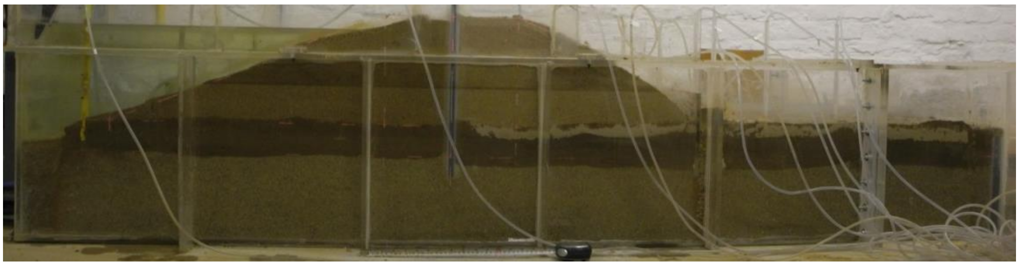

Fig. 7
1:10 small-scale dam model on two-layer strata.
1:10 modèle de barrage à petite échelle sur les strates à deux couches.

Fig. 8 shows the pressure distribution lines beneath the blanket for test series with single relief element depending on its permeability and embedment length into the aquifer. Both – the relief gravel column as well as the relief well – lead to a significant reduction of the hydrostatic pressure. If no relief measures would be installed, due to the blocked outflow boundary the hydrostatic conditions on the landside would became equal to the hydrostatic head on the waterside. It can be also seen that the element permeability significantly influences the pressure reduction. A similar behaviour can also be observed in terms of embedment length. However, the effect of embedment depth on the pressure relief, as supplementary investigations with the calibrated numerical model show, is also strongly influenced by hydraulic parameters of the aquifer.

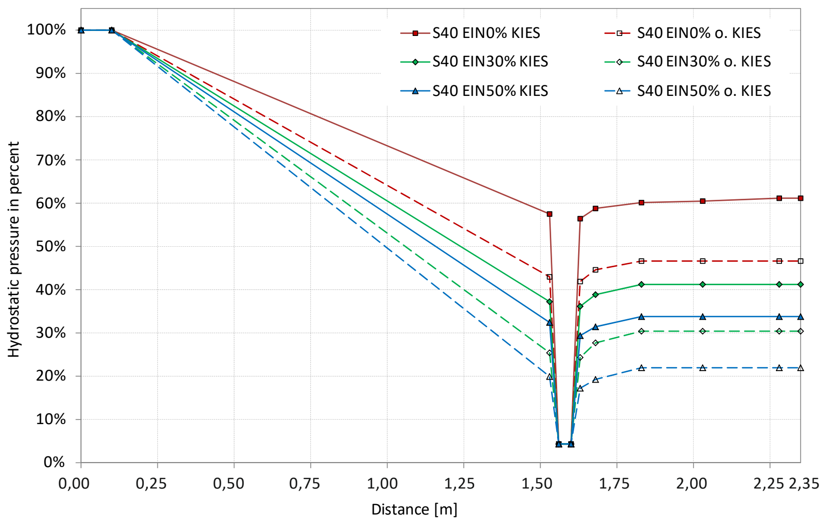

Fig. 8
Pressure along the longitudinal axis of the 1:10 model with a single relief column.
Pression le long de l'axe longitudinal du modèle 1:10 avec une colonne en relief.

Based on the small-scale modelling, a large scale test facility (1:1) was built to study pressure relief drainages. The ground plan area of the reinforced concrete box was 25 x 4 m with a constant wall height of 5 m.

The 1:1 dam model represents a 4 m wide and 25 m long cross-sectional model of a dyke on two-layer strata (Fig. 9). The homogenous dam had a height of 2.5 m and the slope ratio of 1:2.5. For the dam sealing a silty-clayey core was installed, which penetrated the clayey blanket (thickness of about 0.7 m) and embedded only few centimetres into the 1.3 m thick aquifer layer of sandy gravel.

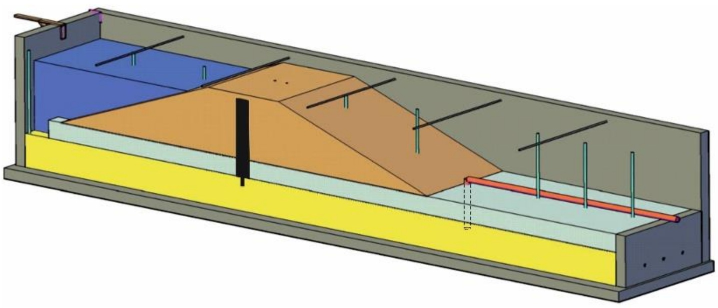

Fig. 9

Schematic drawing of the 1:1 dam model on a two-layer foundation.

Le schéma du modèle de barrage 1:1 sur une fondation à deux couches.

For the pressure relief observation due to the controlled underseepage, a measuring system was used, which allowed a continuous recording of the pressure potentials beneath the blanket as well as a time-synchronous recording of the water discharge from the relief gravel column.

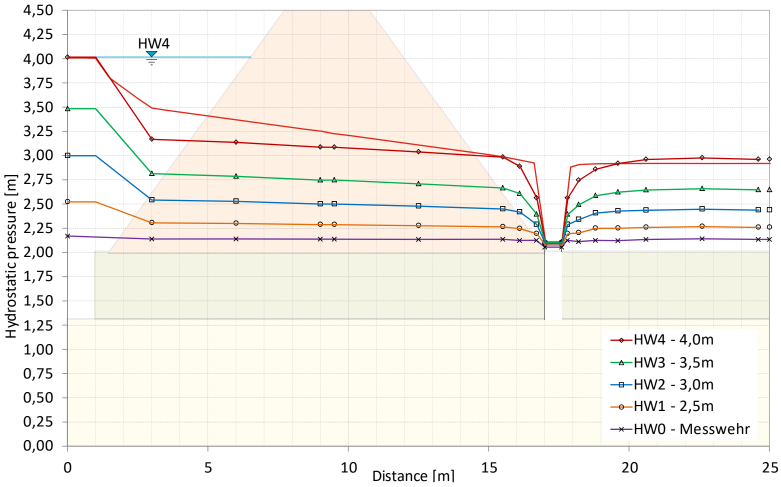

Fig. 10

Pressure distribution due to a single relief drainage column of 600 mm diameter and without embedment into the aquifer in a 1:1 model. (HW = water level)

Répartition de la pression dûe à une de la colonne de la decompression de 600 mm de diamètre et sans enfoncement dans l'aquifère dans un modèle 1:1.

In numerous series of measurements, a clear relief behavior of drainage columns could be confirmed despite certain anomalies. An example of the pressure relief behaviour due to a single relief column (Ø 600 mm) shows Fig. 10. The pressure reduction at the beginning of the measuring profile was partly caused by possible local clogging of the aquifer in combination with the relieving effect by the relief column. This resulted in a reduction of 50% in the hinterland. The maximum discharge for the highest water level was about 0.95 l/s per relief column with 4 m spacing.

4.5. NUMERICAL MODELLING

In order to examine the general application of numerical results, a model calibration with the GGU Software was carried out based on the model tests. For this purpose, the small-scale model test results were used, because the 1:10 model had a higher degree of homogeneity as the 1:1 dam model. The calibration was first carried out for a fully penetrating relief trench by variation of the aquifer permeability and subsequently extended to a three-dimensional model with a single relief column. Based on the model calibration, numerous comparative simulations were performed for both models. They verified the application of the calibrated three-dimensional numerical model for further studies of different geometric and hydraulic parameters (diameter, permeability, embedment length, spacing of a multiple column system) beyond the limits of the physical modelling.

The results from the numerical calibration of the three-dimensional model with a fully penetrating single relief column (with/without gravel) are shown in Fig. 11. The diagrams show the comparison of the measured pressure potential lines and the discharge from the relief column with the results of the numerical calculation.

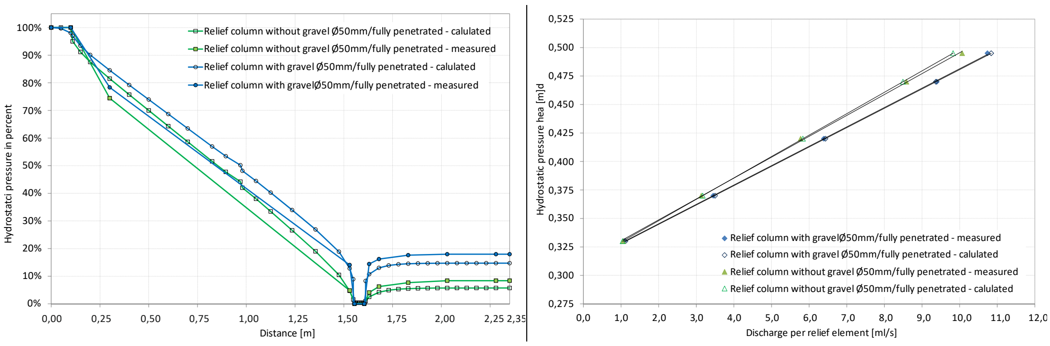

Fig.11

Results of numerical calibration for a model with a single relief column: pressure lines (left) and discharge from the relief column (right)

Résultats de l'étalonnage numérique pour un modèle avec une seule colonne en relief: lignes de pression (à gauche) et décharge de la colonne decompression (à droite)

SUMMARY

Underspeepage of dams, dykes or levees may lead – especially in the long-term – to erosion of the ground due to (subsequent) floods. The pressures that develop landside of the dyke during floods may cause heaving or uncontrolled rupture of the near-surface blanket resulting in a concentration of seepage flow, often accompanied by piping, and potential dyke failure. Such a hydraulic failure develops mostly rather inconspicuously; therefore it is often underestimated in practice. Erosion criteria can be used to describe the critical state for different soil types found during ground investigation. For the control of underseepage pressures in the aquifer and for hydraulic failure prevention stabilizing measures at the embankment toe zone are essential. Filter stable berms, relief drainage columns or trenches, sometimes also relief wells have proven very successful.

If pressure relief measures are required, the selection of a suitable relief system has to consider the geotechnical, hydraulic and local conditions. For the design of the selected relief system (drainage columns, trenches, wells) numerical methods are commonly used in practice. A technically and economically optimized design is only possible, if hydraulic boundaries of the flow field (e.g. long-term data from groundwater observation) and the permeability of the aquifer can be determined as precisely as possible, as could be experienced in experimental and numerical studies. Finally, monitoring of existing projects contributes significantly to continuous calibration and sophistication of numerical modelling and practical design.

1. INTRODUCTION

The Glevard Dam project is located in Mazandaran Province and constructed on Neka River, and its middle point situated on the coordination of 36.59 N and 53.61 E. The type of dam is CFRD and the maximum height of the dam from riverbed is 103 m and from bedrock is 113 m. Dam crest elevation is 739 m.a.s.l. with the dam crest length of 250 m and width of 10 m as shown in figure.1.

Based on the geological report of the project, left and right abutments of the dam consist of white limestone (Lw) and grey limestone (Lg). The material of riverbed includes floodplain and alluvium on the top following by gray limestone, Shemshak Formation and Gorgan metamorphic rocks at the bottom, respectively, as shown in figure.2. Selection of the grout curtain and grout boreholes shall be in a way that their direction has the optimum status in relation with the dip and dip direction of discontinuities.

The main criteria for selecting the optimum status of the dip and dip direction of grouting boreholes at Gleavard dam site to cover predicted curtain plane appropriately is that pay attention to the direction of grouting galleries especially in bending parts in the left bank. The direction of the galley in the first 130 m is 7°. Afterward, two bends; one is located in 24° direction for 40 m, following 40° for the last bend with 52 m length, towards to the dam axis as shown in figure.3 and 4. Based on the existence of the effective major joint sets in the limestone, selection of inclined boreholes and inclined water tightening grout curtain plane at the left abutment of the Glevard dam proposed according to the following criteria:

a) The necessity of drilling cross boreholes, b) more appropriate contact with effective major joints and c) more success in sealing the rock mass of foundation.

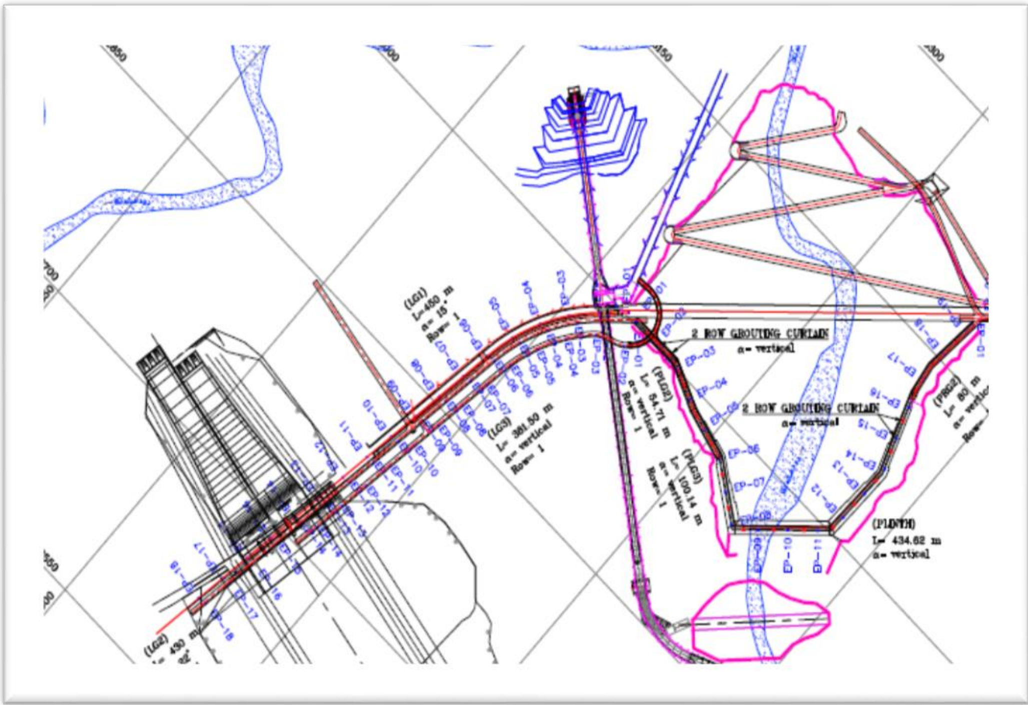

Fig. 1
General Plan of Glevard CFRD Dam

The existing effective joint and fissures crack system in the limestone, mainly with 60 to 90 degrees angle with two dominant directions, using an inclined curtain with drilling inclined borehole, will result in successful sealing of the water-tightening curtain. The inclined grout boreholes should drill in two opposing directions and inside the grout curtain plane with an appropriate angle and direction regarding joint sets at the left abutment with 140/20 and 50/20.

The existing effective joint and fissures crack system in the limestone, mainly with 60 to 90 degrees angle with two dominant directions, using an inclined curtain with drilling inclined borehole, will result in successful sealing of the water-tightening curtain. The inclined grout boreholes should drill in two opposing directions and inside the grout curtain plane with an appropriate angle and direction regarding joint sets at the left abutment with 140/20 and 50/20.

2. CONCEPT OF DRILLING INCLINED CROSS BOREHOLES FOR THE WATER TIGHTENING

Drilling inclined cross boreholes for the water tightening at the left abutment rock mass in Glevard dam is necessary. However, there are some challenges and uncertainties raised on the rate of success of the inclined curtain compared to the vertical curtain. However, in this project increase the construction costs of the inclined cross boreholes can be justified due to technical and construction reasons, as follows:

1. Based on the Fig. 5, it can be seen that the vertical / inclined combined borehole system produces rhombuses shapes with longer diameters twice as long as the longer diameter of cross boreholes. Therefore, this area is twice as large as the similar rhombus shape obtained from the inclined cross boreholes. It makes the areas among the boreholes twice and with regard to the situation of discontinuities, the limestone rock masses of the area have more uncertainty compared to the cross boreholes. It results in less effective grounding practice.

2. Selection of the inclined cross boreholes system, in terms of the costs and other economical basics, does not increase an additional cost to the project.

3. In this project, inclined boreholes drilled for exploration grouting which shows the grout curtain as almost 15° from vertical, have very good results in terms of crossing the joint and cracks system (discontinuities) and grouting in them will

considerably increase the effect of grouting. The results will be clearer in systematic grouting test panels and drilling of control boreholes. However, with regard to the findings on these boreholes, dominant discontinuities are mainly inclined in different directions in the plane, which indicate more success in contact between the boreholes and joints, as clarified in joint surveys obtained from investigation of surface discontinuities.

3. ASSESSMENT THE JOINTS STUDY OF WHITE LIMESTONE

After measuring discontinuities in the white-colored limestone (Lw) where the LG1 tunnel has been excavated, it was found that the joint sets are a little different from those selected based on the surface mapping. However, the dips are more or less consistent and joints of 104/80 and 113/78 can be considered as one group (50/83 with 63/84). Measurements were done in the 100-m long trench at the LG1 tunnel outlet portal, which is totally 84 joints. Stereographical image of the discontinuities shown in figure 6 and 7 and their engineering geological features have been provided in table 1.

Table 1
Discontinuities in white limestone surrounding gallery LG1. (SP = Spacing, W1 = slightly weathered base on the IAEG suggestion)

Joint sets	spatial	Length (m)	Spacing (m)	opening	weathering
J1	063/84	1-3	20-40	2-10	W 1-3
J2	351/82	0.5-2	15-30	3-4	W 1-3
J3	113/78	3-6	10-40	1-5	W 1-3
J4	284/67	1-4	20-50	3-5	W 1-3

A distinct reality in the white limestone rock masses (Lw) is the formation of slickenside along some joints, which is very crushed and erodible (photos 1 and 2) and the rock mass is highly crushed and full of joints and cracks.

In underground investigations of the boreholes drilled at the left abutment of Glevard dam site [phase I exploratory-grouting boreholes (LG01-EP) and exploratory boreholes (BH02,3,4)] and joints and fissures of 60 to 90 degrees, a large number of joint and fissures have been identified. The summary of the results provided for white and gray limestone in table 2. In upper white limestone which have more joints and fissures, crushing and water seepage, the frequency of joints and fissures in different zones are as follows:

Zone 1: Includes boreholes EP1 to EP4 in the inclined curtain. 272 out of 780 discontinuities (34.8%) have angles of 30 to 60 degrees and most of them have had angles of 80 to 90 degrees. In the inclined plane, these angles identified and assessed as 15°.

Zone 2: Includes boreholes EP-5 to EP-9 in the inclined water-tightening plane. Out of the 743 identified discontinuities, 28% have 60 to 90 degrees angle, showing a slight decrease compared to Zone 1. However, it still includes a large percent. It once more noted that these joints observed in the drilled boreholes in the inclined grout curtain plane.

Zone 3: Includes boreholes EP-10 to EP-12. Out of the 520 identified joints, 37.7% have 60 to 90 degrees angle, most of them have 80 to 90 degrees angles, and all of them are located in the mentioned inclined curtain plane.

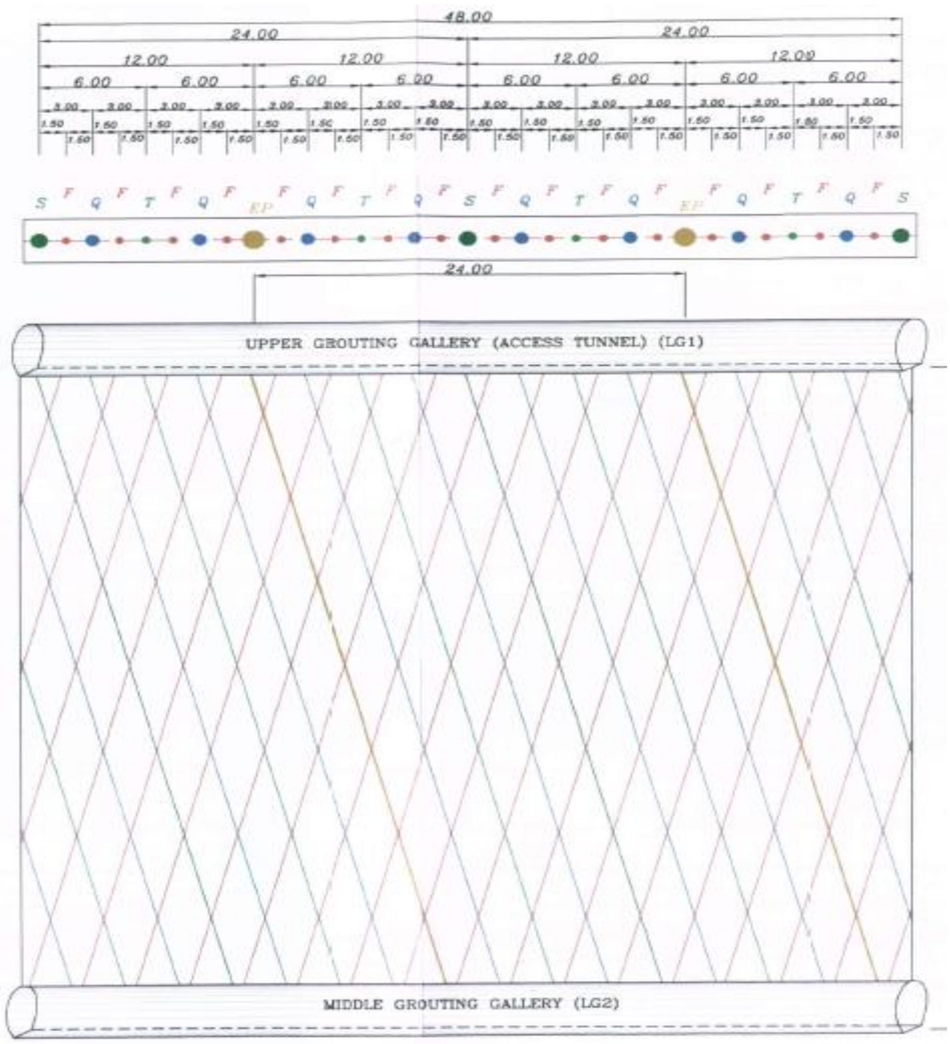

Fig. 5

Schematic Plan and Section of Grouting and Curtain Boreholes at the Left Bank of Gelevard Dam including primary, secondary, tertiary and quaternary boreholes

Zone 4: Includes boreholes BH-2 to EP-13. Out of the 151 identified joints, 69.5% have 60 to 90 degrees angle and most of them have 80 to 90 degrees angles.

Zone 5: Includes boreholes EP-14 to EP-16 and BH-3 to the south of the free spillway. Out of the 385 identified joints, 49.8% have 60 to 90 degrees angles and most of them have 80 to 90 degrees angles. Drilling of the mentioned boreholes carried out in the 15 degrees inclined plane against the vertical.

The average number of joints with 60 to 90 degrees gradients in these boreholes is 30 to 50, sometimes 70%, which compared to other joints include the maximum number, and most of them have open joints with high seepage and cement consumption. This cause an increase in the grouting radius and thickening of the grout curtain, which is of the main objectives of this work.

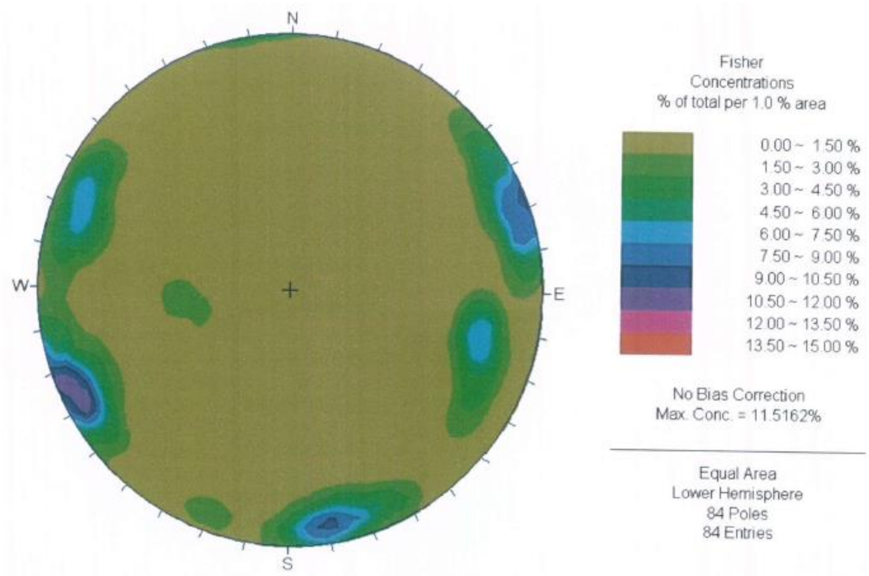

Fig. 6
Cyclographical diagram of the measured join sets (4 sets) of Lw

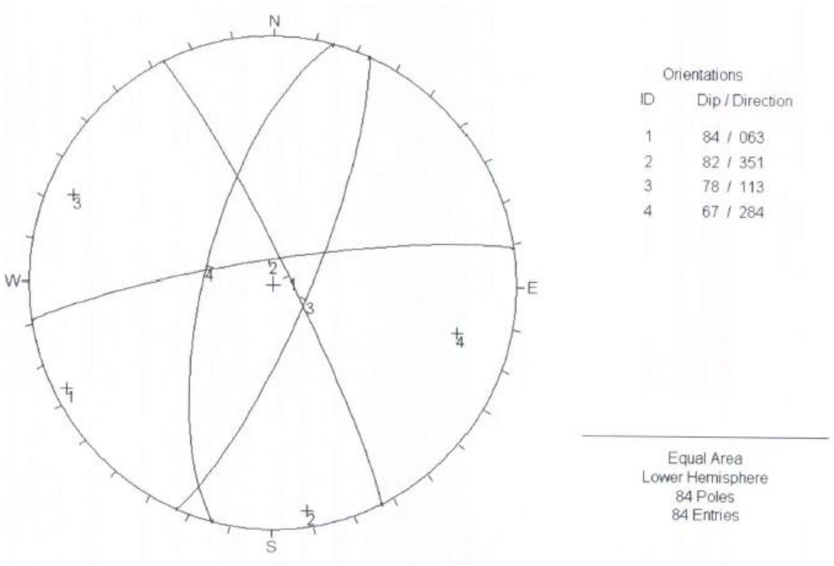

Fig. 7
Stereographical diagram of the measured join sets in Lw (84 joints).

This investigation only relates to the number of joints, regardless of their effect on seepage). If the effect of joints with high angle compared to the joints with low angle considered on the seepage, their weight effect will be considerably more than the mentioned values.

Table 2
Summary results of classification with the angle of joints and fissures in the limestone

Location	0-30	30-60	60-80	80-90	60-90	No. of Dis.
Z.1	36.3	28.9	11.8	23	34.8	780
Z.2	42.1	29.8	8.9	19.1	28	743
Z.3	41.3	21	9.4	28.3	37.7	520
Z.4	10.6	19.9	19.9	49.6	69.5	151

Joints with high angle have much more length compared to the joints with low angle and length of up to 2.2 m reported in this project. These joints with relatively high width lead to high seepage amount (specifically in zones 1, 2, 3 and 4). As the result, drilling the inclined curtain plane, which will provide the best result in order to cover more joints.

4. SPATIAL LAYOUT OF THE GROUT CURTAIN AND TESTING EXPLORATORY GROUT HOLES

Base on the primary site visit of the outcrop of the limestone (LW) in the trench of the access way to the grouting gallery outlet portal, engineering judgment, and work experiences dip and dip direction of discontinuities are such as 210/74, 104/80, 050/83 and 180/80. This limestone has outcrops in both slopes of the gorge and in the Glevard dam axis; and LW (White Limestone) limestone include milky white, fine-grained, crystallized and dense limestone with average to high compressive strength and high weathered. They are quite different in terms of different tectonic effects, weathering, color, Karstic event, crushing, joints and fissures, filling, etc. However, generally, there have also vertical open joints with medium to high permeability in this area. As the spacing and number of these four joint sets are not available (in the report), it is not possible to use the method suggested by Zhou and Maerz (2003) in finding the spatial layout of the grout curtain [1]. As for a more appropriate evaluation, estimate of the weight of the joint sets is needed, the simplest method which is the homogeneity of the frequency of the joint sets. According to the result of this method, inclined boreholes are more efficient than vertical boreholes (figures 8 & 9).

Fig. 8

View of the crushing and jointed nature of the (Lw) limestone rock mass in trench of outlet portal.

Using the approximate method of bisectors [2], first the appropriate dip of grouting estimated as shown in fig.10. The bisector of the dip of two joints sets 104 and 50 degrees will be in 77-degree direction. The bisector of the dip of two joint sets 180 and 210 degrees is in 195 degrees direction and bisector of 77 and 195 degrees delineated, it will be in 136 degrees direction. homogeneity of the frequency of the joint sets. According to the result of this method, inclined boreholes are more efficient than vertical boreholes (figures 8 & 9).

Table 3
Calculating LSBI θ, (84 joints)

210/74°	104/80°	050/83°	180/80°	Dip	Sum
1.040	1.015	1.008	1.015	0	4.079
1.113	1.064	1.046	1.064	10	4.287
1.236	1.155	1.122	1.155	20	4.668
1.440	1.305	1.252	1.305	30	5.303
1.788	1.556	1.466	1.556	40	6.366
2.459	2.000	1.836	2.000	50	8.295
4.134	2.924	2.559	2.924	60	12.540
14.336	5.759	4.445	5.759	70	30.299
9.567		19.107		80	
3.628	5.759	8.206	5.759	90	23.351
2.281	2.924	3.420	2.924	100	11.549
1.707	2.000	2.203	2.000	110	7.904
1.390	1.556	1.662	1.556	120	6.163
1.206	1.305	1.367	1.305	130	5.184
1.095	1.155	1.192	1.155	140	4.596
1.031	1.064	1.086	1.064	150	4.245
1.002	1.015	1.026	1.015	160	4.060
1.006	1.000	1.001	1.000	170	4.007
1.040	1.015	1.008	1.015	180	4.079

Using this method, the direction between 136 and 142 has been selected for the grouting direction and 140 degrees has been suggested which makes a 47degrees gradient (p) with the tunnel direction. It is clear that a vertical surface in such a direction will cut the four joint sets with 74, 80, 83 and 80 degrees dips, with decreased gradients (apparent dip).

This gradient will be 50, 77.7, 0.0 and 77 degrees. All boreholes are on the mentioned surface. It is clear that each borehole can be located in this vertical surface but a borehole, which is more prominent with the dip of the joint sets, is more appropriate.

This, it is quite clear that inclined boreholes can pass by the highly dipped joints better and more appropriately. Therefore, estimating the average of the mentioned gradients, which is 63 degrees, 70° accepted as more appropriate than other gradients.

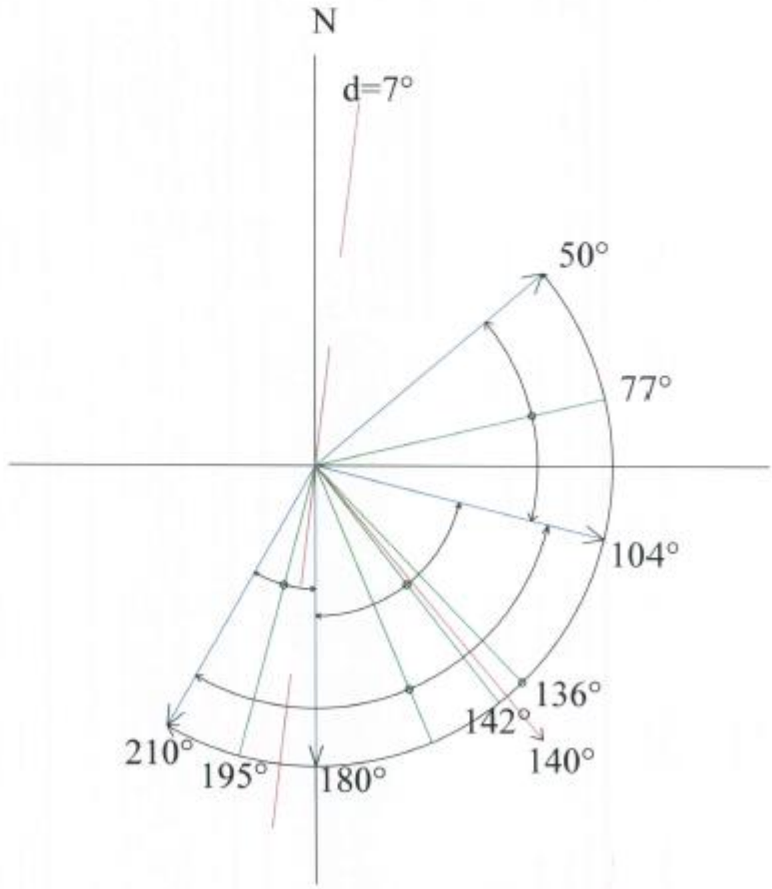

Fig. 11

How to find the more appropriate grouting direction to include all four joint sets.140° is the direction selected for the azimuth of the exploration grouting borehole (d=7° is the direction of the grouting gallery).

Inclined borehole suggested in the Zhou and Maerz method. Selection of an inclined borehole in 140 degrees direction on a surface with 7 degrees direction (direction of the access tunnel) would be impossible unless with an inclined grouting curtain. Thus, the following method used for finding the gradient of the grout curtain. Boreholes 140/70 will be more applicable in grouting and each of the boreholes drilled in a depth 45 m lower than access tunnel invert in 16 m spacing. For such boreholes to be within the grout curtain, the direction of the grout curtain is the same as the access tunnel (7 degrees), the spatial layout of the grout curtain must be 97/α. It can be easily found out that if the gallery is lower than the access tunnel in 45 m depth, the spacing between the axis of the access tunnel and the parallel gallery beneath it would be 12 m (m = m' Sin 13 = 12 m). This method reveals that the grout curtain should be 45 m deep, with 12 m perpendicular spacing and therefore, the curtain should be inclined, with a dip of α = (tan = 45/12). Thus, 097°/75° would be its spatial layout as shown in figure.11.

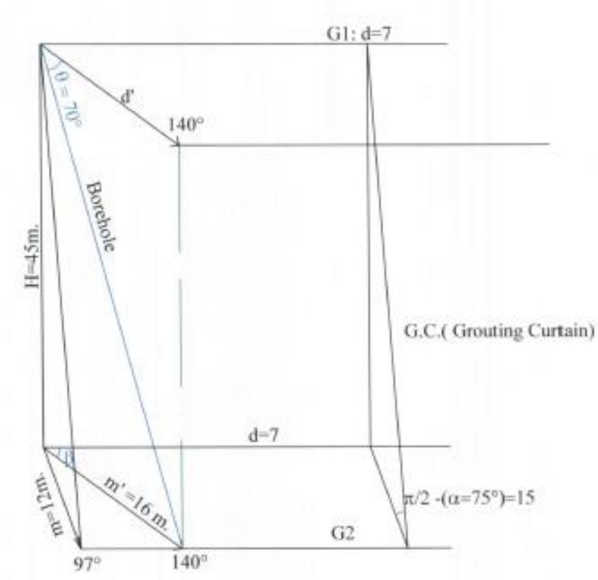

Fig. 12
The layout of the grout curtain and the 140/70 inclined borehole.

Selection of Spatial Layout of the Grout Curtain and Grouting Borehole Based on the white Colored Limestone Joint Sets To estimate the dip and dip direction of the grouting borehole, the following two methods used:

1. Bisector Approximate Method

This is the same method shown in figure 8 & 9. The result of this method provided in the figure.12 where dip direction of the grout borehole obtained as 50 degrees. Thus, the grout borehole will have a 69-degree dip towards 50 degrees.

The bisector of 88 and 318 degrees is in 23 degrees direction, which will be in the grout curtain if the direction of the borehole is 23 to 27 degrees (25°) and its dip is 49°. However, its slope is not so much appropriate. The bisector of 113 and 351 degrees is in 52 degrees direction, which will be in the grout curtain with the slope of 68.7° and will be more appropriate than the borehole with 49° dip and it is so suggested (borehole 0.05/69 or 0.50/70). See figure 5. (d=70°: the direction of the access tunnel).

For a borehole of 50° dip to be located in 0.97/75 grout curtain its dip should be 69.9 or 79 degrees. Figure 13 shows how to estimate the gradient and it can also be shown that in case a borehole is drilled towards 50°, the curtain should be inclined, a = 75, if it is to be in the 097/a grout curtain. Followings are the marks used in this general figure:
p = gradient between the axis of the access tunnel or galleries and the grout curtain = gallery Gl.
d' = direction of the grout borehole which should be in the grout curtain.
m = spacing between the direction of the grout curtain and gallery G2.
m'= spacing between the direction of the grout curtain and the grout borehole (d').

θ = grout curtain gradient
θ' = grout borehole gradient
I = length of the largest dip of the grout curtain to the surface of gallery G2, 6which is H m lower than GI as shown in figure 14.
With θ = 75°, m = 12.06 m, 11= 47° and H = 45, it is easily possible to estimate θ' and m'.

Θ'= tan-1 (H/m3)*(m'/sinβ),or (conversely, it is possible to obtain θ, having d/δ).
The result would be θ =69.8° or 70° and therefore, the grout borehole with the spatial layout of 050/70 will be located in the grout curtain of 097/75.
Conversely, if Θ'=70°, m = 12 and tan θ = 45/12 and so, θ = 75°.

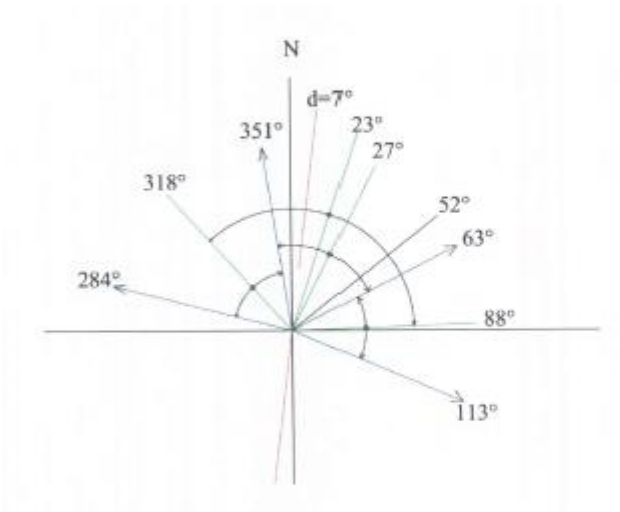

Fig. 13

Selection of grout borehole based on white-colored limestone joints in gallery (bisectors method) is 4 joint sets of 63/84, 351/82, 113/78 and 284/67.

2. Zhou and Maerz Suggested Method (2003)

In this method, based on a bias index of the measured discontinuities (Linear Sampling Bias Index= LSBI), a borehole which will optimally cut all joint sets (optimum borehole of δ/θ). Bias index of the borehole dip slope is:

$$LSBI\ \theta = \sum_{1}^{n} (1/\sin \alpha i) * \mathrm{Wi}$$

and the bias index of the borehole azimuth is:

$$LSBI\ \delta = \sum_{1}^{n} (1/\sin \beta i) * \mathrm{Wi}$$

In the above relations, wi is the weight which is the ratio between the spacing of each joint set and all joint sets. αi is the dip gradient of the joint set i and βi is the gradient between δ and direction of the joint.

To estimate optimum θ and δ, their values estimated in the mentioned relationships from 0° to 180° for θ and from 0° to 360° for δ.

In the x and y diagram, where x is θ or δ and y is LSBIθ or LSBIδ, the least values of these two diagrams provide values of θ and δ.

As shown in figure 15, the value of θ has been selected as equal to 130° in relation to the horizontal surface (0° is another answer which is not used (horizontal borehole)).

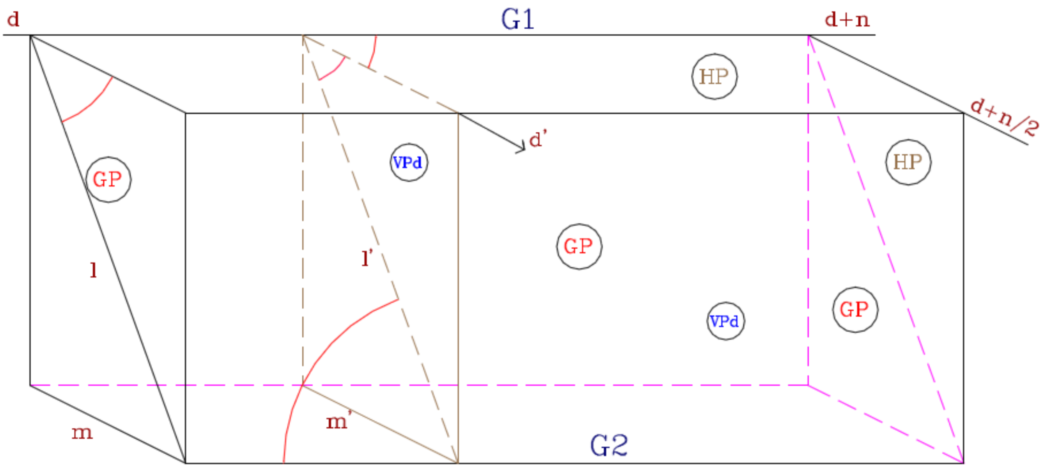

Fig. 14

Demonstration of grouting plane (GP) along galleries LG_1, LG_2, Glevard dam site

VP: d = 7°, θ = 70°, H = 45 m, l = 47 m, m = 12.06 m
VPd: β = 47°, d' = 140°, θ' = 70°, l' = 47.9 m, m' = 16.4
HP = Horizontal Plane
VP = Vertical Plane Crossing d'
VPd = Vertical Plane Crossing d
G1, G2 = Galleries
GP = Grouting Plane
λ = Angle Between l' & axis of G1, G2, on the Gp

Value of δ estimated in figure 16 and the borehole azimuth selected as 125°. According to the mentioned researchers, if the value of θ is more than 90°, δ with a value of less than 180° will be more appropriate. Based on the two values of θ and δ, the spatial layout of the borehole will be 125/160 and as the dip gradient is against the horizon, the spatial layout obtained as 125/30.

This spatial layout is for a general statement; however, it cannot be sufficient for a special feature such as grout curtain where grout galleries are within a tunnel or gallery [3]; like grouting in Glevard where the 30° dip never accepted. The mentioned method, which mentioned to clarify that the selection of the requested feature, based on the engineering geological investigation strategies (at least with two methods).

For a borehole which is drilled towards 125° (D=62° and m'=13.6°) to be within the grout curtain, it is necessary that its dip is 73°, which is very inconsistent with 30°. As the result, dip of the best borehole, which is 30° with this method, not accepted, as it is not located in the grout curtain.

Therefore, selection method will be the same approximate method that provided the borehole as 50/70, which is quite different from the primary state of 140/70 (perpendicular to it) and these two boreholes, which have crossing state, used to fill out the grout curtain [4].

The least value in this diagram is zero and 130 degree (borehole dip is in the inclined plane). The horizontal borehole is not acceptable and therefore, $\theta = 130°$. The dip of four joint sets is 67, 78, 82 and 84 degrees, with an effective weight of 31, 22, 20, and 27 from 100(wi).
The least value is 125 and 305 degrees. As the value of θ estimated at 130°, the 125° azimuth selected.

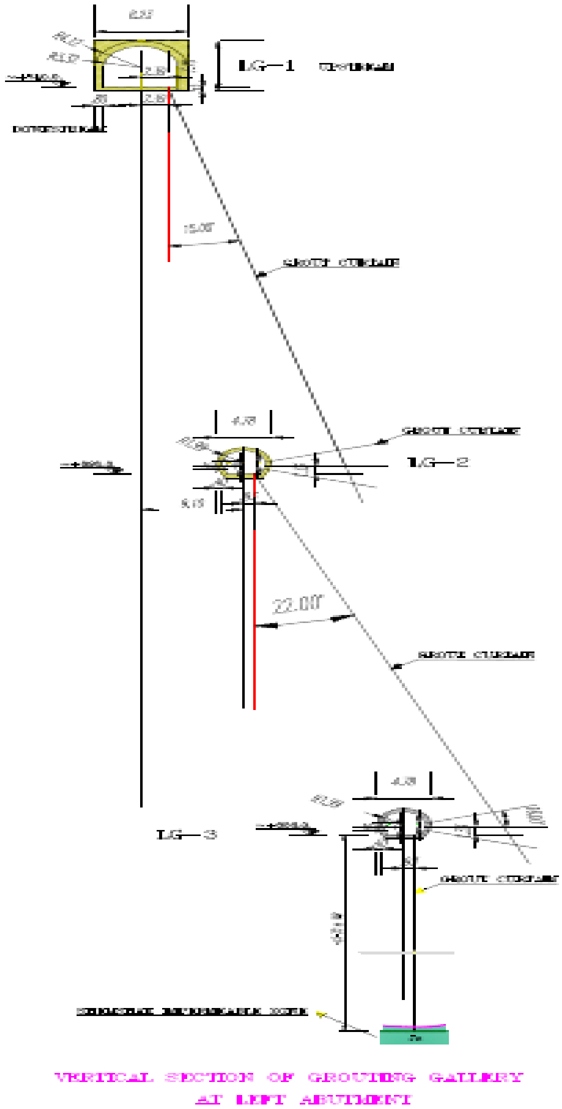

Fig. 15
Vertical section of grouting gallery at left bank of Glevard dam site.

5. MAIN SELECTION OF GROUT GALLERIES IN BENDING PARTS OF THE TUNNEL G1

As already mentioned, the direction of the gallery in its first 120 m is 7 degrees. Afterward, there two bends, one in 24 degrees direction, for 40 m, and then in 40 degrees for 52 m, up to the dam axis. For the grout boreholes to be carried out with the very 140 and 50 degrees directions, they need to have different dips, which belongs to the values of f3 and m'. If the dip of these boreholes is not known, there is no way but to change their dip direction.

5.1. FIRST BENDING PART (D=24°)

For 140 degrees borehole direction: 13=64, m'=13.35, 0=73.5 and they are resultant would be a borehole of 140/73/5. For 50 degrees borehole direction: f=26, m'=27.37, 0=58.7 and their results would be a borehole of 50/58/7. If the borehole dip direction is selected as 70°, p=46° and m'=16.68 and the dip gradient will be 69.6 or 70°, which is more appropriate.

5.2. SECOND BENDING PART (D=40°)

For 140 degrees borehole direction: 13=80, m'=12.19, 074.8, with a 140/75 view.For 50 degrees borehole direction: 13=10, m'=69.11, 0=33, with a 50/33 view, which is not appropriate (the dip is very slight) and if the dip direction is 90°, borehole dip will be 71 degrees (P=50, m'=15.66).

Zonation of the G1 access tunnel based on the direction of its bending part, has been carried out with the view that the bending parts are replaced with straight parts, so that the ratio of the straight part, (li), to its bending part (Ci) is not less than {li/ci} ≥ 0.95. The straight part of the tunnel is 130 m long, which considered as the starting part of the access tunnel. The straight part, with a length of 40 m, has been replaced for the 41.5 m long first bending part (with a ratio of 0.96) and the second bending part which is 52.8 m long and its straight part which is 52 m long will provide a ratio of 0.98 (figure 4).

Access tunnel G1 is located at El. 740 — 743 m.a.s.l. and based on boreholes 01 and 01G, Shemshak Formation with very low permeable to impermeable is located at 150 m below the access tunnel (El. 590 m.a.s.l). Therefore, at least two galleries parallel with the access tunnel and below is carried out for grouting purpose. Gallery G2 has been foreseen 45 m below the G1 at (El. 695 m.a.s.l) and dip and gradient of the grout galleries was estimated based on it.

6. FINAL TECHNICAL NOTE

With regard to the explanations provided above, following complementary notes, along with some figures and diagrams seem to be useful for a better understanding of the described technical points. So the following notes provided hereunder:

1. More suitability of inclined boreholes compared to the vertical ones in each vertical surface including the joint sets discussed here. This is a very clear understanding and is certainly known by an expert, however, three directions have been selected here to show it; 7° (access tunnel direction) which will be at the same direction with the grout curtain, too, 140° (azimuth of the grout gallery) and 50° (azimuth of the grout gallery).

2. To do this, joint sets in table 1 (based on the 84 measured joints) have been delineated in 1 m2 of the vertical surface, so that the maximum number of joints can be shown. The spacing (SP) of these joints is available which will be as Sph = SP/sin a on a horizontal line along the dip direction of the joint [5]. Figure17 shows the vertical boreholes in all the three vertical surfaces with the mentioned directions. It can be clearly seen that at the contact point of the borehole with the joints at 140° direction surface, it is more than the other two directions; 5 against 4.

7° is the direction of the access tunnel and grout curtain. It clearly concluded that there are clear advantages in 50 and 140 degrees directions compared with 7-degree direction, in the vertical curtain. The opening of the joints in three directions have been estimated using the following relationship and β is the gradient between d' and δ[6].

$$\mathrm{Sph}\,\beta = sp.\frac{cotg\alpha'}{cos\alpha}$$

$$\alpha' = tg - 1\ (cos\beta . tg\alpha)$$

The number of boreholes to be drilled in this 1 m2 with the most contact points, in the 50° direction surface is 3 boreholes and in the other two directions is 2. View of the joints contacts clearly shows more and wider open spaces in the 7° direction. Generally, advantages of the 50 and 140 degrees directions seen from the 7° direction.

This view shown in figure 10 for the inclined boreholes in all the mentioned three vertical surfaces where advantages of inclined boreholes compared to the vertical ones in 50 and 140 degrees direction are quite clear.

3. If we look at the inclined curtain with 097/75 spatial layout, if the same features of the joints existing in vertical surfaces turn by the value of the 0 slope, the difference in the sooner contact of the inclined boreholes with the joints will be clearly recognized. It is impossible to drill a vertical borehole in such an inclined surface. However, the view of the four joints and cross of the boreholes shown with the following relationships

4. All of the observed discontinuities at the ground surface and walls of the river and the excavated trenches, mainly express figures whose geometrical forms and surface forms of the discontinuities shown on figure 18.

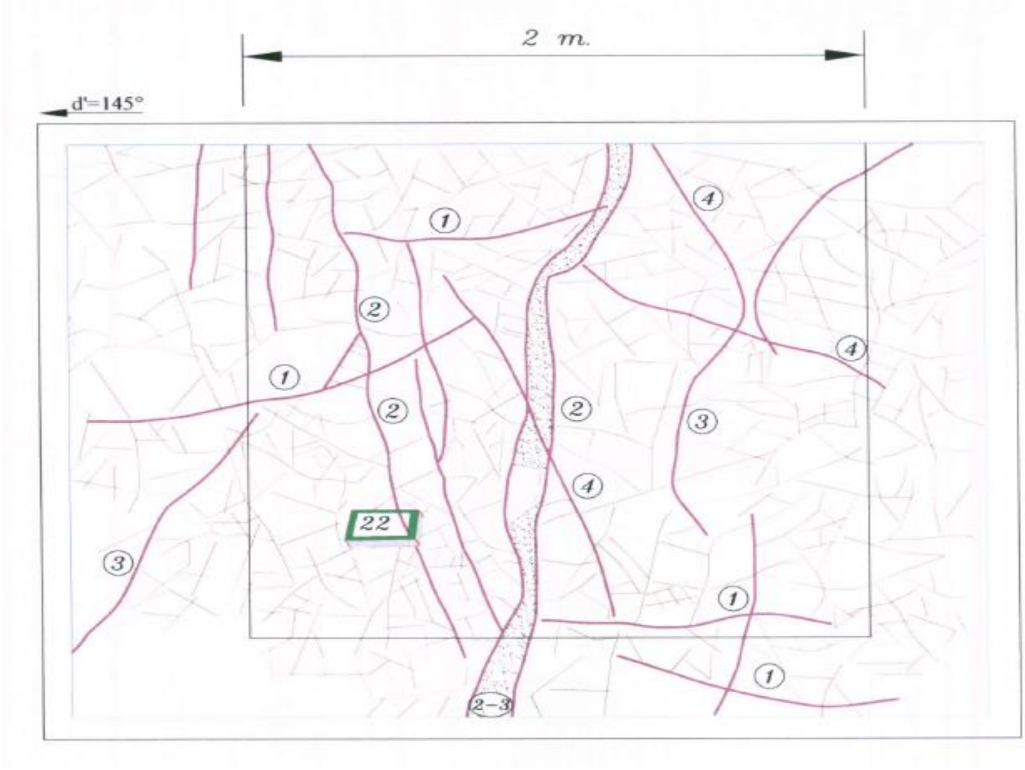

Fig. 16
View based on the spacing of the joints and the decreased angle of the joints at 145° direction, where the difference are very clear.

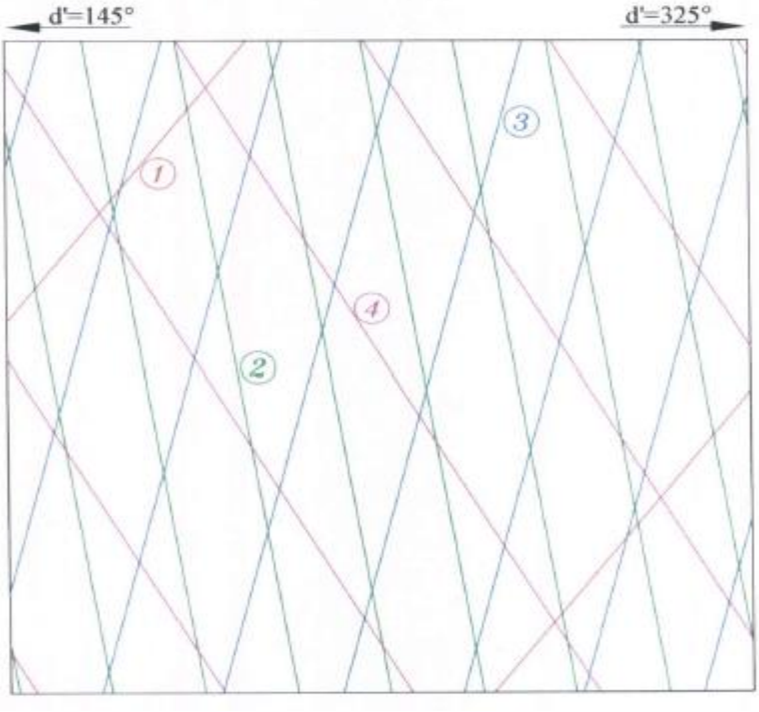

Fig. 17
View of discontinuities in 4 m2 of the trench wall

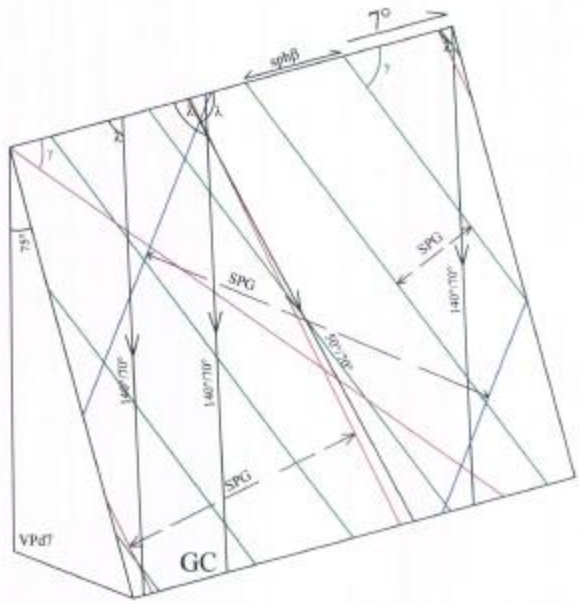

Fig. 18

Number of joint contacts in vertical borehole in vertical surface in the three direction.

5. All of the dominant discontinuities in the white-colored limestone rock mass (1w) at the surface have dips more than 67° and even up to 84° (joint sets J1 and J2 have 84 and 82 degrees dips, respectively. Therefore, the vertical nature of drilled boreholes in terms of cement grout and success is not appropriate, useful, and rejected.

6. Figures 3, 4 and 5 show the delineation status of the planes with 40, 24 and 7 degrees directions. With regard to these values, it can be seen that change in the direction of the planes is highly effective on the contact with the discontinuity planes and the most effective can be seen in the figure below figure 19. As is seen there, what observed on the ground surface has totally complicated and complex conditions and has different bends. This is so that imaging the observed planes on the ground surface on one plane, is not so much compatible and is no help in recognizing their geometrical status with changes from the surface to depth [7]. Thus, the information obtained from the exploration grout galleries in the selected 15° inclined plane for the grout curtain shows a very different situation, in terms of contact with discontinuities through the mentioned boreholes, compared to the surface information.

7. Delineation of the diagram of discontinuities as mentioned here above and referred to in different figures indicate that no important visual feature can be shown in 15° inclined plane. This is because; part of the discontinuities with the provided geometrical relations cannot be in contact with the mentioned inclined plane. However, drilling boreholes in this plane revealed that the effectiveness and usefulness of an inclined grout plane effects on the degree of groutability and success of the work through an increase in the thickness of the grout curtain and

decrease in its hydraulic gradient [8]. This carefully proven after the accomplishment of the work and control of the obtained results.

8. By comparing the above-mentioned, it is seen that the contact of discontinuities in the inclined plane is considerably more than that of the vertical plane. However, some of the discontinuities not shown in the inclined plane.

SUMMARY

1. The grout gallery will so cross that its slope with 7o° direction will be equal to λ, $\sin\lambda = \sin\varphi'/\sin\theta$. In this equation, $\theta = 75°$ and $\varphi' = 70°$ and as the result, for 113/78 joints with SP = 27 cm, this angle will be equal to $\lambda = 76.5°$.

2. Decreased angle (α) in the vertical surface (d=7°) will be equal to α' and in the vertical surface at the direction of the inclined borehole will be equal to α''. For the mentioned joints, these two values are: $\alpha' = 52°$ & $\alpha'' = 78°$.

3. Length of the spacing (SP) on each horizontal line, which makes the p angle with the direction of the joint, will be equal to:

$Sph\beta = SP/\cos\alpha(\cos\alpha)$ which will be Sph13 = 101 cm for this joint (SP = 27 cm), as shown in figure 20.

4. Angle α' which is 52° in the vertical surface (d = 7°), will be 62° in the 097/75 inclined surface.

5. $SPG = Sph\beta \sin\gamma$ will be the value of spacing (SP) on the 097/75 grout curtain surface, which will be equal to 89 cm and clearly less than $SPV = Sp/\cos\alpha$, which is almost 130 cm (which shows a more number of joints).

6. Explanations on 113/78 joints are applicable to other joints and therefore, the structural drawing of the inclined grout curtain can be easily delineated having the values of θ, α and SP and angles λ and γ and the value of SPG.

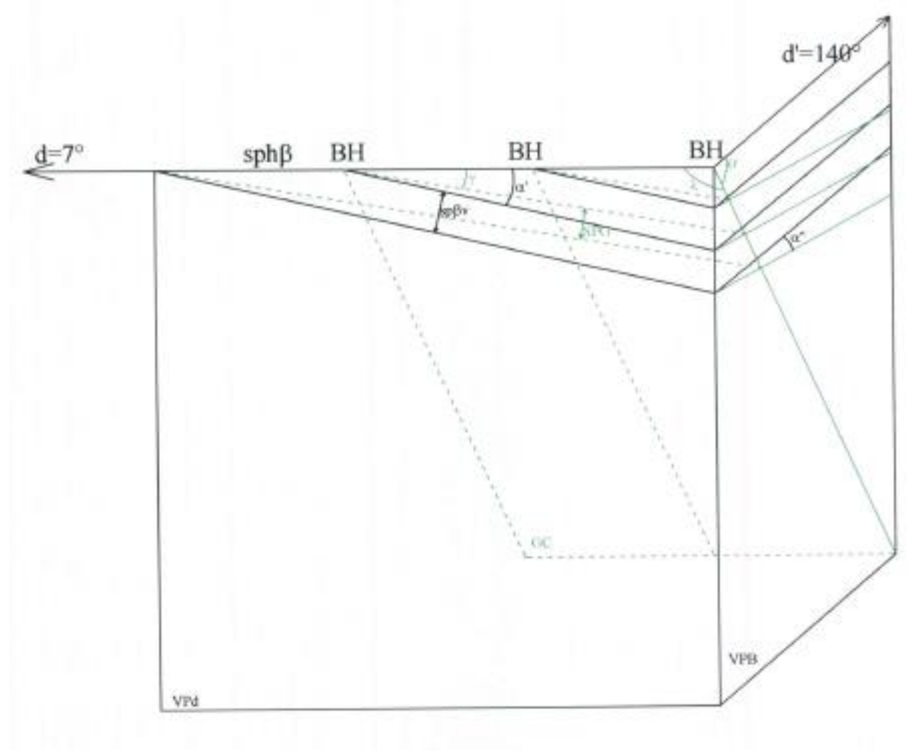

Fig. 19

demonstration of inclined borehole d’/θ’= (140/70) and joint δ/α = (113/78) on the inclined grouting curtain d/θ = (7/75).

VP =vertical plane of d 7°.

VPB = Vertical Plane along d’ (d’ = 140°)

GC = inclined grouting curtain.

α’, α” = reduced dip angle of joint on the vertical plans of d 7° and d’ 140°.

λ = angle between trace of inclined borehole on the GC.

(λ = sin-1 (sin θ’ / sin θ))

γ = reduced angle of joint on the GC.

($\gamma = cotg - 1\ (\frac{sin\theta' + tan\alpha' \cos k}{tan\alpha' \sin k}$), (k = π – λ)

sphβ = horizontal spacing of joint set on the line d 7°.

Borehole BH are lying on the GC.
SPG = inclined SP on the GC.
(SPG = sphβ sinγ)

CONCLUSION

1. With regard to the results obtained in the surface and underground investigations in the boreholes, the large number of vertical joints and fissures found with two dominant directions. Indeed, it is necessary to drill cross boreholes to have more appropriate and more numerous contacts with discontinuities and more appropriate grout to attain more success in water tightening.
2. For a better understanding, the conditions of boreholes presented in geometrical view, in both vertical curtains with vertical- inclined and inclined - inclined cross-borehole systems, as shown in Fig. 1. In the inclined cross-borehole system, there is a number of crosses and smaller areas found among the boreholes, which is itself a reason for the necessity of carrying out inclined cross boreholes to obtain more success compared to the vertical — inclined cross boreholes.
3. Regarding the effectiveness of the grouting radius, it again pointed out that the rhombic forms among the inclined cross boreholes have areas equal to one-half of the rhombus forms obtained in vertical-inclined boreholes. Penetration of the vertical-inclined grout obtained with smaller penetration radius but in the inclined-inclined cross borehole system, resulting a better overview of the grouting layout and attain more success. In addition, the construction has no additional cost for the inclined-inclined cross boreholes as well as increasing the grout radius and thickness of the curtain. Based on the results, drilling the inclined curtain plane, which will provide the best result in order to cover more joints.
4. It can be concluded from the above-mentioned descriptions that the grout curtain should drill with the inclined cross boreholes and spatial layout of 97/75, 114/75 and 130/75. These inclined borehole located in the three directions of the access tunnel to the dam crest and middle and lower grout galleries of the limestone rock mass is carried out with a better groutability. With an increase in the grout radius, the thickness of the water-tightening curtain increased and the hydraulic gradient (for a more appropriate longer performance) decreased, which is totally justifiable and necessary for construction purpose.

SUMMARY AND KEYWORDS

The most important morphological feature of the left abutment at the Gelevard CFRD dam site is the bend and change of direction in the Neka River course at the downstream and its crossing from the downstream of the left abutment at the dam axis. Different factors will provide a place for large seepage from the reservoir water into the tailrace and into the Neka River. Firstly, Existence of steep cliffs on the slopes and a very small distance between the dam reservoir and the Neka River pathway in the downstream. Secondly, the existence of dominant joints sets with 60 to 90 degrees dip and the E-W or SW direction which can connect the dam reservoir to the Neka River at the downstream left abutment, if its length is sufficient and in case of lack of appropriate sealing. These specific conditions make this project an especial case in terms of topography and morphology of the left bank of the Gelevard dam. In this project, drilling of investigation boreholes carried out in phase I and II in the constructed grouting gallery, indicating inclined grout curtain shall be selected with a dip of θ= 75 °, according to the estimation of elaborate discontinuities in the rock mass. Therefore, the grout curtains should also be inclined ones.

Based on the proposed design, the locating of the grouting gallery and dip of the joints, spatial layout of the grout curtain for the first 130 m will be 097/75. As the grouting gallery direction towards the dam axis has a double bend, the mentioned spatial layout will be amended after the first 130 m.

In order to elaborate the details of grouting curtain design, a set of discontinuities, specifically, the joints, have been considered. Grout boreholes within the LG1 grouting gallery shall be drilled in the cross inclined direction in the inclined plane of grout curtain.

1. ABSTRACT

The most important hydroelectric project in Colombia's history, located 171 km north of the city of Medellin (Fig. 1), HydroItuango will begin to operate partially in 2018 and with its full capacity in 2026. With 2400 MW of installed capacity distributed in eight Francis turbines, this megaproject icon of the Colombian engineering has presented many challenges before giving its light.

* *Étude de cas: Projet hydroélectrique d'Ituango – Relatif aux affaires géologiques et géotechniques dans la conception de la fondation du barrage en enrochement avec cœur d'argile.*

Fig. 1 Hydro-Ituango dam construction process november 2016 photographic taken downstream

HydroItuango features a rockfill-clay core dam of 235 meters high and 965 meters wide, located in the denominated canyon of the Cauca river. This dam has presented multiple difficulties during its construction process, mainly due to the geological condition of the area, which shows the confluence of two fault systems called Mellizo and Tocayo, along the two sides of the river and that have conditioned sensibly the design of the dam, particularly the left abutment, where, in addition to the faults, has a series of discontinuities with high presence of clay material and fractured rock.

In this paper, a solution to prevent that the clay core of the dam suffers from non-permissible differential settlement is presented, integrating the geology features by means of a 3D numerical model (Fig. 2), to evaluate the shear strains in the core, comparing them with the available results of the big scale triaxial tests, verifying the stability of the dam against construction process, full reservoir and seismic conditions.

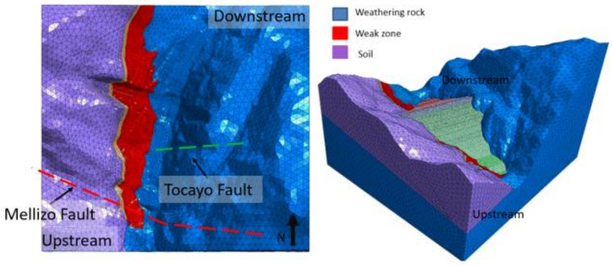

Fig. 2 Finite element numerical model-representation of the dam foundation and rockfill dam.

1. INTRODUCTION

Engineering technical standards are the basic criterion to guide the construction of engineering project[1]. However, the inadaptation of the related international engineering technical standards severely restricts the competitiveness of contractors in the international market[2]. Thus, improving the application level of international engineering technology standards will be great helpful to strengthen project execution ability. Foundation treatments, as the crucial part of hydroelectric project, will be able to keep the stability and improve the bearing capacity of foundation if the treatments are appropriate. But, there still exist some conditions where the engineers are not familiar with the technical standards for foundation treatments in the hydroelectric project. Sometimes, it can cause design errors, unreasonable purchase plans, construction costs increase, delay in time and other situations that relevant technical personnel don't have comprehensive understanding of the difference between Chinese and foreign standards. What's more, there is a lack of systematic and comparative research on the technical standard of foundation treatment for international hydroelectric engineering at present. As a result, the comparative research on international technical standards of foundation treatments have great guiding significance to contractors which will be beneficial for project completion.

2. CONTRASTIVE OBJECTS, CONTENTS AND METHODS

From the whole object, the foundation treatment measures for hydropower projects can be classified into dam foundation treatment and slope treatment, and from the concrete treatment measures, it can be divided into grouting, diaphragm walls, shotcrete, anchorage, deep mixing, etc. China-US standards are selected as the main object of comparison in consideration of Chinese and American hydro-related standards are relatively similar and comprehensive. The scope of comparison includes design and construction of foundation treatment. The standards of dam foundation and slope treatment and kinds of specific foundation treatment measures between China's electric power industry(DL), water conservancy industry(SL) and United States Army Corps of Engineers(USACE), United States Department of the Interior Bureau Reclamation(USBR) have been comprehensively and systematically compared. The standards contrast framework between China and the United States is shown in Fig. 1.

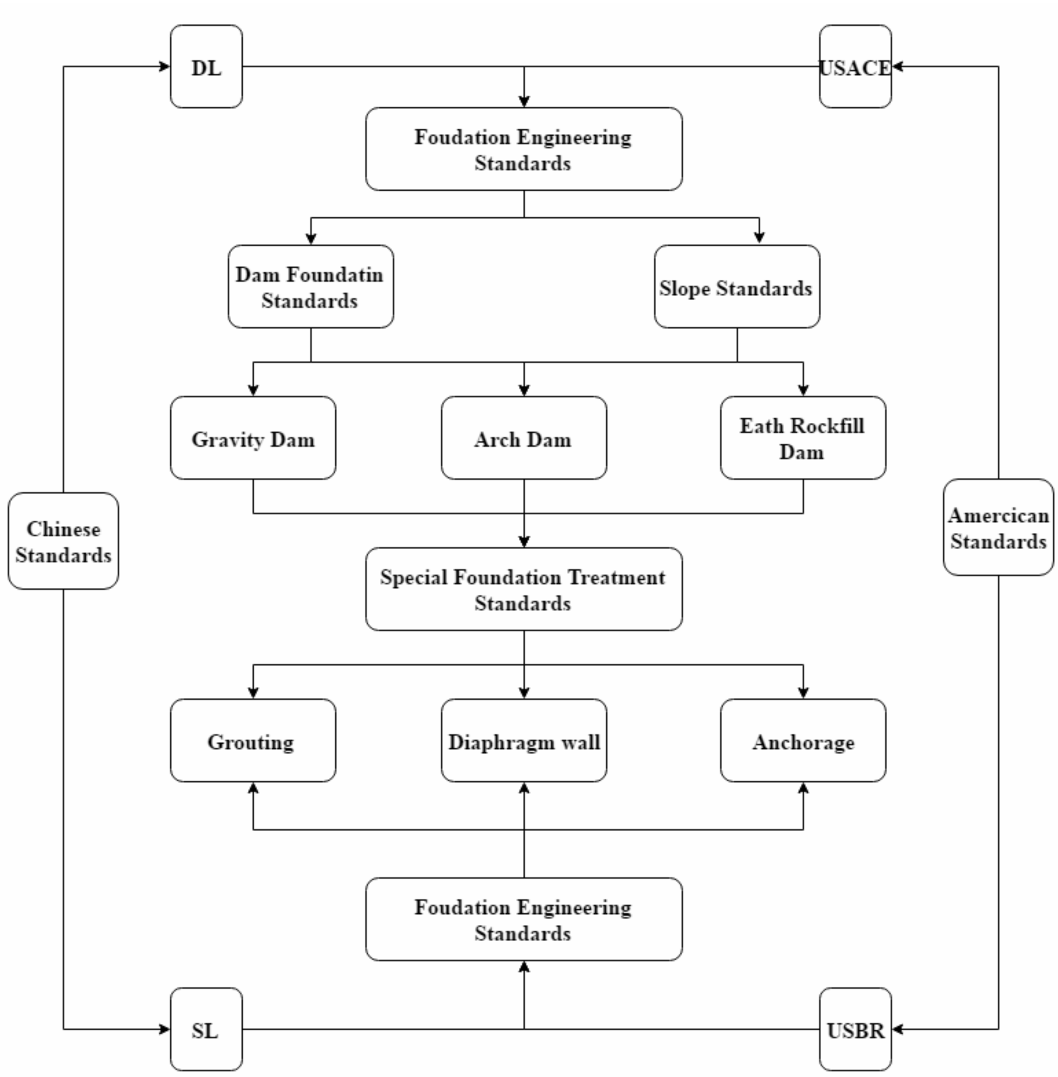

Fig. 1
Standards contrast framework between China and the United States

In order to compare the Chinese and American standards more rationally, hierarchically and systematically, based on Chinese standards as the basic contrast template, the comparison content can be divided into four parts: gravity dam foundation treatment, arch dam foundation treatment, earth-rock dam foundation treatment, slope treatment and specific foundation treatment measures. For the dam foundation treatment, the main contrast points are the treatment of excavation, consolidation grouting, curtain grouting, drainage and weak structural plane treatment. For the slope treatment, the points are excavation, drainage, reinforcement. As for the specific foundation treatment which also includes some the European countries' standards in addition to American standards, the differences in construction materials and technology are compared. Some of the compared standards have been categorized as shown in Table 1.

Table 1
Category of Compared standards

Object	Chinese Standards	American/ European Standards
Gravity Dam	Design Specification for Concrete Gravity Dams (SL319-2005)	Design of Gravity Dams (USBR)/1976
Arch Dam	Design Specification for Concrete Arch Dams (SL282-2003)	Arch Dam Design (EM 1110-2-2201)/1994
	Design Specification for Concrete Arch Dams (DL/T5346-2006)	Design of Arch Dams (USBR)/1977
Earth-Rockfill Dam	Specifications for Rolled Earth-Rockfill Dam Construction (DL/T5129-2013)	General Design and Construction Considerations for Earth and Rock-Fill Dams (EM 1110-2-2300)/2004

	Technical Specifications of Slope Construction for Hydropower and Water Conservancy Project (DL/T 5255-2010)	Rock Foundation （EM 1110-1-2908） /1994
Grouting	Technical Specification for Cement Grouting Construction of Hydraulic Structures (DL/T 5148-2012)	Grouting Technology (EM 1110-2-3506)/2017
Diaphragm Wall	Specification of concrete cut-off wall used for hydropower and water conservancy project (DL/T 5199-2004)	Execution of special geotechnical works —Diaphragm walls (EN 1538:2010)
Anchorage	Design Specification of Prestressed Anchorage for Hydropower Project (DL/T 5176-2003)	Rock Reinforcement (EM 1110-1-2907)/1980
Shotcrete	Construction Specifications for Anchor and Shotcrete Support of Hydropower and Water Conservancy Engineering (DL/T 5181-2003)	Standard Practice for Shotcrete (EM 1110-2-2005) /1993
Deep Mixing	Technical specification for deep mixing method (DL/T 5425-2009)	Execution of special geotechnical works —Deep Mixing (EN14679:2005)

3. COMPARISON OF STANDARD DIFFERENCES

3.1. OVERALL DIFFERENCES

The overall differences are as follows.

(1) The description of Chinese technology standards focuses on the requirements of principle and lack specific guidance on how to operate, leading to the difficulties for designers to understand and apply them. But at the same time, Chinese standards involve more contents and clauses than American standards. On the contrary, the American standards pay more attention to the instruction and explanation of operation methods, which is relatively comfortable to understand. Sometimes, it may adopt a long length to illustrate a concept or method, which Results in less content coverage.

(2) Chinese standards sum up a lot of experience, design parameters and requirements, the design and construction work of architecture can be completed according to the requirements of the code. However, it is easy to ignore the application and analysis of the basic theory. American standards attach great importance to the application of basic theory and for the specific project design, American standards can help engineers carry out a large number of calculation and analysis, giving full play to the initiative of engineers.

(3) The United States standards count the accidents statistics happened in constructed structures from the government level and develop deep analysis into published research findings which have great reference value to similar engineering projects. Chinese standards, by contrast, rarely involve engineering situation which causes many precious experience locked in a very small scope and hinders the exchange and process of technology. So It is suggested that the work of accident analysis and experience exchange should be upgraded to the government level.

(4) The source of many regulations can be found in American standards by the lists of related research references. Chinese standards, however, just give a pure rule which should be strictly implemented causing engineers not to know why they should do like this. For example, about the calculation of the thickness or length of the upstream pavement of the earth rockfill dam constructed on sand and gravel foundation, American standards give the reference of theoretical design method of pavement: “Bennett P.T. The Effect of Blankets on Seepage Through Pervious Foundations. Trans. ASCE, vol. Ⅲ, 1946.”. Chinese standards just give an explanation that the pavement should be gradually thickened from the upstream to the downstream, and the minimum thickness of the front end should be 0.5-1.0m. And any reference can’t be found.

(5) On the whole, Chinese standards, in which the requirements on design and construction are incline to keep safe, are stricter than American standards. Chinese standards care about ensuring structures’ safety and stability, but simultaneously the cost also increases, which may cause the waste of materials. For example, Chinese standards require the depth of curtain grouting up to the aquifers, but American standards don’t have this requirement.

3.2. DIFFERENCES ON MAIN COMPARE POINTS

3.2.1. Position of the base level for foundation

Chinese standards determine the base level for foundation by the weathering degree of rock mass(SL) or the the grading of rock mass (DL) The SL’s standards stipulate that “when the dam height exceeds 100m, it can be built on fresh, slightly weathered to weak weathered underlying bedrock. When the dam height is 100m to 50m, it can be built on the bedrock of gently weathered and weak weathered bedrock. When the height of the dam is less than 50m, it can be built on the middle to the upper of the weak weathered underlying bedrock."[3] The DL's standards demand that "high dams should be excavated to class II rock mass and can be excavated locally to class III rock mass. Moderate and low dams can be loosened properly."[4] The developing trend of construction base selection in Chinese standards is single weathered estimate to rock mass classification.

The USBR's standards determine the base level according to the maximum allowable stress in the foundation. The USACE's standards emphasize the application of the dam's stress to determine whether the foundation is suitable. The USBR's standards provide that the maximum allowable stress in the foundation should be less than the compressive strength of the foundation material, divided by the safety factor 4, 2.7 and 1.3[5], which are respectively for normal, extreme and extreme loading combinations.

The USACE's standards require that if the deformation modulus value below 500000 pounds per square inch (3.4GPa), the reasonable value of deformation modulus should be adopted to conduct stress analysis fully and if the stress of the dam are within the allowable stress range in a variety of conditions, the design is acceptable[6].

3.2.2. *The treatment of weak structural plane*

The USBR's standards introduce the "dental treatment" which means that weak planes and zones require special treatment in case of removing the weak material and backfilling with concrete, and develop general rules for guidance as to how deep transverse seams should be excavated. Based on foundation conditions and stresses at Shasta and Friant Dams, the USBR's standards have resulted in the development of the following approximate formula for determining the depth of dental treatment[5]:

$$\begin{aligned} d &= 0.002bH + 5 \qquad H \geq 150\,feet(45.72m) \\ d &= 0.3b + 5 \qquad H \geq 150\,feet(45.72m) \end{aligned} \qquad [1]$$

where:

H = height of dam above general foundation level.

b = width of weak zone.

d = depth of excavation of weak zone below surface of adjoining sound rock. (In clay gouge seams, d should not be less than 0.1 H)

These rules provide a means of approach to the question of how much should be excavated, but final judgement must be exercised in the field during actual excavation operations.

Chinese standards, however, just suggested that the depth of treatment can approximately equal to 1.0-1.5 times the width of the weak zones or determined by calculation, but didn't give the specific computational method.

3.2.3. *Cement grouting*

About grouting materials, Chinese standard “Technical specification for cement grouting construction of hydraulic structures” (DL/T 5148-2012) give the requirements of cement sieve: “The sieve residue is not more than 5% through 80 μm hole sieves”. and the demand of specific surface area: “The specific surface area of Portland cement is not less than 300kg/m^2”. But the quality requirements of slurry raw materials remain generally high in the foreign projects where the specific surface area of cement must not be less than 350 kg/m^2.and the sieve residue of American standard sieve is 0 through No.200 mesh (0.075mm)[7].

With regards to grouting pressure, DL/T 5148-2012 tends to make use of high pressure. The definition of “high-pressure cement grouting” can be found – cement grouting whose pressure exceeds 3 MPa. During the domestic grouting construction, the tendency of high-pressure grouting (⩾3MPa) is more and more obvious, it seems if the pressure must keep high enough to ensure the quality of grouting. However, in international projects, it is not thought to be better to use higher grouting pressure. Merowe Project and the Upper Atbara Project technically require that the maximum grouting pressure does not exceed 1.6 MPa (maximum hole depth exceeds 50m)[8].

4. CONCLUSION

The differences on foundation treatment technical standards of hydropower engineering between Chinese and American standards have been discussed. The results can be applied in the international hydropower project as a reference for engineers and technicians. Engineering standards are the critical guidelines for the construction of a project. Therefore, the standards need to be used in a specific project item should be clearly studied. The overall and some detailed differences on Chinese and American standards have been compared in this paper, and the differences between China and other countries such as Britain, Germany, France, Australia and so on, whose standards are often applied in international project, remain to be investigated more deeply.

SUMMARY

In recent years, China's international hydroelectric engineering business is growing rapidly, but the inadaptation of the related international engineering technical standards, in which the foundation treatment standards play an important role, has been seriously restricting the competitiveness of Chinese enterprises in the international market. In order to solve this problem, the comparation on foundation treatment standards of hydropower engineering from different countries has been studied. Based on the current understanding of the foundation treatment technology with respect to hydroelectric engineering, taking China-America standards as the primary object, foundation treatment measures as the main content, gravity dam, arch dam, earth-rock dam and slope as the key points, and excavation, consolidation grouting, curtain grouting and drainage as the chief route, the design and technical differences of the standards between China's electric power industry, water conservancy industry and United States Army Corps of Engineers, United States Department of the Interior Bureau Reclamation have been comprehensively and systematically compared. The core differences of gravity dam and arch dam lie in the location determination of dam base and the treatment of weak structural face. About the earth-rock dams, Chinese standards divide them into rolled earth-rockfill dams and concrete face rockfill dams and have the design and construction requirements respectively, but American standards just make unit regulations on earth-rock dam's foundation treatment. As for slope's treatment, specialized standards can't be found in American standard system, where relevant standards only introduce the concept of some treatments. However, Chinese standard system includes many slope specifications and provides corresponding detailed regulations. The comprehensive comparison shows that the overall requirements on foundation treatment of China's hydroelectric industry standards are slightly higher than the American standards, and China's electric power industry a little higher than China's water conservancy industry. This study will be hepeful to understand the differences of standard on foundation and slope treatment between China and America, and provides technical support for international projects to strengthen the performance capability of international projects.

1. INTRODUCTION

The Cathaleen´s Fall power station is a hydroelectric power plant, located on the river Erne at Ballyshannon in County Donegal, Ireland. It is owned and operated by the ESB (Electricity Supply Board) Group. The construction of the concrete gravity dam started in 1946 and was completed in 1955. The dam is about 256 m long and 10 - 27 m high and has an installed capacity of 45 MW. The associated reservoir has an area of 2 km². The catchment associated with the river is just under 4,350 km². To discharge floods, the dam is equipped with 3 spillway gates, each about 11.0 m long.

The dam was constructed in 11 blocks each with a vertical water bar detail labelled Blocks C to V. The dam was constructed in on average 1.2 m high concrete pours. Over the life span of around 60 years the mass concrete of the gravity dam has begun to leak at some of the horizontal construction joints. The main leaks were within the inspection gallery in blocks S, T, U & V (near the orographic right bank of river Erne) and on the downstream face of these blocks. These were on the north of the spillway gates. To the south of the spillway gates the main leaks were on the downstream face of blocks N, O & P. The inspection gallery and the downstream surface near the orographic left bank of river Erne were in good order.

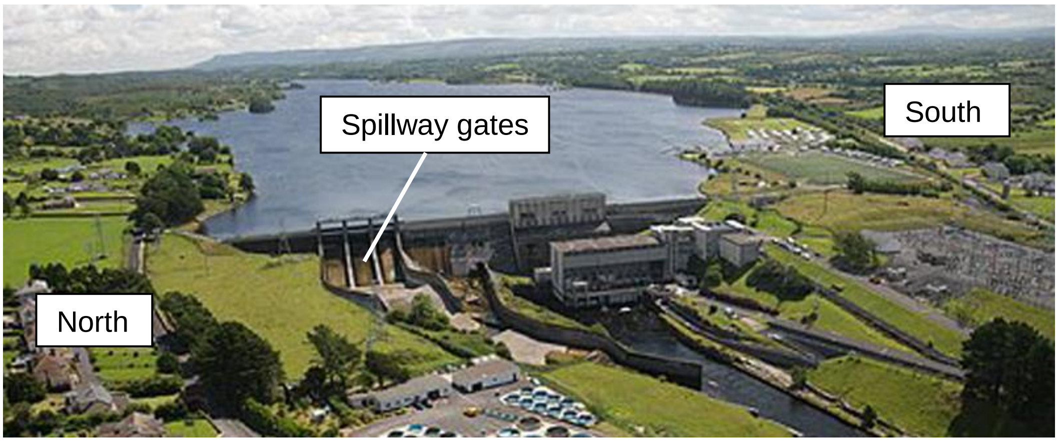

Figure 1: Aerial View of the Cathaleen's Fall Dam

2. DESIGN APPROACH

2.1. HISTORY AND FEASIBILITY STUDY

There had been leakage in the dam for many years since construction. Station Drawings from 1969 detail each leak on the face of the dam. Unsuccessful attempts to seal the leaks had been made in the past. In 1987 grouting was carried out by station staff in Block U from within the inspection gallery. In 2008 divers had tried to seal the upstream face of the joints using an underwater sealing material. None of these attempts had any long-term benefit.

As part of the management of Dam Safety within ESB, an External Dam Safety Committee (EDSC) advise ESB on Dam Safety at each of their installations in Ireland on an annual basis. In their 10 Year Inspection Report of 2010, the EDSC had recommended action to be urgently taken to reduce these seepages in Cathaleen’s Fall Dam. ESB considered different sealing options for the dam however the EDSC preferred option was to seal the upstream face of the dam using geomembrane. ESB investigated this option but ruled it out due to the number of the leaking construction joints being buried in rockfill. To carry out this method would have required underwater excavation works in rock on the upstream side of the dam to expose the joints and create space for sealing works. This would have been a hugely expensive project to undertake. Figure 2 shows the leaking sections of the concrete gravity dam including the section where some of the leaking construction joints were buried.

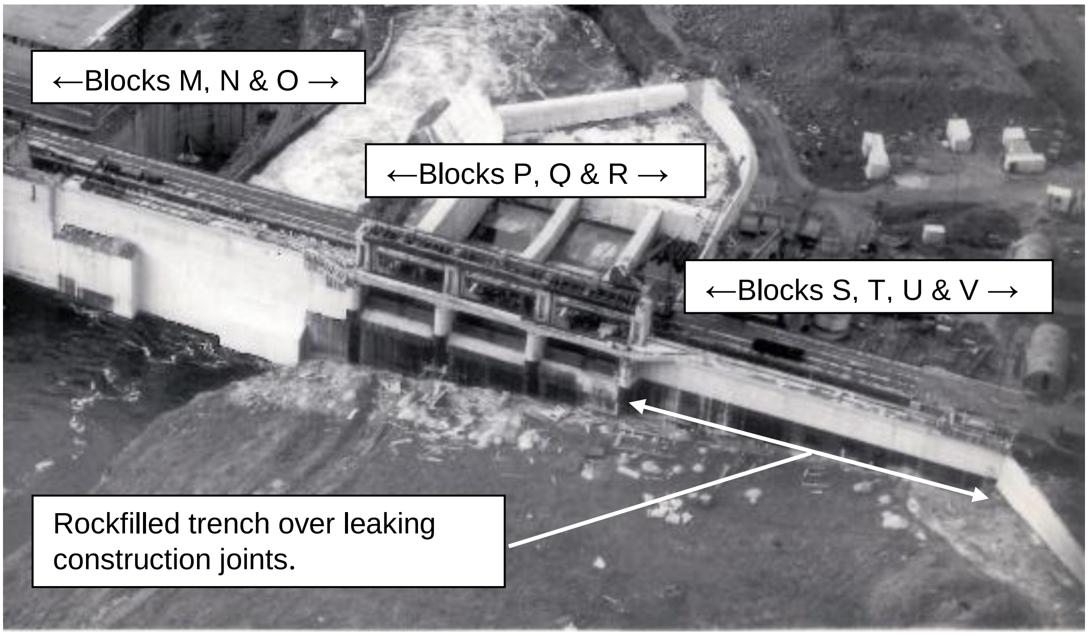

Figure 2: Upstream View of Affected Blocks - Prior to Reservoir Filling

Block O would have been considered the most difficult of blocks to seal due to its history. During construction of Cathaleen's Fall Dam, diversion channels with gates were constructed at Blocks M and O to facilitate completion of the closing Block N. After construction, the gate at Block M was retained as a scour gate and the channel at Block O was blocked up at the upstream end by means of a concrete wall. Over the years the cavities in Block O were filled with concrete on a phased basis. In 1995 the channel cavity was filled and in 1999 the redundant gate shaft was filled with concrete. The integrity of the cavity filling works was questionable and seepages from this block were evident for many years.

ESB consulted with an EDSC recommended Civil Engineer with Dam Sealing experience, Mr. Elmar Netzer from Vorarlberger Illwerke in Austria, who recommended further investigations including drilling boreholes in each block and carrying out water pressure tests. Mr. Netzer recommended drilling and grouting from the inspection gallery and the crest of the dam. ESB accepted this as the only technically feasible option for sealing the leaks.

Following these investigations, with the assistance of Mr. Netzer, ESB International prepared a detailed specification and tender documents for the proposed sealing works.

2.2. TENDER DESIGN

The proposed works involved extensive grouting of the upstream face of ten blocks in Cathaleen's Fall Dam, i.e. Blocks M to V. Grouting had to be carried out in stages, with each of the existing horizontal construction joints, as well as any voids, being treated. Water pressure tests had to be carried out in boreholes during the course of the works to monitor the adequacy of the grouting. Permanent drainage holes had also be provided to reduce the adverse effects of any remaining or future seepage.

2.2.1. Grout Holes

The grout holes in the inspection gallery had to have a minimum diameter of 46 mm and a maximum diameter of 72 mm with depths up to 10 m in downward direction and depths up to 5 m in upward direction. The grout holes on the crest had a depth up to 20 m in downward direction. The grouting sequence of the downward drill holes was bottom-up with ordinary portland cement or microfine cement. The packer had to be raised in a way, so that the packer is always midway between the joints. The primary grout holes were spaced at 2 m, and the secondary grouting holes 2 m between the primary holes, so that there is one hole every meter.

2.2.2. Requirements for Equipment

The drill rigs had to be of a suitable size for use on the crest and particularly in the confined space of the inspection gallery. The inspection gallery was 1.2 m wide and between 1.75 m and 2.1 m high and no widening of or cutting out of recesses in the gallery walls were permitted. The drilling method had to provide accurate results for judgement of the actual conditions in the dam – structural condition of in-situ concrete, cracks, joints, voids, porosity as well as the actual uplift pressure.

2.2.3. Requirements for Grouting Works

Since the dam had to remain in operation during the sealing works, high demands on grouting works were set. The flow rate had to be kept low – under normal circumstances well below 2 ltr/min. The maximum grouting pressures were limited as follows:

- from crest (35.36 m O.D.) to 29.5 m O.D.: 3 bar
- below elevation 22.0 m O.D.: 5 bar for cementitious materials and 4 bar for synthetic resins
- for elevations between 29.5 m O.D. and 22.0 m O.D.: the allowable maximum pressures had to be interpolated

2.3. Execution Design

In the year 2014 Züblin Spezialtiefbau Ges.m.b.H. was commissioned from the ESB (Electricity Supply Board) Group to seal the porous mass concrete with ordinary portland cement, microfine cement and synthetic resin. To meet all requirements for the equipment, the tender design had to be adapted partially in the execution.

2.3.1. Drill Holes from Gallery in Lot 3

The drill holes from the crest in Lot 3 – Spillway Blocks P to S – have been moved to the inside of the inspection gallery as shown in Figure 3. Upward drill holes with a depth of about 7 m simplify the construction progress as there is no need of a platform on the spillway. Furthermore, the discharging of floods over the spillway during the sealing works was guaranteed. The grouting of upward drill holes was only possible using lost single packers.

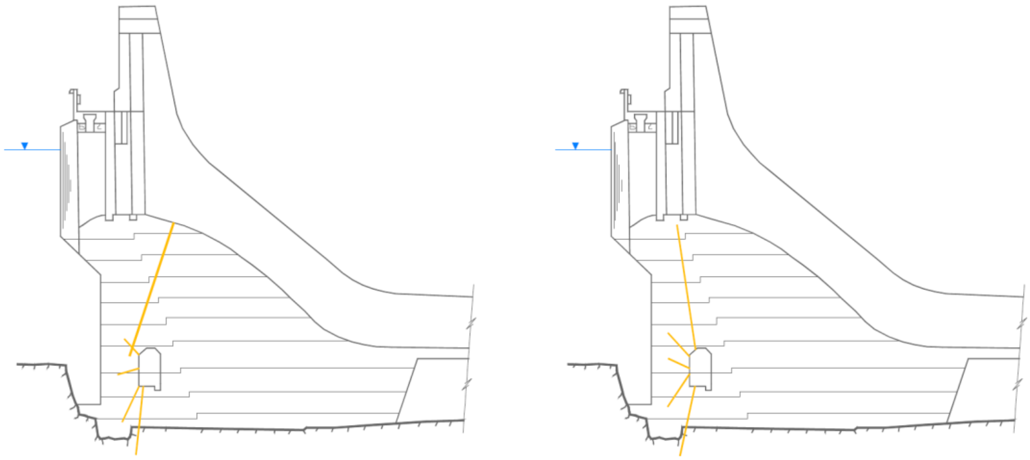

Figure 3: Tender Design (left) with Primary and Secondary Grout Holes (orange) – Drill Holes from Crest; Execution Design (right) with Primary and Secondary Grout Holes (orange) – Drill Holes from Gallery

2.3.2. Drill Holes from Crest in Lot 2

The secondary drill holes from the gallery in Lot 2 - Blocks M to P – have been moved completely to the crest. The use of the adequate drilling method made it possible to drill accurately between the inspection gallery and upstream side of the dam. The length of the secondary downward drill holes was up to 30 m. The primary drill holes have been kept inside the gallery and the crest as shown in Figure 4.

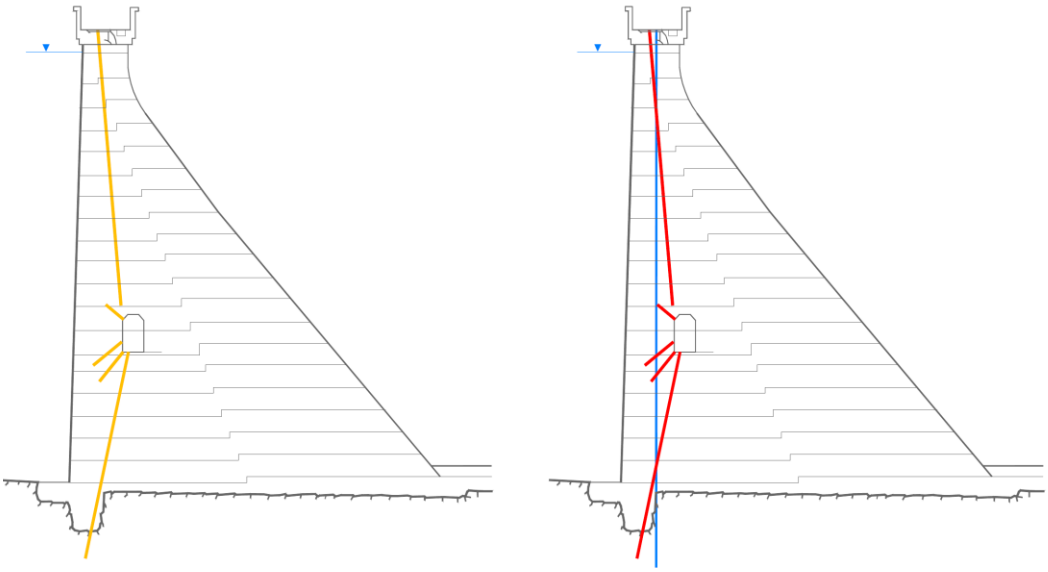

Figure 4: Tender Design (left) with Primary and Secondary Grout Holes (orange); Execution Design (right) with Primary (red) and Secondary Grout Holes (blue)

3. DRILLING WORKS

All drilling operations for the grout holes were performed as rotary core drillings (with diamond core bits) with 46 mm diameter, the drainage holes were performed with 86 mm. For the core extraction (core diameter of 33 mm), a double tube core barrel was used. Narrow space on the crest of the dam required the use of a small, light-weight portable hydraulic core drill. On the crest a Sandvik DE110 drilling equipment was used for the downward grout holes. Confined space inside the inspection gallery and the possibility to drill a grouting fan in 360 degrees required the use of a light rotary drilling rig Hilti DD200.

Figure 5: Drilling Works from Inspection Gallery (Hilti DD200)

4. GROUTING WORKS

Low pressure grouting was used to seal the slightly to highly water-permeable joints. Ordinary Portland Cement (OPC) and microfine cement was generally used to seal thin and slightly water-permeable joints, synthetic resin was used to seal highly water-permeable joints, as the synthetic resin has a high resistance to washout and a short setting time.

The first step of each grouting was the core extraction and judgement of the condition of the in-situ concrete, cracks, joints, voids and porosity. Based on these results, the single packer was brought into the right position within a centimeter to reach all leakages. Furthermore, it was reacted constantly to the actual grouting volumes to define whether tertiary drillings are necessary (split-spacing-method).

The basic grouting sequence was from coarse to fine. Generally, it was started with Ordinary Portland Cement (OPC) such as Dyckerhoff VARIODUR 50 and later grouted with finer materials such as Dyckerhof MIKRODUR R-F/E plus and MIKRODUR R-U/E plus. In exceptional cases (highly water-permeable joints and high flow velocities) synthetic resin such as Sika RODUR 505 / 510 was used.

The stop criteria had to be derived from the Grouting Intensity Number (GIN) and is described as follows:

- Cementitious Grouts: 40 ltr . bar / 1.20 m grouting length with a maximum grout volume of 50 liters / stage
- Synthetic Resin: 30 ltr . bar / 1.20 m grouting length with a maximum grout volume of 40 liters / stage

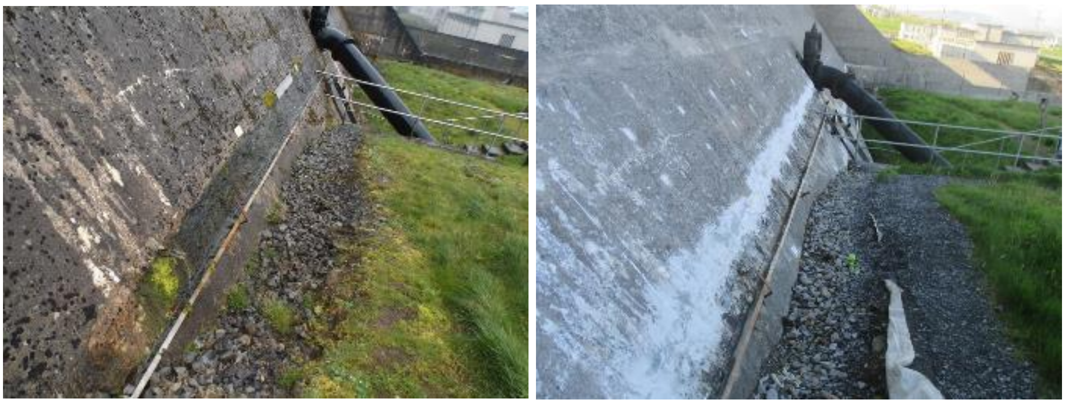

Figure 6: Photo of Downstream Face of Block U showing seepage (left) and results of sealing works (right)

In Figure 7 and Figure 8 the grout volumes per unit grout length are shown for the primary and secondary grout holes. It is clearly visible that the grout volumes have decreased from the primary to the secondary grout holes. The highest grout volumes were recorded in Block O, as there were possibly still remaining cavities in the section of the filled diversion channel.

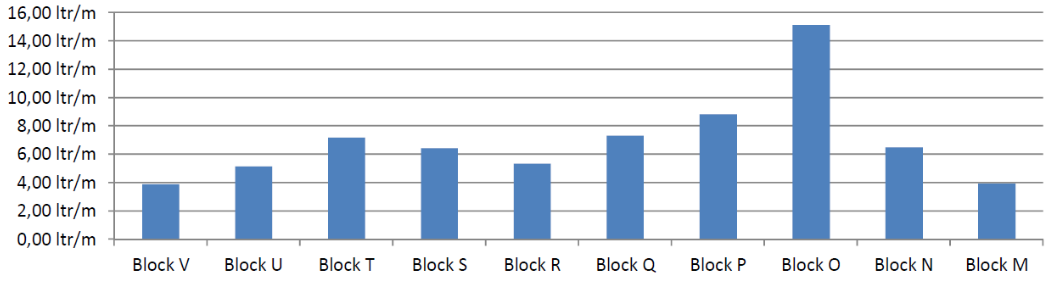

Figure 7: Grout Volume Per Unit Length (Primary Grout Holes)

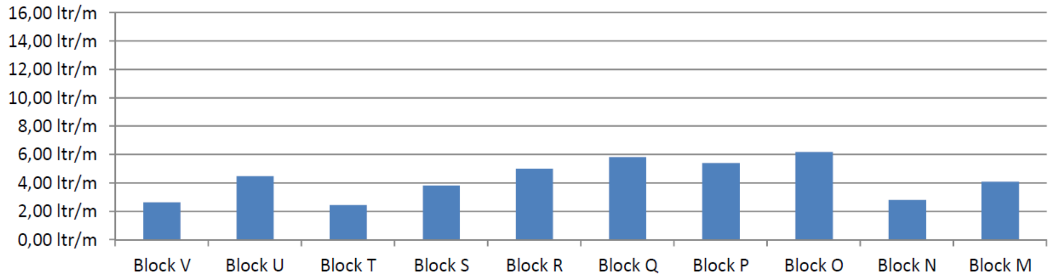

Figure 8: Grout Volume Per Unit Length (Secondary Grout Holes)

5. DATA LOGGING SYSTEM

The grouting module was equipped with a computerized data logging system which provides accurately and continuously monitoring of the grout parameters like flow rate, grout pressures and grout volumes. In Figure 9 (left) a GIN-Graph of a grouting sequence with cementitious material is shown. There the grouting stopped when reaching the GIN-Value of 40 ltr . bar / 1.20 m grout length.

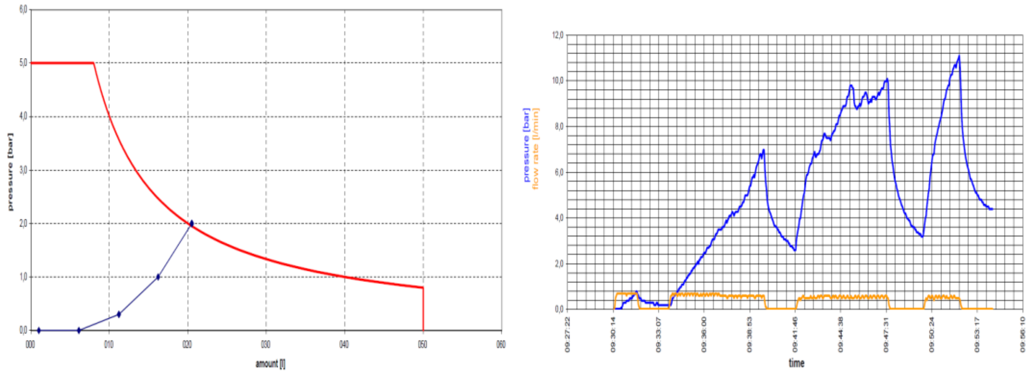

Figure 9: GIN-Graph (left) and Grouting Graph (Pressure / Volume)

In Figure 9 (right) a Grouting Graph of a cementitious grouting (grout pressure in blue, flow rate in orange) is shown. The grout pressure is steadily increasing until reaching the stop criterion. After every pump stop the pressure decreases and stays steady at the effective pressure (pressure at rest).

6. DRY CRACKS

The last operation was the frictional connection of the so-called “dry cracks”. These cracks were opening more each year and remaining open. Figure 10 shows the seasonal opening and closing of these cracks. The vertical axis shows the deviation from the baseline (mm) and the horizontal axis the date (years).

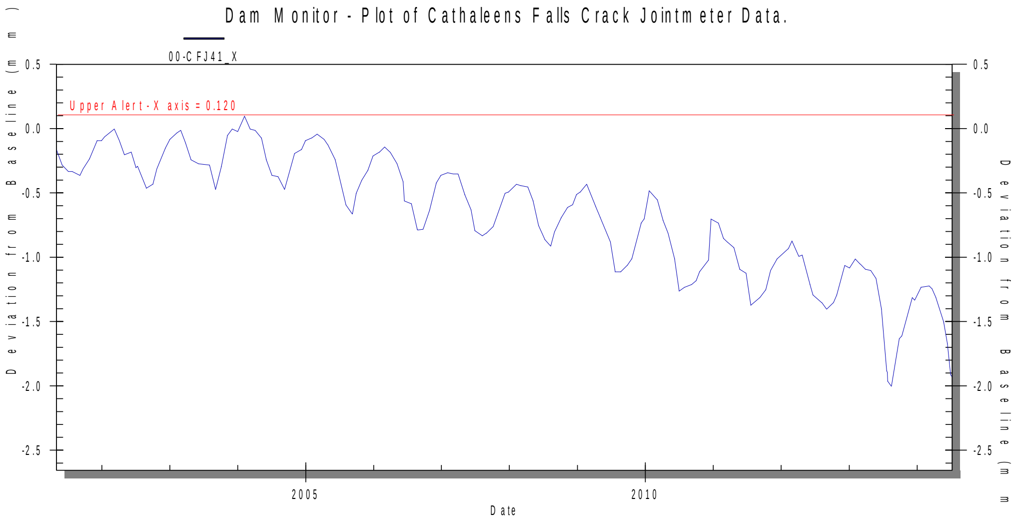

Figure 10: Seasonal Movement of Dry Cracks

These dry cracks were equally sealed and frictionally connected with low pressure grouting using synthetic resin. Figure 11 shows the grouting works of the so called “Dry Cracks” with synthetic resin.

Figure 11: Grouting of the "Dry Cracks"

SUMMARY

Over the life span of around 60 years the mass concrete of the Cathaleen's Fall gravity dam has begun to leak at some of the horizontal construction joints. These joints were sealed with low pressure grouting of microfine cement and synthetic resin. The entire work was finally completed in autumn 2014. The following graphs (Figure 12 and Figure 13) show how the grouting has successfully reduced the seepages in the dam. The vertical axis shows the seepage (ltr/s) and the horizontal axis the date (years).

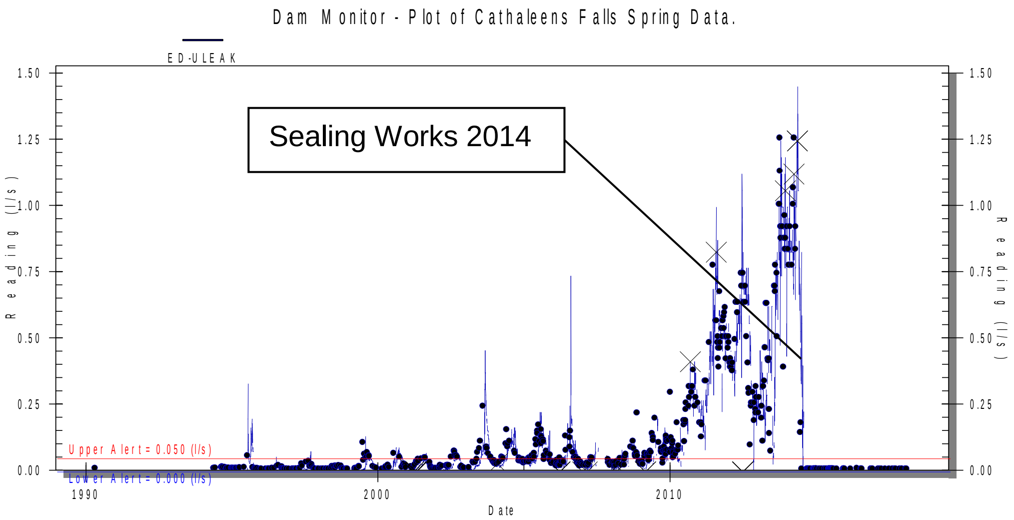

Figure 12: Plot of Seepage 'U Leak' on Downstream Face of Block U (showing results of sealing works)

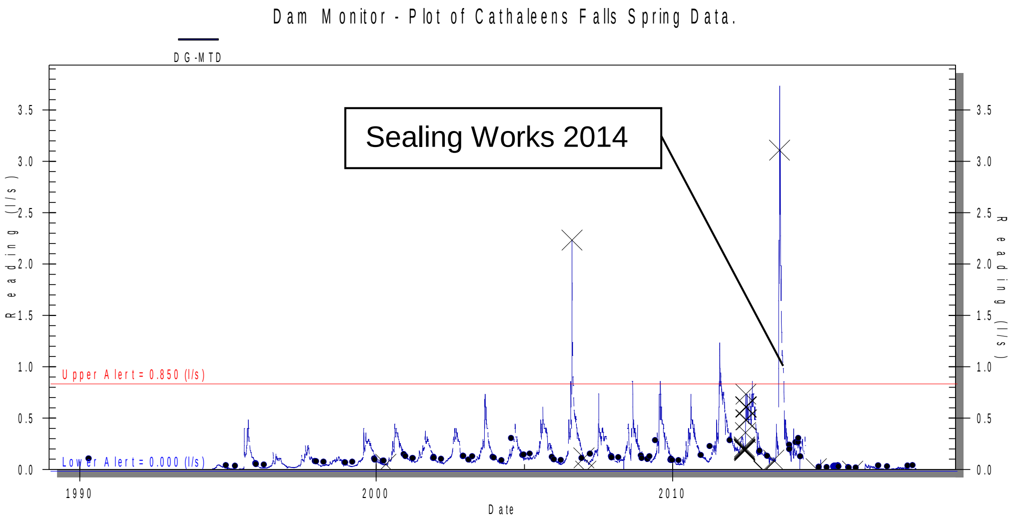

Figure 13: Plot of Seepage 'MTD' within Inspection Gallery from Blocks S & T (showing results of sealing works)

1. INTRODUCTION

Karst area all over the world always faces water scarcity. However, the water potential runs deep under the ground can be extracted using new technology and high-risk undertaking. The case study presented here is located in a Karst area of the Gunungsewu Geopark (1) Java. The discharge data was the results of MacDonald's & Partners in 1984, which gave a baseline for all potential of groundwater in Yogyakarta(2). This potential is seen as a pilot for the German-Indonesian IWRM project. Since the year 2007, the potential of the cave and its underground streams was under scrutiny. According to the two years feasibility study by KIT, an engineering approach can be used in damming this stream to elevate the height of water to 15m. Thus, the water can be pumped using its kinetic energy (Pump as Turbine) to the surface 100 meters above the cave(3). This study brought hopes of clean water for the severe drought season in the area. As this dam is located in the limestone bedrock 'deep-seated solution channels, the flow of water would not cause rapid erosion or cause instability of the dam' (4).

The catchment area of Bribin in the Gunungsewu Karst Region consists of 1300 km^2, which originated at Petung (surface) River, Gilap Cave, Luweng

Jomblangan (5). Most of the catchment is still forest, agroforestry or seasonal agricultural land. The Karst type consists of a mixture of labyrinth cone karst type: polygonal karst and residual cone karst with conical shape reached 30 hills/km^2 (5,6). With the precipitation rate between 2,000-2,500 mm/year, the average humidity is about 60%-90%, and temperatures of 24-28'C (5).

The Bribin Dam project also called Bribin II is supported by the German–Indonesian "IWRM" project, s of scientific, governmental institutions, companies of both countries to develop and implement the management strategies (3,7) of the first underground dam in a natural Karst cavern in Indonesia. The barrage design is of a multi-angular low-reinforced concrete with the dimension of 8.5 x 2.5 meter. This paper would focus on sharing the operation and maintenance experience of the Indonesian operational team of Bribin, from 2010 to 2017.

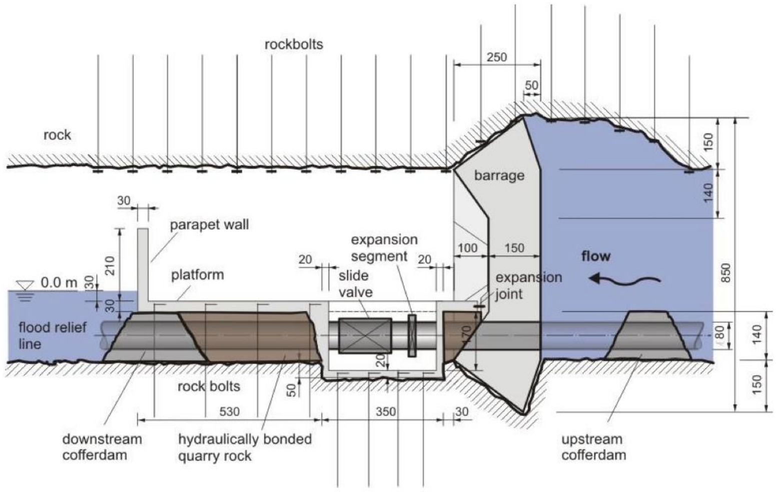

Fig. 1
Longitudinal Section of Bribin Dam (8)

This barrage is used (figure 1) with the pressure head of 15m in the upstream cavern and resulted in the volume of water yield of approximately 400,000 m3. However, this volume is not constant as the water is by-passed through pipes directly linked to Pump as Turbine (PaT) system with five modules, at approximately 400l/s per module. Thus, the hydro-power plant potential water supply discharge at full capacity is supposedly at 62l/s. A dry working platform connected to a vertical shaft housing these modules, where the PaT delivers the water 220 m above it (9). The natural Bribin river discharge is up to 1000 l/s, but due to the limitation of the PaT design and higher safety factors, the yield is only between 30 to 45 l/s (3).

2. CONCEPTS AND METHODS

2.1. CONCEPTS ON DAM OPERATION AND MAINTENANCE IN KARSTS

In general, the Bribin dam operations procedures mainly use the Standard Operating Procedures as the results of lengthy studies within the research cooperation of the German-Indonesian team (3). The lists of core duties:

- Heighten safety standard for a dam in Karst: concrete dam construction
- Dam operation rule curve: water level monitoring
- Hydrological data: upper stream precipitation data

However, as not much literature is found on dams in Karst, let alone an underground one. This condition places the case study in a unique position and a fragile one. The Bribin dam is the first attempt of its kind to be located in Indonesia. Earlier attempts were involving weir and PaT scheme, but not a whole cave structure as in Bribin. The literature review is using the Scopus indexed titles are reviewed on 78 titles, which then eliminated to 14, out of which three were about Bribin. These papers relate directly to underground dams in Karst area construction. Based on these, an overview of what to be expected in dealing with the maintenance of a dam in Karst areas are highlighted as the following check-up activities on:

- Equipment (pump, turbine, etc.)
- The behavior of the underground reservoir (Karstification, flood, etc.)
- Continual watertight structures (suspended grout curtain)
- Instrumentation for geological deformations (piezometer, etc.)

In this research, some of the following concepts are defined for the context of Bribin Dam: (1) normal operation, (2) flood operation, and (3) maintenance. Each of these concepts plays an important role in the daily activities of the Bribin Operation Team as they work 24 hours non-stop. To understand these definitions, the way the PaT system works in Bribin. This system is completed with the ASK and RKV modules as an additional by-pass (added in 2012 after the big flood in the rainy season of 2011/2012).

Firstly, in normal operation pattern in 2011-2016, it includes the condition of water level between 13-15 m. For this pattern, the required data to be calculated would be average discharge and yields annually compared to total annual discharge and yields ranging. Additional data to be compared would be annual rainfall pattern and its correlation to the discharge. This pattern also would highlight normal operation activities by the team. Second, flood operation is when the highest water level will be more than what the modules were designed for. Thus, the PaT will stop operating. The flood happenings set its pattern, which disturbs the normal pattern. This pattern related to the normal should be recorded for future data analysis. Third, the maintenance definition is when downtime is needed to check the equipment and supporting facilities for the dam to be operationalized.

2.2. METHODS

The methods used here are qualitative research tools. The primary data are acquired using site visits, interviews conducted with main respondents (operation team members), with a historical review of operation reports. The main respondents are the O&M team of Bribin hired by BBWS Serayu Opak, which has been actively involved since the construction phase. These individuals are of high value in the completion of O&M tasks annually and throughout these times. Site visits by the authors' team were done in 2016 and 2017 to make sure the conditions reported in the notes and reports are on point. Meanwhile, the historical reviews of the reports were gathered from 2010 to 2017. They began when the Bribin Dam is operational. The document analysis using Atlas.ti software and coded were based on the activities' types number based on the concepts: (1) normal operation, (2) flood operation and (3) maintenance, which later on being arranged historically. These printed materials were written in Bahasa Indonesia, German or English. All of the field data used are from 2009 to 2016 will be provided by the O&M project office of BBWS SO and the KIT.

3. RESULTS

3.1. DAM MANAGEMENT

This dam management is fully operating under the national government mandate, which is the river basin organization or BBWS Serayu Opak. The operation team at the location in Bribin is fully capable and has been following the development of the dam since its construction phase. The team is highly capable and experienced in managing the dam using the SOP that was put together with the German team. Based on reports and interviews, the following (table 1) are the management units of the Bribin Dam.

Table 1
Management Units of Bribin Dam

<table>
<tr><td>Underground dam and reservoir operation</td><td rowspan="2">BBWS Serayu Opak (National Government-Ministry of Public Works and Housing, Directorate General of Water Resources)</td></tr>
<tr><td>Pump as Turbine Operation</td></tr>
<tr><td>On land reservoir (Kaligoro) and water treatment plant</td><td>Satker CK SPAM DIY (National Government-Ministry of Public Works and Housing, Directorate General of Cipta Karya/ Human Settlements)</td></tr>
<tr><td>Water Supply Operation</td><td>PDAM Tirta Handayani (Local Government Owned Company)</td></tr>
<tr><td>Catchment Management</td><td>BPDAS Serayu Opak Progo (National Government-Ministry of Forestry and Environment)</td></tr>
</table>

Here these management units performed with the help of the German Team from KIT as the designer and researcher based on the Bribin logger data management (2010-2015), which consist of the water level data and geodetic measurement data. The cooperation continued with the transfer of knowledge in 2014 in managing the measurement data.

3.2. DAM CONDITION

Since the 2011 flood, the modules were submerged during the flood and not running. In 2012, additional modules being installed, the ASK and RKV (figure 3). These modules are by-pass pipes, which are used to evade floodwater. These submerged modules were significant concerns by the BBWS SO as they were not 100% functioning after the flood. Maintenance works were done to the PaT since 2010. Unfortunately, most spare parts for the PaT still need imports from Germany. Ever since then, the maintenance works were done in stages. Also as budgeting standard for the O&M at Bribin by the BBWS SO required one year in advance information, these maintenance works were not done timely. Flexibility for budgeting in this kind of pilot project is also essential for the successfulness of the project in the long run. In 2017, the current condition shows that the PaT and the platform are still functioning. Although, at times there were downtimes due to maintenance work, in principle the Bribin Dam can supply water up to 100l/s to the 369,000 residents of Gunungkidul in the Karst area.

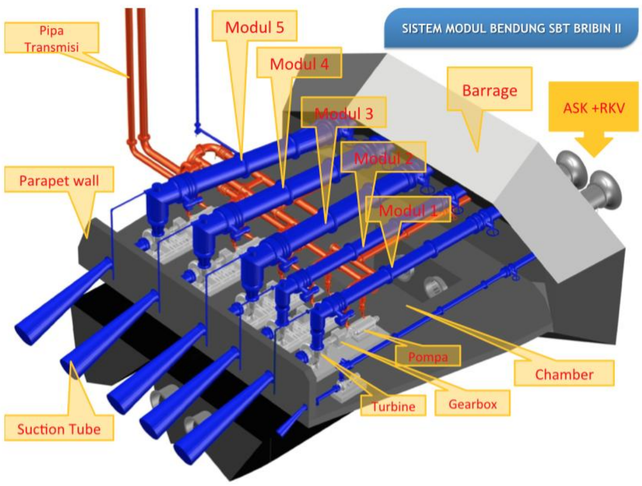

Fig. 2
Elaborated Diagram of Modules of Bribin in 2012 (10)

At other times the events of flooding submerged the platform, which stops the PaT from working and completely hinder the operation. In daily operation, the Bribin team does not have to come down to the platform (110m underground) but monitor through the equipment.

However, based on the interviews with the team members: the team does regular two times daily checkup to the platform (in morning and evening), using the generator run elevator. The main concern of the team; the electricity used for the elevator, the seepage submersible pump, and the instrumental components on the platform is also high, which made the operation of the dam not 100% electricity free as what the KIT suggest. Daily checkups consist of (1) temperature check, when it is over 90'C the module has to be stopped, but when under it, the module works continually, (2) seepage calibration, whether the sensors are working correctly and the submersible pump running, (3) nanometer check, whether it is showing the same number as the panel on the ground. Without the daily checkups the platform could be flooded, and the PaT cannot work effectively.

Fig. 3
The condition of Bribin in 2012-left (10) and 2016-right (BBWS SO documentation)

3.3. HISTORICAL REVIEW

This Bribin Dam review (shown in table 2) at the operational phase starts from 2010 to 2017. Reports, interviews, and notes on the dam operation and maintenance are used came from different sources: the German team and BBWS Serayu Opak team. These reports will be arranged using a timeline to compare and analyze also triangulate using Atlas.ti software to find the patterns of operation and maintenance of Bribin. The following patterns will be sought and numbered as (1) pattern of normal operation, (2) pattern of flood operation, and (3) pattern of maintenance, M for medium scale and L for large scale. The BBWS SO does all the operation, while the maintenance activities were done jointly. From 2010 to 2014, the KIT did the maintenance, while from 2015 and on, the BBWS SO fully maintain the Bribin II. Aside from these activities, the KIT provides annual assessment and monitoring, also consultation. However, the Bribin team at BBWS SO did most of the ground works and since 2014 has been self-reliant to operate and maintain Bribin II.

Table 2
Activities in Bribin Dam O&M (2010-2017)

Year	Condition	Operators	Activities	Type	Information
2010	Normal	KIT & BBWS SO	The first operation of Bribin Dam	1	Water level starts at 13m for the initiation of the operation
		KIT	Modules maintenance	3-M	Spare part change
2011	Normal	BBWS SO	Operation	1	Water level at 13m
	Flood	BBWS SO	Stop operating	2	Water level +15m
	Normal	KIT	Modules maintenance	3-M	Spare part change: all modules
2012	Normal	BBWS SO	Operation	1	Water level added to 14m, as discharge became more reliable
	Normal	KIT	Modules maintenance By-pass installed	3-L	Spare part change: all module Additional ASK and RKV modules
2013	Normal	KIT	Grouting campaign 3 Modules maintenance	3-L	Each grouting campaign has a risk of hydraulic breakthroughs Spare part change: all module
	Flood	BBWS SO	Stop operating	2	Water level +20m
2014	Normal	BBWS SO	Operation	1	Water level at 14m
	Normal	BBWS SO	Modules maintenance	3-M	Spare part change: all modules
2015	Normal	BBWS SO	Operation	1	Water level added to 15m
	Normal	KIT	Installing hanging structure	3-L	To strengthen cave walls and lessening vibration
	Normal	BBWS SO	Modules maintenance coupling change Elevator change	3-L	Rubber coupling and bearing of the PaT modules, spare part change, a safer elevator (with counterweight) and more efficient model (40kW to 15kW)
2016	Normal	BBWS SO	Operation of Bribin Dam	1	Water level at 15m
	Flood	BBWS SO	Stop operating	2	Water level 34m (October)
	Normal	BBWS SO	Modules maintenance	3-M	Spare part change: all modules Ring installations on the bypass
2017	Normal	BBWS SO	Operation of Bribin Dam	1	Water level at 15m
	Normal	BBWS SO	Modules maintenance	3-M	Module 1, 3, 4, module 5 (shaft sleeve, etc.)
	Flood	BBWS SO	Stop operating	2	Water level up to 64m and error occurred

3.4. Normal operation

Like any other dam operation pattern, Bribin's is also based on the water level in the reservoir. As the water discharges in underground streams also based on the rainfall, although it needs some time (5 hours) before reaching into Bribin. Thus, there are three basic patterns, wet year, normal year and dry year (PP No.37 on Dams). Indicators of wet, normal and dry are based on rainfall data in Gunung Sewu catchment (2). During normal operation, the current water level is maintained at 13-15m in the reservoir. This condition is due to the supply needs for the drinking water has to be between 40l/s to 60l/s. The PaT is automatic and works 24/7. However, monitoring of the water level also uses human to guard at all times in responding to a sudden change of the upstream condition, especially during rainy seasons. At least twice a day, the O&M team has to check the water level also the PaT condition (temperature, seepage, etc.)

by going down on to the platform using the elevator. This condition shows that the PaT is still in need of human monitoring, even if the modules are automatic.

3.5. FLOOD OPERATION

Flood operation of Bribin II differs as the dam blocks the whole river. Therefore, water level above normal standard operation (more than 15m) would be categorized as a flood. During this condition, all pump modules stop operating:

- Over 15 m: Modules off, ASK+RKV Open 100%
- Over 20 m: Modules off, ASK+RKV+BYpass Open 100%

During the flood, the PaT modules completely stop working and there is only one thing to do, which is to wait until the flood passed. At these times, the O&M team monitors the water level through the panels on the ground. As Bribin river system has input from three locations, it is also possible that sudden flash flood happens. The biggest flood happened on 29 Nov 2017, when the manual log shows these levels in comparison to the panel when the panel shows 64m at 13.40 and the error data of -3.4m at 16.31 (figure 3):

Fig. 4
Flood condition Bribin on 29th November 2017 (BBWS SO documentation)

3.6. MAINTENANCE

Maintenance in Bribin Dam includes all activities in getting the dam to operate normally. Hence, with the specific Karst context, it adds more than regular spare parts and oil change, it also asks for specific timing, especially as the modules work non-stop 24 hours. The following are the maintenance task for the O&M team: (1) Modules check, (2) Platform seepage, (3) Elevator and generator check, (4) Automatic water level and information systems (electrical). The maintenance check is done at least one time per year. However, due to the high humidity of the cave, there are always the possibilities that the equipment may run down faster than its actual normal lifetime. An excerpt of the annual O&M report is added here to visualize what the activities are consist of. These pictures (figure 4) are taken from 2016 report, where the team works tirelessly in keeping the Bribin Dam up and running. The personnel in this team has been trained to obey the Standard Operating Procedure and updated with new developments as the nature of the pilot project.

Fig. 5
O&M works in 2016 (BBWS SO documentation)

4. CONCLUSION AND RECOMMENDATION

Bribin dam as a pilot project for Indonesia has proven to be a success story, however, as it is the first underground dam in a Tropical Karst, several things that were not calculated at the first phase of construction and first years operation. These things are what made the Bribin, a unique dam, as it is a running project, which supports water supply, but also a research project: cave laboratories. This condition means that there are things not perfected when it was first installed. We have learned from the experience of the O&M team at BBWS SO, the range of activities varies differently and may be interesting to other countries who have similar dam projects in Karst area to make this idea of underground dam works. These activities are divided into normal condition operation, flood condition operation, and maintenance. These categorizations is used by the management unit will be able to note for future reference and transfer this knowledge.

Although there are some things, which were not done ideally as the design, the Bribin Dam is still functioning to supply the drinking water to the much-needed Karst residents of Gunungkidul Regency. Further underground dam development on similar Karst conditions must be as flexible as the current team to facilitate innovations. Other recommendations are: fully automatized operating modules, waterproof camera systems for monitoring, more intensive use of solar panels for all electrical equipment.

5. ACKNOWLEDGEMENT

The authors would like to express their gratitude to BBWS Serayu Opak and INACOLD for their continuous support in the writing process and also the chance to present this paper at ICOLD 2018.

SUMMARY

The paper focuses on the operation and maintenance experience of the Indonesian operational team of Bribin, from 2010 up to 2017. The methods used are document analysis of printed materials, reports and site visits and will be dealt through historical review. Lessons learned from this pilot project include normal tasks, curtain grouting injections, spare parts changing, coupling problems, etc., which enriched the Indonesian counterparts to excel on the operational experience on this subject.

Lessons learned from this pilot project's O&M is divided into normal tasks (daily operation tasks, data monitoring, advancing reservoir level, etc.), medium scale maintenance (spare parts changing, coupling fixing, etc.) and big scale maintenance (curtain grouting injections, additional grouting campaigns, lift change, etc.). These experiences enriched the Indonesian counterparts to excel on the operational experience on this subject.

Keywords: CONCRETE DAM, DAM OPERATION, RESERVOIR OPERATION and MAINTENANCE.

HYDRAULIC DESIGN OF DIVERSION-CUM-DEPLETION TUNNEL

Balkrishna Shankar CHAVAN

Scientist-D, Central Water and Power Research Station, Pune, India,

1.0 INTRODUCTION

A river diversion tunnel is used to divert river water during construction of a project. Once construction is over, diversion tunnel is plugged before initiating storage of water consequently tunnel part becomes redundant. No universally accepted standards are available for design of temporary structures like coffer dams and diversion tunnels. Tunnel construction has high costs and usually adopted when other solutions are unfeasible. To minimize the project cost, part of diversion tunnel can be reused for depletion of storage of reservoir water.

2.0 Components of diversion –cum- depletion tunnel-Main components of a water conveyance system for diversion of river water and depletion of reservoir consist of the following components:

1. Intake structures
2. Water conducting system (Tunnel) comprising of control structures.
3. Transition portion connecting diversion tunnel with depletion tunnel
4. Outflow structure, which joins river flow downstream

2.1 Intake structures Entrance

An intake is provided at the mouth of a water conveyance system for a diversion of river flow. It is designed with the following points:

1. There should be smooth entry of water in to the tunnel as water enters from the reservoir behind a dam or the pool behind a barrage into the tunnel.
2. There should not be any formation of vortices that could draw air into the water conducting system.
3. There should be minimum entry of sediment into the water conducting system.
4. Floating material should not enter the water conducting system.

2.2 Inlet structure: Inlet transition facilitates the flow acceleration, ensuring the transition from subcritical flow which is established upstream in the reservoir created by the construction of the cofferdam or, in some cases, the channel connecting the bed to the frame, to supercritical flow that occurs in the diversion tunnel. The implementation of this structure aims to promote sufficient air to the flow, so that it develops a pressure equal to atmospheric pressure along the tunnel. This avoids the possibility of reaching pressures near the water vapour pressure, reducing the risk of cavitations phenomena in the diversion tunnel and hence its erosion. Regarding installation of the inlet structure it may be implemented directly on the ground or resort to auxiliary concrete that supports it above the ground level.

For smooth entry of water in to the depletion tunnel, generally following elliptical equation is used

$$\frac{x^2}{D^2} + \frac{y^2}{0.33D^2} = 1 \qquad (1)$$

In the inlet structure design it is important to proceed to the analysis of flow velocities that are practiced within and upstream the structure. To this end, the ratio of the velocity flow in the control structure and velocity flow upstream the structure must be in a range of 2 to 5. In order to drain maximum water sometimes no curve is provided to bottom surface of tunnel which is in touch with invert of approach channel. The flow separation may occur in the transition river section with irregular section for the tunnel section, usually circular or horseshoe sections are used.

3.0 Geometric design

Sections usually adopted for tunnels are covered in IS 4880 (Part III, Hydraulic design) -2000[1]. Five basic design steps are outlined below:

The functional requirements are defined in a broad sense. They include all hydraulic and geometric requirements, ancillary and environmental requirements and limitations, logistics, and maintenance requirements.

Cross section: Area of cross section of a tunnel shall be of sufficient size 'to carry the maximum required flow on the head available and in addition shall conform to construction requirements.

Tunnel dimensions should be decided on the basis of economic studies so as to obtain a most economical section. The following should be taken into account:

Discharge passing through the tunnel flowing partial full is given by:

$$Q = \frac{2}{3} B C_d \sqrt{2g} H^{\frac{2}{3}} \qquad (2)$$

Where Q= Discharge passing through the tunnel in m^3/s

B= Width of tunnel in m

C_d= Coefficient of discharge

g=   Acceleration due to gravity

H=   Net head in m

Velocity in tunnel, computed by Manning's equation

$$V = \frac{1}{n} R^{\frac{2}{3}} S^{\frac{1}{2}} \qquad (3)$$

Where V= Velocity of water in the tunnel in m/s

n= Coefficient of rugocity for unlined tunnels may range from 0.04 to .06

R= Hydraulic radius in m, for sections other than circular R = 4

S= Longitudinal slope

3.2 Head loss- Following losses may be expected for flow in diversion Tunnel:

- Head loss in approach channel, if tunnel is located away from reservoir
- Head loss at intake entrance

$$h_e = k_e \frac{V}{2g}^2 \qquad (4)$$

Where

h_e , K_e are head loss and loss coefficient s respectively

K_e = 0.16 for square bell mouth entrance

= 0.03 for circular bell mouth

= 0.1 for gate wall rounded corners

Head loss due to gradual contraction

$$h_e = K_e \left(\frac{{V_2}^2}{2g} - \frac{{V_1}^2}{2g} \right) \qquad (5)$$

Here K_e =0.10

Other losses as at bends, transitions, etc.

Head loss due to tunnel friction, calculated with the help of Darcy Weisbach resistance equation:

$$Head\ loss = h_f = \frac{fLV^2}{2gD}$$

Where

h_f = Head loss in m

f = Friction factor

L = Length of stretch

3.3 Estimation of friction factor

Implicit equation for estimation of friction factor was given by Colbrook in 1939

$$\frac{1}{\sqrt{f}} = -2log\left[\frac{\frac{e}{D}}{3.7} + \frac{2.51}{Re\sqrt{f}}\right] \tag{6}$$

This equation is implicit in nature and needs time consuming iterative steps for its solution. Many investigators proposed approximate solution of the Colbrook equation in a form of explicit equation (some of them are listed in Annexure A).

Two power explicit equation given by the author Chavan (2017)[3] is very convenient :

$$f = \frac{0.0075\left(\frac{(4000)^{0.05}}{R_e}\right)}{0.25+\left(\frac{4000}{R_e}\right)^5} + \frac{20}{R_e} \tag{7}$$

Where f = Friction factor

R_e = Reynolds Number given by

$$R_e = \frac{\rho DV}{\mu} \tag{8}$$

μ = Coefficient of Dynamic viscosity

Exit head loss is

$$h_e = k_e \frac{V^2}{2g} \tag{9}$$

Discharging capacity- Discharge passing through the tunnel flowing full is computed backwardly, using known head loss, known conditions in which tunnel is being operated i.e. Reynolds number, and friction factor curves for operation characteristics of particular tunnel are prepared.

Based on the above losses, the diameter of the tunnel has to be fixed, such that it results in an overall economy. This is because if the diameter of a tunnel is increased, for example, the friction losses reduces

The tunnel diameter determined as a result of economic studies should be examined from practical considerations, such as space requirements for the excavating equipment and the section may be modified if necessary, based on the above considerations. A minimum height of 2 m is necessary. For mechanized handling of excavated material a minimum section of 2.5m x 2.5 m is required.

4.0 DIVERSION-CUM-DEPLETION TUNNEL – DOYANG PROJECT,NAGALAND

The Doyang H.E. Project envisages generation of 75MW power. It is located on river Doyang in Wokha district of Nagaland State. Project comprises 87.5 m high and 462 m long rock fill dam. During construction of dam river flow is proposed to be diverted through a 12 m dia. Diversion tunnel 633 m long is designed to pass the maximum flow of 2298 Cu.m per second. After construction of dam, it is proposed to make use of major part of diversion tunnel for depletion purpose by connecting it to the reservoir through 6.0 m dia. depletion (Gooseneck) tunnel. During depletion stage of reservoir, gooseneck tunnel is to be operated under maximum head of 37 m and discharge of 568 Cu.m per second.

General lay out plan of the project showing alignment of diversion tunnel, location of control gates, energy dissipation arrangement is shown in figure 1.

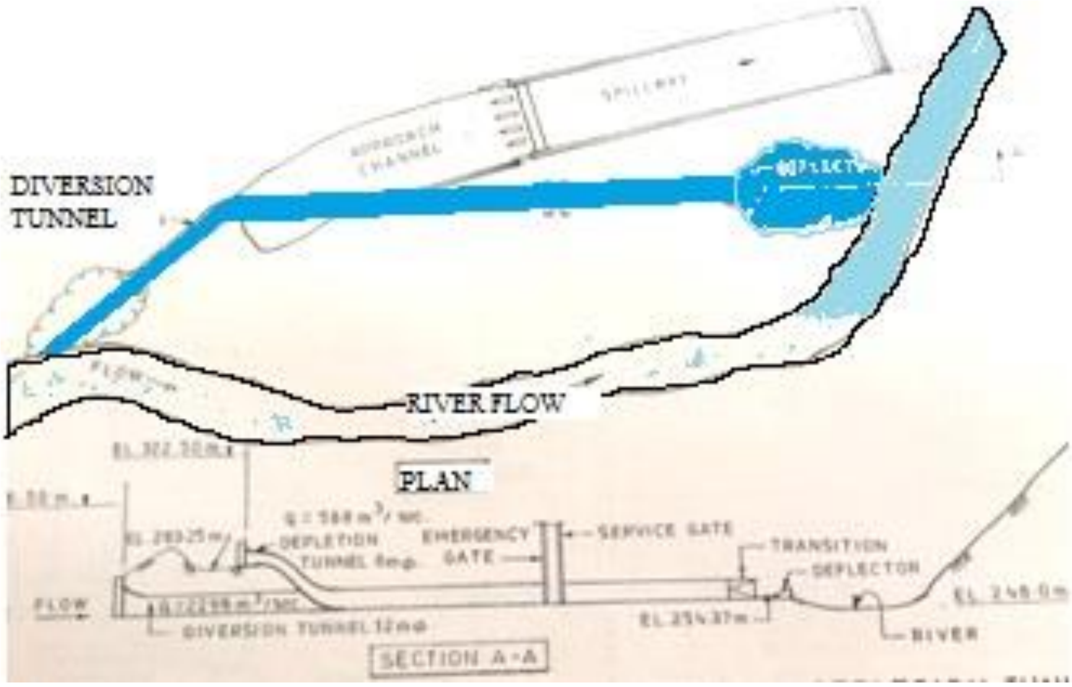

Figure 1.Alignment of diversion tunnel showing location of control gates, energy dissipation arrangement

SALIENT FEATURES OF DIVERSION-CUM-DEPLETION TUNNEL, DOYANG H.E. PROJECT, NAGALAND

(I) DIVERSION TUNNEL

Size of bell mouth entrance	:	9.5 m x 12 m
Length of transition	:	10.4 m
Diameter of tunnel	:	12.0 m
Length of diversion tunnel	:	633.0 m
El. of tunnel entrance	:	255.0 m
El. of tunnel exit	:	254.37 m
Design discharge	:	2298 Cu.m/sec

(II) DEPLETION(GOOSENECK) TUNNEL

Size of bell mouth entrance	:	5.0 m x 9.5 m
Length of transition	:	6.6. M
Size of gooseneck tunnel	:	6.0 m dia.
Elevation of tunnel at entrance	:	El. 287.0 m
(III) SERVICE GATE DETAILS		
Size of Gate	:	9.5m x 4.57m
Number of Gates	:	2 Nos
Head on gate at FRL	:	67.5m

Depletion tunnel comprises elliptical entrance, transition from rectangular to circular section,25m radius vertical bend straight circular section of 6.0m dia. followed by transition to join diversion tunnel.. Energy dissipater for the diversion-cum-depletion tunnel was required to perform for maximum observed flood discharge of 1500 Cumecs in diversion stage and 568 Cumecs under head of 37.0m for depletion stage. Diversion stage was to exist for 3-4 years where as depletion stage is a permanent feature. Keeping in mind site constraints and already constructed end portion of the tunnel, number of alternatives were suggested by NEEPCO, CWC and CWPRS. .Based on model studies and discussions deflector type energy dissipater without splitter blocks was finalized

5.0 THE MODEL

A 1/ 40 scale geometrically similar model of diversion tunnel including bell mouth entrance, circular tunnel, gate well, transitions was reproduced in smooth, transparent acrylic sheets. A high level steel-cum-masonry chamber was constructed to represent the portion of reservoir. Hill contours in the vicinity of entrance to diversion tunnel and depletion (gooseneck) tunnel was reproduced in masonry. A part length of river portion along with hill contours at tunnel exit was reproduced in masonry. For GS model of scale 1/40 various hydraulic parameters for the model are
shown in Table i

Table.1 Hydraulic Model Scale for Diversion-cum Depletion Tunnel

Scale type	Length scale	Flow velocity scale	Flow quantity scale	Force Scale	Roughness coefficient scale	Time scale
Actual scale	40	6.325	10120	64000	1.849	6.325

Discharge flowing through the tunnel was measured on a sharp crested Rehbock Weir with an aerated lower nappe. Hydraulic pressures inside the tunnel were observed with piezometric tubes by connecting them to a water manometer. Propeller type current meter was used for measuring velocity of flow. Hydrodynamic forces on service gates were measured with Load Cell fixed on service gate and gate operating mechanism.Load cell readings recorded for gate opening ranging fro 0 % to 30 % with gate opening interval of 10%.

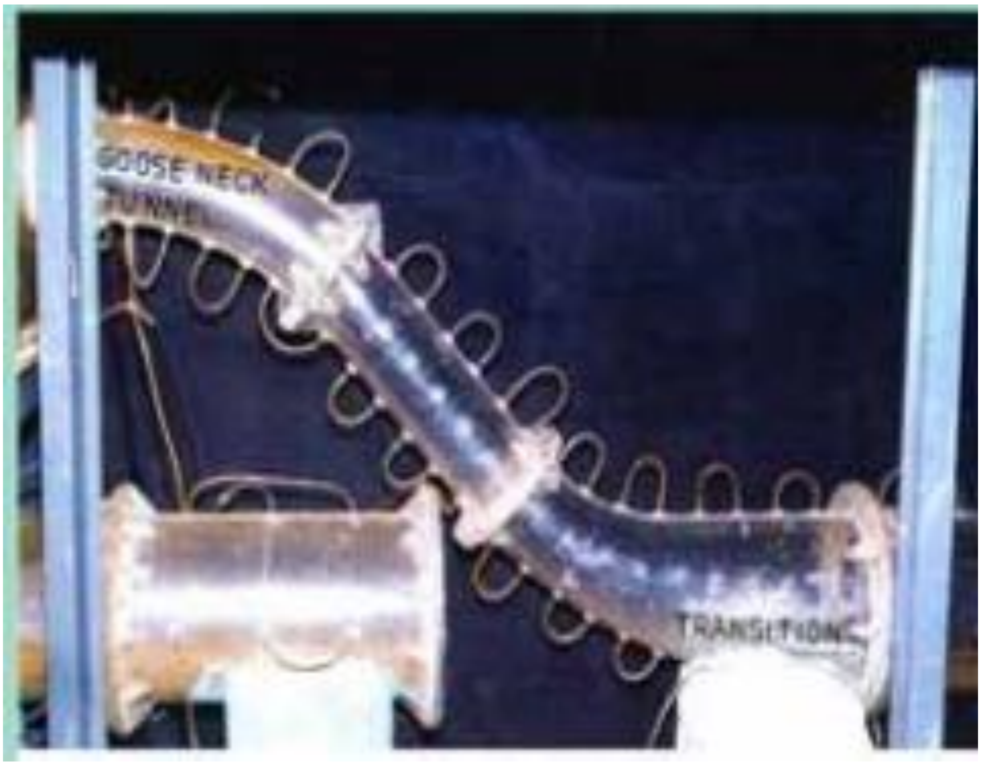

Figure 2 Photograph of the model showing diversion and depletion tunnels

Figure-3. Typical Set Up For Estimation of Hydrodynamic Forces on Service Gate

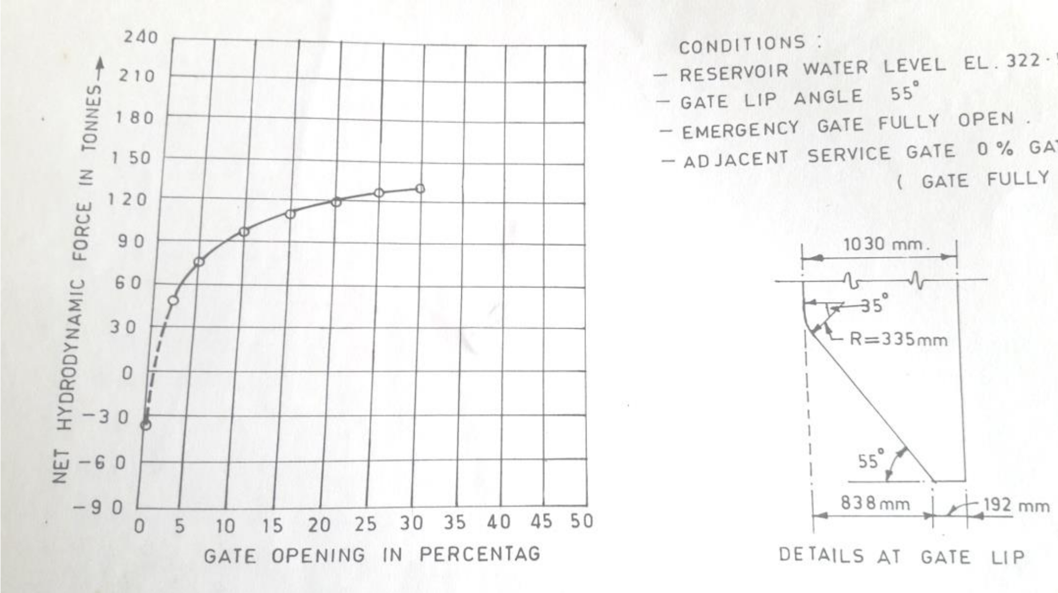

Figure-4. Results of model studies on Service Gate

MODEL STUDIES FOR ENERGY DISSIPATOR DOWNSTREAM OF TUNNEL EXIT

5.2 ALTERNATIVE DESIGN – I

Layout of the energy dissipation arrangement based on the site conditions consisted of a parabolic glacis followed by horizontal stilling basin. It was made curved (35 m radius) in plan to meet the river flow, as shown in the fig 3

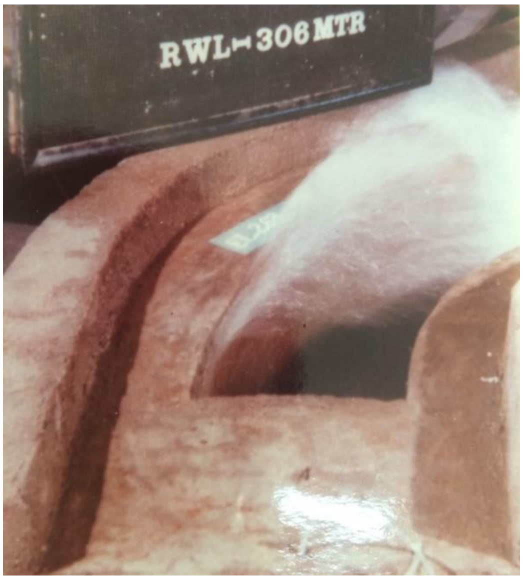

Figure 5. 35m Radial Curve type Energy Dissipator at the exit of depletion tunnel.

Studies for the maximum discharge during depletion stage of about 568 cumecs indicated that due to radial curve in plan, the high velocity jet coming out of the depletion tunnel was hitting and overriding the opposite sidewall as shown in photo-3

ALTERNATIVE DESIGN – II

Layout of the energy dissipation arrangement consisted of a parabolic glacis followed by stilling basin with horizontal apron with flaring sides in plan.

As requirement of sequent depth of 8 m below river bed could not be met with, performance of this dissipater was not satisfactory.

ALTERNATIVE DESIGN - III

Layout of the energy dissipation arrangement consisted of deflector having radius of 70.18 m,
exit angle of 13.5 and 15 degree (I) without splitter blocks

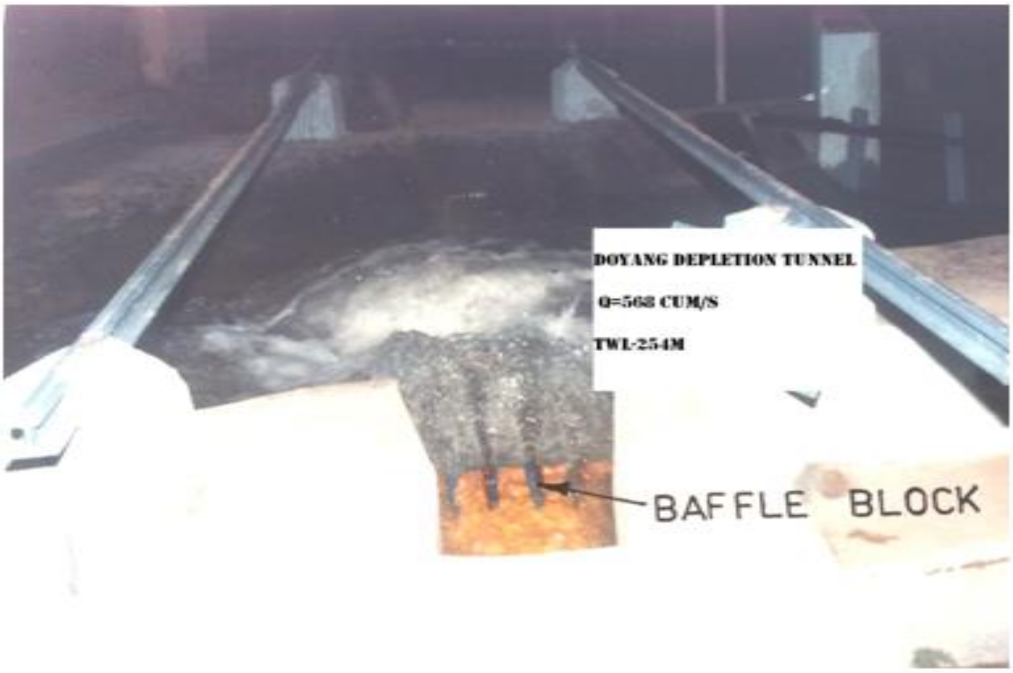

Figure 6. Photo of model showing Energy Dissipator with Baffle Blocks at the exit of depletion tunnel

(ii) with splitter blocks to improve energy dissipation by intermixing jets.

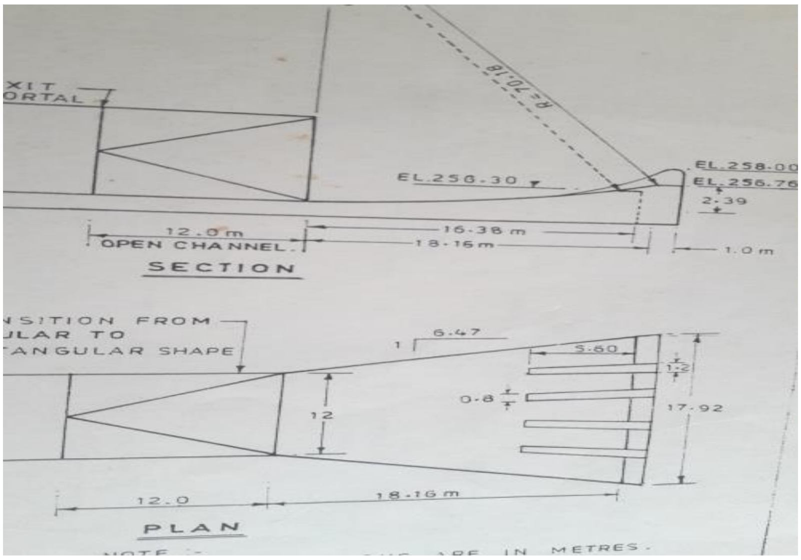

Figure 7. Deflector type Energy Dissipator with Baffle Blocks at the exit of depletion tunnel

DISCUSSION OF RESULTS

Selecting the energy dissipation arrangement for satisfying both conditions of diversion and depletion, model studies were conducted for

(I) Diversion stage discharge of 2298 Cu.m per second, with RWL 306 m.
(II) Depletion stage discharge of 568 Cu.m per second with RWL 322.5 m..

Design of the energy dissipater in terms of stilling basin running across the width of river with apron bed at 8 m below river bed were unsuitable due to fear of silting cistern of stilling basin .

The performance of the deflector type energy dissipater for diversion stage –

The performance of the deflector type energy dissipater studied in detail with velocity distribution. It was found to be satisfactory up to 1500 Cu.m. /second discharge. It was observed that high velocity jet after impinging in to river pool rushed along side slopes with rough (boiling) water surface and return flows in both directions. For discharge of 2298 Cu.m/sec, overriding of the jet extended up to el. 261.0 m. Return flow on right bank of river up to 60 to 80 m were observed in both directions. Observed velocities along left banks of river were in the range of 2m/s to 6.1m/s

Performance of deflector type energy dissipater for depletion stage

Deflector with exit angle of 13.5degree without splitter blocks it was observed that equally distributed jet impinged in to the river pool at about 60 m from the exit of the tunnel. Velocity along the right bank of the river varied from 2.5 m/s to 7.6 m/s.

Deflector with exit angle of 15 degree equally distributed jet impinged in to the river pool at about 70 m from the exit of the tunnel. Velocity along the right bank varied from 4.0 m/s to 5.6 m/s and 6.1 m/s to 6.9 m/s. for the conditions of with splitter blocks and without splitter blocks. To avoid the scour at the toe of the deflector tip before commencement of ski action for small tunnel overflows, suitable protective measures in the form of concrete apron or dumping boulders along full width of deflector was suggested.

For proper aeration of the jet issuing from the deflector a recess of about 5 m on either side of the deflector may be provided .It may effected by cutting the left riverbank and then joining the deflector through suitable curve.

RECOMMENDATIONS:

1. In order to reduce the heavy negative pressures on gooseneck tunnel, its profile is modified to parabolic shape
2. A suitable obstruction in diversion tunnel to reduce area to 25% to prevent negative pressures in gooseneck area .
3. According to model study maximum down-pull force of 180 tonnes and uplift of 36 tonnes is recommended for design of hoist capacity.
4. The transition from 12 m circular to 12 m rectangular in a length of 12 m to be provided between the exit of tunnel and beginning of the deflector (Fig. 5)
5. The deflector type energy dissipater with radius of 70.18 m exit angle of 13.5 degree without splitter blocks recommended for installation.
6. Suitable bank protection measures may be adopted considering maximum velocity along right bank to be without splitter blocks 6.9m/s and 5.6m/s with splitter blocks in energy dissipator .
7. For better aeration of the jet, recess on either sides of the deflector may be provided.
8. Bank protection works may be provided accordingly and toe of the deflector may be founded and keyed to hard rock.

SUMMARY

There are instances where part of river diversion tunnels have been used as depletion tunnel after construction of dam is completed. In India projects such as Yamuna, Doyang, Nagarjunsagar, Salal have successfully used the concept of multipurpose tunnel for diversion of river flow during construction of project and depletion of reservoir after construction of project is over. Hydraulic design associated with such tunnels has to function satisfactorily for high discharge at low head during construction and also high head low discharge during operation period of project. Present paper describes hydraulic problems associated with design of diversion cum depletion tunnel. Methodology adopted to arrive at solutions for design parameters in estimating frictional head loss, inlet transitions, energy dissipater at tunnel exit and smooth return of flow to river downstream of the structure. Design parameters are illustrated with a case model study of Diversion-cum—Depletion Tunnel, Doyang Hydro Electric Project, Nagaland, conducted at Central Water and Power Research Station (CWPRS).

Paper starts with describing various components of a tunnel. Frictional loss estimation in a tunnel flow by implicit and explicit equations given by various investigators is discussed in detail. Flow control structure such as emergency / service gate needs hoist for operation of gates. Estimation of hydraulic uplift / down pull is essential for finalizing the gate hoist capacity. Energy dissipater downstream of tunnel exit is important to mitigate erosion of river banks. Various alternatives for energy dissipaters studied in the model are described.

ANNEXURE-A

TABLE-2 Application of Friction Factor Formulae

No	Investigator	Year	Formula	Validity Range	R^2
1	Chavan	2017	$f_f = \frac{20}{Re} + \left[\frac{0.0075\left(\frac{4000}{Re}\right)}{0.25+\left(\frac{4000}{Re}\right)^5}\right]^{0.05}$	Valid for wide range of Reynolds number	0.9777
2	Morrison	2013	$f = \frac{16}{Re} + \left[\frac{0.0076\left(\frac{3170}{Re}\right)}{1+\left(\frac{3170}{Re}\right)^7}\right]^{0.165}$	Inaccuracy crept in for higher values of Reynolds numbers

RESEARCH ON CONTROL MEASURES OF LIMNOPERNA FORTUNEI IN PUMPED STORAGE POWER STATION WATER DELIVERY SYSTEM

Sheng WAN[1,2] Xueshan LIU[2]

1.Hubei Key Laboratory of Road-bridge and Structure Engineering,
2.Qingyuan Pumped Storage Power Generation Co., Ltd

CHINA

1. INTRODUCTION

In the region of southern power grid, there are Guangzhou Pumped Storage Power Station and Huizhou Pumped Storage Power Station, while Qingyuan Pumped Storage Power Station (PSPS) will be soon put into operation. Due to the characteristics of water quality in Guangdong Province, the Limnoperna fortunei will breed in the water delivery channels. For this reason, the specialized studies on the prevention and control of Limnoperna fortunei or are carried out.

2. CHARACTERISTICS OF LIMNOPERNA FORTUNEI

2.1. BIOLOGICAL CHARACTERISTICS

Impersonate fortunei is a gregarious mollusks belonging to freshwater mussels, with a thinner shell and developed byssus. They can usually form densely stacked groups, with a growth thickness of up to 3-5 cm, and they live on diatoms, protozoa, organic debris in the water body [1]. For the eutrophication of water body, the water dissolved oxygen content is low and it is not conducive to the growth of limnoperna fortunei; a big turbidity of water body is in favor of the formation of mud membrane on the water delivery buildings or facilities, which is conducive to the attachment of limnoperna fortunei. Studies have shown that the limnoperna fortunei has a stronger reproductive ability and a fast growth when the water temperature is at 16 - 28 ℃ [2]. The floating stage of the early lifecycle of the limnoperna fortunei is key to its distribution and at this stage, the water temperature and dissolved oxygen are the main determinants affecting the larva life [3]. The breeding season of the limnoperna fortunei is generally February to September each year, and the best breeding season is March through July. At this stage, it is required to make adequate preparations for the breading [4]. The survival period of limnoperna fortunei is generally two years or so [5].

2.2. HAZARD ON WATER DELIVERY BUILDINGS

In the late 1960s, limnoperna fortunei invaded Hong Kong, resulting in a pollution density of 11,000 limnoperna fortunei per square meter in the pipelines and pumping stations, and they formed a permanent breeding population since then [6]. The breeding of a large number of limnoperna fortunei not only reduces the orifice area of the water delivery pipelines [7], but also increases the pipe wall roughness. The intercepted limnoperna fortunei before the grille will not only reduce the discharge capacity of the grille, but also plug or block the pump station pipelines and power station cooling water pipelines. The limnoperna fortunei consumes the dissolved oxygen in the water during its respiration and excretes the ammonia nitrogen and nutrients during the metabolism [8], which will result in that the shell attached to the wall is rotten to produce bad smell and deteriorate the water quality so as to indirectly cause the corrosion of water machinery system. In addition, globally, there have also been examples of the destruction of ecosystems caused by the migration and multiplication of limnoperna fortunei, resulting in its infringement into the local water delivery pipelines and water conservancy facilities as well as the ecological structure of local water bodies [9].

3. RESEARCH SITUATION OF PREVENTION & CONTROL MEASURES OF LIMNOPERNA FORTUNEI

At present, the prevention & control study of limnoperna fortunei is generally aimed at the water delivery pipeline of conventional waterworks, and the study simply on the large cross-section and large flow of hydroelectric power plants has not been carried out yet. In general, the prevention & control measures generally include the following aspects:Biological prevention & control, Surface painting, Manual and mechanical removal and Chemical prevention & control.

4. STUDY ON TREATMENT OF GUANGZHOU PUMPED STORAGE POWER STATION

4.1. GENERATION OF LIMNOPERNA FORTUNEI

Guangzhou Pumped Storage Power Station (hereinafter referred to as “Guangzhou PSPS”) is divided into A/B plants and it is built by two phases and it is put into production in 2000.Guangzhou PSPS found a large amount of limnoperna fortunei when it drained the downstream waterway of Plant B on October 11, 2012. The downstream waterway of Plant B was drained up in October

2008 and there was no such a situation at that time. It was thus determined that the large population of limnoperna fortunei was bred in the four years from November 2008 to October 2012.

3.2.1. Water quality of the reservoirs:The water quality monitoring report of the Pearl River Basin Water Environmental Monitoring Center shows that the large population of limnoperna fortunei in surge shafts and culverts has not yet led to the deterioration of water quality in the reservoir areas. The water quality of Guangzhou PSPS upper reservoir was among poor nutrition and medium nutrition, and the water quality of lower reservoir was in a state of medium nutrition. The abundance of phytoplankton was at the lower middle level and the clear water species predominate. However, the eutrophic cyanobacteria appeared in the lower reservoir and became the dominant species, which indicates that the water quality and nutrient level of lower reservoir was higher than that of the upper reservoir.

3.2.2.Gregarious causes:The bottom material (or sediment) of lower/upper reservoirs in Guangzhou PSPS is sand, only with scattered limnoperna fortunei in the sediment. The limnoperna fortunei gathered and distributed only on the rough stone walls in the shade of individual banks in lower/upper reservoirs, which indicates that the water quality and sediment condition of the reservoir areas in the reservoir areas were not suitable for the large-scale reproduction of limnoperna fortunei. However, they were bred largely in culvert waterways, which indicates that the main factors affecting the distribution of limnoperna fortunei in Guangzhou PSPS is not the water quality, but the sunshine and attachment matrix, and other factors.

4.2. TREATMENT MEASURES

4.3.1.Selection of prevention & control materials:According to the selection principle of environmental protection, safety and construction features, 16 sorts of materials were selected for the experiments.

4.3.2.Experiment methods:The erosion effect of limnoperna fortunei on the concrete was evaluated by immersing the concrete specimens in flowing water for a certain period of time and then taking them out to test the compressive strength, superficial porosity, depth of carbonization and other indicators; after different protective materials were sprayed or coated on the concrete specimens, the limnoperna fortunei were attached naturally or manually to the specimens in the laboratory sinks. After the attachment was stable, the adhesion resistance of protective materials against the limnoperna fortunei was quantified and evaluated by regularly observing the adhesion density, biomass, attachment rate, lethality, escape rate, byssus number, adhesion and other indicators. In combination with the safety, construction property, durability and economic benefit of the protective materials, the selected protective materials were comprehensively selected.

4.3.2.1.Natural attachment experiment:The specimens were soaked for about 9 months. Because only one side of some materials were painted, the black bold numerals in the table represented the blank base without any coating. Facing the downstream direction of the water sink, the base of the left side is defined as the left and the base of the right side is defined as the right. Due to a limited space, only a part of test results are cited here.

Table 1

4.3.3.Test Results

4.3.3.1.Adhesion resistance:Centered on the natural attachment density and biomass and supplemented by the remaining test results, SK-polyurea 1, silane impregnation, SK-epoxy YEC and fluorocarbon resin presented a better performance in all indicators, and followed by modified silicate, modified acrylic resin and cementitious permeable crystals.

4.3.3.2.Erosion resistance:From the perspective of erosion resistance, especially carbonization resistance, we can learn that the effect of SK-polyurea 1, SK－epoxy YEC, modified elastic epoxy resin and SK-polyurea 2 are better in all aspects, but SK-polyurea 2 will be blistered after being immersed in water for a period of time, which will affect the durability. Therefore, according to the erosion resistance performance, SK-polyurea 1, SK-epoxy YEC and modified elastic epoxy resin are the best painting materials. However, it shall be noted that, for new concrete, if polyurea and epoxy are selected, the construction time shall not be too early according to their performance of compressive strength and the painting operation cannot be carried out until the concrete is fully hydrated. For the existing concrete, if a better construction effect will be guaranteed, certain construction conditions (for example, surface moisture content shall be within a certain range) shall be satisfied before the construction.

4.3.3.3.Comprehensive result:The attachment experiment results show that SK-polyurea 1, silane impregnation, SK-epoxy YEC, fluorocarbon resin, modified silicate, modified acrylic resin and cementitious permeable crystals have a better adhesion resistance. Considering a poor durability of silane impregnation and fluorocarbon resin and a higher cost of polyurea and other factors, SK-epoxy YEC, modified acrylic resin and cementitious permeable crystals are recommended as the suitable protective materials for concrete in combination with the consideration of adhesion resistance, erosion resistance, environmental protection, construction feature, durability, economic benefit and other factors.

5. STUDY ON TREATMENT OF QINGYUAN PUMPED STORAGE POWER STATION

Qingyuan PSPS is arranged using the “one hole and four machines”, and the longitudinal section of water diversion waterway uses the layout mode of three-stage adit, one-stage shaft and one-stage deviated wells. Other hub structures are the same as Guangzhou PSPS. Qingyuan PSPS takeS “beforehand prevention” measures for the treatment of limnoperna fortunei according to the experiences of Guangzhou PSPS and in combination with its own characteristics.

5.1. WATER QUALITY

According to the test result of environmental water erosion in Qingyuan PSPS, the surface water has a medium corrosion of decomposition dissolution type and general acid type; the underwater has the medium acid of decomposition dissolution type, weak-medium corrosion of general acid type and weak corrosion of carbonate type and magnesium sulfate type; the test results show that the environmental water of Qingyuan PSPS has a slightly more serious corrosion.

Table 4

Comparison of corrosively-test results of environmental aqueous

Item	Guangzhou PSPS	Huizhou PSPS	Qingyuan PSPS
pH	6.8 - 7.6	6.0 - 7.6	5.6 - 8.3
Corrosion	5 - 10mg/l	5 - 10mg/l	5 - 10mg/l

5.2. PREVENTION & CONTROL MATERIALS

Based on the experiences of Guangzhou PSPS, it is decided to brush or coat the cementitious permeable crystals onto the concrete of inlet/outlets and brush the epoxy to the concrete of waterways after the comprehensive consideration of the material prices and construction process safety technology and other factors.

5.3. COATING LOCATIONS

Concrete is a building material that absolutely produces cracks [10], so, it is planned to brush or coat all water delivery tunnels of Qingyuan PSPS. However, since epoxy is a hydrophobic material, it is required to keep the painting surface clean during the coating construction. For the shafts and deviated wells and other special parts, the coating or brushing operation can be carried out only when the grouting facilities are operating. In case of foggy weather, there will be a very serious fogging and condensing phenomenon in the shaft as the main air ventilation channel of diversion tunnel during the brushing or coating construction, so, the brushing test at this site is basically failed. For this reason, Qingyuan PSPS only brushes or paints the protective materials of limnoperna fortunei at outlet/inlets of lower/upper reservoirs, upper adit, middle adit, deviated wells, lower adit, HP bifurcated pipe, tail water concrete branch pipe, tail water bifurcated pipe and tail water tunnel.

5.4. COATING PROCESS

5.4.1.Coating/brushing procedure:Epoxy coating operation is divided into two stages. Epoxy coating operation of erosion resistance of concrete above 3m at the bottom will firstly be carried out, and then the epoxy coating operations of erosion resistance of concrete at the bottom and below 3m will be performed. During the coating operations, the concrete grouting scaffold is used as the coating work plant. The basal plane is flushed from top to bottom and after it is dried and accepted, it shall be coated or painted also from top to bottom.

5.4.2.Coating Process

(1) Install and check the equipment of work plant to ensure the construction safety.

(2) Before the formal construction, check the construction surface 4 hours in advance to ensure that the concrete surface is dry during the construction.

(3) The coating operation direction is initially determined from top to bottom and it can be adjusted according to the actual situation on the site during the actual construction. The airless high pressure sprayer is used and the body pressure of the sprayer is 12MPa and the outlet pressure is controlled below 1MPa. On the work plant, the spraying nozzles are tied onto the bamboo poles of different length for the coating operations. The long bamboo pole is used to spray the remote ends, and the short bamboo pole is used to spray the near-ends. The length of the bamboo poles is determined experimentally to ensure they can cover all ranges. The nozzle shall be perpendicular to the concrete surface and at 30 -50 cm away from the concrete surface. The prepared paints shall be transported to the storage tank on the work plant through a high pressure hose.

(4) The concrete surface shall be brushed or sprayed twice. For the first spraying operation on the adit wall, the spraying shall be performed along the structural surface from top to bottom. The second spraying operation shall be performed perpendicular to the first spraying direction. The spraying operations shall be performed along certain direction and law to ensure all concrete surfaces

are covered. The paints cover the basal plane and flow slightly when spraying. The operator shall swing the nozzle uniformly and the nozzle pressure shall be controlled not to exceed 1MPa. It is required that the coating thickness shall be even and the surface is level. The first spraying operation cannot be carried out unless the paint of the first spraying operation is not sticky.

(5) During spraying construction, attention shall be paid to the following:First of all, the coating thickness must be under control when the spraying operation is performed, that is, the calculated amount of paint is evenly brushed on the stipulated construction area until the paint is used up. Secondly, if the current working procedure is unqualified, it cannot be transferred to the next working procedure. When any defect is found, it shall be promptly repaired and treated. The surface shall be free from any missing area, sags or bubbles. It shall be solidified completely, with smooth surface and uniform color; thirdly, the construction and curing of coating is completed and the coating meets the requirements of the design specifications. Finally, as for the control range of consumption: the consumption of epoxy resin for spraying two times is about 0.7kg/m2.

6. CONCLUSION

As two typical pumped storage power stations, Qingyuan PSPS and Guangzhou PSPS have done a great deal of in-depth research on the prevention and control of limnoperna fortunei in the operation period and construction period. However, because the implementation time of treating the limnoperna fortunei is not long, the treatment effect cannot be immediately revealed and it shall be announced in the future operation overhaul.

1. INTRODUCTION

An adequate management of an aging underground powerhouse is recognized to be a mandatory issue through the experience of which significant damages were happened in a few support members of approximately 40-year old cavern for the powerhouse. The studies have been made to verify the soundness of the cavern by arranging two diffused laser range finders at the generator sections for monitoring the convergence, in-situ stress measurements of major concrete structures of the cavern and lift-off tests of pre-stressed (referred to as PS) anchors. Based on these results, the present soundness of the cavern was confirmed with the interpretation by the structural calculation using the simple frame model of the underground powerhouse. The management criterion was updated by applying the future scenarios of the deterioration of the cavern supports to its present structural condition [1], [2], [3].

Following updated management criteria at the above-mentioned underground powerhouse, seven-year convergence data at two generator sections has been accumulated so far. While one is stable, however another section has been shortened gradually, but does not touch the maintenance criteria. In this paper, the convergence behaviors are examined from the standpoint of the structural response of the cavern.

2. OUTLINE OF AN UNDERGROUND POWERHOUSE STUDIED

The underground powerhouse studied in this paper, is located in the central part of Japan, includes output of 220 MW, two generator units and discharge of 266 m^3/s, with completion in 1968. It has the dimension of 23 m wide, 42.25 m high and 70.2 m long. Due to the existence of the reservoir above 100 m of its location, the underground powerhouse was constructed with grouting as the watertight structure. The surrounding weak geological zone caused excessive displacement of the cavern and imposed the additional structures to strengthen the stability of the cavern, such as additional arch structures and thicker side wall and slab during the construction. Its characteristics are shown in Fig. 1.

A few damaged PS anchors were identified in 2008, which was 40 years after the completion of the cavern, while no other deterioration in the cavern was found. These are shown in Fig.2. PS anchors arranged in the cavern are a type of un-bond with applying the bituminous coating around the tendon and mortal grouting in the boreholes. It is considered that a few damaged supports did not affect the stability of the cavern. However additional monitoring, which involves measuring the tension stress of existing anchors and monitoring the cavern convergence and major structural beams, was planned to clarify its long-term performance.

The monitored convergence performed in seven years is only examined in this paper from the mechanical view point of the cavern behavior.

3. CONVERGENCE OF THE CAVERN

Monitoring plan is shown in Fig. 3. The convergence is monitored at the middle elevation of two generator sections of No. 1 and No. 2 in the machine room using a new device using the diffused laser beam, referred to as the diffused laser range finder (DLRF) [1], which consisting the laser transmitting and receiving unit and the reflecting board. The distance between the unit and the board is continuously measured in a precision of 0.1 mm with any interval. The overview of DLRF is shown in Fig. 4. The circumstance conditions of the reservoir water depth and the ambient temperature of the cavern are simultaneously measured.

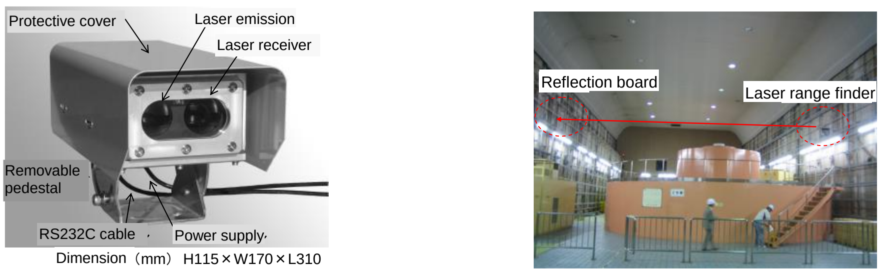

Fig. 4
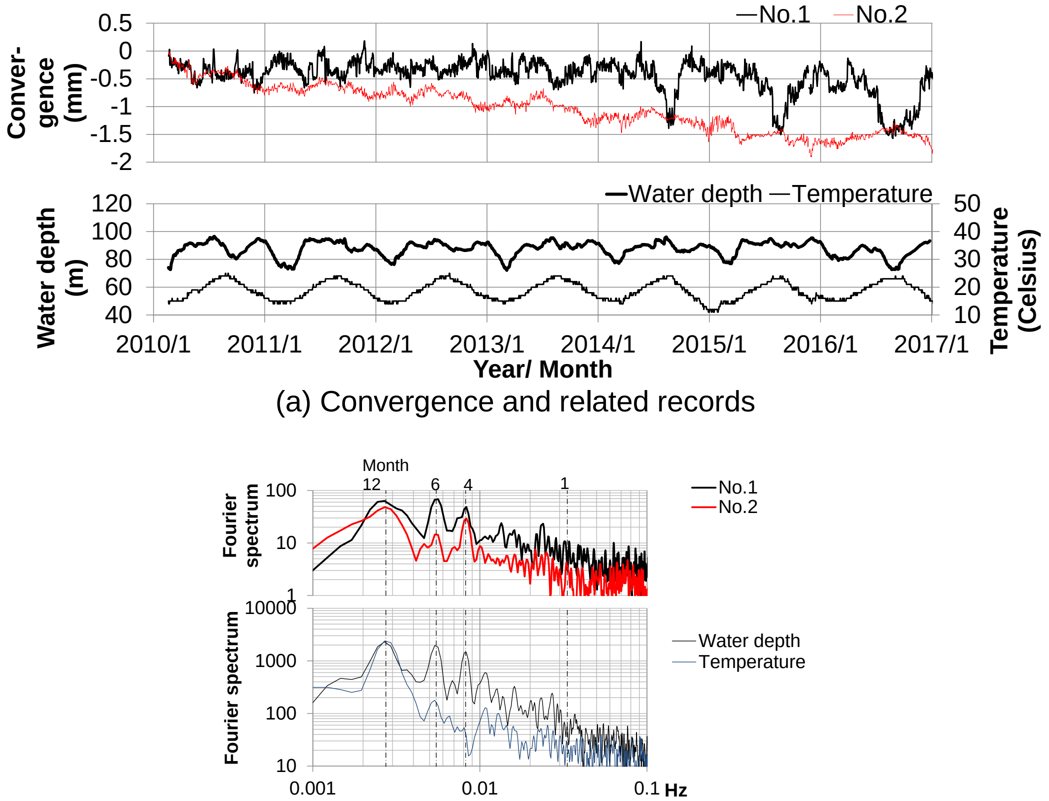
Diffused laser range finder (DLRF)

The seven-year convergence histories of the cavern are shown in Fig. 5 with the reservoir water depth (referred to as the water depth) and the ambient temperature in the machine room (referred to as the temperature, simply). The data are compiled as daily ones. The water depth is measured from the top of the cavern (EL 463 m) to the reservoir surface. Fourier spectra are shown to identify the frequency characteristics of the data.

The water depth shows several cyclic fluctuations a year, while the temperature in the powerhouse fluctuates once a year. The convergences of both sections (referred to as No.1 section and No.2 section) show gradual shrinkage with higher frequency fluctuation, which are approximately 1 mm and 1.5 mm for No. 1 and No. 2 sections respectively and still less than the maintenance threshold of 2.5mm [1].

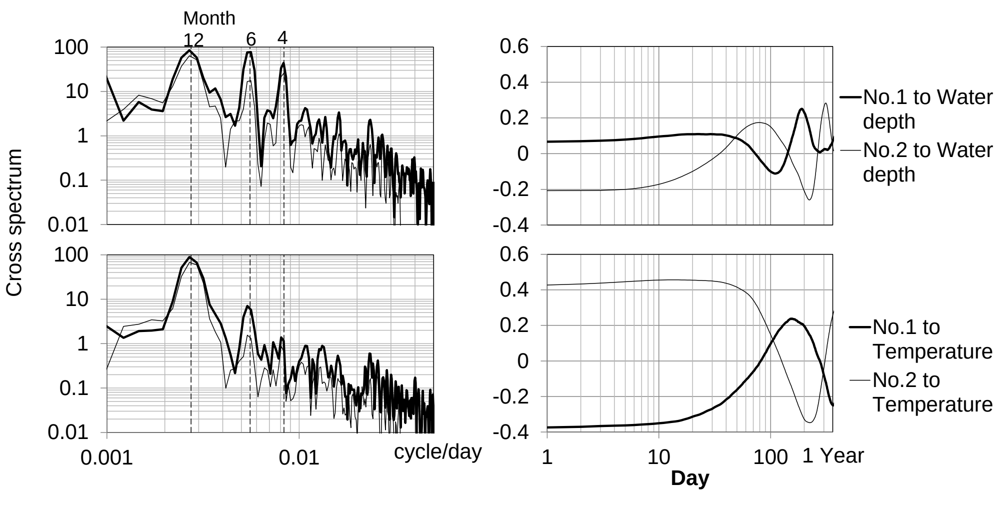
The frequency of the data is characterized with the peak of the Fourier spectrum. The water depth has significant peaks at 12, 6 and 4 months which are considered corresponding to the yearly reservoir operation and seasonal precipitation fluctuation. The temperature spectrum in the cavern shows the peak at 12 months, corresponding to the yearly temperature cycle. The frequencies of both convergences have significant peaks at 12, 6 and 4 months. This figure implies that the cavern convergence could behave under the influence of the water depth and the temperature in the cavern.



(a) Convergence and related records

(b) Frequency characteristics

Fig. 5
Convergence records of the cavern



(a) Cross spectrum (b) Cross correlation

Fig. 6
Correlation among convergence, water depth and temperature

The relations among them are examined deeply with cross spectra and cross correlation coefficients (referred to as CCCs) as shown in Fig. 6, the water depth in the above and the temperature in the below. The cross spectra show the similar peaks described above. The convergences of the cavern are affected strongly by the water depth and the temperature in the cavern. The CCCs within one year lag shows low values to the water depth and the temperature. It is considered that the cavern behaves promptly corresponding to the fluctuation of the water depth and the temperature. This paper focuses the relations between the convergences and their circumstances of the reservoir water depth and the ambient temperature of the cavern numerically in the following sections.

4. STUDY OF THE CAVERN BEHAVIOR

4.1. EXAMINATION OF CAVERN BEHAVIOR WITH THE SIMPLIFIED CONVERGENCE

The cavern convergences are processed by eliminating the long term trend and higher fluctuation than ones of the water depth and the temperature. The filtering techniques are applied in the processing using Trifunac method and low-pass-filter of 0.033 cycle/day (ie, once in a month). The processed results are shown in Fig. 7 for the convergences, the water depth and the temperature. The convergences fluctuated in the amplitude of 0.3 mm approximately. One of No.1 section began the wider fluctuation corresponding to the peak of the temperature at most in 0.8 mm from 2014.

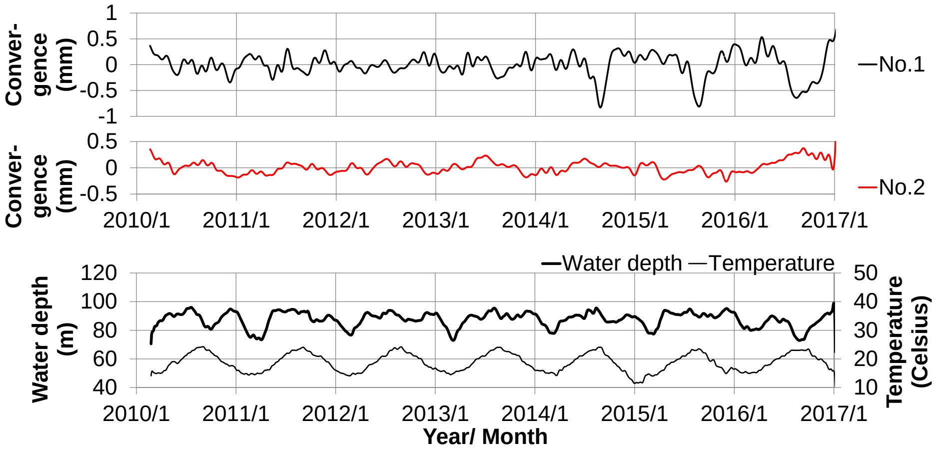


Fig. 7
Processed convergence records

The simple correlations between the convergences and the water depth or the temperature are examined in the durations of (1) 2010 to 2013 and (2) 2014 to 2016 as shown in Fig. 8. The convergence of No. 2 section shows consistent behavior to the water depth and the temperature in both durations. One of No. 1 section shows relatively complicated manner and has not been consistent in a whole duration. Due to the location of the monitored section of No.1, the three-dimensional behavior may predominate. The further study is necessary to explore the convergence behavior at No. 1 section.

Left law: 2010 to 2013（4 years）,Right law:2014 to 2016（3years）

Fig. 8
Simple correlation among convergence, water depth and temperature

4.2. REGRESSION OF CONVERGENCE

Regression formula is examined for the convergence of the cavern in terms of the water depth and the temperature change in the cavern. A simple physical model of the cavern is introduced as shown in Fig. 9 referred to [1]. The load due to the water depth acts mostly laterally on the model. Considering the physical behavior of the model due to both loads, it will be deformed linearly to the water depth and the temperature changes. The regression formula of Eq. [1] is assumed.

$$u = A + B(p_0 - p) + C(t_0 - t) \qquad [1]$$

Where, u: convergence, p: water depth , p_0: reference water depth , t: temperature, t_0: reference temperature, A,B,C：constant

The histories of the water depth and the temperature, p and t are examined by ignoring p_0 and t_0. The constants of A, B, C are estimated by multiple correlation study for the processed data as shown in Fig. 7. The results are illustrated in Fig. 10 and Table 1. The multiple correlation coefficients are 0.54 and 0.59 for the convergence of No.1 and No.2 sections. These indicate a certain degree of the correlation of the convergence to the water depth and the temperature in the cavern. The standard partial regression coefficient indicates the degree of the correlation among the parameters. The convergence of No.1 section behaves inversely by almost the temperature change. The change of the water depth and the temperature comparably induce the convergence of No. 2 section in an inverse and a proportional manner, respectively. These manners are consistent to the characteristics shown in Fig. 8. The estimated convergences for both sections by Eq. [1] provide reproducible results as a whole, although the wider fluctuation of the No. 1 section since 2014 is not followed. The fluctuations of the convergences are the amplitude of 0.5 mm and 0.2 mm approximately for the yearly changes of the water depth and the temperature, respectively.

Regression of convergence
Table 1

Regression formula for the cavern convergence

Parameters		For No.1 section	For No. 2 section
Constant	A	0.0862	0.4709
	B	-0.0416	0.0216
	C	0.00787	-0.00986
Cross correlation coefficient		0.54	0.59
Standard partial regression coefficient	B’	-0.590	0.586
	C’	0.195	-0.469

4.3. CONSIDERATIONS

The safety assessment of the cavern has been conducted by the following manner [1], [2]. The current loading condition was assumed by the in-situ stress monitoring of the ceiling beam shown in Fig. 9(a). The convergence of 2.5 mm of the cavern was estimated by incorporating the risk scenario of the loss of the support effect due to the entire deterioration of supports. As the further risk, higher loading which could cause the damage in the main concrete structures was incorporated for the terminal condition of the cavern. These convergences of 2.5 mm and 6 mm were set as the maintenance criteria of the convergence.

The current convergences are less than the criteria and correlate to the water depth and the temperature with repeatability. The fluctuation amplitudes are smaller enough than the criteria. However, the cumulative convergence is clear in the No. 2 section and larger amplitude has been found in the No. 1 section since 2014. The continuous monitoring of the convergence has been essential from the view point of the soundness assessment of the cavern, taking into account the relationship among the convergence, the water depth and the temperature such as Eq.[1]. When the abnormal behavior would be found in the future, the re-evaluation of the cavern behavior will be indispensable.

5. CONCLUSION

The convergence monitoring has been conducted in the cavern of the hydropower plant since 2010 and these data are examined for the soundness assessment of the cavern. The conclusions are listed as follows.

(1) The convergence monitoring using a DLRF provide the useful convergence data with the high precision of 0.1 mm for the soundness assessment of the cavern without any troubles and missing observation in 8 years so far.

(2) The convergence at the representative two sections behaves corresponding to the yearly and/or the seasonal fluctuations of the reservoir water depth and the ambient temperature in the cavern. One of the center section at No. 2 machine develop the cumulative convergence, while one of another section near the end of the cavern shows less cumulative convergence and wider amplitude especially since 2014.

(3) These are less than the unusual convergence which is designated as the maintenance criteria under the assumption of the entire loss of the support effect as the risk scenario. The convergence behavior is stably reproducible to be consistent with the water depth and the temperature fluctuations. No concerns are found in the current situation of the cavern so far.

(4) The DLRF has been renewed in beginning of 2017. It caused certain discontinuities for the convergence monitoring. The cumulative deformation at No. 2 section and the wider amplitude at No. 1 section will be clarified using the data accumulated in the future.

SUMMARY

A few damaged pre-stressed anchors were identified in the 40-year aged underground powerhouse, while no other deterioration in the cavern was found. The monitoring of the cavern convergence has been conducted to clarify its long-term performance using a newly developed precise range finder since then. The convergences of two sections during seven years are examined. These have behaved stably reproducible and been consistent with the yearly and/or the seasonal fluctuations of the reservoir water depth and the ambient temperature in the cavern. These are less than the unusual convergence which is designated under the assumption of the entire loss of the support effect as the risk scenario. No concerns are found in the current situation of the cavern so far.

INTRODUCTION

Enel Green Power is constructing a RoR hydroelectric power plant in Peru (Monzón district), named Ayanunga. 20 MW installed capacity, 2 small dams of approximately 6m high, equipped with Tyrolean intakes and desanders, 2 free-flow adduction channels in site-cast concrete (total length more than 7km), until the forebay, a penstock made of GRP, and 2 Francis turbines. The plant will have a rated flow of 12.38 m^3/s. The gross head is of 190.5 m and the average annual expected production is 141.64 GWh/y. It is currently under construction, first synchronization is foreseen for may-2019, and full production by the end of 2019.

This plant is equipped with a unique forebay, despite of two intakes and two adduction channels: this give advantage as cost savings and increased production.

However, this design generates unexpected problems: vortices in the forebay and problems in the good performance of its emergency spillway. These difficulties usually emerge in the operational phase, but the experience of the group

* Modélisation des phénomènes de turbulence et de la propagation des ondes dans le bief amount et le système d'adduction de la centrale hydroélectrique Ayanunga, à travers IBER-2d et ansys-3d

allowed detecting and optimizing it in the design phase. In order to optimize, two analyses will be performed using IBER-2D and ANSYS-3D:

1) Assess the occurrence of turbulence phenomena in the forebay near the penstock inlet, and evaluate measures to allow good functioning of the system and avoid inlet of air into the penstock, managing to optimize the basic design;

2) Study the propagation of the big wave (surface wave) caused by the turbine load rejection, and model its evolution in time and space from the forebay to its spillway, characterizing discharged water behavior during this case. Furthermore, big wave propagation throughout the plant's adduction system has been modeled, in order to assess the risk that the wave crest touches the upper limit of the adduction conduction.

2. MODELING OF AYANUNGA FOREBAY

2.1. STUDY ZONE DESCRIPTION

The study is on Ayanunga forebay and adduction channel and more specifically in the forebay tank, and outlet, where is located the penstock inlet, according to Figure 1. Ayanunga's forebay receives water from both adduction (north and south) thanks to two inlets that churn in the forebay. At the junction, two sloping floors develop in the pool, and finally the bottom of the tank, which coincides with the lowest point of the penstock inlet.

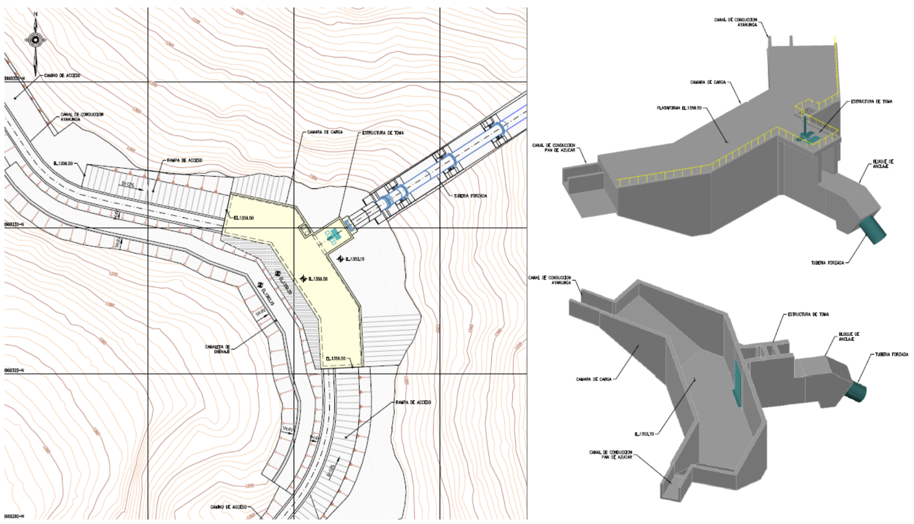

Fig.1
Forebay: Plan view (left) and isometric view with platform (top right) and without platform (bottom right).

2.2. TWO-DIMENSIONAL NUMERICAL MODELING WITH IBER

The 2D numerical modelling approach has been developed with the public domain code IBER [3]. It is a modelling system that uses high resolution schemes (FVM with TVD schemes), with a user friendly interface, compatible with GIS system. IBER solves two-dimensional (2D) depth averaged equation, also known as 2D Shallow Water Equations (2D-SWE) or two-dimensional St. Venant equations. These equations assume a hydrostatic pressure distribution and a uniform vertical velocity distribution. It solves mass and momentum conservation equations in the two horizontal directions:

$$\frac{\partial h}{\partial t}+\frac{\partial (hu)}{\partial x}+\frac{\partial (hv)}{\partial y}=0 \qquad [1]$$

$$\frac{\partial u}{\partial t}+u\frac{\partial u}{\partial x}+v\frac{\partial u}{\partial y}=-g\frac{\partial Z}{\partial x}+\frac{1}{\rho h}\frac{\partial h\tau_{xx}}{\partial x}+\frac{1}{\rho h}\frac{\partial h\tau_{xy}}{\partial x}-\frac{\tau_{bx}}{\rho h} \qquad [2]$$

$$\frac{\partial v}{\partial t}+u\frac{\partial v}{\partial x}+v\frac{\partial v}{\partial y}=-g\frac{\partial Z}{\partial y}+\frac{1}{\rho h}\frac{\partial h\tau_{yx}}{\partial x}+\frac{1}{\rho h}\frac{\partial h\tau_{yy}}{\partial x}-\frac{\tau_{by}}{\rho h} \qquad [3]$$

Being h depth, u, v the velocity components in the horizontal x and y coordinate directions, g is gravity acceleration, z is water surface elevation, τ_{xx} and τ_{yy} are the normal turbulent stresses in the x and y directions, τ_{xy} and τ_{yx}, are the lateral turbulent shear stresses, τ_{bx} and τ_{by} are the bed shear stresses in the x and y directions and ρ is the water density.

2.3. ORIGINAL FOREBAY DESIGN: INPUTS AND RESULTS THROUGH IBER

In this case of study, the original design of forebay has been modeled in GID by importing a dwf file. The dominium has been discretized with a mesh of rectangle triangle cells, size 100 x 70 x 70 cm. manning roughness has been set equal to 0.014, both the adductions and in the forebay. The penstock is in GRP, Manning= 0.009. On the other hand, the boundary conditions, introduced to the program, that fix the hydraulic behavior, of the system subcritical regime are (for the original case study):

- Upstream (inlet): inflow (Q_i) uniformly distributed, equal to operation condition: 12.38 m3/s divided between 7.49 m3/s for north adduction and 4.89 m3/s for south adduction.

- Initial condition: Forebay and adduction channels without water.

- Downstream (outlet): The condition of pressure inlet into the penstock can be modeled in IBER only using the option “culvert”, which allow the program to calculate flow which go under pressure under a square or circular culvert (the pipe of a penstock for example) in every condition.

The problem has been set with these parameters:

- Initial time = 0 s
- Max simulation time = 3600 s
- Results time interval = each 120 s
- Max increment time = 2 s
- CFL = 0.45
- Wet/dry limit 0.01 m
- Molecular viscosity = 0.000001 m2/s
- Turbulence model = k- ε, limit depth 0.01 m, first order scheme.

Performing this simulation, it can be observed that stabilization time for normal condition (uniform flow at the inlet and at the outlet of the system) is around 2800 s. Finally, in the results are observed two big recirculation areas of turbulence, just near the penstock inlet, affecting the submergence safety conditions.

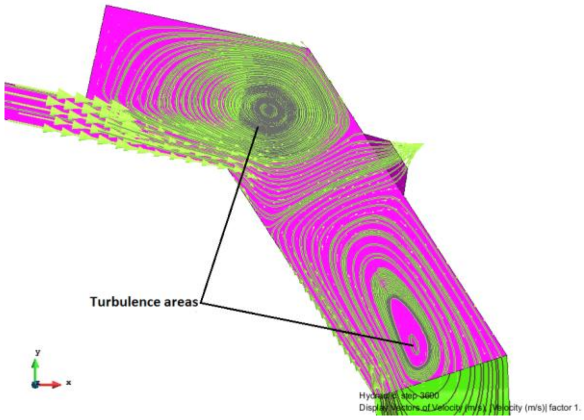

Fig.2
Forebay: Plan view of resulting turbulence areas for the original design

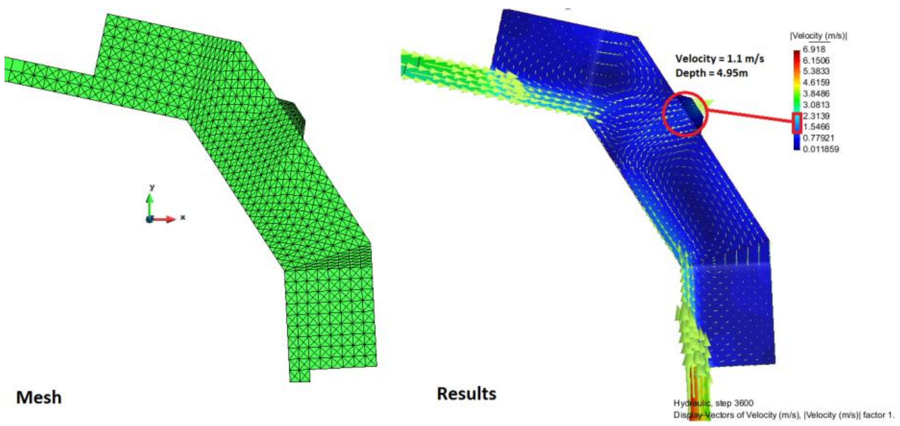

Fig.3
Forebay: Plan view of mesh cells (left) and resulting velocities vectors and contours, with legend.

Furthermore, water velocity in module is around 1.1 m/s in the penstock inlet section, and almost 2.5 m/s just 2 meters upstream the same section, values equals and higher than the maximum recommended in literature (1 m/s).

2.4. THREE-DIMENSIONAL NUMERICAL MODELING WITH ANSYS

Among the different models of turbulence that complements the RANS equations, ANSYS CFX is widely applied in the solution of many flows of engineering interest. This software allows to use two-equation turbulence models based in k-ε and in k-ω. In order to have a better knowledge of the numerical results, the k-ε model has been selected in the two CFD codes, so that results can be compared. This model is implemented in most general purpose CFD codes and is considered the industry standard model. The effective viscosity is calculated as:

$$\mu = C_\mu \rho k^2 / \varepsilon \qquad (4)$$

where C_μ= 0.09 is an empirical coefficient, k the turbulent kinetic energy and ε the dissipation rate of turbulent kinetic energy. The k and ε values can be obtained from the following equations:

$$\frac{\partial(\rho k)}{\partial t}+\frac{\partial}{\partial x_i}(\rho U_j k)=\frac{\partial}{\partial x_i}\left[\left(\mu+\frac{\mu_t}{\sigma_k}\right)\frac{\partial k}{\partial x_j}\right]+P_k-\rho\varepsilon+P_{kb} \qquad (5)$$

$$\frac{\partial(\rho \varepsilon)}{\partial t}+\frac{\partial}{\partial x_i}(\rho U_j \varepsilon)=\frac{\partial}{\partial x_i}\left[\left(\mu+\frac{\mu_t}{\sigma_\varepsilon}\right)\frac{\partial \varepsilon}{\partial x_j}\right]+\frac{\varepsilon}{k}\left(C_{1\varepsilon}P_k-C_{2\varepsilon}\rho\varepsilon+C_{1\varepsilon}P_{kb}\right) \qquad (6)$$

$C_{1\varepsilon}$, $C_{2\varepsilon}$, σ_k and σ_ε are constants (1.44, 1.92, 1.0 y 1.3, respectively), P_k is the turbulence produced by viscous forces, while P_{kb} and $P_{\varepsilon b}$ represent the influence of the gravity forces. In ANSYS CFX and both phases, air and water, can be solved through an homogeneous model. Actually, in order to compare with IBER model, only the water phase has been solved. Meshes have been compounded with hexahedral elements with a length scale of around 50 cm. Boundary conditions and initial conditions are the same adopted for the 2D analysis in IBER.. Finally, in the results are observed two big recirculation areas of turbulence, just near the penstock inlet, affecting the submergence safety conditions. Furthermore, water velocity in module is around 1.5 m/s in the penstock inlet section, and almost 1.3 m/s just 2 meters upstream the same section, values equals and higher than the maximum recommended in literature (1 m/s) and quite similar to the results of IBER 2D modeling.

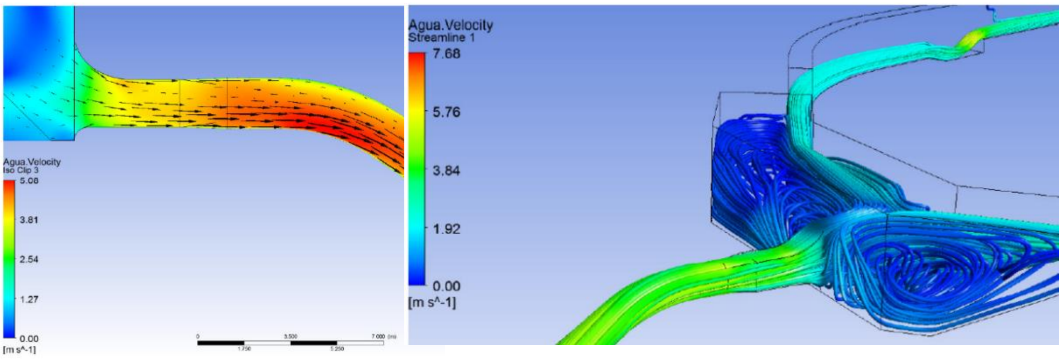

Fig.4
Section view (left) and isometric view (right) of velocities distribution at the penstock inlet in ANSYS

2.5. OPTIMIZATION OF THE EMERGENCY SPILLWAY

Furthermore, through ANSYS has also been studied the propagation of the big wave (surface wave) caused by the turbine closing due to load rejection, and model its evolution in time and space from the forebay to its spillway, characterizing discharged water behavior during this case. The target of this analysis was to assess the safety of the adduction system in case of load rejection, against the

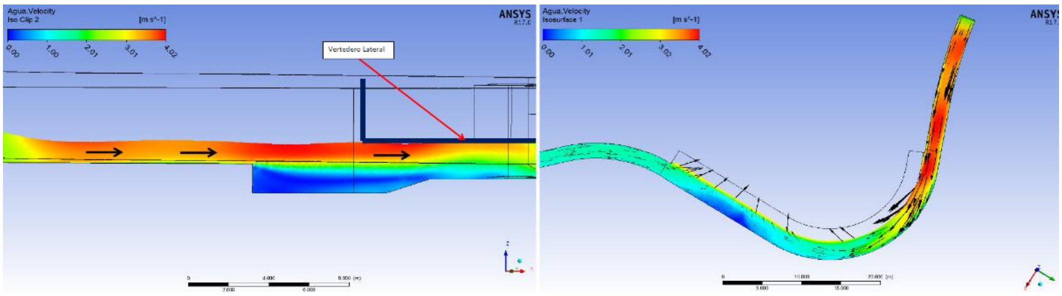

Fig.6
Section view (left) and plan view (right) of diverted flow in case of turbines fast closing due to load rejection in ANSYS.

water local elevations caused by the big propagation wave, in order to avoid that water flow out of the system in not allowed zones. The big wave propagation throughout the whole plant's adduction system has been modeled, in order to assess the risk that the wave crest touches the upper limit of the adduction conduction. It has been observed that wave propagation modeling reduces spillway efficiency. Results helps on proper re-location and optimal design of spillway to improve its discharge capacity. By optimizing position of the spillway, the wave crest cannot reach the upper threshold of the emergency spillway, due to a proper design of its height. Furthermore, the water along the whole adduction never reaches the top pf the channels walls.

Finally, has been computed and plotted the flow diverted by the optimized emergency spillway, in the same scenery of load rejection and closing of turbine valves. Due to transient condition it’s observed that max diverted flow is more than inlet flow, for almost 100 seconds, until stabilization.

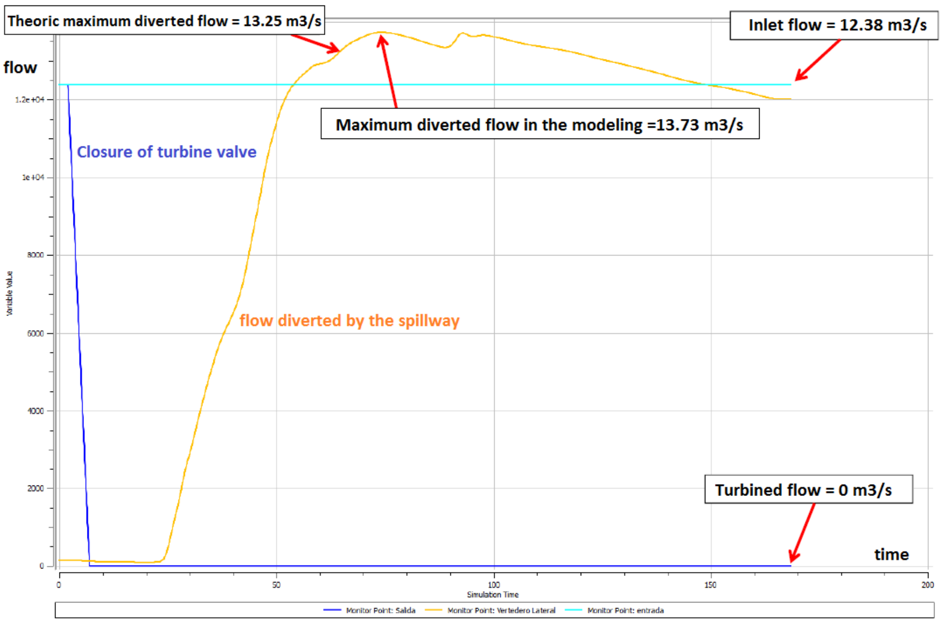

Fig.7
Diagram of diverted flow by the emergency spillway in case of turbines fast closing due to load rejection in ANSYS.

3. DESIGN OF A SYSTEM TO AVOID THE TURBULENT RECIRCULATION ZONES

Due to the big recirculation areas located near the penstock inlet, and to the high velocities affecting submergence stability, original design has been modified, by introducing two internal walls in the forebay. These are located in the slides located just downstream the lateral inlets of the forebay, 6.35 m downstream the channels junction. Inclination of wall is 45° as shown in figure 8, these are 4.5 m long, and its height is equal to internal forebay height. The analysis has been performed both in IBER and in ANSYS and the results obtained are impressively similar. As general outstanding, the vortices are localized upstream of the walls and far from penstock inlet. Maximum velocities of vortices are around 1m/s, and most of the channel energy is lost just some meters downstream their inlet in the forebay, by the formation of a little hydraulic jump, as can be observed in figure 9.

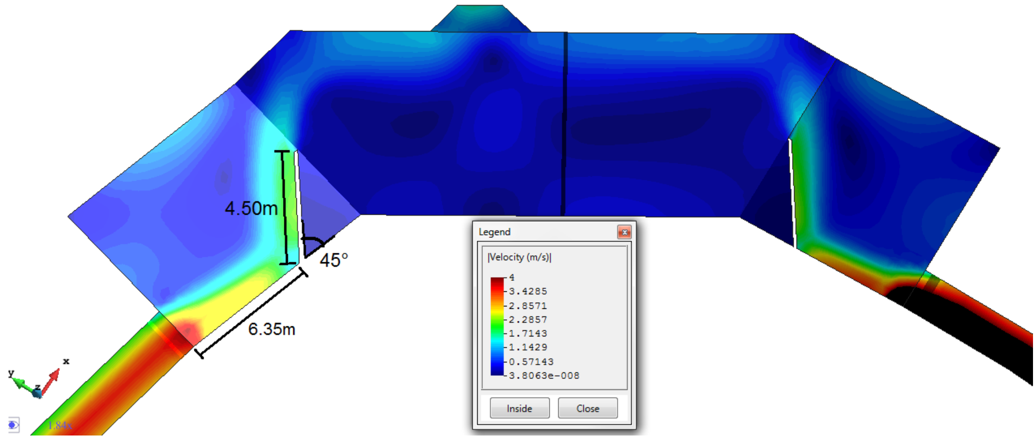

Fig.8
Plant view of velocities contour after installing walls, and dimensions

An unexpected benefit has been obtained: the hydraulic jump is located upstream the walls, in a defined area, increasing only the energy required for the water to flow into the forebay, without increasing the height of water in the forebay more than 5cm. Above all, in the remaining part of the forebay, water velocities are strongly reduced, and near the penstock inlet water velocity in module is less than 0.75 m/s, as shown in figure 9. The walls, so designed, represent a smart solution in terms of cost, because are the simplest and cheapest solution in case you need to make up for a bad basic design.

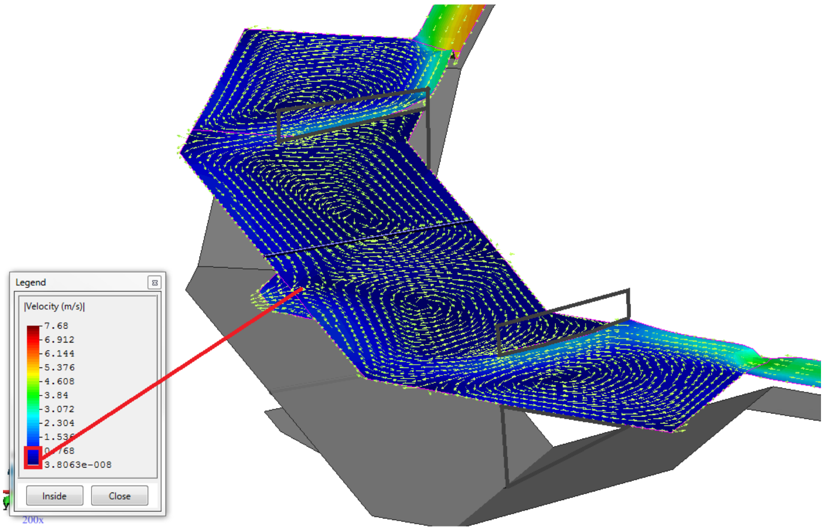

Fig.9
Isometric view of velocities vectors and contours while using walls

4. CONCLUSIONS

In the original design of Ayanunga's forebay, flow velocity near inlet was almost 2 m/s, exceeding submergence safe conditions (1m/s as recommended by good practice). Furthermore, two big vortices were localized near the penstock inlet with noticeable recirculation motion. This was due to high flow speed of water, which enters forebay from adduction channels, and also due to its uncommon shape. Consequently, thanks to the first analysis, original design was modified, by introducing internal walls in the forebay. As result, the vortices are localized upstream of the walls and far from penstock inlet. The second analysis observed that wave propagation modeling reduces spillway efficiency. Results helps on proper re-location and optimal design of spillway to improve its discharge capacity.

In conclusion, a deep knowledge of hydraulics allows savings and efficiencies (forebay optimization): the use of 2D (IBER) and 3D (Ansys) simulations allows to solve complex problems like vortices formation and transients with tools that, until recently, for their cost, were reserved to much larger projects.

SUMMARY

This study takes advantage of the power of 2D (IBER) and 3D (ANSYS) calculation codes to analyze and study the flow in a forebay of a hydroelectric plant currently under construction by enel green power, in peru. In the first part, the re-circulation zones in the forebay are modeled and analyzed; in a second part, are studied and modeled the propagation of the wave in the case of load rejection, along the adduction channels, optimizing the position and the threshold height of the emergency spillway. Finally, is provided a very simple and effective solution to the formation of turbulences and recirculation zones, in order to avoid affecting the submergence in the forebay at the penstock inlet. The application of 2 simple ad-

hoc inclined walls, placed in such a way as to locate and limit the recirculation zones, lowering the flow velocities in the area under analysis.

RÉSUMÉ

Cette étude tire parti de la puissance des codes de calcul 2D (IBER) et 3D (ANSYS) pour analyser et étudier le flux dans un bief amount d'une centrale hydroélectrique actuellement en construction par Enel Green Power, au Pérou. Les zones de recirculation dans le bief amont sont modélisées et analysées; dans une seconde partie, on étudie et modélise la propagation de l'onde en cas de rejet de charge, le long des canaux d'adduction, en optimisant la position et la hauteur de seuil du déversoir d'urgence. Enfin, on propose une solution très simple et efficace à la formation de turbulences et de zones de recirculation, afin d'éviter d'affecter la submersion dans le bief amont à l'entrée de la conduite force. L'application de 2 parois inclinées ad hoc simples, placées de manière à localiser et limiter les zones de recirculation, abaissant les vitesses d'écoulement dans la zone analysée.

1. INTRODUCTION

The performance of pressure conduits has caused costly problems for a significant number of hydropower projects and has prompted studies and investigations with the aim of developing concepts and methods for their safe design. This task has been approached in mainly two different ways: (1) basic physical concepts backed up by empirical data (e.g. [1, 2, 3, 4], with focus on unlined tunnels) and (2) engineered design using rock mechanical parameters (e. g. [5, 6, 7]). The latter approach was further enhanced by incorporation of hydrogeological phenomena (e.g. [8, 9, 10, 11, 12]).

Benson [13] comprehensively discussed the various factors and conditions to be considered in the design of pressure conduits and Swiger [14] cautioned against the use of "rules of thumb" in this context. Nevertheless, in spite of the ample experience accumulated with the performance of pressure conduits and the

---

* *Les réponses hydrogéologiques complexes défient la conception conservatrice d'un tunnel sous pression – rupture du tunnel d'amenée de Besai*

advances made in the computational analysis since Frey-Baer [5], incidents continue to occur. Some of these incidents are caused by unstable rock and could have happened as well in non-pressurized tunnels (Higuera, Glendow, see [4]) but other incidents resulted from the complex interaction of pressurized water and difficult geological and hydrogeological conditions. This applies to the case history of the Besai headrace tunnel, which, although thoroughly investigated and conservatively designed, developed excessive leakage. The investigations following the incident identified a number of diverse geological details, which in combination caused the failure. In retrospect, the process of the failure that advanced over a sequence of different effects was found to have been virtually unpredictable. It is for this reason that the incident is described in the following, illustrating the particular hazards potentially linked with pressure conduits and the need for particular precautions in their design.

2. THE BESAI HEADRACE TUNNEL

The Besai hydropower plant, with an installed capacity of 90MW, is located in Sumatra, Indonesia. The headrace tunnel, inner diameter 4.30m, descends over a length of 4900m from the intake at el. 708m to the base of the surge tank at el. 636m. The pressure shaft and penstock tunnel connect with the power plant, discharging to the tailwater at el. 472m, giving a net head of 250m with the storage level at el. 722m.

Maximum upsurge: El. 733.37 m, Maximum downsurge: El. 706.28m

Following investigation and design in 1991, construction started 1995.

3. INVESTIGATION AND GEOLOGICAL CONDITIONS

A generous program of subsurface explorations provided geological and geotechnical information for the tunnel, including geophysics, 15 boreholes along the route of the headrace tunnel, totalling 1,540m, drilled with core recovery and, near the level of the tunnel, permeability testing.

Bedrock in the project area consists of a sequence of volcanic and volcanoclastic rocks, dating from the Pleistocene (Fig. 5). The strata with their undulating contacts dip flatly in various directions. Near the level of the tunnel, the boreholes found a cemented, massive volcanic breccia (Tbr), covered by argillaceous tuffs (Tf3 and Tf4). Tuff layer Tf5, encountered at the bottom of the surge tank, was assumed to wedge out intermittently. After the incident, a layer of partially soil-like tuff intercalated in the breccia was encountered. It possibly connects with the Tf5 but differs decisively in geotechnical properties from those observed in the tunnel upstream and downstream of the damaged section. The intercalation has, therefore, been identified as "TfX".

Table 1 compiles geotechnical characteristics for the rock.

Table 1
Rock mass parameters
Paramètres du massif rocheux

Lithologic Unit	Bulk Density	σc	φ	c	E	Kf
	[g/cm³]	[kg/cm²]	[°]	[kg/cm²]	[kg/cm²]	[m/s]
Breccia	1.7	30	40	10	7500	2E-6, grouted 5E-7
Tuff	1.6		20-30	1-5	1000 - 1500	anisotropic 1E-4 - 1E-7

The strength of the TfX detected after the incident reached only half of the values previously found for tuff layers.

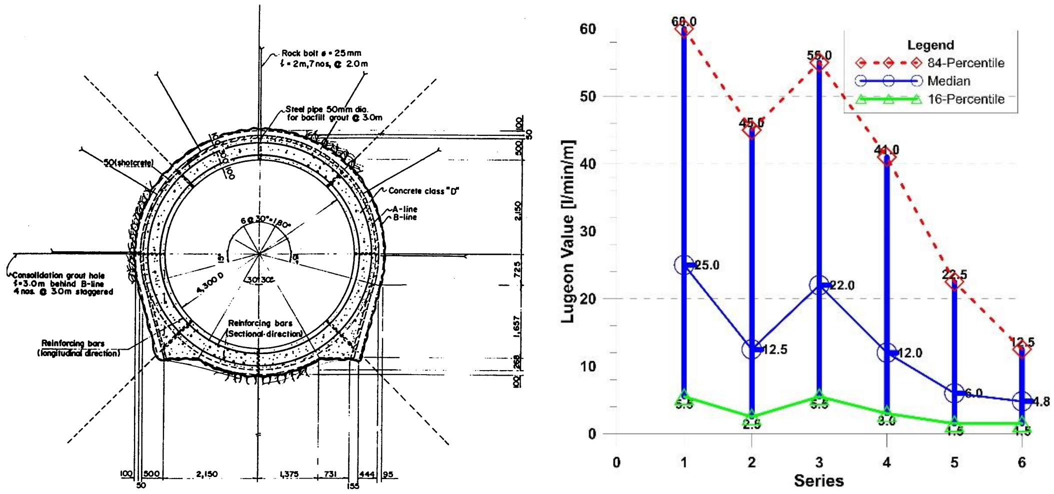
Boreholes in the low-cover stretch found groundwater levels 46 to 48.6m above the tunnel. The design of the lining adopted 30m external head. Jacking pressures estimated from water pressure tests near the failure ranged 4 to 5 bar above the groundwater level.

4. DESIGN AND CONSTRUCTION OF THE TUNNEL

Evaluating several alternatives, the designers, in concurrence with an international Board of Consultants, adopted the following criteria.

- The tunnel should be placed as high as the hydraulic conditions permit to keep the internal pressure low but still maintaining a rock cover of more than 0.7 times the hydraulic static head [2, 15]. Even with these precautions, the design provided a continuous concrete liner, reinforced, with contact and consolidation grouting. As verified by the Frey-Baer method [5], supported by FEM analysis, the width of cracks in the liner would stay below 0.25 mm and the leakage be limited to 20 l/s.
- The Tf4 tuff layer should be avoided, because it was suspected to contain low-modulus horizons, undesirable for the construction and stability of the tunnel.
- The tunnel should run in the tuff breccia, aiming to keep a distance of about 15m from the Tf4 tuff horizon. According to a FEM simulation, the convergence observed in the tunnel would alert on the critical presence of a weak layer in its vicinity.

Excavation and preliminary support followed the concepts of NATM, with geological logging, rock mass classification and convergence monitoring.



a) Preliminary support and final lining, arrangement of consolidation grout holes

b) Reduction of Lugeon Value with successive steps of consolidation grouting

Figure 1:
Support of tunnel in damaged section and results of consolidation grouting
Revêtement du tunnel dans le tronçon endommagé et résultats des injections de consolidation

In the stretch of the failure, RMR averaged 82 – best along the entire tunnel - and only three discontinuities were logged, subvertical and at an acute angle to the tunnel axis. Convergence in the subsequently failed stretch stayed below 1 mm, in agreement with the favorable rock mass classification.

The tunnel was preliminarily supported by 5cm shotcrete and grouted bolts and finally lined with 50cm reinforced concrete (circumferential inner and outer ring Φ22 at 15cm, longitudinally inner and outer ring Φ19 at 7,5°, area ratio of steel 1%, see Figure 1). Concrete strength of the liner exceeded 300kg/cm². A 200mm waterstop seals the block joints. After contact grouting in the crown, consolidation grouting followed with rings spaced at 4m, staggered. Grouting pressure reached 6 bar (following [16]). Thus, the rock surrounding the tunnel had been pre-loaded to 6 bar and had built a hydraulic resistance to that pressure.

5. THE LEAKAGE INCIDENT

I. Pinkerton, member Board of Consultants, described the incident: “The Besai power tunnel was pressurized in early December 1999, over a period of about 10 hours with the static pressure head in the downstream section of the tunnel being about 80 metres. Falling water levels in the desanders indicated that water was escaping from the tunnel. Over a period of about 6 hours the tunnel pressure head fell by around 20 metres but a general inspection the next morning did not reveal where the water was going. The same day the tunnel was again brought up to the operational static pressure over a period of a few hours but again next morning the water level in the tunnel was observed to be falling. After further pressurization the water remained at the static level overnight, but the next morning the water drained rapidly from the tunnel with a calculated loss of the order of 1.5 m^3/sec. ….. It was then observed that a failure had occurred on the riverside slope.”

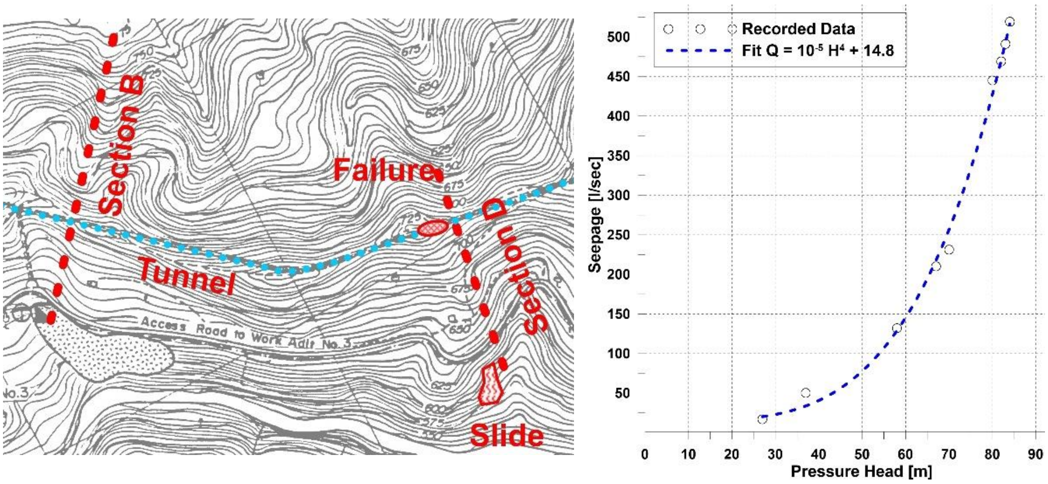


Figure 2:
Location map of low cover stretch and failure of headrace tunnel (grid spacing 500m) and tunnel seepage. Diagram of loss against head.
Endroits du toit minimal et de rupture e tunnel d’amenée (grille 500m) et filtration de tunnel. Diagramme pertes contre pression.

The slope failure affected overburden and decomposed rock, exposing the TfX layer at its back. The water had eroded cm-sized pipes into the tuff.

6. POST-FAILURE INVESTIGATION

Mapping and chipping of cracks: Ten blocks displayed longitudinal cracks with more than 0.2mm, finer cracking of liner extended another 100m upstream and downstream. In the most notably affected blocks, mapping was repeated after chipping the concrete. In blocks 337 to 344 isolated cracks continued to 15 cm depth into the concrete, 5 cm beyond the interior reinforcement. Block 342 showed several deep cracks that were opened up to 5 mm. A crack at the downstream end of block 342 could be followed into the rock, where it gaped about 2 cm.

Acoustic probing: notable anomalies from block 338 in half way into block 343. Blocks 340, 341 and particularly block 342 severely affected.

Core drilling: detected a separation between concrete and shotcrete or shotcrete and rock, in some cases with traces of circulation of silt-laden water.

Permeability: notably increased from block 329 to block 353. Water lost from boreholes in some instances issued at the slope failure. Jacking pressures in the most severely damaged stretch 3 and 5 bar, elsewhere >5 bar.

7. INTERPRETATION, ANALYSIS, REPAIR

Seepage discharge quite accurately increased with the fourth power of the internal pressure (Figure 2). Accordingly, hydrojacking did play an important role (crack opening linearly related to pressure and permeability following the “cubic law” with the third power of the opening). Therefore, the adequacy of the burden above the tunnel was checked.

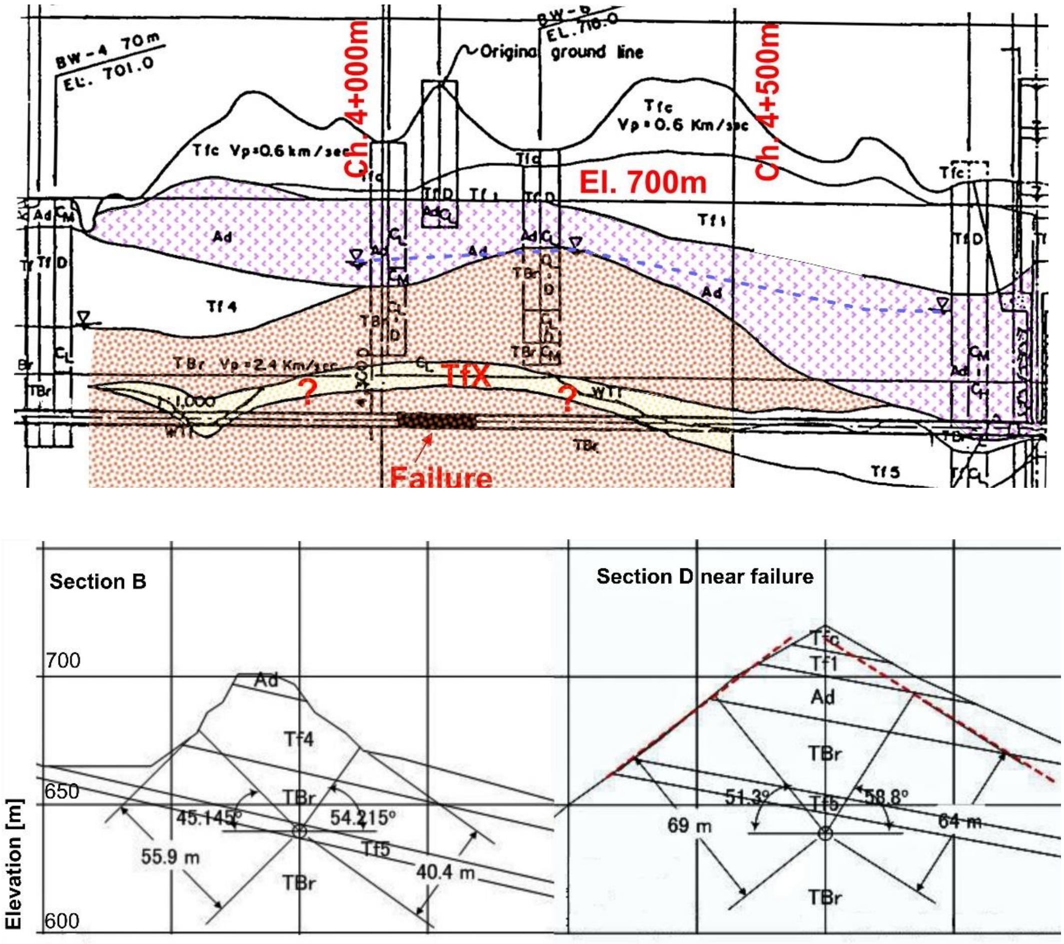

Figure 5
Longitudinal and transverse sections for low cover stretch and failure. Location see Figure 2
Coupes longitudinale et transversales, toit minimale et site de la rupture. Emplacement voir Figure 2

Figure 5 displays a longitudinal and transverse section for the low cover (B) and failed stretch (D) of the tunnel. The sections meet the “Australian Criterion” for lateral cover [1]. For the “Norwegian Criterion” (e. g. [4]), the safety factor arrives at 0.68 for Section B and 1.25 for Section D, the latter with correction for lateral cover. These safety factors apply to unlined tunnels, disregarding the reinforced liner with consolidation grouting. Therefore, hydrojacking because of low cover cannot constitute the sole cause of the failure. A FEM simulation of the stress distribution in the failed section supports this conclusion. As Figure 6 shows, the TfX layer causes a distortion of the stress field in the ridge, raising σ3 near the tunnel to arrive at levels similar to that derived from the Lugeon tests (cf. [18] for similar effects).

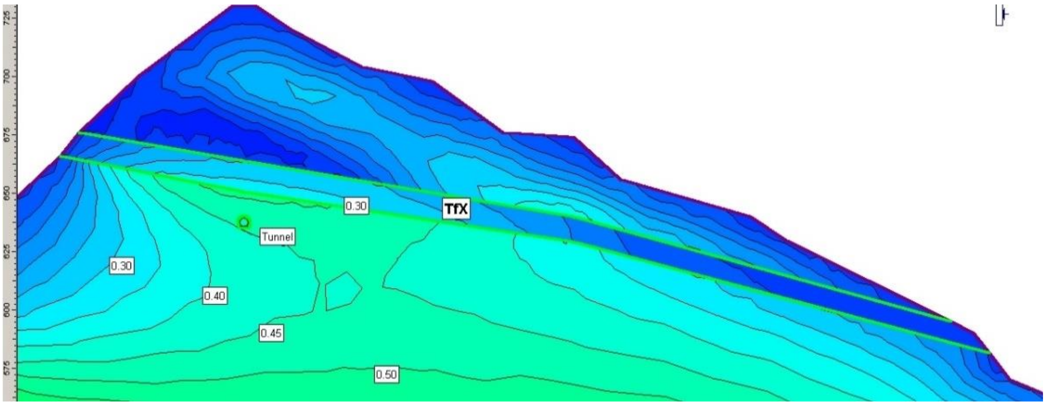

Figure 6
σ3 contours for cross section at tunnel failure according to FEM simulation
Simulation MEF des contours σ3 en coupe transversale près de la rupture

Looking for an explanation for the tunnel failure, the effect of tensile stresses caused by seepage water around the tunnel was also evaluated [according to [11, 12]). Allowing for an uncertainty in the hydrogeological regime, two alternatives were studied, with 46.5 m external head, as suggested by the piezometer data from the exploratory borehole, and 17 m, as implied by a hydrogeological model introducing a drainage effect due to TfX. For the alternatives, the Fernandez method estimated seepage losses between 0.1 and 0.27 l/s/m (which agreed closely with the results of a hydrogeological simulation) and an average crack width of less than 0.1mm. Estimates following [8, 9] indicated a crack width of up 0.14mm and seepage of 0.38 l/s/m. Thus, also these approaches did not explain the failure of the tunnel. Still other factors and processes must have contributed. In this context, the study of Lugeon and dilatometer tests gives hints: Lugeon values had notably increased (Figure 4) after the incident, but the deformation modulus had not changed, hydrogeological characteristics were more notably affected than mechanical. The crack in the concrete of block 342 was opened 5mm but the continuation into the breccia gaped 2cm. At the slope failure, the water issued from pipes in the TfX layer. Apparently, the clastic dike had collected seepage water and eroded the breccia and dispersivity of TfX had permitted rapid piping. This means, a geological detail – the clastic dike – and a local condition – the pronounced dispersivity – had prominently assisted in the failure process.

Hydrogeologic modelling, assuming high infiltration rates exceeding 600 mm/year, failed to reproduce the groundwater level found in the exploratory boreholes. Therefore, in the original state, the overburden (young tuffs, residual soil, decomposed rock) had obstructed the drainage of the TfX layer. Initial seepage from the tunnel raised the pore pressure in the slope, triggered the failure and opened the drainage. The hydrogeological regime changed drastically, resembling a scenario, which Benson [13] had presented as Case D, the intercalation of a pervious zone in the rock. The distance of the potentially pervious zone to the failed block measured only 9m, a strong seepage gradient developed (see Figure 7) and the rock eroded. The hydrogeological regime progressively deteriorated and the damages along the tunnel propagated laterally. Figure 8 attempts to interpret and illustrate significant steps in the failure process.

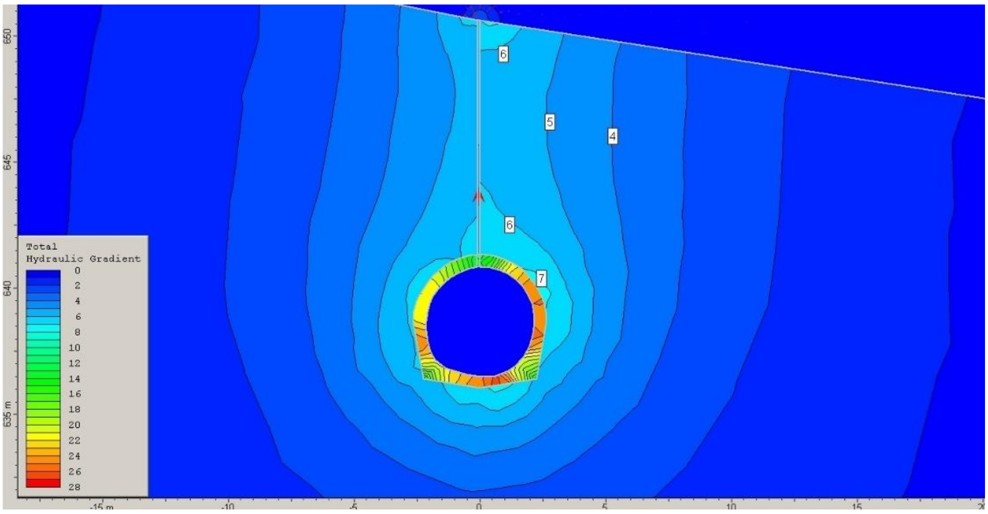

Figure 7
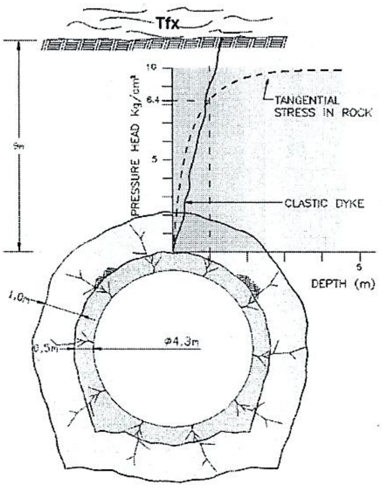
FEM simulation of hydraulic gradient in crown pillar between tunnel and TfX layer
Simulation MEF du gradient hydraulique entre le toit du tunnel et TfX en haute

Comparing options for rehabilitation of the tunnel (repair and strengthening of the liner, new concrete liner, geomembrane or steel liners), the steel liner emerged as optimal solution. After installation of 300m steel lining for the damaged stretch, initial leakage amounted to 20 l/s. With time, the losses declined to 6 l/s.

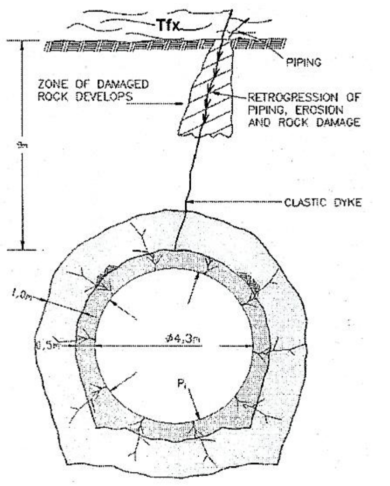
8. CONCLUSIONS

The conservatively designed tunnel failed in a stretch of good rock where the cover according to Norwegian and Australian criteria would have admitted an unlined tunnel. Checking the design against the concepts proposed by Schleiss [8, 9] and Fernandez [11, 12] also predicted an acceptable performance. Analytical methods (e.g. [18]) as well as digital simulation, based on information available at design stage, indicated minor steady state seepage relaxing stresses on the liner.

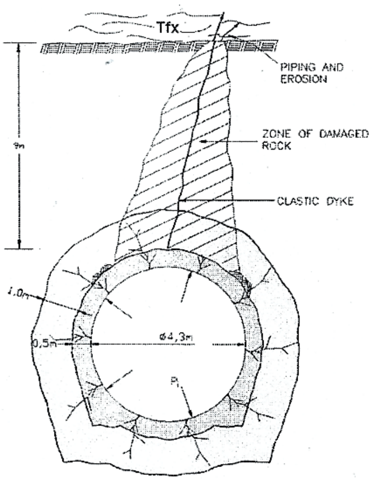
The post-failure investigations traced the causes of the failure to a combination of geological and hydrogeological details. The interaction of these details in the successive steps in the failure process had defied prediction. The experienced problems essentially derive from an unforeseen instability of the hydrogeological regime, which is attached to several features: the temporarily blocked drainage of the TfX layer, the dispersivity of the TfX (not detected previously in the project area), which permitted rapid piping, and the clastic dyke, which promoted hydrojacking and with its erosion paved the way to the failure.



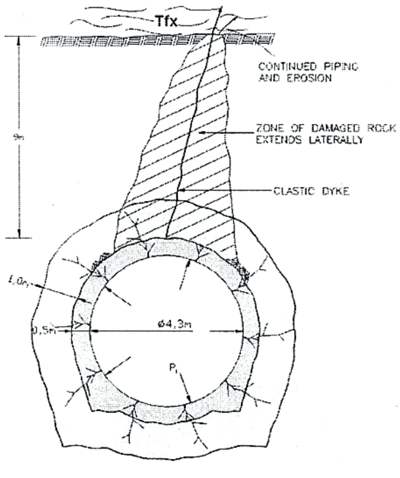
1. Internal Pressure P=84m. Hydraulic jacking opens cracks in concrete and starts jacking in rock. Limited leakage



2. Piping and erosions along clastic dyke, full internal pressure builds in clastic dyke, damage to rock pillar and local loss of stress



3. Severe damage to rock pillar. Piping in TfX opens outlet to ground surface. Vertical offset of tunnel crown, start of collateral damage. Seepage 1.5m³/s



4. Propagation of damage along tunnel. Erosion and piping continue. Seepage increases to 1.8m³/s

Figure 8
Sketches illustrating significant steps in the development of the failure
Croquis illustrant les étapes importantes dans le développement de la rupture

According to observations in the Besai tunnel, the steel reinforcement does not fully guarantee an even distribution and equal opening of the radial cracks in the concrete liner. The most severe cracking concentrated in the crown, and in these cracks the steel had been strained beyond yield strength. In consequence, the elastic action assisting the balancing of internal and external head was impaired. Perhaps consolidation grouting to notably higher pressures than suggested by EPRI [16] would be helpful in this context.

This case history emphasizes the importance of hydrogeological studies. Such studies are indispensable to assure the geohydraulic steady state assumed for the design methods according to [8 to 12]. Where the geological setting indicates potential for hydrogeological complexities, specific investigations may become necessary, in addition to the geotechnical exploration, and these investigations may have to cover an ample margin beyond the perimeter of the tunnel. Even with such thorough additional studies, it is prudent to monitor the hydrogeological response during construction and filling. Such monitoring will have to be of high quality, e.g. with pore pressure cells and/or multi-port piezometers.

9. ACKNOWLEDGEMENTS

The authors gratefully acknowledge the backing by the owner of the project – Perusahan Listrik Negara – who supported the investigation and analysis of the incident and granted use of the data and information discussed in this text.

SUMMARY

Upon first filling, the Besai headrace tunnel failed and seepage caused a slope failure. The conservatively designed, reinforced concrete lining had severely cracked along a stretch of good rock where conventional criteria would even have admitted an unlined tunnel. Comprehensive post-failure investigation and analysis identified a complex sequence of processes, which progressively led to the failure. The processes involved hydraulic fracturing/jacking, erosion and in dispersive layers piping. A drastic change in the hydrogeological regime resulted, which in turn promoted damages to the rock in the perimeter of the tunnel as well as of the liner. Steel lining of the failed stretch satisfactorily repaired the tunnel

RÉSUMÉ

La galerie d'amenée de Besai a subi des dégâts lors du premier remplissage et causé un glissement de terrain en surface. Le revêtement du tunnel en béton armé qui semblait à première vue même superflu et d'une conception pourtant très classique, a été sévèrement fissuré le long d'un tronçon en bon rocher. Les

investigations et analyses qui ont suivi les dommages ont identifié une succession de dégradations complexes qui ont abouti à l'incident: fracturation par pression hydraulique et claquage, érosion et renardage à travers des couches dispersives. Il en est résulté un changement fondamental du régime hydrogéologique qui s'est propagé dans le revêtement du tunnel et dans le rocher environnant. La réparation a nécessité la pose d'un blindage métallique le long du tronçon endommagé

1. INTRODUCTION

The evaluation of the hydraulic conductivity of a rock mass must take into account the characteristics of the discontinuities. The issue is to define the dimensions of the representative element and deduce its hydraulic behavior from the geometrical and mechanical properties of the discontinuities. The rock mass can then be handled as an equivalent porous medium. The accuracy of the flow estimation in a porous medium depends largely on how well the permeability of the representative element is characterized. It is vital to have a precise estimation of the equivalent permeability for calculating seepage into underground openings such as tunnels and caverns. The uncertainties that characterize the rock mass parameters make the estimation of the equivalent permeability tensor a challenging task.

Many methods are used to obtain the hydraulic conductivity tensor from the geometrical characteristics of the discontinuities. One of these methods is the discrete fracture network (DFN), as a numerical method, that is used to obtain a representation of the rock mass, simulate the flow in the discontinuities and calculate the hydraulic conductivity or HC tensor [1]. There are always some uncertainties in characterizing the entire properties of the discontinuities due to the fact they are buried in the rock mass [2]. DFN models remain advantageous in reproducing 3D realizations of the fracture network in view of determining the overall behavior of a representative element [3, 4].

In this research, the noncommercial discrete fracture network code, 3DFAHAM*, will be used to generate 3D representations of the rock mass at Rudbar-Lorestan pumped storage power plant and predict the HC tensor of a representative element. To this end, the geometrical and mechanical characteristics of 1035 recorded discontinuities at Rudbar-Lorestan powerhouse cavern will serve as input data. The predicted hydraulic conductivity will be compared to the hydraulic conductivities that are obtained by back analysis of the recorded volumetric flow rate. Analytic methods will be used for the back analysis. When the volumetric flow rate in an underground opening is available, the equivalent hydraulic conductivity of the rock mass can be calculated inverting one of the several analytical or empirical equations to calculate discharges into tunnels [5, 6, 7, 8].

2. CASE STUDY

2.1. LOCATION

Rudbar Lorestan Pumped Storage Power Plant with the hydropower generation capacity of 1000 MW is under construction100 km south of the city of Aligoodarz in Lorestan Province of Iran. The main objective of this project is to generate the peak electricity required for the national grid through the storage of the surplus water in a separate reservoir. The powerhouse cavern of the pumped storage plant is located at the right bank of the main dam (earth dam). The distance between the reservoir and the powerhouse cavern is approximately 350 m. The normal water level is 1756 m.a.s.l and the elevation at the powerhouse crown 1700 m.a.s.l. The height, width and length of the powerhouse cavern are 49.5, 26.3 and 129.75 meter respectively. It will be excavated at 400m depth.

2.2. GEOLOGY AND TECTONIC

In accordance with the structural - sedimentary classification of Nabavi (1976), Rudbar Lorestan Pumped Storage Power Plant is located in the structural-sedimentary zone of High Zagros. As per the defined structural characteristics, this zone consists of numerous thrust faults, rough topography and lots of anticlines and synclines. In regional scale, the bedrock of this zone includes the rocks of the Paleozoic to tertiary geological eras. In accordance with the field and laboratory investigations (on local scale basis), the powerhouse cavern area has been constituted by Dalan Formation. The outcrops of Dalan formation with a thickness of about 350 m to 400 m consist of the moderate to thick bedded

---

**3 Dimension of Fracture Characterization and Hydraulic Analysis using Mapping Methods* limestone and dark gray dolomitic limestone.

Field investigations, discontinuities map inside and around the powerhouse cavern have shown no particular geological feature except for F6, F7 faults and Rudbar fault, Fig. 1. The Geological longitudinal section along the powerhouse cavern is presented in Fig. 1. The Rudbar fault is semi-vertical and has scissors mechanism. According to the field investigations, Rudbar Fault is not completely integrated from downstream of main dam to the powerhouse cavern [9]. The pale blue line is probable underground water level after impounding of the main dam.

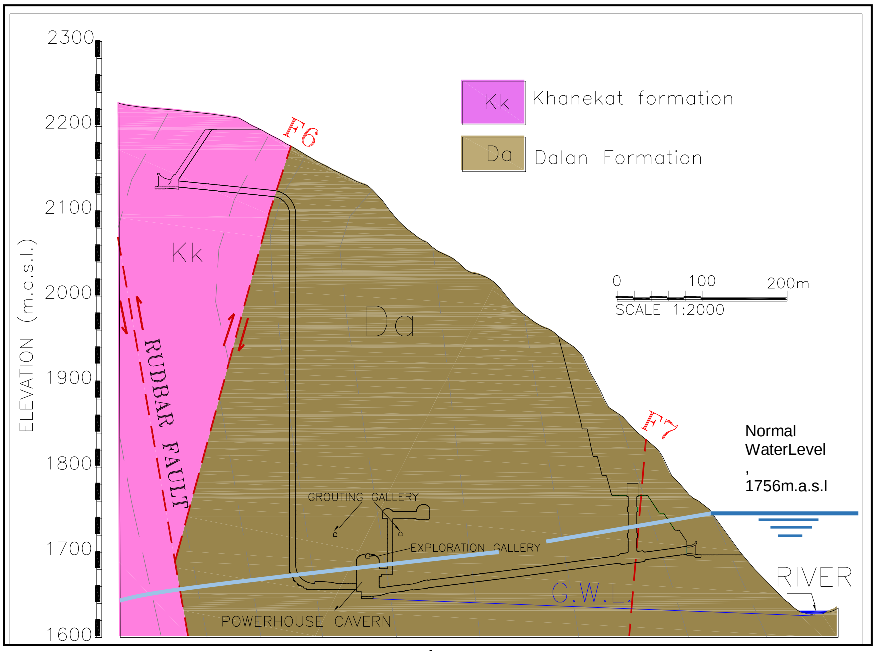

Fig.1

Geological longitudinal section along the powerhouse cavern [9]

2.3. DEFINE THE PROBLEM

Two tunnels have been designed to convey water from the main dam reservoir to the powerhouse cavern and vice versa. More than half of the lengths of these tunnels have been lined keeping the remaining lengths unlined. A 1200m drainage tunnel that starts at the bottom of the powerhouse cavern (1650 m.a.s.l.) and ends downstream of the main dam has been constructed, Fig 2. The main object of this tunnel is discharging of seepage during construction and operational period. A close view of the study area is shown in Fig. 3.

A 120 m exploratory gallery has been excavated in the crown of the power house cavern with a 6mx6m horseshoe-section. Eight exploratory boreholes, with a depth varying between 50 and100 m have been drilled in the exploratory gallery of the powerhouse cavern Fig. 3. The main dam has been impounded and the powerhouse cavern should be excavated in a distance not longer than 350 m to main dam reservoir. After impounding and increasing the reservoir height (100 m), the water level in the boreholes of the powerhouse cavern raised 30 meter, Fig 4. The location of exploratory boreholes are shown in Fig. 3.

Assessing underground water flow around the powerhouse cavern and estimating the amount of seepage is necessary to understand the observed behavior. Therefore, the hydrogeological modeling of the interaction between the cavern and reservoir is assigned a high priority to understand the problem of the water level raise into the cavern.

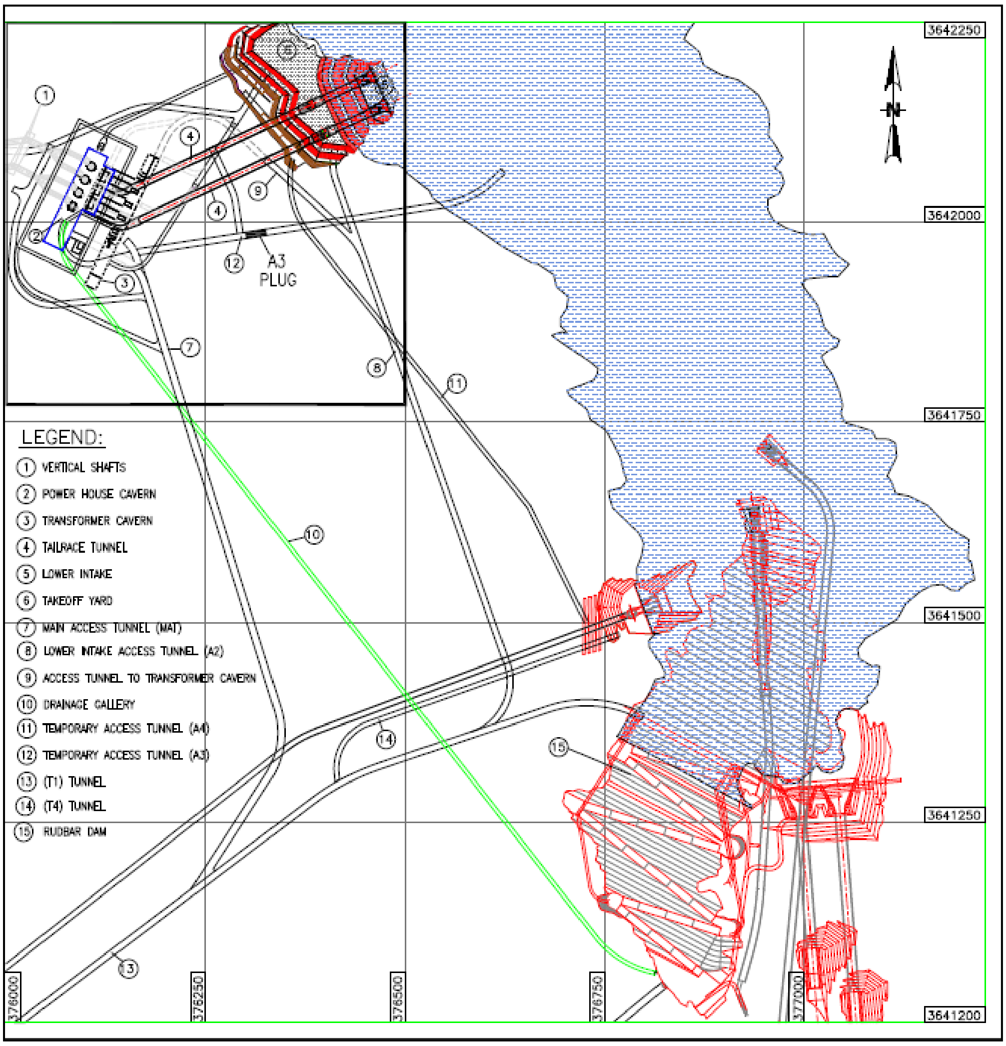

Fig. 2

General Plan of study area

In addition to the mapping of discontinuities in the study area, measuring of seepage in all underground structures and water level in the exploratory boreholes has been done. The water levels in the exploratory boreholes at the beginning and at the ends of the powerhouse cavern are 1665 and 1672 (m.a.sl), respectively, Fig 4. The gradient of the water table along the longitudinal axis of the powerhouse cavern is 7%. And, the gradient perpendicular to the axis of the powerhouse cavern from the main dam reservoir is 27%. In this regards, the measured uplift pressure behind the lining of the drainage gallery varies between 2.2 and 3.2 bar, Fig 5.

3. ESTIMATION OF EQUIVALENT PERMEABILITY

3.4. ANALYTICAL METHODS AND BACK ANALYSIS

There are several analytical and empirical equations to estimate the water inflow into tunnels. The rock mass permeability, water head above tunnel and tunnel radius are the major parameters that enter these equations. In this project, the amount of water ingress into 200 m of unlined tailrace tunnel (part no. 2) has been measured, Fig 3. The groundwater level in the exploratory boreholes, the water level of Rudbar main dam and the radius of the tunnel are known. The equivalent permeability was estimated by back analysis using El Tani's equation [8].

$$Q = 2\pi k \frac{\lambda^2 - 1}{\lambda^2 + 1} \frac{h}{\ln \lambda} \quad \text{where} \quad \lambda = \frac{h}{r} - \sqrt{\frac{h^2}{r^2} - 1} \qquad [1]$$

Q is the amount of water inflow into the tunnel per meter, (m^3/s/m), k is the equivalent permeability of the rock mass (m/s), h is the water head above tunnel (m) and r is the radius of tunnel (m). The measured amount is 35 lit/s water into the 200 m of unlined part of the tail race tunnel. The device to measure the flow rate is a Moulinet.

The radius of tunnel is constant and the water head is variable around the underground structures. The average of groundwater level measured in these boreholes (22 m from center of tunnel) has been selected for back analysis. The normal water level of main dam reservoir also selected for sensitivity analysis. In order to evaluate the influence of water head variation on the rock mass permeability, the two different cases are considered.

1-The tunnel is completely affected by the normal water elevation in the
2-reservoir (1756 m.a.s.l.), about 100 m above the unlined tailrace tunnel
The head of water in exploratory boreholes, 22 m above the tunnel

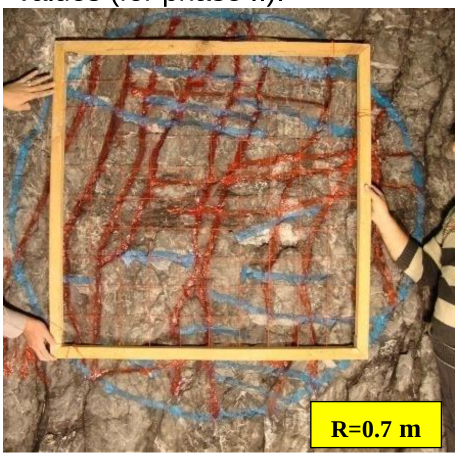
The equivalent hydraulic conductivities of the rock mass that are obtained using Eq. [1] are show in Table 1.

Table 1
Estimated rock mass permeability

Tunnel radius(m)	Q(m3/s/m)	Water head above tunnel center (m)	Rock mass permeability(m/s)	Permeability (Lu)
3	0.0001753	100	1.15e-6	9
3	0.0001753	22	3.31e-6	26

3.5. FIELD MAPPING

The main input data that are needed to generate a DFN representation of the rock mass and calculate the HC tensor are the geometrical and mechanical) characteristics of the discontinuities. Scanline sampling and areal sampling including circular, rectangular and square windows have been resorted to obtain the geometrical and mechanical characteristics of the discontinuities around the powerhouse cavern. Eleven scanline lengths ranging between 10 m and 16 m have been used to survey the discontinuities. Eleven circular windows sampling with radius of 55 cm to 1.5 m and 15 rectangular window sampling with dimensions of maximum 2.2 m*1.9 m have been used as well, Fig 6. The discontinuities were sufficiently mapped in the underground spaces and include 1035 joints, 639 fractures with Scanline and 396 fractures with areal sampling, which are considered well above the required minimum limit that is fixed to 100 for each joint set [10]. The most important parameters to estimate the equivalent permeability of the rock mass and seepage values are the mechanical and hydraulic aperture of discontinuities. With regards to the importance of the mechanical aperture, this characteristic has been measured. Discontinuities aperture have been measured during the detail design period (phase II) and construction period (Phase III). The mechanical aperture values extend on a wide range and have been separated in three classes including low, average and high values (for phase II).



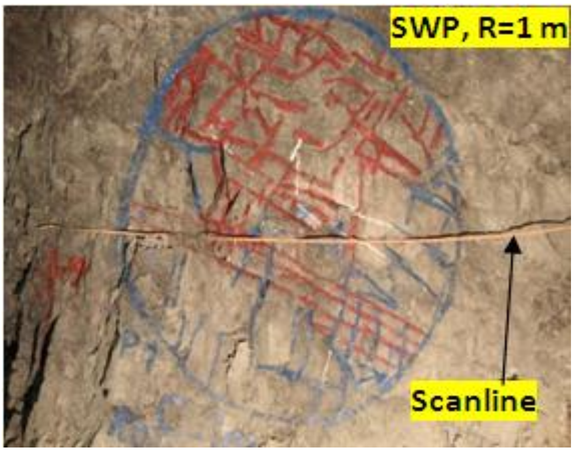


Fig. 6 Scanline and areal samplings in exploratory tunnel in the crown of the powerhouse cavern, (R. is radius of the circle sampling)

According to the discontinuities mapping, four sets of joint sets exist in the studied area. The geometrical and mechanical characteristics of the joint sets are shown in Table 2.

Table 2

The geometrical and mechanical characteristics of the joint sets

Type of discontinuities	Dip (Deg.)	Dip Direction (Deg.)	K-Fisher	Mean Hydraulic aperture, Phase III (mm)	Persistence (cm)	Spacing (m)
Bedding	76	033	28.6	0.2836	1600	0.52
J1	60	123	13.5	0.0016	56	0.588
J2	46	280	6.6	0.0023	68	0.588
B.P.J.	70	029	11	0.0302	219	0.5

3.6. DISCRETE FRACTURE NETWORK (DFN) METHOD

The geometrical properties of the discontinuities include the number of sets, dip angle, dip direction, length, frequency, intensity, density, Fisher's constant, location and diameter (size). An accurate description of discontinuities network that is based on the geometrical characteristics is an outstanding stage in studying the permeability of the rock mass. The numerical code 3DFAHAM produces a stochastic representation of the rock mass conforming with the statistical nature of the data and the uncertainties in their determination. The fractures center are represented as Baecher's disk and their dip angle are distributed using Fisher's model. The number of fractures has been generated using homogenous and stochastic Poisson's process [3]. The uniform distribution function has been used to simulate the fractures location [11].

In order to study the effective connectivity between the fractures, it is needed to omit the fractures or cluster of fractures which are hydraulically inactive and do not contribute to transferring the flow. This process is called Fractures Regulation. The REV† of a fracture network has been estimated on the basis of the network connectivity parameter. The dimensions of an REV have been calculated to determine the size of 3D block and the largest section for calculating the HC tensor (HC window). The REV block is a cube whose edge is 6 m.

The modeling information such as simulation number and dimension of 3D block are presented in Table 3. In each simulation, three sections are considered in each block. Fig.7 illustrates a generated 3D block with its fractures and a regulated 2D section. Due to the uncertainty of hydraulic aperture calculation and high effect of this parameter on the equivalent permeability of the rock mass, four aperture classes have been used in DFN analysis. So, 60 models have been run. The calculated equivalent permeability with DFN code are shown in Table 4 using the hydraulic gradients mentioned in section 2.3 and four aperture classes.

† *Representative Elementary Equivalent*

The equivalent permeability according to Table 4 extends over a wide between 7.7 to 157 Lugeon for i=7% and 5 to 115 Lugeon for i=27%. This is due to the predominance of the aperture on the HC values. On the other hand, according to Tables 1 and 3, the calculated HC by back analysis and those obtained with the DFN code at Phase II with an average aperture are close. The average equivalent permeability that is calculated with the DFN code in the upper aperture range is 136 Lugeon.

Table 3 Specifications of models by 3DFAHAMcode

Simulation number	dimension of 3D block (m)	dimension of HC window (m)	Location of HC window in 3D block (m)	Hydraulic gradient (%)	
				7	27
S1	10*10*10	6*6	3, 6, 8	√	√
S2	10*10*10	6*6	3, 6, 8	√	√
S3	12*12*12	8*8	3.5, 6, 9	√	-

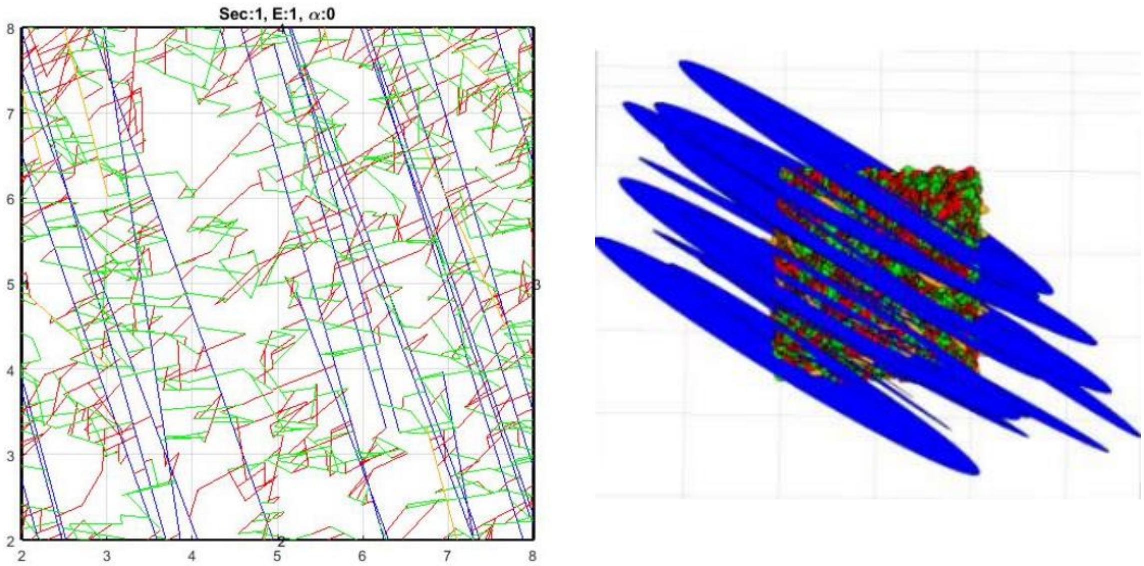

Fig.7
Generated 3D fractures block and regulated 2D section (four joint sets)

Table 4
Calculated equivalent permeability (or HC) with DFNE code (3DFAHAM)

Aperture type / Gradient	Phase II			Phase III
	Lower	Average	Upper	
i=7%	0.03	7.7	145	157
i=27%	0.02	5	104	115
Average of both gradient	0.026	6.4	124	136

4. CONCLUSION

The geological and hydrogeological investigations have been used to calculate the equivalent hydraulic conductivity tensor at the powerhouse cavern in Rudbar-Lorestan hydroelectric project. The estimated values of HC by DFN code are larger than those estimated by analytical method.
Various studies revealed a low level of the water table, a smooth slope of its gradient, water bearing zones with weak and crushed rocks, local openings and various discontinuities and fractures, leak points and local springs. So, the hydraulic conductivity that is obtained by back analysis with the analytic method for a homogeneous aquifer should be considered cautiously. And the calculated value with the DFN code that attained 136 Lugeon should be considered an upper limit or a maximal value for homogenous rock mass.

1. INTRODUCTION

The pumped storage plant Obervermuntwerk II with an underground powerhouse cavern is located in the western part of Austria. The construction of the approximately 500 million € project began in May 2014 and the power plant is expected to start operating in 2018. In the pre-designing phase 2D-FE analysis for the powerhouse cavern were performed and during the main excavation of the cavern, 3D finite element calculations using Plaxis 3D [1] have been conducted. One objective of the paper is to summarize results from 3D finite element analyses performed in order to assess the performance of the two main caverns of the hydro power plant project. Additionally the headrace system of the power plant and its geotechnical design is presented. Finally, also some experience gained during the construction works is discussed.

2. PROJECT DESCRIPTION

The new pumped storage power plant (PSPP) is located parallel to the existing Obervermuntwerk I. The average construction altitude in the powerhouse cavern is 1700m above sea level. The Obervermuntwerk II will utilize the existing water capacities of the Vermunt and Silvretta reservoir to generate peak and balancing energy. The water from the Silvretta reservoir feeds the underground powerhouse cavern through the 2800m long Silvretta high-pressure tunnel. The maximum overburden is roughly 1100m. Fig.1a shows an overview of the entire project area. The Silvretta high-pressure tunnel is lined with pre-casted segmental linings in the invert and an in-situ concrete shell. The last 600m of the Silvretta tunnel are first lined with a thin steel shell and an interior concrete core ring (length of 255m) followed by a thick-walled steel lining, which is designed to withstand the external pressure.

The Vermunt reservoir acts as a storage reservoir for pumping mode and is connected to the cavern with a 380m long tailwater tunnel. The length of the powerhouse cavern is 125m, the width is 25m and the average height is 33m. The powerhouse consists of two ternary machine units with a capacity of 180MW and two pumps of 180MW each. The turbines are designed to have a height between 240m and 310m. Fig. 1b shows a schematic plan view of the two caverns and Fig. 2 shows a detail of a typical cross section through the powerhouse cavern including the anchor design and the different excavation levels. A detailed description of the project and the design procedure can be found in Dich et al. [2].

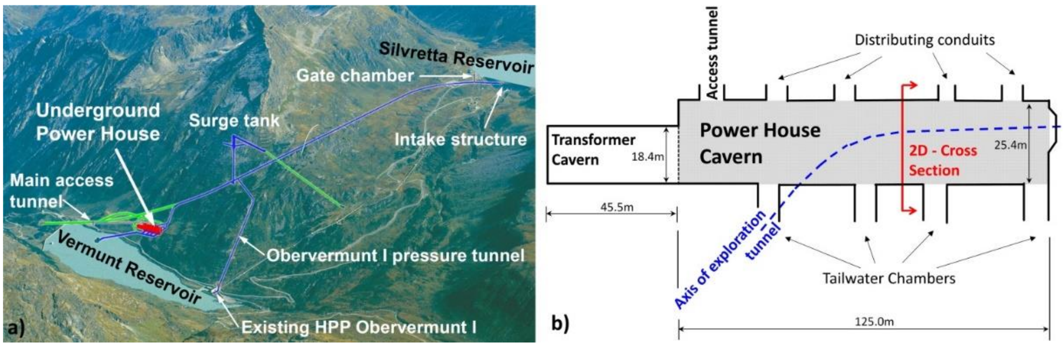

Fig. 1
a) Project overview; b) Plan view of transformer and powerhouse cavern

3. ROCK CONDITIONS

All plant components of the Obervermuntwerk II lie in the Silvretta crystalline. This formation consists mostly of granite gneisses, amphibolites, slate gneisses and mica schist, with the latter being encountered at the intake structure and the gate chamber. The Silvretta tunnel, the pressure tunnel and the tailrace tunnel lie completely in the granite gneiss, as can be seen in Fig. 2. The granite gneisses generally show low to moderate rock mass permeability. A detailed description of the geological conditions is given in Dich et al. [2].

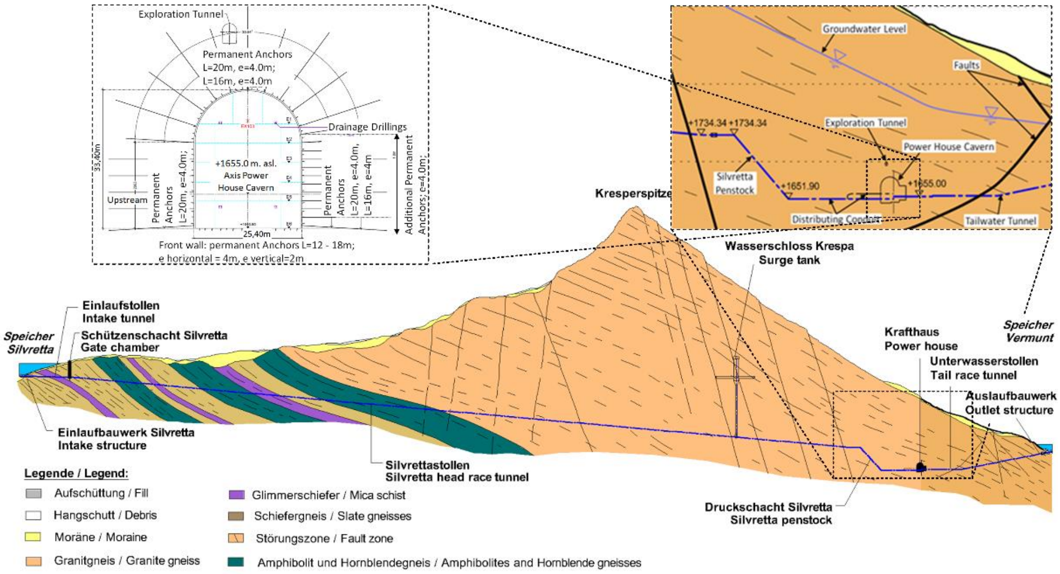

Fig. 2
Longitudinal section and details

In the exploratory tunnel and with investigations from the surface an intense testing program has been performed in 2010 and 2011. Seven drillings with core tests, water pressure tests and joint expansion tests have been conducted. Additionally plate load tests, mineralogical analysis and rock mechanical laboratory testing were executed to obtain uniaxial compressive strength, tensile splitting strength, stress and deformation characteristics. The UCS has a range from 77 to 130N/mm², the tensile splitting strength ranges from 9 to 15N/mm² and the deformation modulus is determined with 15 to 18GPa. For the FE predictions presented in the following only one material set was classified, which is defined with a linear elastic – perfectly plastic constitutive model using a Mohr-Coulomb failure criterion.

4. FINITE ELEMENT ANALYSIS

4.1. Preliminary 2D Analysis

Because of the geological situation (see Fig. 2), it was expected that the principal stresses in the initial state are not horizontal/vertical but rotated. To determine the initial stress situation in the area of the powerhouse and the transformer cavern two dimensional plane strain models were defined in Plaxis 2D (Brinkgreve et al. [3]). A cross section ranging from the sea level of the Vermunt reservoir up to the peak of the Kresper mountain was modelled. The location of the cross section is shown in Fig. 1b.

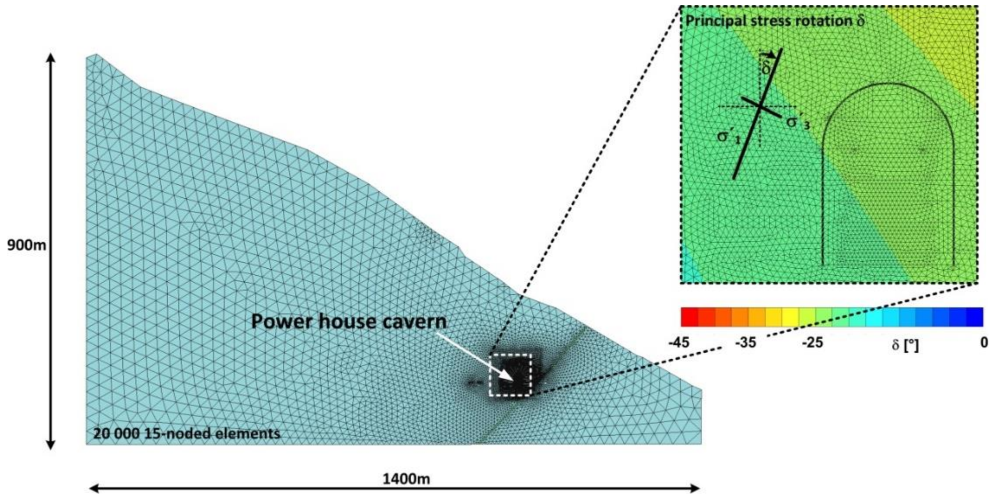

Fig. 3
Preliminary 2D plane strain model and predicted principal stress rotation

The model has a length of 1400m and a height of 900m and consists of about 20000 15-noded elements. The results of this analysis confirmed a significant rotation of principal stresses in the region of the powerhouse cavern. Fig. 3 shows the entire 2D FE model and a zoom of the region next to the powerhouse cavern. The results indicate a rotation of the major principal stress σ_1 to the vertical axis of roughly 25°.

4.2. 3D Finite element analysis

Since the stress distribution (and redistribution) in the region of the side tunnels and gate chambers during the construction of the caverns is one of the key issues of the 3D FEA, the mesh discretization of the caverns and the surrounding material has to be relatively fine and therefore the finite element models discussed consist of about 500000 10-noded elements with quadratic shape function. The model dimensions L/B/H are 550/165/175m. Fig. 4a shows the geometrical definition and the finite element discretization of the two caverns, the side tunnels and the gate chambers. All calculations were performed under drained conditions. To obtain realistic deformations of the caverns and a reliable stress distribution in the surrounding soil, it is necessary to model a realistic initial stress field and the relevant construction phases. Therefore the “rotated” initial stress field, as defined from the preliminary 2D FE analysis (briefly discussed in chapter 4.1), was imposed (see Tschuchnigg et al. [4]). To include the construction sequence of the caverns, the cross section was subdivided into 6 or 7 main sections respectively (see also Fig. 2 - excavation level E1 to E6). In longitudinal direction, the excavation phases are modelled with excavation lengths between 3.0 to 9.0m. In total, 187 calculation phases are defined in the analysis. Fig. 4b shows exemplary the excavation phase of excavation level E2 in the powerhouse cavern.

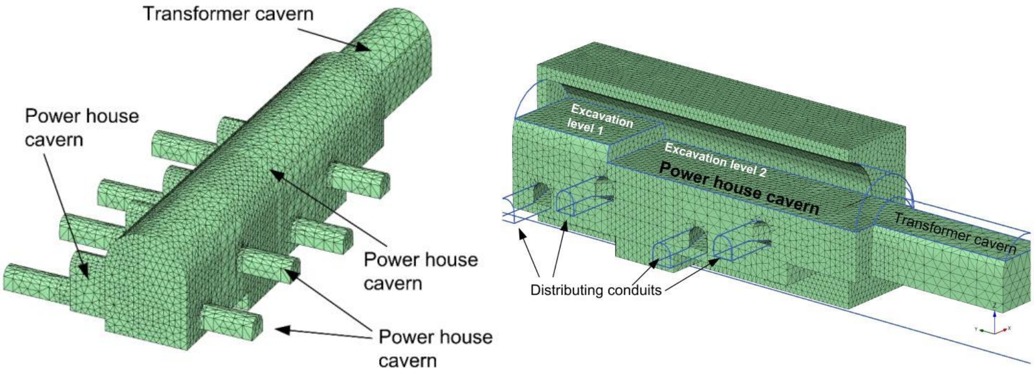

Fig. 4
a) 3D FE model: powerhouse cavern, transformer cavern, side tunnels and gate chambers, b) Calculation phase - excavation level E2 of powerhouse cavern

The maximum vertical displacements in the powerhouse cavern are in the range of 15 to 20mm. Fig. 5a shows the contour lines of vertical displacements after the final construction step. The maximum vertical displacements do not occur at the center of the caverns due to the rotation of principal stresses at the initial stress state. The analysis showed that the maximum deviatoric stresses occur in the powerhouse at and slightly above the gate chambers. In addition, the relative shear stresses (τ_{rel}), which represent the ratio between current shear stress and maximum shear stress, the rock can sustain, indicate sensitive zones at and right above the gate chambers. Fig. 5b represents the contour lines of deviatoric stresses after the final construction phase. However, it has to be mentioned that the anchors and the shotcrete lining are not modelled in this 3D finite element analysis, and the results shown in Fig. 5b indicate that the depth of high shear stresses is relatively small (which corresponds also to the evaluation of relative shear stress). Thus, it can be concluded that this stress concentrations are well covered by the anchors.

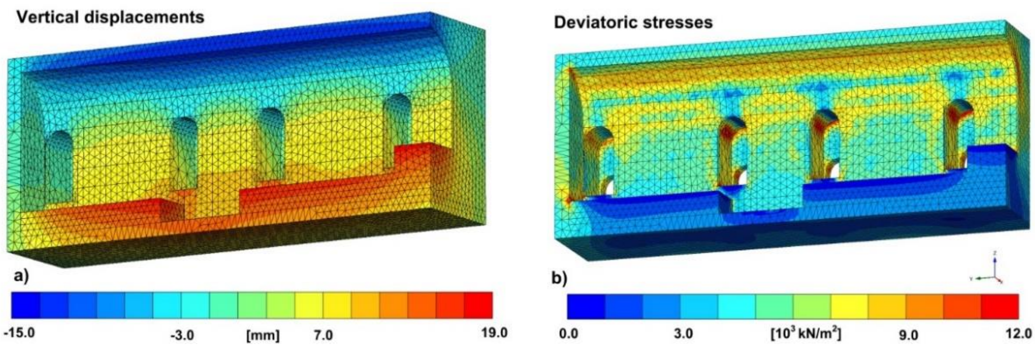

Fig. 5
a) Contour lines of vertical displacements, b) Contour lines of deviatoric stresses

To investigate the behaviour of the shotcrete lining additional 2D finite element analyses have been performed where the three shotcrete layers of the powerhouse cavern were modelled with an advanced constitutive model for shotcrete taking account of tension softening (Schädlich et al. [5]). Details of these FEA can be found in Tschuchnigg et al. [4].

5. HEADRACE SYSTEM OF OBERVERMUNTWERK II

5.1. SILVRETTA TUNNEL, PRESSURE SHAFT, MANIFOLD

The generation water system of the pumped storage works consists of a number of plant components (see Fig. 1 and Fig. 2). In the following the headrace tunnel called "Silvrettastollen", the pressure shaft and the manifold including tailrace tunnel and outlet structure are presented in detail.

The 2773m long Silvretta headrace tunnel, with a gradient of about 9%, starts downstream of the gate chamber at chainage 184 and ends at the "Kaverne Ausbaurohr" near chainage 2947. At chainage 2490 the headrace tunnel branches off for the Obervermuntwerk I, which is also supplied with headwater from the Silvretta tunnel. The connection tunnel to the Krespa surge tank is located at chainage 2550. Up to chainage 2570 the Silvretta tunnel (with a clear internal diameter of 6.8m) has a 30cm thick unreinforced concrete lining with invert segments. At this chainage is the transition to the 256m long section with thin-walled steel lining (Fig. 6). The thin walled steel lining (with a diameter of about 6m) has a thickness of 10mm. The thin steel lining is protected against external water pressure with a support ring with a wall thickness of 0.55m. In this area, the tunnel has an internal diameter of 4.9m. At chainage 2825 is the transition to the thick-walled armored section (Fig. 6), where the internal diameter reduces to 4.5m. The thickness of the steel lining varies between 44mm at the transition to the thin-walled steel lining and 36mm at the transition to the downstream pressure shaft.

The pressure shaft is designed as an inclined shaft with a slope of 48°; the inclined length is about 110m. The circular flow section has a thick-walled steel lining with wall thicknesses between 32mm at the upper bend and 35mm at the adjoining manifold. The manifold, consisting of the upstream Y-ducting with the two main runs and the subsequent two turbine feed pipes and two pump risers, is designed for hydraulic short circuit operation (simultaneous operation of turbines and pumps). The water from the two machine sets in turbine operation is collected in the tailrace tunnel and flows down to the outlet structure in the Vermunt reservoir. In its vertical alignment, the tailrace tunnel is divided into a horizontal and a sloping section with a constant inclination of 19.5% towards the outlet structure. The internal diameter of the cast concrete ring is 6.4m, with a wall thickness of 0.35m.

5.2. DESIGN OF THE HEADRACE SYSTEM

For the geotechnical design, a difference between the excavation of the cavity in the course of tunneling and the design of the tunnel lining in operation is made. The design of the cavities is done in line with the ÖGG guideline for geotechnical design [6]. The deformation of the excavated cavity have been determined by means of the convergence confinement method (Kolymbas [7]) in each section of 25m and additionally at any important section. Considering the deformations and the depth of the fractured zones, rock mass behaviour types GVT1/2 to GVT 4 can be derived analytically. Rock mass behaviour types GVT 5 to GVT 11, if present, are determined with delineation criteria based on Steiner [8], but modified for the specific project.

Four different lining types were used for the headrace and tailrace tunnels of the Obervermuntwerk II:

– Unreinforced cast concrete
– Reinforced cast concrete
– Thin-walled steel lining
– Thick-walled steel lining

Fig. 6 shows the determination of lining type zones over the whole part of the water system. An unreinforced concrete lining was constructed in the intake tunnel, parts of the Silvretta tunnel and in parts of the tailrace tunnel, where the groundwater table lies securely higher than the internal pressure line of the system.

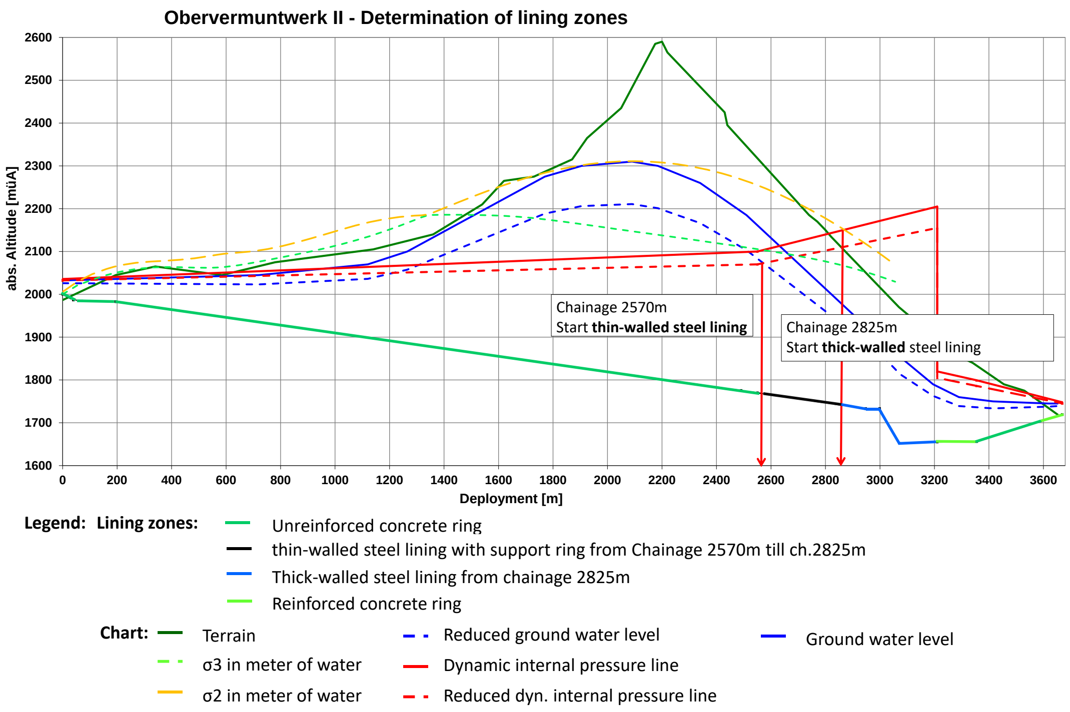

Fig. 6
Determination of lining zones

Cast concrete inner linings with reinforcement (to distribute cracking) were used at the transitions between the rectangular cross section of the gate chamber and the adjoining circular tunnel, as well as at branches. In the tailrace tunnel, further reinforced concrete inner linings were used near the caverns and the outlet structure. In areas where the stresses from internal pressure could indeed be resisted by the rock mass but water losses were possible due to the low groundwater table in relation to the internal pressure, a thin-walled steel lining was used. The thin steel lining is not designed to withstand buckling due to external pressure, therefore it requires a support ring, which was designed to resist the groundwater pressure of up to 39bar in this area. The dimensioning of the thick-walled steel lining was performed in accordance with the work of Seeber [9], including considerations of the collaborative action of the rock mass. Thick-walled steel lining was used in zones where the collaborative action of the rock mass was not able to resist loading from internal pressure alone. Thick-walled steel lining was also used in zones near large cavities with atmospheric pressure conditions, such as the powerhouse or gate chamber. The thick-walled steel lining was designed to resist not only internal pressure but also external water pressure. This design was done in in accordance with the calculation models of Amstutz [10]. The transition from the unreinforced cast concrete inner lining of the Silvretta tunnel to the thin-walled steel lining was placed at the intersection of the characteristic dynamic internal pressure curve with the design value of the groundwater table. The transition from thin-walled to thick-walled steel lining was placed at the intersection of the design internal pressure curve with the smallest normal stress in the cross section (estimated from the FE analyses). This procedure includes the consideration of the geological and topographical conditions. The dimensioning of the thick-walled steel lining was based on steel grade S 690. The material parameters for the steel and the rock mass are given in Table 1.

Table 1
Steel and rock parameters

Steel quality S 690	Tensile yield strength $\sigma_{0,2\%} = \sigma_F$	Minimal flexural stress $\sigma_{b,min}$	Young´s Modulus	Poisson´s ratio
	690N/mm^2	770N/mm^2	210000 N/mm^2	0.3 [-]
Rock parameter	Young´s Modulus	Deformation Modulus VF*- Modul	Specific weight	Poisson´s ratio
	8GPa	6.3GPa	27kN/m^3	0.27 [-]

5.3. CONSTRUCTION – EXPERIENCE

In summer 2014 conventional tunneling started simultaneously from four starting points. The excavated cross section was horseshoe-shaped for all tunnels. Each face was monitored with instrumentation. The drives generally ran according to the geotechnical calculations made in advance and the geological predictions.

The only surprise was in the Silvretta tunnel, with a significant increased water ingress (peak of about 120l/s) along a length of about 200m. Consequently, the round length was reduced from 3.0m to 1.5m and the instrumentation of the monitoring system was increased.

In the intake tunnel and the Silvretta tunnel, which are lined with cost concrete inner lining, the formwork striking time was ten hours. At the time point of striking, an average early strength of 6MPa was reached, with a specified minimum strength of 2MPa. The concrete was then cured to avoid shrinkage cracking. Concreter repairs were only required to a very small extent. In the sections with thin-walled steel lining, the external ring was backfilled with concrete after installing the 14m long pipe sections. The formwork unit for the concreting of the support ring followed offset at a spacing of 7m. Due to a coordinated sequence, the works proceeded without delays. No concrete repairs were necessary.

The thin-walled steel lining had to be secured against floating in order to ensure its circularity. This provided a binding band and two invert ties in the middle and four invert ties at the ends of each 14m long pipe section. The pipe section lengths for the thick-walled steel lining were generally 10.5m. After attachment and quality controls, each pipe section was concreted. The backfill concreting of the turbine feed and pump riser pipes was carried out in a filled state under pressure in order to achieve a pre-stressing in the longitudinal direction of the manifold.

SUMMARY

3D finite element analyses were performed in order to assess the performance of the two main caverns of the PSHPP Obervermunt II. Of main concern was the stress redistribution within the surrounding rock and the settlement behaviour of the cavern powerhouse during the different excavation phases. The computations predict 15 to 20mm of displacements at the crown of the powerhouse cavern and show that next to the side tunnels stress concentrations have to be expected.

The article provides also a brief overview of construction progress on the major project pumped storage works Obervermuntwerk II. Both the geotechnical design and the experience gained during the construction of selected sections is discussed. The complexity of the project with the technical requirements for the tunnel linings require some special measures, which are presented in detail.

Also described is the headrace system with the 2.4km long Silvretta headrace tunnel, which is first lined with a non-reinforced in-situ concrete lining, then with a thin-walled steel lining (including an inner in-situ concrete core ring) and the last part is lined with a thick-walled steel lining. Both the Silvretta penstock and the distributing conduit are designed with a thick-walled steel lining. The decision where to use which of the four lining parts is based on a number of constraints, namely the rock and steel parameters, the inner and outer pressure and the minor principal stress in the surrounding rock mass.

In the last part of the article an overview of the construction experiences is presented. It can be concluded that almost all parts of the excavation works ran according to the geotechnical calculations and the geological predictions.

CONSTRUCTION AND MONITORING OF POWERHOUSE CAVERNS THE CIRATA HYDRO POWER PLANT

1. INTRODUCTION

Powerhouse construction of PLTA Cirata (Hydropower Plant of Cirata) is located underground with 1.008 Mega Watt (MW) of installed capacity and the mean annual generation of electrical energy is 1.428 Giga Watt hour (GWh). To produce 1.428 GWh, eight turbines are operated with the capacity of each turbine is 126.000 KW and 187,5 RPM for *rotative* speed. The effective head through penstock is 112,5 meters and the water discharge is 135 m3 per second. The tunnel (an excavation area) below the rock mountain is one of the largest *Power House Caverns* constructions in the world by regarding to its wide. The construction which is located among the rocks will be affected by enormous pressure from the surrounding rocks; therefore the design of the tunnel is made as it aims to limit the impact of pressure from the rocks as small as possible.

For the construction design of PLTA Cirata, it had been chosen the shape for the tunnel which is rather curved similar to egg shape. The decision was made by considering the simulation result using structural software and the number of stress for reaching the stability of underground structure. Oval tunnel has certain area which is affected by certain stress that is limited to shallow area, so the structural stability becomes better. Since the benefit obtained from the oval shape is very large, thus, the oval shape like egg shape for the tunnel shape is decided for the underground building of PLTA Cirata.

The structure of *Power House Caverns* of PLTA Cirata has 320.000 m^3 in volume with longitudinal dimension of 1300 m^2, 49,5 m of the height and 35 m of the width of the tunnel. This construction was built by using Geo New Austrian Tunneling Method (NATM) in 1984. The cavern structure reinforcement used rocks around the tunnel as the prior buffer, then it was shotcrete-lined and it was reinforced by rock bolt and pre-stressed concrete. Since NATM was a method for rational construction by using surrounding rocks as the buffer, so it was very important to do monitoring towards the change of the rocks regularly and to keep the safety and the reliability of the underground construction; the monitoring and maintenance activity towards caverns wall were implemented.

The monitoring and maintenance system for the safety of *Power House Caverns* structure of PLTA Cirata, which had been operated for 30 years, are regularly implemented every month. The monitoring activity uses three instruments, i.e. *Rock Displacement Extensometer, Crack Displacement Meter*, and *Convergenmeter*. The instruments of Power House Caverns of PLTA Cirata were installed when the cavern construction is being built.

2. MONITORING SYSTEM OF POWER HOUSE CAVERNS

The activity of regular maintenance and monitoring was done to know the structural safety early; it had been mentioned in Ministerial Regulation of PUPR Number 27/PRT/M/2015 as one of the requirements for the management of dam and complementary construction. The Power House Caverns of PLTA Cirata had some monitoring instruments such as Rock Displacement Extensometer, Crack Displacement Meter, and Convergenmeter. The functions of each instrument of PLTA Cirata Power House Caverns could be seen as follows:

Monitoring the instrumentation on the implementation of Power House Caverns of PLTA Cirata has been being done continuously up till now. In geological conditions, the Power House Caverns of PLTA Cirata was located between the rock layers of volcanic breccias which could gradually be decomposed. Based on the phenomenon, the maintenance and monitoring activities was done towards the instruments related to the rocks which become the buffers of Cirata cavern. This is the description about installed instruments and the monitoring result from Power House Caverns of PLTA Cirata:

2.1. ROCK DISPLACEMENT EXTENSOMETER

The monitoring activity of rock mass which was located on the Power House Caverns structure was done by using rock displacement extensometer (Extensometer). This instrument was installed in rock bolt structure to monitor the displacement of rock mass which was located on the roof of Power House Cavern.

The displacement of rock mass at Power House Caverns of PLTA Cirata was measured by using censor which records the stress and strain happened on the rocks. Currently, there are seven installed Extensometer lines. Six lines of them were automatic measurements and one line was manual measurement.

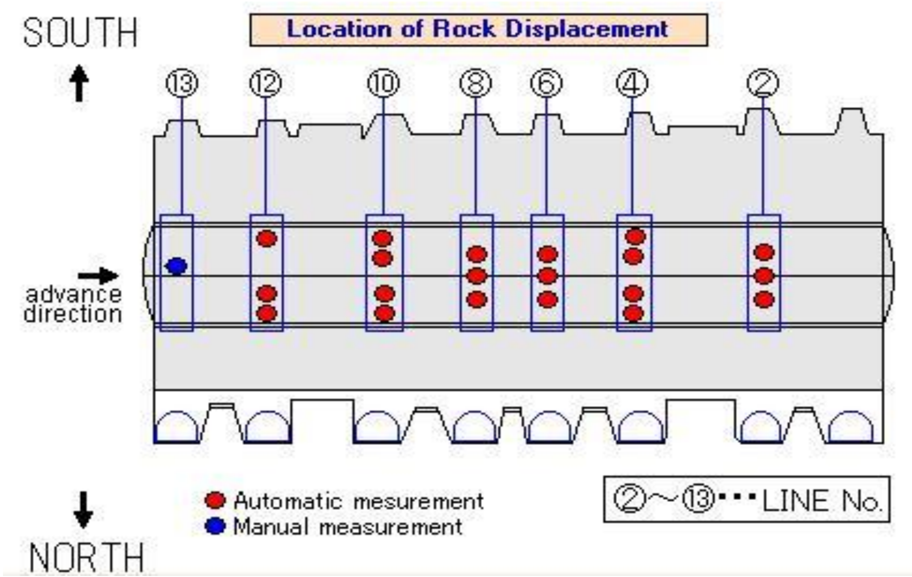

Figure 1. Layout of Location for Monitoring Points of the instrument of Rock Displacement Extensometer

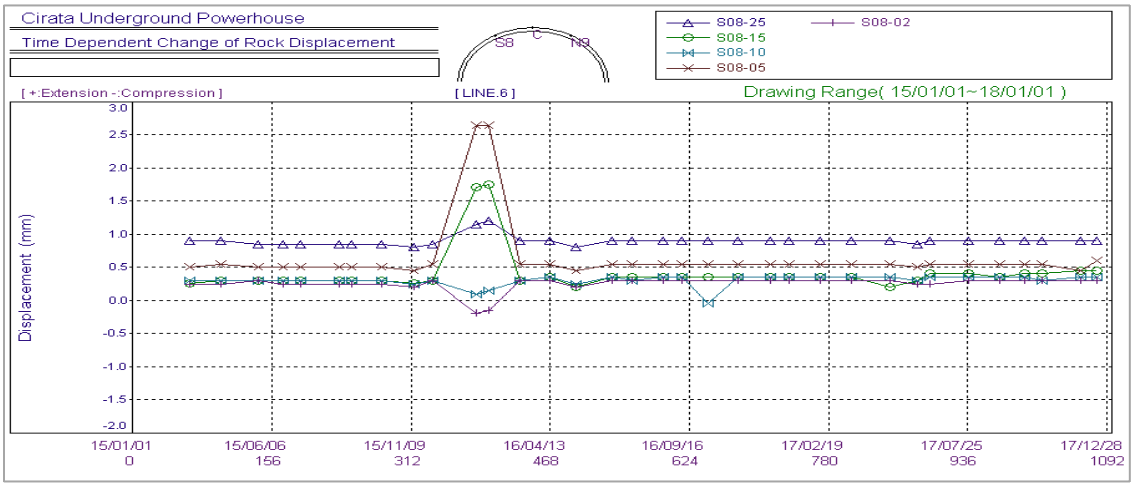
The monitoring result of Rock Displacement Extensometer until December 2017 showed the normal behavior towards the rock displacement of top oval cavern of underground power house. There was no significant fluctuation in every line since the maximum displacement of the design was 2mm.



Graphic 1.The Monitoring of Rock Displacement by using the instrument of Rock Displacement Extensometer

The rock displacement which is monitored until now shows various displacement in every point. The direction from the rock displacement was various. It could be seen in the graphic below. It showed that there were displacement to the positive area and displacement to the negative area. Thus, the rock structure could be considered as safe.

2.2. CRACK DISPLACEMENT METER

The displacement on the surface of Power House Cavern shotcrete which is indicated by the existence of crack is measured by using Crack Displacement Meter. The installation is located in the existed crack line. It aims for identifying the development of damage of the cracks.

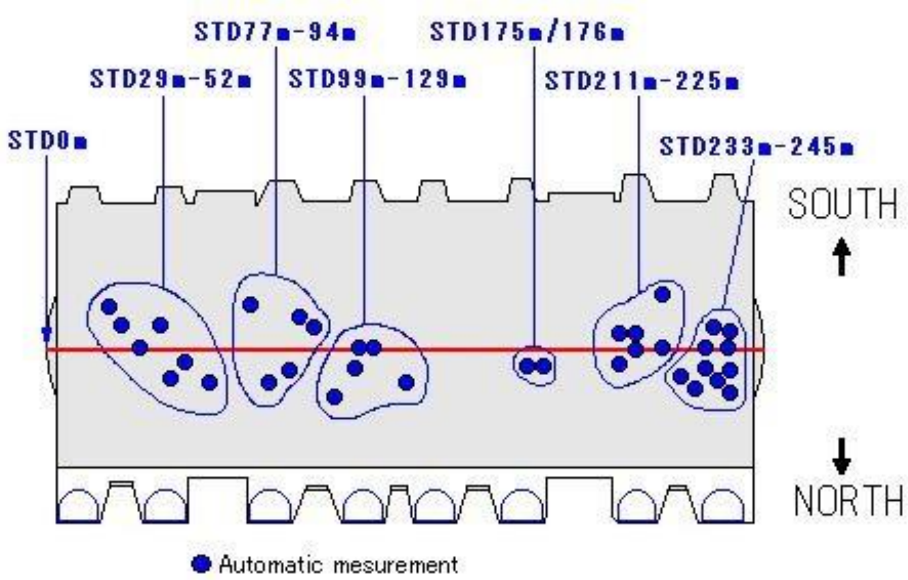


Figure 2. Layout of Location for Monitoring Points of the instrument of Crack Displacement Meter

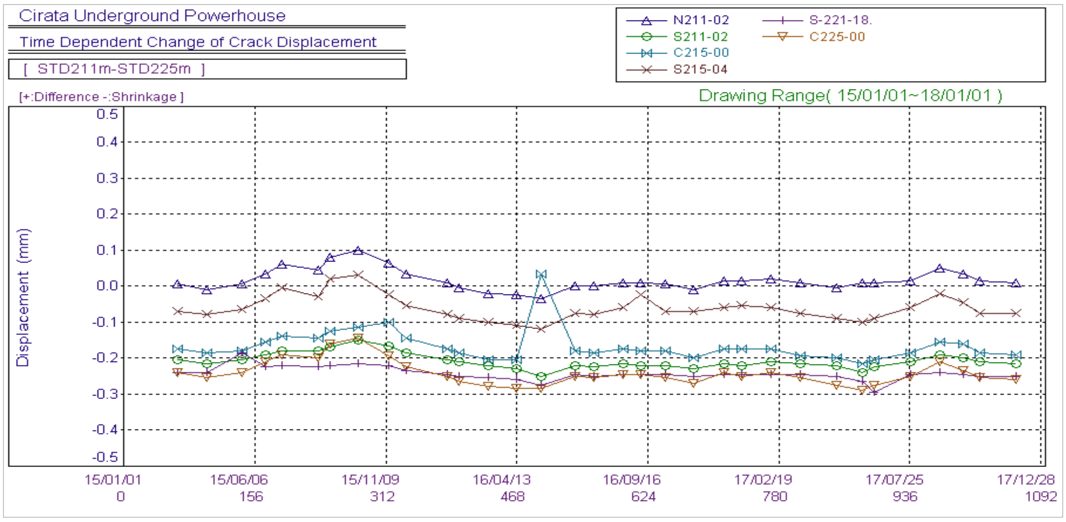
The instrument of Crack Displacement Meter was installed on six crack lines by using automatic censor with various numbers. Then, there is manual censor which is installed on two crack lines. The measurement was done by using Avometer which was located in measurement room.



Graphic 2.The Monitoring of Crack Displacement by using the instrument of Crack Displacement Meter

The monitoring towards crack displacement until year 2017 showed normal digit on the result. It could be seen that the displacement of data trend was still less than the maximum value i.e. between 0,0 mm to 0,3 mm, where the maximum value was 2 mm. The monitoring towards cracks will continuously be done up till now since the bigger number of the age of crack, the bigger cause of crash happens. It happens since the crack caused by the age of building cannot be avoided and the crash signal can be initiated from a crack.

2.3. CONVERGENMETER

Deformation which is happened in Power House Cavern was not only caused by the impact of rock pressure or the characteristic of the rock, but also the moving load inside the cavern such as the generator equipments. Based on the condition, the regular monitoring was applied by using Convergenmeter to detect the potential failure and damage early which were happened on cavern wall.

The deformation monitoring towards Cavern wall was done by measuring the displacement of a couple of monuments which were installed along the terrace upstairs by using Convergence meter. The measurement was aiming to know the span between the north wall and the south wall of the Power House. So, the displacement of the wall was known by the difference number between the new and the old measurement.

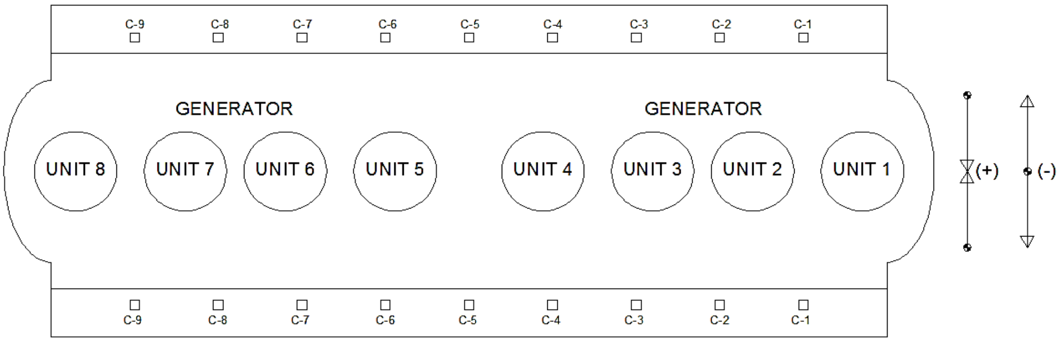


Figure 3. Layout of Location for Monitoring Points of the instrument of Convergenmeter

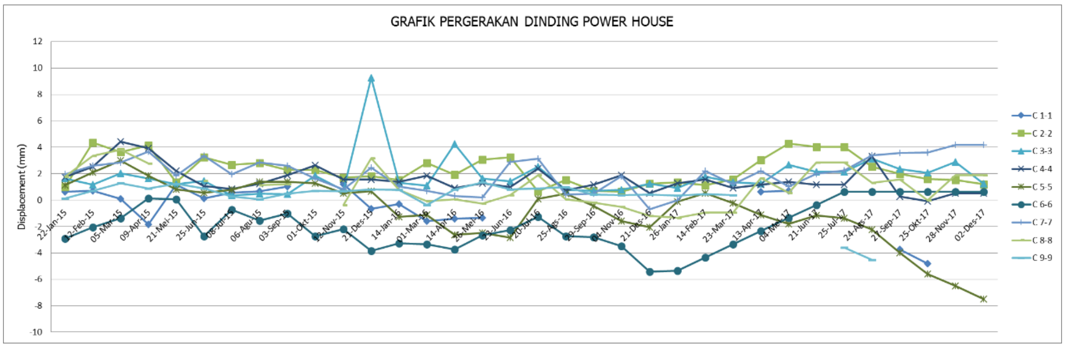
In monitoring the wall displacement of Power House, the positive value occurred when the Power House wall was deforming, so both monitoring monuments moved inside or were being closed. Meanwhile, the negative values occurred when the two monitoring monuments moved outside or were being apart. Figure 2. Lay Out of the location of monitoring points on Convergenmeter instrument

On the measurement for the period 2015-2017, significant trend displacement was happened towards two monitoring points i.e. C 5-5 and C 9-9. The graphic of both monitoring points were deteriorated or it could be said that the condition of PH wall was constricting in both locations. The maximum value of convergence measurement for the period 2015-2017 was about -7.487mm on C 5-5. Meanwhile, the minimum value was about -0.101mm on C4-4.



Graphic 3.The Monitoring of Wall Displacement by using the instrument of Convergenmeter

From the visual inspection, there was no increasing number of structural damage on the monitoring point. Therefore, the monitoring towards vertical wall of cavern for the period 2015-2017 showed that the displacement was still categorized as normal.

3. CONCLUSION

The monitoring system towards Power House cavern of PLTA Cirata was being done regularly in every month by PT PJB BPWC. Monitoring was done by using three instruments where each of the instruments had different monitoring function. On the cavern age which almost reached 30 years, the monitoring showed that the construction behavior was categorized as normal. These are the conclusion of each monitoring instruments:

3.1. Rock Displacement Extensometer

The monitoring towards rock mass which was located in the Power House Cavern structure was done by using rock displacement extensometer (Extensometer). The result of monitoring until December 2017 showed that there was no significant displacement. Then, there was no structural damage on the result of visual monitoring.

3.2. Crack Displacement Meter

The displacement on the surface of Power House Cavern shotcrete which was indicated by the existence of crack was measured by using Crack Displacement Meter. For the result of monitoring towards the instrument until December 2017, the displacement which was monitored was safe. From visual monitoring, there was no increasing number of cracks or there was no additional number of structural damage.

3.3. Convergenmeter

The deformation process happened to Power House Cavern was caused by the impact of rock pressure or the characteristic of rock. Regular monitoring by using Convergence meter aimed at detecting the potential of failure and damage happened early on the wall for crane seats. The monitoring for the period 2015-2017 showed that the displacement was categorized as normal. From the visual inspection, it was found that there was no increasing number of structural damage at the monitoring points.

RÉSUMÉ

La Construction de Power house de Cirata hydro-électricité située à le sous de terre avec une capacité installée de 1 008 méga watts (MW). La production d'énergie électrique par an est à la moyenne de 1 428 Giga watt heures (G Wh). Pour générer les 1 428 G Wh, il fonctionne huit turbines qui chacun a capacité 126 000 kW, et ronde 187,5 tr/mn.

Cette pièce qui a été creusée au sous de la montagne en roche est l'une des plus grandes constructions de Power house tout le monde, en termes de largeur d'envergure. La construction qui est située entre les roches est affectée par l'énorme pression des roches entourages. Ainsi la forme de la pièce est conçue pour baisser la pression de roche devient au peu que possible.

La construction d'hydro-électricité de Cirata est courbe qui semblable au forme d'œuf. La structure de Power House sur les cavernes hydroélectriques Cirata a volume atteint 320 000 m3, avec une superficie de 1300 m2, transversale hauteur de section de 49,5 m et la largeur de 35 m Runganan. Cette construction est construite en utilisant la nouvelle méthode de tunneling de GEO (NATM) autrichienne en 1984.

En termes de condition géologique, Power House sur les cavernes hydroélectriques Cirata, situé entre les couches de brèche volcanique, qui peut subir lentement la météorisation. C'est pourquoi on doit faire la maintenance et surveillance de l'instrumentation Rock sur la caverne tampon de Cirata.

Cette hydro-électricité a été opérée depuis 30 ans. La maintenance et surveillance a la sécurité de structure de cavernes Power House sur Cirata hydro-électricité est effectué régulièrement chaque mois. On utilise trois instruments dans cette surveillance, c'est-a-dire extensomètre de déplacement de roches (Rock Displacement Extensometer), compteurs de déplacement de fissures (Crack Displacement Meter) et Convergenmeter. Instrument de Power House Cavernes hydroélectrique est installé quand la construction de caverne était construit.

On utilise le déplacement de roche extensomètre pour surveiller la masse de roche qui est située au-dessus de la structure de caverne Power House. Le résultat de la surveillance jusqu'en décembre 2017 montre qu'il n'y a pas de déformation dépassant à la conception maximale. Tandis que le mouvement a la surface de short crête Power House caverne qui a indiqué la présence de fissures, on la mesure par l'aide de compteur de déplacement (Crack Displacement Meter). La surveillance jusqu'à maintenant donne le résultat avec la bonne et normale condition. Aussi par le résultat de surveillance visuelle il n'y a pas les nouveaux dommages structurels aux cavernes de mur. Donc, les résultats de la surveillance en général des a montré un comportement normal dans la construction.

SUMMARY

Engie's 118 MW Quitaracsa hydropower project is located in the Cordillera Blanca mountain range in Ancash/Peru, on the Quitaracsa River, a main tributary of Río Santa, which is one of Peru's mayor rivers flowing into the Pacific Ocean. HPP Quitaracsa's gross head is 874 m and its design flow 15 m³/s. The plant comprises an hourly regulation reservoir of 270 000 m³ and a 5.5 km long inclined pressure tunnel, with 16% constant slope, connecting the reservoir and intake works with the underground powerhouse.

The entire underground structures of the project are located in granodiorite of the Cordillera Blanca Batholith, and the original design provided for only 160 m of steel lining, followed by 200 m of concrete lining, to protect the powerhouse cavern against seepage inflow. However, the Cordillera Blanca Fault Zone, tectonically active, runs in the immediate vicinity of the power cavern.

In combination with low horizontal and vertical overburden, the presence of this fault affects the stress pattern, and several hydro-fracturing tests, performed during tunnel excavation, determined significantly reduced horizontal stresses, with k_0-values between 0.2 and 0.3, which is uncommonly low for a young mountain range. Coping with the insufficient in-situ rock stresses, the steel liner had to be extended for 2000 m upstream of the power cavern.

The literature lists ample precedence of unlined pressure tunnels with satisfactory performance and offers empiric and semi-empiric methods and criteria for their design, but the experience with the Quitaracsa pressure tunnel serves as an example of exception from the rules and demonstrates the need for reliable and representative information on rock mechanical and hydrogeological conditions, particularly for projects with medium or high pressure tunnels.

RÉSUMÉ

L'aménagement hydroélectrique Quitaracsa d'Engie, d'une capacité de 118 MW, est situé dans la Cordillère Blanche dans la Province d'Ancash au Pérou, sur la rivière Quitaracsa, affluent principal du Río Santa, l'une des rivières majeures du pays. Sa chute brute est de 874 m et son débit nominal est de 15 m³/s. Il comprend un bassin de régulation horaire de 270 000 m³ et une galerie en charge inclinée à 16% de 5.5 km de long, reliant le bassin à l'usine en caverne.

Les divers ouvrages souterrains étant excavés dans les granodiorites du Batholithe de la Cordillera Blanca, le Projet original ne prévoyait que 160 m de blindage, et 200 m de revêtement en béton, afin de protéger la caverne de l'usine contre les infiltrations, étant donné que celle-ci se trouve à faible distance d'une zone de failles actives de la Cordillera Blanca.

L'influence sur le profil des contraintes de ces failles conjuguée avec des couvertures rocheuses relativement faibles - tant verticales qu'horizontales - a pu être quantifiée par plusieurs tests d'hydrofracturation effectués lors de l'excavation. Ceux-ci ont révélé des contraintes horizontales k_0 comprises entre 0,2 et 0,3, particulièrement faibles donc pour une géologie jeune. Du fait de ces contraintes insuffisantes, le blindage de la galerie en charge a dû être prolongé de 2000 m en amont de la caverne.

Se référant à de nombreuses galeries en charge non revêtues aux performances satisfaisantes, certains auteurs s'aventurent à proposer des méthodes empiriques et semi-empiriques, ainsi que des critères de dimensionnement. L'expérience faite avec la galerie en charge de Quitaracsa illustre bien la validité toute relative de ces méthodes. Elle démontre aussi la nécessité de pouvoir disposer d'informations fiables, représentatives des conditions mécaniques et hydrogéologiques effectives du milieu rocheux, en particulier pour les projets comprenant des galeries en forte et moyenne charge.

INTRODUCTION

Engie's 118 MW Quitaracsa hydropower project is located in the Cordillera Blanca mountain range in Ancash/Peru, on the Quitaracsa River, a main tributary of Río Santa, which is one of Peru's mayor rivers flowing into the Pacific Ocean. HPP Quitaracsa's gross head is 874 m and its design flow 15 m^3/s. The plant comprises an hourly regulation reservoir of 270 000 m^3 (shown in Fig.1) and a 5.5 km long inclined pressure tunnel, with 16% constant slope, connecting the reservoir and intake works with the underground powerhouse. The scheme does not provide for a surge tank, because of the sufficiently slow closing time of the Pelton turbines, and accepting that pressure fluctuations during turbine start and shutdown cause pressure fluctuations along the inclined pressure tunnel.

The entire underground structures of the project are located within grano-diorite of the Cordillera Blanca Batholith, and the original design provided for only 160 m of steel lining, followed by 200 m of concrete lining, to protect the powerhouse cavern against seepage inflow. However, in the immediate vicinity of the power cavern, this bedrock is traversed by a highly fractured zone of the Cordillera Blanca Fault (shown in Fig.2, right), which is an active tectonic fault and considered as an important source of mayor earthquakes.

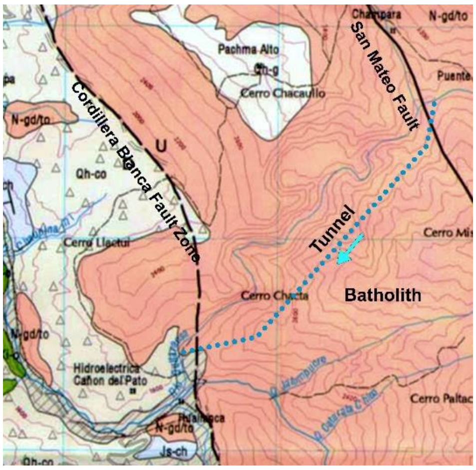
GEOLOGICAL SETTING

Granodiorite of the Cordillera Blanca Batholith exclusively forms the bedrock in the project area. The fault zone of the Cordillera Blanca Fault runs at the downstream end of the project area (see Figure 2 left). This is a normal fault, which continues for about 200 km, following the general NNW-SSE direction of the Cordillera. A local fault, the San Mateo Fault, runs in the same direction at the upstream end of the project area.



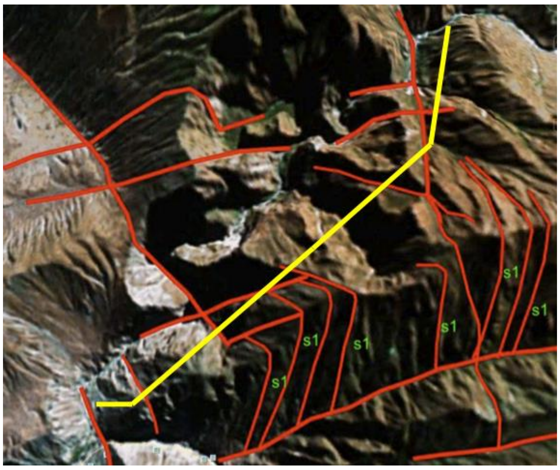


Fig. 2

Carte géologique du site de la C.H. Quitaracsa, INGEMMET, 1995 (à gauche); Image Google avec linéaments (à droite)

Secondary effects have modified the originally uniform characteristic of the granodiorite: at the Cordillera Blanca fault zone a pronounced schistosity has developed. With increasing distance from this fault this features reduces to a cleavage and eventually to slab-jointing. Concurrent with the grade of schistosity also the mineralogy and the strength of the rock change: the schistose rock in the fault zone becomes friable, along the access tunnel to the power cavern the unconfined compressive strength already reaches 70 MPa, averages 100 MPa near the cavern and increases to 130 MPa farther along the headrace tunnel. The variation in strength is related with the degree of kaolinization of the feldspar.

The rock modulus, determined on core samples, averages 44 GPa.

In the orientation of the schistosity also shear zones have developed, which show up as lineaments in the satellite image. Additionally to the schistosity/slab jointing two more principal sets of discontinuities and another set of shears dominate the fabric of the rock mass (Figure 2 right, Figure 3 left).

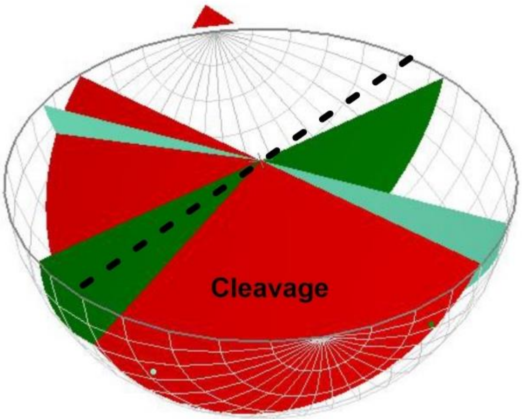

Fig. 3

Stereogram of main discontinuities (left); rock outcrop in Quitaracsa valley (right)

Stéréogramme des diaclases principales (à gauche); affleurements rocheux dans la vallée du Quitaracsa (à droite)

Figure 4 indicates the range of GSI encountered in the headrace tunnel. For most part of the tunnel the GSI exceeded 50, lower values apply to local sheared or faulted zones.

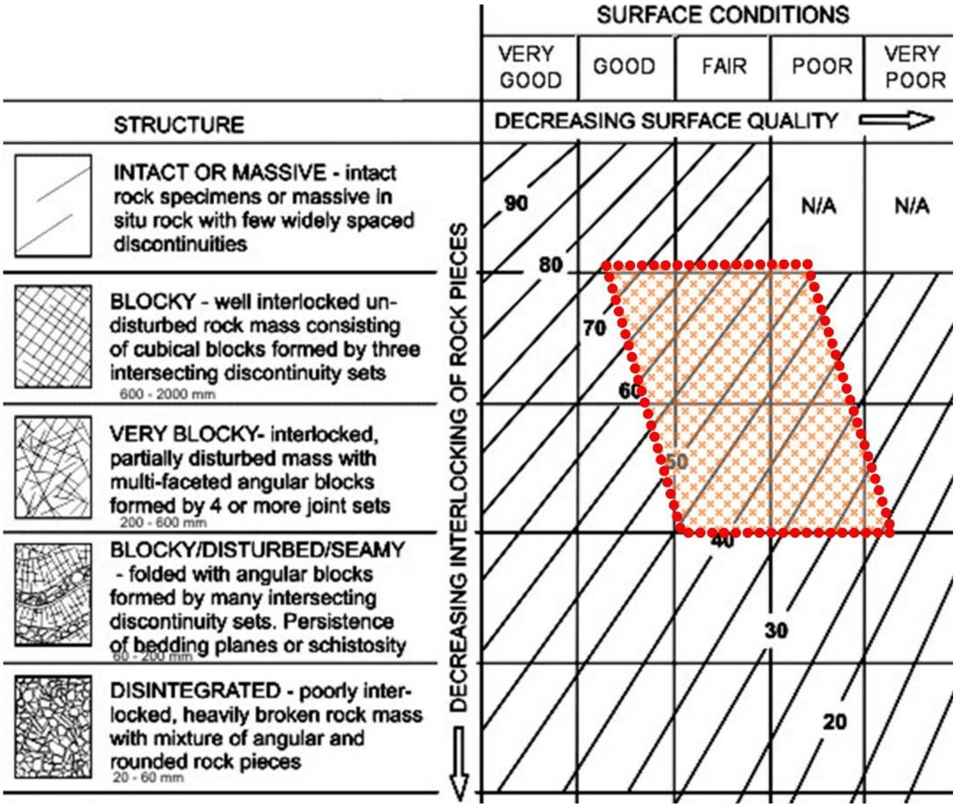

Fig. 4

GSI range recorded in the headrace tunnel

Domaine de variations GSI relevées dans la galerie en charge

In the exterior zones of the rock mass, the permeability reaches and exceeds 10^{-6} m/s. Along the headrace tunnel in sound rock the permeability stays below 10^{-7} m/s. The tunnel was almost dry with only shear zones notably discharging water.

REVIEW OF DESIGN CONCEPTS

The rock outcrops on the walls of the Quitaracsa canyon are virtually inaccessible, but some information could be derived from the experience with the construction of the Cañon del Pato hydropower plant in the immediate vicinity. On this basis, favorable conditions for the underground works were predicted, with Q > 40 for most of the length of the pressure tunnel. Accordingly, an unlined tunnel, only locally supported with shotcrete and bolts, and a 75 m long penstock in the stretch immediately upstream of the power cavern was foreseen. However, a review identified uncertainties in the assumptions with potential impacts for the design and performance of the headrace tunnel. These were primarily:

- Level and pattern of stresses along the tunnel route were unknown. This condition significantly affects the Q-rating and is decisively important in relation to potential hydrojacking of the rock mass due to the high pressure in the tunnel.
- There was no information on hydrogeological characteristics and regime in the rock mass. Discontinuities, specifically shears, traversing the tunnel (Figure 2 right) could convey tunnel seepage towards the canyon and, with the prevailing rock mass structure, locally destabilize the slopes. In several locations, the tunnel alignment did not meet the “Australian Criterion” (Dann et al. [1]) for horizontal lateral cover.

These reservations were debated, alleging that, (a) the route of the headrace tunnel complies with the Norwegian criterion, and (b) the saturation line, calculated according to Bouvard [2] stays safely inside the slope.

However, these arguments are flawed: the respective analyses ignored conditions implicit to the application of the methods. The original Norwegian criterion, as e. g. formulated by Broch [3] assumes $\sigma_h/\sigma_v \approx 1$, a condition, which quite frequently obtains, but is by no means guaranteed. The saturation line, as the title implies, applies to “terrain sec”, with free vertical drainage, which is not the case for the Quitaracsa headrace tunnel.

Figure 5 shows σ_3 contours, the groundwater table and flow lines, simulated by FE-model, with the “saturation line” superimposed. The saturation line rises above the groundwater table, i. e. this method indicates a higher external head than the FE simulation and, in consequence, reduced risk of hydrojacking. In the FE model, the seepage flow from the tunnel drains towards the river, whereas the saturation line would have the seepage disappearing in the depth of the rock mass, which in this case is impossible.

The results of geotechnical and hydrogeological model simulation depend on the input, its completeness and reliability and, therefore, have to be viewed with due reservations. Nevertheless, in this case they clearly demonstrate the uncertainties inherent to schematic design concepts and emphasize the need for specific investigations and analyses.

Considering the risks linked to the uncertainties in rock mechanical and hydrogeological conditions, the owner of the project decided to conduct investigations concurrent with the construction of the headrace tunnel. From the advancing tunnel, exploratory drilling with core recovery, permeability, dilatometer and hydro-jacking and on core samples laboratory tests was performed. Table 1 summarizes the results of the hydrofracturing tests, and Figure 6 shows the stress ratio σ_h/σ_v at the six test sites.

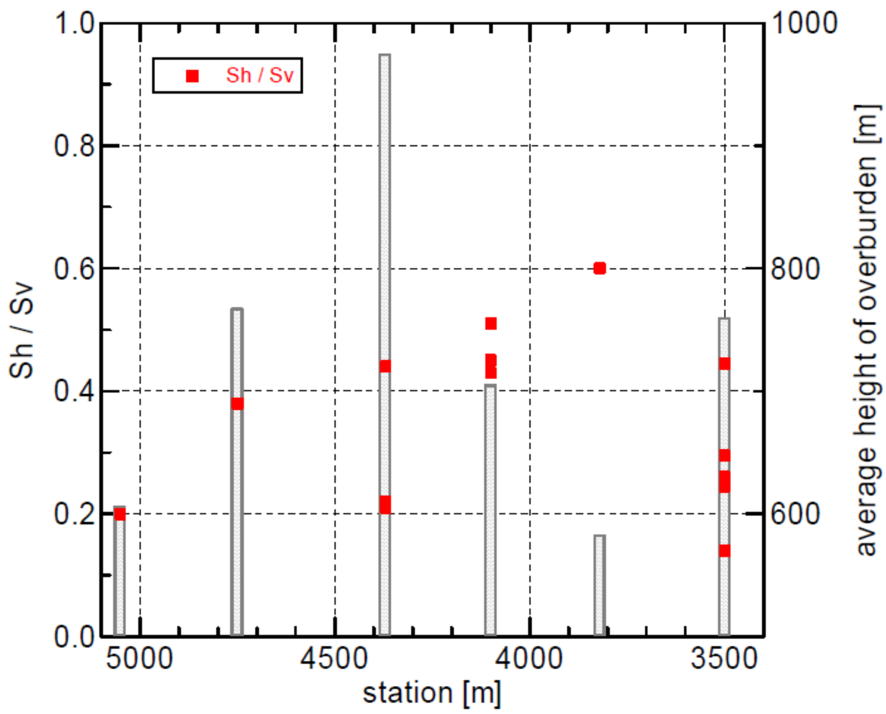

Fig. 6

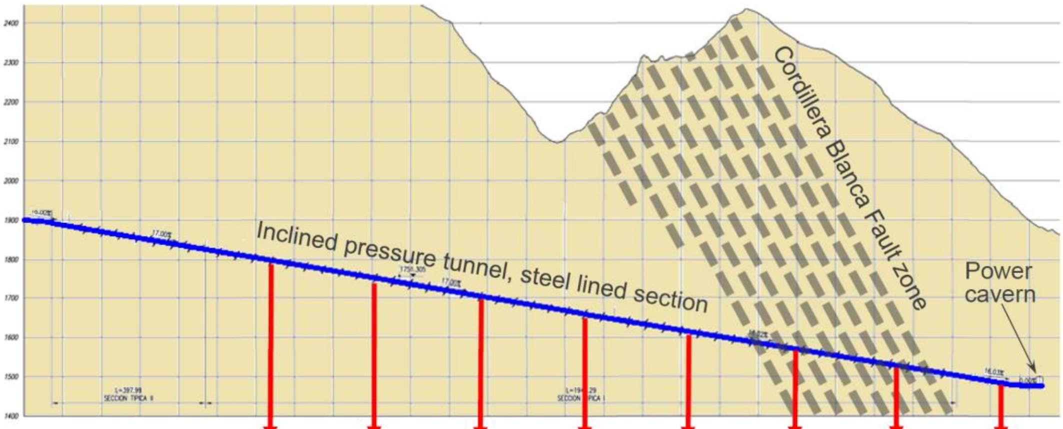
Cover above tunnel (columns) and stress ratio at the six test sites (upstream on right)

Couverture rocheuse au-dessus de la galerie en charge (colonnes) et rapport de contrainte aux 6 points d'essai (amont à droite)

The minimal in-situ stress in the rock mass, independently of the direction, must be higher than the maximal internal water pressure in the tunnel (confinement criteria above 1.0, cf. Marence [4]). Under such conditions, leakage water will not be able to open existing joints and discontinuities causing high water losses and possibly instabilities on the surface.

The results of the hydro-fracturing tests performed in the Quitaracsa pressure tunnel indicate unexpectedly low minimal stress levels, basically due to the minor horizontal principal stress σ_h having been found in the order of only 20% to 40% of the corresponding σ_v values. In order to not over-estimate the minimum stress ratios, a presumed value of 0.25 seemed to be a conservative and thus acceptable assumption for the prediction of the k_0 ratio. In tunnel portions, where existing stresses do not satisfy the confinement criterion, a watertight tunnel lining has to be provided.



Hydrostatic pressure [MPa]	5.0	5.5	6.0	6.5	7.0	7.5	8.0	8.5
Minimum shut-in pressure [MPa]	5.0	2.6	2.4	8.4	6.1	4.5	5.7	2.1
Safety factor	1.00	0.47	0.40	1.29	0.87	0.60	0.71	0.25

Fig. 7

Comparison of hydrostatic water pressure with the minimum shut-in pressures within the 2000 m of the inclined pressure tunnel close to the power cavern

Comparaison de la pression de l'eau hydrostatique avec les pressions de fermeture minimales dans les 2000 m du tunnel à pression inclinée près de la caverne de puissance.

Figure 7 compiles the minimum shut-in pressures obtained from the hydro-fracturing test campaigns, carried out approximately every 250 metres, starting from the Powerhouse Cavern. By comparison with the hydrostatic water pressures inside the tunnel during operation, the safety factor against hydro-fracturing was determined, resulting in values below 1.0 over large portions of the tunnel length. In order to meet the confinement criteria a watertight element was required along the first 2.0 kilometers from the power cavern, and it had been decided to install a steel lining within this reach, with steel plate thicknesses of up to 34 mm.

In combination with low horizontal and vertical overburden, the presence of the Cordillera Blanca fault zone negatively influences the stress pattern, which was determined during tunnel excavation by several hydro-fracturing tests, showing significantly reduced horizontal stresses, with k_0-values within 0.2 to 0.3, which is unusually low for a young mountain range.

The diagram Figure 8 indicates the topography (brown line), the elevation of the tunnel axis (blue line), the required level of safety according to EM-1110-2-2901 (yellow line) and shows the achieved safety factors (red and green dots) for a minimum stress ratio of $k_0 = 0.25$ in the tunnel section upstream of the steel lining.

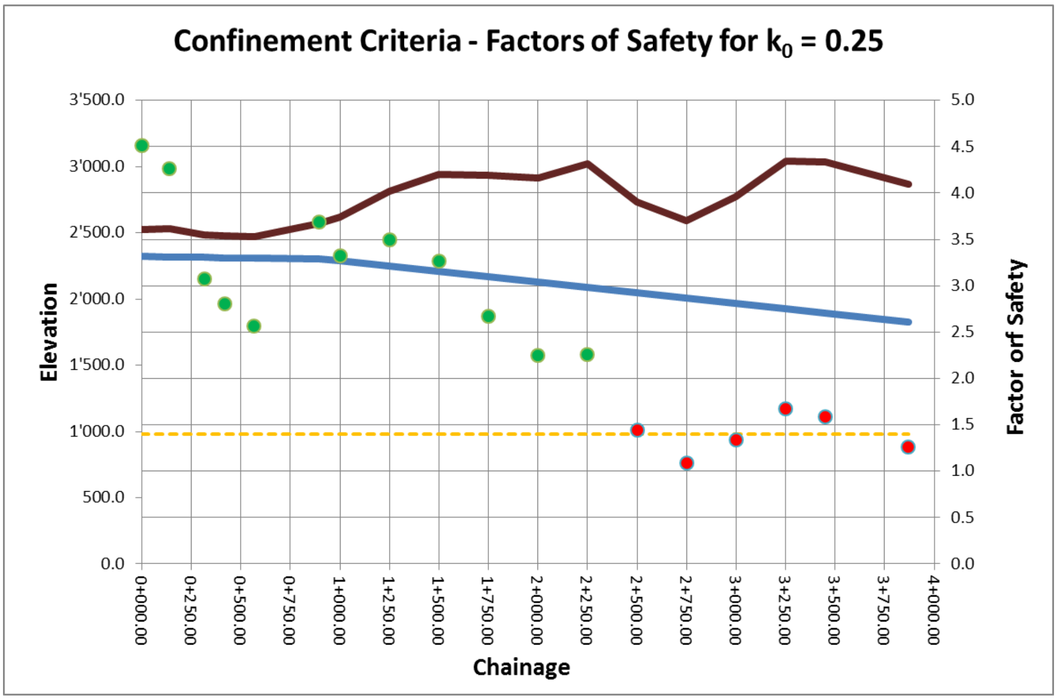


Fig. 8

Surface elevation (brown line), pressure tunnel elevation (blue line) and safety factors according to confinement criteria (red and green dots), along pressure tunnel chainage up to km 4+000

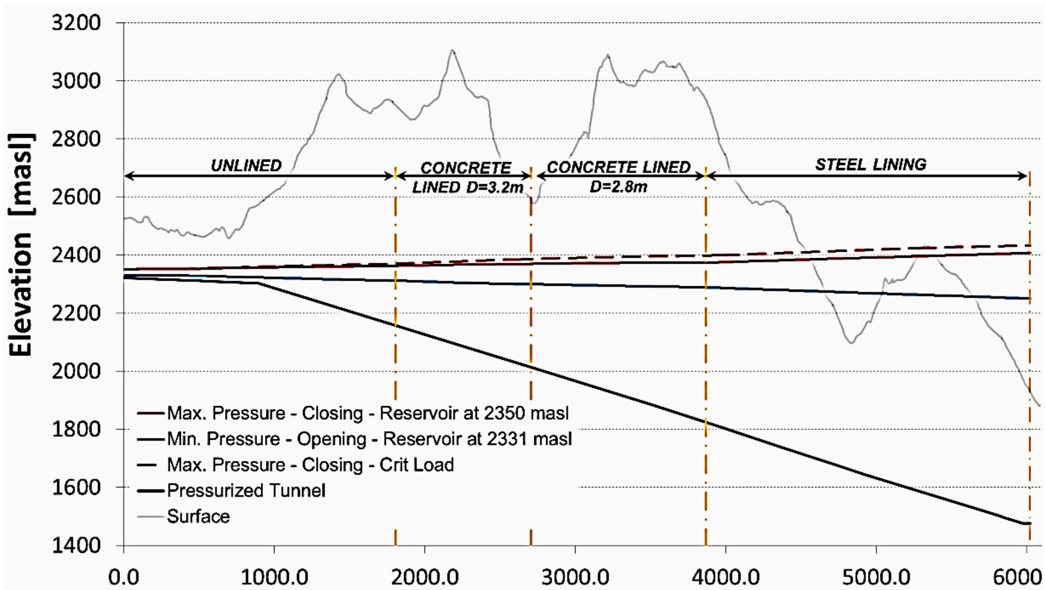

Fig. 9

Distribution of applied lining types, along pressure tunnel chainage up to power cavern

Différents types de revêtement appliqués le long de la galerie en charge depuis le puits amont jusqu'à l'usine en caverne

Even with allowance for accuracy of the test results, they unquestionably establish $\sigma_h/\sigma_v<1$. This fact was to be taken into account in the design of the headrace tunnel and eventually called for a substantial extension of the steel liner in upstream direction. This had two consequences for the project: (a) added cost for the steel liner and (b) problems with the construction time schedule. The cost for delayed commissioning of the plant was the more serious aspect and remedial measures were taken in this regard, to the best possible extend. A long bypass tunnel allowed opening of additional working fronts and saving of time.

Figure 9 shows the distribution of applied lining types, along pressure tunnel chainage up to power cavern. Thanks to the installation of these linings, performance of the completed tunnel was overall very good, without mayor leakages observed.

CONCLUSION

The literature lists ample precedence of unlined pressure tunnels with satisfactory performance and offers empiric and semi-empiric methods and criteria for their design, e. g. Blind et al. [5], Broch [3], Buen et al. [6], Deere [7], Palmström et al., [8]. However, Benson [9] described the complexity of the subject and Swiger [10] questioned the use of rules of thumb. Schleiss ([11], [12]), Hendron et al. [13] and Fernandez ([14], [15]) analyzed the hydrogeological effects on the performance of pressure tunnels.

The uncertainties, critical for the design of the Quitaracsa headrace tunnel, were identified in time for the required investigations and adjustments. Without these adjustments, the Quitaracsa tunnel would have failed and required extensive repair works, resulting in a long interruption of plant operation with high consequential loss of production.

Under conditions similar to those present at Quitaracsa, empirical methods for the design of pressure tunnels can offer a reasonable approach in early stages of a project, but for final design it must be carefully checked if the assumptions inherent to such methods do apply. This was not the case for the Quitaracsa tunnel and similar experience was also made on other projects. The uncertainties, critical for the design of the Quitaracsa pressure tunnel, were identified in time for the required investigations and adjustments. Without these, extensive repair works would have resulted in long interruptions of plant operation and loss of production.

In this context, the experience with the Quitaracsa pressure tunnel serves as an example of exception from the rules and demonstrates the need for reliable and representative information on rock mechanical and hydrogeological conditions, particularly for projects with medium or high pressure tunnels.

1. INTRODUCTION

Since 1968, the original Linth-Limmern power station with the Limmern dam, located in the Swiss Alps in the Canton of Glarus, was fully operational. To increase the peak-shaving capacity in meeting fluctuating electricity demands, the project “Linthal 2015” for the underground pumped-storage power plant Limmern was one of the most important expansion projects of Axpo, a Swiss energy utility. Water is pumped from the storage reservoir Limmern to the upper lake Mutt, situated 630 m higher up. The pumping and turbine capacities of the new pumped-storage power plant reach 1,000 megawatts (MW), increasing the output of the Linth-Limmern power plants up to 1,420 MW. The project realization took one decade between the decision of the local government and the start of full operation in 2017. Pressure, head race and access tunnels as well as three large cavern (max. length 150 m, max. width 29 m and max. height 51 m) for the turbines, power house and valve chamber were excavated and a large gravity dam built to increase the storage volume of the lake Mutt. A comprehensive hydrogeological and geotechnical in-situ testing and monitoring program was implemented [1]. An overview is given in Fig. 1.

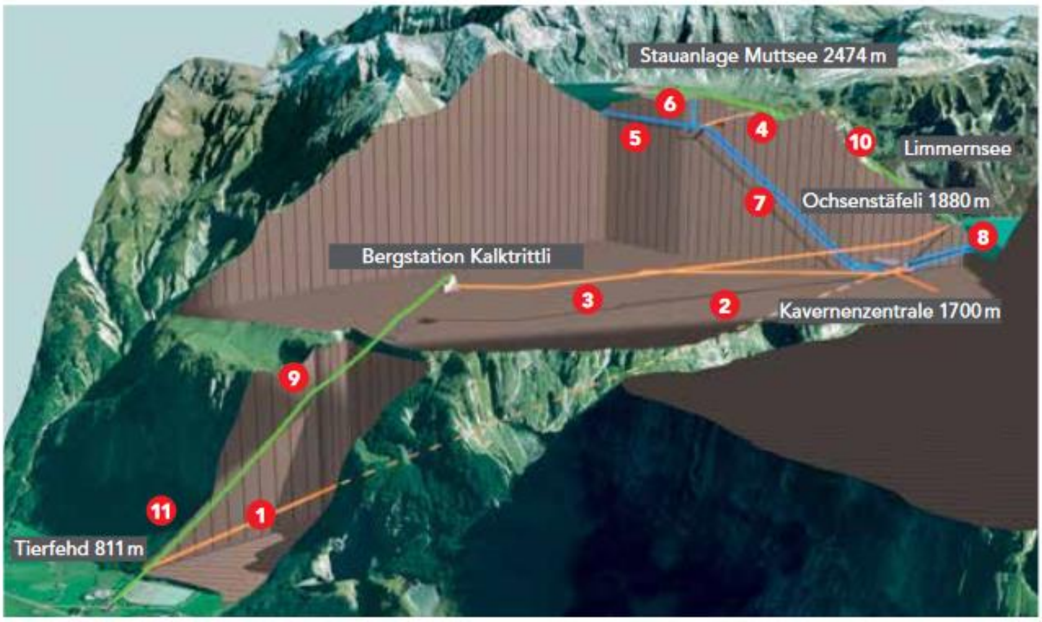

Fig. 1
Overview of the pumped-storage power plant Limmern

2. PRELIMINARY IN-SITU TESTS

The central cavern is partly located in the Quintner limestone of Malm and Cretaceous origin with locally developed schistosity and karst formation. Because of the extension of the caverns, the hydraulic and rock mechanic properties were estimated during a preliminary investigation phase. Therefore, in-situ tests were performed in ten boreholes between horizontal and upwards vertical direction with a diameter of 96 mm (HQ) and a length of maximum 130 m. The locations of the boreholes are shown in Fig. 2. The main goal of these in-situ tests was:

- Information on rock structure, schistosity, fractures, faults, karst
- Determination of the mechanical rock properties, elasticity and deformation moduli through dilatometer tests
- Determination of the minimal principal stresses through hydraulic fracturing tests
- Identification of water-bearing features and determination of static formation pressures and rock permeabilities through hydraulic tests.

The task was particularly demanding, as all the tests had to be performed in boreholes drilled from small exploration tunnels without the help of the drilling crew (Fig. 3). The particular boundary conditions of the test sites and the relatively short time window for the performance of these extended test series in combination with the logistic challenges required a careful planning and a novel testing approach for the more time-consuming implementation of the hydraulic tests.

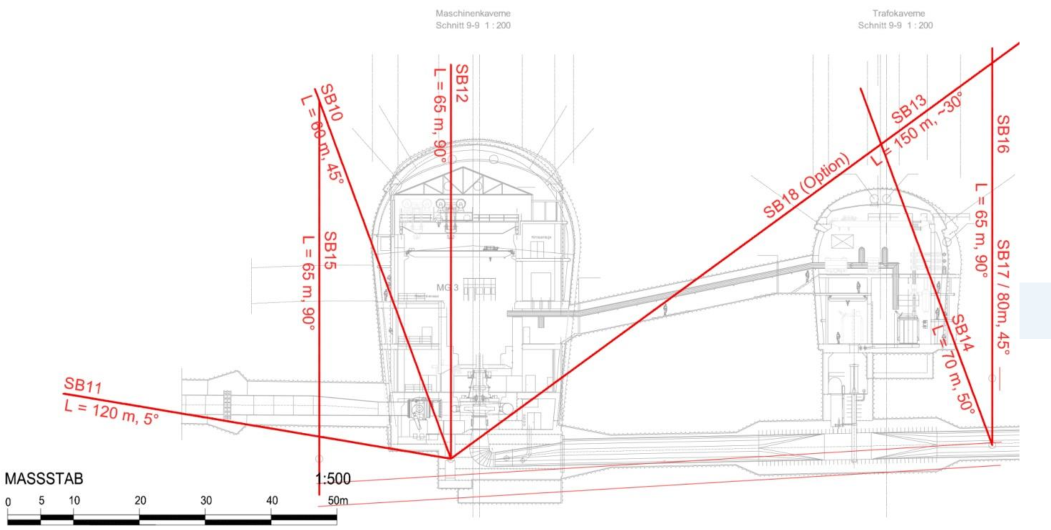

Fig. 2
Overview of boreholes drilled in the area of the future central cavern

Fig. 3
Installation of dilatometer system in small exploration gallery

The main challenge was the performance of the hydraulic tests. To avoid the slow natural saturation of the de-saturated formation due to the drilling of the upwards inclined boreholes and the trapping of air in the intervals, a customized 4-fold packer system was developed (Fig. 4). In total, three similar systems were simultaneously used to cope with the time limitations. The advantages of the systems can be summarized as follows:

- Saturation of the entire borehole after inflation of the packer nearest to the well head
- Simultaneous de-airing of the boreholes through the line situated at the bottom of the system
- Simultaneous monitoring and performance of parallel hydraulic tests in different intervals because of two individual lines within each test/ observation interval (Fig. 4)
- Long-term monitoring of the pressure recovery
- Optional cross-hole tests.

A total of 40 hydraulic tests were performed. In addition, 55 dilatometer tests, 23 hydraulic fracturing tests and 18 impression packer tests were conducted without problems. Dilatometer tests supplied reliable ranges of in-situ rock E- and D-moduli. Hydraulic fracturing tests defined principal stress magnitude and orientation [2]. The results considerably contributed to the proper design of the caverns and the optimization of the layout and the construction work [3] [4].

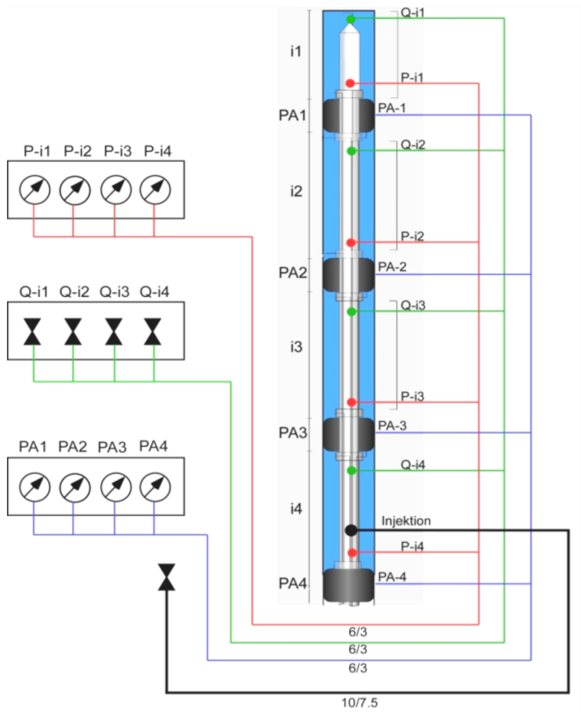

Fig. 4
4-fold packer system used for hydraulic testing

In addition, the hydraulic properties of the debris cones around the lake Mutt were investigated. Hydraulic tests were performed in three boreholes up to a depth of 38 m using a standard double packer system. These tests provided essential information, which was used to estimate the debris behaviour under the expected lake level increase from 2446 m asl to 2474 m asl and the water level changes during the operation of the power plant and to prevent slope instabilities along the lake Mutt.

3. MONITORING OF CAVERN EXCAVATION

The excavation of the central machinery caverns, consisting of machine and transformer caverns and the valve chamber (machine cavern see Fig. 6, left) was performed from top to bottom. This required a continuous monitoring of the rock deformations and the anchoring forces during the excavation process. The convergences were recorded with 30 m long 4-point extensometers, installed in cross-sections (Fig. 5). As the extensometers were immediately installed close to the working surface to obtain a complete data set of the convergences, their heads had to be protected from the potential damage by blasting. Initially the extensometers were equipped with data loggers and were wirelessly readout. In a later stage, the extensometers and the anchor load cells were connected via a bus cable (Fig. 6, right) to a central data acquisition system and subsequently uploaded to a Web database with close-to-real-time data plots, which were available to the responsible engineers at their workstation for permanent control.

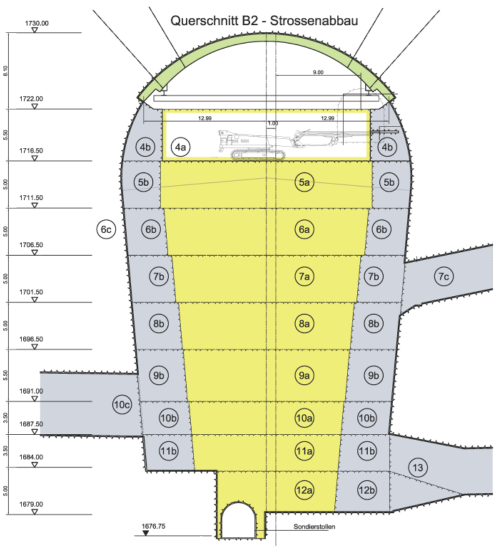

Fig. 5
Cross section of the machine cavern with excavation stages and uppermost extensometers

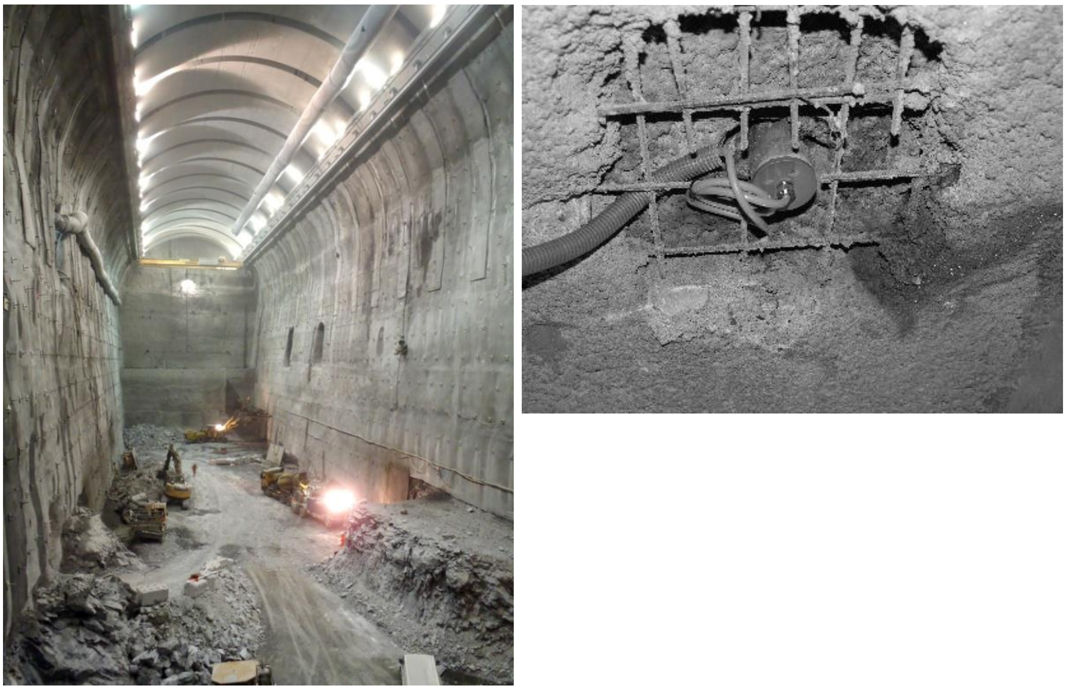

Fig. 6
Machine cavern during 2012 (left), extensometer head with bus cable (right)

4. INSTRUMENTATION OF LAKE MUTT DAM

The new dam of the lake Mutt has a length of 1050 m and a height of 35 m and is Europe’s longest gravity dam. The total volume of the lake is thus increased from 9 to 25 million cubic meters. The installation of the dam safety monitoring started in 2015 and included:

- 76 pressure sensors for flotation measurements
- 74 concrete temperature
- 7 seepage surveillance points
- 8 pendulums
- 1 lake water table measurement station.

Solexperts obtained the task to install the flotation measurement points. Eleven cross-sections were instrumented. The flotation, which normally depends on the lake water lever, is measured at different depths in the underground and at the contact between concrete and rock. The boreholes were drilled from the control gallery over the entire foundation width to monitor the pressure potential decrease from the upstream to the downstream side of the dam (Fig. 7, left). One to three vibrating wire pressure sensors were installed at different levels in each borehole. One measuring position in each cross-section was equipped with a retrievable pressure sensor using a Solexperts Piezopress system consisting of a plastic casing with a filter element and the sensor seat at the bottom (Fig. 7, right). After the installation of the casing, the borehole was filled with sand along the filter section and with a cement injection as sealing section. The sensor was installed after the backfilling at the sensor seat in the filter section and sealed to the casing by O-rings. The other sensors were directly installed as lost sensors at the required depth in a sandy filter section, which was isolated by cement injection to avoid a hydraulic short circuit between different aquifers.

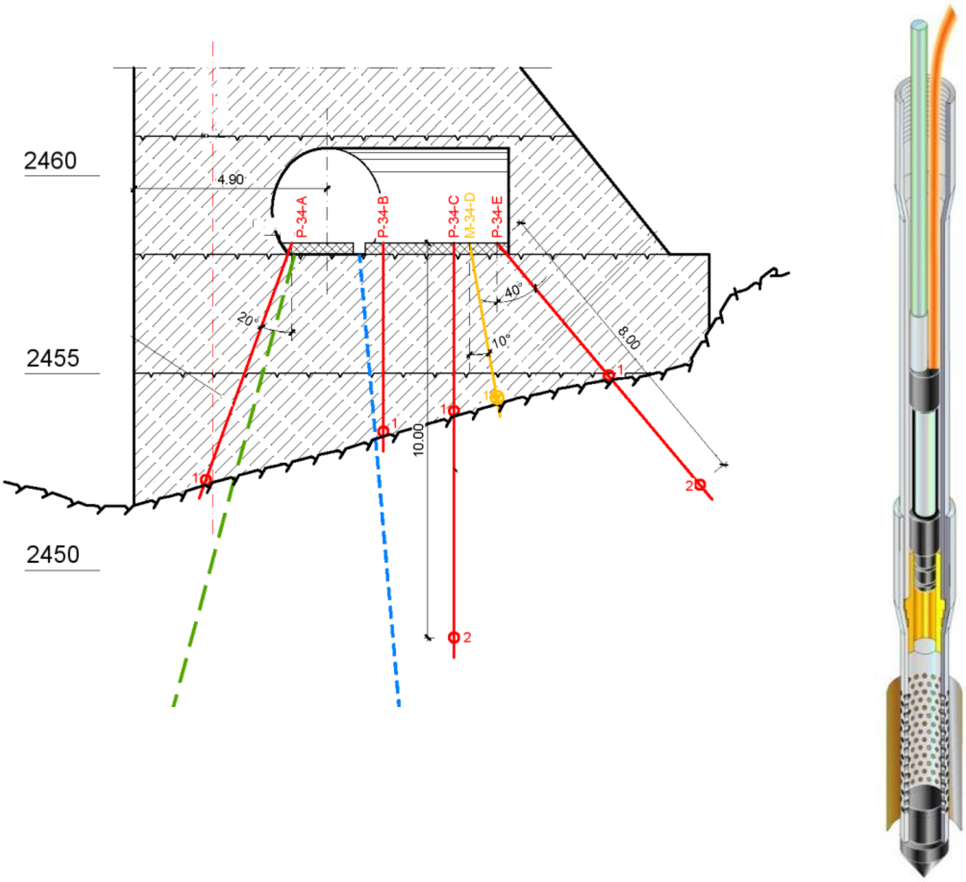

Fig. 7
Measuring section in the lake Mutt dam, in red the boreholes for the flotation measurements (left), schematic cross-section of a Piezopress (right)

All sensors installed in one measuring section are connected with a measuring box with the possibility to manually readout all sensors. Furthermore, the sensors are connected to the automatic data acquisition system and the current calculated heads are automatically displayed at the front of the measuring box (Fig. 8).

Besides the flotation, further parameters are monitored. The concrete temperature sensors are installed in several cross-sections and primarily serve for the quality control of the concrete. The seepage water is collected in a canal along the downstream side of the dam and the water amount is measured at seven V-weirs with ultrasonic sensors. Furthermore, the position of the dam is recorded to estimate its stability. Therefore, four measuring sections are equipped with a pendulum and an inverted pendulum. The pendulum measures the inclination from the dam crest to the measuring location in the control gallery. The inverted pendulum is anchored in the rock and provides information on the relative movement of the dam with regard to the foundation. In addition, the water level in the lake Mutt is recorded.

Fig. 8
Measuring box for the flotation measurements with digital displays of the current heads

5. DATA ACQUISITION SYSTEM

An automatic data acquisition system was installed in the dam guard cabin directly besides the lake Mutt dam. The power supply includes a UPS (uninterruptable power supply). All described instruments are readout via a data bus system. The communication of the DAS with the sensors is ensured by a backbone system and multiple sub-bus systems. Therefore, most parts of the measuring points would still be monitored also in the case when main components of the system might be subject to failure. A total of about 250 sensor channels is recorded which, in addition, are partly calculated into target units. All data is integrated in the higher-level analysis system of the dam operator.

SUMMARY

The pumped storage power plant Limmern in the Swiss Alps was an important hydropower project during the last years. To pump water from the lake Limmern in the about 600 m higher lake Mutt and to increase the power production up to 1,420 MW, a new underground machinery centre and a new gravity dam for the lake Mutt were constructed. The design required comprehensive investigations of rock parameters. Hydraulic tests were performed to obtain information on the hydraulic conductivities and the static formation pressures in the partly schistose and karstic Quinter limestone. The E- and D-moduli of the rock were determined with dilatometer tests. Finally, hydraulic fracturing tests were conducted to estimate the minimum primary stresses in the rock. These investigations considerably helped to improve the models of the underground and to adjust the design of the three caverns.

During the construction of the central machinery cavern, a complete data set of the convergence behaviour was obtained from the anchor forces and the extensometers, which were installed in cross-sections close to the advancing excavation.

A further task was the long-term monitoring of the lake Mutt dam. 166 sensors were installed, including pressure sensors for flotation measurements and lake level monitoring, sensors for temperature and seepage measurements and pendulums. All sensors were connected with a redundant bus system to a

data acquisition system installed in the dam guard cabin. The database is transferred to the dam operator's main analysis system.

The combination of in-situ measurements and monitoring of critical geotechnical parameters for the design and during the construction of the pumped-storage power plant has significantly contributed to optimize the construction process by reducing uncertainties regarding the subsurface properties and their associated risks. The final geotechnical monitoring of the lake Mutt dam is still ongoing and represents an essential part of the safety assessment of the dam.

La centrale de pompage-turbinage de Limmern dans les Alpes suisses a été un important projet hydroélectrique au cours des dernières années. Pour pomper l'eau du lac de Limmern vers le lac de Mutt situé 600m en amont, une nouvelle caverne souterraine pour la salle des machines et un nouveau barrage-poids au niveau du lac Mutt ont été construits dans l'objectif d'augmenter la capacité de production de la centrale à 1,420 MW.

Des études approfondies des paramètres du massif rocheux ont été nécessaires pour la conception du projet. Des tests hydrauliques ont été effectués afin d'obtenir des informations sur les conductivités hydrauliques et les pressions hydrostatiques dans la formation calcaire de Quinten partiellement schisteuse et karstique. Les modules d'élasticité des roches ont été déterminés à l'aide de tests au dilatomètre. Enfin, des essais de fracturation hydraulique ont été menés pour estimer les contraintes primaires minimales dans le massif rocheux. Ces études ont considérablement aidé à améliorer les modèles du sous-sol et à adapter la conception des trois cavernes de la centrale.

Durant la construction de la caverne pour la salle des machines, une multitude de données sur les caractéristiques de convergence du massif rocheux ont été récoltées par le biais des mesures des cellules de chargement sur les ancrages, ainsi que des extensomètres installés au niveau des sections transversales proche du front d'excavation.

Une autre tâche a consisté en la surveillance à long terme du barrage du lac de Mutt. 166 capteurs ont été installés, comprenant des capteurs de pression pour les mesures de flottabilité et la surveillance du niveau du lac, des capteurs de température, des capteurs pour les mesures d'infiltration et des niveaux à pendule. Tous les capteurs ont été connectés de façon redondante à un système BUS contrôlé par une centrale d'acquisition des données installée dans la station de surveillance du barrage. Les données sont ensuite envoyées vers le système général de l'opérateur du barrage.

Le couplage des mesures in-situ avec la surveillance du comportement hydro-mécanique du terrain avant et pendant la construction de la centrale de pompage a contribué significativement à optimiser le processus de construction de la centrale en réduisant les incertitudes sur les propriétés du sous-sol et les risques associés. La surveillance géotechnique du barrage du lac de Mutt est toujours en cours et représente une composante importante dans l'évaluation de la sécurité du barrage.

INDONESIA

Wlingi Dam in Blitar, East Java Province, Republic of Indonesia is a multipurpose dam which one of the purposes is to supply Lodoyo Irrigation Area in Blitar and Tulungagung District of 12,687 Ha, through Lodagung Irrigation Canal. According to the importance of this food security infrastructure, the guarantee of discharge dependability becomes an absolute necessity. The outflow for irrigation is 8.89 m^3/s to 13.78 m^3/s that is available throughout the year. There is also a gross head of 12.50 m between the water level on Wlingi Reservoir and after canal escape. Thus, the availability of head and discharge make the potential of additional small hydroelectric power plant (SHPP) in Lodagung Irrigation Canal sounds very promising.

Jasa Tirta I Public Corporation, a State-Owned Corporation on Water Resources Management in the Republic of Indonesia has been constructing SHPP Lodagung 2x850 kVA since August 2016 and scheduled to be completed on December 2017. This project is expected can meet the lack of electricity supply that has been relied only on two local hydropower plants, HEPP Wlingi and HEPP Lodoyo with total installed capacity of 75.38 MVA. These supplies have not increased since 1983, whereas in 2010 the peak load exceeded 75 MVA and in 2017 is projected to be at 92 MVA.

The Wlingi Dam itself encountered geological problems during impounding in 1977. At that time, there was an excessive leak in the formation of lime soil, in form of seepage in left abutment of the dam. The seepage appeared also in the raising of well water level in the village around downstream of the dam and reached parallel to the yard. The investigation was conducted on 12 February – 14 March 1978 using radio isotope tracer with “multi well technique” method. Radioisotope Cr^{51} and Br^{82} injected into a borehole and then observed on the other holes. The investigation concluded that seepage raised on the left bank of the dam, mainly through the upper part of the limestone rock and centered near the irrigation outlet. Then the problem was dealt with the three curtain grout lines on the left bank area, and until now is an effective treatment.

Crossing curtain grout lines that intersect with the irrigation canal, so far become the most economical path for intake pipes and penstock. However excessive digging will surely disturb curtain and have bad impact on overall dam safety. Therefore, the design of the intake and water way are planned to be placed on top of crest dam. Siphon intake that made from steel pipe was chosen as a best solution for the design, even though need precise hydraulic calculation to ensure that it will work properly. The challenge is that it will be also the first application for hydropower intake and water way in Indonesia.

Siphon intake was designed by steel material SS 400 with specification technical data: 2 units each diameter 1.5 m, thickness 10 mm, length 60 m. The specification technical data of penstock i.e.: Inner Diameter 2.5 m, thickness section-I 10 mm with length section-I 315 m, thickness section-II 12 mm with length section-II 30 m, total length 345 m. After the installation and construction works has completed in January 2018 since construction works started in August 2016 (18 months), the system performed well. The turbines and generators worked with the pressure in penstock similar with turbines in range 0.83 – 1.03 bar with output capacity of each turbine 407 – 643 kW.

(Keywords: SEEPAGE, SIPHON, POWER PLANT)

1. Introduction

1.1 Background

The deficit of electricity supply in Blitar Regency, East Java Province, Republic of Indonesia was strived to be fulfilled by the development of hydro electricity. The supply of electricity by HEPP Wlingi and HEPP Lodoyo of 75.38 MVA through the Wlingi Substation has not increased since 1983, while the peak load of the surrounding areas of Blitar and beyond has exceeded 75 MVA after 2010. In 2017, the peak load is projected at 92 MVA. In accordance with Government of Indonesia policy set forth in Power Supply Business Plan (RUPTL) 2015-2024 (PT PLN (Persero), Electricity Supply Business Plan (RUPTL) PT PLN (Persero) 2015-2024 Jakarta, 13 and 25.) that every new primary source of local electrical energy derived from renewable energy, i.e geothermal and water power, can be fed in directly to the power network system whenever it is available. This is one of a government policy for climate change mitigation.

There was a potential of hydroelectricity that can be generated in Lodagung Irrigation Channel, one of the Multipurpose Dam “Wlingi” facilities in Blitar. One of the development goals of Wlingi Dam was to supply irrigation demands for agricultural land in Blitar and Tulungagung regencies and operated since 1978. Water from the Wlingi Dam is flowed through Lodagung Irrigation Channel to irrigation area of 12,687 Ha. Considering the important role of the irrigation infrastructure, the guarantee of water availability throughout the year becomes an absolute demand for farmers. Maximum outflow for irrigation water is 13.78 m3/s with probability 2.70%, while minimum is 8,89 m3/s with probability 97,30%. The Wlingi Reservoir has a high water level at El + 163.50 m, normal at El + 162.00 m, and average at El + 162.75 m. The water level ini irrigation channel in the lowest segment after the plunge escape regulator is at El + 150.25 m. From the data there is a gross head of 12.50 m. The availability of heads and constant discharge makes the potential of electricity in Lodagung Irrigation Channel was feasible to be realized.

But, there is an important issue that must be considered if the hydropower potency in Wlingi Dam will be generated. That is “How to flow the water from reservoir to power house without build an intake and water way with excessive digging?” There are two reasons why it should be built on that condition. First, Wlingi Dam itself encountered geological problems during impounding in 1977, then the problem was dealt with the three curtain grout lines on the left bank area, and until now is an effective treatment. Excessive digging will surely disturb curtain and have bad impact on overall dam safety. The second, the strength of the existing irrigation conduit channel initially designed for free flow, so when connected to the penstock it becomes a pressurized counduit. It will result significant construction works on left bank of the dam if the existing conduit is connected to the penstock. The strength of the conduit channel strengthens the motivation to design the intake and water way at Lodagung Hydropower does not connect to existing irrigation conduit outlet.

1.2 The Problem

The problem examined in this paper is: what is appropriate type of water intake of hydropower plants which crossing the dam body, without disturbing the dam structures and keeping the reservoir performance in supplying water requirements for irrigation at best level?

2. Library Review

2.1 Formula for Annual Energy Generating and Production Capacity

To calculate the capacity (P) and annual energy production (E), the equation formula (Damanik, A.K. et.al) Main Book of Feasibility Study of MHP PLATMH Directorate General of Electricity and Energy Utilization of Department of ESDM Jakarta, 9.), namely:

$$P = g \times Q \times H \times (\text{Ef system}) \quad [1]$$

information :

P : Estimated power generated (kW)
G : Gravity (9.81 m / s2)
Q : The water discharge (m / sec)
H : High effective fall (m)

Ef system is the mean value of the efficiency of the turbine: η_T = 0,925, efficiency of generator: η_G = 0,97, transformer efficiency: η_{TR} = 0,98. If the generation discharge decreases to 40%, the turbine efficiency is estimated to decrease by 70% (Perum Jasa Tirta I, 2014, Final Report of Capacity Design and Layout of Lodagung MHP Project (2 x 0.65 MW) .Wiratman Power Jakarta, 2 .).

To calculate the annual energy production used the formula:

$$E = \xi \times P \times 8.760 \text{ hours} \quad [2]$$

E : annual energy (KWh)
ξ : Capacity Factor

2.2 FAO method (Food Agriculture Of Organization) for Siphon Intake

$$Q = CA\sqrt{2gH} \quad [3]$$

C = discharge coefficient
A = cross-sectional area (m2)
H = gross head (m)

Discharge coefficient can be calculated by this formula:

$$C = \frac{1}{1+\lambda\frac{L}{d}+\sum k} = \frac{1}{1+\frac{TotalHeadloss}{\frac{V_{siphon}^2}{2g}}} \quad [4]$$

λ = roughness coefficient of pipe = 0.02 (Steel pipe)
L = length of conduit
d = siphon diameter
$\sum k$ = loss coefficient in pipe

3. Discussion

The power plant utilizing the Lodagung Irrigation Channel is a small-scale hydro power plant, hereinafter called Lodagung Small Hydro Power Plant (SHPP Lodagung), located in Jegu Village, Sutojayan District, Blitar Regency, East Java Province. Discussions on the power plant plan are as follows:

3.1 Capacity of Power Generation and Annual Energy Production

The installed capacity (P) and annual electric energy (E) capacity are calculated as follows equation [1] and [2]:

$$\begin{aligned} P &= g \times Q \times H \times \eta_T \times \eta_G \\ &= 9{,}81 \text{ m/s}^2 \times 14 \text{ m}^3\text{/s} \times 10{,}30 \text{ m} \times 0{,}925 \times 0{,}97 \\ &= 1.276 \text{ kW} \Rightarrow \text{installed capacity} = 1.300 \text{ kW (common value)} \end{aligned}$$

$$\begin{aligned} E &= \xi \times P \times 8.760 \text{ hours} \\ &= 83{,}43\ \% \times 1.276 \text{ kW} \times 8.760 \text{ hours} \\ &= 9{,}325 \text{ GWh} \end{aligned}$$

3.2 Main Building Arrangement

The optimization of SHPP Lodagung layout is based on survey measurement and field condition identification to determine the location of penstock and powerhouse, with the following development criteria:

a. Determination of the location of the penstock to the powerhouse refers to the longitudinal section of Lodagung Irrigation Channel.
b. Determination of the penstock line is made by avoiding turns with sharp angles, with the shortest length to minimize losses, and is in a good soil structure and stable.
c. Determination of powerhouse locations in areas with good accessibility and location stability, located not far from the tailrace outlet.
d. The location of SHPP Lodagung building placement (penstock and powerhouse) also consider the topography, geology, access roads, the nearest 20 kV transmission line.

Conditions that must be considered is the geological history when impounding Wlingi Reservoir in year of 1977 in the form of excessive seepage on the left back of the dam (left abutment). The investigation was conducted on 12 February to 14 March 1978 with tracer technique. Tracers use the radioisotope Cr51 and Br82 with multi well technique, ie the tracer is injected into a borehole and the observations are performed on other holes. The investigation concluded that the seepage encountered on the left back of the dam came from the eastern direction veering northwest to tailrace hydropower. Details of the conclusions on the seepage description are described as follows:

a. Right abutment area there is no seepage from the reservoir on the right side downstream.
b. Seepage occurs in the left back area mainly through the upper part of the limestone rock.

c. Direction of seepage in the left back area is concentrated to the left open channel area near the irrigation outlet, then flows to the tail race area through fractures in the rock chalk.
d. There is direct seepage from the left side reservoir area (see attachments 1 and 2: C-11 and C-20) to the power house (PH) hydropower and spillway (SPL).

Impounding of Wlingi Dam in 1977 had a problem of water leakage in the formation of lime soil that resulted in raising of the land water table. The elevation caused the well water to reach parallel to the land in the settlement of residents around the downstream of the dam or powerhouse of hydropower. To overcome it then the protection with 3 (three) curtain grout path in the left bank area / left bank body dam were built. The "Additional Curtain Grout Line Section I, II and III" show the location of the intersection of the three curtain grout lines located near the conduit channel outlet of Lodagung Irrigation Channel. One path of curtain grout consists of two types, namely:
a. The inner side adjacent to the reservoir is 2 (two) cement grouting lines;
b. The outside as a curtain is 1 (one) line of chemical grout.

The initial phase of the study was to establish the main structures of SHPP Lodagung and its layout taking into account the geological history during the implanting of the Wlingi Reservoir in 1977, thus setting the following structure:
a. The generator discharge is taken directly from the reservoir using the siphon pipeline intake. The siphon pipeline intake is the most likely design to be realized because it does not modify the irrigation conduit channel based on the dam safety considerations.
b. After being sucked by the siphon pipes, water flows to the pipe (penstock) on the left and parallels the open irrigation canal.
c. Consideration for optimum head and dam safety, which is the minimum of vibrations occurring to the dam body during construction, the power house is placed more than 400 meters from the dam near the escape gate.
d. The flow of water coming out of the turbine (draft tube) is redirected back to the tailgate and returns to Lodagung Irrigation Channel. This design will keep water allocation for irrigation is still full filled

3.2.1 Intake

The design of the selected intake building is siphon pipes and it is decided that irrigation conduit outlet lines are not disturbed. The siphon intake design and water way are planned to be placed on top of crest dam, and sucked water from Wlingi reservoir without pump or other mechanism except first pumping to make pre-condition of water pressure along the pipe. Then, waterflow goes down to penstock and finally run the turbine. The system, therefore needs precise hydraulic calculation to ensure it will work properly. Consideration of choosing the intake design are:

a. A similar risk during impounding in 1977 is worried to recur when the existing curtain grout layer is disrupted or broken by heavy engine vibration or deep excavation in the area around the irrigation outlet located on the third intersection of the grout path.
b. The strength of the existing irrigation conduit channel originally designed for free flow. When connected to a penstock, it will become a pressurized channel then, and the strength of conduit will not be adequate. So, new intake was designed and use siphon intake system.

Data planning intake siphon as follows:

Design discharge	= 14 m3 / s @ 7 m3 / s
Number of siphon pipe	= 2 units
Siphon pipeline length	= 60 m
Elevation of the dam peak	= +167.00 m
Upper elevation siphon pipe	= +168.50 m
Low water level	= +162.00 m
Suction head siphon on low water level	= 6.5 m (ΔH critical)
Suction head maximum	= 7.11 m
Total Gross Head	= 2,20191 m

The calculation of siphon intake based on equation [3] and [4]:

$$C = \frac{1}{1+\lambda\frac{L}{d}+\sum k} = \frac{1}{1+\frac{TotalHeadloss}{\frac{V_{siphon}^2}{2g}}} = \frac{1}{1+\frac{2,20191}{3,96^2/(2x9.81)}}$$

$= 0,556$

$Q = CA\sqrt{2gH} = 0,556 \times (\pi \times 1,5^2 / 4) \times \sqrt{2\times 9.81\times 12,50}$

$= 15,38\ m^3/det$

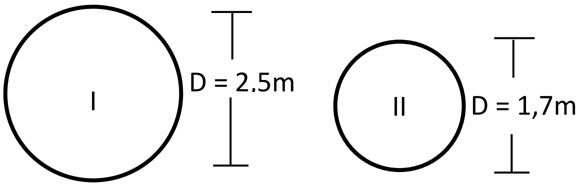
Based on the calculation obtained the maximum discharge (without regulation) on the channel of 15.38 m3/s. With the help of pipe regulation, the design discharge 2 x 7 m3/s using 2 pcs of 1.5 m diameter then the water velocity in siphon pipes is 3.96 m/s. Suction head siphon on low water level (6.5 m) is lower than Suction head maximum (7.11 m).

The siphon method of operation is a filling method that utilizes pressure differences due to the high difference between upstream water level (reservoirs) and turbine inlet valves. The way it works are described consecutively, firstly, the turbine inlet valves at the end of the penstock are closed, fulfill the pipe with water, using small pump to make desire vacuum condition at beginning of siphon until penstock so that due to the difference water pressure, water from the reservoir will be constantly inhaled and rotating the turbine. The tip of the siphon pipe is fitted with a litter filter and a rough material (trash rack) that protects the area around the end of the pipe. Its function is to select the material that goes into the penstock and turbine with water to fit the allowed size.

3.2.2 Penstock

The penstock path to the powerhouse location is located on the left and parallel to the existing open irrigation channel of 367.59 m. The minimum distance from the irrigation channel to the penstock is 15.00 m. The technical data for hydrolysis calculations on penstock are:

a. Debit = 14 m3 / s
b. Manning Roughness = 0.014
c. Total penstock length (I and II) = 367.59 m
d. Types of tunnels = Circles



Types of tunnels = Circles

The press flow occurs when the ratio of water level to the penstock (h / D) diameter is more than 1.5 with the following checks:

Water level, H = 12,50 m

Diameter penstock, D = 2,50 m

$\frac{h}{D}$ = 5 > 1,5 (OK)

From the penstock calculation, primary penstock diameter was set at 2.50 m by the cross-sectional area of the penstock pipe was 4.91 m^2. With the generation discharge Q = 14.00 m^3 / sec, the flow velocity in the penstock pipe is (14.00 m ^ 3 / s) / (4.91m ^ 2) = 2.85 m / s. From the calculation results, a 2.50 m diameter penstock was selected based on several considerations, among others:

a. Ease of pipeline treatment process,
b. Minimal energy loss levels
c. The economic value of the penstock pipe,
d. Pipes that have larger diameters have a lower level of energy loss because the water flow rate is smaller, but the size is bigger, heavier and the price is higher. While the pipe that has a smaller diameter the price is cheaper, but has a greater energy loss rate.

3.2.3 Turbine and Generator

Data design of turbine i.e.:

Net Head	10,3	m
Flow	14	m3/ s
Turbine Type	S-Type Horizontal Kaplan	
Turbine Capacity	2 x 675	kW
Flow/unit	7	m3/ s
Speed	400	rpm

runway speed	800	rpm
Specific Speed	555,21	
Diameter Runner	1,13	m
Suction Head	2	m
Turbine efficiency at 100% load	93	%

Runner Material X3CrNiMo 13-4 or equivalent
Draft tube, elbow and cone material S355J2G3 or equivalent, after welding galvanized

Data design of generator i.e.:

Generator efficiency	97 at pf-0.8	%
Generator Output	2 x 650	kW
Voltage Output	6,3	kV
Excitation System	Brushless	
Frequency	50	hz
Speed	1000	rpm
Runaway speed	2000	rpm
Automatic Voltage Regulator	+5 to -10	%

3.2.4 Power House

Turbines and generators with other equipment are placed in a power house. The structure of the building is designed to be stable against the load of hydro mechanical engines and earthquake, and meet the limits of the voltage permit according to the design criteria.

3.2.5 Tailrace

Tailrace is planned to boil down the existing irrigation channel in the form of a natural channel located after the irrigation measurement or bridge building for access to Wlingi hydropower. The natural channel base elevation as tailgate channel outlet location is +149.00 m, tailrace water level is +150.25 m with a threshold width of 6 m).

3.2.6 Spesification Technical of Siphon pipe and Penstock

Intake Siphon by Material SS 400

Diameter	1,5	m
Thickness	10	mm
Units	2	
Lenght	60	m
Connection Box (Expansion and Reducer)	1	unit

Penstock by Material SS 400

Inner Diameter	2,5	m
Thickness Section-I	10	mm
Length Section-I	315	m
Thickness Section-II	12	mm
Length Section-II	30	m
Total Lenght	345	m

3.2.7 The Performance of Lodagung SHPP

After the installation and construction works has completed in January 2018 since construction works started in August 2016 (18 months), the system of Lodagung SHPP performed well. The turbines and generators worked with the pressure in penstock similar with turbines in range 0,83 – 1,03 bar with output capacity of each turbine 407 – 643 kW.

4. Conclusion

a. The small scale hydropower is potential and promising to be built because there is continuity of flow which using irrigation water allocation and effective head is adequate
b. There is a need of additional electricity supply in the adjacent and surrounding area
c. The construction of hydropower particularly water intake should not disturb dam embankment and also keep reservoir performance for irrigation supply.
d. Development of siphon intake model then become best solution, even though needs precise hydraulic calculations.
e. Small scale hydroelectric power with siphon intake technology which may be first been built in Indonesia finally come through in early of year 2018.
f. It becomes a challenge that siphon intake as hydro power water way or water way for other purposes, could be implemented to other small dams without disturbing existing dam embankment, in consideration with dam safety.

1. INTRODUCTION

The Patrind hydropower project developed by SHPL (being a special purpose company established for the project) and owned by K-water(being the main sponsor for the project) is a run of river type hydropower project on the Jhelum River, approximately 200km northeastward of Islamabad and at the west bank to the township of Muzaffarabad in the Azad Jammu & Kashmir, Pakistan.

According to the project overall layout conditions, water diversion and power plant using a three-hole machine layout. The inner diameter of the straight penstock is 5.5m and the branched penstock is 3.2m.The maximum water level for the dam is 767.5masl. The installation elevation of turbine that is the elevation of steel liner center in the lower part is 645.0masl.The discharge of single unit is 51.22 m^3/sec, that is, when in full load, the discharge of the straight penstock is 153.66m^3/sec.

In order to minimize the head loss, the hydraulics conditions of two trifurcation types (spherical type and shell type) are compared. Because of the significant head losses are suspected to be increased in the water flows through trifurcation.

In general, due to the sudden change at the joint point of straight penstock, branched penstock and the spherical trifurcation, the flow condition is bad and the head loss is large. The water flow is expected to be smooth and head loss will be relatively small through the shell type trifurcation employing gradual taper penstock. From the hydraulic conditions aspect, the shell type trifurcation with deflecting plates is chosen as shown in Fig. 1 and Fig. 7.

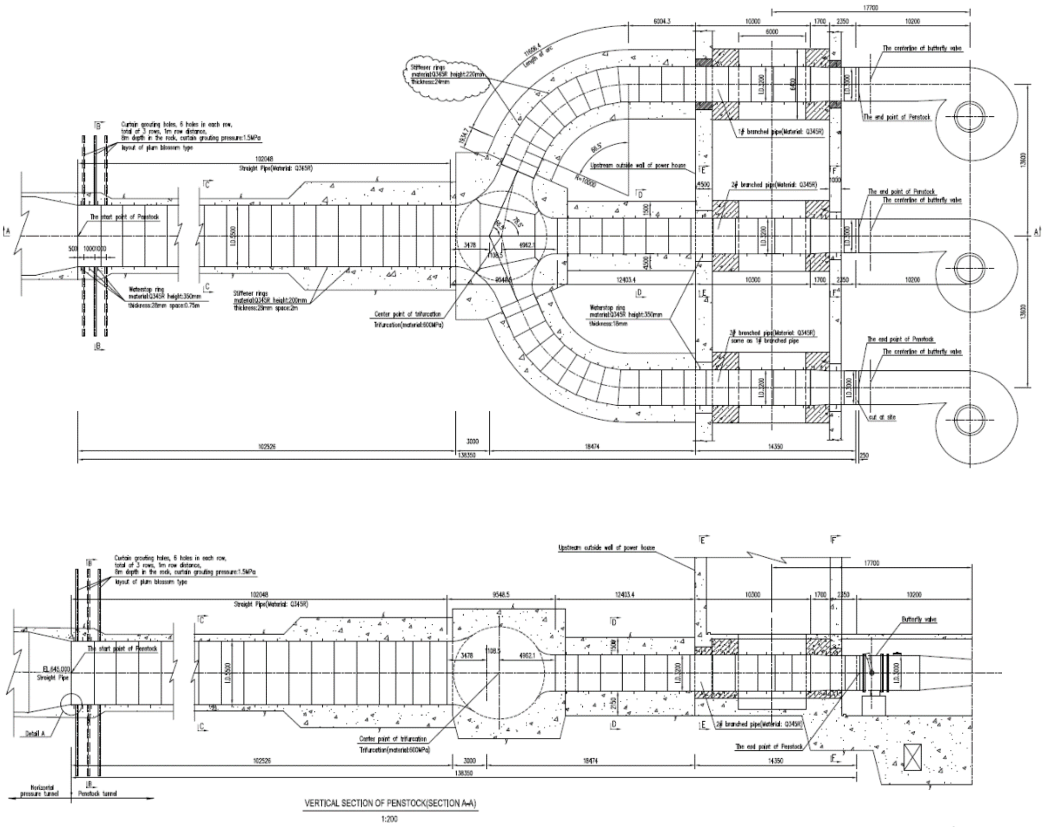

Fig. 1
Installation Condition of Penstock and Trifurcation

2. OCCURRENCE OF POWER SWING

2.1. OCCURRENCE OF POWER SWING

The active power is shown in Fig. 2 below. It can be seen that with increasing power output, severe power oscillations occur especially at the conditions of three units' simultaneous full load operation.

The size of oscillation did not meet the IEC 60308 standard, and for this reason, the power output test failed during the commissioning test and substantial completion of the project was not achieved on time and got delayed several times under this situation.

According to the IEC standard, the acceptable power swings on a hydro generation unit should not be more than 5%(peak to peak) of the rated power, but, the measured power swings on two of the three units in the Patrind plant were approximately around 20%.

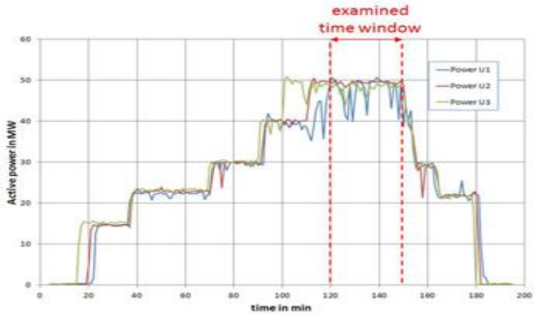

Fig. 2
Active power output

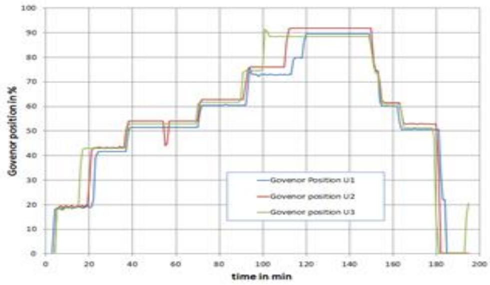

Fig. 3
Governor position

2.2. Cause Analysis of Power Swing

In Fig.3 above, the corresponding governor position is shown. It can be clearly seen that the governor position shows no oscillation. Consequently, the power oscillations are not expected to be caused by an insufficient control algorithm or by the governor's instabilities.

Since the severe power oscillations occur at high loads, we concentrate our examination on the time region between 120 minutes and 150 minutes of the measured data. In Fig.4 below, the governor position is plotted again but only in the examined time region. Here again, it can be observed that the governor position is nearly constant and cannot be the reason for the oscillations.

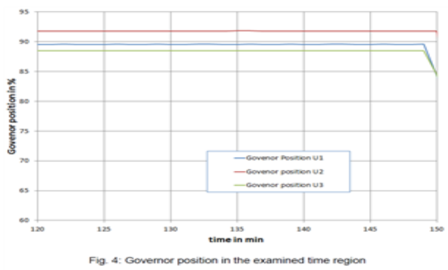

Fig. 4
Governor position

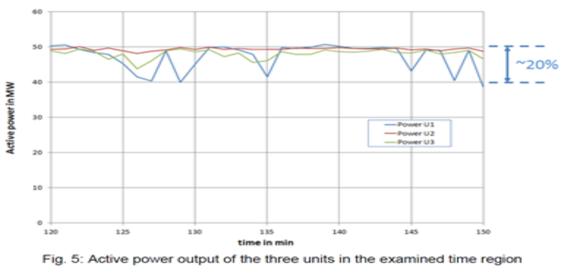

Fig. 5
Active power output of threeunits
in the examined time region

In Fig.5 above, the active power is shown for the examined time region. It can be seen that the power fluctuations of unit 1 are higher than those of unit 3. Unit 2 shows nearly constant power output. The maximum power changes are approximately 10 MW, which is approximately 20% of the output.

Assuming that by relations of output variation with head variation according to hydraulic similarity;

$$N \propto H \cdot Q = H^{3/2} \qquad [1]$$

{N : Avtive power(MW), H : Head(m), Q : Discharge(CM/s)}

According to the above formula, 12% of pressure variation makes 17.4% of power variation. Referring to Fig. 6 below, there are some gaps between measured power variation (20%) and calculated power variation (17.4%).

The reason for the gap is the inaccuracy of the pressure data, which was measured at a certain cross section having unsteady water flows due to the vortices, so that the measured pressure is not representing the real pressure at the certain cross section. Anyway, we can verify, there is a strong relation between power variation and head variation.

It can be found that the power oscillations are caused by the pressure drop. This pressure drop is caused by the unsteady vortices in the trifurcations. When a vortex from the trifurcation enters one of the penstocks (left or right), the head losses at the penstock inlet significantly increase because of the swirl component. It could be observed from the measurement data that the dominant reason for the power oscillations is the pressure drop in penstock and consequently the reduction of pressure in the spiral case and turbine leading to critical velocity of 4 m/sec (approx.). Therefore, it seems obvious that the unsteady water flow, vortices in the trifurcation and the critical velocity of around 4 m/sec are causing the power oscillations and not the other factors such as the governor or unsteady water flow through the draft tube and tailrace.

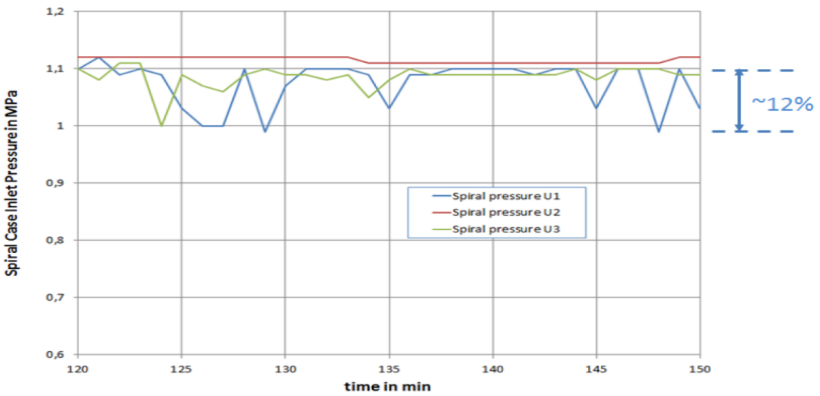

Fig. 6
Pressure at the spiral case inlet in the examined time region

To minimize the head losses and vortices through the trifurcation, the shell type trifurcation with deflection plates is chosen as shown in Fig. 7 below. Despite of this consideration, there is still a possibility of occurring unsteady water flow because of the sudden change at the joint point of straight penstock, branched penstocks and the trifurcation.

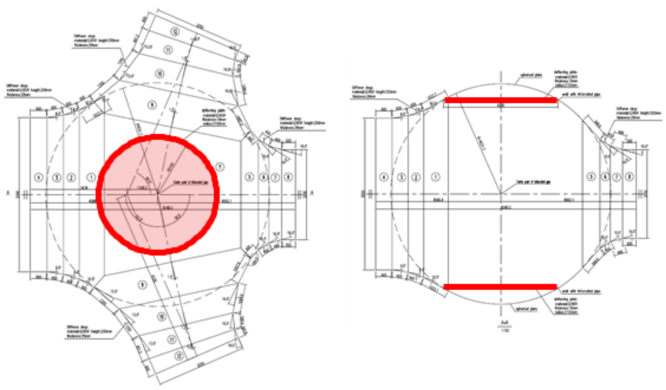

Fig. 7
Shape of previous trifurcation

After examining the data in detail, the power oscillations having a certain regular period were detected in unit 1 and unit 3 in the Patrind plant. We can estimate that the period of power oscillations is determined by the velocity of water passing the penstock and the length from the trifurcation to the spiral case.

The discharge through the branched penstock is reduced with growing vortices and the velocity passing through the trifurcation is also decreased. When the growth of vortices is culminated, the power output drops most. The next moment the size of vortices is gradually reduced in proportion to the decreasing rate of velocity.

When the vortices are almost disappeared, the velocity and power output get back to the normal status and the next moment creation of vortices kicks and grow to maximum. This process is repeated and continuous. To the contrary, the other sides of the branched penstock faced the reverse process at the same time means if vortices are created in one side branch penstock the other side branch behaves normal.

It is obvious that the discharge varies alternatively between branched penstocks of unit 1 and unit 3. Low discharge corresponds with the location of the branched penstock having large vortices. If the vortices are located in the other side of the branched penstock, the discharge is higher. The discharge in the middle branched penstock only shows much smaller oscillations.

3. METHOD OF MODIFYING

It is not possible to replace readily the trifurcation with modified trifurcation because the trifurcation is embedded in the deep underground and covered with thick steel-concrete.

The only one solution is to modify the inner side shape of the trifurcation and improve the water flow conditions as shown in Fig. 8. For more stable water flow distribution, it is planned to install the enlarged deflection plates linearly connecting and covering the inner space of trifurcation between the main penstock and the branched penstocks.

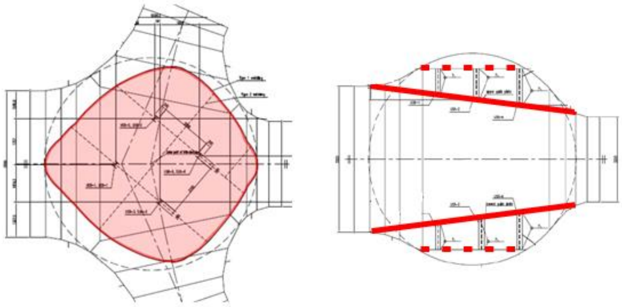

Fig. 8
Shape of modified trifurcation

4. COMPARING THE BEFORE AND AFTER MODIFYING THROUGH THE SIMULATION

4.1. SIMULATION CONDITIONS

For the simulation, a computational grid of approximately four million grid nodes was applied for a numerical model. The grid was refined towards the wall in order to satisfy that the relative wall distance y+ of the nearest cell is in the range between 10 and 300, which has to be satisfied for an accurate prediction. The distribution of the y+-value is shown in Fig. 9 below.

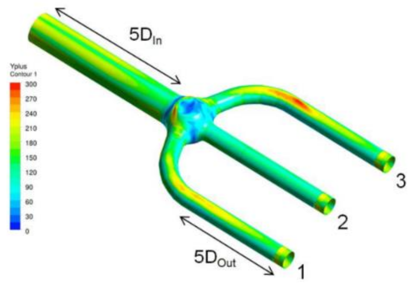

Fig. 9
Distribution of the y+-value on the geometry

The investigated load cases are shown in Table 1 below. Since the geometry is completely symmetric, it was not necessary to simulate all combinations, so we concentrated on the operation of unit 1.

Table 1
Investigated load cases

OP	Penstock 1(Side)	Penstock 2(Middle)	Penstock 3(Side)
1	100%	100%	100%
2	100%	-	-
3	100%	100%	-
4	100%	-	100%

Because in the previous investigation of the measurements it was found that the reason for the oscillations is the pressure drop, the variation of the total pressure between inlet and outlet is examined. This is done for different load cases.

4.2. LOAD CASE 1

This load case corresponds to the measurement data. In Fig. 10 below, the total pressure differences are shown.

For the reference geometry in the left and right penstock, oscillations of pressure differences of approximately 70 kPa can be observed. This corresponds quite well to the value of measurements even when the amplitude in the simulation is smaller. This can be explained because in strong swirling water flows, the simulation usually under-predicts the swirl intensity.

As a consequence, the losses caused by the swirl component are under-predicted as well. However, it is obvious that the original geometry pressure vibrations exist, which would lead to power oscillations.

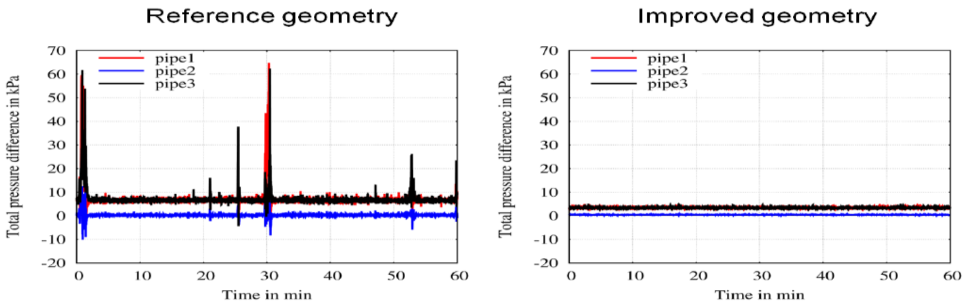

Fig. 10
Total pressure difference between inlet and outlet cross-sections, load case 1

In Fig. 11 below, the vortex behavior in the trifurcation for different time steps can is plotted. It can be seen that the vortex structures and intensities are unsteady and lead to the oscillations. Also, it can be observed that in the middle penstock, there is little vortex. Therefore, unit 2 in the middle shows no power oscillations.

Looking at the right hand side of Fig. 11below (the improved geometry). it can be observed that pressure oscillations no longer occur. The pressure shows a smooth behavior and no power oscillations would be expected.

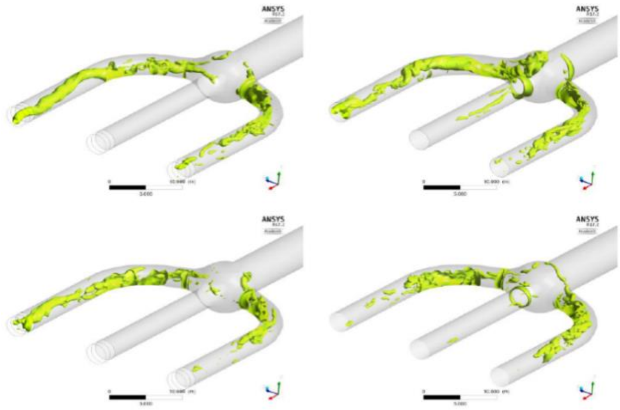

Fig. 11
Vortex structures for different time steps, load case 1

4.3. LOAD CASE 2

When operating only unit 1 there are also pressure oscillations with the original geometry as shown inFig. 12 below. However, the amplitudes are significantly smaller (less than 20% of the oscillations in load case 1). The installation of deflection plates significantly reduces these pressure oscillations and are assessed to be tolerable.

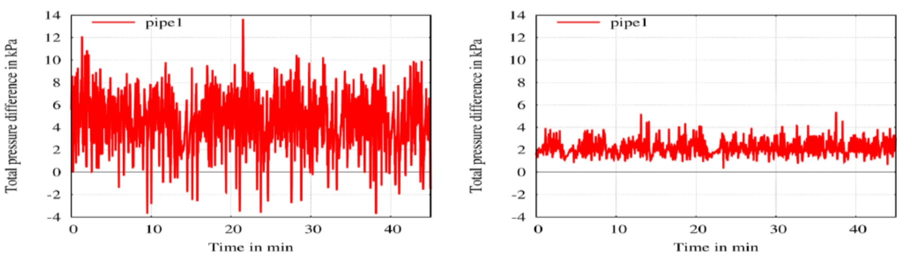

Fig. 12
Total pressure difference between inlet and outlet cross-sections, load case 2

4.4. LOAD CASE 3

The same applies for the operation of the middle unit and a side unit. Here also pressure oscillations occur for the existing geometry as shown inFig. 13 below. When installing the deflection plates, pressure oscillations no longer occur.

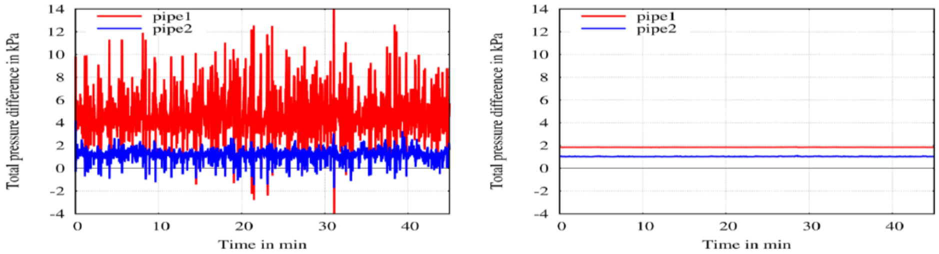

Fig. 13
Total pressure difference between inlet and outlet cross-sections, load case 3

4.5. LOAD CASE 4

When both side units are in operation, severe oscillations reoccur. The amplitudes are approximately half of those in load case 1 as shown in Fig. 14 below. However, the installation of deflection plates cures the problem and no further oscillations occur.

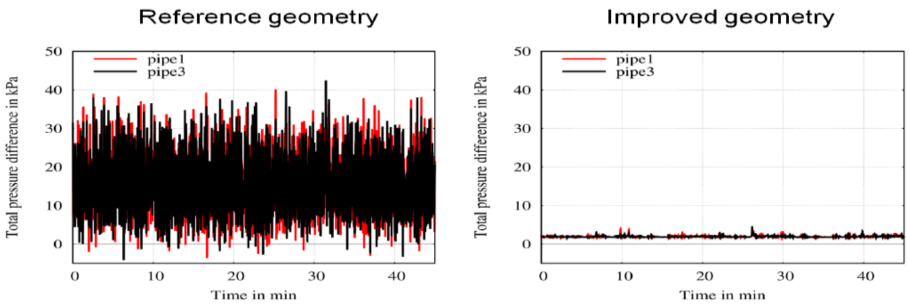

Fig. 14
Total pressure difference between inlet and outlet cross-sections, load case 4

4.6. THE RESULTS OF NUMERICAL ANALYSIS

The analyses of the measurement data and the numerical simulation of the existing geometry clearly show that the power oscillations are caused by the trifurcation. The installation of enlarged deflection plates leads to a significant reduction of the oscillations for the investigated operation conditions.

With the modified design of the trifurcation, the power plant is expected to operate without oscillation problems that may be caused by the trifurcation without modification.

5. CONDUCTING MODIFYING WORKS

For more stable water flow distribution, enlarged deflection plates are installed at the top and bottom of trifurcation. ASTM A537 steel plate (22mm in thickness) is selected for the deflection plate and it is installed from the main penstock to each branched penstocks at the top and bottom areas.

To keep the structural reliability, each deflection plate has four supports which are selected with H-beam (200mm x 200mm). The deflection plate, except for 300mm edge, has holes for the water path, it is drilled each 200mm in length.

To improve water flow distribution at the trifurcation, it is planned to restrict the water path through deflection plates at the top and bottom of trifurcation. However, to avoid the reduction of trifurcation air volume, the deflection plate has enough holes to fill with water.

For the sake of material transportation works to the inside of trifurcation, the deflection plate is divided into suitable size of 7 pieces, considering the diameter of branched penstocks and the narrow gap of extension-joint of main inlet valve as shown in Fig. 16 and Fig. 17 below.

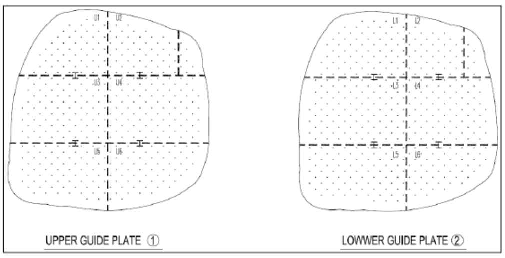

Fig. 16
Drawings of deflection plate

Fig. 17
Photographs of installing deflection plate

6. POWER OSCILLATION AFTER MODIFYING THE TRIFURCATION

The size of power oscillations is smaller than the older and meet the IEC standard such as shown in Fig. 18 below after completing remedial works.

Before Modifying	After Modifying
	Power Swing : more than 20%	Power Swing : less than 2%

Fig. 18
Comparison of power oscillation after modifying

7. CONCLUSION

Except for the case of very slow velocity of water flow, sudden expansion and reduction through the water way should be removed, especially in the trifurcation.

Where there are some uncertainties about water flow conditions, the hydraulic model test should be conducted in order to get an optimized design and mitigate the risks from uncertain hydraulic conditions.

ABSTRACT

Construction of Ir. H. Djuanda Dam or better known as Jatiluhur dam which was implemented from 1957 until 1967, this construction project called "Jatiluhur Multipurpose Project" and after its completion was named as Juanda Dam and Power Plant, after finished the name was changed to Juanda Dam and Power Plant because remembering the role of Prime Indonesia's last minister that is Ir. H. Djuanda. Basically Jatiluhur / Juanda Dam construction project is designed to irrigate tens of thousands hectares farmland and fisheries, electricity for Java - Bali lighting, main supplier of water for industry, raw water supply for capital city and tourism. Currently Jatiluhur Dam/Juanda age have reach 50 years, pollution and sedimentation become a worrying problem so that in 2012 there is great inspection by ACE Pakistan JV consultant through Dam Operation Improvement Safety Project (DOISP) obtained description of dam condition and facility building has decreased function as in mechanical equipment that is hollow cone valve. Referring to Decree of Public Works Minister Number 315/KPTS/M/2011 about Authority Delegation to General Director of Water Resources to regulate operation of Saguling Dam, Cirata Dam and Jatiluhur Dam which main task is monitoring and evaluation cascade dam by Balai Besar Wilayah Sungai Citarum through Operation and Maintenance of Citarum Water Resources for doing repair/replacement the mechanical equipment above.

Replacement of two hollow cone valve diameters of 3.85 m with material (stainless steel) meets the same standard as Z5 CN 17-04 M in accordance with asbuilt drawing on previous data. The making of this HCV has been awarded the Indonesian Record Museum (MURI) which is work of nation's children, as well as manufacture and installation of replacements process has been written simply.

There are several problems in the implementation that can be solved there are:

1. HCV manufacturing and auxiliary equipment (cantilever) are new in Indonesia both from size and mounting method with mathematical models only for model test.

2. HCV mobilization from Gresik factory to location is doing by a special trailer that refers the rules of freight traffic to reservoir, from that location using phonton for morning glory and cantilever tool must be installed.
3. When disassembling and installation operations with condition of water surface elevation should be maintained for reservoir operations.

HCV, Manufacturing, MURI Record

1. INTRODUCTION

1.1. Background

The construction of Jatiluhur Dam (Ir H. Djuanda) was built from 1957 to 1967 by Compagnie française d'entreprise, French contractor. This construction project named "Jatiluhur Multipurpose Project", after finished the name was changed to Juanda Dam and Power Plant because remembering the role of Prime Indonesia's last minister that is Ir. H. Djuanda. Basically Jatiluhur / Juanda Dam construction project is designed to irrigate tens of thousands hectares farmland and fisheries, electricity for Java - Bali lighting, main supplier of water for industry, raw water supply for capital city, tourism, and equally important as flood control for downstream Citarum area.

Currently Jatiluhur Dam/Juanda age have reach 50 years, pollution and sedimentation become a worrying problem so that in 2012 there is great inspection by ACE Pakistan JV consultant through Dam Operation Improvement Safety Project (DOISP) obtained description of dam condition and facility building has decreased function as in mechanical equipment that is hollow cone valve. Referring to Decree of Public Works Minister Number 315/KPTS/M/2011 about Authority Delegation to General Director of Water Resources to regulate operation of Saguling Dam, Cirata Dam and Jatiluhur Dam which main task is monitoring and evaluation cascade dam by Balai Besar Wilayah Sungai Citarum through Operation and Maintenance of Citarum Water Resources for doing repair/replacement the mechanical equipment above.

1.2. PURPOSE AND OBJECTIVES

This HCV replacement is one of main tasks of BBWS Citarum, and with this paper as material information in maintenance implementation of mechanical replacement and electrical equipment hollow cone valve on Jatiluhur/Juanda Dam. The purpose of this paper as one example reference for other dams in replacement maintenance of mechanical and electrical equipment hollow cone valve.

1.3. GENERAL DESCRIPTION

Jatiluhur Dam (Ir. H. Juanda) is located approximately 100 km southeast of Jakarta, which can be reached through Jakarta-Cikampek toll road and Cipularang toll road (Cikampek-Jatiluhur), and 60 km northwest of Bandung, which can be reached by road toll Cipularang (Bandung-Jatiluhur). From Purwakarta City about 9 km west. Based on geographical coordinates, main position of Jatiluhur Dam is 6^o 31' South Latitude and 107^o 23' East Longitude. This dam began built in 1957 marked with laying the first stone of development by first Indonesia President that is Ir. Soekarno.

Jatiluhur Dam is the largest dam in Indonesia, damming Citarum River flow in Jatiluhur District - Purwakarta District - West Java Province, forming a reservoir with an area of ±8300 ha and around 150 km of reservoir at normal water surface elevation ±107 m above sea level (mdpl). Total area of Jatiluhur Dam catch is 4,500 km^2. While catch area large that direct to dam after built Saguling and Cirata Dam in upstream reaches 380 km^2 which is 8% from catch area total. The catch area (upper Citarum) covers Bandung district, West Bandung district, Bandung city, Cimahi city, Cianjur district and Purwakarta district. Originally designed to have a capacity of 3 billion m^3, but currently only 2,685 billion m^3 (bathymetry in 2013) this reduction is due to sedimentation. However after built Saguling and Cirata Dam in Jatiluhur upstream area, sedimentation rate is decreasing. Jatiluhur Dam is a multipurpose dam, with 6 turbines with capacity 248 m^3/s and power plant with capacity 187 MW, irrigation water supply for ±240.000 ha rice field, capital city raw water, fishery cultivation and flood control at downstream of Citarum river which managed by Perum Jasa Tirta II.

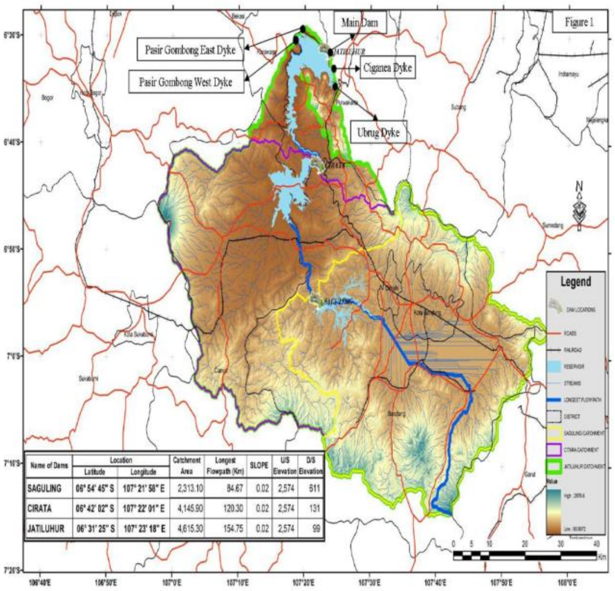

Figure 1.1 Cascade Dam of Saguling, Cirata, and Jatiluhur

1.4. Activities

Activities that implemented in this writing papers by:

- Primary and secondary data collecting
  Primary data collecting is doing by field survey to get accurate data while secondary data by collecting existing and related literature.
- Doing discussion and problem solving
  The discussion is doing by reviewing existing data of existing condition that get from survey and literature then expected conditions. While problem solving is doing by adjusting implementation plan above.
- Conclusion and recommendation
  Make conclusion from paper that have been made and recommend which related or needed.

2. EXISTING CONDITIONS AND PROBLEMS

2.1. Existing Conditions

Mechanical equipment existing condition in Jatiluhur Dam at this time has decreased function, hollowcone valve only optimal at opening position 20%.

Hollowcone equipment is under the morning glory tower which is a tower structure made from concrete that has an outside diameter of 90 m and height 110 m. This tower function as main valve (spillway threshold elevation ±107.00 m) and hollow cone valve is located on el. 49.00 m. Morning Glory has 14 windows without a door (ungated spillway) with an overall length of 151.1 m. Abundant capacity is 3,000 m^3 / s at water surface elevation of 111.6 m.

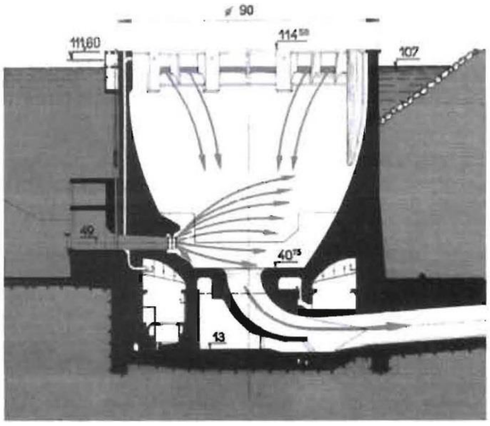

Figure 2.1 Cutting of Morning Glory Tower and Hollow Cone Valve

2.2. Current Problems

Based on results from a large inspection in 2014, hollow cone valve left there is a leak due to stoplog is not able to close perfectly. As well as the unbalanced of openings up to 100%. The following photos show the current hollow cone valve and rail condition.

3. THE PROBLEM ISSUES

3.1. Problem Solving

3.1.1. Technically

With the mechanical equipment condition of Jatiluhur dam which has decreased function on two hollowcone and two stoplog so it needs to replace and repair. For hollowcone valve will be total replacement while stoplog only on rubber seal. In the implementation of hollowcone valve replacement, problems will arise because in Indonesia never implemented Hollowcone manufacture and replacement with a large enough size (3850 mm) with technical spesification material in accordance with the original so that most of materials imported from abroad (manufacture time 7 months).

HCV delivery requires a review of traffic and possible road conditions by using trailers to climbs then derivatives and bridges to location of dam puddles. Hollowcone installation implementation requires special tool such as cantilever which doing by own fabrication (manufacture 3 months) mounted on top of morning glory, so it requires special calculation and skill at dam water surface in operating condition as needed. Disassembly and installation Hollowcone valve takes four months. Before the replacement of hollowcone must repairs stoplog so that hollowcone replacement implementation is not disturbed by stoplog rubberseal leak. Replacement rubber seal takes three months.

Rules of works this activity are limited by reservoir water surface elevation, which the unloading implementation is optimized at elevations below ±105.50 mdpl.

3.1.2. Administration

Funding for replacement of Hollowcone valve and stoplog is funded by loan from World Bank and APBN companion with activity value 43.230.000.000 rupiah. The implementation of the activity is required to be completed before June 30th, 2017.

4. UNLOADING AND INSTALLATION HCV PROCESS AT IR. H DJUANDA DAM

4.1. MANUFACTURING PROCESS

In November 2016, HCV metal structures construction and installation support tools such as balanced cantilever, custom pontoon HCV, and others are ready delivered to Jatiluhur Dam, where the manufacturing and testing process is doing at PT. Barata Tegal. Workshop distance from Tegal to Jatiluhur Reservoir, Purwakarta District is ±250 km by road, or approximately 2 days by truck, due to steering effective time at night. The technical data of hollow cone valve diameter is 3850 mm, with material ASTM A240 Gr. 2205, is planned to burdened with pressure of 15 Bar. In mobilizing HCV to site using low bad trailer with packing size of 5070 mm long and 5020 mm wide and 4120 mm height, if height of packing is added with tub height of transport vehicle to road 600 mm it becomes 4720 mm so it is still safe against high net between road and bridges girder concrete along toll roads having an average of 4900 mm.

4.2. Unloading and Installation

4.2.1. Supporting Equipment

In November 2016 until beginning of February 2017 water surface elevation above 105.50 and even runoff, which means that contractor/implementer does not get discharge recommendation permit due to work safety support at bottom. As a result of limpas water in morning glory there are some workbench components process of disassembly and installation hollow cone valve lost carrying water flow. Some missing components are immediately followed up by creating a replacement. The material is unloaded from the freight at logistics warehouse location and gradually shipped to morning glory gradually due to load for passing main dam should not exceed 3 tons.

In February 11th, 2011 Jatiluhur water surface elevation is still above the elevation 105.5 but if see the trend of reservoir water surface elevation is decreasing plus reference from Prakirawan BMKG West Java through portal http://www.bmkg.go.id weather for upstream area which precipitate reservoir tends to narrow with frequency decreasing so that decided as beginning of discharge old HCV followed by installation new HCV. Beginning installation of work aids discharge and installation HCV begins with installation of safety net that functioned as last safeguard in case of work accidents and material tools that fall not directly into drainage hole.

The next installation work tool is installation of lifting table components which lost due to washed away by water runoff. The next work process is checking the wheels of trolley wheels and coloumn wheels lifting whether the bearings on the wheels are still functioning properly.

Another work tool is lifting column which function to lifting and lowering old and new HCV from moving table to lifting table then vice versa.

Figure 4.6 Installation Lifting Table Component

Working tools for HCV lift overhaul using balanced cantilever. The tool was designed by LAPI ITB then tested on September 8th, 2015 at PT. Barata Tegal and test site on February 20th, 2017 with conclusion that this tool can lifting and lowering HCV.

The next step is preparation path road for vehicles and destruction heavy equipment at dock/port. Preparation that has been done by adding *sirtu* (sand stone) on the entrance to dock (entrance portal) and dredging of pontoon area for pulled over and stone pile addition in heavy equipment position (car crane) which lifting HCV.

4.2.2. Unloading

Process of diasassemble old HCV begins with release 84 pieces flange bolt then right and left arm drive bolts, then the trolly is positioned just below the HCV and tied with the trolly by using the sling.

The detached HCV and above trolley move out just below the lifting table and lifting column.

Lifting process the old HCV from trolley upwards using a 20 ton chain block of 2 pieces which located at lifting column, was manually lifted with human power.

Balanced cantilever is prepared for lifting old HCV by lowering binding hook on hoist and tied to old HCV. Lifting process approximately 2 hours get to morning glory side because lifting equipment speed is made at low speed to HCV that weighs nearly 35 tons in process of lifting is not rocking.

After old HCV on morning glory side and shifts to outside then the pontoon that has been prepared with holder/saddle near to morning glory just beneath balanced cantilever arm and continued lowering process of old HCV which placed on pontoon saddle.

Old HCV on the pontoon are tied with steel string sling and chain block to avoid rocking then immediately sent to blue dock/harbor with assistance of 2 tug boats.

Heavy equipment (capacity of crane car is 100 ton) is prepared to disassemble/lift old HCV from pontoon and lift new HCV. Furthermore, new HCV is delivered to morning glory.

4.2.3. Installation

New HCV removal process from pontoon and drop to baseline morning glory, the sequence is almost same as old HCV lifting process but reversed sequence. It starts from new HCV lifting from outside of morning glory and lowered down using balanced cantilever.

Figure 4.15 New HCG Lifting and Lowering Process

Before new HCV installation, first doing the rail replacement and brushing flange existing.

Figure 4.16 Replacing Process of Rail and Brushing Flange Existing

After the work of rail replacement and brushing flange then continued by lowering new HCV using chain block and shifted trolly into approaching flange. Flange bolts installation is doing with a firming load of ±610 kg for each bolt by looking at digital scales.

Figure 4.17 Bolt Installation Process with Specified Load

5. COMMISIONING

5.1. COMMISIONING TEST

After Hollow Cone Valve is mounted, continuously with disassembly of work desk tool, safety net and doing the Commissioning Test on June 12th, 2017.

Commissioning test is a part of final stage to try hydromechanical and mechanical reliability of Hollow cone valve, in implementation of this test is divided into two parts. Dry test is a test of HCV motion function without any load with stop log concrete (check name to pjt) in closed position. This test only checks the HCV motion when open and close 5% increments start from 0 until 100% and 100% to 0 position. Load Test is a test such as dry test but with hydrostatic load which stop log concrete in opened position so that causing burden to mounted HCV.

Figure 5.1 Commissioning Test

Testing of HCV load test reliability that has been installed is implemented until 100% aperture, because in order to anticipate the cessation of 6 turbines simultaneously which water drainage for industry and raw water to DKI Jakarta can be disbursed through two HCV each has opening discharge 197 m^3/s on reservoir water surface elevation ±105,00 mdpl.

5.2. COMMISSIONING RESULT

For this test, HCV reliability is tested with the parameters seen from testing time, bolt ampere read, rail condition, etc. which presented in the table:

Table 5.1 Ampere Load Test Measurement Data HCV-1 (Right) and HCV-2 (Left)

Load Test Open 20 %					
No.	**HCV**	**Open**	**Ampere**	**Time (Minute)**	**Information**

		40 % - 0 %	12,6 A	02. 57. 80	Bolts, rail and wheels are all still safe

5.3. Old Hollow Cone Valve Monument

Old HCV are moved and placed at designated place near PJT II archives warehouse area. This HCV is temporarily stored near the building of hydropower plant in Jatiluhur, HCV is planned to be a monument in Jatiluhur dam main area. For this HCV get MURI record from Museum Muri Records, category largest HCV with diameter 3850 mm.

Figure 5.2 Old HCV

6. CONCLUSION AND RECOMMENDATION

6.1. Conclusion

- Hollowcone valve (HCV) mechanical replacement at Jatiluhur / Juanda Dam requires special skills to be initiated during HCV manufacture at the plant up to the installation in the field (Jatiluhur Dam / Juanda). Hollowcone valve Jatiluhur / Juanda Dam is the largest HCV in Indonesia even in the World, so MURI Indonesia record museum awarded the certificate with the largest valve category (diameter 3850 mm)
- All activities ranging from manufacturing process, transportation, demolition, HCV installation, and Dam history Ir. H. Djuanda, fully documented recorded and popularized into the book "SETENGAH ABAD HCV BENDUNGAN IR. H. DJUANDA" compiled and written by Joko Mulyono and Chainur Fauzi
- The success of this HCV replacement is inseparable due to good coordination between Balai Besar Wilayah Sungai Citarum (BBWS CITARUM), Pembangkit Jawa Bali (PJB) Saguling Dam, Indonesia Power (IP) Cirata

Dam, PJT II Juanda Dam and BMKG. This HCV installation activity is limited when the water elevation of reservoir is below 105.5 mdpl according to the agreement in Tim Koordinasi Pengelola Bendungan Kaskade Citarum (TKPBKC).

6.2. RECOMMENDATION

Implementation of Operation and Maintenance must be as much as possible with the implementation of development, since continuous of Operation and Maintenance can make development outcomes more guaranteed useful life and function. Therefore continuity according to Operation and Maintenance manual should be implemented.

1. INTRODUCTION

Todays, construction of dam and power plant projects with the aim of electricity generation, flood control and water storage for use in industry, agriculture and drinking is a part of the government's development plans, and in Iran, these plants are being pursued. For instance, one of the project is 4 km pressure tunnel under construction in West Azerbaijan province, northwest of IRAN.

The construction of each tunnel always has unique technical geological/engineering problems. On-time solution of such problems is very effective in achieving the schedule of project planning, and it can provide the satisfaction of the client.

Rock mass classification systems developed by international society of rock mechanics to achieve uniformity of rock mass description all around the world. Rock mass classification is a basic communication between the geologists and engineers [1]. The RMR and Q systems are two rock mass classifications most commonly used in rock engineering, which values of each rock mass class relating it to specific engineering problems [2]. These systems provide guidelines for the selection of rock reinforcement for exposed area. The guidelines present shotcrete and lattice girded/Steel Ribs for weak unstable rocks during tunnel excavation [3].

In traditional tunneling methods, over-excavation due to geological conditions and collapse of weak rock area is almost inevitable [4]. In these situations, reinforcing methods should be used, in according to rock mass classification systems, to prevent occurring and/or development of rock collapse [5]. However, empty spaces remain behind the rock reinforcing systems.

Any gaps between tunnel ceiling and reinforcement system can cause unpredictable deformations (such as collapse etc.) of the surrounding rock [6]. Therefore, such gaps should be filled with stiff and solid materials. Contact grouting is a most common practice for backfilling of the gaps [7], [8]. In case of collapsed area, empty spaces behind the reinforcing systems mainly could be filled by desirable material for instance packed pumice pieces in, and then injected by cement grout to get a solid portion between rock and lining [9].

2. DEFINATION OF THE PROBLEMS

The project is a hydroelectric power plant, including of about 4 Km water transfer tunnel. The tunnel is excavated by the traditional method, using excavation machines such as Jack Hammer, Rodheader and sometimes with explosives. Type of the rock along this tunnel is a poorly-grade of metamorphic rocks, often containing meta-sandstone, slate and phyllite, and in some cases schist. During the tunnel excavation, problems such as rock collapse and over-excavation due to the intersection of faults, major joints, crushed zones and particularly wet areas are encountered; several times. If necessary, initial tunnel-supporting systems consist of lattice girded/steel ribs; wire mesh and shotcrete were installed at collapse and over-excavated areas during the excavation phase. Two type of plastic sacks was used for placing of pumice pieces in gaps behind reinforcing systems, as shown in figure 1, type A: flour sacks and type B: onion sacks. After the completion of the tunnel excavation, the final concrete lining was installed.

Now, there are three main questions?

First: is it possible to filling the porosity between sacks and inside pumice pieces? On the other hand, which type of sacks is better to use that has cement grout penetrability?

Type " A "　　　　　　　　　　Type " B "

Figure1
Types of Sacks for Pumice Packing

Second: when is the appropriate moment for contact grouting? Before or after concrete lining was completed?

Third: Is it necessary to revise the contact grout holes' arrangement? which has already designed.

To find the answer of the first question, a simulation phase has been done on the workshop. Answering the second question by selecting of two situations in tunnel. One situation was shotcrete face finished and the other was finished face of lining. The last question was find out after implementation of grouting and according to the check-holes result.

3. SIMULATION OF CONTACT GROUTING

The purpose of this simulation is to investigate the grout penetration in the empty space between the pumice pieces as well as the gap between the sacks. Metal barrels were used to simulate contact grouting. One side of the barrels were cut and two type of pumice sacks placed in and packed by welding. Two valves were installed at the other side of barrels in order to grout injection and air evacuation. Barrels abide for injection was maximum pressure of 1.5 bar. Water Cement ratio of contact grout is 0.8.

Seven days later, grouted portion was hardened, then in laboratory the barrels were rifted carefully and solid portion were taken out to prepare for core drilling. Samples were used to determine the uniaxial compressive strength and control the quality of the grouted solid portion.

The quality of core samples can be seen in figure 3. It shows two different pumice packed types. As it shows the grout has penetrated in both types of packed pumices and the voids between pumice pieces and gaps around the sacks filled by injected cement properly. On the other hand, type of sacks has not affected the grout penetration.

A: barrelles stacked by two type sacks

B: view of grouting line

C: barrel expansion due to grouting

Fig. 2
Sequence of Simulation in Metal Barrels

Cores of both types of packed pumice indicate that solid specimens with no voids or un-cemented pumice pieces. Average of compressive strength 28 days' age were 165 and 151 kg/cm2 for onion sacks and flour sacks respectively. As a result, the both pack of sacks get acceptable groutability.

Fig. 3
Left: Core of Onion Sacks, Right: Core of Flour Sacks

4. COMPARE OF CONTACT GROUTING IN PHASE

In order to grouting gaps during tunnel construction, two opinions have proposed. When is the appropriate time for grouting? After initial supporting (lattice grade, shotcrete and wire-mesh) or after final concrete lining?

To answer the above questions, two test panels have selected in tunnel. One panel was located in initial support area (ISA). Second panel was in final lining area (FLA).

4.1 CONTACT GROUTING IN INITIAL SUPPORT AREA

Sequence of initial support system execution in ISA panel including first shotcreting on collapse area rock face, installation of lattice/steel ribs, wire-mesh installation, stacking of pumice sacks and final shotcreating on wire-mesh to cover the area (see figure 4).

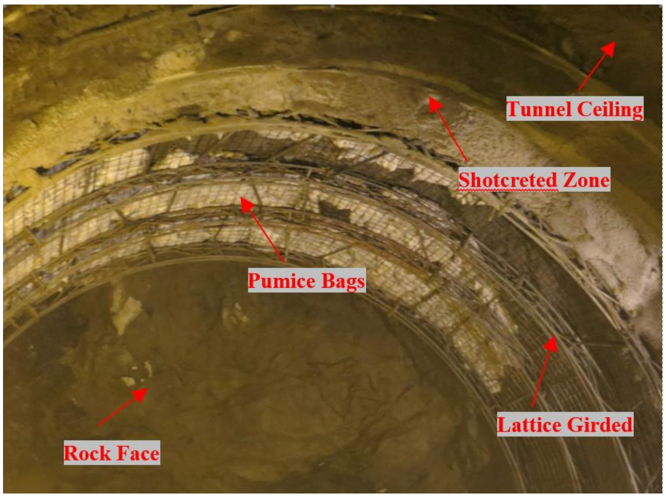

Fig. 4
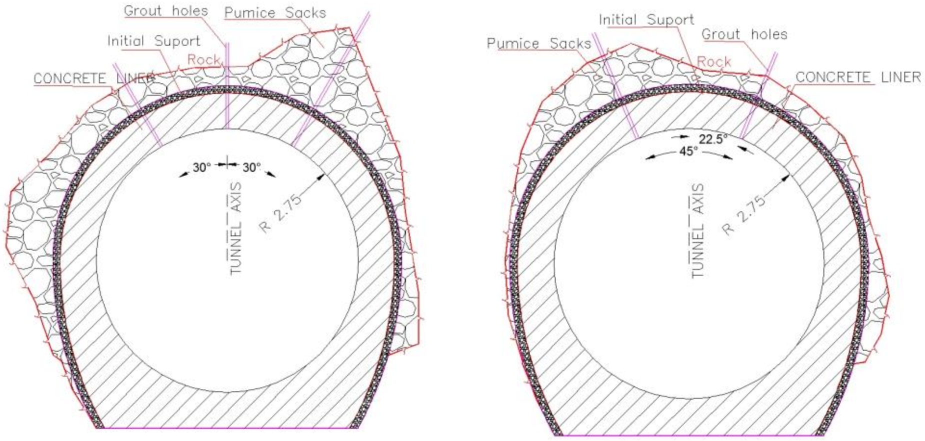
Inside Tunnel, View of Initial Support System

When the initial support was completed, drilling and grouting activities were carried out. Because of the inadequate strength of the initial support, it was not possible to apply injection pressure greater than two bars. Therefore, it was decided that the grouting activities would be tested in a panel where the final concrete lining was performed in that area.

4.2 CONTACT GROUTING IN FINAL LINING AREA

Based on technical office protocol, it was decided that drilling and grouting activities would be done within the concrete lining area as a comparing panel. The process and consequences of this panel (FLA) will be compare with ISA panel. According to the technical specification, drilling and grouting in FLA panel will be done after final lining installation. Concrete lining were placed whole the tunnel, so it cover the initial supporting system. The grout holes arrangement was carried out according to the design drawings in initial “A” and secondary “B” series separately (see figure 4). Spacing of A and B series were 3 meters. Pressure for contact grouting in FLA panel increased up to 7 bars due to concrete lining bearing. Water cement ratio of grout is 0.8 by weight.



A: pattern of initial holes B: pattern of secondary holes

Fig. 4
Contact Grout Holes Arrangment

4.3 COMPARING OF ISA AND FLA PANELS GROUTING PROCESS

Although drilling of borehole in ISA panel could be done faster and lower cost also does not delay the project schedule, but due to technical limitations in applying the injection pressure, satisfied results of grout penetration inside the gaps and sacks h not achieved. Inspection of core samples indicate that the grout penetration in the voids is not desirable and the pumice pieces were not consolidated predominantly (see figure 5-a).

In FLA panel, injection pressure up to 7 bars were possible, so the penetration of grout in the voids were acceptable. As a result, injection in the FLA panel were get the pumice pieces and cement parts integrated, and solidified in the cores mostly (figure 5-b).

A: Core sample of ISA panel B: Core sample of FLA panel

Fig. 5
Core Samples from ISA and FLA Panels

Figure 6 shows the results of grouted cement of A and B series for FLA panel. In general, the amount of injected cement in the B series has been significantly reduced compared to the A series, but the B series still shows a peak absorbed cement locally.

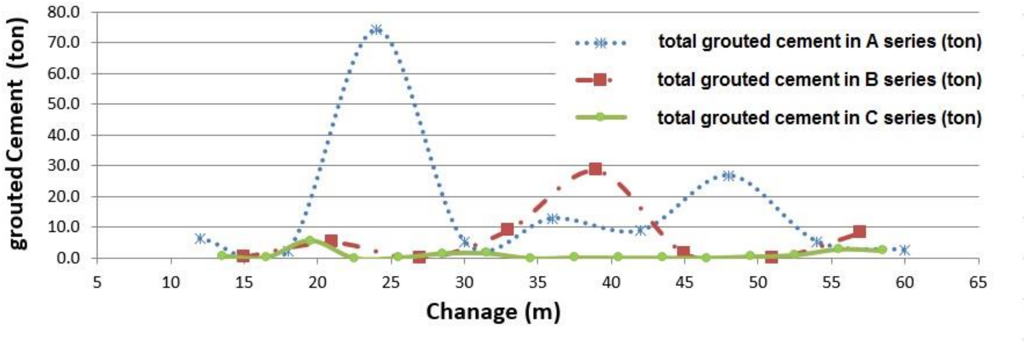


Fig. 6
Grouted Cement in Contact Holes Series

The necessity of implementation the third series "C" was established. C series were placed beetwen A and B series (see figure 6).Cement absorption in C series could be seen in figure 7. Cement grouted in the C series has been extremely reduced compared with A and B series and cement absorbed peak is not seen in this chart.

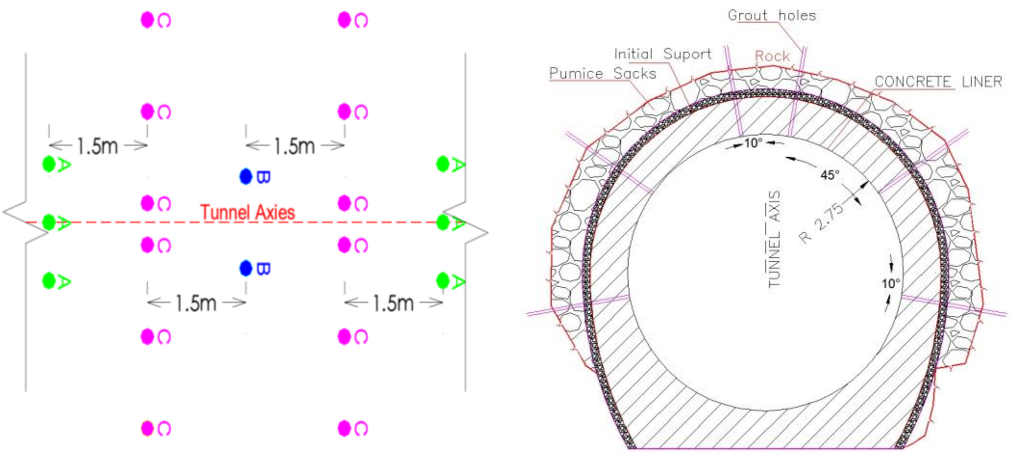

Fig. 5
Left: Plan View of Grout Holes Right: Typical Section of C Series

When the grouting of all three series completed as mentioned above, check-holes were drilled to evaluate the effectiveness of grouting. Therefore, the check-holes indicated the gaps behind final concrete lining, have filled and consolidated with cement firmly (see figure 8).

SUMMARY

Both types of sacks (onion and flour sacks) used to placing pumice pieces in the empty space behind the lining have acceptable groutability.

The results of contact grouting taken after the initial supporting is not satisfactory, therefore the implementation of contact grouting was postponed after the installation of the final lining.

The grouted cement in secondary grout holes still shows a peak absorbed cement locally, therefore the third grout holes grouted between initial and secondary holes.

Check-holes drilled after grouting of third series shows that the voids inside the pumice sacks and the gaps between sacks completely filled with cement grout.

RÉSUMÉ

Les deux types de sacs (sacs d'oignon et de farine) utilisés pour placer des morceaux de pierre ponce dans un espace vide derrière la doublure ont une aptitude au coulage acceptable.

Les résultats du jointoiement de contact pris après le support initial ne sont pas satisfaisants, par conséquent la mise en place du joint de contact a été reportée après l'installation du revêtement final.

Le ciment injecté dans les trous de coulis secondaires montre encore un pic de ciment localement absorbé, donc les trous de coulis troisième joint entre les trous primaires et secondaires.

Les trous de contrôle forés après le jointoiement de la troisième série montrent que les vides à l'intérieur des sacs de ponces et les espaces entre les sacs sont complètement remplis de coulis de ciment.

1. INTRODUCTION

Worldwide use of hydropower grew over 5% between 2009 and 2010, according to new research published by the (World watch Institute for its Vital Signs Online publication). Hydropower use reached a record 3,427 TWh, or about 16.1% of global electricity consumption, by the end of 2010, continuing the rapid rate of increase experienced between 2003 and 2009. And continued to increase in 2011, reaching 3,498 (TWh) and 970 GW respectively. Total consumption got increased each year between 2003 and 2011. But in 2011 the growth rate slowed, recording only 1.6% increase from the previous year. China was the largest hydropower producer and is expected to continue to lead global hydro use in the coming years. The country produced 721TWh in 2010, representing about 17% of national electricity use. China also had the highest installed hydropower capacity, with 213GW at the end of 2010. It added more hydro capacity than any other country, 16 GW in 2010, and plans to add 140 GW by 2015. Hydropower is produced in at least 150 countries but is concentrated in just a few countries and regions. The Asia-Pacific region produced about 32% of world hydropower in 2010. Africa produces the least hydropower, accounting for 3% of the world total, but considered the region with the greatest potential for increased production. According to China's first national water census data released in 2013, the number of hydropower stations and the installed capacity of the distribution in China [1], as shown in Figure 8, the size of the following (i.e., power plant installed capacity of less than 500 kW) 658, accounting for 52.5% of the total number of 46 758 units, the corresponding installed capacity of 5.591 4 × 106 kW, the total installed capacity of 3.3 × 108 kW of 1.7%. These data show that small and micro hydroelectric power generation benefits are small.

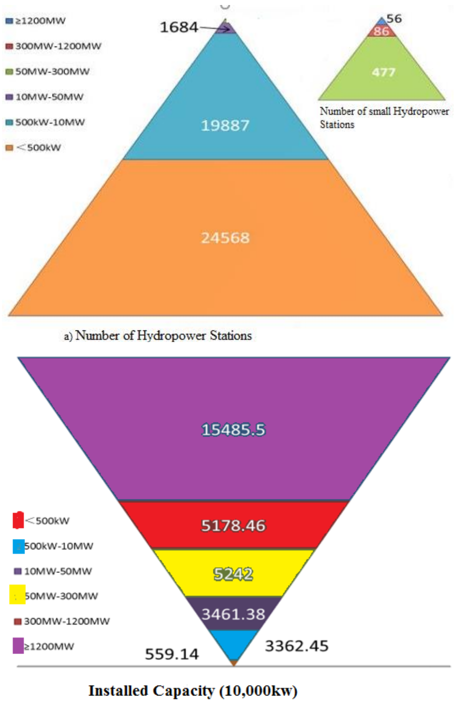

Fig.1 Statistics of hydropower plants of first national census for water

2. CURRENT SITUATION AND STRATEGIC PLANNING OF SMALL HYDROPOWER IN EU 27 COUNTRIES

INTRODUCTION

In 1989, when the European Commission initiated the establishment of the European Association of Small Hydropower Stations to stimulate the growth of small and micro hydroelectric power generation, the importance of developing small hydropower was recognized: in the energy plan of 2050, the energy plan of the year stressed that the proportion of renewable energy must be increased with the proportion of demand for energy growth in the future, in order to achieve the following objectives [2]:

- Maintain the sustainability of energy production;
- Independence of energy production;
- Adopt positive measures to address climate change.

Over the past 20 years, the development of small hydropower in the EU-27 has achieved very positive results, appreciations to the EU's Water Framework Directive, 2020 targets for renewable energy and greenhouse gas emissions reductions, and the active promotion of the European Association of Small Hydropower Stations. Fig.2 shows the Statistics and prediction of SHP installed capacity in the EU countries from 2005 to 2020. In 2010, nearly 21,800 small hydropower stations were in operational, that is in Germany (more than 7,500), Austria (2,590), Italy (2,303), France (1,900), Sweden 1 900), the Czech Republic (1 450). The total number of small hydropower stations is expected to reach 24,000 by 2020 [1].From 2010 to 2020, the installed capacity of the power station is expected to increase from 13.7 GW to 17.3 GW, with the annual power generation capacity also increase from 49.3 TWh to 59.7 TWh, the annual growth rate of small hydropower generation should also reach Total of 21%., the strategic plan for small hydropower in EU-27 from 2010 to 2020 is to increase the installed capacity of small hydropower by adding 2,100 small hydropower stations (with an average annual increase of 210 power stations) 3.62 × 106 kW (an average annual increase of 3.62 × 105 kW) and an increase of about 10.37 GWh (an average annual increase of 1.037 GWh) in the annual production of small hydropower.

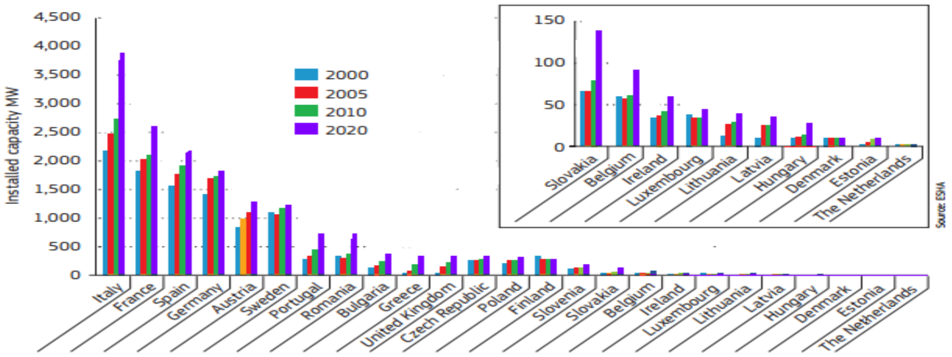

Fig.2 Statistics and prediction of SHP installed capacity in the EU countries from 2005 to 2020

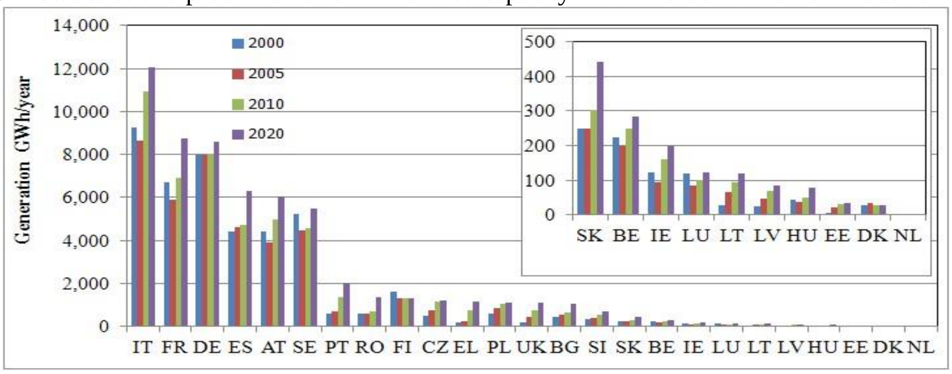

Fig.3 SHP electricity generation in the EU countries

Figure 2 and Figure 3 for the EU countries from 2000 to 2020, showing hydropower installed capacity and small hydropower generation statistics and forecasts [2]. Italy is far ahead in the EU countries, in the installing capacity of small hydropower and annual electricity generation. Italy in 2010 had an installed capacity of 2735MW small hydropower with an annual Energy generation reaching 10958GWh; and still expecting the installed capacity of small hydropower to reach the scale of 3,900 MW by 2020, compared to 2010 growth of 42%. Ranked 2ndto 4th countries are France, Spain and Germany respectively. Countries with low installed capacity and annual electricity generation are countries or regions with relatively low terrain, for example, the Eastern Baltic Sea region, Hungary, Denmark and Ireland. (Note: Figures for Malta, Cyprus and Greece are not included in the charts). From the structure of the whole renewable energy and distributed energy, the current situation of the EU and the forecast for 2015 and 2020 are shown in Table 1. The data in the table are from the report of the European Small Hydropower Association [2]. Data may be available 0.1% of the error.

	CLASSIFICATION	PARTICULAR			
		2005	2010	2015	2020
Hydropower generation	Hydropower generation	71.3	53.7	39.4	30.9
	Small hydropower	8.9	7.8	6.1	4.9

Wind power		14.8	25.8	34.3	40.7
geothermal energy		1.1	0.9	0.8	0.9

Table 1 Structure of renewable energy and distributed power generation%

According to China's first national water census data released in 2013, the number of hydropower stations and the installed capacity of the distribution in China [1], as shown in Figure 8, the size of the following (i.e., power plant installed capacity of less than 500 kW) 658, accounting for 52.5% of the total number of 46 758 units, the corresponding installed capacity of 5.591 4 × 106 kW, the total installed capacity of 3.3 × 108 kW of 1.7%. These data show that small and micro hydroelectric power generation benefits are small.

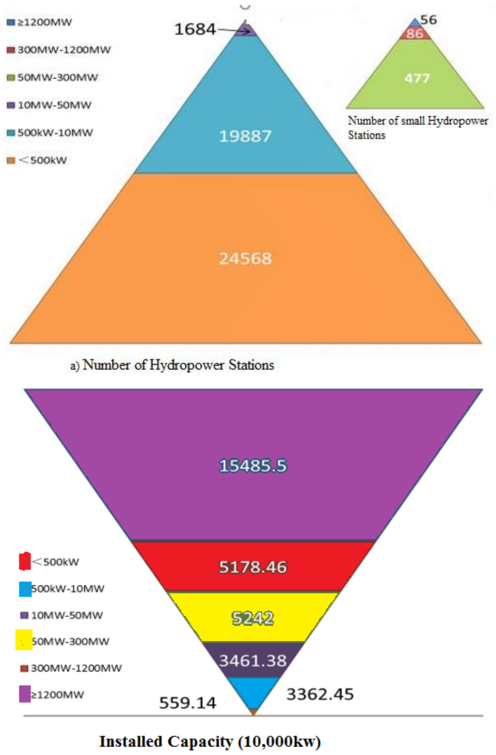

Fig.4 Statistics of hydropower plants of first national census for water

2.1. OVERVIEW OF AFRICA'S ENERGY

Africa's hydropower investment channel highlights the potential for renewable energy expansion across the continent. Hydroelectric power is a very attractive investment in Africa due to its huge potential for hydro power generation. access to modern energy, is minimal in the Region, over 645 million people live in the region without access to modern Energy especially those in the rural areas. The Democratic Republic of the Congo has a large part of Africa's stated potential It currently carries 40 projects for hydropower of which nine of them are located in Democratic Republic of the Congo in addition to the two largest Inga I (354 MW) and Ingla II (1,424 MW). The Zambezi River is the most important resource of hydropower and the terrain of Zambia dwell in a larger portion of the river basin i.e. 41%, compared to the other seven riparian countries. Zambia has reached hydropower installed capacity of 2,257 MW, based on the accomplishment of the upgraded Lunzua station (14.8 MW) in 2014, Representing 94% of the total energy mix of the nation [3]. The total highest SHP potential in the African continent is located in The Eastern Africa region with a total potential of 6,759 MW. With only 216 MW installed capacity. Western Africa has the second-highest SHP potential in the continent with 3,113 MW yet the second lowest in installed capacity with only 86.1 MW representing only 3% of the total potential. the Middle African region on the other hand has the largest amount of undeveloped SHP potential. Northern Africa has insufficient potential of 225 MW, being one of the lowest in the world, with 112 MW already developed. Africa's Small Hydro Power can be considered as having a comparatively low level of installed capacity but with huge potential for development. The total SHP potential is estimated at 12,197 MW with an installed capacity of 580 MW. This indicate that only about 5% of the potential have been developed. Figure5 shows the Share of Small Hydro Power installed capacity in Africa (%) [4]

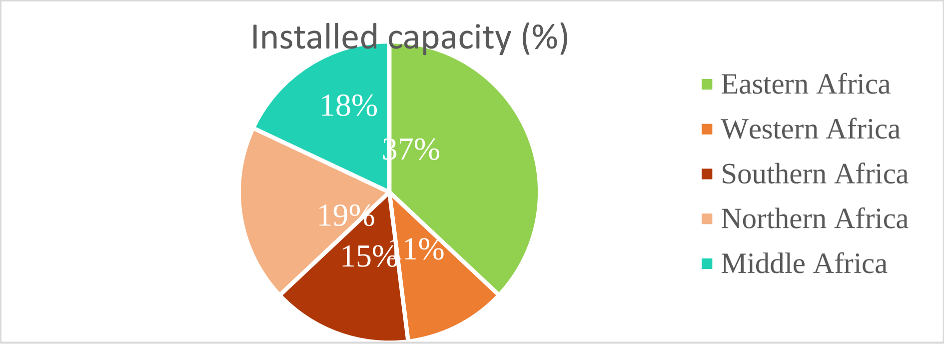

Fig. 5 Share of installed SHP capacity in Africa (%)

Countless of the world's fastest-growing economies are located in the resource rich African continent. Accelerated economic growth in the region is determined by rising in commodity prices. Nevertheless, growth in sub-Saharan Africa is not always comprehensive, and there is a low level of access to modern energy, water and other basic services throughout the region. Access to energy will continue to achieve a high level on the policy agenda, Particularly the work of the new United Nations sustainable development goals agenda which includes a devoted goal to deliver universal access to modern energy services, relying on Millennium Development Goals which they supplanted in 2016[5]. Reasonable price along with Consistent power supply is an important requirement for economic growth. Electricity from renewable sources can play an important role in the improvement of electricity supply in Africa [6]. Access to electricity in Africa is a very big canker to the continent. In adequate electricity supply in many African countries has been noticed as the most pressing obstacles to economic growth. roughly 10% of the worldwide small hydropower potential is located on the African continent, specifically in the sub-Saharan African region but only few of these potentials have been developed. [7,8]. It is therefore necessary to adopt the pumping method for power generation by using Pump As Turbine for small hydropower power generation. fig.6, Electricity generation by fuel in sub-Saharan Africa under the new policies scenario, 2012 and 2040.

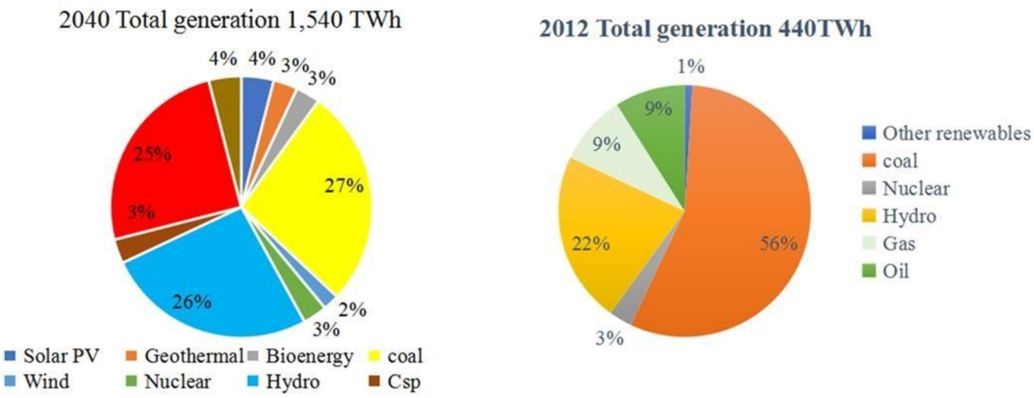

Fig. 6 Electricity generation by fuel in sub-Saharan Africa under the new policies scenario, 2012 and 2040

CURRENT SITUATION OF SUB-SAHARAN AFRICAN RENEWABLE ENERGY

The potential for renewable energy development in sub-Saharan Africa is experiencing an increase attention recently as investors and world leaders seek a new clean energy boundary. The continent could become a gold mine for renewable energy because of its abundant solar and wind resources for instance According to Statistics Botswana figures, there was a decrease of 63.9% in power generation imports during the first quarter of 2017. Comparing figures from the first quarter of 2016, there is an indication that decreased in electricity imports from 523,736MWh to 189,052MWh accounting for 63.9% decrease. This is as a result of the enhancement in local power generation at Morupule B, as the plant is now said to be producing more than half of its capacity. It can further be explained that the physical volume of electricity generation in the first quarter of 2017 was 698,451MWh, causing an increase of 57.4% compared to the first quarter of 2016 generation of 443,628MWh [9]. But barriers to clean energy worldwide are augmented all over the concerned countries of sub-Saharan Africa, also financial resources are minimal as well as unreliability of infrastructure. In sub-Saharan Africa, there is a lack of electricity infrastructure for large-scale renewable energy industries. For example, in Kenya, there are at least 50 power outages per year. Increasingly, countries in sub-Saharan Africa are implementing energy through renewable energy resources and efficacy. Kenya, as one of the most dynamic countries, increased its geothermal energy capacity to 740MW in 2015, and plans to launch a $ 150 billion project to invest solar energy in areas where Electricity is not accessible and are not connected to the grid. Ethiopia on the other hand is also principally active in wind power (150MW), and also stepping up its efforts in solar energy with the construction of a 5.200MW plant which is the largest in the region. In addition, several projects in Addis Ababa are underway, including geothermal and solar projects, and are intended to be open to the private sector. The figures below show renewable status in the region between 2010 to 2016[10]

2.2. CONCEPT OF PUMP RUNNING IN REVERSE MODE AS TURBINE

The velocity diagram for the flow at the inlet and discharge of a pump runner are basically matching when the unit operates as a turbine, except for the reversing of each vector as can be seen Fig. 9.5 and Fig. 9.6. Fig. 10 provides better understanding to the concept of pump operating in pump mode and in reverse mode as turbine

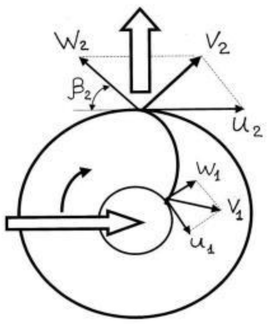

Fig. 7.5: Velocity Diagrams at the Inlet and Outlet of Centrifugal Pump [11]

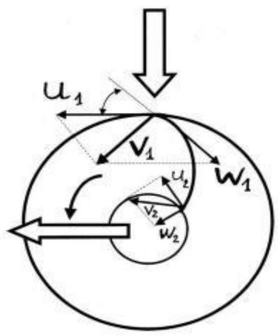

Fig.7.6: Velocity Diagrams at the Inlet and Outlet of Impeller Under Reverse Flow [11]

PAT CHARACTERISTICS

It is well known that efficiency of a centrifugal pump decreases rapidly with a drop of specific speed, and the impeller outlet diameter should be reduced considerably to increase its efficiency. With a reduced outlet diameter, it is necessary to select a larger blade discharge angle and more blades to produce the rated head. However, too many blades result in a decrease in efficiency due to the increasing blockage and skin friction in the impeller passage. Yuan [13] revealed that the splitter blade technique is one of the techniques to solve three hydraulic problems of low specific speed centrifugal pumps (lower efficiency, drooping head-flow curve and easily overloaded brake horsepower characteristics). It was observed from the studies that low or high blade numbers had increased the instability risk of head-flow curves [14], and the optimum efficiency was obtained when the blade number was between 4 and 6 [15]. M Asuaje et al. [16] studied the splitter blades effect on the performance of a centrifugal pump through both numerical simulation and experimental results. Adding splitters has negative and positive effects on the pump behavior. It increases the head rise compared to the original impeller, it has positive effect on decreasing the vibrating and radiated noise; but the efficiency is not improved since the hydraulic losses are greater. J. Zhang et al. conducted a study using the A BP artificial neural network (BPANN) model of a three-layer with 5 inputs, 20 hidden neurons and 2 outputs for predicting the efficiency and head of centrifugal pumps with splitters were built. The average relative deviation for the predicted efficiency and head were 5.97% and 4.78% respectively. And by comparing with test data, the predicted data has the similar trend, and the value of R for the predicted efficiency and head are 0.978 and 0.989 respectively, which prove that the correlation between the predicted and test value and the generalization capability are very good, and the trained network model can meet the requirement for the performance prediction of centrifugal pumps with splitters [17].

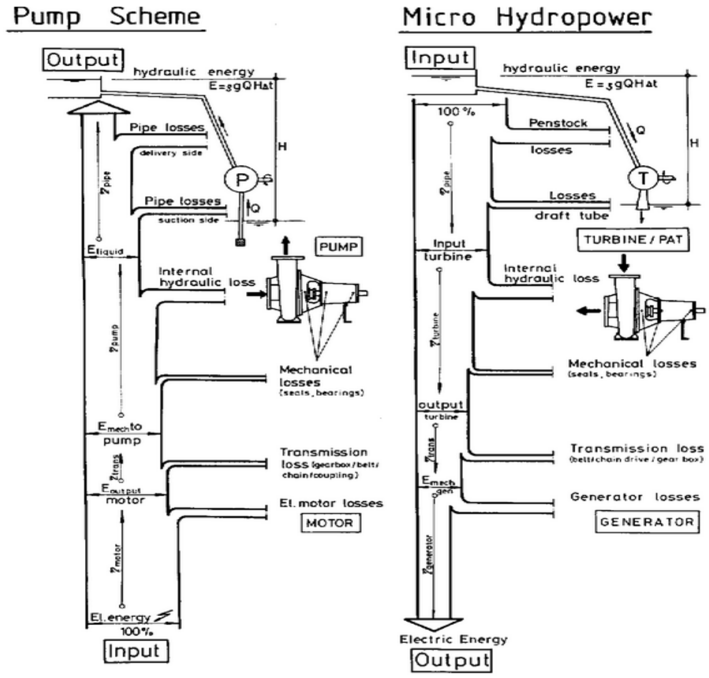

Fig.8 Working of Pump in Pump Mode and Pump in Turbine Mode and Losses

RENEWABLE ENERGY PROSPECTS AND FUTURE PREDICTIONS IN SUB-SAHARAN AFRICA

sub-Saharan Africa has a vast renewable energy potential, some of which are the world's largest alternative energy sources in the form of solar, wind, hydro and biomass. A total of 17 sub-Saharan African countries are among the world's top 33 countries with joint solar, wind, hydro and geothermal energy reserves far more than the annual consumption. The majority of sub-Saharan countries have a solar radiation range of 6-8 kWh / m 2 / day, which counts among the world's largest solar radiation. So far, only a small part of sub-Saharan Africa's huge potential for renewable energy has been tapped out. Renewable energy has the potential to meet the energy needs of the entire continent. Several African countries, such as South Africa, Egypt, Morocco, Kenya, Senegal, Madagascar, Rwanda and Mali, have adopted national targets for renewable energy and have proposed feed-in tariffs on renewable energy. In South Africa and Kenya. Countries such as South Africa, Morocco, Egypt, Cape Verde, Ethiopia, Kenya and Tanzania are developing wind farms. sub-Saharan Africa's investment lines in hydropower, wind farms, solar PV, solar thermal, geothermal and biomass technologies underscore the potential for future expansion of renewable energy in the continent. Sub-Saharan Africa has abundant renewable energy resources that have yet to be developed to meet its electricity demand. Its technical generation capacity potential largely from renewables is estimated to be 11,000GW. Almost all the countries in the region have a solar potential of up to about 10,000 GW, and the PV potential is estimated at 6,500 TWh per year [18]. Majority of its coastal countries have huge potential for wind power, with a total of about 109 GW. the main power source in many sub-Saharan Africa countries is hydropower, with an Estimated power generation of about 350 GW, largely in Ethiopia, South Africa, Egypt, the Democratic Republic of the Congo, Zambia and Mozambique this is as a result of the Congo and the Nile Rivers which are among the world's longest rivers are located in the region. For example, Mozambique has twice as much hydropower generation capacity as the UK and it accounts for 99.9% of all electricity generated. Coal resources are estimated at 300 GW, mainly in Botswana, Mozambique and South Africa [19]. Over the past decade, the average annual growth rate of sub-Saharan African financial prudence is 5.3%. Energy demand has increased dramatically even though the region has the lowest per capita power consumption Estimated at 157kWh, despite the fact that there is a rapid population growth and is expected to double by 2050[20]. on the word of IEA Renewable energy will virtually constitute half of sub-Saharan Africa's energy generation growth by 2040. There has been a rapid growth in Sub-Saharan Africa's economy since 2000, nevertheless there is a confusing in the growth.as two-thirds of the population in the regions have no access to electricity. at present only about 10% of sub-Saharan's hydropower potential has being developed. it is expected that sub-Saharan Africa will start developing these huge untapped renewable energy potentials resources. [21] The report predicts that, over the next 26 years, sub-Saharan Africa will start to unlock its "vast renewable energy resources" and that solar energy will lead the growth in renewables in the region. According to the report, just 10 percent of sub Saharan's hydropower potential is currently being exploited.

SOLAR POTENTIAL IN SUB-SAHARAN AFRICA

Sub-Saharan Africa has abundant renewable energy resources which are yet to be developed to meet their electricity call. Its technical generation capacity potential largely from renewables is estimated to be 11,000GW. Almost all the countries in the region have a solar potential of up to about 10,000 GW, and the PV potential is estimated at 6,500 TWh per year [18]. The entire continent has a long day of sunshine with an annual period of about 4300 hours [22], which equates to 97% of the total possible. [23] The continent has the highest average annual solar radiation values [24] (up to over 220 kcal/cm2 [18]. The low latitude of the landmass is another is another source: most parts of the continent are in the equatorial regions where the intensity and strength of the sun's rays are always high. There are arid and semi-arid forests in the northern part of the region, with fewer in the south and east. The combination of all these geographical and climatic factors is the reason for a huge potential of solar energy in sub-Sahara Africa. This enables solar to be powered in almost all of Africa devoid of the costly, large-scale grid level infrastructural developments. solar equipment costs reductions are anticipated to promote solar installations in sub-Saharan Africa with an industry projection estimating that there will be an annual PV market expansion of
2.2 GW in the region by 2018. [25]

-Saharan African continent is leading solar power in Africa with an installed capacity of 1329 MW in 2016. [26] South Africa Solar power is rising faster. Quite a lot of 75 MW PV plants and 2 CSP plants at 100 MW each were the largest in the country and among the largest in Africa. South Africa is currently leading in both solar thermal and PV solar energy in Africa. And has developed a lot of solar thermal plants, both parabolic trough and power tower types. A 50 MW photovoltaic power plant is planned for Garissa in Kenya which is projected to produce about 76,473 MWh/year. [27] Ghana has also planned for a 155 MW Pv plant with the government planning to increase solar power in the country from 22.5MW in 2017 to 300MW by 2020. [28] [29] There are also many small-scale modular solar power installations being implemented across the continent at villages and household levels. [29] Sub-Saharan Africa was on top for purchases of off-grid solar products in 2015, [30] Morocco's solar plan, which is one of the world's largest solar energy projects aim to produce 2,000 MW of solar power by 2020. with the 500MW phase one solar power complex at OuarZarate being the first to be developed. [31] The first part of the 500MW project. Morocco happens to be the only African country having a power cable link to Europe. Morocco's solar plan, which is one of the world's largest solar energy projects aim to produce 2,000 MW of solar power by 2020. with the 500MW phase one solar power complex at Ouarzazate being the first to be developed. The first part of the 500MW project. Challenges to The Renewable Energy Development

Absence of system capacity. Continued electricity shortages in the region have led to a slowdown in economic growth, obstructing the implementation of various health and educational development goals [14]. This is due to insufficient power generation capacity in the network area, inadequate power grid infrastructure, poor power generation maintenance, new generation capacity investment, and decentralization in remote areas. The lack of systematic planning of renewable energy sector led to a transmission and distribution of larger losses in the region.

Policy and regulatory framework: undefined or non-appearance of policies and regulations that sees renewable energy development in most of the Countries in sub-Saharan Africa is one of the major challenges. The region wastes billions of dollars in lost public services and oil subsidies, that are not beneficial for the energy sector development. Assuming that most utilities cannot recover their costs without these subsidies, the development of energy systems is perceived as a high risk and therefore not attractive to private investors [33].

Lack of Finance: One of the biggest challenges facing sub-Saharan Africa on solar power development is financing. Funds are not available for the feasibility studies on these potential site as well as construction and maintenance. Almost all the new developments on the continent are relying in one Way or the other on donor financing.

SUMMARY

Renewable energy technologies can play an important role in the energy sector of sub-Saharan African continent. sub-Saharan Africa's renewable energy industry can become a major player in the energy sector to meet the energy needs of a large part of the population through the use of centrifugal carefully chosen as turbine for small hydropower generation. since pump As turbines are a leading solution for small hydropower generation, especially in rural areas. The initial project cost has dropped significantly, making it more viable. The specific location of the pump can be further limited by selecting the appropriate pump turbine. The characteristics of the best efficacy point can also be improved by applying the various modifications proposed by the earlier researchers. There is a need to actively lobby for renewable energy at the national, regional and sub-regional levels. Development and promotion of new business models for the maintenance of renewable energy development for rural electrification should also be mainstreamed in the continent. Supportive inducements at the local level, when combined with energy sector reform, can become a powerful lever for private investment, but they must be specific, beyond the political correctness of high-level statements. This solution will make the region economically and environmentally sound and promote development of the people. Achieving 100% power access Throughout the area needs mix of pathways and scales

"THEORY OF EVERYBIM" – WORKFLOW OPTIMIZATION HYDROPOWER NORWAY

Kristoffer S. BUGGE

Hydropower Engineer and Head of BIM Coordination - Energy Division, NORCONSULT AS

NORWAY

1. INTRODUCTION

Traditionally, construction and hydropower projects have been designed and built based on multiple 2D drawings. Drawings have been used since ancient times, when they were cut into stone. Our experience with drawings is that a lot of time is spent on unnecessary perfection of the appearance of the drawings, such as line thickness, textures, company standards, etc. Much of this is not relevant for building the desired construction and can be considered poor use of valuable time. Technology is at the same time changing rapidly around us, and its growth is almost comparable to an exponential curve (Fig.1).

This growth/development is particularly relevant in our industry, as it represents an enormous potential that is accessible to all. We wanted to take advantage of this potential and we had to make a major change in the way we worked. Major changes are not easily implemented in a company or in a project since humans by nature are reluctant to change and tend to favor established routines. We had to challenge the established routines and get started. Our main goal was to be the first to complete an entire project without traditional 2D drawings at all. We wanted to deliver a fully integrated “Building Information Model” (BIM) that was available to everyone at any time throughout the project, consisting of all necessary geometry and information for both design and construction phase. This leads to more constructive use of time since changes will be made on dynamic objects rendered in an interdisciplinary model and not on many drawings with countless references. The concept was "Paperless Design, Paperless Construction ". No one had done this before. The whole Industry said it was too early, even the software developers said we had to wait a couple of years before this could be done in full scale. Someone had to take the first step.

The 125 MW Run Of the River hydro power plant “Vamma 12” was our “chosen one”. The interdisciplinary complexity, size and location made it the perfect choice. Today, in line with our goal, the project is close to being finished and represents a milestone for us and the construction industry in relation to how projects are being implemented. The work has been innovative and inclusive where the team was put before individuals and the project itself was delivered by close collaboration of the involved firms. It has turned a lot of skepticism into motivation. Following the successful delivery of the Vamma project, a new generation of many fully integrated BIM projects of all sizes and complexity are being undertaken. All project teams work on a continuation of the same theory / workflow, so that we can shift resources between projects in case of sickness and produce the same quality on a wider range of deliverables. At the same time no project teams can work without asking critical questions or looking for places where the theory can be improved. It is accessible to all and is regularly updated in line with smarter processes and technological development. This paper gives an insight into how we have worked as a team to establish our current workflow for fully integrated BIM projects. BIM is so much more than just the 3D-model. It is a process enhanced by technology, combining everything that has to do with delivery and construction of a project. This is the reason why we have called it – “The Theory of EveryBIM”.

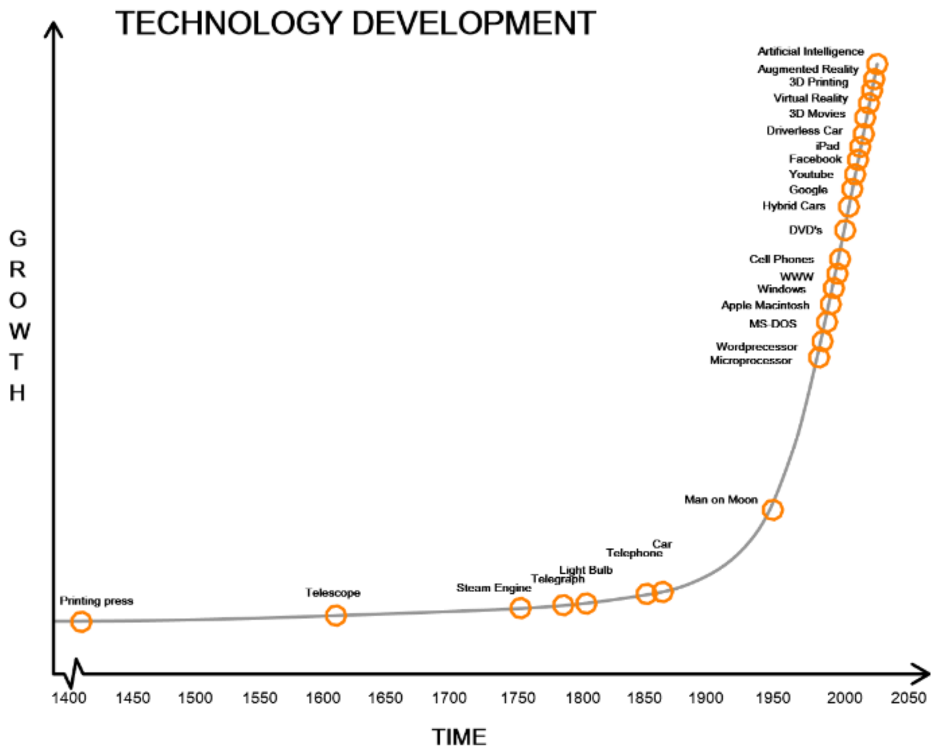

Fig. 1
Technology growth illustrated by an exponential curve

2. THE THEORY OF EVERYBIM

The first we did was to carry out a creative process to look at the big picture. Here we decided to make a solid overall plan, not to plan everything in detail. Many of the necessary details evolve through cooperation in the project and uncovering of relevant issues. We identified that our goal required much more than just better utilization of technology. It is more about man than machine (the things that cannot be measured). We ended up with four main categories for our theory; Strategy, Mindset, Technology and Collaboration.

(Strategy + Mindset ^{3} + Technology) x Collaboration ~ Theory of EveryBIM

2.1. STRATEGY

2.1.1. Gears of change

"It is not the strongest of the species that survive, but the one most responsive to change" – Charles Darwin.

The constant pressure to achieve sufficient billable hours and to deliver to agreed deadlines, might be reasons why many leaders and employees avoid risk and keep on doing what is already known. Companies or projects solely consisting of this kind of employee provide a poor environment for innovation and change and will most likely fall behind competition in the long run. They need those who believe the impossible is possible, who never give up and are willing to fight for a change regardless of potential internal and external skepticism. If you manage to place a few of them together in a team and trust them to work towards a goal, you have what we in Norconsult like to call a "Gear of Change" (Fig.2). Work with establishing new workflows usually needs to withstand some initial disappointment and anxiety from leaders and clients regarding time and progress since you don't know all the answers to begin with. Perseverance is the key to success. When new solutions emerge, and useful experiences prove to be better than existing ones, the small "gear" moves a "click" and starts off a reaction that inspires and moves adjoining "gears" that want to be part of the new process. This movement goes on to the next "gear" until the change (if relevant) has been established in the entire company or project. This chain-reaction is incredible to experience. It is happening from the inside and out, usually ignited by motivation, curiosity and ambition. Trying to make a change for an entire company or project at once (make all gears rotate at the same time) is probably not beneficial but quite common. Such initiatives are often stopped by bureaucracy or by fear of failure when the amount of information and digital tools provide so many alternatives that it seems overwhelming.

Fig. 2
One “Gear of Change” can inspire and affect an entire company or project

2.1.2. Linear or exponential workflow

We looked at the curve that illustrates technology development and discussed the potential of exponential growth further. We saw that we could use a similar representation to illustrate the expected results over time by working with either known (2D drawing production) or unknown (full BIM) workflows and routines (Fig.3). We like to think that if you are skeptical to changes, don’t take any risks and only work by established routines that are already known; you work linearly. You know where to start, how long it takes, what tools to use and what results to expect. On the other hand, if you challenge existing workflows and search for efficient processes, investigate the latest technology, help to establish and share new experiences and dare to fail without giving up; you work exponentially. When working exponentially, you must make it through “the disappointment” phase to reach the “turning point” where you cross the linear workflow. From this point on, both foreseen and unforeseen results take place. This is where the hard work pays off. Do not let others take away your inherent initiative before you reach it.

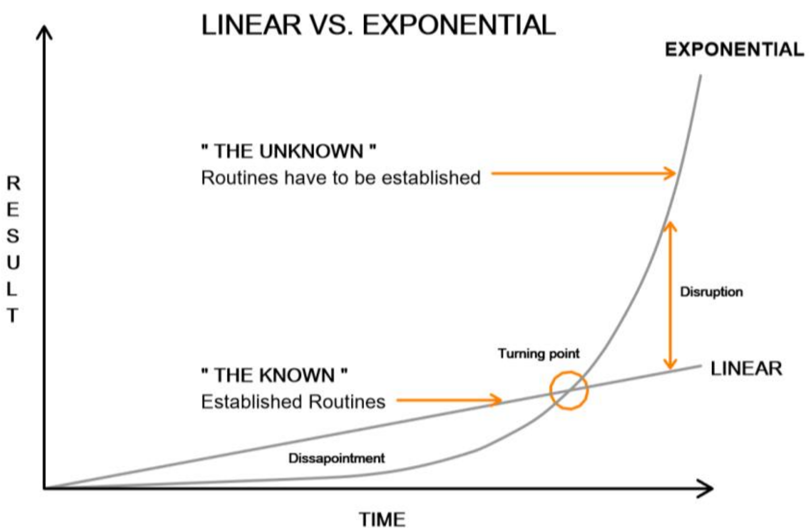

Fig. 3
Linear and Exponential workflow

2.1.3. The Trinity

A project is an interaction between several parties, and it is insufficient if everyone focuses on their own needs instead of the project and the team. Too many projects have been undertaken in separate "trenches" where the different parties try to point out where the others are doing wrong, instead of communicating and helping one another. Although this conservative behavior is probably motivated by financial reasons it leads to poor cooperation and progress which is very expensive. Major disagreements are often pushed to the end of the project when much is forgotten, and everyone ends up losing money in a time-consuming final settlement. The project itself can then be considered as unsuccessful (Fig.4).

This time we wanted to do it differently. We wanted to work more closely with the other parties in an a more humble and inclusive manner, listening to and respecting their expertise, as well as realizing that we may not always be right. It was important to prepare a new contract adapted to the workflow we planned to implement together. We had to make a clear delineation off who was responsible for what. We solved this by first inviting the major contractors in Norway to hear from them what they need in the coordination model (BIM) to be able to build from it. Then we invited the major owners in Norway to clarify their needs and wishes. Overall, this enabled us to create the contract in a constructive way.

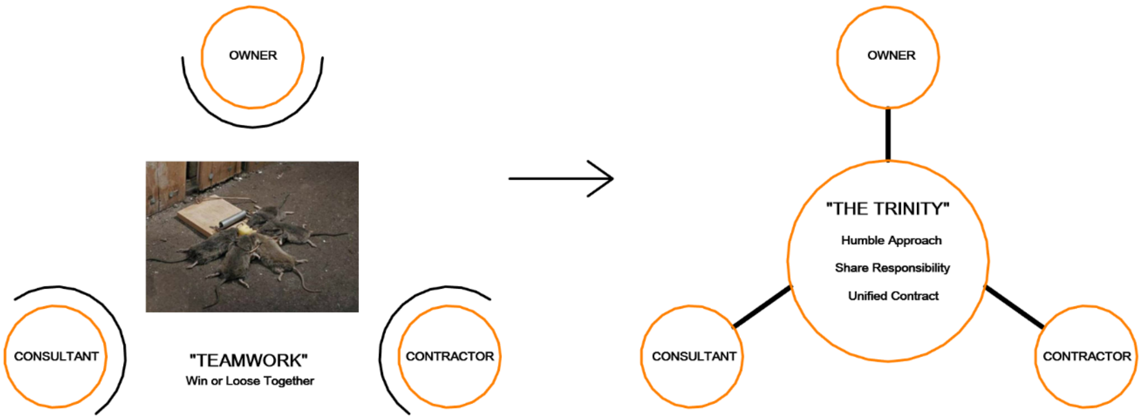

Fig. 4
What happens if the team and project come first or last

2.2. MINDSET

"Not everything that counts can be counted, and not everything that can be counted counts" – Albert Einstein

Good attitudes and mindset throughout the project are the single most important factor in our theory and the reason why we have highlighted this as a cubic function in our Theory of EveryBIM. Negative attitudes are far more infectious than positive, so providing this got highest priority. The team motivated itself by establishing and following some simple principles.

2.2.1. "Don't ever give up"

Giving up is never an option. It's about endurance every time a problem occurs and there are no projects without problems. When they occur find a solution. It is most likely not the perfect solution to begin with, but it can be evaluated by others, improved and optimized over time until it's final. Difficult technology, poor time, external pressures, and anxiety can feel overwhelming. Adopt and overcome to turn the problem into improved technology, good timing, inner calm and excitement.

2.2.2. Don't sit on your egg

It is common practice for individuals or companies to keep smart solutions and innovations for themselves. We call this to "sit on an egg". This is probably done to acquire an advantage over the others and to feel irreplaceable. We wanted to avoid this and made a rule about mandatory sharing of good ideas (hatching of eggs). This increases the ideas value by getting different considerations from others, and in most cases the origin is known anyway.

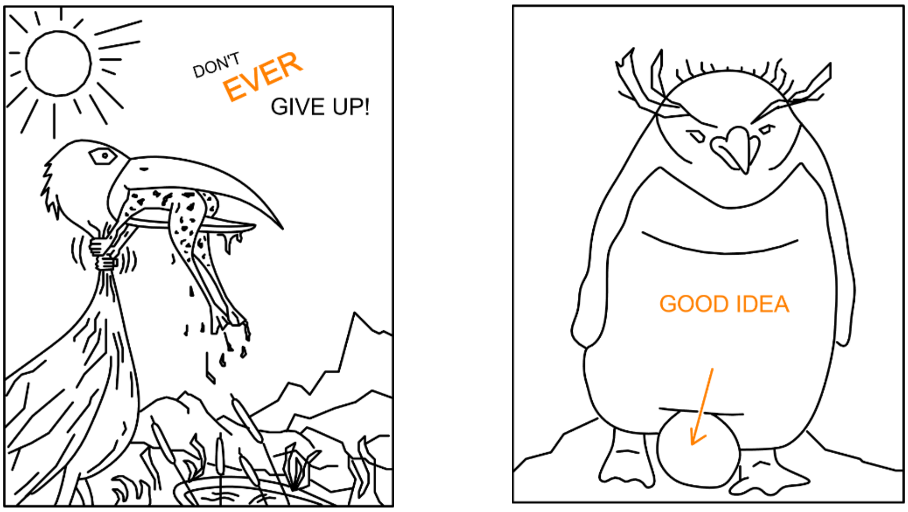

Fig. 5
Don't ever give up – don't sit on your egg

2.3. TECHNOLOGY "ATTACK ALL FRONTS"

When attitudes and mindset were in place, the project team could begin to look at how to utilize today's available technology. We agreed to consistently evaluate whether we were working with the right digital tools. "Attack all digital fronts" is our motto. We focused on digital interaction with those who would receive the models, not just what gets the job done at our end of the process. If the Contractor would be unable to build from the model, then it would have no value. Our initial plan had basic guidelines for technology as well.

2.3.1. Utilization of existing software.

We investigated how far we could push the software we already possessed. This was fun and gave us a lot of new and useful methods valuable for our design. Our biggest discovery was Parametric Design. We utilized our existing software in a new and better way to create formulas which were able to solve problems we were not able to do before. This was especially relevant for our rebar design. We believe that in a matter of years we will be able to model entire projects based on formulas that can be reused with minor changes in required input.

2.3.2. Cooperation with external developers

Even though we pushed our existing software to the extreme, we discovered that some of them were not suitable. We still had processes to improve. We started searching for alternative software elsewhere. This gained huge benefits as we found several small external partners that could deliver niche tools to solve issues for us and even adjust and upgrade their functionality to meet our specific needs. It required some hard work to learn the new platforms but it payed off.

2.3.3. In-House Development.

Where neither existing or new software could solve our problems, we had to develop our own functionality. We are lucky in Norconsult to have our own sister company, Norconsult Information Systems (NOIS), who work with programming and software development. They were able to develop indispensable tools that have revolutionized the way we work. The best application they developed was to integrate functionality for a dynamic link between the project's bill of quantity and the BIM Model. This made us feel innovative and not restrained by old methods and rules.

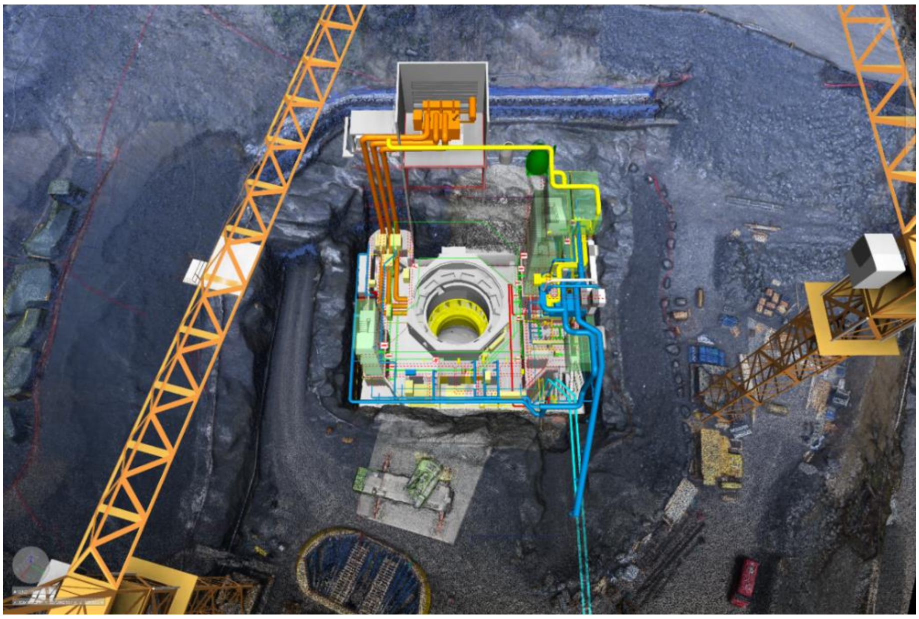

Fig. 6
The Digital Coordination Model – Vamma 12

Fig. 7
The construction site – Vamma 12

2.4. COLLABORATION

Collaboration with the chosen contractor is perhaps the area that has changed the most. We compared the necessity of our cooperation with two people on a tandem bike, one missing both arms and the other missing both feet. The entrepreneur's contribution to the workflow, endurance in the field and the ability to find new solutions has been inspiring and crucial to our success in meeting our common goal. We met regularly and had good discussions on how we could improve the model and procedures for the best possible performance. We called ourselves "The Fellowship of the BIM". It has been practical to have a contractual agreement which defined responsibilities at all times, coupled with a mindset which allowed all parties to contribute across responsibilities for the project's best. Our meetings led to “tailored” digital communication. The Contractor had a proprietary tool which is used by all their personnel and machines in the field. They recommended that we also used this tool in design, so they could receive models directly without the need for further processing. Furthermore, we identified what information was necessary in the elements of the model and used this to structure the model to be readable and useful for construction. The experiences we have shared together have been written down and put into system. In addition to the overall theory, we have many detailed recipes of a technological nature that can be used and updated further.

3. CONCLUSION

We discovered that we worked with outdated methods and digital tools. Why do we still design and build from 2D drawings when technology has so much more to offer? This was the starting point for our bold goal of being the first to design and build from one collaborative model. We worked patiently and discovered early in the planning phase that it was about much more than technology alone. It was just as much about attitudes, mindset and teamwork. Our workflow and routines have been completely revised. All work is based on a unified, but not limiting, plan. Many solutions have emerged along the way in collaboration with all parties in the project. We have succeeded in reaching our common goal.

The results from the Vamma project are beyond expectations. The model ("the digital twin") is a realistic duplicate and has a lot of potential for further operation and maintenance of the plant. Never before has the owner had the same opportunity to use the product as a tool throughout the life of the construction. They must use the same curiosity and innovation that they have had in the design and construction phases to make the most of this phase. The whole process has been a team and project victory. We have experienced a reduced number of misunderstandings and better communication. There has been a massive reduction in change orders and discussions around quantities are almost non-existent. The management of health and safety has been better because we have been able to see all the different disciplinary designs together and dynamically changed designs accordingly as the project has developed.

The project has gained national and international attention and was awarded 1st place (Autodesk AEC Excellence Awards) at the world's largest BIM conference in 2016 for its innovative use of BIM. It all started with a gear of change.

Today we see a number of new tools and opportunities that should be explored; Virtual reality, artificial reality, artificial intelligence, 3D printing etc. Where will we be within the next year, in 5 years or 10 years? Nobody knows the answer, but it is likely that we will do everything in a whole new way. We will never stop exploring new opportunities or conclude that what we do today is good enough for tomorrow. The theory will never be completed but is as good as it gets today.

"People who say it cannot be done should not interrupt those who are doing it" – George Bernard Shaw

1. INTRODUCTION AND SUMMARY

Pressure tunnels of either, the headrace- and/or the tailrace system of high head (gross head >500m) hydroelectric power plants commonly are those parts of the plant that are bearing the maximum costs and the maximal potential of cost saving as well. For that reasons the optimization of the technologies applied has performed steadily within the last 20 years.

The performance has rather developed within the following topics:

- Optimized layout selection allowing a maximal benefit from the geological and hydrogeological surroundings.
- TBM- excavation predominantly based upon hard rock double shield technology.
- Precast segmental linings optimized towards the fundamental requirements of pressure tunnels.
- Grouting technologies in order to involve the rock mass into the lining concept as much as possible.
- Construction concepts that allow the performance of construction with a high percentage of semiskilled local workers supported by a small, specific skilled key staff.

The paper at hand is dealing with the key tasks lined out above. It mainly is focusing upon pressurized headrace tunnels. Regarding pressure shafts, references are given [14], [15].

2. CLASSICAL ALPINE HHP PROJECT SCHEMES

Figure 1 is showing a classical Alpine high head power plant (HHP) project scheme with a gross head above 500m.

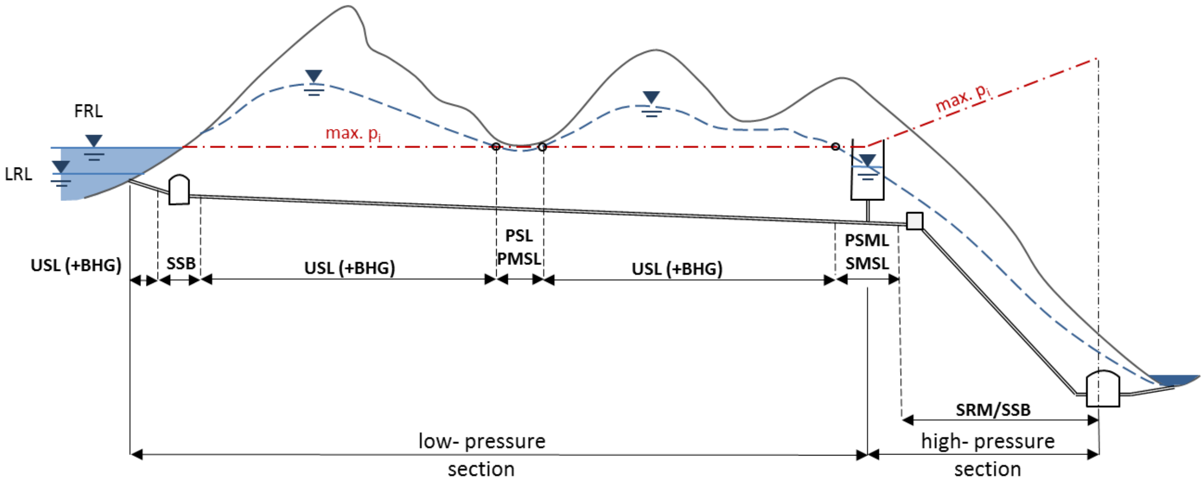

Figure 1: Longitudinal section of a typical Alpine high head power plant

The key task of the headrace system is to transfer the turbine water from intake to the power station with reasonable head losses and to bear the maximal internal pressure. The goal is to gain as much support as possible from the surrounding rock mass. Economically sealing and grouting of the pressure tunnel will require sufficient overburden. This can be achieved by an optimized layout design. A special benefit can be gained, if the ground water table is located above the internal pressure of the tunnel. For those reasons, a typical Alpine high head power plant tries to meet the following goals [1]:

- To subdivide the headrace system in a long low- pressure section and a short high- pressure section.
- To gain the benefit from a ground water pressure above the maximal internal pressure and to remain beyond the “Walch’ border” [1] as far as possible.
- To place the surge system completely below the surface

This can be achieved if the layout (Fig. 2) is designed in a way that most of the cross sections fulfill the conditions shown in Fig. 3.

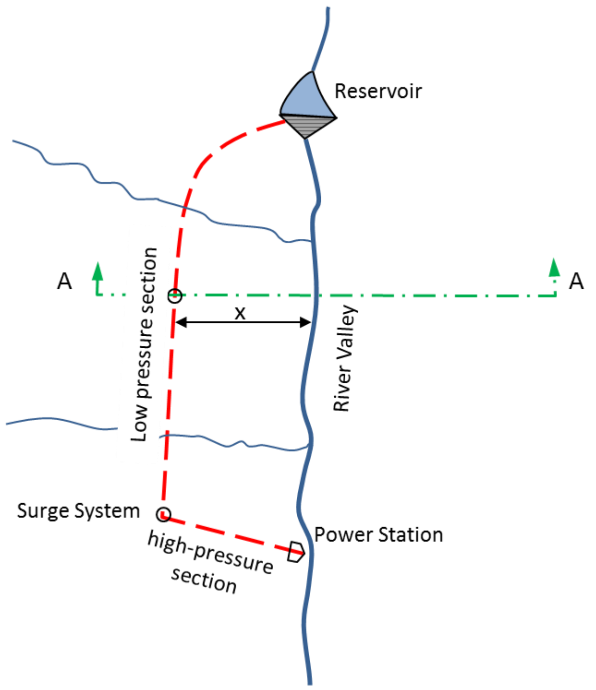

Figure 2: Layout of a typical Alpine high head power plant

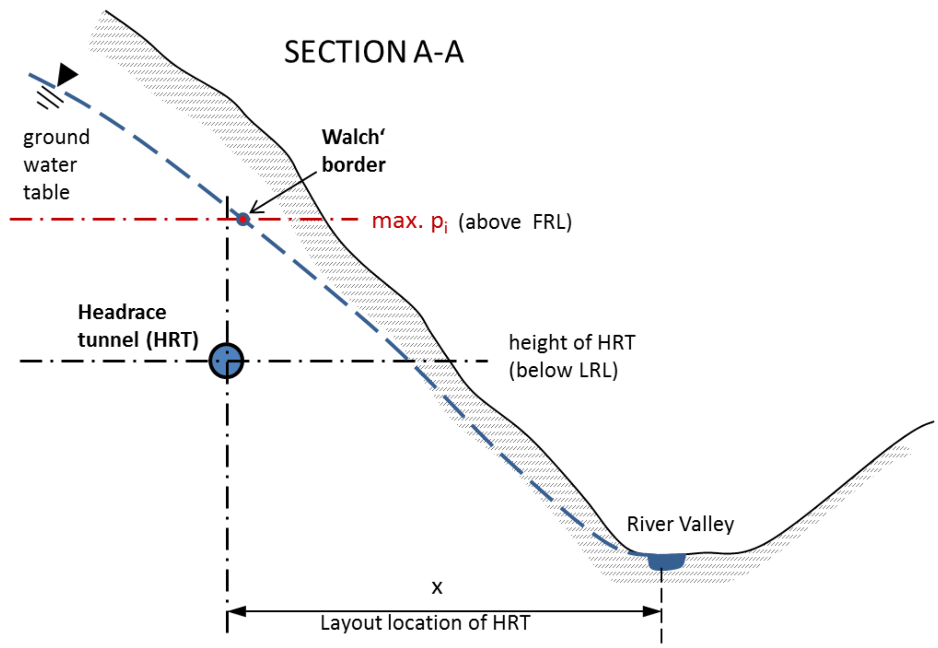

Figure 3: Cross section to place the headrace tunnel behind the Walch' border [1]

3. GEOTECHNICAL APPROACH & HYDRAULIC DIMENSIONING

The focus of the geotechnical approach predominantly has to be lain upon the feasibility of the excavation method and not upon the lining. Since mechanical excavation in most cases is a preferable method to excavate headrace systems, the focus will lay upon the feasibility of TBM excavation for the headrace tunnel of the low-pressure section. The same is due for an inclined shaft of the high-pressure section or for raise boring, in case of a vertical shaft.

Regarding the geotechnical approach, it has proofed to follow the guideline for the Geotechnical Design of Underground Structures of the Austrian Society for Geomechanics [2] and to determine the "ground behavior types" (BT) systematically along the longitudinal section and especially in disturbed zones. If the ground behavior predominantly works out "stable" (BT1) to "disintegrated" (BT2) behavior types, excavation with an open Gripper TBM might be a proper solution. If the ground behavior predominantly offers disintegrated rock, as well as shallow and deep reaching rock-mass failure or rock burst(BT2 and above), an open Gripper TBM especially equipped for such behavior or a shielded TBM may be the best choice [3], [7].

For hydraulic dimensioning, the "Strickler- Formula" is serving properly and with sufficient accuracy. For cast in situ concrete, the Strickler roughness coefficient k_{STR} might be chosen with 80-90 [$m^{1/3}s^{-1}$]. For a segmental lining with mortar joint fill, the Strickler roughness coefficient k_{STR} might be chosen with 75-80 [$m^{1/3}s^{-1}$]. The roughness coefficient for segmental linings is considering smooth surfaces without pockets, which may exist in bolted linings.

4. HIGH PERFORMANCE EXCAVATION AND ROCK SUPPORT

The internal diameter of pressure tunnels most frequently is ranging from 4 to 7 meters with a tendency towards bigger diameters. This range of diameters is a range, where TBM-tunnelling in most cases is the most preferable and economical construction method.

Fig. 4 is showing the results of a comparison of achievable net advance rates between TBM and D&B excavation with a single heading either (1 D&B heading) and a D&B counter heading in addition (2 D&B headings). For the TBM heading, the net advance rate [m/wd] can be derived as follows:

$$net\ advance\ rate\ =\cdot \frac{p\cdot n\cdot 60\cdot 24}{1000}\eta_{TBM,24h}\cdot \eta_{(p\cdot n)} \qquad [1]$$

- p… penetration with, p=7mm/rev
- n… cutter head speed [rev/min], derived with
- $n = 50/D_{exc}$ [2]
- D_{exc}… Excavation diameter [m]
- $\eta_{TBM,24h}$… TBM net boring time utilization, with $\eta_{TBM,24h}$ =35%

- $\eta_{(p \cdot n)}$... Utilization of penetration & cutter head speed : $\eta_{(p \cdot n)}$=65%.

For D&B it has been anticipated, that the length of one round is 3m and 3 rounds can be achieved per working day, independent from the excavation diameter $D_{exc.}$. Fig. 4 clearly shows that for the common diameter range for headrace tunnels, the TBM is the preferable method regarding net-advance rates. This off course only is due if TBM has worked out as a feasible excavation method.

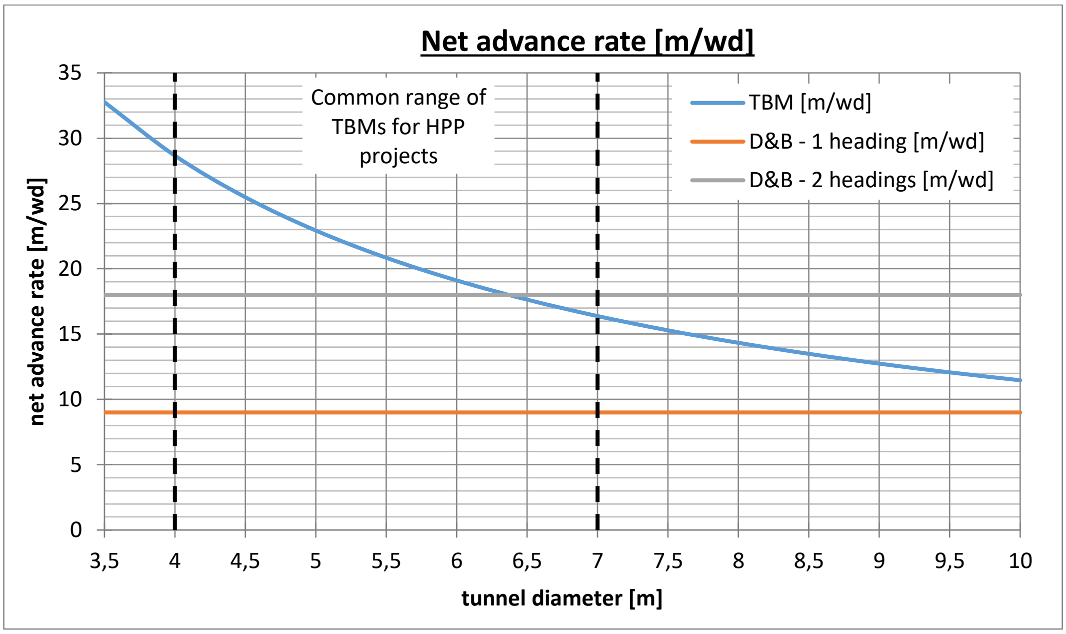

Figure 4: comparison of TBM and D&B regarding achievable net advance rates

Considering the TBM preferable for high performance excavation and a shielded TBM most appropriate for a wide range of rock mass behavior (BT), the maximal benefit can be gained from a double shield TBM (TBM-DS) together with a simple segmental lining. The TBM-DS is offering a Gripper mode for high performance under preferable geological conditions and a single shield mode, probably together with special pretreatment measures, for special zones.

Tunnel support according NATM and in situ concrete lining of course can be the best choice on a Gripper TBM [4] for special projects with a short length and / or small diameters. However, most probably it requires especially skilled workers and is bearing a high risk regarding construction time and costs. The qualification in skills and the risks regarding construction time and costs can rather be reduced by applying the technology of mono shell precast tunnel linings. Such precast segmental linings are linked to high performance excavation, predominantly with double shield hard rock TBM's.

For worldwide application of economically high performance pressure tunneling and lining, it is a postulate, that construction can be performed with a high percentage of semiskilled local workers supported by a small specific skilled key staff. This postulate is fulfilled with the technologies lined out. Segmental lining is offering the advantage of high quality segment prefabrication outside the tunnel and quick and accurate installation within one working cycle inside the tunnel. Remaining in full compatibility with high performance TBM-DS excavation, simple precast lining systems, meeting all requirements of common headrace tunnels, have been developed and optimized during the recent 20 years [5], [6], [8], [9] [10], [12], [13].

Such lining systems commonly are composed of a parallel ring system with rhomboidal or hexagonal precast segments. The annular gap fill most frequently is mortar in the invert and pea-gravel in the circumference, which is systematically contact grouted within a separate step, followed up by borehole grouting where required. Such a lining system is able and suitable to fulfill most requirements of a final lining of a headrace tunnel.

5. BEST FITTING LINING SYSTEMS

As already lined out above, the key task of designing a headrace tunnel, is to gain as much benefit and cost saving potential from the surrounding rock mass. In terms of the sealing and bearing requirements, the most common lining types for headrace tunnels can be defined as follows (Tab. 1):

NOL	no lining(invert only)
USL	unsealed concrete lining
USL+BHG	unsealed concrete lining + borehole grouting
PSL	pre stressed lining
PMSL	plastic membrane sealed lining
SMSL	steel membrane sealed lining
SRM	rock mass supported steel liner
SSB	self bearing steel liner

Table 1: Legend for different lining systems

Tab.2 comprises the main tasks and requirements for the applicability of the common lining types.

Requirements	no lining (invert only)	unsealed lining (USL)	unsealed lining + borehole grouting (USL + BHG)	pre-stressed lining (PSL)	plastic membrane sealed lining (PMSL)	steel membrane sealed lining (SMSL)	rock mass supported steel liner (SRM)	self bearing steel liner (SSB)
rockmechanical requirements	stable rock-mass under internal pressure fluctuation too; non erodable rock mass	massive to disintegrated, non erodable rock mass	highly jointed to disintegrated rock mass	every kind of rock mass; minimal principle stress above grouting pressure			every kind of rock mass; minimal principle stress must be known	no relevant requirements
hydrogeological requirements	external watertable above inner pressure; or watertight rock mass	external watertable above inner pressure; or watertight rock mass ($k_f < 10^{-7}$ m/s)	external watertable preferable above inner pressure; groutability with cement grout ($k_f > 10^{-5}$ m/s)	no relevant requirements; groutability with cement grout ($k_f > 10^{-5}$ m/s) in case of consolidation grouting			external water pressure must be known; groutability with cement grout ($k_f > 10^{-5}$ m/s) in case of consolidation grouting	external water pressure must be known
int. pressure conditions	slow dynamic pressure fluctuation (up- and downsurge only)			minimal principle stress emply above dynamically internal pressure			no relevant requirements	
environmental restrictions	expected water inflow in line with restrictions			no relevant impact				

Table 2: Basic requirements for different lining systems

Fig. 5 is showing a comparison of those lining types regarding construction cost. As a basis, a design discharge has been chosen with 30m³/s. Considering tunnel diameter optimizations, for the concrete or segmental lined types, a flow velocity was anticipated with about v=3m/s; for the steel lined types the flow velocity was anticipated with about v=6m/s.

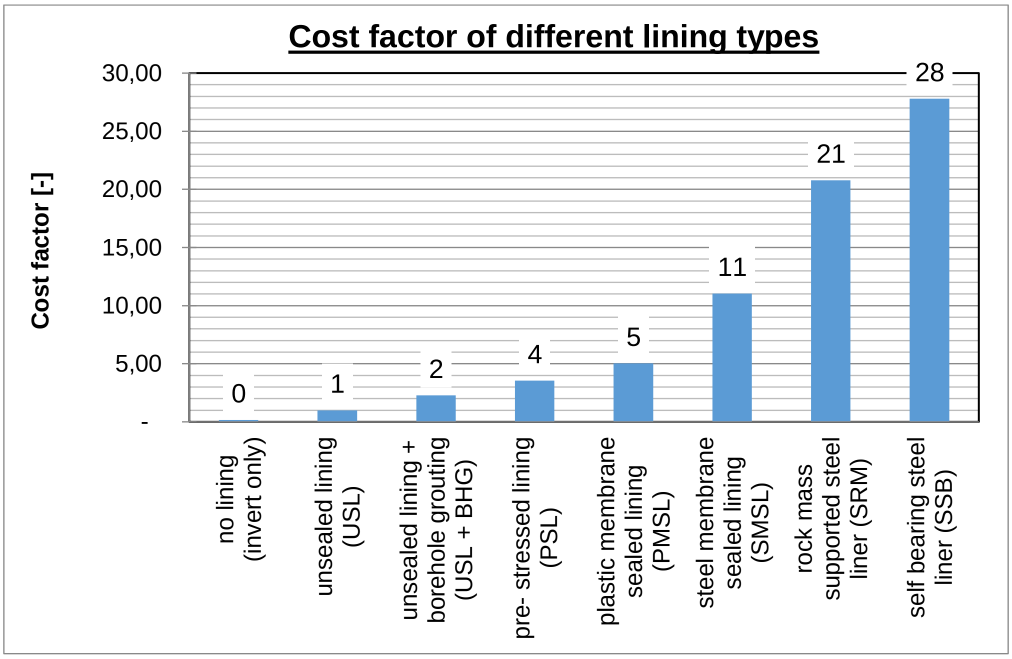

Figure 5: Cost factor for different lining types considering lining costs

The “cost factor” shown in Fig. 5 comprises the relation of the construction costs of the lining calculated for the different lining types. The costs per meter for an unsealed concrete lined tunnel was taken as a reference value with “1”. From Fig. 5 the benefit can be derived, to remain with an unsealed lining as far as possible. Unlined tunnels, which would comprise the lowest construction costs nowadays, became more and more out of fashion due to risk in terms of falling rock into turbine water.

6. GROUTING AS A KEY TASK

The principle to gain most benefit from the surrounding rock mass in order to achieve the most economical lining type is determined by the following tasks:

- To activate a sound rock mass load bearing ring in order to reduce the bearing capacity required from the lining.
- To hide below the ground water table in order to reduce sealing tasks to a minimum.
- To improve the surrounding rock mass by grouting in order to achieve most uniform and consolidated rock mass conditions, to reduce the rock mass permeability in order to control water communication between inside and outside the tunnel and pre-stress the ling system in order to improve with regard to internal pressure fluctuation.

The first task can be met by applying the construction principles of NATM. The second can be met by a sound layout design of the headrace system [1]. The last can be met by grouting. Grouting in any case should comprise systematically contact grouting as a basis and consolidation- and/or sealing grouting, in terms of borehole grouting, systematically or where required [11].

7. HOW THE CIRCLE GETS CLOSED

At high head hydropower plants with gross height greater than 500m of the conventional “Alpine type”, in most cases the headrace system comprises the mayor part of the plant costs. At the other hand, especially this part comprises the mayor chance to gain as much benefit from the surrounding rock mass, to keep the overall projects costs low, and to turn a project towards economic feasibility.

The first step starts with a layout design keeping the cost-factor of the lining type in focus. The next step is to achieve a high performance excavation method and economic support method comprising already a final lining, meeting the requirements of a headrace tunnel. Both steps are linked to each other and must be considered as a decision loop (Fig. 6).

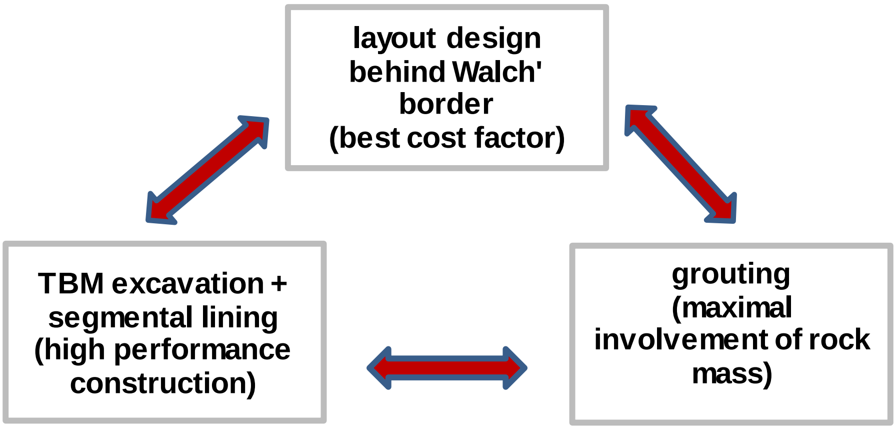

Figure 6: Link between layout, excavation, lining and grouting

1. INTRODUCTION

Hydraulic tunnels and shafts are underground water ways that, with the exception of old tunnels excavated in rocks, are usually lined. The lining provides stability and watertightness to the excavation line, avoiding that excessive water infiltration may undermine the stability of the slopes and of the structure itself, and minimises head losses, due to the low friction of the lining in contact with water.

Traditional lining systems have been steel, and reinforced or un-reinforced concrete. The construction of steel and concrete linings is expensive and time consuming, can be further complicated in locations with difficult access, and may require expensive maintenance: over time, or in presence of particularly difficult geological conditions, concrete linings deteriorate, water infiltrates into the soil through fissures, and/or failing joints and increased permeability, increased roughness results in reduced hydraulic efficiency. Similarly, steel liners may be stressed above their yielding point.

Deterioration of the lining and subsequent loss of watertightness can have serious consequences: continuous water seepage into the surrounding soil may in the long term affect the stability of steep natural slopes, eventually triggering landslides that can ultimately cause the partial or total collapse of the structure. Deterioration of a concrete liner means not only in loss of water but also increased roughness. The Owners therefore face risk of instability, power loss, and head loss.

Rehabilitation must restore watertightness and bring the pressure tunnel/shaft back to its design conditions. Local repairs with mortars and resins have shown drawbacks in respect to efficiency and durability. Overall repair with a new liner must be designed to optimise several parameters: hydraulic efficiency, lifetime, outage time for installation, costs, future maintenance. Geomembrane lining systems have proved to be a permanent repair solution, and in case of new construction a solution increasing the project's safety. This paper focuses on exposed geomembrane systems, which are applied to rehabilitation and new construction.

2. THE GEOMEMBRANE SYSTEM

2.1. RATIONALE

The rationale of the system is to provide a practically watertight liner capable to maintain imperviousness under the acting loads, and with elongation characteristics allowing bridging those discontinuities that may arise in the subgrade (e.g. cracks forming in the concrete liner on which the geomembrane is applied). A geomembrane liner stops leakage: it prevents water entering the deteriorated concrete lining through cracks and joints, and affecting the durability of the reinforcement, and avoids that water inside the tunnel can escape into the surrounding ground with potentially dangerous effects on the stability of the slopes and consequently of the structure. Additional assets are that an exposed geomembrane system does not significantly reduce the tunnel envelope, improves hydraulic efficiency through low friction, and by deleting future maintenance provides savings on costs due to outage.

Design parameters for the choice of the liner, of its anchorage system, of drainage and support layers if any, are water head, static and dynamic pressure, water velocity, negative pressure outside the structure when it is empty, way of operating the structure, roughness of the subgrade, etc. The geomembrane liner is anchored by mechanical fastening lines whose type, number and position is designed based on the mentioned designed loads at full and empty tunnel, and taking into account also the dynamic action of water that would result from a tear in the geomembrane liner. Water velocities of several meters/second and pressures of several MPa can be accommodated.

A drainage system is provided behind the geomembrane to collect and discharge water that should be present behind the geomembrane liner, be it water migrating from the slopes towards the structure, or already impregnating a deteriorated concrete liner. The drainage system avoids that if the tunnel is dewatered backpressure can build up and ultimately exceed the resistance to burst of the geomembrane.

2.2. COMPONENTS

The liner adopted in all state-of-the-art projects is SIBELON® CNT, a geocomposite consisting of a flexible polyvinylchloride geomembrane, heat-bonded to an anti-puncture geotextile. The geomembrane, with hydraulic conductivity $k = 6.25 * 10^{-14}$ cm/s, provides the water barrier, the geotextile protects the geomembrane against puncturing from the substrate. The geocomposite shows the tensile stiffness of the geotextile up to a strain > 60%, for larger stresses the material presents the characteristic elastic behaviour of the geomembrane up to a strain > 250%. The design strength of the geocomposite liner is assumed to be the geotextile break tension, in the range of 50-60 kN/m, while the geomembrane elasticity is activated only in case excessive stresses would produce delamination of the backing geotextile. For design purpose, the strength parameters of the geocomposite, are corrected to account for potential defects not detected by the QC process, for incorrect installation, and for ageing of the polymeric material.

The anchorage system consists of continuous stainless-steel anchorage lines parallel to the water flow. These longitudinal fastening lines can be tensioning profiles, or batten strips, designed/installed to avoid slack areas and folds in the liner. The design of the anchorage lines is based on exceptional scenarios, aiming at avoiding that extreme loads may cause the failure of the anchorage system with the risk of detachment of metal elements and geocomposite fragments. The calculations are based assuming that, in case of accidental damage resulting in the perforation and/or cutting of the geocomposite liner, the water infiltrating through the damage can generate a negative pressure behind the liner equal to the internal pressure in the tunnel/ shaft. In this condition, remote but crucial for a correct design, the kinetic head of the water flow can generate uplift and deformation of the geocomposite liner. The tension in the geocomposite is obtained by an equation based on the kinetic head (function of the water velocity and density) and on the geometry of the deformation, and using the stress-strain curve of the selected geocomposite. The tension in the geocomposite liner thus obtained must be at least equal to what imposed by the established Factor of Safety (FS). The tension transmitted to the anchorage lines results in a pull-out component and a shear component: the design condition for the calculation of the pull-out force on the anchors corresponds to the case in which two adjacent sheets of geocomposite liner are simultaneously damaged and uplifted, resulting in the combination of the pull-out components (one for each sheet), while the design condition for the calculation of the shear force on the anchor corresponds to the case in which only a single sheet of geocomposite liner is uplifted, resulting in an asymmetric shear component. The data obtained by calculations of the tension in the geocomposite, of FS on the geocomposite, of pull-out and shear forces on the anchors, and of FS for pull-out and shear, verify the soundness of the anchorage system.

A transverse stainless-steel watertight seal is placed at the beginning and end of the lined area to avoid water infiltrating behind the liner.

The drainage system is designed based on an analysis of the estimated amount of water that can accumulate behind the liner, leaking through the ground/cracked concrete lining when the tunnel/shaft is empty. The inflow is essentially due to a) the intrinsic permeability of the outer ring/concrete lining and b) the leakage through the concrete cracks. Given the low permeability of the concrete, leakage through cracks can be considered as the primary source of inflow, while other sources can usually be neglected. A continuous drainage layer consisting of a geosynthetic having high in-plane transmissivity is often applied to enhance efficiency of drainage transmission to the custom-designed drainage discharge components. In case of subgrade with large cracks/discontinuities/irregularities, additional geosynthetic layers are used to provide support/anti-puncturing.

2.3. PAST EXPERIENCE AND PERFORMANCE DATA

To the knowledge of the authors, experience of watertight geomembranes in high-pressure conduits dates back to the late 1970ies- early 1980ies, when Austria saw several applications with water heads in the range of 0.2 to 0.7 MPa, where the geomembrane was sandwiched between the outer regularization ring and the inner concrete ring. Carpi started installing totally or partially exposed geomembranes in pressure tunnels in 1984 (Gorghiglio pressure tunnel, Italy). The feedback of several installations proves the effectiveness of the system and its capability to resist high pressures and water velocity. Outstanding examples summarized below and detailed in international literature are Thissavros [1] and Belden [2].

Thissavros is a 11 meters diameter pressure tunnel in Greece. The inside water pressure is 1.5 MPa, maximum water velocity exceeds 4 m/s. Water infiltrating from the reservoir generates a negative uplift pressure of about 0.5 MPa. The tunnel was originally lined with concrete, which started to crack. At first reservoir filling, because of some changes in the location of the dam grout curtain and of the cracks in the concrete of the tunnel, the dam galleries were flooded. It was decided to extend upstream the concrete plug for a length of 60 m. Time constraints and a much more attractive price suggested to split the required extra works in two sections: one section by extending the conventional concrete plug and its steel lining, the second section by using only an exposed geomembrane against the fractured concrete liner. Installation of a watertight SIBELON® CNT geocomposite, anchored with tensioning profiles and watertight sealed at peripheries, upstream on concrete and downstream on steel, required 3 weeks and cost was approximately 25 % of the cost of an equivalent steel liner, which would have required more than 3 months' time for installation. The geomembrane system was installed in 1997. A few weeks after it had been installed and the tunnel had started operating, the tunnel had to be emptied to execute some extra grouting works in correspondence of the concrete plug. That situation allowed testing the fully satisfactory behaviour of the geocomposite and of its drainage system, which worked as designed. After grouting works were completed, the tunnel was filled again and it will be always full of water, with no plan to dewater it again. The geomembrane liner is working effectively since 1997.

Belden hydropower plant, built in 1958 and owned by Pacific Gas and Electric Co. (PG&E), includes a 2941.41 m long concrete lined tunnel (Tunnel 2). In 1970, during an outage, two large circumferential cracks and additional cracks were identified in the lining of Tunnel 2. The cracks were repaired on several occasions; instrumentation showed that d repairs the ground was continuously moving and slowly accelerating. PG&E undertook studies to determine the best method to rehabilitate the tunnel whose leakage was the main cause for the sliding of the ground. A geomembrane liner was selected because of speed of installation, lower cost, and potential ability to accommodate future ground movements. The geomembrane design was challenging due to the changing shape of tunnel, the water velocity (4.27 m/s), the hydraulic head (0.54 MPa), the groundwater pressure (0.24 MPa), and the drainage requirements due to the high water table in the mountain and the need to drain upstream. A complete survey of the tunnel showed that in one section the cracks could reach width > 22 mm over the design life of the project. Such opening, together with the pressure applied to the surface, could induce large strains in the selected watertight SIBELON® CNT geocomposite. A support system able to withstand the load transmitted by the water pressure on the span created by the big cracks was designed, consisting of a support geogrid placed on the concrete. A drainage geonet was installed on the geogrid. Both under-layers were placed in the full area to be lined, and anchored with mechanical anchors. The geocomposite was anchored with tensioning profiles and watertight sealed at peripheries with a mechanical seal consisting of 80 x 8 mm batten strips with regularising resin, gaskets and splice plates to evenly distribute compression. Installation was made in 2008, the tunnel was immediately put back to operation for a couple of days, then dewatered and inspected, and put back in service. In 2014, 6 years after installation, the tunnel was again dewatered and inspected by PG&E. The detailed inspection did not find one single damage, no repairs were needed, and the tunnel was put back in service. Data readings have shown that the geomembrane system is successfully dewatering the mountain and preventing seepage that could aggravate ground movement.

3. RECENT CASE HISTORIES

3.1. HELMS HIGH-PRESSURE TUNNEL

The Helms Pumped Storage Project conduit and penstock system, owned by PG&E, connects Courtright and Wishon reservoirs in the Sierra Nevada Mountains of central California. The powerhouse complex is located more than 330 meters underground in granitic rock. The Helms Penstock Access Tunnel, approximately 76 m long and > 8 m in diameter, terminating into a 10.6 m thick concrete plug with maximum static hydrostatic pressure exceeding 5.1 MPa, has been in operation for more than 30 years and there was a desire to reduce seepage of high pressure water from the tunnel into the mountain. PG&E had installed a geocomposite liner into Belden hydraulic tunnel in 2008. Helms represented an approximately tenfold increase in pressure in respect to Belden, and more than threefold in respect to the Thissavros tunnel cited above.

Full scale testing was undertaken to validate a preliminary design based on anchorage with special tensioning profiles and perimeter seals conceived to resist the high pressure. The Deep Ocean Test Facility in Maryland, where the US Navy deep submergence vehicles were tested, was the only facility found with adequate equipment to allow testing under the required maximum pressure of 8.52 MPa. All components and design details of the geocomposite system (“Fig. 1”) were tested to full dynamic pressure. The results proved a SIBELON® CNT 5050 geocomposite, a 3.5 mm geomembrane with a geotextile layer heat-bonded onto bottom sides of the liner, and its all-stainless-steel anchorage components, would withstand the pressures.

In the final design, the SIBELON® CNT 5050 geocomposite is anchored to the concrete subgrade by sixteen longitudinal fastening lines consisting of tensioning assemblies placed at appropriate spacing, and of one fastening line consisting of flat profiles, centred at the crown of the vault. The tensioning assemblies consists of two profiles: a first solid trapezoidal profile is fastened to the concrete (“Fig. 2” at left), the geocomposite is laid and punctured on the anchors fixing the first profile, and then permanently anchored by installing over it a second profile, whose shape is such that when the two profiles are tightly connected they achieve tensioning of the geocomposite (“Fig. 2” at right).

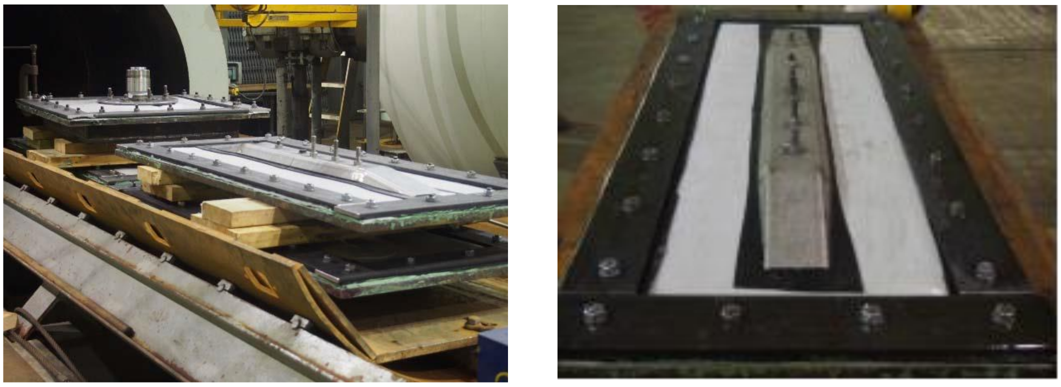

Fig. 1
Testing under 85.2 bar pressure for Helms. At left the tested components (drainage discharge valve, tensioning profiles and perimeter seals) ready for testing on wood blocks. In each test, the tank is filled with water through the instrument port. Water and air are pushed out of the system while the tank is pressurizing. At right, detail of the tensioning profiles and of the perimeter seal after a test

The anchors penetrating the geocomposite are equipped with suitable outfits and gaskets to make the penetrations watertight.

Fig. 2
Helms high-pressure tunnel. At left the solid trapezoidal tensioning profiles and flat profile anchored at the vault. At right a view of the completed anchorage lines

The upstream and downstream transverse perimeter seals consist of flat profiles, section 80 x 8 mm. Seven one-way mechanical pressure relief valves, distributed along the lined area, act as drainage discharge when the tunnel is emptied (“Fig. 3”). Construction of the waterproofing geocomposite began in September 2017 and was completed in October 2017, with the reservoir being placed back into operation in early November 2017.

Fig. 3

Testing drainage discharge capacity at Helms high-pressure tunnel. At left, after sealing of the geomembrane system, water present behind the liner exerts backpressure deforming the geocomposite. At right, the pressure relief valves have discharged the water inside the tunnel, the geocomposite is recovering the deformation

3.2. TUNJITA SURGE CHAMBER AND SHAFT

The Tunjita scheme in Colombia includes a surge shaft, an access gallery at the bottom of the shaft and a headrace tunnel ("Fig. 4"). All these structures are lined with three 0.05 m thick layers of shotcrete reinforced with a steel mesh, and with a 0.25 to 0.40 m thick layer of reinforced concrete. In 2017, an exposed SIBELON® CNT geocomposite system has been installed as safety water barrier on the surge chamber and shaft, and on the tunnels.

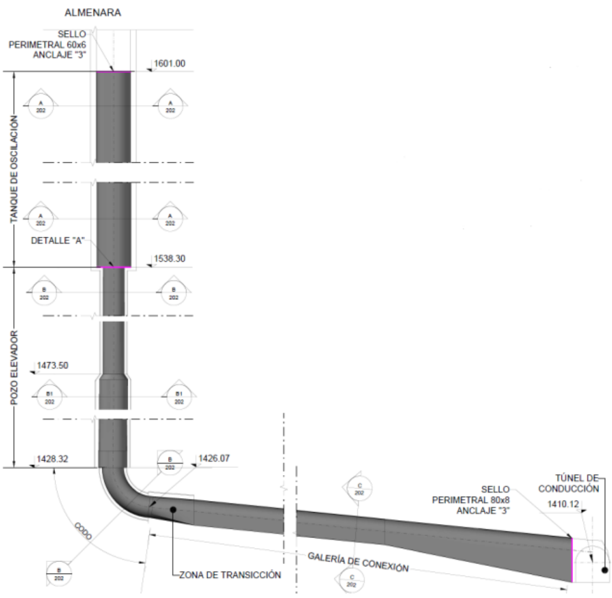

Fig. 4
The Tunjita scheme

The upper shaft is about 71.5 m high and with internal diameter 4.1 m, the surge shaft about 108.9 m high with an internal diameter of 2.5 m. The maximum hydrostatic pressure in the surge chamber is about 0.6 MPa, in the surge shaft about 1.74 MPa. The elevation of the water table is such that the bottom part of the upper shaft and the rest of the structure are permanently below the water table, with consequent presence of water in the rocky mass during the period of emptying.

The selected waterproofing liner is the geocomposite SIBELON® CNT 4400 (3.0 mm thick geomembrane heat-bonded to a 500 g/m^2 geotextile). Due to the water pressure, a support geocomposite layer, consisting of a geogrid backed by a nonwoven polypropylene geotextile, is placed under the SIBELON geocomposite ("Fig. 5" at left). The geocomposite is fastened longitudinally by stainless-steel batten strips, section 60 x 6 mm, anchored by mechanical anchors selected in function of the strength of the concrete. The surge chamber has 10 fastening lines, the surge shaft has 8 fastening lines. Tensioning of the geocomposite is achieved by an installation sequence of progressive closure, placing the "First phase" anchorage lines and subsequently the "Second phase" anchorage lines, which produces a tensioning effect on the geocomposite liner in between two adjacent first phase anchorage lines. This method avoids formation of slack areas and wrinkles in the geocomposite. Perimeter seals are the same as for Belden.

Fig. 5
Tunjita surge shaft. Vertical view from bottom to top of the support geocomposite, and of the waterproofing geocomposite fastened and tensioned

3.3. TUNJITA TUNNELS

The connection and pressure tunnels, have a length of about 142 meters and a horseshoe section 3.60 m wide and with height varying up to 5.85 m. The maximum hydrostatic pressure in the connection tunnel is about 1.90 MPa, and in the pressure tunnel about 1.91 MPa, and 2.2 MPa at closing of the gates. The maximum water velocity is 2.4 m/s.

The waterproofing system is the same adopted in the surge chamber and shaft. The tunnels have 8 fastening lines, except than in correspondence of the sand trap, where the bottom is not lined and there are 7 fastening lines.

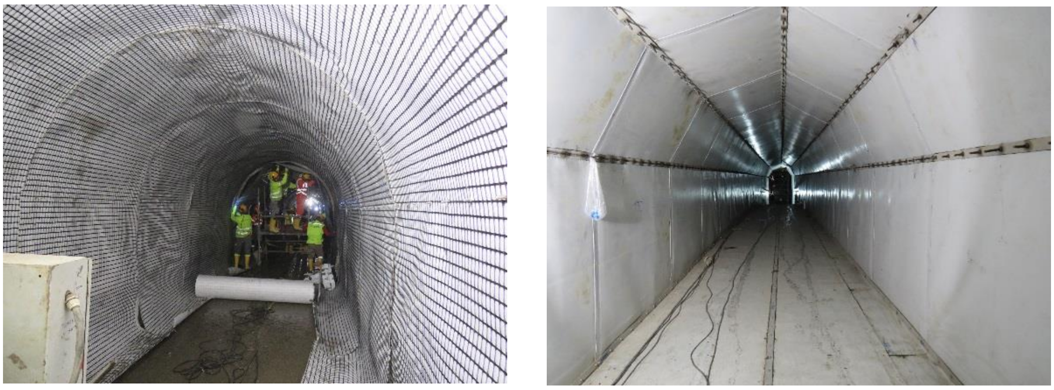

Fig. 6
Tunjita tunnels. At left the support geocomposite, at right the waterproofing geocomposite fastened and tensioned

4. FUTURE PROJECTS

The same geocomposite, and the same approach for the fastening system, has been adopted for the high-pressure shaft that is part of the Gilboa Pumped Storage Power Plant under construction in Israel. The PSPP comprises a nearly 480 m high vertical shaft with 4.5 m constant internal diameter. The rock excavation has been stabilised by a nearly 0.1 m thick shotcrete layer. The shaft lining consists of a 0.5 m thick heavily reinforced concrete (external diameter 5.5 m), increased to 1.5 m (external diameter 7.5 m) in the bottom section. Maximum internal pressure at the bottom bend is about 5.94 MPa; maximum external (negative) pressure is potentially equal to internal static pressure due to leakage through concrete lining; steel reinforcement concrete cover is 50 with tolerance ± 10 mm, which will require using special anchors for short embedment. The design water velocity is 6 m/s, resulting in 14 fastening lines placed at regular spacing.

1. INTRODUCTION

In a changing energy market with decreasing energy prices, energy suppliers try to sustain their financial return with their existing hydro power plants. One possibility to increase the annual turnover is not only to increase the power output but also the availability and flexibility of an existing power plant. Most of the older power plants – in particular storage power plants – are not designed for such operating modes – especially not for rapidly changing and fluctuating loads.

As many plants operated today were constructed decades ago, the original plant design was based on operating conditions that were completely different to the ones actually required. To prove the ability for higher flexibility in power generation, detailed investigations of the power water way, especially the surge tank limitations, are necessary. Since the main constructive infrastructure cannot be changed or just in a restricted way, usually only limited additional power generation is possible. The higher the demand for an increasing power output, the higher are the limitations in operational flexibility. An overflow of the surge tank must be prevented in any potential operational or exceptional scenario of the power plant. On the other hand, a ventilation of the headrace system by means of an ineligible empty surge tank must not occur during operation.

Flexible operation induces a highly transient fluid flow in the hydraulic system and especially the surge tanks of high head hydro power plants. In the planning phase of activities to increase the power output and/or the flexibility, a reliable prediction of the transient plant behaviour and especially the surge tank performance in unsteady load cases – such as periodic machine starts and stops or switching load cases – is necessary.

Modern techniques in numerical simulation methods provide the only feasible possibility to accurately calculate the occurring mass oscillations and pressure pulsations. Thus providing a for the optimization of the transient behaviour. Commercial software-packages for water hammer simulations usually do not provide numerical models for a realistic calculation of complex components like surge tanks, hydraulic turbines or emergency closing valves in a high head hydro power plant. But especially these components need to be modelled correctly in order to get a significant and reliable solution [1], [2].

2. OVERVIEW OF THE INVESTIGATED POWER PLANT

The Kops I hydro power plant was set into operation in 1970 with a maximum power output of 245 MW. The hydraulic system consists of a headrace tunnel with a length of 4.500 m which connects the Kops lake (upper reservoir) with the surge tank of the power plant from where the penstock feeds three Pelton units with four nozzles for each turbine.

The throttled chamber surge tank (see Fig. 2) is constructed with an upper and a lower chamber, which is quite common for alpine high head power plants [3]. At the base point of the surge tank, at the connection with the headrace tunnel, one of two throttles is located. Since there is a second vortex throttle at the intersection of the surge tank main shaft and the upper chamber, a differential effect is created that supports damping of the mass oscillations. The fluid flow in the lower chamber of this surge tank design will have two different states:

- open channel flow if the lower chamber is aerated
- pressurized flow in case of a full lower chamber combined with a charging or discharging procedure of the surge tank

Fig. 1. shows a general hydraulic layout of the power plant, for the main data of the original power plant setup see Table 1.

In the course of a rehabilitation of the generator sets of the power plant, there was an attractive possibility of a power increase of the machinery sets.

set into operation	1969-1970	
number of units	3	#
nozzels per unit	4	#

maximum gross head	780	m
minimum gross head	700	m
maximum power	245	MW

3. NUMERICAL MODEL

A large number of simulations was performed to examine the maximum power increase where a secure plant operation is guaranteed in a wide operation range and under all circumstances. It would be far out of the scope of a conference paper to show even a larger portion of the results found.

The focus of the presented results is on the water level in the surge tank and its chambers as this is one of most crucial components of the plant. Additionally, some of the most challenging operational modes will be presented.

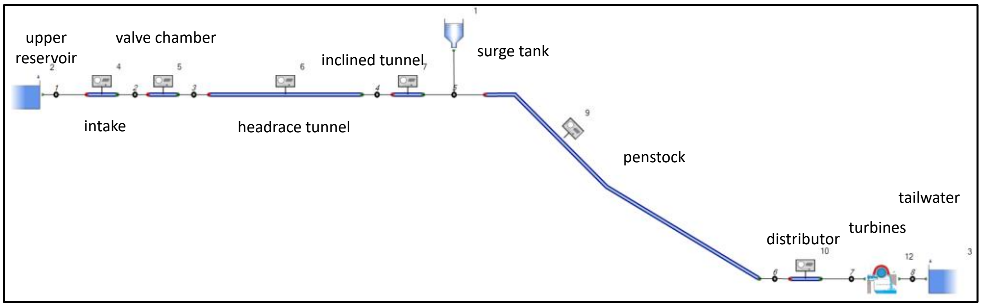

Fig. 1
Numerical model of HPP Kops I

The 1-dimensional water hammer analyses, which are shown in this paper, were performed using the commercial software package Flowmaster [4]. In addition to the standard components further improved hydro power components were especially developed for this purpose [1], [2]. In fact, Flowmaster is designed to enable the implementation of these customized components in form of user built Component Analytical Models (CAM). Their purpose is to model their hydrodynamic behavior by a linear function for the mass or volume flow rate, respectively of the pressure of the connected pipe work and a constant that hydrodynamically would be a source or sink. In case of the simulation network for Kops I the custom designed numerical models are the surge tank and the Pelton turbine. Sophisticated mathematical models were required in order to find detailed results on different positions in the surge tank chambers such as water levels, throttle flow rates and pressures. It also allowed the estimation of the probability of air being sucked into the headrace system when the lower chamber of the main surge tank is being emptied.

3.1. SURGE TANK MODEL

Since the surge tank is the most critical component for the given task, the numerical model for this component must be able to represent the real behavior in a detailed way. The invented simulation model is therefore able to represent the above-mentioned states of the lower chamber. It can act as pressurized pipe or as a partially filled pipe with open channel behavior. If the lower chamber is full, liquid inertia of both, the chamber and the rising shaft, is considered. A local rise or fall of the liquid level at the base point throttle is also numerically possible as well as different liquid levels in the rising shaft and the upper chamber mainly resulting from the differential effect caused by the vortex throttle. Horizontal liquid levels in the aerated chambers are assumed since there were no significant effects of surface waves expected. This assumption is confirmed by the comparison with measurements shown below. The charging and discharging of the upper chamber is possible in two different ways depending on the liquid level:

- By means of the vortex throttle if the liquid level is below the weir crone of the rise shaft (1)
- And additionally by means of weir overflow if the liquid level is above the weir crone (2)

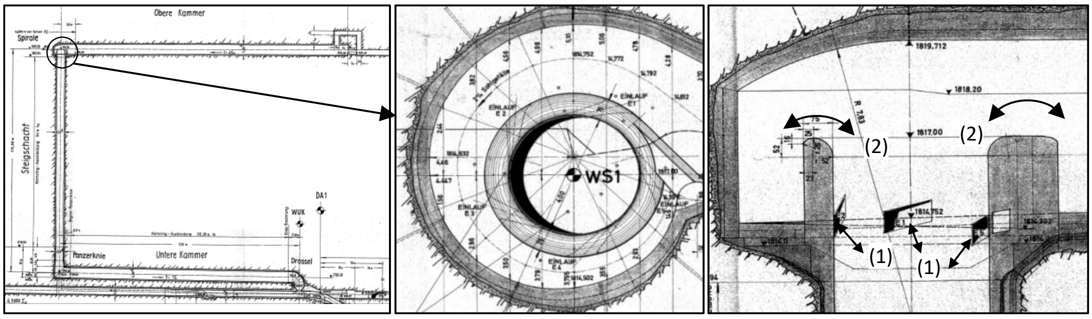

Fig. 2
Surge Tank of HPP Kops I: left: general view, middle: top view of vortex throttle, right: cross section of vortex throttle

For a correct modelling of the surge tank behavior in such detail, additional information and boundary conditions are necessary. To get appropriate data of the hydraulic losses of the throttles and the hydraulic behavior of the chambers and weirs, analytical models based on technical literature [5], [6], [7], [8] or 3D numerical simulations have to be developed. A successful application of 3D numerical simulations to get the necessary information of hydraulic data to model the surge tank behavior correctly in the course of 1D numerical waterhammer simulations has been shown by Meusburger [9] and Veide et al. [3].

4. NUMERICAL RESULTS AND COMPARISON WITH MEASUREMENTS

4.1. VALIDATION OF THE NUMERICAL RESULTS

A comparison of the numerical result for the original power plant configuration with on-site measurements was carried out at the beginning of the numerical simulations. In that course a validation of the numerical model, especially for the surge tank behavior, as well as the losses in the power water way, was possible. Measurement data of the pressure at the base point of the surge tank, at the downstream end of the penstock and at the inlet of the pelton turbines, as well as the position of the pelton needles were available. In the bottom diagram of Fig. 3 the liquid levels in the surge tank are shown for both simulation and measurement results for a serial starting of the units followed by a synchronous stopping off all units in parallel. The corresponding measured nozzle positions supplied the boundary conditions for the numerical simulations and are drawn in the top diagram in Fig. 3.

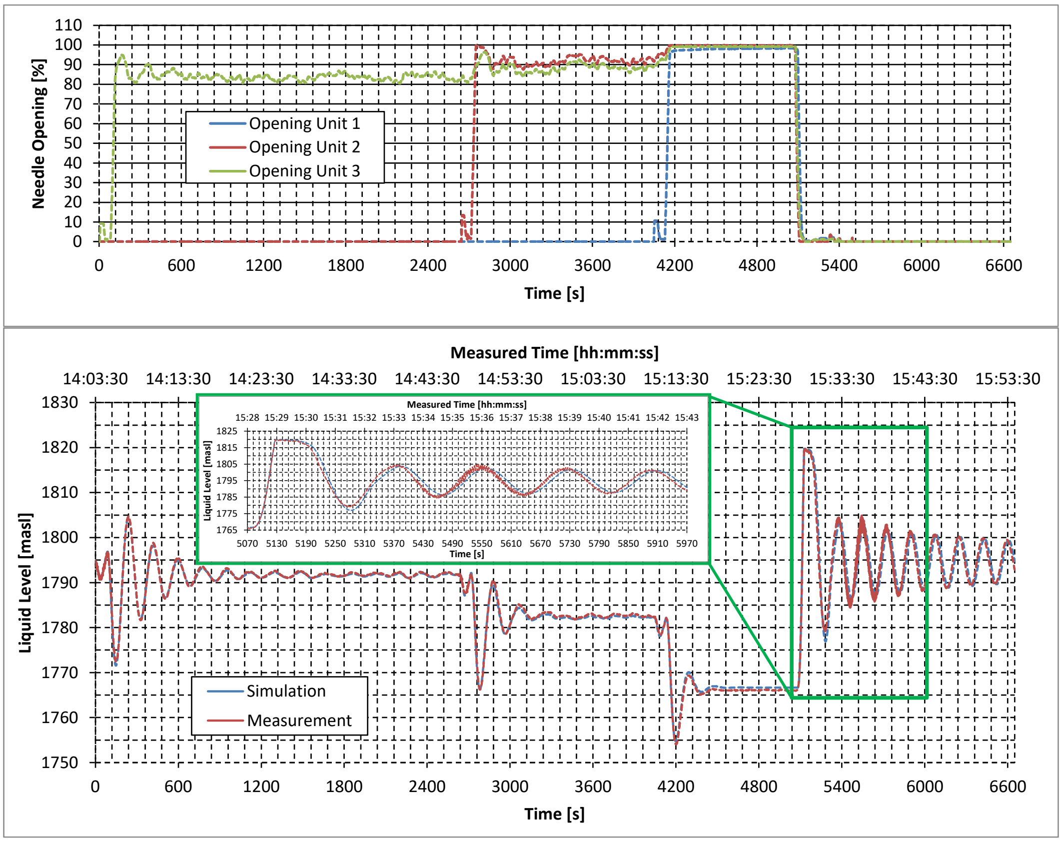

Fig. 3

Comparison of simulation results and field measurements

The comparison shows very good correlation for the measured and simulated liquid levels in the surge tank. A detail view of the time when the units are stopped (after around t = 5100 s) is presented in the small diagram in Fig. 3. After approximately t = 5130 s the upper chamber is activated, indicated by a nearly horizontal water level.. Again, a very good correlation of the simulation and the measurement is shown for both, filling (rising liquid level) and emptying (falling liquid level) of the upper chamber as well as the surge tank in general.

Therefore the accuracy of the numerical model is confirmed and yields additional confidence for the simulation results.

4.2. Maximum Surge Tank Oscillation

In order to achieve the allowable operating limits for the power plant with increased power output, the maximum occurring surge tank oscillation must not exceed the allowable limits in any possible operating mode. Therefore the maximum and minimum liquid levels in the surge tank for a given gross head and power output have to be identified.

The criterion for determining the **maximum water level** in the upper reservoir (i.e. gross head) for a given power output is the maximum surge tank oscillation (i.e. the maximum filling of the upper chamber). The maximum allowable gross head is determined by following worst case scenario:

If all three turbines are put into operation from a standstill, the increasing turbine flow rate will lead to a rapid decrease of the water level in the surge tank. The nozzles are opened as far as possible for the given gross head, but the maximum opening is limited with the maximum power output of the generator. The system inertia of the headrace tunnel leads to an oscillation of the liquid level in the surge tank. When the turbines are stopped in parallel at the same time when the liquid level rises again, the surge tank oscillation can be forced to its maximum amplitude.

The resulting maximum water level in the surge tank increases with increasing gross head and turbine flow rate.

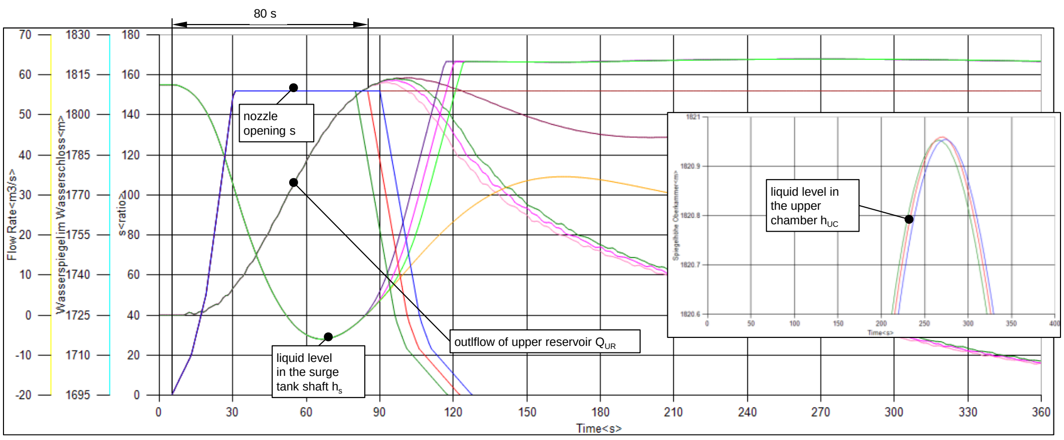

Fig. 4
Determination of maximum liquid level in the surge tank

The most critical time for stopping the turbines was found iteratively at 80 seconds after the start of the previous nozzle opening, by varying the closing time. An example procedure is shown in Fig. 4 where the nozzle opening (s), the liquid level in the surge tank (h_s) and in the upper chamber (h_{UK}), as well as the outflow of the upper reservoir (Q_{UR}) are shown for four different load cases:

- start-up of 3 units in parallel
- start-up of 3 units in parallel followed by synchronous stopping at 3 different times.

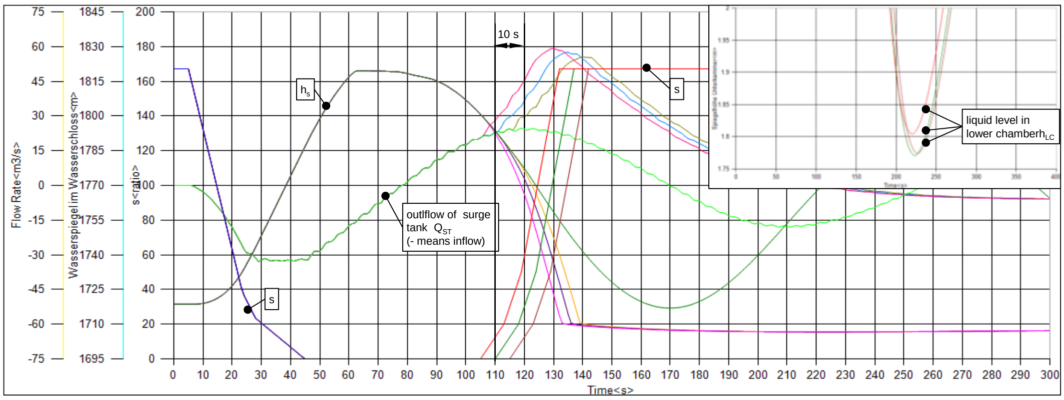

Fig. 5
Investigation of minimum water level in the surge tank

The **minumum water level** in the surge tank is determined when the units are started in parallel in resonance after a previous synchronous shut-down of the power plant. The procedure for the iterative investigation process is shown in Fig. 5. It shows the nozzle opening as well as the transients for h_s, the flowrate in the surge tank (Q_{ST}) and the liquid level in the lower chamger (h_{LC}) for four different loadcases.

The synchronous closing of the nozzels leads to a water level oscillation with corresponding flowrate in (- sign) and out of (+ sign) the surge tank. It turned out that the lowest liquid level in the lower chamber results when the opening of the nozzels is started 10 seconds before Q_{ST} would reach its maximum value of the preceding turbine stop.

If the above described maximum or minimum liquid level exceeds the surge tank limitations the power output will be decreased until the resulting surge tank oscillation is below the limitations. This procedure is then repeated for different gross heads to receive the maximum allowed power output.

4.3. Cyclical Operation

As already described above forced, water level oscillacions caused by syncronous start and stop in resonance to the natural frequency of the hydraulic system must be given extra attention. With completely free power plant operation, it might be possible that such cyclic resonance manouvers are neccesary several times in succession for grid service reasons (e.g. power control or frequency control). Therefore also multiple surge tank excitation has to be examined in order to investigate whether possibly even higher water level amplitudes can result. Again several iterations are necessary to identify the worst time for each closing or opening cycle to gain highest or lowest liquid levels in the surge tank of the power plant.

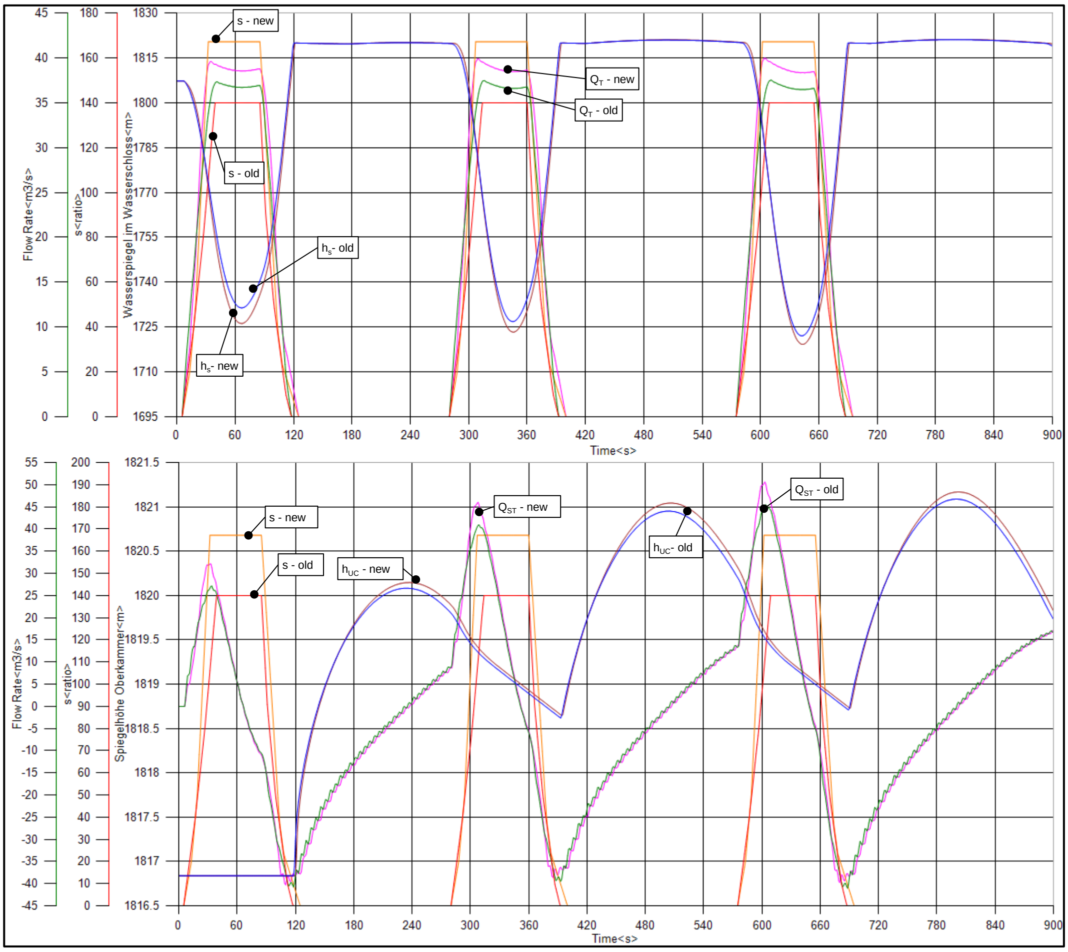

Fig. 6

Cyclical forced surge tank oscillation before and after power increase

An exemplaric multiple resonance cycle for both, the existing power plant configuration (old) as well as with increased power output (new), is shown in Fig. 6. In the upper diagram the transients for the nozzle opening (s), the liquid level in the surge tank shaft (h_S) and the turbine flowrate (Q_T) for both configurations are shown, whereas in the lower diagram the history for Q_{ST} and h_{UC} are drawn. It turns out very clearly that the maximum liquid level in the surge tank is increased if multiple resonance cycles are applied.

Investigations have shown that after 3 starts and stops the maximum water level amplitude is resulting. More cycles will not increase the liqud level oscilliations for both load cases maximum and minimum liquid levels.

The new configuration with increased Q_T and thus increased power output has also increased operational fexibility since the maximum nozzle opening is reached in a shorter duration compared to the old configuration. In both scenarios the liquid level in the upper reservoir is at the same level near its maximum. It is clearly visible, that due to increased turbine flowrate, Q_{ST} is also increased and thus higer maximum amplitudes of the surge tank oscillations are resulting.

Like described above, the admissible water level in the upper reservoir for a certain maximum power output was found by stepwise reducing the gross head if the maximum surge tank limit was exceeded. Thus operational limits for a totally free power plant operations are necessary. For each gross head again several iterations were needed to determine the maximum amplitudes of the surge tank oscillations.

An overview of the resulting permissible operating range between minimum and maximum liquid level in the upper reservoir is given in Fig. 7 where the power limits for fully flexible operation are drawn. Due to massive numerical simulations linear operating limits within the range of minimum and maximum gross head could be found. Compared to stepwise limits additional operating range and therefore increased gross annual earnings were gained (orange areas in Fig.7).

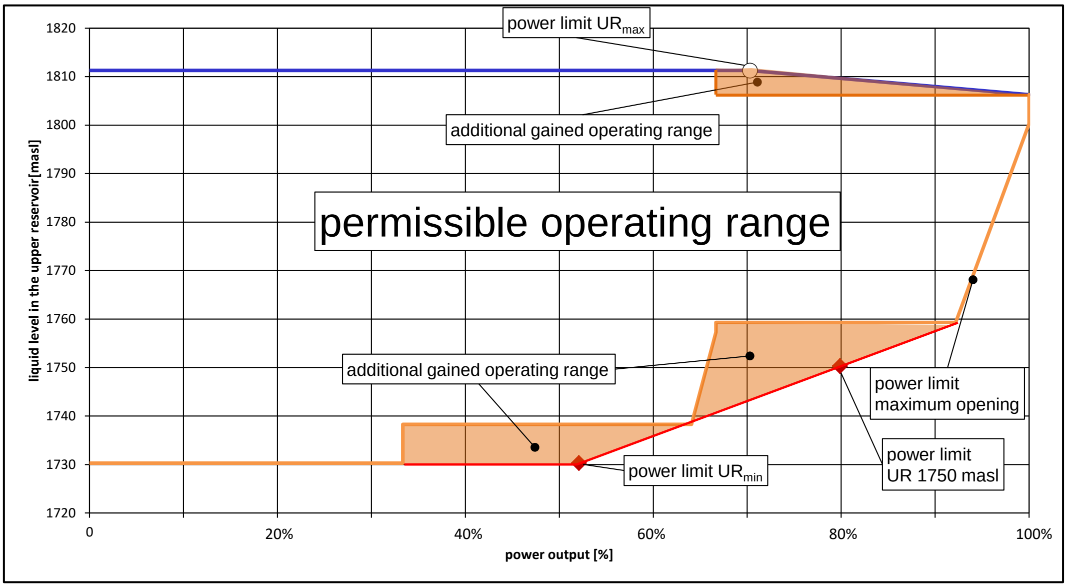

Fig. 7
Permissible and addtional gained operating range

5. CONCLUSION

This paper presents a way to identify the possibility of an increase of power output and power plant flexibility at the same time for high head hydro power plants. With the help of transient 1-D numerical simulations and a validation with measurements on the existing power plant, the surge tank oscillations with increased power output can be calculated precisely. It could be shown that the given hydraulic infrastructure is able to allow for greater flexibility and higher power with only minor additional limits in the permissible operating range.

The focus in the present paper was on mass oscilliation and the surge tank limitations. Additional investigations like the maximum pressure in the penstock due to increased waterhammer have also been carried out but exceed the scope of the present paper.

1. INTRODUCTION

The design of inlet and outlet areas of hydro power plants significantly influences the overall cost of a plant not only in the design and construction phases but also during operation. Due to an incorrectly shaped inlet geometry, vortices and flow separation occurred at several river power plants. These phenomena can cause flow problems and losses at the turbines and must not be neglected, especially for low head turbines with relatively high specific speed turbines. Sources of such inhomogeneous inlet flow distribution could be a wrong design of dividing piers, gravel steps and other points of discontinuity in the flow guiding walls and river bed. In this paper, samples of water way designs and their optimisations, whose target is to avoid wrong inflow and outflow designs, are presented together with cost-optimised design.

During the last decades, turbine intake structures have been investigated in more detail. Based on the systematic analysis of vortex types, design rules for the design of intakes to avoid free surface vortices as well as other publications referring to swirling flow problems at intakes have been published [1]. Problems of intake vortices have long been known [2, 3] and tests at laboratory scale were realised in a systematic way including categorisation of vortices and empirical correlations ([1], [4] newer ones [5], [6]). Since numerical simulations are getting more and more reliable, investigations of these flow phenomena increased – but also the effort connected to them. During the last few years LES and SAS simulations [7, 8] captured the flow field with acceptable accuracy.

2. HPP GÖSSENDORF

2.1. PLANT OVERVIEW AND CFD MODEL

The plant consists of two units with a maximum discharge of Q = 100 m³/s per turbine and a total nominal power of P = 18.75 MW. Its yearly production amounts to 89 GWh, and the units were brought into operation in 2012. Each unit consists of a bulb turbine with 16 guide vanes, a 4-blade runner and a nominal diameter of $D_{Nominal}$ = 3.6 m as well as a straight conical draft tube (Table 1).

Table 1: Turbine main data of HPP Gössendorf

Year of construction	2010-2012		Rotational speed	150	rpm
Number of units	2	#	Runner diameter	3.6	m
Max. flowrate per unit	100	m³/s	Number of blades	4	#
Net head	11.2	m	Level maschine axis	314	masl
Maximum power	18.75	MW	Head water level	330.8	masl

A lack of efficiency could be identified for turbine no. 2 (closer to the pier, see Fig. 1) at only a short time of operation after the start-up of the turbines in 2012. At identical runner blade and guide vane positions of both units the power output of the two identical turbines was different (see measurement curves later in Fig. 3). With the help of index tests, a failure at the turbines could be excluded and the efficiency level in general was tested in a model test as well. During the hydraulic development phase also a comprehensive numerical investigation of the turbine with the help of CFD was carried out. An idea regarding the reason for the lack of power was, that the flow distribution to the turbine must be disturbed and thus vortices are generated.

During the planning phase of the power plant a model test was carried out in the course of the hydraulic engineering [9]. During this model test (scale 1:40) vortex generation could be found in the intake and a new design of the pier was realised. This new pier works well for flood water, but influences the inflow situation negatively. The finally designed pier ends 3.5 m below the head water level and is shown in Fig. 1b. To avoid vortex generation in the intake bed, a smooth crossover with a ramp (Fig. 1c) and a gravel step (Fig. 1d) with a height of 2 m (due to rubble in the river bed) were realised.

The model starts 240 m upstream the machine runner. Based on 2D drawings and profiles for different sections of the river bed, a smoothed simplified section of the river was generated and is shown in blue in Fig. 1e. Then, the exact remodelling of the intake situation of the two units, including the three weirs, started. First, the turbine itself was calculated with a complex model which is shown in Fig. 1f. It consists of the intake, the bulb and a 360° section of the guide vanes, a whole runner and the straight draft tube with an enlarged section downstream. Finally, the entire power plant was investigated. This means, that the two units were installed in parallel (including turbine, guide vane, draft tube and inflow structure as well as the intake structure and the two installed screeners visualised in red in Fig. 1g with a useable clearance of 88 mm). Downstream of the draft tube an additional component, the so-called outblock, was connected directly to the draft tube. The function of this component is not exactly a representation of the tail water, but helps to avoid the setting of boundary conditions directly at the draft tube outlet, which would influence the draft tube simulation and prescribe the flow situation. Pressure type boundary conditions were set for inlet and outlet, and thus the flow rate resulted. Menter's SST turbulence model with automatic wall functions was applied for the stationary calculations, and in order to achieve a satisfying convergence level all sensitive variables and imbalances were monitored.

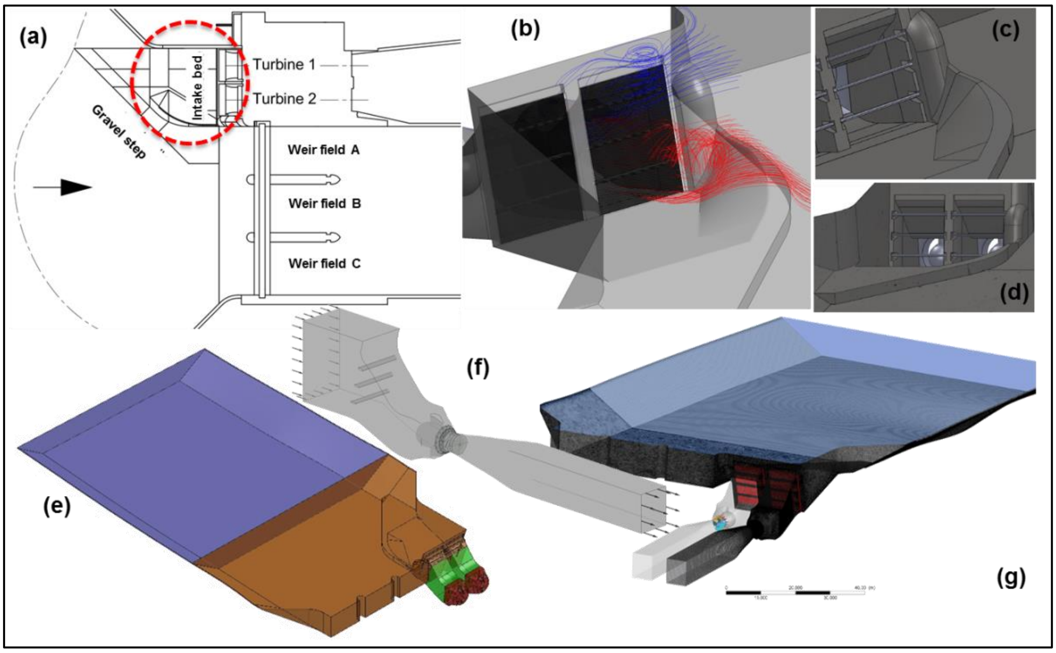

Fig. 1: Inflow situation

2.2. FULL MODEL, INTAKE FLOW SITUATION, PERFORMANCE DIFFERENCE

When analysing the numerical simulations results for the intake only and for a full model calculation, an influence on the flow distribution to the bulb could be detected. The plane shown in Fig. 2 is located just in front of the bulb. It is clearly visible that the flow distribution is strongly inhomogeneous for turbine 2 (left) in comparison to turbine 1 (right). Anyway, both are outside of the Fisher-Franke criteria [10]. For the evaluation of the flow situation the velocity was evaluated, normalised and sorted from the largest deviation to the mean value and to the lowest.

For the simulation including the turbines the situation was slightly better, as the distance to the allowed values (marked in grey) is smaller, however unit 2 was definitely outside of these criteria Also, during the model test in the lab a similar situation happened and optimisation was provided, but due to a lack of time and higher costs not all modifications could be integrated into the final intake design. Yet, according to [11], more deviation is allowed for the velocity in the intake and a summary of additional criteria is given by [12].

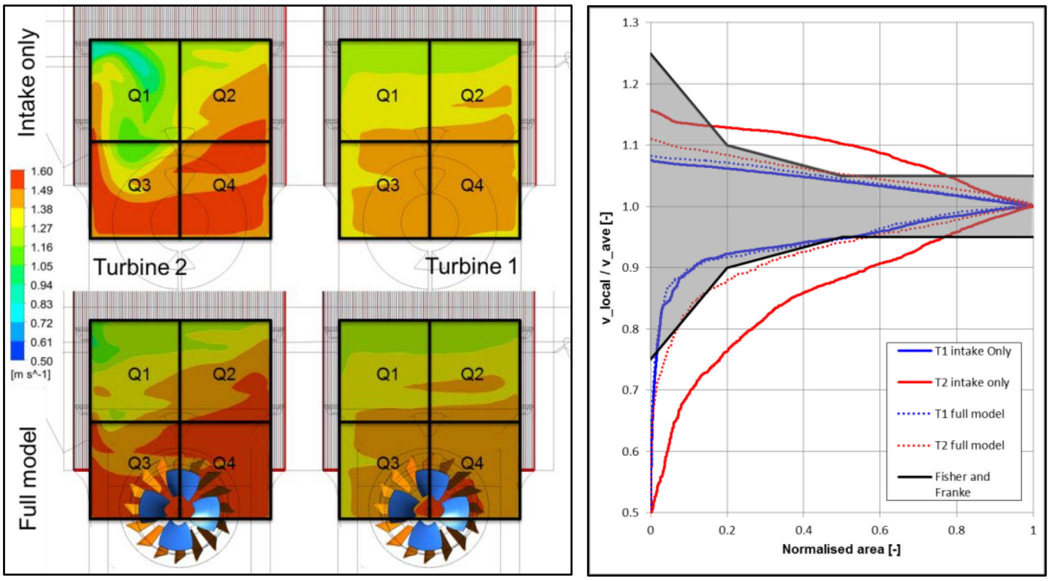

Fig. 2: Left: Velocity distribution at intake, full model and intake only simulation, Right: Fisher Franke analysis for full model and intake only simulation

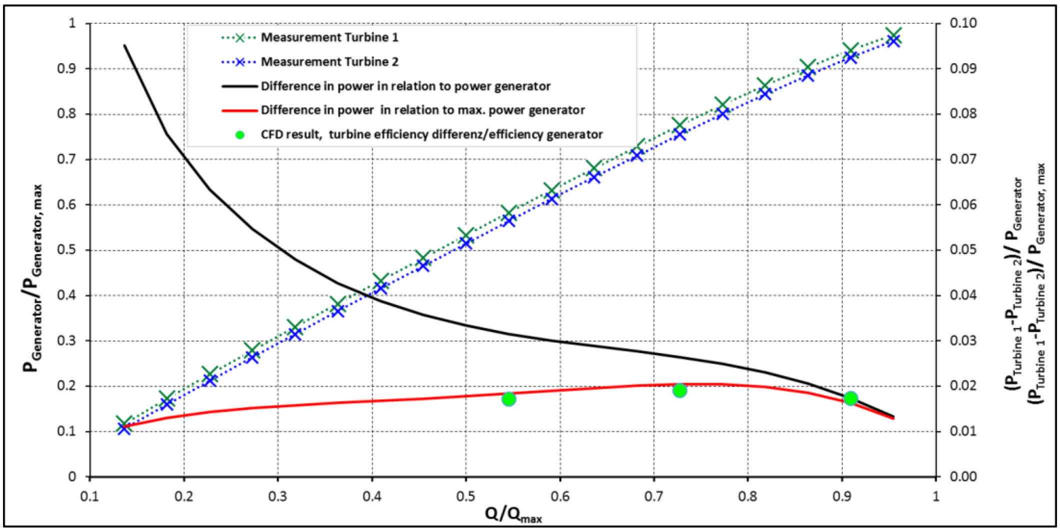

Fig. 3: Numerical simulation versus prototype test

The turbines were model-tested and during the development phase also numerically analysed. After the start-up of the turbines a comprehensive test of the two units was realised, including efficiency and vibration tests. In Fig. 6 the measurement data for the electrical power is shown versus the flowrate for the two units normalised with a maximum flowrate of Q_{Max} = 115 m³/s and the maximum generator power of $P_{Generator,max}$ = 11 MW. The differences between the two units are visualised in red for the relative difference and in black for the absolute difference. Three operation points were calculated for the full model with the intake and the operation of the two units in parallel.

The difference in efficiency is shown by means of green dots. For the generator efficiency and other losses a constant value of eta_{Geno} and other losses = 98% was used to calculate the electrical power output based on the CFD data. The CFD analysis correlates with the on-site measurement data and confirms the findings established during the hydraulic structure model test [9]. Over the whole operation range the measurement of turbine 1 shows a higher performance as turbine 2. In relation to the generator output the relative losses are in the range of 7% at 20% flowrate and approx. 1.5% at 95% of the maximum flowrate (black line). In terms of losses in relation to the maximum generator output the range is between 1 and 2% (red line).

2.3. OPTIMISATION

Multiphase calculations were realised to verify the air sucking turbulences and swirls. Based on the results of these simulations, different kinds of structural measures were developed. The various types of measures were simple accessory elements as well as large-scale structural interventions at the inlet area of the power plant. The effects of all these different structural adjustments on the inflow were further investigated by means of computational fluid dynamics. The inferior inflow situation is a fact, optimisation with additional guide walls and other modification was analysed. 34 different variants were investigated, but with simple elementary structures no substantial improvement could be realised. With more complex and extensive guide walls also at the bottom of the intake a flow distribution approximately comparable to turbine 1 could be realised. However, with no option the Fisher-Franke [10] criteria are satisfied.

Fig. 4 shows the initial situation and 2 modifications. With the modification of 3 guide walls a more homogeneous flow distribution could be realised (see velocity distribution), and with the second modification presented even the swirl at the bottom could be avoided (red streamlines). The velocity distribution presented in absolute values at the right side of Fig. 4 also shows a flat gradient for version (c), which indicates a smoother velocity distribution. Still, all these variants could not satisfy the Fisher-Franke criteria or a comparable velocity distribution of turbine 1. The operator of the power plant defined the possible frame conditions with a few mandatory criteria. This includes the project costs, the operational capability of the track rack cleaner, secure operation and massive construction of the structures (e.g. guide wall made of steel) especially for flood water. A solution without modifications of the pier made of concrete and other structures has to be found in order to avoid the necessity of emptying the head water reservoir. The best solution would be a massive guide wall made of steel (Fig. 4), which is a modified and enhanced version of the principle idea presented in [9]) and a modification of the pier made of concrete. These measures would incur expenses more than 3 times higher as the given budget (calculated by the operator including operation interruption).

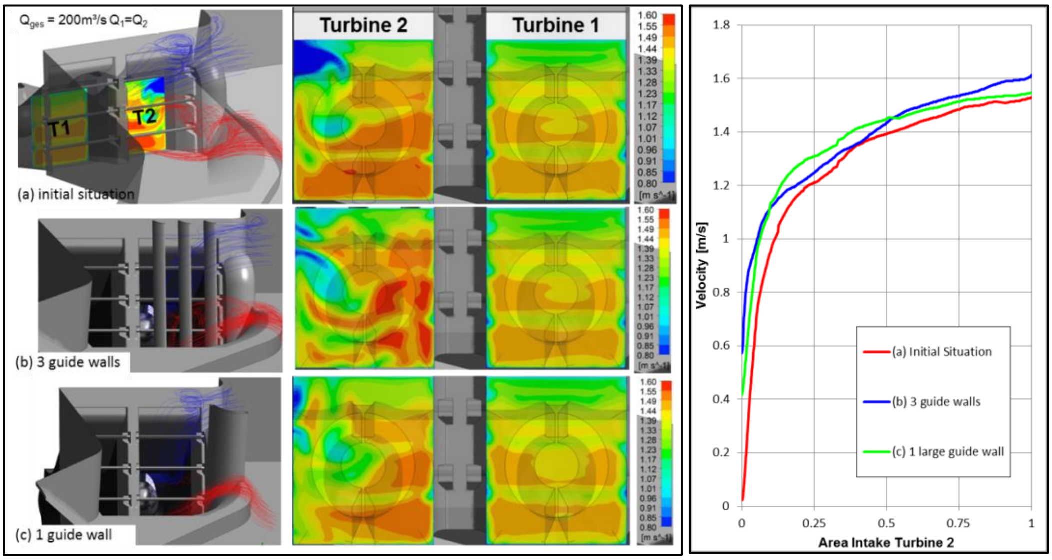

Fig. 4: Numerical simulation versus prototype test

3. GRENZKRAFTWERKE INN HPP GKI

A new diversion power plant located at the Swiss-Austrian border at the river Oberer Inn is currently under construction. In Ovella the intake structure consist of a 15m high weir canal to collect water for the GKI power plant. The weir was planned as a multi-functional structure and includes the weir valves for the barrage, the inlet channel for the approximately 23 km long gallery to the main stage (powerhouse Prutz / Ried), a small turbine for residual water delivery and a device for barrier-free fish migration. The plant data of the power plant project are summarised in Table 2.

Table 2: Turbine main data of HPP GKI

	Main turbine	Residual water turbine
Planned start-up	2018	
Type of turbines	2 x verticale Francis	1 x Kaplan-S
Net head rated	160.7 m	15 m
Flow rate rated	75 m³/s	20 m³/s

Fig. 5 (left) shows a visualisation of the planned reservoir with the intake structure on the orographic side (right), which was examined in the course of a comprehensive CFD study. The flow rate at the intake structure is max. 95 m³/s. Then 75 m³/s feed the headrace channel to the inclined shaft where the powerhouse Prutz / Ried is connected. The remaining amount of water is processed at the small turbine and discharged as residual water in the original river. It should be mentioned, that – as an additional special feature – the use of a fine screener with a clear width of only 20 mm was prescribed at the transition from the reservoir to the intake structure. In order to obtain a flow velocity of max 0.75 m/s in front of the trash rack and a mean velocity of 1 m/s in the trash rack itself, the dimension of the screener was determined to be: width = 19 m and height = 6.5 m (steel bar width 8 mm).

The focus of the investigations carried out based on CFD calculations lay on the optimisation of the flow guidance in the inlet structure in order to obtain an ideal flow of the calculation field and to improve the geometric connection of the small residual water unit and thus to ensure a swirl free homogenous flow situation at the inflow there. Fig. 5 shows the two-axis 3D CFD model used as well as an example result of the calculated phase boundary (= water surface).

The CFD calculations were all carried out for the maximum intake at the intake structure ($Q = 95\ m^3/s$) at the design water level ($H_{max} = 1029.5$ m) and the minimum water storage elevation ($H_{min} = 1025.5$ m). The implementation of the fine screener was a specific challenge in the CFD calculation, as it resulted in a particularly complex two-phase CFD model. While a mesh with approximately 5 million nodes was created for the course of the river and the inlet channel, approximately 25 million hexahedral elements had to be used in the area of the fine screening. The CFD model used for the calculation from the storage reservoir to the intake structure is shown in Fig. 6. Velocity vectors were plotted on an evaluation plane placed in the middle of the arithmetic field. The left diagram shows the flow situation in the case of the originally planned geometry variant. While the screener field in the middle (pos. 2) is expected to flow well, a false flow appears to occur at the edges (pos. 1 and pos. 3). This leads to pronounced flow separations between the screen bars in these areas (see Fig. 6 – left) and thus the flow is not divided equally across the screener field. Furthermore, the inclined computing field of the inflow can cause vibrations on the bars. The justified alignment of inlet structure and screener field therefore appears to be inappropriate.

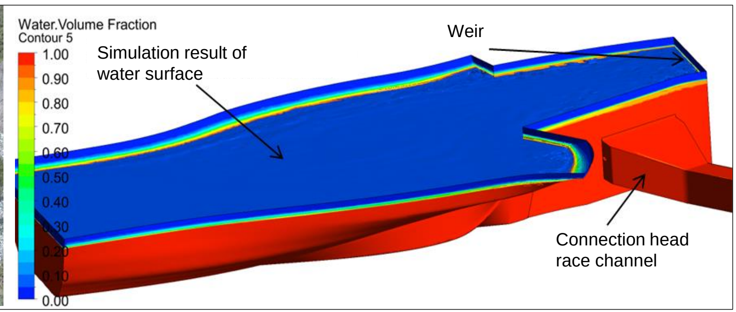

Fig. 5: Planned hydro power plant intake structure and CFD model

The flow situation at the inflow is more homogeneous and looks much better in the case of the improved geometry (see Fig. 6 – right). Due to the offset of the plane, where the screener is located in a distance of about 2 m to the rear and the attachment of an elliptical fillet before the area 1 and a the circular contour in front of the area 3, a false flow can be prevented (see also Fig. 6 – right) and a homogeneous velocity distribution over the entire calculation field is ensured.

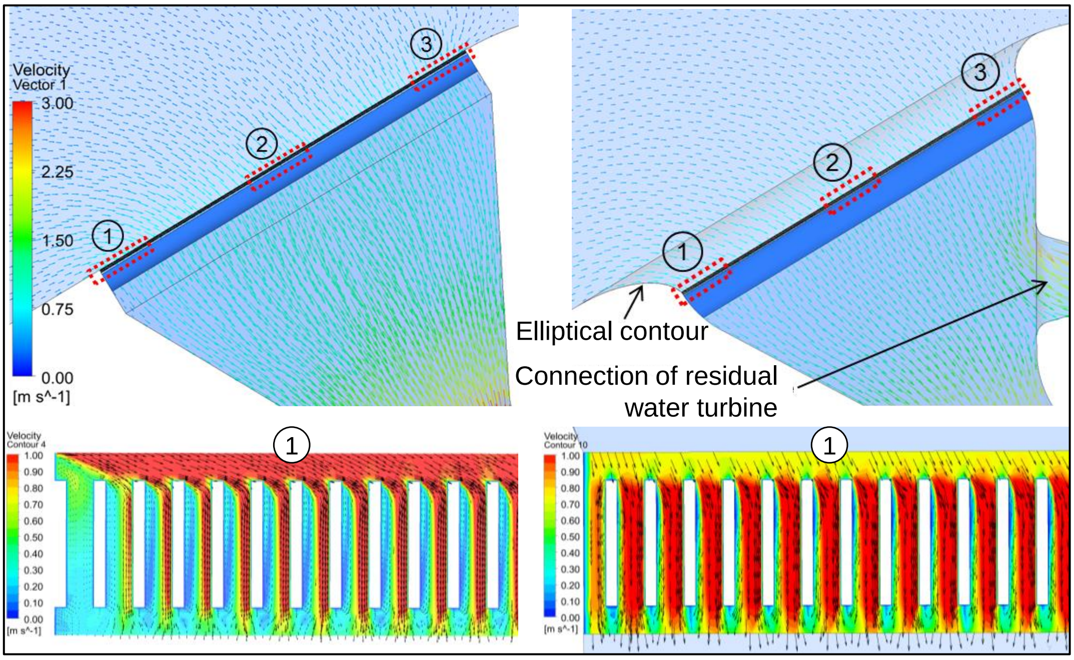

Fig. 6: Velocity distribution at different locations

Further improvement of the originally planned design of the intake structure becomes apparent when analysing the flow situation in a side view. Figure 8 shows a visualisation of streamlines in a vertical central section through the inlet structure. The left-hand illustration shows, that in the original design along the sharp edge at the transition from the flow to the inlet channel (marked red) pronounced detachment zones occur, which on the one hand cause flow losses, on the other hand these zones can lead to oscillation problems in the screener area. Furthermore, the shape of the screener's beam also does not seem ideal. A fillet around the intake structure and the use of two beams turned into the flow direction significantly improve the flow situation.

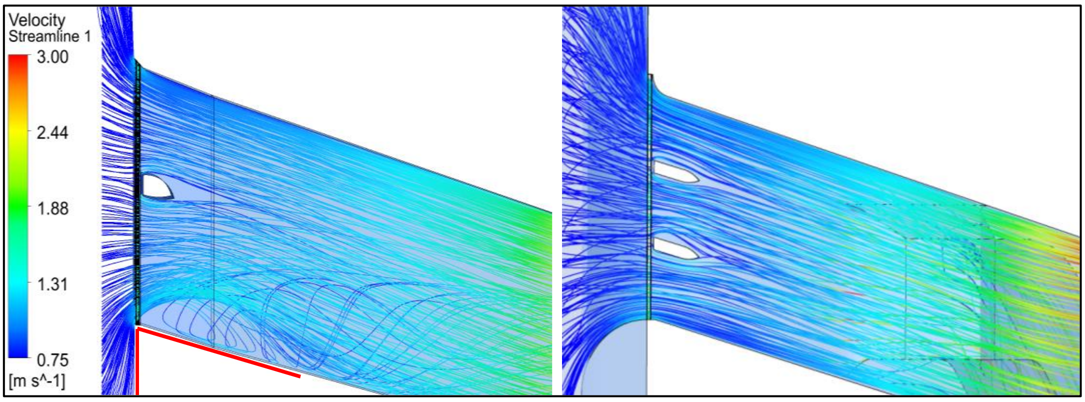

Fig. 7: Streamlines, connection of headrace channel

4. MUR POWER PLANT FRANZ, HPP MKF

The new MKF hydro power plant, designed as weir turbine, is located at the intake structure of an existing headrace channel for a diversion power plant with a maximum flow rate of $Q_{max,Diversion}$ = 100 m³/s at the river Mur. The design flow rate for the new power plant is $Q_{max,MKF}$ = 40 m³/s whereas the minimum residual water through the turbine is $Q_{min,MKF}$ = 11 m³/s. The power plant is located on the inner curvature of the river bend opposite the headrace channel for the existing power plant (Fig. 8). The turbine's direction of rotation must be investigated as it has an enormous influence on the civil engineering construction cost due to power transmission lines located in the air space above the excavation zone. The investigation was based on qualitative flow evaluations at different planes. The evaluation levels 1, 2 and 3 each represent horizontal sections through the flow field at different height levels (Fig. 8c). Additional evaluation criteria represent the ratios of maximum and minimum occurring flow velocity to average flow velocity for the evaluation of a uniform flow towards the turbine. The comparison for the left- and right-hand turbine configuration is shown for load case 1 (see Table 3 for load case details) with Fig. 9. It clearly shows that the right-hand variant for evaluation levels 1, 2 and 3 has a more inhomogeneous flow distribution in the MKF bay compared to the left-hand turbine. This statement is also confirmed by the evaluation of the maximum and minimum relative flow velocity at the spiral inlet – there are increased secondary flows at the spiral inlet when using a right-hand machine. Other load cases are presented in Table 3. Based on these test results, the installation of left-hand machines is recommended, the construction of which is also cheaper.

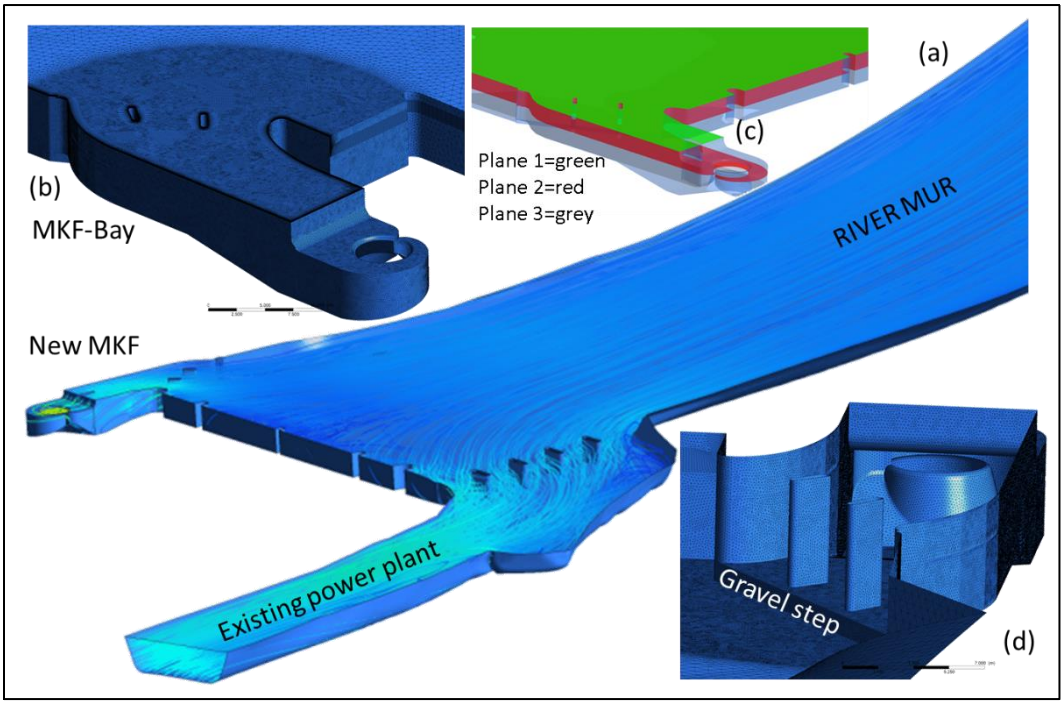

Fig. 8: Velocity distribution at different locations

Table 3: Load cases HPP MKF

Load case	Q_{Mur}	Q_{MKF}	$Q_{Existing}$	$C_{ratio,min}$		$C_{ratio,min}$	
				left	right	left	right
	m³/s	m³/s	m³/s	m³/s	m³/s	m³/s	m³/s
1	140	40	100	1.827	2.073	0.054	0.031
2	111	11	100	1.810	1.961	0.005	0.046
3	61	11	50	1.820	2.071	0.059	0.013
4	40	40	0	1.944	2.033	0.028	0.054

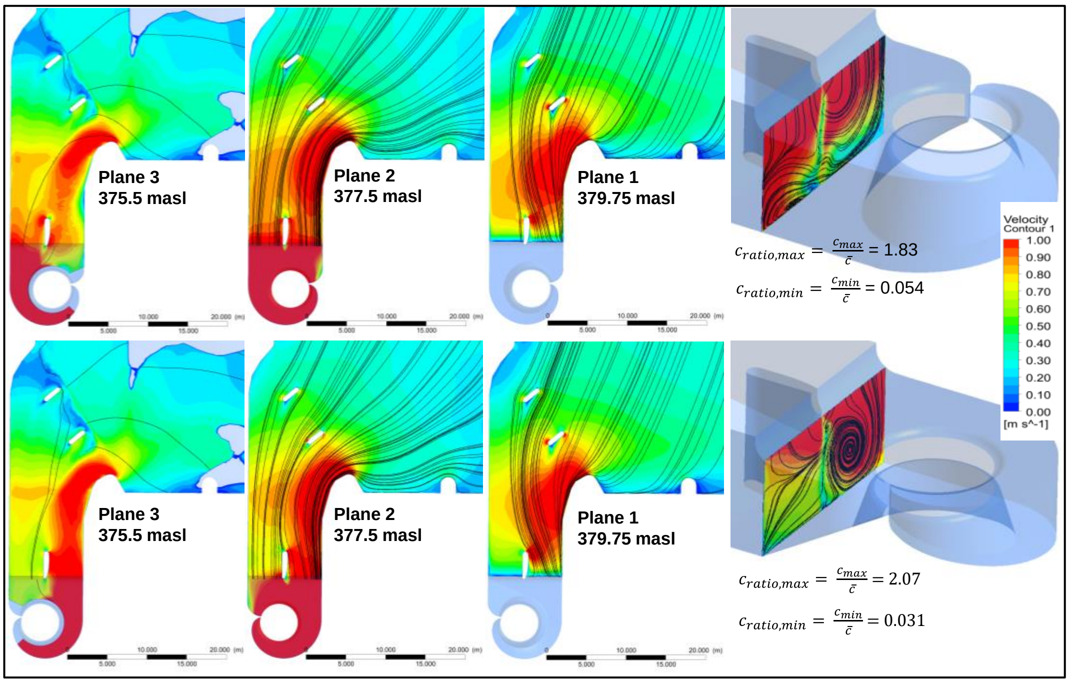

Fig. 9: Streamlines for left-hand (top) and right-hand (bottom) turbine configuration

4.1. OPTIMIZED GEOMETRY

The single-phase calculation shows a non-optimal orientation of the supporting pillars in the inflow region of the power plant inlet for the left-hand rotating turbine. In all tested load cases it shows, that the pillars should be rotated by up to 15° counter clockwise. In addition, the analysis of the flow field in the horizontal evaluation levels shows optimisation potential in the hydraulic design of the existing wall between the MKF bay and the right bottom outlet.

The flow situation at the water surface shows that a dead water zone is to be expected in the inlet area in the bay power plant on the orographic side (right). A hydraulic optimisation (enlargement of the radius) of the right orographic boundary in the inlet area of the MKF bay has been proposed in order to avoid this unfavourable flow situation together with a gravel step (see Fig 8d). A stationary approach is used with the SST turbulence model, with the flow rate as boundary condition at the MKF and the existing power plant, and furthermore a pressure boundary condition was set at the inlet. The investigations now were all carried out by means of two-phase CFD simulation. For the numerical modelling of the flow with free water level for the project in question the "homogeneous multiphase model" in Ansys CFX, the one based on a Volume of Fluid approach (VOF), is used. For the multiphase studies the calculation area was extended upwards (airspace) and very finely resolved with prismatic layers in the area of the expected water level. This ensures, that the water level can be precisely calculated during the CFD simulation. An optimised geometry proposal of the hydraulic contour of the MKF bay was developed. Turning back the pillars and the removal of the right bank embankment detected and included in the new geometry model with 4.87 million nodes, respective 15.44 million elements. The hydraulic contour of the existing wall between MKF bay and right to bottom outlet was modified to achieve the desired effect of no detectable level reduction. The water level is now constant along this wall as visualised in Fig. 10, whereby the optimised contour is shown at the bottom left.

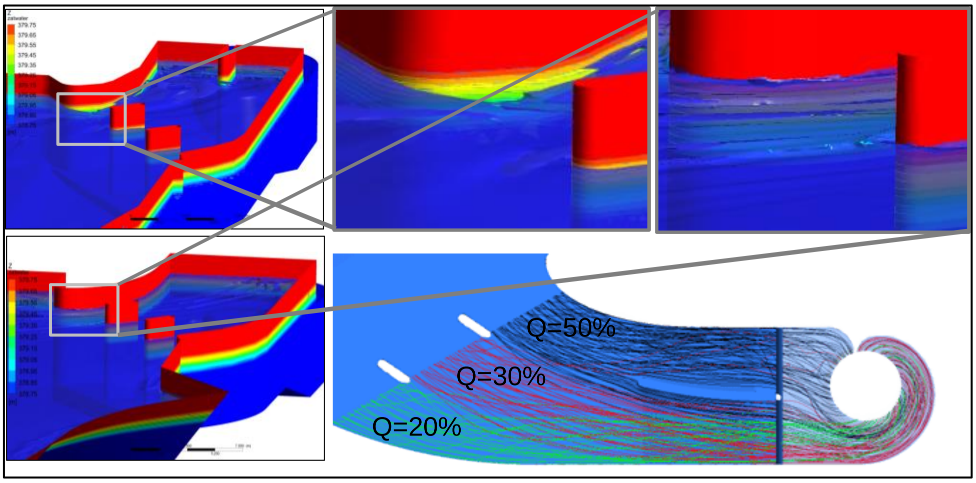

Fig. 10: Water level at wall, distribution of intake water

The last optimisation step deals with the installation of a baffle before the spiral entry. This should attenuate the formation of the vortex structures on the water surface or, in an ideal case, suppress it completely and lead to a further homogenisation of the velocity distribution in front of the turbines. At the same time, an extended partition before the spiral entry can be used as a support structure for a pedestrian walkway in this area of the power plant.

However, Kaplan turbines with a concrete semi-spiral have an asymmetrical quantity distribution due to the geometric conditions at the entrance to the spiral. The water masses entering MKF bay through field 1 are shown in green, those in field 2 in red and those in field 3 in black (Fig. 10 right bottom). An approximate distribution of volumes between the fields at the entrance to the bay shows the previously mentioned circumstance of an unequal collection of quantities in a concrete semi-spiral (Q_{Field1} = 20%, Q_{Field2} = 30%, Q_{Field1} = 50%).

SUMMARY

Based on three case studies the Institute of Hydraulic Turbomachinery at the Graz University of Technology has worked on in recent years, it can be shown that the numerical flow simulation is very well suited for the detailed analysis of the inflow of power plants as well as for the development of geometric improvements. Especially in the area of low head power plants, where axial turbines are often used (such as Kaplan tube or S-turbines), such studies should be carried out in the planning phase already in order to avoid potential problems in advance.

1. ABSTRACT

Chinese contractors play a more and more important role in the hydropower industry worldwide due to the experience and technological strength accumulated from delivering many significant hydropower projects such as the Three Gorges Dam. However, the Chinese contractors encounter ongoing difficulties in achieving the objectives of developing international hydropower projects, which arise from unfamiliarity with the differences between Chinese and foreign technical standards. This research collected the data from international hydropower projects, which are scattered in Asia, Africa, Oceania and Latin America. With support of the case studies, this research reveals the impacts of the technical standards' differences on hydropower project development processes, including bidding, design, procurement, construction, occupational health and safety management, and environment protection. It is suggested that Chinese contractors should more

clearly understand the differences between Chinese technical standards and foreign technical standards in project delivery for providing more cost-effective and environment-friendly hydropower projects worldwide.

2. INTRODUCTION

Over the past 15 years, Chinese contractors play a more and more important role in the international construction industry with more than 20% annual growth rate of contract amount (Zhao et al., 2017). Nevertheless, when delivering a global project, participants from different countries with differing institutionalized practices may come into conflict (Mahalingam, 2006). Although there exist opportunities, international hydropower projects also face more uncertainties than domestic projects since foreign contractors have to work in unfamiliar environments, including different regulations, norms, and cultural beliefs (Javernick-Will et al., 2010). In these situations, the unfamiliarity with different environments can increase misunderstandings and risks, thus result in project delays and cost overruns (Javernick-Will et al., 2009). Many researchers have studied the impact of unfamiliar environments on international project delivery. For example, Orr et al. (2008) built a conceptual framework to analyses unforeseen costs of a project in an unfamiliar host societal context base on an examination of 23 cases; Han et al. (2007) indicated that unfamiliarity with different regulations and norms was one of the significant distinctions between successful and failed international projects from a comparative case study; Chua et al. (2003) identified five risk factors, namely business environment discontinuity, contractual issues, differences in standards, regulation obstacles, and cultural differences, that can lead to cost overrun in the East Asian construction industry. Among the unfamiliar environments, such as different regulations, norms and cultural beliefs, technical standards particularly remain a great challenge for Chinese contractors (Lu et al., 2009), since technical standards of Chinese and other countries in hydropower industry can vary significantly. Lei et al. (2017) confirmed that Chinese contractors perceived significant difference between foreign standards and Chinese standards, which resulted in greater challenges in implementing foreign standards in international projects. In order to provide more cost-effective and environment-friendly projects worldwide, Chinese contractors should more clearly understand the differences between Chinese technical standards and foreign technical standards in project delivery.

Although many researchers have pointed out the importance of understanding the differences of technical standards (Orr et al., 2008; Javernick-Will et al., 2009; Kwon and Kareem, 2013; Lee et al., 2016; Lei et al. 2017), there is still a lack of solid and practical investigation to reveal the impacts of the differences in technical standards on developing international hydropower projects. Thus, this research aims to demonstrate such impacts on international hydropower project development processes together with the outcomes.

3. RESEARCH METHODOLOGY

3.1. DATA COLLECTION

Data was collected through questionnaire survey. The questionnaire aims to investigate Chinese contractors' perceptions on how technical standards affect the delivery of an international project according to their practical experience in a specific project. The questionnaire is divided into 5 sections: 1) Background of the respondent under investigation and the project that he/she participated in; 2) Frequency of using different technical standards; 3) The differences between Chinese and foreign technical standards; 4) Technical standard differences related problems in project implementation; 5) Project performance. The respondents were requested to answer the questions according to their experience learned from international hydropower projects that they were engaged. They were asked to answer the questions using a 5-point Likert scale, except the question on the frequency of using technical standards.

Questionnaires were sent to 17 Chinese construction companies, which all have rich experience in international hydropower projects with over $30 million contract value in international market annually, through fieldtrips as well as e-mail. The selected respondents have 8.82 years (on average) of experience in overseas projects. All sent 362 questionnaires were collected and 294 of them were used for analysis, excluding 68 invalid ones with incomplete information.

3.2. DATA ANALYSIS

With the help of the software Statistical Package for Social Science (SPSS), ranking analysis and Pearson correlation analysis were applied in this research. Rank analysis was used to reveal current application status of different technical standards applied in international hydropower projects and to identify the most significant factors that affect the technical standard selection; Pearson correlation analysis was performed to exhibit the relationships among the differences between technical standard differences related problems in project implementation and project performance.

4. RESULTS AND DISSCUSSION

4.1. FREQUENCY OF USING DIFFERENT TECHNICAL STANDARDS

18 kinds of technical standards were selected, because they have important influence worldwide. Respondents were requested to identify whether or not these selected technical standards were used in the projects that they were engaged. The using frequency of each technical standard was then calculated and is shown in Table 1.

Table 1
Frequency of using technical standards in international hydropower projects

Technical standards	Using frequency (represented by percentage)	Rank
American Society for Testing and Materials (ASTM)	52%	1
International Organization for Standardization (ISO)	47%	2
Chinese Standards (including GB, DL, SL, NB, etc.)	46%	3
American Concrete Institute (ACI)	32%	4
European Norm (EN)	31%	5
British Standard (BS)	29%	6
International Electrotechnical Commission (IEC)	20%	7
The American Society of Mechanical Engineers (ASME)	19%	8
Institute of Electrical and Electronics Engineers (IEEE)	17%	9
German Institute for Standardization (DIN)	15%	10
The American Society of Civil Engineers (ASCE)	14%	11
French Standards Association (NF)	13%	12
American Association of State Highway and Transportation Officials (AASHTO)	13%	13
United States Army Corps of Engineers (USACE)	12%	14
United States Bureau of Reclamation (USBR)	8%	15
International Telecommunication Union (ITU)	6%	16
Australian Standards/New Zealand Standards (AS/NZS)	4%	17
Indian technical standards	2%	18

Since the data was collected through survey of 17 representative Chinese construction companies, the result can well reflect the frequency of using different kinds of technical standards in international hydropower projects delivered by

Chinese contractors. As shown in Table 1, ASTM, ISO and Chinese technical standards are most frequently used in international hydropower projects delivered by Chinese contractors, with a frequency of 52%, 47% and 46% respectively. Other frequently used technical standards are ACI, EN, BS and IEC, with frequency larger than 20%. In general, USA, ISO, Chinese and European technical standards have significant influence on international hydropower projects conducted by Chinese contractors.

4.2. THE DIFFERENCES BETWEEN CHINESE AND FOREIGN TECHNICAL STANDARDS

Eight aspects were selected to evaluate the differences between Chinese and foreign technical standards, including *philosophy of the standard, completeness of the standard, application conditions of the standard, logical structure of the standard, material, theory for calculation, construction method* and *test method.* The respondents were asked to rate the differences on these aspects using a 5-point Likert scale, with 1= no difference and 5= huge differences. Results are shown in Table 2.

Table 2
The differences between Chinese and foreign technical standards

Aspects	Score	Std.	Rank
Philosophy of the standard	3.36	0.98	1
Material	3.30	0.89	2
Completeness of the standard	3.27	0.85	3
Construction method	3.21	0.87	4
Application conditions of the standard	3.16	0.86	5
Logical structure of the standard	3.16	0.84	6
Test method	3.13	0.88	7
Theory for calculation	3.10	0.94	8

The results in Table 2 show that the scores of all the aspects are above 3.0, indicating that there are significant differences between Chinese and foreign technical standards from all angles. Among them, *philosophy of the standard* is ranked first with a score of 3.36, and other aspects with relatively larger scores are *material, completeness of the standard* and *construction method*. Nonetheless, although *theory for calculation* ranks last among these 8 aspects, it still gets a score of 3.10, which must not be neglect.

4.3. TECHNICAL STANDARD DIFFERENCES RELATED PROBLEMS IN PROJECT IMPLEMENTATION

During the implementation of an international hydropower project constructed by Chinese contractors, different kinds of problems may occur due to the unfamiliarity with the differences between Chinese and foreign standards. 19 problems were selected and displayed for the respondents to rate on their occurrence frequency using Likert scale with 1= never happened and 5=usually happened. These problems were then classified into 5 kinds, shown as Table 3. The results are presented as below.

Table 3
Technical standard differences related problems in project implementation

Problems	Score	Rank	Cronbach'α
Standard management problems	**3.11**		**0.892**
Lacking well-rounded talents	3.46	1	
Incompletely understanding foreign standards	3.14	7	
Inadequate collection of foreign standards	3.02	10	
Barriers to learning foreign standards	3.01	11	
Poor translation of foreign standards	2.94	14	
Engineering-Procurement-Construction integrated management problems	**3.10**		**0.858**
Low coordination efficiency between design, procurement and construction	3.17	4	
Lacking incentives for design optimization	3.16	6	
Poor constructability of designs	2.96	13	
Design problems	**3.06**		**0.894**
Design's low approval rate from engineers	3.19	3	
Poor communication with engineers	3.17	5	
Design delay	3.12	8	
Uncompetitive design for bidding	2.99	12	
Design error or defect	2.83	18	
Procurement problems	**2.92**		**0.887**
Procurement scheme not cost-effective	3.03	9	
Unreasonable procurement scheme	2.87	16	
Improper selection of suppliers	2.86	17	
Construction problems	**2.89**		**0.933**
Construction cost increasing	3.30	2	
Construction delay	2.93	15	
Improper construction method	2.70	19	
Poor construction quality	2.64	20	

The reliability test shows that the value of Cronbach'α for all the 5 sorts of problems are larger than 0.85, indicating a good consistency for all the 5 sorts, hence the classification is reliable. The results shown in Table 3 reveals the following findings:

1. In general, *standard management problems* gets the highest score, reaching 3.11. It shows that integrated management in standard issues is a key to promote the ability of Chinese contractors;

2. *Engineering-Procurement-Construction integrated management problems* gets a high score of 3.10. Specifically, *low coordination efficiency between design, procurement and construction* gets 3.17, indicating the significance of interface management between design, procurement and construction.

3. *Design problems* scored 3.06, ranked third. Moreover, we can find that *low approval rate for design* and *poor communication with engineers* scored 3.19 and 3.17. These reveal that there is an urgent need to improve the design capability of Chinese contractors using foreign standards.

4. *Construction problems* scored 2.89 with the rank of 5, showing a good construction ability of Chinese contractors. Nevertheless, *construction costs increasing* got a 3.30 score, ranking second among all. This demonstrates that cost increasing due to unfamiliarity with the differences between Chinese and foreign standards is a critical issue that Chinese contractors need to deal with.

4.4. PROJECT PERFORMANCE

In order to understand the performance of an international hydropower project conducted by Chinese contractors, respondents were asked to rate the status of 11 indexes (see Table 4).

Table 4
Performance of international hydropower projects

Performance	Score	Std.	Rank
Safety	4.16	0.68	1
Client's satisfaction of the contractor's service	4.16	0.75	2
Corporate-Social-Responsibility (CSR)	4.15	0.72	3
Environment protection	4.14	0.72	4
Client's satisfaction of the product	4.11	0.72	5
Quality	4.07	0.76	6
Enhancing the brand effect	3.99	0.84	7
Occupational health	3.98	0.72	8
Time	3.82	0.88	9
Cost	3.66	0.78	10
Profitability	3.51	1.05	11

As shown in Table 4, Chinese contractors performed well in international hydropower projects, with all scores higher than 3.50, among which *safety* ranked first with a score of 4.16. In addition, the project's quality, time and cost performance ranked 6, 9 and 10 with scores of 4.07, 3.82 and 3.66 respectively, indicating that Chinese contractors’ time and cost control abilities have more room for improvement. Profitability got the lowest score of 3.51, which needs to be enhanced urgently.

4.5. IMPACT OF TECHNICAL STANDARD DIFFERENCES RELATED PROBLEMS ON PROJECT PERFORMANCE

Pearson correlation analysis was performed to reveal the relationships among the differences between technical standard differences related problems in project implementation and project performance, with the results shown in Table 5.

Table 5
Impact of technical standard differences related problems on project performance

	I	II	III	IV	V
Quality	-0.207*				
Cost	-0.296**	-0.292**	-0.214**	-0.167*	-0.229**
Time	-0.246**	-0.232**	-0.272**		
Client’s satisfaction of the contractor's service	-0.189*				
Profitability			-0.207*		-0.240**
Enhancing the brand effect					-0.212**

Note : I =Standard management problems; II =Engineering-Procurement-Construction integrated management problems; III=Design problems; IV=Procurement problems; V=Construction problems.

*=correlation is significant at the 0.05 level (two-tailed); **=correlation is significant at the 0.01 level.

As shown in Table 5, *quality, cost, time, client’s satisfaction of the contractor's service, profitability* and *enhancing the brand effect* have significant negative correlations with technical standard differences related problems. Specifically, cost performance is negatively correlated with *Standard management problems*, *Engineering-procurement-construction integrated management problems*, *design problems* and *construction problems* at 0.01 significance level, and negatively related to *procurement problems* at 0.05 significance level, indicating that technical standard differences related problems due to unfamiliarity with the differences between Chinese and foreign standards have a significant impact on the project cost performance.

Time performance is significantly correlated with *Standard management problems, engineering-procurement-construction integrated management problems* and *design problems*, which indicates that the key to improve time performance is to focus on these technical standard differences related problems. *Profitability* performance has a significant negative correlation with *design problems* and *construction problems*, showing that the impact of design and construction problems on the profitability of the project is of the utmost importance.

5. CONCLUSIONS

This study investigates the current status of applications of different standards in international hydropower project conducted by Chinese contractors and further reveals the impact of the differences between Chinese and foreign standards on developing international hydropower projects with the findings as follows:

- USA, ISO, Chinese and European technical standards have significance influence on international hydropower projects conducted by Chinese contractors, with ASTM most frequently used in international hydropower projects;
- *Philosophy of the standard* ranks first among 8 aspects of differences between Chinese and foreign standards. Other aspects with relatively larger scores are *material*, *completeness of the standard* and *construction method*;
- *Standard management problems* are most frequently occurred in implementation of an international hydropower project, indicating that integrated management in standard issues is a key to promote the ability of Chinese contractors;
- *Engineering-Procurement-Construction integrated management problems* also happen constantly, which reminds Chinese contractors to concentrate on interface management between design, procurement and construction;
- *Design problems* usually occur, showing that there is an urgent need to improve the design capability of Chinese contractors using foreign standards ;
- *Construction cost increasing* has a significant impact during project implementation, revealing that cost increasing due to unfamiliarity with the differences between Chinese and foreign standards is a critical issue in international hydropower project delivery;
- Technical standard differences related problems have a significant impact on project performance, especially on project cost and time performances. It is necessary for Chinese contractors to figure out the differences between Chinese and foreign standards in order to perform better and provide more cost-effective and environment-friendly hydropower projects worldwide.

6. ACKNOWLEDGEMENTS

Sincere thanks are given to the National Natural Science Foundation of China (Grant Nos. 51379104, 51579135，51079070), the State Key Laboratory of Hydroscience and Engineering (Grant Nos. 2015-KY-5，2013-KY-5) and Major Science and Technology Research Project of Power China (Grant Nos. DJ-ZDZX-2015-01-02, DJ-ZDZX-2015-01-07). Special thanks are also given to the respondents for their contributions during the survey.

1. INTRODUCTION

Due to a high number of new small hydro projects (SHP) in the last decade many cost-reducing innovations have been developed [1]. Still, the conduit system remains the most costly item in the SHP, representing 40 – 60% of the total investment cost. In the same period, electricity prices in Europe have dropped and further cost-saving innovations must be made to maintain SHP as one of the alternatives for feasible new renewable energy.

Today, the construction of buried penstocks is based on the principle of gravel/crushed rock as backfill, and anchoring of bends with concrete thrust blocks. With SHPs often located in remote areas without pre-existing connection to the main road network, the transportation of materials for penstock construction has to be carried out by constructing new access roads or by helicopter, which is both time consuming and costly.

Penstock BV (now VelociFoam Ltd) invented a method using polyurethane foam (PU-foam) as a replacement for gravel and rockfill. The PU-foam concept was presented internationally in 2017 in [2] after the commissioning of the first full scale penstock constructed using this concept. The project at Lille Måsevann was a development project; a brief program to study and follow up the quality and performance of the penstock was implemented. This paper describes the performance of the penstock in two full seasons of pumping. Since completion in November 2016 the penstock has performed perfectly well without any indication of unexpected behaviour.

2. THE PU-FOAM CONCEPT

The main motivation of the concept is to lower cost of buried penstocks with the same safety or better. Applied at straight sections of the penstock, the main purposes of the foam are:

- To provide mechanical protection of the pipe, against sharp edged gravel and stones
- To allow more native soil material to be used as backfill, reducing the amount of transported or locally-crushed gravel/aggregate and reducing the need to dispose of unused excavated material
- To increase the periphery towards the native soil material (normally not a critical condition)

In bend application, the function is different; the PU-foam act as a structure exposed to tensile stress and absorbs the hydraulic forces from the bend. In addition, the effect s of adjacent ‘straights sections’ are still taken into consideration as part of the bend system. This lower the costs of bends by eliminating the demand for expensive on site constructed concrete blocks.

Fig. 1
PU-foam used as backfill

3. PU-FOAM

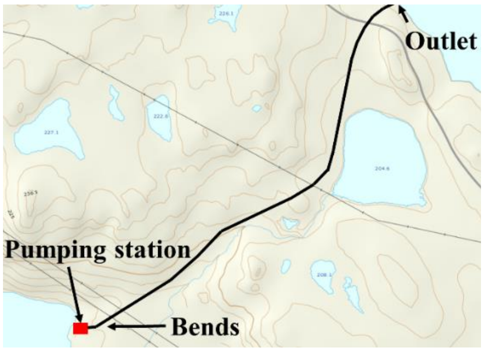
The quality and the performance of rigid closed-cell PU-foam for outdoor use is briefly described in [2]. The foam typically expands up to 30 times, and is 70 % cured 10 minutes after the initial reaction, although the reaction profile can be controlled by manipulation of pressure and heat. In order for the foam to expand, a blowing-agent is needed. The most commonly used blowing-agent is water – an eco-friendly blowing-agent where no harmful gasses are released into the atmosphere.

Rigid closed-cell PU-foam is normally divided into two categories; ‘pour foam’ and ‘spray foam’. The main difference between the types is the proportion of mixing between the components and the way they are applied to the object. For experimental purposes and to optimize the total concept of anchoring of penstocks by PU-foam both methods have been fully tested in lab and in the field. Both the behavior of the foam and the procedure for application is very different and requires two very different set of equipment and set-up of the working teams. The experience from both quality and speed of construction will be discussed in later parts of the article.

No prior findings indicate that the foam, after curing, has a negative effect on the environment [4]. Cured foam is considered ‘inert’ and does not react easily with other substances in any natural environment. During application of the foam, health and safety measures need to be met. This certificate information has not been possible to verify during the rather short available lifetime of this specific penstock.

4. THE PENSTOCK AT LILLE MÅSEVANN

The penstock at Lille Måsevann is the first of its kind that uses PU-foam as backfill at parts of the penstock. Lille Måsevann is a pumping station for lifting water with maximum discharge 1,4 m^3/s from Lille Måsevann reservoir up to Store Måsevann reservoir. The water is further used in the 50 MW Adamselv hydropower project and increases the annual energy output with 7 GWh. Construction took place during the summer and fall of 2016 and were commissioned by a start-up and sudden shut down at the 24. November 2016, see Figure 6. The pumping station conduit consists of an 1130 m long, buried DN800 and 900 GRP pipe. Approximately 1/3 of the total length, including two bends, was covered by foam. A map showing the penstock alignment can be seen in Figure 2a. On the same Figure 2b, the penstock both with and without PU-foam is shown, before application with gravel.



a)

b)

Fig. 2

a) Map of the penstock alignment b) The penstock at Lille Måsevann (from west)

Three different methods were used to apply the foam to the penstock; 'Open formwork' (Figure 3a), 'Closed formwork' (Figure 3b) and 'Spray application' (Figure 3c).

Both methods using formwork is developed for 'pour foam' material. The open formwork application gave dry conditions in the formwork and controllable curing conditions see Figure 3. The closed formwork application is a better concept on the way to automatize the construction process but there is still large challenges to overcome about the quality, see Figure 3. The direct spray application is a manual based process with limited speed of construction but with very good conditions to control the curing and the quality of the foam.

a) b)

c)

Fig. 3

Different methods for foam application a) Open formwork with roof to protect against rain b) Closed formwork to be placed around the penstock c) Spray-foam is applied to the pipe, two persons are required as work force

As in many development projects the progress and quality were not uniform. The foam produced at the start of the project showed greater property deviation compared to the final product. The method with direct application to the pipe provides for the best progress and predictability in the project. Besides, research by [3] indicate that spray-foam end up with better mechanical properties and density than pour-foam.

5. ANCHORING OF BENDS

The penstock at Lille Måsevann includes two 15° bends which were constructed without any concrete or rock bolt measures. Static head acting on the bends are 44 mWC. Both bends were anchored using 300 mm of spray-foam with spray application. The bends were anchored to the gravel bed by a combination of the gravity of the penstock system and the resulting ''locking' interaction between the foam and the gravel.

a)

b)

Fig. 4
a) Application of foam at the bend b) The bend after removal of the tent

To monitor displacement over time, four displacement transducers were installed at one of the bends, described in [5]. The type of equipment used was WA Inductive displacement transducers with a measuring range of 20 mm. The measuring Is based on the differential inductor principle with an inductive quarter bridge. The system is highly accurate to 0,2% of the measuring length, in this case 0,04 mm. The deformations can be monitored in real-time inside the pumping station. Figure 5 shows which direction the plunger is extended. The axial deformations in the direction is given as decreasing values in the graph Figure 6.

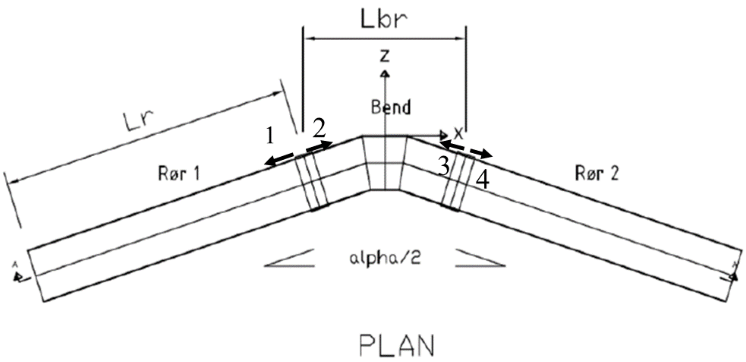


Fig. 5
Placement and measured direction of the displacement transducers

Two full seasons with pumping have been experienced at the time of this presentation. Figure 6 shows measurements conducted 28.04.17, during first filling of the penstock. The displacement transducer's position is given on the left axis, and water pressure (black line) is given on the right axis.

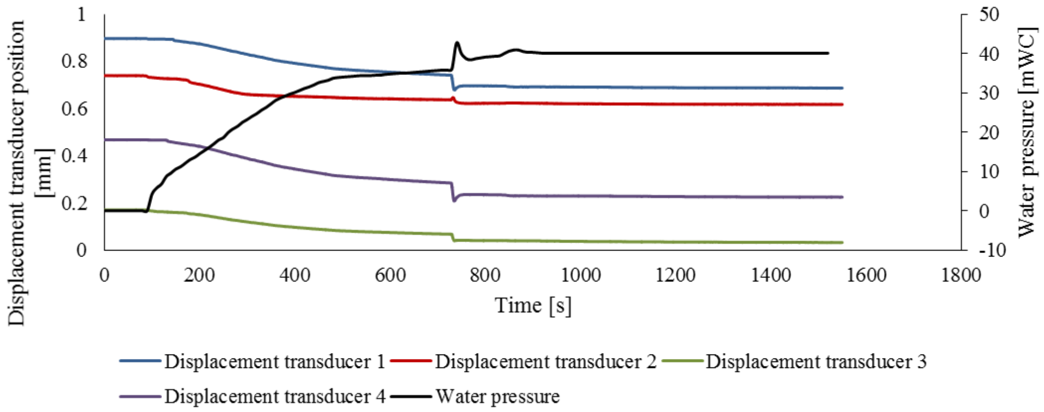

Fig. 6
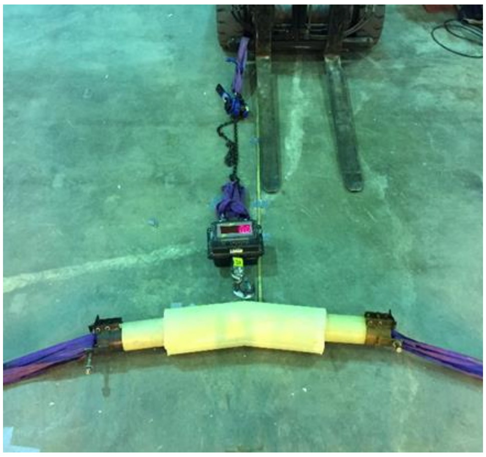
Deformation measurements at Lille Måsevann, 28.04.17

The results shows that the bend has very small deformation in the pipes axial direction (~0.2 mm). The small deformation can indicate that the forces are distributed as a combination of compression and tension in the foam. The measurements confirm that the foam distributes a fraction of the hydraulic forces as tensile stress in the pipe axial direction. No measurement of foam compression deformation in force resultant direction was carried out.

In addition, deformation and angle deflection in the pipe joints had to be verified within the engineering requirements set by the regulator. Deformation calculation was carried out, stiffness of foam, backfill and in situ soil was taken into account. As a conservative approach for first time use in penstock, tensile restraining capacity was not included. Further, a scale test rig was set up at NTNU the spring of 2016, to investigate the capacity of bends anchored with PU foam. The scale test rig is shown in Figure 7a.



a)

b)

Fig. 7
a) Setup of the bend test rig b) Bend in full scale

The test rig was set up without a bend coupling to ensure that all forces acting on the bend was distributed in the foam. A concentrated load was set up directly in the bend with a metal hook inserted in the pipes to simulate forces from internal pressure in the pipe. Test results indicate that the capacity of the foam increases with larger cross-sections and increased bend angle. For instance, the test with foam thickness of 40 mm at 30° bend had an ultimate bend load of 1 kN corresponding to 19 mWC internal pressure. The idealised distribution of the forces in the foam in the test is not possible to verify exactly by the full-scale monitoring program. In the field distribution of forces in the bend will not only occur in the foam; the surrounding masses, bend coupling and interface layer between the foam and drainage layer will also absorb the forces. This is the main explanation of the large difference in displacement between laboratory and field results; the field displacements are much lower than predicted, according to the conservative calculation model, which is a result of not taking the full set of stabilizing factors into account.

6. VIBRATIONS IN THE PENSTOCK

Vibrations from the rotating runner propagate along the penstock. This was recognized even the first hour of operation in November 2016 for a long distance upstream of the pumping station. Both sound and remarkable vibrations on the frozen ground were recognized. The frequency in the vibration corresponded with the rotational speed of the runner. This could easily be proved, because the unit was operated by the frequency controller on several different rpm's. The runner is an asymmetric 'pump wheel' which introduce significant but predicted vibrations in the unit. The test program in the lab in 2015, 2016 and 2017 didn't include yield tests for the foam and it's not clear how this may will influence the long-term quality of the anchoring. The effect of the foam layer on the pipe is to attenuate the energy propagating from the runner through the water mass, by reducing amplitude and dissipating the energy as heat. The energy absorbed in this dampening effect would otherwise be transmitted from pipe surface to granular backfill in a classic system, with the attendant risk of damage of the pipe surface from sharp stones edges. Absorption of acoustic wave energy in foam is a well-understood phenomenon. The full set of mechanical interactions between pipe, pipe bend and surrounding PU-foam and soil masses are not yet fully understood or modelled, but this is an objective of further research, both in academic and operational settings.

The long term behavior of the foam in frozen soil is still based on the results from the lab tests. Samples may subsequently be extracted from the foam in the field and tested. This will verify the extent to which foam in the field is sensitive to the freeze-thaw processes. How any variations in mechanical properties due to freeze-thaw cycle affect system performance can only be established by pushing comparative samples to failure, which is not possible in the field.

7. CONCLUSIONS FROM OPERATION

At Lille Måsevann 300 m of buried penstock was enveloped in foam, including two bends. The commissioning of Lille Måsevann penstock proves that the method with PU-foam as backfill works on a full-scale project, both for construction and operation.

The PU-foam absorbs water at varying rates, but tests in the frost laboratory indicate very little influence on the strength. Long term deformations in the bends shows no development, while displacements are followed closely by the monitoring program.

PU-foam as backfill and for anchoring of bends is a promising alternative to the traditional method. However, to obtain desired quality and safety, precautions on-site needs to be met. As such a strict quality test program must be followed to verify the statement in a longer term perspective.

ACKNOWLEDGEMENTS

The authors like to acknowledge Nina Johnsen for contribution to this article and ENOVA for financial support to make this project possible.

SUMMARY

Today the most commonly used backfill for penstocks for small hydro are gravel and rockfill, which is time consuming and costly due to transportation. Penstock BV with Guy Harris developed a method with polyurethane foam as a replacement for gravel and rockfill which may lead to lower investment costs and reduced construction time. NTNU made the required initial laboratory tests in 2015 and Statkraft AS initiated a research project to verify the method in 2016. The project involves the construction of Lille Måsevann Pump with a buried penstock connecting Lille Måsevann to Store Måsevann – the intake reservoir for Adamselv hydropower plant. Lille Måsevann Pump is the first of its kind where sections of the penstock, including two bends, are enveloped in polyurethane foam (PU foam). Previously only scale tests have been carried out.The full-scale project is located in Finnmark County, Norway, and the construction work was done the summer of 2016. By the summer 2018 this DN800/900 mm penstock have experienced two years of operation. Monitoring of elastic and non-elastic displacement of the bends proves the behavior during start/stops and other dynamic load situations. Out of the total length (1130 m) approximately 300 m were anchored by in foam.

The experiences made from both construction and two years of operation at Lille Måsevann Pump has acquired new knowledge to the subject. The behavior of the penstock is without any kind of unexpected observations and the penstock performance is as for other penstocks constructed in traditional ways.

DESIGN OF AERATOR FOR ORIFICE SPILLWAY

Balkrishna Shankar CHAVAN.
Scientist-D, Central Water and Power Research Station, Pune
India.

1 INTRODUCTION

Orifice spillways combine the advantages of greater depth of flow over the crest and moderately sized gates – an arrangement made possible by inclusion of a breast wall. An orifice spillway would allow the setting of its crest at significantly lower elevation, yet retaining the choice of a high dam for creating head for power generation. The main advantages of orifice spillway are: Reduction in height of the spillway gates, reduction in number of spillway spans, ease in regulating flood discharge and storage, reduction in the cost of gates and operating mechanism.

ORIFICE SPILLWAY BREAST WALL Breastwall / sluice spillways have been widely recognized as the most appropriate especially for run-off river projects for handling both flood releases and flushing of sediment. Generally, two configurations of the breast walls are provided on a high head spillway. In one of the alternatives, bottom profile of the breast wall starts from the upstream face of the over flow spillway crest. In other alternative the bottom profile of the breast wall starts at an intermediate location on the spillway pier. In the latter, the breast wall facilitates provision of stoplog gate groove upstream of crest axis, whereas in the former arrangement, the stop log groove has to be provided through the body of the breast wall and is not desirable because of the high velocity flow or the stoplog gate groove has to be provided upstream of the spillway face by providing cantilever structure.

The bottom profile of the breast wall starts at an intermediate location on the spillway pier, the breast wall facilitates provision of stoplog gate groove upstream of crest axis, whereas in the former arrangement, the stop log groove has to be provided through the body of the breast wall and is not desirable because of the high velocity flow or the stoplog gate groove has to be provided upstream of the spillway face by providing cantilever structure.

Sluices are essentially large capacity outlets placed in the body of the dam and controlled by gates.

The following parameters are required to be determined for the orifice spillway :

a) Bottom profile of the spillway crest including the upstream and downstream quadrants
b) Roof profile of the breastwall or sluice barrel
c) Estimation of discharge characteristics of the spillway
d) Size and dimensions of the orifice spillway and its disposition with respect to power intakes
e) Structural design considerations and Protection of the spillway surface to resist abrasion
f) Special considerations for energy dissipater.

2.DESIGN OF SPILLWAY CREST PROFILE

The hydraulics of orifice spillway changes with the varying reservoir levels. The flow is free flow for reservoir water levels below the top of the roof of the sluice. For higher water levels the flow is orifice flow. The crest profile is required to be designed for orifice (pressurized) flow. The spillway crest profile is flat as compared to the standard WES crest profile to avoid separation and negative pressures on the crest for small partial gate openings. The crest profile follows the equation x2 = 4 H y. where H is the head over the centreline of the orifice. Design of Roof Profile of Breastwall / Sluice Spillway

Hydraulic design of roof profile of breast wall is very important, because the bottom profile of the breast wall guides the flow smoothly. This governs the coefficient of discharge of the spillway. This profile should be simple to construct and the pressures on the profile should not be excessively negative. Usually, a profile in the form of quarter of an ellipse in provided bearing the equation

$$\frac{x^2}{a^2} + \frac{y^2}{b^2} = 1$$,

where

. a = width of semi-major axis i.e. the width of breast wall,

b = width of semi-minor axis which governs the steepness of the profile.

Figure 1 shows the setup constructed for testing of spillway profile and aerator.

Figure1. Model set up for measurement of air concentration in an orifice spillway overflow

Usually steep profiles yield increased coefficient of discharge, whereas flat profiles tend to reduce the discharging capacity. However, negative pressures increase as the profile becomes steep. High negative pressures with cavitation index below 0.2 are undesirable. The bottom profiles of breast wall are usually steel lined to avoid cavitation damage.

Discharge Characteristics of the Orifice Spillway

The spillway operates as free overflow spillway for lower discharges whereas for higher discharges effect of breast wall comes into play and flow through the spillway is governed by the orifice flow. Generally, the orifice flow condition sets in for heads over crest in excess of about 1.5 to1.7 D, where D is the height of the orifice opening.

For free flow conditions the discharge is given by

$$Q = \frac{2}{3}\sqrt{2g}\ cd.\ LH^{3/2}$$

when Q = discharge in cumec

Cd = coefficient of discharge

L = length of spillway in m

H = head over the crest in m

For orifice flow,

$$Q = C_d . n.A. \sqrt{2g\left(H - H_m\right)}$$

Q = discharge in cumec

Cd = coefficient of discharge

n = number of span

A = area of orifice in m2 = L x D

H - Hm = head over the center line of orifice

The coefficient of discharge is influenced by the entrance profile – composed by root profile or the bottom profile of the breast wall, spillway crest profile, side wall profiles if provided, inclination of the orifice barrel with reference to horizontal. The coefficient of discharge for the orifice flow is in the range of 0.75 to 0.95. Figure 2 shows a typical discharging capacity curve. Unlike ogee spillways, the design of breast wall spillways has not been standardized. Therefore, a recourse is taken to study the existing structures, while designing a new project.

3. Size and Dimensions of the Orifice Spillway and its Disposition with respect to Power Intakes

In the past, flushing used to be carried out by providing small sluices (of the size of 3 m x 4 m or so) at very low level. However, it was realized that these sluices were effective only locally. Also, there was a tendency of choking of sluices within a short period. Large openings of the size of [6-10 m (w) x 10 m x 15 (H)] are required to be located 30-40 m (w) below the full reservoir water level for flushing of the reservoir. This results in high velocities of the order of 20-25 m/s over the spillway crest corresponding to discharge intensity of the order of 200-250 cumec /m.

Structural design Considerations and Protection of Spillway Surface to resist Abrasion

3.1 Breastwall spillways necessitate some special design considerations. Breastwalls have to bear the upstream water head with beams or slabs spanning between and fixed with two piers. As such, the breastwall and both the piers have to be constructed as a single structural unit. The construction joint is, therefore, provided at the center of each pier, except the end piers. Thus, a single pier is virtually a combination of two full piers separated by a construction joint, and a typical spillway monolith is composed of two piers and breast wall. In a standard overflow spillway without breast wall, construction joints are provided at the center of the monolith. Special care is also required in respect to the top seal of the radial gate in ensuring water tightness.

3.2 The larger velocities associated with the high heads may increase the potential for cavitation and erosion damage to the structure. Adequate protection measures should be taken during the construction of the sluice barrel and breastwall spillway, to withstand the erosive power of the silt laden water while flushing the reservoir and flood routing, by way of special type of concreting (poly impregnated concrete) or providing steel lining along the discharge channel of the spillway.

4 Special Considerations for Energy Dissipator

Special considerations are required for design of suitable energy dissipator, since the spillway has to surpass both the flood and the sediment. Ski-jump bucket is found to be the most suitable form of energy dissipator because of its obvious advantage during flushing operation. The sediment passes down the spillway with supercritical flow without deposition and churning in the bucket. Fortunately, steep bed slopes of the rivers result in low tail water depth permitting this type of energy dissipator. If the geological conditions are not favourable, a hydraulic jump stilling basin may have to be adopted. Because of the requirement of passing silt-laden flows, use of energy dissipating appurtenances like chute and baffle blocks is not advisable. The resulting basin is excessively long and often deep-seated below the general river bed, making it vulnerable to deposition by silt during flushing operation. A trade-off is desirable between the hydraulic efficiency of energy dissipation and the self-cleansing potential of the stilling basin during flushing operation. Cylindrical end - sills are generally preferred for easy movement of sediment out of the basin. A concrete apron downstream of the end sill is required to protect the spillway against undermining due to scour during transition action from hydraulic jump to flip action and vice versa. Provision of roller bucket is generally avoided as an energy dissipator due to likelihood of abrasion damage of the bucket due to churning of sediment. The flow surfaces of spillway and energy dissipater suffer abrasion damage due to passing of sediment laden flow. Adequate care should be taken in the structural design.

5.0 **Data Acquisition System**-Industrial PC based multifunction Data Acquisition System consists of Kulite make pressure transducers 20 Nos. of +/- 2 &+/- 5 psi range, Aplab make linear power supply for pressure transducer excitation, PCI-6143 DAQ -2 Nos. , BNC-2110 analog input board - 2 Nos, air vent tube, 4-core shielded cable, Data Cables-2 Nos, Industrial PC having 2 GB RAM, 200 GB Hard Disc Drive, Core 2 Duo processor with LG make 17" LCD display. Application software is based on Labview 8X platform for data acquisition, monitoring & reporting. Data Acquisition System (DAS) can collect data samples at a rate of 10,000 samples per second per channel for 10 channels continuously for 30 minutes. Pressure transducer works on the principle of piezoresistive technology. It converts applied hydraulic pressure into an electrical signal using diaphragm as a pressure sensing element. Miniature ruggedized pressure transducers of size 4mm diameter having 0.15mm diameter holes positioned on a circle are used. Resonance frequency of the sensor is 160KHz. Analog to Digital Converter has a resolution of 1 part in 65536. The accuracy of the ADC is 0.01%, taking care of A/D nonlinearity, amplifier non linearity, gain, offset errors, drift and noise. Facility of simultaneously viewing and analyzing experimental data in digital and analog form

6. MODEL STUDIES FOR AERATOR OF ORIFICE SPILLWAY- DESIGN TESTING. Preventive measures such as control by geometry, smoothness of surface, use of cavitation resistant materials etc. are expensive and labour intensive.Aeration on the spillway surface is one of the most reliable and economic measures used at present for mitigating cavitation damage.Aerator is a device that deliberately causes a large cavity to be formed underside of a high velocity jet.

The void created is a negative pressure region relative to atmospheric pressure.

Air is drawn into the void when a vent is connected

Performance of aerator on orifice spillway was assessed based on following aspects:

- General flow conditions
- Length of trajectory
- Pressure field around aerator and in cavity below jet
- Air entrained by aerator
- Air concentration downstream of aerator

Jet Length $\lambda = L / d_0$

λ = non dimensional jet length

L = length of the jet in m

d_0 = incoming depth of water at aerator in m

- Cavity Pressure $P_n = \Delta p / \rho g d_0$

  Pn = non dimensional cavity pressure

  Δp = cavity pressure in Pascal

  ρ = density of water in kg/m3

  d0 = incoming depth of water at aerator in m
- Air Entrainment Coefficient $ß = Qa/Qw$

  ß = air entrainment coefficient

  Qa = air discharge m3/sec

  Qw = water discharge m3/sec
- Three alternatives of spillway profiles
  - Profile conforming to x2= 220y (Subansiri spillway)

  (slope varying between 100 and 200)
  - Slope 150
  - Slope 200
  - Two alternatives of aerator
  - No ramp and;
  - 3^0 ramp

– Precise mechanism by which small air concentration protects concrete surface is unclear, however it decreases the velocity of compression wave and hence any shock pressure.

– For zero air concentration this velocity is 1470 m/s, but for C=10% this velocity is approximately 50 m/s.

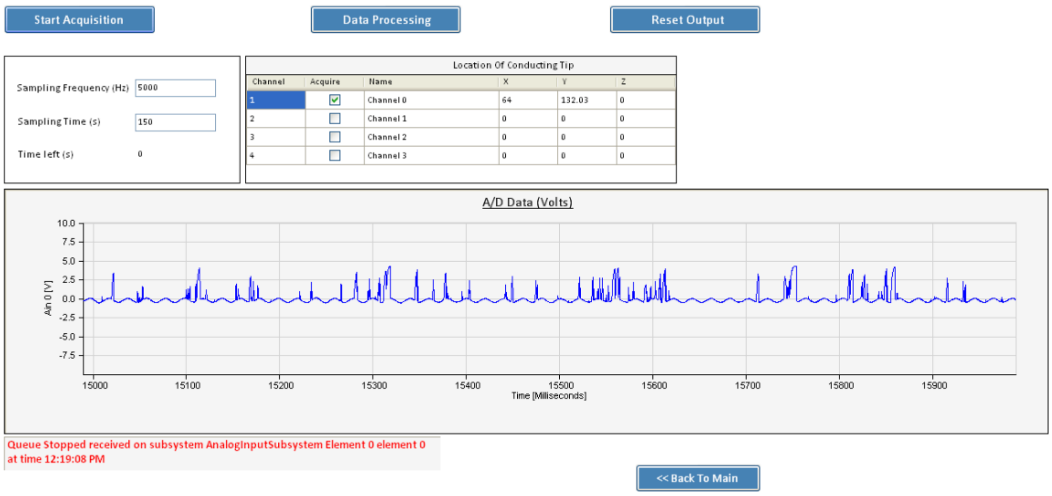

Figure2. Typical air concentration measurement output.

is available. During the data acquisition elapsed time, channel details , its configuration and hydraulic parameters with respect to time can be viewed. For system calibration special water column of height 3.75m was fabricated. This system was calibrated & tested on hydraulic model for obtaining experimental data.. Analysis of experimental data collected from model was done to obtain values of maximum, minimum, mean, standard deviation, turbulence intensity, no. of zero crossings, skewness, kurtosis, and stationarity test. In addition FFT analysis, Probability Density Function, Cumulative Distribution Function, Auto correlation, Cross correlation can be performed.

- Advanced DIAdem computing software is installed in the system to overcome the limitation of the excel file format which can store only 60.053 data points. DIAdem is an interactive tool for mathematics and visual data analysis and report generation. It is used to abstract necessary information from experimental data in order to make technical decisions.

7. SALIENT FEATURES OF ORIFICE SPILLWAY OF SUBANSIRI PROJECT

- Maximum design discharge 35000 m3/s , q = 338 m3/s/m
- Head over orifice spillway crest = 60 m
- Velocity =25 to 30 m/s
- Spillway profile equation x2 = 220 y, Spillway length 88 m
- Energy dissipator ski jump bucket
- Positive pressures on the surface of spillway for ungated operation
- Negative pressures of - 1.0 m to - 3.0 m with partial gate operation
- Cavitation index for negative pressures between 0.16 and 0.13 which was lower than critical cavitation index of 0.2

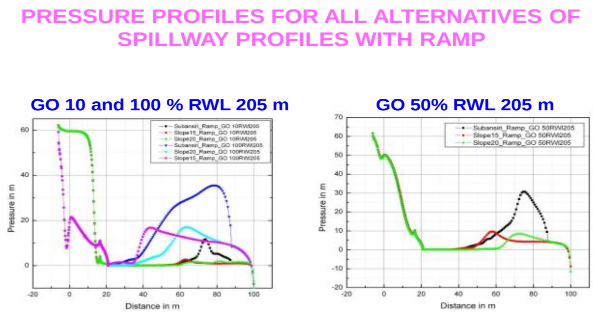

Figure 3. Typical pressure measurement on orifice spillway

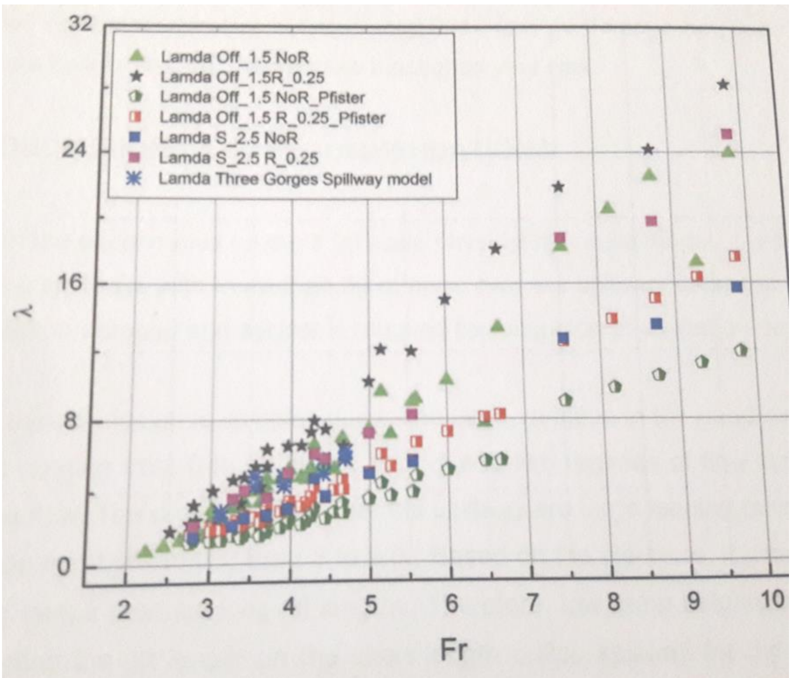

Figure 4. Plot of Froude Number and Jet length

Following ideas were gathered and research gaps identified:

- Various design approaches proposed by IAHR, ICOLD and USBR are for overflow spillways with steep slopes
  - Scanty data is available for spillway slopes<300
  - Large ramp angles 7-110 are not studied
- Recently, Pfister and Hager (2010a and b) published the research work on flat slope overflow spillway with steep ramps
- No systematic research work is reported for aerator on orifice spillway Orifice spillways with more than 50 m head over crest are susceptible to cavitation damage and aerator is required for mitigation of cavitation damage

- Aerator design is complex due to large variation in the head over spillway crest and also due to two regimes of flow viz. free flow and orifice flow
- Low ramp heights are preferred for restricting jet length on short length orifice spillway
- Jet action does not start up to a head of 17 m above the orifice spillway crest. Cavitation index is much above the critical cavitation index of 0.2. Therefore, there is no danger of the aerator inducing cavitation
- Jet reattachment point is farthest for lowest gate opening and decreases for increasing gate openings for a given reservoir water level
- Jet length and air entrainment increase with increase in air vent size till the cavity pressure reaches near atmospheric
- Non dimensional pressure in the cavity below jet decreases with increase in Froude number
- Air entrainment coefficient ß decreases with increase in gate opening
- Addition of ramp enhances performance of aerator
- Flow is fully aerated across the depth and air concentration is found in the range of 30 to 50% for low gate openings.
- Clear water core appears in the central portion of the jet between upper and lower nappe aeration with increase in gate opening and the air concentration along the spillway surface decreases
- Physical model studies provided a good first hand information and insight in the hydrodynamic characteristics of aerator on orifice spillway
- Comparison of present study with aerator on flat slope overflow spillway revealed that characteristics of aerator on flat slope orifice spillway are totally different
- Philosophy of the functioning of aerator on orifice spillway is different than the aerator on flat slope overflow spillway
- Jet is lifted from the spillway floor in the area susceptible for cavitation damage. Smaller quantity of air induced by flat ramp remains in the flow till the end of short spillway length and is sufficient to mitigate cavitation damage

SUMMARY

Recent trends in run of the river projects involves high intensity discharge and high heads. Such situation leads to pressures on the surface of spillway to drop below atmospheric leading to cavitation damages. To mitigate cavitations damage, measures such as control of geometry, smoothness of the spillway surface, use of cavitation resistant materials are adopted. There are limitations for adopting preventive measures. Provision of aerator only alternative to mitigate cavitations damage. There are various methods to measure air concentration in a spillway overflow flow . Most reliable being intrusive phase detection probes, like optical probe and resistivity probes. Present study employs use of resistivity probes along with PC based Data Acquisition System (DAS) to measure air concentration in a spillway over flow downstream of aerators. Two locations were selected to measure the air concentration. Two alternatives with offset of 1.5m and 2.5m namely without ramp and with ramp upstream of aerator were studied in the model. Comparison of various alternatives are presented in a table using non dimensional parameters jet length λ, air entrainment coefficient β, cavity pressure. Model study indicated that provision of ramp increases the air entrainment. Air concentration along the bed is more for small gate openings and decreases drastically in the vicinity of 2-3% for decreasing Froude number. Flow depth is fully aerated for small gate openings. β decreases with increase in gate openings. Addition of ramp improved pressures in aerator, jet length increases with addition of ramp. Study also proved that functioning of an aerator on the orifice spillway is different from the flat slope chute spillway. Spillway surfaces of high dams are susceptible to cavitation damage due to high velocities, surface roughness and geometrical deformities.

1. INTRODUCTION

A new steel lined pressure shaft was constructed for the existing Kaunertal high head hydro-power plant in the years 2012 to 2015. The project included the construction of a 1430 m long 4.3 m diameter inclined pressure shaft, a 325 m long penstock tunnel section, a new surge tank consisting of two chambers connected by a 150 m deep vertical surge shaft [1].

Before starting operation, initial filling tests were carried out in particular to investigate the stress and strain distribution of the steel penstock. Each test consisted of two loading and unloading cycles of the new facilities. The first fill-test was carried out before the interface between steel lining and backfill concrete was grouted. The second fill-test started after interface grouting was completed. This rather lengthy testing procedure should primarily facilitate the grouting. The rock mass / steel lining response to loading and unloading of the shaft and eventual benefits gained from interface grouting were recorded with optical strain gauges spot-welded to the steel lining.

The axial force in the pipe due to internal pressure acting on the end cover of the pipe is necessarily transferred via friction into the rock mass embedding the penstock. Based on strain measurements at several pipe sections the distribution of the axial forces was studied in detail.

In particular the following scope was investigated

- Adequacy of assumptions in the structural analysis
- Back-analysis of rock modulus "V_F" and thermal gap "u_0"
  (Reduction of pipe stresses in circumferential direction)
- Behavior of the shaft lining in case of several loading and unloading cycles
- Isotropic / anisotropic rock mass reaction
- Distribution of strains at transitions of embedded to the exposed penstock
- Redistribution of internal (cover-) pressure into the rock mass

2. STRAIN MEASUREMENT

2.1. MONITORING ARRANGEMENT

Monitoring sections were situated at various locations along the alignment. Eight sections "A" aiming to monitor a standard shaft section in varying geologic conditions and three locations "B" aiming to monitor the lining behavior at transitions into the rock mass were installed (Fig. 1).

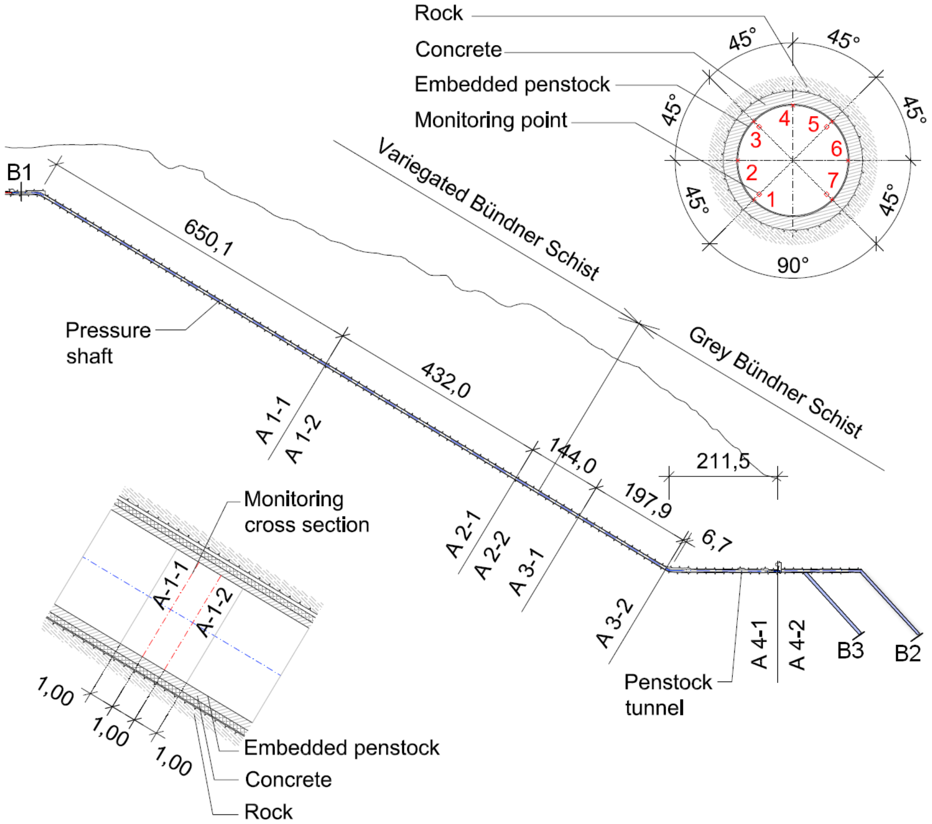

Fig. 1
Monitoring cross sections "A" and locations "B"

Monitoring cross section “A” arrangements (Fig. 1) consisted of two identical monitoring cross sections at a distance of 1.0 m to cover redundancy (e.g. A1-1 and A1-2). Each monitoring cross section included seven monitoring points around the circumference to measure circumferential strains at 45° angles. Every second monitoring point was also fitted with a longitudinal strain gauge to measure in addition the longitudinal stress behavior of the steel lining. For practical reasons no strain gauges were installed in the invert of the lining (see Fig. 1, danger of damage).

Each monitoring location “B” arrangement was fitted with strain gauges inside the pipe at an angle of 45° left and right of the center line in the invert of the steel lining. Six monitoring cross sections were placed near each transition of embedded to exposed penstock. Spacing of monitoring cross sections was selected to take measurements approx. 10 m deep into the rock mass along the penstock axis. At one monitoring location “B3” (Fig. 2) additional strain gauges were mounted on the outside of the pipe before it was embedded in concrete. For monitoring the outside of the steel pipe electrical strain gauges were used.

Due to long distances (up to 700 meters) between monitoring cross sections, the feedthrough traversing the penstock lining and the long monitoring period, standard electrical strain gauges could not be used inside the penstock. Optical strain gauges were applied instead. The optical sensors were mounted on thin metal strips which were spot welded onto the lining. The spot weld points were grinded and tested after removal of the strain gauges to exclude damages to the pipe surface.

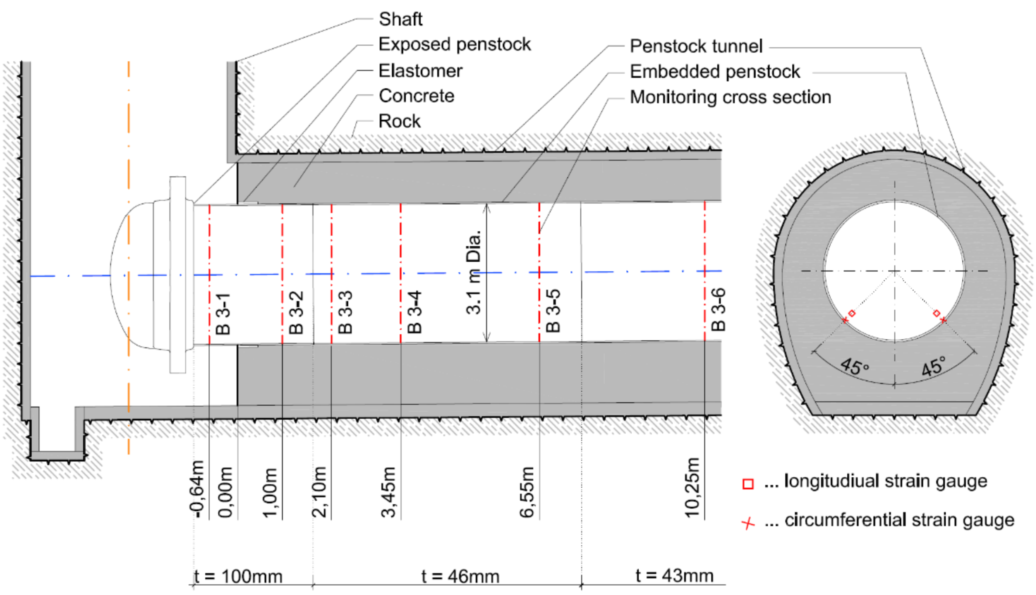

Fig. 2
Monitoring cross section “B” at pipe transition into the rock mass [2]

2.2. Measuring principle of optical sensors

Optical strain sensors use light with the initial Bragg-wavelength (λ_0), which is reflected by a grating. The wavelength is measured by an interrogator. Strains applied to a Fibre Bragg Grating (FBG) increases/decreases the distance between the “mirrors” of the grating. This shifts the Bragg-wavelength of reflected light, dependent on the compression or tension and length. The Bragg-wavelength shift ($\Delta\lambda$) on a FBG subjected to strain is dependent in a linear way on the applied strain [3].

$$\Delta\varepsilon = \frac{\Delta\lambda}{k \cdot \lambda_0} = \Delta\lambda \cdot S$$	$\Delta\varepsilon$	… measured strain [µm/m]
	k	… gauge factor [-]
	S	… strain sensitivity [µm/m/nm]

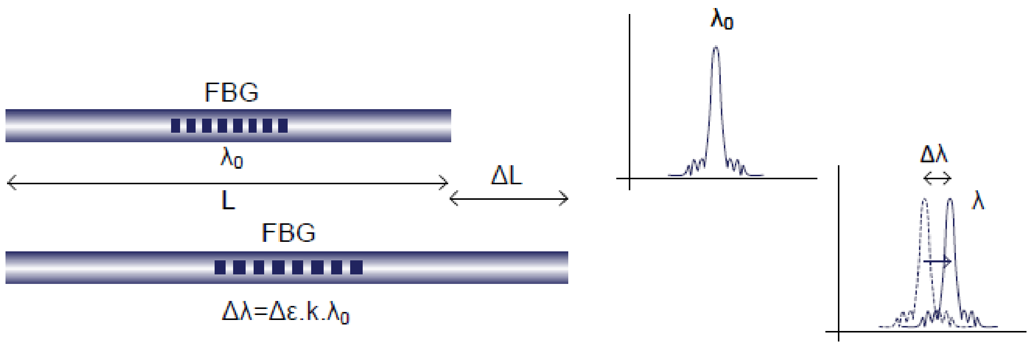

Fig. 3
Measuring principle of optical sensors using FBG [3]

The FBG is “written” into a single-mode optical fiber by activation of Germanium dopings or by inscription of morphological defects into the fiber core with high level energy lasers [4]. The advantages of the FBG technology as compared to standard electrical strain gauges are:

- Application of up to 20 sensors in one measurement chain
- Possible length of measurement chains up to several kilometers
- Redundancy when providing a measurement loop
- No destruction of FBGs due to high water pressure
- Small number and diameter of cables permit small feed-through
- Linear correlation between applied strain and measurement unit
- No danger from humidity (no short circuit, no electrical issues)

As shown in Figure 4 a typical measurement chain consists of a connection fiber which may be as long as required. At the end it is spliced with the sensor fiber which is up to 200 meters long. Up to 20 FBGs with different nominal wavelengths are provided in one measurement chain. The total amount of damping loss in the measurement chain has to be smaller than the value allowed by the interrogator. Finally the emitted light reflects at each FBG and the wavelength of the reflection is measured by the interrogator $\Delta\lambda_1$.

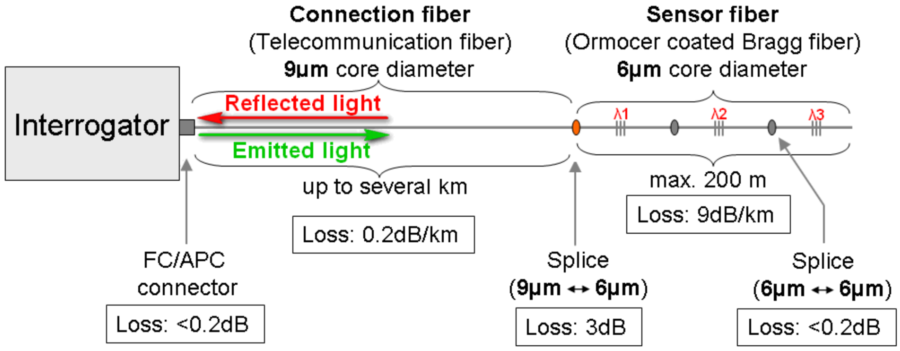

Fig. 4
Typical measurement chain with several FBGs

3. INITIAL FILL-TESTS AND RESULTS

3.1. PENSTOCK BEHAVIOR

In June 2015 the new shaft was filled for the first time and measurement results recorded for this Fill test 1 (FT 1). A pressure of 88 bar was reached at the shaft bottom after three days of filling and held for another three days until the facility was emptied again (Fig. 5).

After a waiting time of approx. one day the shaft was filled again and emptied. At first loading the measured strains at sections “A” were already close to values predicted in the analysis (Fig. 6). Compared to the calculated strains without any rock support, substantial interaction between rock mass and steel lining could be registered even not any interface grouting had taken place. On average the internal pressure was shared half and half between the steel lining and the rock mass. When emptying the facility for the first time the reduction of the shaft diameter due to pressure decrease and temperature effects resulted in a “thermal gap” between steel pipe and backfill concrete. A sudden release of pipe friction along a substantial length of the shaft was the consequence and longitudinal movements associated with substantial negative strains could be measured (e.g. Fig. 7, First Fill-Test (FT 1) at 25-20 bar).

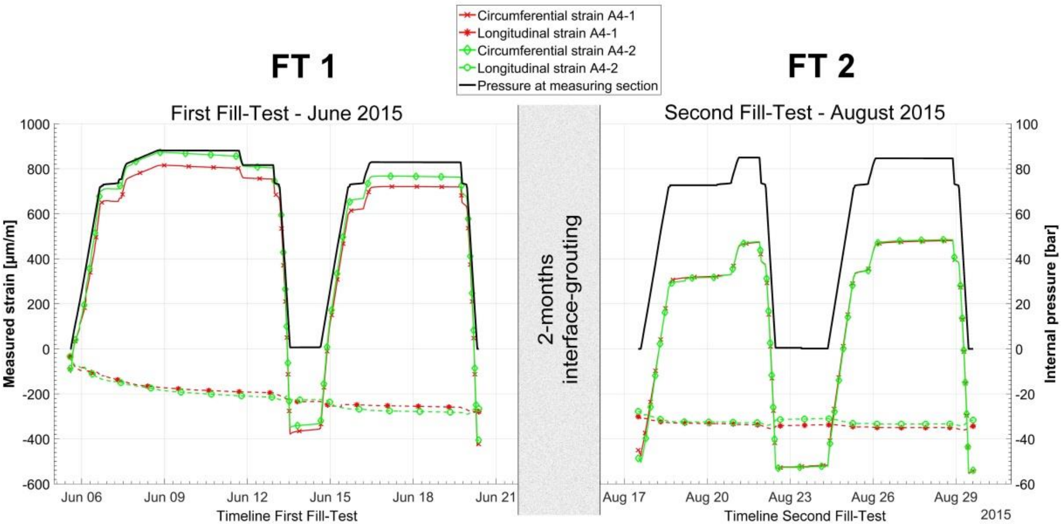

Fig. 5
Measured strains at sections A4-1 und A4-2 for both Fill-Tests (FT1 and FT2) [2]

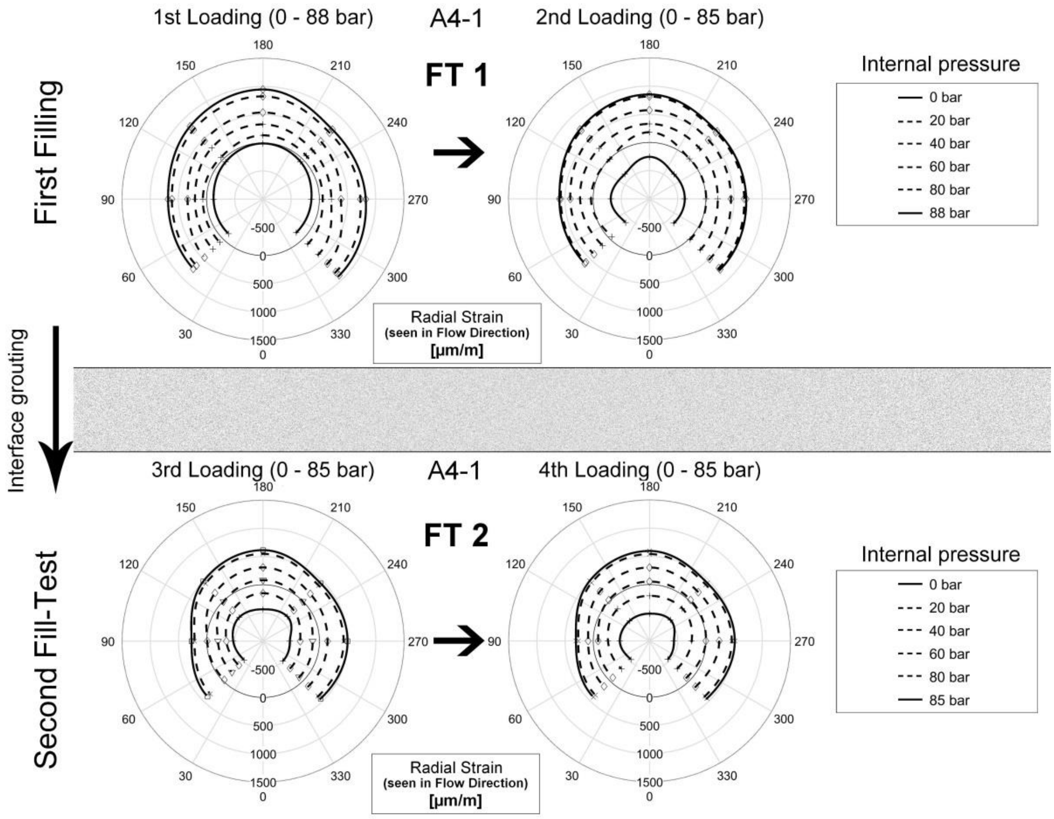

Fig. 6
Typical measurement cycle before (FT1) and after interface grouting (FT2)
at section 4-1 [2]

The “thermal gap” provided space for free deformation of the steel lining at the second loading and unloading cycle of FT 1, which was still before interface grouting took place. This gap closed at moderate internal pressure causing circumferential strains ε_y of 200 to 400 µm/m (equals 0.02 - 0.04%, Fig. 7: FT 1). Subsequently the steel lining was bedded in the rock mass again. The reason for this behavior may be associated with an initial settling of the strain gauges, temperature difference, shrinkage of concrete and creep, which was, however, not predicted to such an extent. The gap had to be filled with grout to improve uniform radial bedding of the penstock in the rock mass. At the second Fill-Test after interface grouting (FT2, loadings 3 and 4) longitudinal strains ε_x were zero. Circumferential strains ε_y responded purely elastically and returned to the starting point at the pressure-strain diagram after emptying the pipe (Fig. 7: FT 2).

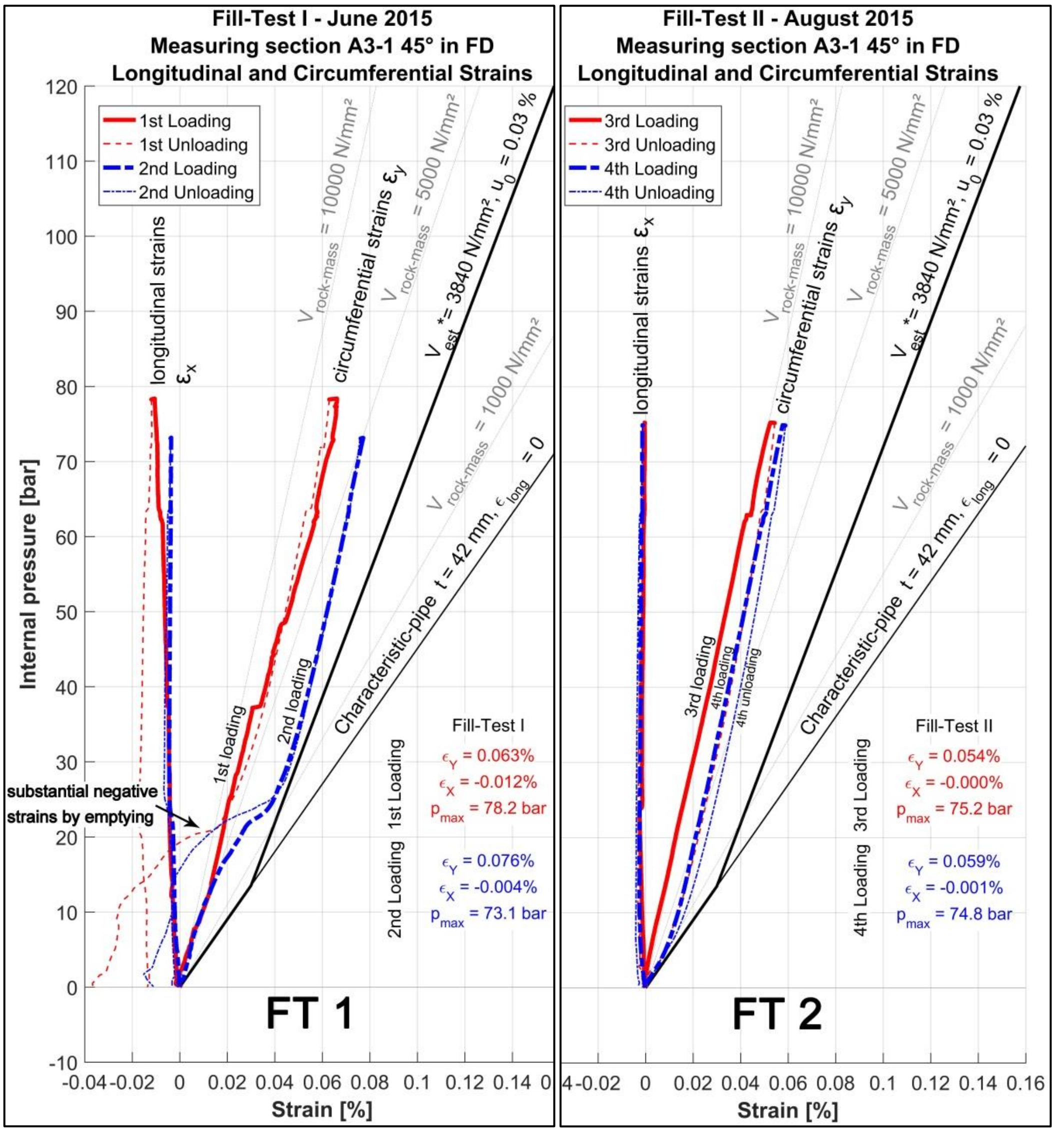

Fig. 7: Typical steel lining response before (FT1) and after (FT2) interface grouting

At locations “B” (Fig. 2) it was discovered that even without any shear rings a high portion of the full cover pressure of up to D = 60 MN, acting as an axial force at the pipe end was redistributed near the transition after only 3 m to 4 m (1.5 diameters) of embedded pipe length. At short distance from the transition a remarkable reduction of axial stress was registered in pipes with moderate wall thickness as compared to thick walled pipes [5], [6]. A considerable improvement for stress redistribution from the steel pipe into the rock mass was noticed in Fill-Test 2 after the interface grouting had taken place. After having redistributed a high portion of the cover pressure into the backfill concrete and rock mass close to the transition, the pipe was locked in with restricted constant longitudinal strain equivalent to a rather constant longitudinal pipe force (e.g. Fig. 8, at 4.0 m to 10.0 m distance to the transition). This remaining portion of the cover pressure results from axial stresses σ_x in the pipe due to internal pressure and full restraint of lateral contraction (see [6]).

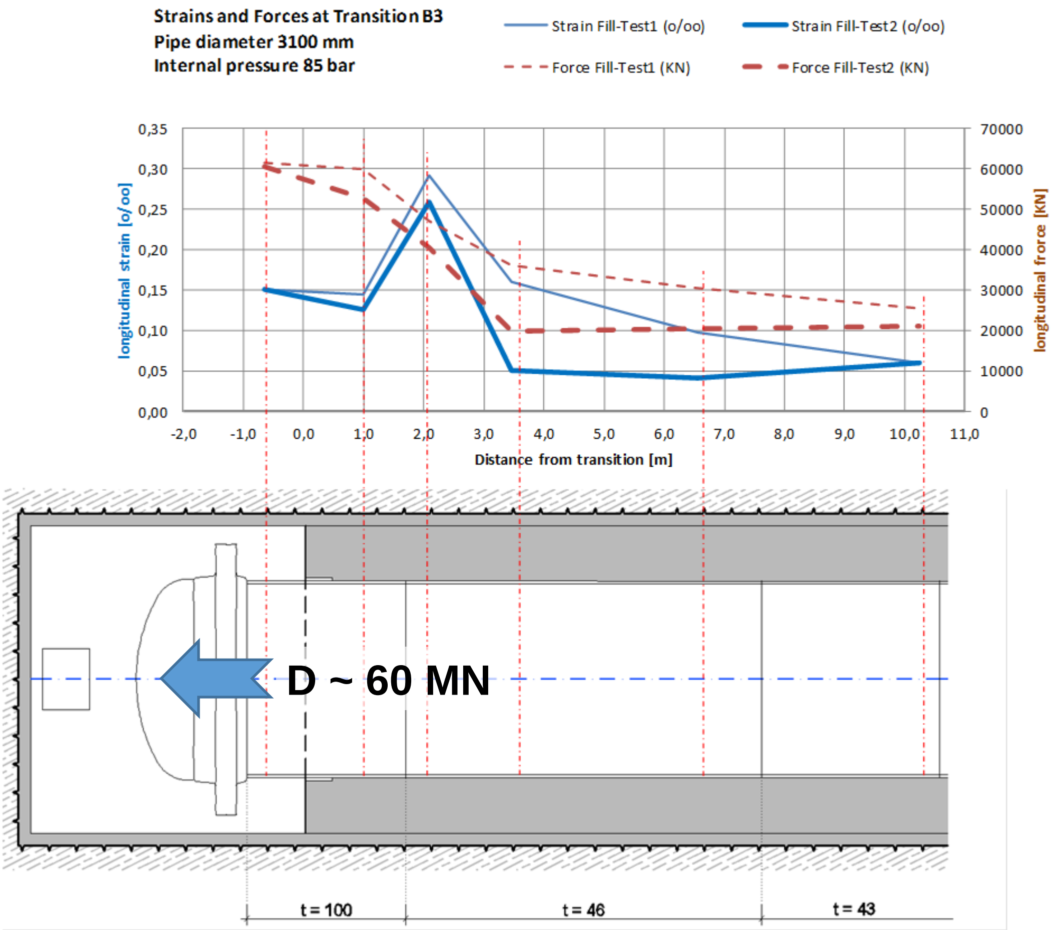

Fig. 8: Typical longitudinal strain and longitudinal force in the pipe at the transition into the rock [2]

SUMMARY

A new steel lined pressure shaft was constructed for the existing Kaunertal high head hydro-power plant. Before starting operation, initial filling tests were carried out in particular to investigate the behavior of the steel penstock. Various monitoring arrangements were used to monitor the rock mass / steel lining interaction and the axial force distribution at the end of the embedded penstock. To verify the effects of grouting the tests were carried out before and after interface grouting took place. The most important findings regarding the results of strain measurements in the steel pipe are listed below:

- Strain measurements can be realized with optical strain sensors at high accuracy, bridging distant locations and sustaining high water pressure.
- At the second loading and unloading cycle of the first fill test (still before interface grouting took place), a “thermal gap” between steel pipe and backfill concrete, which could be detected, provided space for free deformation of the steel lining.
- A considerable improvement of stress redistribution from the steel pipe into the rock mass was noticed in Fill-Test 2 after the interface grouting took place.
- After interface grouting took place circumferential strains responded purely elastically and returned to the starting point of the pressure-strain diagram
- After only 3 m to 4 m (1.5 diameters) of the embedded pipe length a substantial portion of the full cover pressure acting as an axial force in the steel pipe was transferred to the rock mass even without any shear rings.

1. INTRODUCTION

Within a recently finished research-project the load transfer of axial loads in penstocks only due to friction between the filled steel pipe and the surrounding concrete and rock, without thrust rings, was studied. Axial loads arise due to water pressure on caps or valves and temperature differences between steel pipe and surrounding concrete. Thrust rings are traditionally used to transfer the axial loads in the steel pipe into the surrounding concrete and further into the rock. The load carrying and stiffness behavior of thrust rings was recently studied in detail by the authors ([1], [2]), because it was not regulated in common design codes for penstocks ([3] - [5]).

This paper deals with a summary of the measurements on a part of a penstock to evaluate appropriate coefficients of friction µ between steel pipe and the backfill concrete. Then parametric studies are presented to show the principal behavior of load transfer along the pipe, with and without thrust rings.

Based on that, a simplified analytic model was developed for practical design including regions without friction. In addition, the effects of the important boundary conditions – longitudinally free or fixed – of the steel pipe within the rock are presented.

This paper also sums up the results of [6].

2. MEASUREMENTS FOR EVALUATION OF COEFFICIENTS OF FRICTION

During renewal of the penstock of the high head hydropower plant called "Kaunertal" (owner TIWAG Innsbruck/Austria) very comprehensive strain measurements at parts of the penstock after water filling – before and after injection of the interface between steel pipe and concrete – were carried out. Here only the results at a part of the penstock are presented, where in this erection phase a transfer of longitudinal forces via friction only occurs. Fig. 1 shows this part, with an internal diameter d_i = 3100 mm. The six test sections (TS 1 to TS 6) are shown, with two measure points along the circumference. In each point both the longitudinal strains (ε_x) and the strains in circumference direction (ε_θ) were measured, at the inner and outer wall surface, leading to four individual results ($\varepsilon_{i,x}$,$\varepsilon_{i,\theta}$ and $\varepsilon_{o,x}$, $\varepsilon_{o,\theta}$). At the left side of Fig. 1 the steel pipe is longitudinal free and has no concrete surrounding. The pipe has temporarily a bolted steel end cover. In total four measurements for filling situations were carried out.

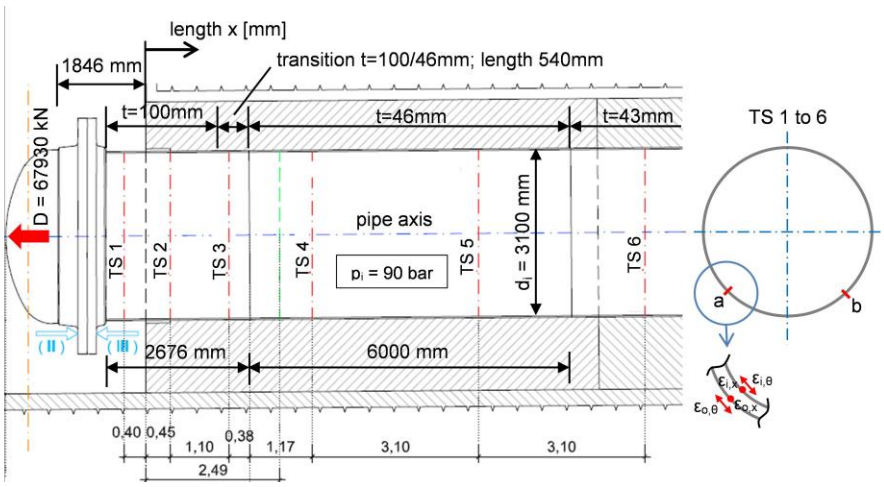

Fig. 1
Penstock at Kaunertal in the erection phase. Transfer of longitudinal force due to internal pressure without thrust ring and measuring points in the individual test sections (TS1 to TS6)

Fig. 2 shows only the results for the 2nd filling after injection of the interface between steel pipe and concrete. Fig. 2a shows the strains in longitudinal, Fig. 2b in circumferential direction. The dots are the measured strains due to internal pressure p_i = 9.0 N/mm^2 (90 bar), also leading to the total force D (Eq. [1]) in longitudinal direction of the pipe (r_i is equal to the inner radius of the pipe). Some measure points were not directly situated at the test sections, leading to the shown shift of Δx = 0.25 m.

$$D = p_i \cdot r_i^2 \cdot \pi = 9 \cdot 1550^2 \cdot \pi \cdot 10^{-3} = 67930\ kN \qquad [1]$$

Some strain measurements failed. Therefore not in each test section four values are visible in Fig. 2. The measured strains in the individual points of each test section show a considerable scattering, probably due to different radial stiffness of the surrounding concrete and rock. Within a parametric numerical study, calculations for constant radial stiffness C_F and coefficient of friction μ were done. The radial stiffness C_F in N/mm³ depends on the modulus of subgrade reaction V_F in N/mm² of the surrounding rock, as shown in Eq. [2].

$$C_F = V_F / r_i \qquad [2]$$

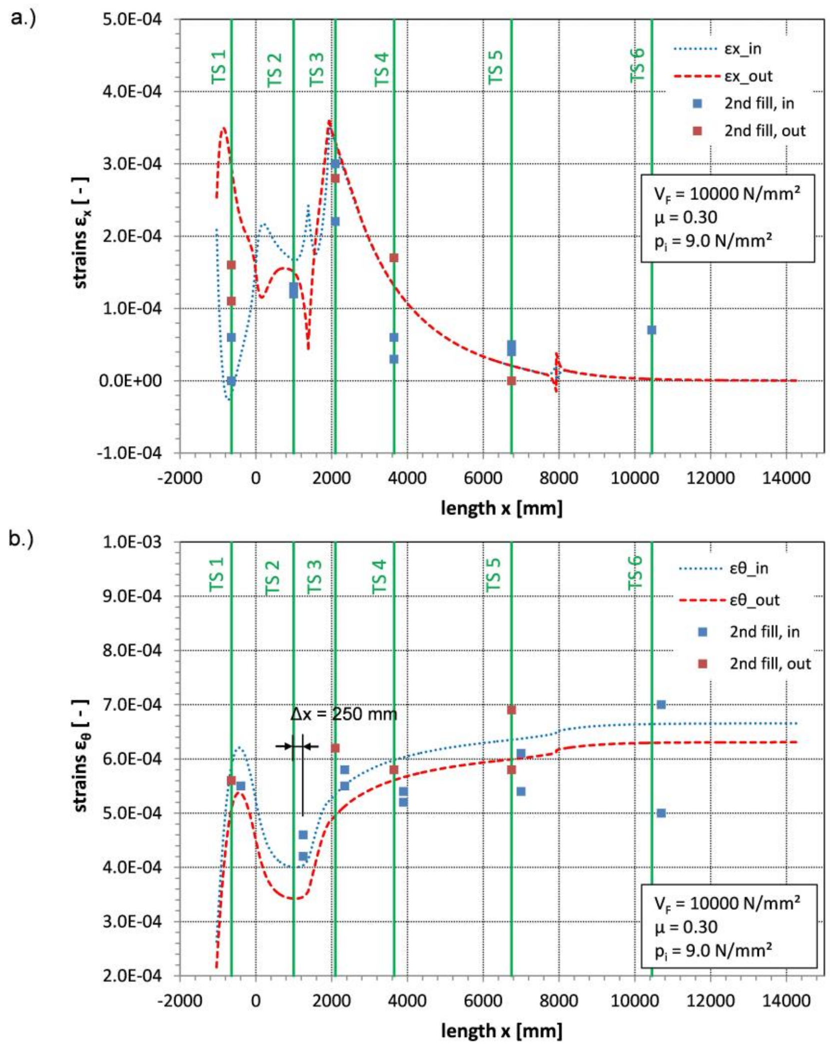

Fig. 2
Strain measurements in the penstock at Kaunertal due to infill (p = 9.0 bar).
Comparison with results of the numerical study, a) strains ε_x in longitudinal and,
b) strains ε_θ in circumferential direction

Based on the strains in circumferential direction ε_θ the accurate radial stiffness C_F can be estimated, because for a pipe with internal pressure according to the simplified Eq. [3] the strains ε_θ decrease with increased radial stiffness (u_0 corresponds to the radial gap between steel and concrete).

$$\varepsilon_\theta = \left(p_i - \frac{u_0 \cdot E^* \cdot t}{r^2}\right) \cdot \frac{r}{E^* \cdot t + C_F \cdot r^2} \qquad [3]$$

with: $E^* = \frac{E}{1-\nu^2} = \frac{210000}{1-0.3^2} = 230770\ N/mm^2$...modulus of elasticity for plane strain

On the other hand the distribution of the strains ε_x in longitudinal direction and the longitudinal deformation u_x at the free end have a direct relationship to the coefficient of friction μ. Reasonable values within the numerical study for best fit with the measured test data are $\mu = 0.25$ and $V_F = 10000$ N/mm². In Fig. 2 the strains for $\mu=0.30$ are shown, because the exact friction coefficient was determined with the longitudinal displacements at the cover and for the calculation with $\mu = 0.25$ only the displacements were plotted (see Fig. 6). In contrast the specific value $V_F = 3800$ N/mm² was also used in the numerical studies, because in the past during tunneling of the penstock additional tests with a radial jack gave this value.

3. NUMERICAL STUDY FOR VERIFICATION OF THE TYPICAL BEHAVIOR

3.1. Overview

The results of the measurements are hard to interpret, on the one hand due to the different thicknesses of the pipe and on the other hand due to the large scattering. To get a better understanding of the transfer of longitudinal pipe forces to the surrounded part of the steel pipe (for x > 0 in Fig. 1, 2) an additional numerical study was done with constant thickness (t_1 = 50 mm at the free pipe, for x < 0, thickness t_2 in the region with concrete surrounding). Different radial stiffness C_F were assumed, leading to different thickness t_2, based on the assumption that the stresses in circumference direction due to internal pressure are equal to 60% of the yield strength (calculations were done with f_y = 460 N/mm² leading to thicknesses t_2 shown in Table 1). For the simplified systems with constant pipe thicknesses a FE-model and also a simplified analytical model were developed. Pipe transitions with ad without thrust rings were analyzed.

3.2. FE-Model

Due to the assumed axial symmetric behavior, also axial symmetric elements were used within the software-code ABAQUS. The steel pipe and thrust ring was assumed with linear elastic behavior (E = 210000 N/mm²; ν = 0.30). For the thickness transition an inclination of 1:10 was adopted only at the outer surface. For the calculations without a thrust ring linear shell elements (SAX2), otherwise volume elements (CAX4R), were used. For the concrete a nonlinear behavior was assumed (concrete damage plasticity [7], [8]), based on the studies with thrust rings ([1], [2]). In the FE-model only the steel pipe, the thrust ring, the concrete surrounding and the radial stiffness of the rock were considered. The end cover was not part of the model, therefore instead of the total force D the membrane force n_D (Eq. [4]) along the circumference was used (similar FE-model as in Fig.7) in longitudinal direction.

$$n_D = p_i \cdot \frac{d_i}{4} = 9.0 \cdot \frac{3100}{4} = 6975\ N/mm \qquad [4]$$

3.3. RESULTS OF LONGITUDINAL FORCE DISTRIBUTION – WITHOUT THRUST RING

In Fig. 3 the typical distributions for the longitudinal membrane stresses $\sigma_{x,m}$ are shown for a varying coefficient of friction and with a very low radial stiffness V_F = 1000 N/mm^2. In addition also the radial stresses σ_r between steel and concrete are shown. The shown characteristic of the longitudinal membrane stresses $\sigma_{x,m}$ is equal to the longitudinal membrane forces n_x.

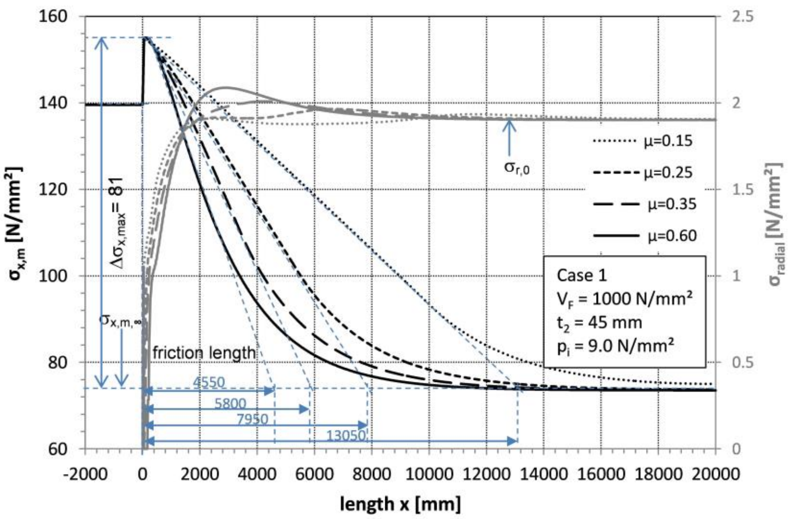

Fig.3
Transfer of the longitudinal force along the length of the steel pipe for V_F = 1000 N/mm². Stresses $\sigma_{x,m}$ in longitudinal and stresses σ_r in radial direction at the steel pipe.

Worth mentioning is that not the entire longitudinal force D is transferred via friction. After a so called friction length l_{fr} (shown with a simplified linear extrapolation for the $\sigma_{x,m}$ curves in Fig. 3) the stresses $\sigma_{x,m}$ doesn't change any more. The background of the limit value $\sigma_{x,m,\infty}$ in Fig. 3 is, that no axial strains in the steel pipe in this region occur. The tension strains due to $\sigma_{x,m,\infty}$ are equal to the compression strains due to the lateral contraction of the tension stresses σ_θ in circumferential direction, due to water infill. This leads to Eq. [5]:

$$\sigma_{x,m,\infty} = \nu \cdot \sigma_{\theta,m,\infty} = 0.3 \cdot \sigma_{\theta,m,\infty} \qquad [5]$$

For the tension stresses $\sigma_{\theta,m,\infty}$ in the circumferential direction also an analytic formulation based on Eq. [6] can be used.

$$\sigma_{\theta,m,\infty} = \frac{E^* \cdot u_0}{r_i} + \frac{E^* \cdot \left(p_i - \frac{E^* \cdot u_0 \cdot t_2}{r_i^2}\right)}{r_i \cdot \left(C_F + \frac{E^* \cdot t_2}{r_i^2}\right)} \quad [6]$$

If a radial gap u_0 can be ignored Eq. [6] leads to Eq. [7]:

$$\sigma_{\theta,m,\infty} = \frac{E^* \cdot P_i}{r_i \cdot \left(C_F + \frac{E^* \cdot t_2}{r_i^2}\right)} \quad [7]$$

Eq. [7] and [5] lead to $\sigma_{x,m,\infty}$ = 74 N/mm² for V_F = 1000 N/mm². This stress value is identical to the numerical result given in Fig. 3. Based on the longitudinal stress $\sigma_{x,m,\infty}$ the reaction force at the anchor point of the steel pipe is determined (n_{AP} in N/mm and N_{AP} in N; with D_m as diameter of the pipe; mean value of inner and outer diameter).

$$n_{AP} = \sigma_{x,m,\infty} \cdot t_2 = \nu \cdot \sigma_{\theta,m,\infty} \cdot t_2 = 0.3 \cdot \sigma_{\theta,m,\infty} \cdot t_2 \quad [8]$$

$$N_{AP} = n_{AP} \cdot D_m \cdot \pi \quad [9]$$

The part of the overall longitudinal force transferred by friction n_{fr} at the beginning of the concrete surrounding (x > 0) is based on Eq. [10], considering also additional longitudinal forces n_{Temp} due to temperature differences ΔT, calculated with Eq. [11] (α_T = coefficient of thermal expansion).

$$n_{fr} = n_D - n_{AP} \pm n_{Temp} \quad [10]$$

$$n_{Temp} = \Delta T \cdot \alpha_T \cdot E^* \cdot t \quad [11]$$

In Table 1 the longitudinal forces transferred by friction n_{fr} for different assumptions of the radial stiffness V_F are shown. With higher radial stiffness the transferred longitudinal force by friction increases and the support force at the anchor point decreases. If no anchor point for the steel pipe is performed, the longitudinal forces will be transferred at the free end inside the mountain also by friction (see section 4).

Table 1

Part of the overall longitudinal force n_D which is transferred by friction (n_{fr}) and support reaction n_{AP} at the anchor point inside the mountain

V_F [N/mm²]	t_2 [mm]	n_{fr} [N/mm]	**n_{fr} / n_D**	**n_{AP} / n_D**
1000	45	3645	**52 %**	**48 %**
3840	30	4785	**69 %**	**31 %**
10000	10	6345	**91 %**	**9 %**

In Fig. 3 also the radial compression stresses between steel pipe and concrete are shown. They are nearly constant after a short length x. For the reference value $\sigma_{r,0}$ only a 2D ring model with plane strain conditions is necessary. Alternatively based on an analytical model Eq. [12] is available, leading to the same values as in the numerical study, if the stiffness of the concrete is neglected (for $V_F \geq 3800$ N/mm² the influence of the concrete ring is very small).

$$\sigma_{r,0} = \left(p_i - \frac{u_0 \cdot E^* \cdot t}{r^2}\right) \cdot \frac{V_F \cdot r}{E^* \cdot t + V_F \cdot r} \qquad [12]$$

Based on this constant radial compression stresses $\sigma_{r,0}$ a simplified solution for the friction length l_{fr} is available:

$$l_{fr} = \frac{n_{fr}}{\mu \cdot \sigma_{r,0}} \qquad [13]$$

This simplified solution leads to a small underestimation of the friction length l_{fr} in the numerical studies, which is shown in Fig. 3 (< 5 %). An overview of the friction length l_{fr} for all studied cases is given in Fig. 4. Based on the determined coefficient of friction μ = 0.25 (see section 2) and a common radial stiffness V_F > 3000 N/mm², it is worth mentioning that only very short friction lengths l_{fr}, smaller than two times the diameter of the pipe ($l_{fr} < 2 \cdot d_i$), occur.

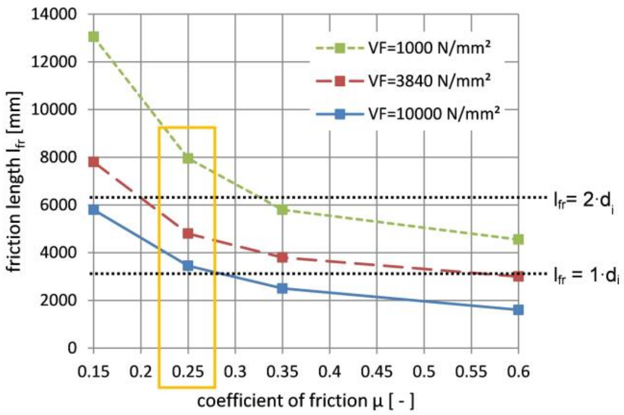

Fig. 4
Summary of the calculated friction lengths l_{fr} for different coefficient of friction μ and stiffness of rock V_F

3.4. RESULTS OF LONGITUDINAL FORCE DISTRIBUTION – WITH ADDITIONAL THRUST RING

In Fig. 5 the results for the solution with and without thrust rings for a small radial stiffness V_F = 1000 N/mm² are compared. The position of the thrust ring was assumed at a distance of x = 6 m (equal to two times the diameter of the pipe) inside the mountain. The results in Fig. 5 show that for higher coefficients of friction (μ = 0.25 and 0.35) nearly no longitudinal forces are transferred by the thrust rings.

Only for a very low value μ = 0.15 approximately 20 % of the overall force is transferred by the thrust ring (n_{TR} / n_{fr} ≈ 0.20). In case of higher radial stiffness V_F also for this low value of the coefficient of friction μ = 0.15 nearly no part of the longitudinal force is transferred by the thrust ring.

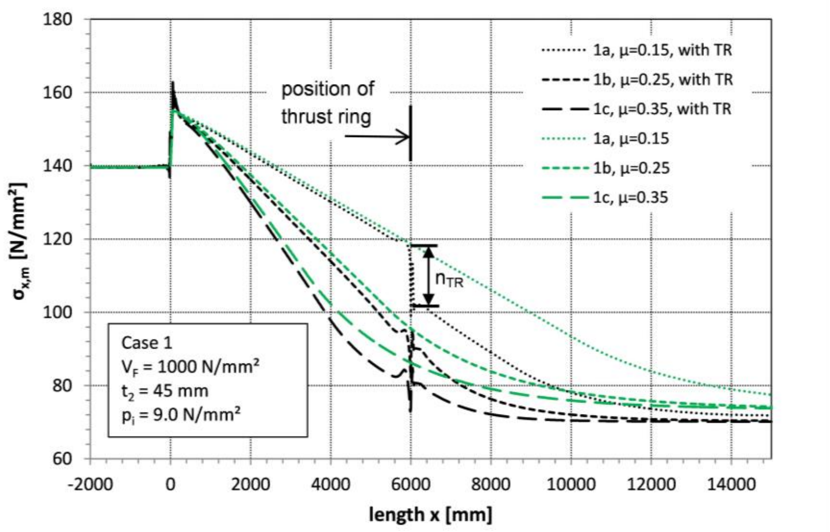

Fig. 5
Transfer of the longitudinal forces along the steel pipe with and without thrust ring (TR). Stresses $\sigma_{x,m}$ at the steel pipe in longitudinal direction.

3.5. PIPE DISPLACEMENTS AT THE PIPE END – WITH AND WITHOUT THRUST RINGS

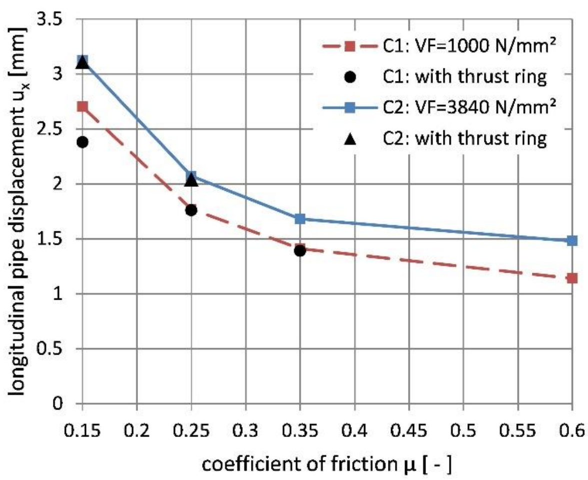

Fig. 6
Longitudinal pipe displacements u_x at the free end of the steel pipe, depending on the coefficient of friction μ and stiffness of the rock V_F – with and without thrust ring at x = 6000 mm

An important issue for the erection of thrust rings is the limited values allowed for longitudinal displacements of the steel pipe near the power houses. In Fig. 6 a summary of the calculated values u_x of the longitudinal pipe displacements at the free end are plotted, depending on the coefficient of friction μ. Due to the assumed position of the thrust ring (x = 6.0 m) nearly no difference in the displacements occurs in the calculation with and without thrust ring.

4. NUMERICAL STUDY FOR DIFFERENT BOUNDARY CONDITIONS AND REGIONS WITHOUT FRICTION

4.1. TYPICAL BEHAVIOR BASED ON FEM-STUDIES

In section 3 the typical behavior for the transfer of longitudinal pipe forces was shown, with constant coefficient of friction between the steel pipe and the surrounding concrete (for x > 0). The steel pipe had a longitudinally fixed boundary condition inside the mountain (boundary condition BC1 in Fig. 7).

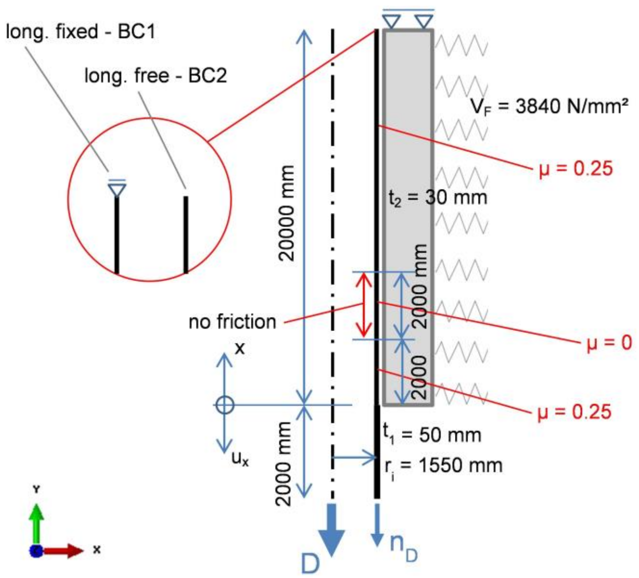

Fig.7
Numerical FE-model to study regions of the steel pipe without friction and different boundary conditions at the pipe end within the mountain.

In Fig. 8 the typical behavior is shown, when along a short region no friction is available (2.0 m < x < 4.0 m). In this region no longitudinal forces are transferred, leading to constant stresses $\sigma_{x,m}$ along this distance. This means that the friction length l_{fr} must be extended by the length without friction ($l_{fr}^* = l_{fr} + l_{\mu=0}$). In Fig. 8 also the results for the steel pipe with a longitudinal free boundary condition inside the mountain are shown (BC2 in Fig. 7). Now at this end the longitudinal stresses $\sigma_{x,m}$ must disappear ($\sigma_{x,m} = 0$). As Fig. 8 shows, there is a similar behavior of the transfer of the remaining part n_{AP} of the total longitudinal force (see Table 1) at x=14000 mm to x=20000 mm. Therefore again for the simplified approach Eq. [13] is applicable, based on the force n_{AP}.

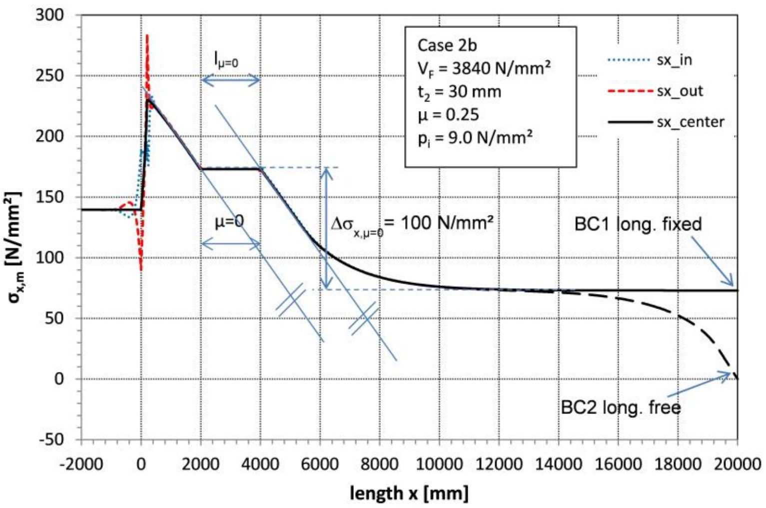

Fig. 8
Transfer of the longitudinal forces along the steel pipe for different boundary conditions of the steel pipe and a region without friction (length $l_{\mu=0}$) within the length l_{fr}.

4.2. SIMPLIFIED ANALYTICAL MODEL FOR END DISPLACEMENT U_X

The occurrence of regions without friction within the friction length l_{fr} significantly increases the longitudinal displacement u_x at the free end (see Fig. 7). Based on the results of the numerical study, for the calculation of the displacement u_x Eq. [14] can be used, leading to underestimations of the correct values of approximately 10 % (for μ = 0,25). This Eq. [14] is applicable for both boundary conditions in Fig. 7, because the boundary condition has no influence on the displacements at the free end.

$$u_x = \frac{\Delta\sigma_{x,max}}{2 \cdot E} \cdot l_{fr} \qquad [14]$$

If within the friction length l_{fr} also regions without friction ($l_{\mu=0}$) are expected the increased deformation u_x can be estimated based on Eq. [15], with $\Delta\sigma_{x,\mu=0}$ given in Fig. 8.

$$\frac{\Delta\sigma_{x,max}}{2 \cdot E} \cdot l_{fr} + \frac{\Delta\sigma_{x,\mu=0}}{E} \cdot l_{\mu=0} \qquad [15]$$

5. SUMMARY

Within this research project, based on measurements on a penstock during erection and a comprehensive numerical study the following results are worth mentioning:

- High local longitudinal forces acting on the steel pipe in penstocks, due to closed valves for example, may also be transferred to the surrounding concrete and rock due to friction only – without thrust rings.
- This requires internal pressure in the steel pipe. Then the length for transferring the longitudinal forces l_{fr} is very short ($l_{fr} < 2 \cdot d_i$, for $\mu = 0.25$ and $V_F > 2500$ N/mm²).
- Only a part of the longitudinal force n_D is transferred locally over the length l_{fr}. This proportion n_{fr} / n_D increases with higher radial stiffness of the rock.
- Additional thrust rings, when they are not directly situated at the beginning of the rock and concrete surrounding, get only small amounts of the longitudinal forces.
- If the transfer of longitudinal forces within the friction length l_{fr} is possible (guaranteed coefficient of friction μ) also the longitudinal displacements u_x of the steel pipe on the free end will be small.
- If the steel pipe has also a free end inside the mountain also the remaining part of the longitudinal force $n_{AP} = n_D - n_{fr}$ will be transferred over a very short length l_{fr}. For the estimation of this length the same behavior is given as at the free end of the steel pipe. It is highly recommended to set up an anchorage point inside the mountain due to safety reasons. If this is not possible, the friction length should be long enough, because the whole longitudinal force is transferred by friction.
- A simple analytical model was developed to calculate the transferred load n_{fr}, the friction length l_{fr} and the displacements u_x at the free end of the steel pipe.

THRUST RINGS FOR TRANSFERRING LONGITUDINAL PIPE FORCES – DEVELOPMENT OF A DESIGN MODEL

Ecker A., Unterweger H.

Institute of Steel Structures, GRAZ UNIVERSITY OF TECHNOLOGY

AUSTRIA

1. INTRODUCTION

Thrust rings with rectangular cross-sections are mainly used in penstocks to transfer the longitudinal pipe forces via the exterior concrete to the surrounding bed rock (Fig. 1). The design model is limited to usual applications with continuous full penetration welds at the thrust rings over the whole circumference.

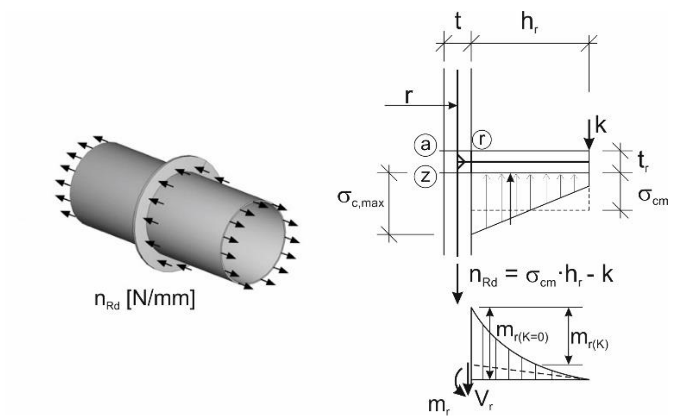

Fig. 1
Overview of pipe and thrust ring and simplified cantilever model used in practice

Thrust rings can be seen as a composite component, which transfers very high pipe forces – up to 50.000 kN, because of increasing diameter and pressure in recently erected penstocks.

Longitudinal forces in penstocks can have various reasons. For example they act due to the internal pressure on a closed valve, throttle, or temperature changes. Surprisingly in relevant design codes for penstocks (e.g. [1], [2], [3]) no detailed information is given for the design of thrust rings. In practice simplified models are used, considering the thrust ring as a cantilever (Fig. 1). The maximum force n_{Rd} and also the maximum moment m_r at the thrust ring are depending on the distribution of the concrete pressure σ_c and the maximum concrete stress $\sigma_{c,max}$ at the thrust ring. In practice different assumptions with no physical background based on test results are used. In some cases an additional prying force k at the non-loaded side of the thrust ring is assumed, which reduces the maximum moment m_r (e.g. [4]). Based on the internal forces m_r and V_r transferred from the thrust ring to the pipe the stresses in the relevant sections (r, a and z in Fig.1) of the thrust ring and the pipe can be calculated, based on shell theory.

For usual large penstock diameters (d = 3-5 m) the cantilever model for the thrust ring is quite accurate, because the effect of the circular ring plate is negligible. These results are based on 3D-FEM-analyses by the authors for cases in practice. That means, if the pressure distribution σ_c and the acting contact force k are known for the simple model in Fig. 1 the design of the thrust ring and the pipe are based on the well-known codes for steel design. Therefore a research project was executed by the authors which includes also laboratory tests to calibrate FEM-models for the prediction of these pressure distributions σ_c at the thrust ring (see [5], [6]).

At the beginning of this paper the load carrying behaviour of thrust rings will be shown based on a practical example with a pipe of an inner diameter d_i = 3800 mm, a thickness t = 74 mm and a thrust ring h_r/t_r = 370/62 mm. In the second part of this paper a design model for thrust rings is presented. In this brief paper only the basic model, considering the elastic behaviour of thrust rings is shown in detail. For thrust rings also a higher plastic ultimate load carrying capacity can be utilized, if a continuous radial elastic support is given by the surrounding bedrock (details are given in [6]). In [5] and [6] the background of the simple design model is presented in detail, based on many FEM-calculations for individual examples within the accurate parameters range of practical application.

2. LOAD CARRYING BEHAVIOUR OF THRUST RINGS – MAIN FINDINGS BASED ON A PRACTICAL EXAMPLE

Varying the main parameters (pipe diameter d; pipe thickness t, thrust ring dimensions h_r/t_r, material parameter for steel and concrete) it can be seen (based on [6]) that the typical load carrying behaviour for transferring longitudinal forces is similar. Therefore in the following only one example is presented in detail. The results are based on a numerical 3D-FEM-calculation with axisymmetric elements, with the assumptions given in Fig. 2. This FEM-model was also calibrated with tests. A pipe with an inner diameter d_i = 3800 (r_i = 1900) mm, a wall thickness t = 74 mm and a thrust ring h_r/t_r = 370/62 mm is assumed. The surrounding concrete cylinder is supported at the bottom. The longitudinal force N_{sr} and the displacement u_2 respectively are also applied at the bottom of the steel pipe. This force will be transferred to the surrounding concrete by the thrust ring, located in the middle of the pipe (at x = 2500 mm from the pipe top). Here an intact rock mass is assumed, leading to a minimum bedding modulus V_F = 2000 N/mm², which gives the additional elastic support in radial direction. In the FEM-calculation an equivalent radial spring stiffness is used: $C_f = V_F / ((1+\nu_F)\cdot r)$. In this equation r is the outer radius of the concrete cylinder and ν_F is the Poisson´s ratio of the rock mass. Without that radial elastic support the results in the elastic range are very similar, but the elastic limit $N_{R,el}$ is smaller (see [5]).

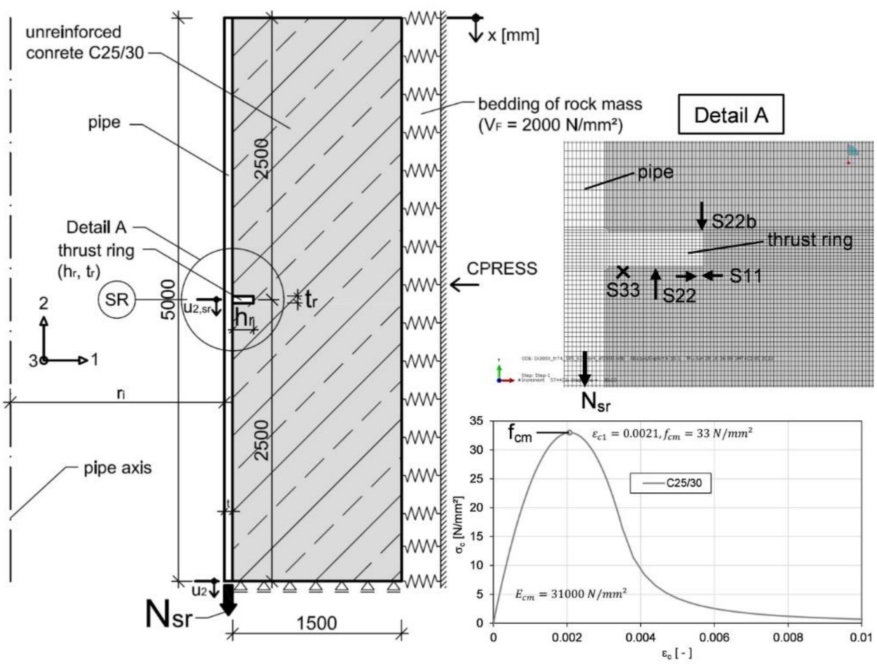

Fig. 2
FEM model for the representative example of a thrust ring, surrounded by a concrete block and the intact rock mass

In Fig. 2 also the fine mesh of the elements in the region of the thrust ring is shown. Conservatively no friction between steel part and surrounding concrete is taken into account. To simulate the ductile behaviour of the thrust ring after exceeding the elastic limit, it is necessary to define the post critical stress – stain curve for concrete in compression (in general concrete C25/30 is used in the FEM-calculations) – in Fig. 2 the assumed realistic assumptions for uniaxial behaviour in the numerical calculation are shown. The concrete has a tensile strength of 2.6 N/mm² in the calculations. The steel has got a yield-strength of 650 N/mm² with an ideal elastic-plastic material law. No gap between steel pipe and concrete is assumed, due to injection grouting used in practice.

The load carrying behaviour of the thrust ring is summed up in Fig. 3. Fig. 3a shows the overall load-deformation behaviour. With increasing overall force N_{sr} transferred at the thrust ring, the maximum displacement u_2 at the pipe increases.

In the following the stresses are presented at the end of the elastic range – $N_{R,el}$ and at ultimate limit load – $N_{R,u}$ as shown in Fig. 3a.

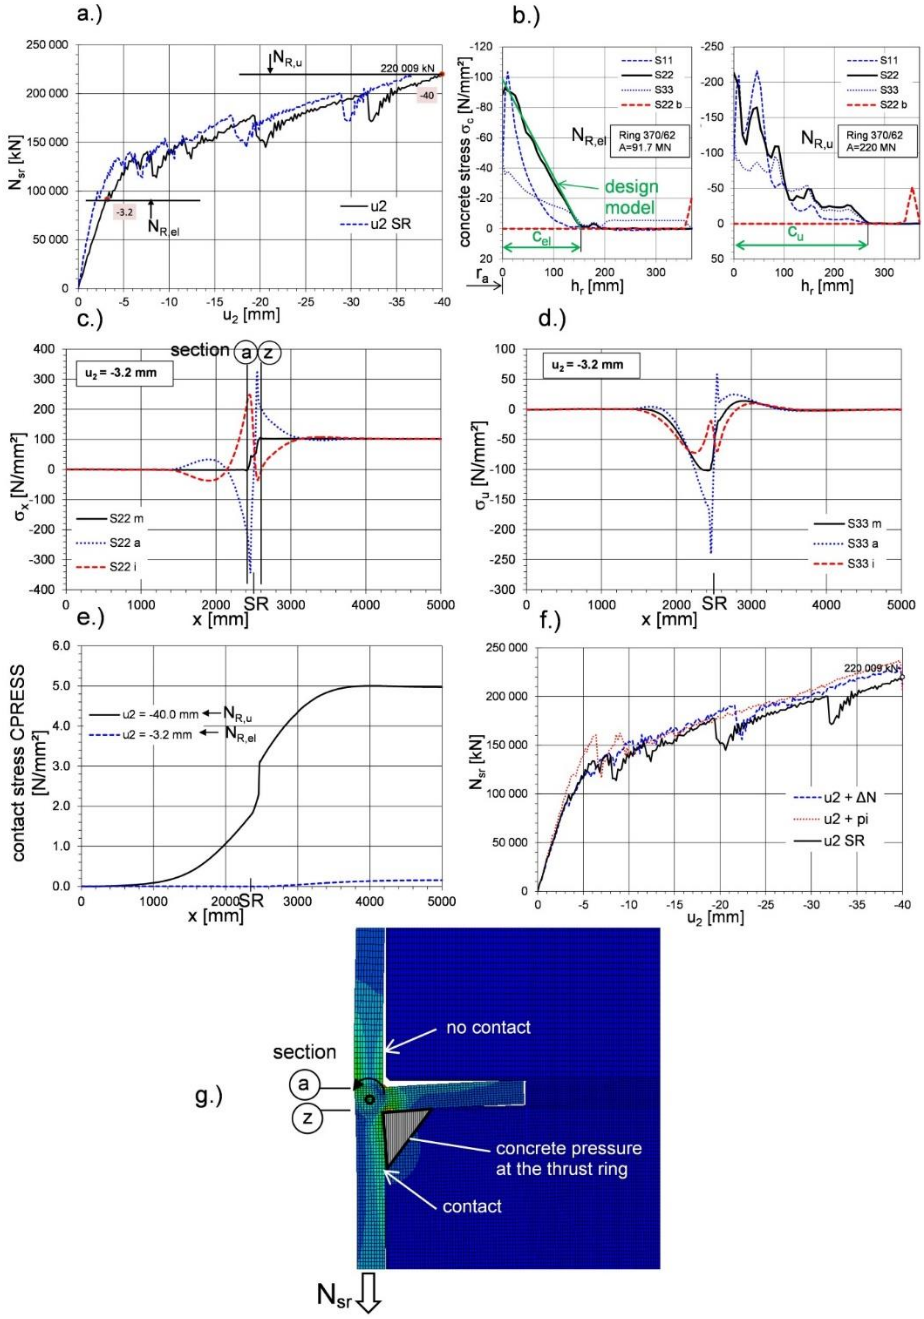

Fig. 3
Load carrying behaviour at the thrust ring – based on an example (d_i = 3800, t =74, h_r = 370, t_r = 62 mm, material S690 – steel, C25/30 – concrete)

Fig. 3b shows for that two load levels the concrete pressure at the thrust ring along the height h_r (the steel pipe is at the left end of both diagrams). The concrete stress is presented in all three directions (notation S11, S22, S33 see Fig. 2) at the “loaded” side of the thrust ring. At the back of the thrust ring only the pressure parallel to the pipe (S22 - b) is plotted. It can be seen that up to the elastic range (force $N_{R,el}$ is explained in Fig. 3a and based on Eq.[2])) there is only a very small negligible contact force at the outer end of the thrust ring. In the elastic range a nearly triangular pressure distribution at the thrust ring (acting parallel to the pipe axis and force direction) will be activated, which is well predictable in the design model (length c_{el}). Due to the compression stresses in all three directions in the concrete directly at the steel pipe, the maximum concrete stress – also at the end of the elastic range $N_{R,el}$ – is highly above the uniaxial concrete strength ($S11_{max}$ = 90 >> f_{cm} = 33 N/mm²). If the elastic range is exceeded, a pressure re-distribution starts, leading to an increased length c_u. This behaviour leads also to a significantly increased bending effect in the pipe, which must be considered in design if the higher plastic load carrying capacity $N_{R,u}$ should be utilized.

In Fig. 3c the longitudinal stresses (S22; m...middle surface; a…outside; i…inside) in the pipe are shown at the load level $N_{R,el}$. On the one hand the membrane stresses with the discontinuity at the thrust ring are shown and on the other hand the stresses at inner and outer side of the pipe are presented. The latter ones show the significant bending effect in the pipe. The sections a and z are directly at the thrust ring with the highest bending effect. These sections are decisive for the design model.

The Fig. 3d shows the circumferential stresses (S33; m...middle surface; a…outside; i…inside) in the steel pipe. There are compression membrane stresses near the thrust ring, due to the radial component of the support reaction at the thrust ring, based on the radial eccentricity of N_{sr} (resulting vertical reaction force at the bottom of the concrete block acts outside the pipe wall). Also limited bending effects near the thrust ring in circumferential direction are acting due to the Poisson effect. They can be neglected in the design model.

The Fig. 3e shows the radial pressure CPRESS between concrete and bed-rock. Up to the end of the elastic range the compression stresses are negligible small, but they significantly increase in the plastic range. Therefore if the significantly higher ultimate load $N_{R,u}$ should be utilized, a verification of the rock to resist these radial stresses is necessary.

In Fig. 3f again the overall load-deformation behaviour as in Fig. 3a is shown, but now in comparison with cases where additional load cases of very high magnitude are considered. On the one hand an additional longitudinal force ΔN (ΔN results in longitudinal stresses σ_x in the pipe of half of the yield stress) and on the other hand an additional internal pressure p_i = 12.7 N/mm² (p_i results in circumferential stresses σ_u in the isolated pipe equal to the half of the yield stress). It can be seen that the overall behaviour is nearly the same – therefore in the design model for the elastic limit $N_{R,el}$ additional load cases can be ignored, but they must be taken into account for the verification of the section capacity (section a, z). In Fig. 3g finally the deformations of the pipe and the thrust ring are represented. It is visible that only on the loaded side of the thrust ring the pipe is radially supported by the concrete, at the opposite side there is a gap between pipe and concrete. This behaviour also leads to the result, that the bending effect in the pipe is significantly higher in section a, which must be considered in the design model.

3. ELASTIC DESIGN MODEL FOR THRUST RINGS

The developed design model is summed up in Fig. 4. Here only the elastic limit $N_{R,el}$ is presented and the associated verifications in the thrust ring and pipe. Nevertheless the given design procedure guarantees ductile behaviour, as shown in Fig. 4a. The parts of the design model of a cantilever-beam with unit width are (see Fig. 4):

- Elastic limit load $N_{R,el}$ for the thrust ring
- Overall stiffness C_{ges} in longitudinal direction of the pipe in the elastic range
- Simplified cantilever mechanical model with idealised pressure distribution for verification in the thrust ring (section A) and the pipe (section a and z).

The following paragraphs explain the procedure for the elastic design for thrust rings in detail.

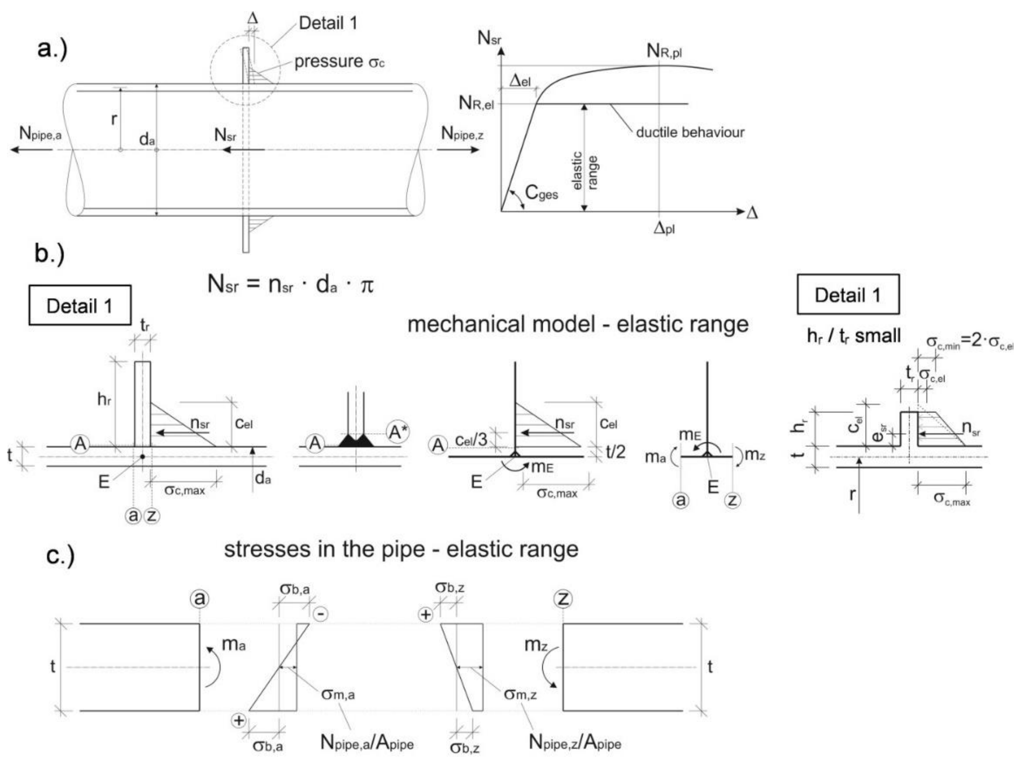

Fig. 4
Basics of the new design model for thrust rings

Limitations of the Design model

Based on the parametric study of the accurate FEM-calculations for verification of the developed design model the following limitations are important:

- Geometry of the thrust ring: $2 \leq h_r/t_r \leq 10$; $t_r \geq 20$ mm
- Thickness relationship: $t_r/t \leq 1{,}5$
- Constant pipe thickness t on both sides of the thrust ring over a length

of at least $r_i/2$

- Rectangular thrust rings – fully welded (butt welded) along the circumference of the pipe

Idealized pressure distribution at the thrust ring

In general a simple triangular stress pattern (see Fig. 4b) – without any contact force at the backside – is applied. The pressured length c_{el} is calculated using Eq. [1]. This equation is empirically determined with the numerical calculations. The accuracy of Eq. [1] is shown in [5].

$$c_{el} = 0.85 \cdot t + t_r \cdot \left[1 + 0.1\left(\cdot \frac{h_r}{t_r} - 2\right)\right] \leq 0.85 \cdot t + 1{,}5 \cdot t_r \qquad [1]$$

For stocky thrust rings in case of thicker pipes, with $c_{el} > h_r$, a modified trapezoidal stress pattern with an increased stress at the outer edge ($\sigma_{c,min} = 2 \cdot \sigma_{c,el}$) is assumed (see Fig. 4b).

Elastic load capacity $N_{R,el}$

Based on the simplified concrete pressure at the thrust ring (Fig. 4b) and an increased maximum concrete strength of $\sigma_{c,max}$ (with f_{cd} uniaxial concrete strength, design value) is available:

$\sigma_{c,max} = 2 \cdot f_{cd}$ (in general)

$\sigma_{c,max} = 3 \cdot f_{cd}$ (special case with radial elastic support of the rock mass and $V_F \geq 2000$ N/mm²); limited value $2{,}5 \cdot f_{cd}$ (if also $h_r / t_r > 7$)

Note: if an increased strength of $\sigma_{c,max} > 2 \cdot f_{cd}$ is used, the rock mass must be able to resist a radial pressure of 0.15 N/mm^2 and the concrete thickness should be at least $d_c > 10 \cdot c_{el}$. The extraordinary high increase of concrete strength is based on the beneficial local 3D-stress state with significant compression in all directions. The elastic load capacity $N_{Rd,el}$ (Note: notation $N_{Rd,el}$ instead of $N_{R,el}$, because design value f_{cd} is used) is based on Eq. [2]

$$N_{\mathrm{Rd,el}} = n_{\mathrm{Rd,el}} \cdot d_a \cdot \pi = \frac{\sigma_{c,max} \cdot c_{el}}{2} \cdot d_a \cdot \pi \qquad [2]$$

For a trapezoidal pressure distribution Eq. [3] must be used

$$N_{\mathrm{Rd,el}} = n_{\mathrm{Rd,el}} \cdot d_a \cdot \pi = \left(\frac{c_{el} - h_r}{c_{el}} + 0{,}5\right) \cdot \sigma_{c,max} \cdot h_r \cdot d_a \cdot \pi \qquad [3]$$

The elastic load capacity $N_{R,el}$ is limited by the increased shear capacity of the thrust ring, based on Eq. [4]

$$N_{Rd,el} \leq N_{Rd,V} = d_a \cdot \pi \cdot t_r \cdot \left(f_{yd,sr}/\sqrt{3}\right) \qquad [4]$$

with: $f_{yd,sr}$ design value of the yield strength at the thrust ring.

Verification of the section capacity of the thrust ring (section A)

Note: The 2D-beam model, shown in Fig. 4b, leads to unit width for the thrust ring and the pipe. Based on the acting overall force $N_{sr} < N_{Rd,el}$ at the thrust ring the bending moment m_A is based on Eq. [5]

$$m_A = n_{sr} \cdot \frac{c_{el}}{3} = \frac{N_{sr} \cdot c_{el}}{3 \cdot \pi \cdot d_a} \quad [5]$$

If a trapezoidal pressure distribution is relevant ($c_{el} > h_r$), then:

$$m_A = n_{sr} \cdot e_{sr} = \frac{N_{sr}}{\pi \cdot d_a} \cdot e_{sr} \quad [6]$$

Stress verification in section A

$$\sigma_A = m_A/(t_r^2/6) \leq f_{yd,sr} \cdot f_V \quad [7]$$

$$f_V = 1 - \left(\frac{2 \cdot N_{sr}}{N_{Rd,V}} - 1\right)^2 \leq 1.0 \quad [8]$$

with: $f_{yd,sr}$ … design value of the yield strength at the thrust ring
f_V … reduction factor, considering additional high shear stresses due to N_{sr}; only relevant if $N_{sr}/N_{Rd,V} \geq 0.50$
$N_{Rd,V}$ … shear capacity of the thrust ring, based on Eq. [4]

Eq. [8] is identical with the formulation in Eurocode EN 1993-1-1, for interaction of bending and shear.

Verification of the section capacity at the pipe (section a and z)

The bending moment m_E, related to the pipe axis is given by Eq. [9]

$$m_E = n_{sr} \cdot \left(\frac{c_{el}}{3} + \frac{t}{2}\right) = \frac{N_{sr}}{\pi \cdot d_a} \cdot \left(\frac{c_{el}}{3} + \frac{t}{2}\right) \quad [9]$$

In case of a trapezoidal pressure distribution ($c_{el} > h_r$) Eq. [10] must be used

$$m_E = \frac{N_{sr}}{\pi \cdot d_a} \cdot \left(e_{sr} + \frac{t}{2}\right) \quad [10]$$

Stress verification in section a: The bending moment in section a is calculated based on Eq. [11]. The factor 0.50 in this equation is empirically determined with the numerical calculations.

$$m_a = 0.50 \cdot m_E \quad [11]$$

$$\sigma_a = \sigma_{m,a} \pm \sigma_{b,a} = \frac{N_{pipe,a}}{A_{pipe}} \pm m_a/\left(\frac{t^2}{6}\right) \leq f_{yd} \quad [12]$$

Stress verification in section z: The bending moment in section z is only half the value of section a, therefore the stress verification is only relevant for high axial forces $N_{pipe,z}$. The factor 0.25 in Eq.[13] is empirically determined with the numerical calculations.

$$m_z = 0.25 \cdot m_E \quad [13]$$

$$\sigma_z = \sigma_{m,z} \pm \sigma_{b,z} = \frac{N_{pipe,z}}{A_{pipe}} \pm m_z/\left(\frac{t^2}{6}\right) \leq f_{yd} \quad [14]$$

Worth mentioning is that the sum of the bending moments in section a and z is smaller than the overall moment m_E, due to the beneficial bending moment distribution in the pipe (see explanation in [5]).

Additional requirements for anchor points are also given in [5].

Elastic stiffness of the thrust ring in longitudinal direction

Worth mentioning is, that the elastic stiffness C_{ges}, given in Eq. [15], is based on a length of 1 mm in circumferential direction. If for the global analysis a beam model for the pipe is used, the resulting spring stiffness C_{sr} using Eq. [16] is necessary.

$$C_{ges} = 0.28 \cdot C_{ring} + 2.9 \quad [kN/mm^2] \tag{15}$$

$$C_{sr} = C_{ges} \cdot d_a \cdot \pi \quad [kN/mm] \tag{16}$$

With: $$C_{ring} = E \cdot A_{ring}/r_a^2 \tag{17}$$

$$A_{ring} = h_r \cdot t_r + b_{eff} \cdot \mathrm{t} \tag{18}$$

The parameter C_{ring} is equal to the radial stiffness of the ring with an effective width of the pipe for the internal pressure. Instead of the radius of the centroid of the ring, the outer radius of the pipe r_a can be used to simplify the calculation (see Fig. 5).

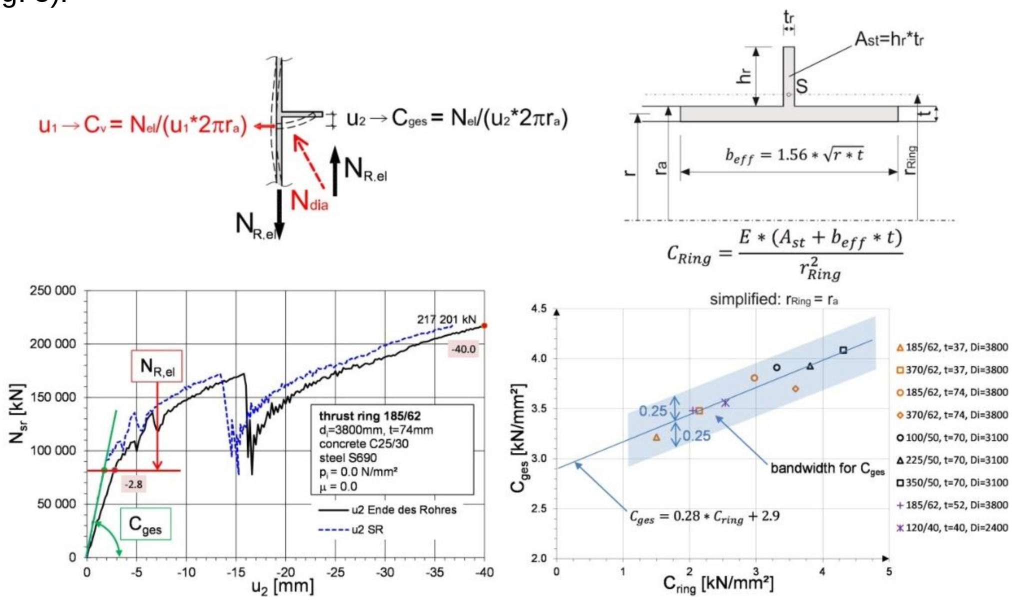

Fig. 5

Elastic stiffness C_{ges} of the thrust ring; real behaviour and background of the design model with most important parameter C_{Ring}

For smaller thrust rings with $20 \le t_r < 40$ mm, a reduced stiffness, based on Eq. [19], must be used.

$$C_{ges} = 0.28 \cdot C_{ring} + 2.1 + \frac{0{,}8}{20} \cdot (t_r - 20) \tag{19}$$

Eq. [15] and [19] are based on curve fitting of the FEM-results for a lot of practical examples, shown in Fig. 5. In this Figure the accuracy of Eq. [15] can be seen (for all given cases t_r > 40 mm). To capture the variation of the elastic stiffness, based on the FEM-calculations, it is recommended to use a maximum/minimum value of C_{ges} by increasing/reducing of the second term in Eq. [15] and [19] with a factor of 1.10/0.90.

The accuracy and background of the design model is shown in [5].

4. CONCLUSION

Based on tests and numerical results of a research project operated by the authors [5] a comprehensive design model for thrust rings was developed. It includes the elastic load carrying capacity of the thrust ring and the verification of the stresses in the steel pipe and the ring. Now it´s also possible to calculate the stiffness of a thrust ring. Also the interaction behaviour of serval thrust rings was investigated, leading to a very simple design rule (see [5]). As a result a significantly higher load carrying capacity $N_{R,el}$ of the thrust ring can be achieved, in contrast to the current design concepts (e.g. [4]). Also higher load carrying capacities than $N_{R,el}$ can be utilized in case of an additional radial elastic support of the rock mass, but they are not described in this brief paper.

1. INTRODUCTION

The application of high strength steels for modern, highly pressurized penstocks allows for reduced wall thicknesses. Hence, this should result in lighter components and easier fabrication, transport and handling conditions. This paper presents a case study of a complex geometric steel liner component – a bifurcation for access to a vertical tunnel – made of steel grade S620QL.

Besides geometrically optimizing the design of a bifurcation with respect to the reduction of hydraulic losses, the choice of an appropriate safety concept influences the layout strongly. Usually, the owner or the owner's engineer specifies a safety concept, which is stipulated by a standard or a guideline. As for steel penstock design, several international standards and guidelines with their own integral safety concepts are available throughout the world. The most common European standard for steel penstocks is still C.E.C.T. [1]. English speaking countries prefer for example ASCE manual no.79 "Steel Penstocks" [2].

The problem now is that the safety concept of C.E.C.T. is historically based on nominal design stress, which means that stresses or minimum required plate thicknesses are calculated by analytical formulae. This approach does not match with the application of finite element analysis, which is the state-of-the-art approach for complex structures (and often required by owner's engineers) and where dimensioning by means of formulae is not possible any more. Moreover, finite element analysis usually shows regions with locally increased stresses due to structural discontinuities. Compared with allowable stresses derived by nominal stress concepts this would unnecessarily lead to increased plate thicknesses and thus a higher dead weight of the component.

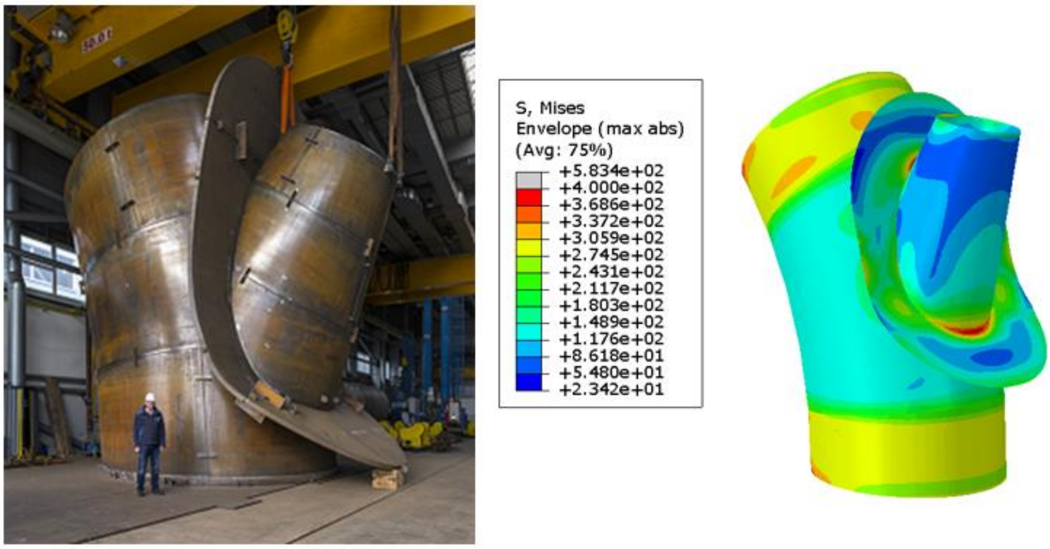

Fig. 1
Left: Shop assembly of a bifurcation; right: Stress plot of numerical simulation model

ASCE manual no. 79 clearly denotes allowable stress intensities for finite element models, which can be increased depending on the respective stress category. It is distinguished between different primary and secondary stresses (e.g. allowable local primary membrane stress for a reinforcing girder of a bifurcation is 1,5-times of the allowable stress intensity). Peak stress assessment, which becomes relevant for fatigue analysis, is also dealt within this guideline. The case study of a bifurcation presented in this paper opposes the traditional C.E.C.T. safety concept to the ASCE safety concept and points out the problems transferred to successive processes, e.g. fabrication and welding procedure, assembling and erection problems, which originate from an inadequate safety concept application and makes the economic benefits from high strength steel irrelevant.

2. EVALUATED SAFETY CONCEPTS

Penstocks and their appurtenances must be designed in accordance with the requirements of certified design criteria which must be prepared by experienced professional engineers. These requirements also comprise a safety concept to be applied.

Two major safety concepts and their further consequences and impacts on the design of special components are analysed in detail in this paper: C.E.C.T. recommendations for the design, manufacture and erection of steel penstocks from 1979 (exceptionally based on the application of analytical formulae for nominal stress assessment and still widely specified in certified design criteria) and ASCE steel penstock manual no.79 from 2012 (including recommendations for finite element analysis of wye branches).

State of the art requires finite element analysis for special and complex parts, such as bifurcations. This method is commonly specified by owner's engineers, regardless of the stipulated safety concept being suitable or not.

ASCE manual clearly distinguishes different stress categories which are based on the stress intensity limit S. These classifications are either of general or of local nature (see Table 1). The stress intensity S follows closely that of ASME Boiler and Pressure Vessel Code. ASCE manual recommends the use of the maximum shear stress theory and also recognizes as acceptable the Huber-Hencky-von Mises or distortion energy theory. ASCE manual denotes allowable stress intensities for steel penstock components for general application (denoted in chapter 3.4.10) and especially in chapter 7.3.3 for wyes in combination with the application of finite element method.

C.E.C.T. recommends minimum dimensioning factors C' which depend on the loading case and apply to the equivalent stress (Huber-Hencky-von Mises theory) calculated with primary stresses. Unfortunately stress categories are not distinguished. Solely two hints regarding secondary stresses are given: *"…the permissible stress will be higher (…) when the secondary stresses are taken into account."* and "*Under the effect of secondary stresses, a certain elongation beyond the elastic limit may be permitted in so far as it is consistent with the conditions under which the part is used and taking into account possible changes that it could cause in the properties of the materials*." A value for this dimensioning factor remains open and is often even not specified.

The stress concepts with their allowable stress limits are summarized in Table 1.

Table 1
Comparison of Stress Concepts

BIFURCATION STRESS ASSESSMENT	STRESS CONCEPTS (for normal conditions)		
	ASCE manual no.79 (chapt. 3.4.10)	**ASCE manual no.79 (chapt. 7.3.3)**	**C.E.C.T.**
SHELL PLATES			
P_m [3] *(primary, evaluated in middle fiber)*	$\leq S = \mathrm{MIN}\left(\frac{R_{eH}}{1.5}; \frac{R_m}{2.4}\right)$	$\leq S = \mathrm{MIN}\left(\frac{R_{eH}}{1.5}; \frac{R_m}{3}\right)$	$\leq \sigma_{SFI} = \frac{R_{eH}}{C'}$ [1]
P_l [4] or $(P_l + P_b)$ [6] *(primary, evaluated in middle and surface fiber)*	$\leq 1.5 \cdot S$	$\leq 1.5 \cdot S$	$\leq \sigma_{SFI} = \frac{R_{eH}}{C'}$
$(P_l + P_b$ [5] $+ Q$ [7]$)$ [8] *(secondary, evaluated in decisive surface fiber)*	$\leq \mathrm{MIN}(3 \cdot S; R_m)$	$\leq \mathrm{MIN}(3 \cdot S; R_m)$	$\leq \sigma_{SFII} = \frac{R_{eH}}{C'} \cdot f$ [2]
REINFORCING GIRDER PLATES (SICKLE)			
$P_l + P_b$ *(primary, evaluated in middle and surface fibers)*	$\leq 1.5 \cdot S$	$\leq 1.5 \cdot S$	$\leq \sigma_{SFI} = \frac{R_{eH}}{C'}$

1) For distributors and special parts C.E.C.T. recommends a factor of C' = 1.8 if the structure is embedded in concrete/rock.

2) The allowable primary stresses are increased by a factor f, which allows higher permissible stresses when accounting for secondary stresses. The value f = 1,35 is a value supposed by Andritz Hydro and other professionals to define analytically calculated secondary stress limits which are not clearly defined by standards or specifications.

3) Pm: General Primary Membrane: Membrane stress intensity away from reinforcing girders, from changes in direction and from discontinuities. Stress averaged across the thickness necessary to satisfy the law of equilibrium, e.g. hoop stress from internal pressure.

4) Pl: Local Primary Membrane: Membrane stress intensity adjacent to reinforcing girders and changes in direction, e.g. stress in the immediate vicinity of miters. A stress region may be considered as local if the distance over which the stress intensity exceeds 1.1S does not extend in the meridional direction more than $\sqrt{R \cdot t}$, where R is the midsurface radius of curvature measured normal to the surface from the axis of rotation and t is the minimum thickness in the region considered.

5) Pb: Primary Bending: Bending stress across the thickness of the plate/shell with no redistribution of the load due to yielding.

6) Pl + Pb: Local Primary Membrane plus Primary Bending.

7) Q: Secondary Stress: Normal stress, either bending or axial, or a shear stress developed by constraint of adjacent parts of by self-constraint of a structure. The basic characteristic of a secondary stress is, that it is self-limiting, e.g. stress due to thermal constraints, bending stress intensities across the thickness of a shell or plate at a gross structural discontinuity. The combination of Q with primary stress intensities should be limited to the lesser of minimum tensile strength (Rm) or 3S.
8) Pl + Pb + Q: Secondary: Combination of secondary stress with local primary membrane and local bending stress.

3. CASE STUDY BIFURCATION – MATERIAL AND BOUNDARY CONDITIONS

This report's case study is a vertical 90°-bend which is part of a high head power plant penstock. The bend with an internal diameter of 3800mm is intersected by a vertical access pipe with an internal diameter of 1500mm. The intersection of these bodies (which means huge opening interrupting the hoop stress) is reinforced by an exterior, multiple curved and massive reinforcement or sickle plate.

The internal design pressure at this location is assumed to be approximately 700mWC or 7N/mm².

The purpose of the access pipe is to enable the lowering of inspection platforms and additional maintenance equipment.

The material of the bifurcation is S620QL with the following guaranteed material properties (deviating from EN 10025-6 but in this case study specified by owner's engineer, a trend being observed in recent projects):

Table 2
Material properties S620QL (special requirements, values from inspection and test plan)

Material	Thickness [mm]	R_{eH} [N/mm²]	R_m [N/mm²]
S620QL	50 < t ≤ 150	620	770

with:

R_{eH} : Minimum specified yield strength of the material
R_m: Minimum specified tensile strength of the material

The stress assessment of the bifurcation is done by means of finite element analysis (FEA). The FEA model has to account for the static system of the conveyance system by applying adequate boundary conditions at the up- and downstream ends of the model. The pre- and post-processing of this case study is done by Abaqus/CAE 2017.

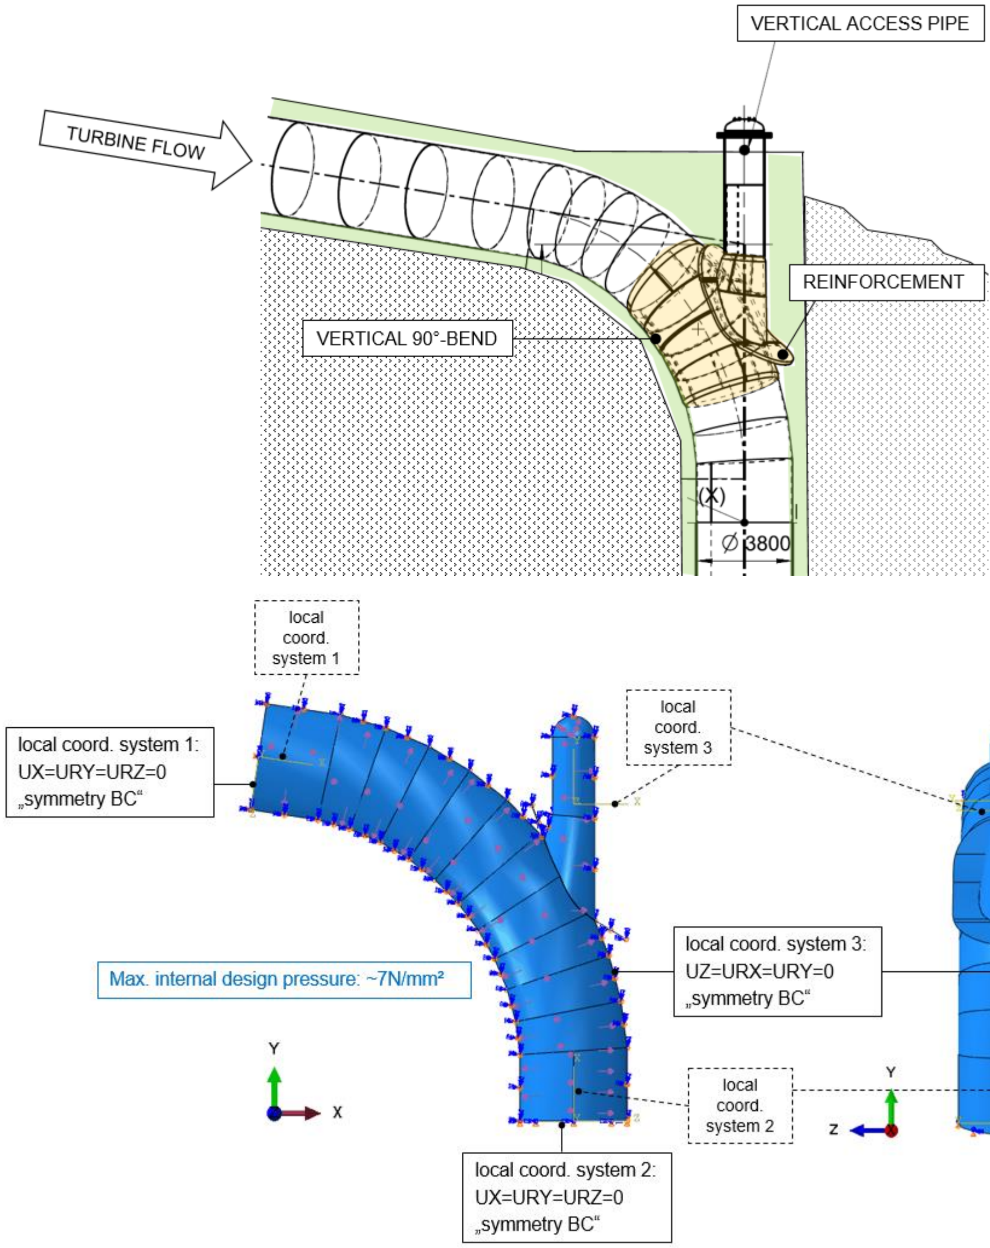

Fig. 2

Case study: Above - vertical 90°-bend with vertical access; below - FEA- model of the bifurcation with boundary conditions

Bifurcations or wye branches are huge, slender structures which justify simulating them on basis of shell models. The stresses across the plate thickness of shell models are evaluated in the middle and in the surface fibers of those elements.

The finite element model is meshed with quadratic shell elements having a maximum element size of 50mm.

Usually such structures are embedded in concrete and surrounded by stable rock. But special components are commonly specified as self-supporting systems without considering the surrounding material in a numerical analysis, as it is assumed for this case study.

3.1. ALLOWABLE STRESS AND RESULTING PLATE THICKNESS

The allowable stresses for the applied high strength steel are summarized in Table 3. Hence it appears that the permissible general primary membrane stress (P_m, hoop stress, undisturbed region) is most strictly restricted by ASCE approach for finite element models (chapter 7.3.3). But for locally increased stress regions (e.g. miters, attachment regions) or for reinforcing girders under mainly bending stress (sickle plate) ASCE concepts allow for higher local stress limits than C.E.C.T. Unfortunately these local stress concentrations often become decisive for plate dimensions. The evaluation of the reinforcement is especially affected since C.E.C.T. makes no difference between certain stress categories (general membrane vs. local membrane/bending). The bending stress of the sickle plate is of general primary nature and is often specified to be evaluated by applying the dimensioning factor for primary stresses (C') acc. to C.E.C.T.

Table 3
Allowable stresses

BIFURCATION STRESS ASSESSMENT	**STRESS CONCEPTS (for normal conditions)**		
	ASCE manual no.79 (chapt. 3.4.10)	**ASCE manual no.79 (chapt. 7.3.3)**	**C.E.C.T.**
SHELL PLATES – Material S620QL			
P_m *(primary, evaluated in middle fiber)*	≤ 321N/mm²	≤ 257N/mm²	≤ 344N/mm²
P_l or ($P_l + P_b$) *(primary, evaluated in middle and surface fiber)*	≤ 482N/mm²	≤ 386N/mm²	≤ 344N/mm²
$P_l + P_b + Q$ *(secondary, evaluated in decisive surface fiber)*	≤ 770N/mm²	≤ 770N/mm²	≤ 465N/mm²
REINFORCING GIRDER PLATES (SICKLE) – Material S620QL			
$P_b + P_l$ *(primary, evaluated in middle and surface fibers)*	≤ 482N/mm²	≤ 386N/mm²	≤ 344N/mm²

Problematic evaluation areas become visible by numerical simulation and are e.g. intersections with locally increased stress concentrations or sickle plate attachments at sharp miters, as illustrated in Fig. 3.

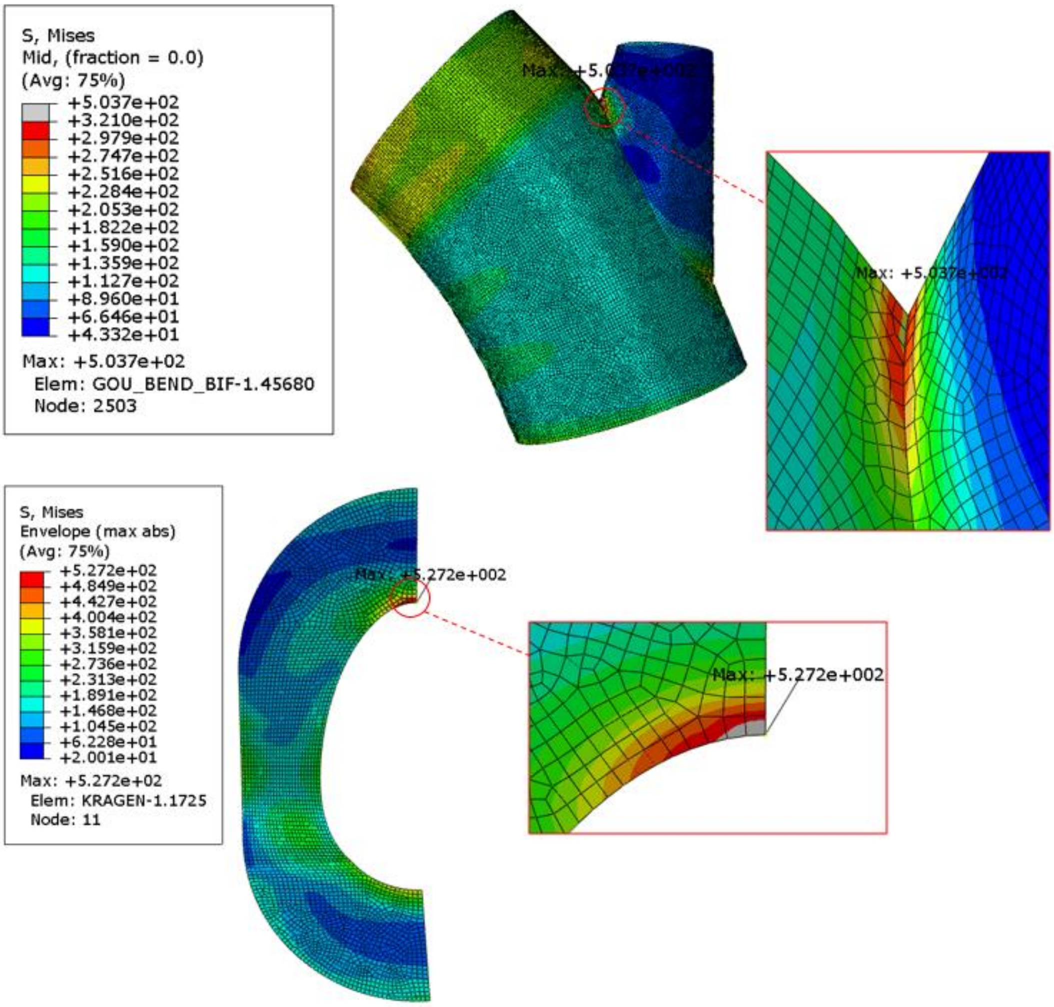

Fig. 3
Local stress concentrations of a bifurcation and a reinforcement; stresses in [N/mm²]

The ASCE approach (regardless of applying chapter 3.4.10. or chapter 7.3.3.) accounts for locally increased stresses and allows a more appropriate stress evaluation with regard to FEA application from authors' point of view.

A comparison of the required plate thicknesses as a consequence of applying above mentioned safety concepts clearly points out the difference in terms of total dead weight, as depicted in Fig. 4: It becomes apparent that the evaluation according to ASCE manual No.79 leads to 20 tons less weight.

It is worth highlighting two more points: Firstly, special parts are usually calculated as self-supporting components without consideration of surrounding concrete/rock. Secondly, advanced quality tests and supervision have evolved in the course of time, which could not be considered in C.E.C.T.

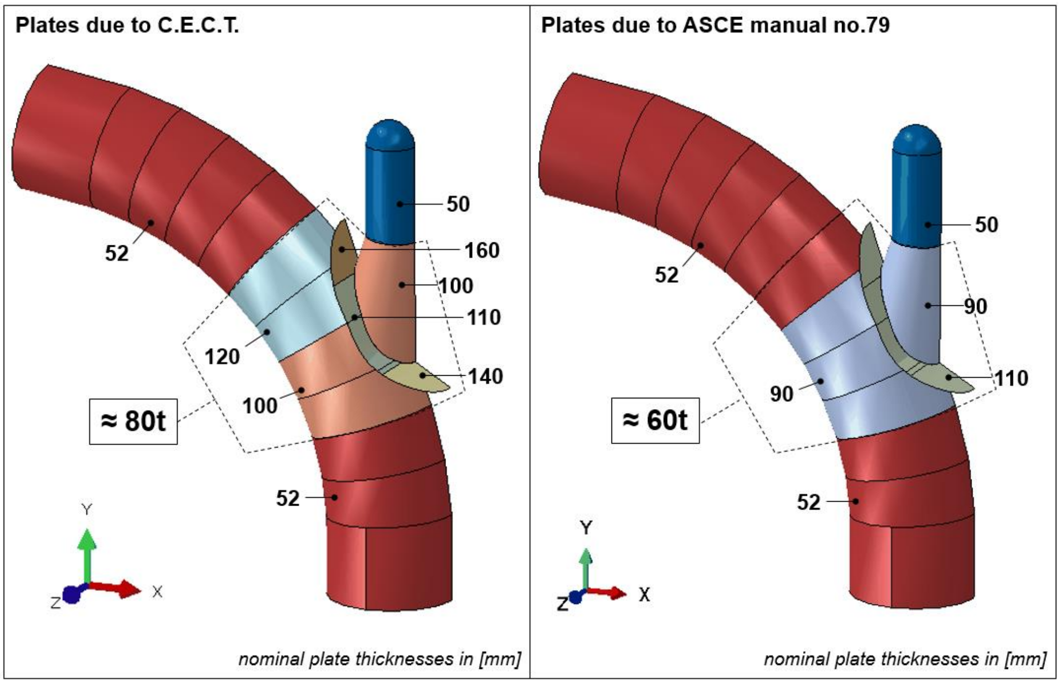

Fig. 4
Comparison of plate thicknesses and total weight

4. IMPACTS ON FURTHER PROCESSES

The choice of an appropriate material quality and its resulting plate thickness is very important. The designed weight due to specified safety concepts strongly impacts further processes. Unnecessarily material, fabrication and installation time and costs will be increased. The whole fabrication and installation method has to be reconsidered. Plate bending machines are limited to certain plate thicknesses. Besides affecting welding preparation requirements (pre-heat, edge prefabrication), also higher welding volume under difficult welding conditions and non-destructive testing needs have to be re-evaluated for example.

Highly pressurized special components are usually made of high strength steel in order to minimize these costs and efforts. As it was pointed out in the previous chapter, safety concepts strongly influence the dead weight of a structural component: The thicker or more robust a structural component is designed with respect to safety against yield, the more complicated it might become for fabrication and welding. Fig. 5 illustrates the high demands on the execution carried out by mounting and welding personnel using the example of full penetration welds between sickle and bifurcation plates. One has to be aware that such huge and heavy components are usually assembled and welded in situ under limited space conditions, where every ton counts. When processes become more complex or complicated, the susceptibility to errors tend to increase and safety margins might be reduced. The application of high strength steel and the determination of plate thicknesses derived by FEA stress results should make such special components both robust and economically justifiable and not lead to the opposite.

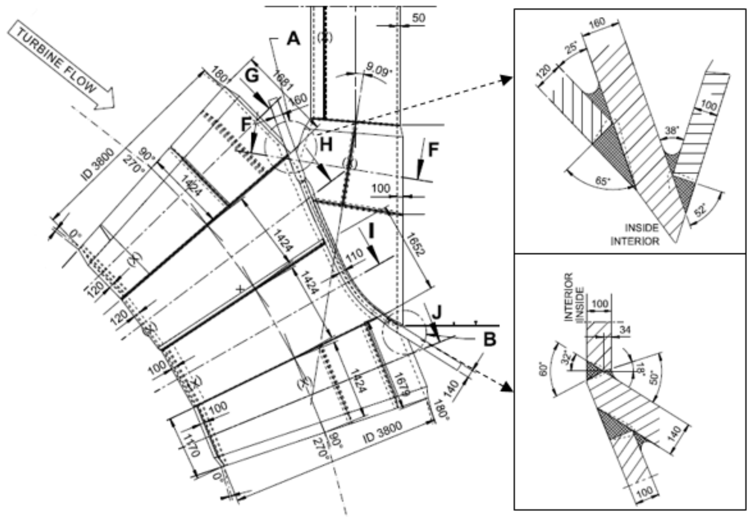

Fig. 5
Weld details of a bifurcation

SUMMARY

Based on a bifurcation design made of high strength steel a comparison between traditional C.E.C.T. safety concept and ASCE manual no.79 approach leads to following conclusion: ASCE manual on steel penstocks which is intended for the design of higher pressure, larger diameter and/or more critical conveyance systems used for power generation appears to be a more accurate standard to numerically evaluate special and geometrically complex parts. Its safety concept accounts for local stress concentrations which become visible by finite element analysis and therefore helps to profit by the benefits of high strength steel applications such as reducing the total weight.

1. INTRODUCTION

Developments of the design of steel linings for pressure shafts are an ongoing process, stimulated by the erection of new plants and the increased dynamic loading due to pumping and intensified operation. At the 3. International Conference “HSS for Hydropower Plants” in 2013 [1] the state of developments of that time was reported, - this paper is to present the progress achieved since then in Austria.

One topic deals with the composite behaviour of the HSS-liner with the rock mass. It gives an overview on a consolidated design concept based on the ultimate limit state of the combined system of steel liner plus rock mass, which accounts for the post-failure capacity of the rock in the cracked state. The new concept results in a mechanical consistent approach and leads to a significant increase of rock participation and saving of steel.

The second topic deals with the effects of cyclic loadings, which arise in the steel liner due to operational pressure variations and to pressure oscillations resulting from emptying the penstock. The first may cause fatigue, the second cyclic plasticity. Both may significantly determine the design of the steel liner and affect the detailing and fabrication of welds and local structural parts. As result of the intensified operation of hydropower plants and of pumping these effects become more important nowadays.

2. ULTIMATE LOAD DESIGN

The design of the composite system of a steel-liner with the rock mass is traditionally based on elastic rock behaviour expressed by the modulus V_R* and on the elastic behaviour of steel expressed by the allowable stress $k x f_y$ (f_y denotes the yield stress). The design criteria currently used in Austria were discussed in [1] and Fig.1 illustrates them here again for better understanding (thereby the terms V_F, p_F,p_S,σ_S correspond to V_R, p_R,p_{ST},σ_{ST} of the present paper).

Criterion 1 describes the uniform state of elastic rock behaviour around the liner and the splitting of the internal pressure into p_{ST} of the steel lining and p_R of the rock. The interaction is both elastic and axially uniform.

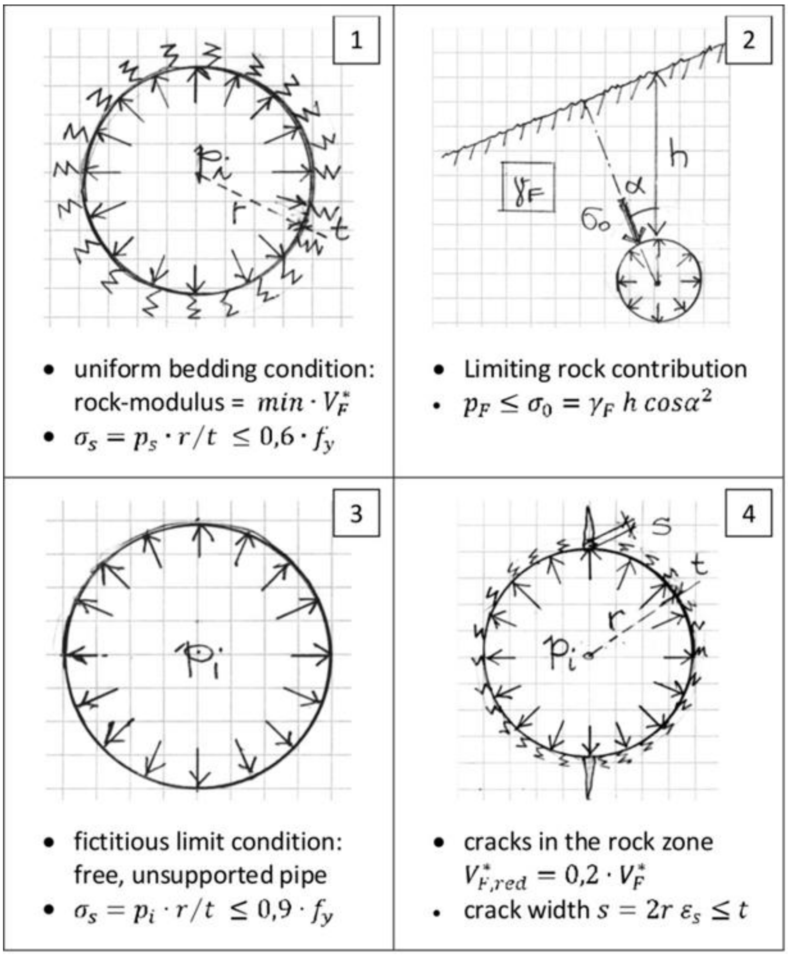

Fig. 1: Current design criteria of steel liners for internal pressure

Criterion 2 defines the limit condition for the rock participation p_R by the overburden of the rock mass.

Criterion 3 represents a fictitious ultimate limit-condition of the steel liner by ignoring any support by the rock and using $0{,}9xf_y$ as limit stress.

Criterion 4 deals with the bridging of a potential crack in the rock soffit by the ductility of the steel lining. The reduction of V_R^* to 20% of the elastic one may be considered as conservatism, but nonetheless it cannot describe the mechanical behaviour in realistic way.

Considering the four criteria in practical design conditions offers that the stress state at the service load level is mechanically reliable and has often been verified in real structures, but that a sound prediction of the capacity of the liner-rock system at the ultimate load level cannot be made. As result - especially in cases of firm rock stiffness - the design is dominated by the criterion 3 leading to unfavourable liner thicknesses.

To this purpose the new concept developed by G. Innerhofer sen. closes the existing gap by providing design rules for the ultimate load resistance of steel liners considering the post-failure capacity of the rock mass in the cracked state. This means that the rock participation is not only the result of the elastic rock behaviour, but is extended to its cracked ultimate state. Further, the steel liner in this interaction may also be considered with its plastic limit capacity. The concept has been mechanically derived for axial uniformity of the rock parameters and conservative preconditions as neglect of tension resistance of the rock and the formation of just one concentrated through-crack (see Fig 1 - *4*) have been made.

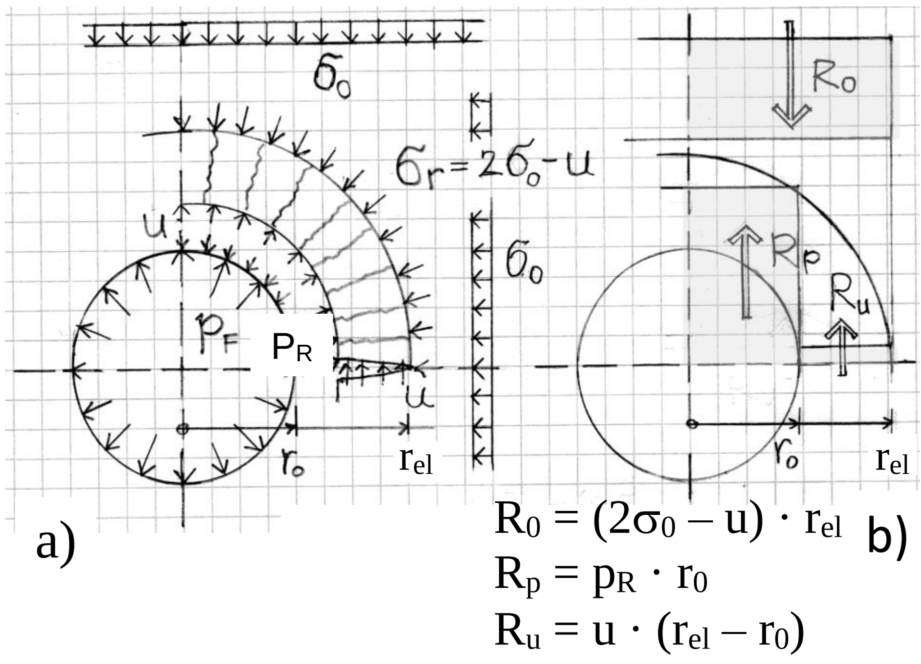

Fig. 2: Ultimate limit state of rock with cracked zone: (a) stress state, (b) stress resultants.

The background of the concept and its derivation is given in [2] but the basic steps are again illustrated here to establish a better context. Fig.2 shows the equilibrium state of the rock mass in the cracked state. Under increasing pressure p_R on the rock surface the radial crack opens and grows to a certain depth r_{el}. Thereby, the crack water pressure u starts acting along the length (r_{el}-r_0) of the crack. The cracked zone propagates as long as equilibrium is found with the primary stress state σ_0 and the crack-water pressure u. Outside of the boundary r_{el} the rock is in the elastic range.

Crack formation at the soffit r_0 starts when p_R reaches the limit ($2\sigma_0$-u); - the same is found at r_{el} for (σ_r=$2\sigma_0$-u). This limit ($2\sigma_0$-u) considers small initial fissures along the soffit after excavation so that $2\sigma_0$ is reduced there by the effect of u before the real cracks start forming.

In form of resultants the equilibrium condition can be set up by the components R_0, R_p and R_u. As result one may find expressions for the crack depth under a given pressure p_R or for p_R under a given crack ratio r_{el}/r_0:

$$\frac{r_{el}}{r_0} = \frac{p_R - u}{2(\sigma_0 - u)} \qquad \text{or} \qquad p_R = 2(\sigma_0 - u)\frac{r_{el}}{r_0} + u \qquad (1)$$

The approach leads to increased radial deformations in the cracked state compared to the current elastic design and therefore the ductility demands on the steel liner for bridging the crack width at the rock soffit play an important role. The crack width must be covered by the critical width of the steel. This condition limits the allowable crack propagation of the rock in the ultimate limit state. Since the plastic elongation of the steel liner –in the local area bridging the crack- is restricted by the friction effect between the outer liner surface and inner surface of the filling concrete this condition may pose a challenge for HSS-liners due to their reduced ductility parameters, particularly in the welds.

The radial deflection Δr_0 of the rock soffit at r_0 consists of 2 parts, i.e. Δr_{cz} of the cracked zone in radial compression plus Δr_{el} of the sound elastic zone outside of r_{el}, see [2]. Thereby ν denotes the Poisson-factor of the rock material:

$$\Delta r_{cz} = (p_R - u).r_0.\ln\left(\frac{rel}{r0}\right) + \upsilon.\sigma_0.r_0 - (1-\upsilon).(\sigma_0 - u).(r_{el} - r_0)/V_R$$
$$\Delta r_{el} = (\sigma_0.r_0 + (\sigma_0 - u).r_{el})/V_R * \quad with\ V_R *= V_R/(1+\upsilon) \qquad (2a), (2b)$$

The crack width for the assumed through-crack is taken equal S_w = 2.(Δr_0 - Δr_A) where Δr_A = ($2\sigma_0$-u).r_0 / V_R* denotes the radial deformation at the point when crack initiation starts at the soffit r_0.

The critical crack width S_{cr} - assuming linearized stress-strain behavior for the rather small stretched length L_S - can be determined from (3a, 3b). Thereby, the notations apply as follows: $\Delta\varepsilon_{pl} = \varepsilon_u - \varepsilon_y$, $\Delta\sigma_{pl} = f_u - f_y$ and μ_F = friction factor. As mentioned above the ductility parameters of HSS may be rather low for thermo-mechanically produced grades, in particular in welded plates where $\Delta\varepsilon_{pl}$ –values may sag to about 2,5% [for more information see [1]).

$$L_s = 2 \cdot \Delta\sigma_{pl} \cdot t/\mu_F \cdot p_R \qquad S_{cr} = (\Delta\sigma_{pl} \cdot \Delta\varepsilon_{pl}).t/(\mu_F \cdot p_R) \qquad (3a), (3b)$$

Concerning the safety requirements specific elements for the rock and the steel behaviour underlie the concept. The hydrodynamic pressure line is usually defined in a conservative way covering also exceptional effects and does not need a further safety factor. The safety factor of the rock parameters is to cover the radial deformations and the crack width and follows from experience and measurements. A factor of 2,0 on the rock modulus V_R* for design calculations can be considered as recommended value. Further, a limitation of the crack-depth would be reasonable. The safety factor of the steel is recommended to 1,75 on f_y. Both factors should be adapted to the risk potential and the state of knowledge of the geotechnical conditions.

Fig.3 presents an example showing the basic design aspects under internal pressure loading for a liner of the steel grade S690 and the rock with the modulus V_R* of 6GPa. The parameters describe a very shallow shaft where the effect of cracked rock is most significant. The outcome may be summarized as follows:

- On the ultimate load level (ULS) based on the reduced V_R* = 3GPa radial cracking starts at the strain $\Delta r/r_0$ of 0,53‰ and the design pressure of 10MPa is reached at 3,25‰, just in the plastic range of the steel with the yield strain of 3‰. The internal pressure is split there to about 60% for the rock mass and to 40% for the liner. The allowable strain of the steel in the ULS is limited by $\Delta r/r_0$ = 3,3‰ where the crack width 5,5mm reaches the critical value. Thus, the limiting condition of crack bridging has just been achieved.

- On the service load level (SLS) -based on V_R* = 6GPa- the design pressure is reached at 1,7 ‰ of strain where the rock is in the cracked state. However the steel liner is elastic, except in the local points where crack bridging occurs. Since crack bridging is an action of imposed local deformation, the stress state may be considered as secondary stress.

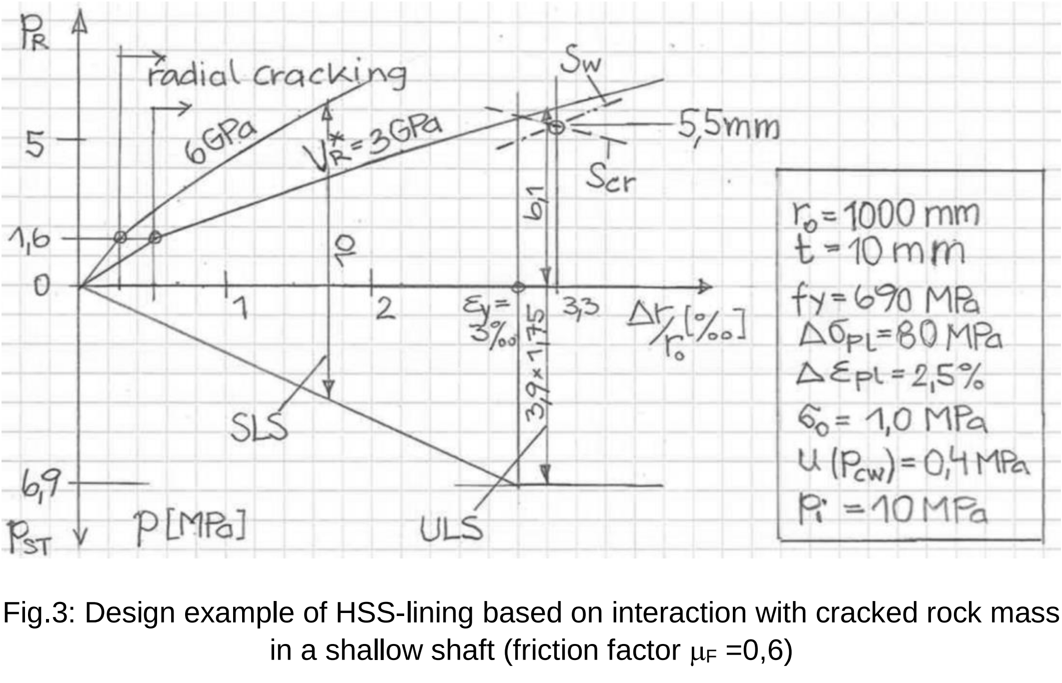

Fig.3: Design example of HSS-lining based on interaction with cracked rock mass in a shallow shaft (friction factor μ_F =0,6)

Three main results of liner-design follow from the new concept:

Firstly, the traditional rock participation is no longer limited by the elastic resistance of the rock in the uncracked state which would amount in the given example to just 1MPa due to the current design philosophy.

Secondly, the traditionally used ULS-check under internal pressure based on the fictitiously free, unsupported liner with the allowable limit stress of $0{,}9xf_y$ is now overcome. In the given example, this leads to a reduction of wall thickness by about 33% in case of ultimate design under internal pressure.

Thirdly, liners in shallow shafts may exhibit the phenomenon of crack bridging even on service load level – and if, this occurs also in case of the current design conditions. Although any damage due to this effect has not yet been discovered, for such cases further studies are needed to evaluate this influence also under cyclic load conditions. Accordingly, this topic is not included in the next chapter.

3. CYCLIC LOADING OF HS-STEEL LINERS

The second topic deals with the effects of cyclic loading on the steel liner. There are two kinds of cycles; - those with high frequency leading to failure by fatigue and those with low frequency, which may lead to cyclic plasticity. The first ones are summarized by load spectra (Δp_i, $N=2.10^6$) resulting from pumping and turbine-operation, the second ones are pressure oscillations due to emptying the penstock, which arise between the maximum hydrodynamic level p_{imax} and the level of crack-water pressure p_{cw} in the empty state ($\Delta[p_{imax} - p_{cw}]$, N=50). Thereby, both states also include their specific temperature variations.

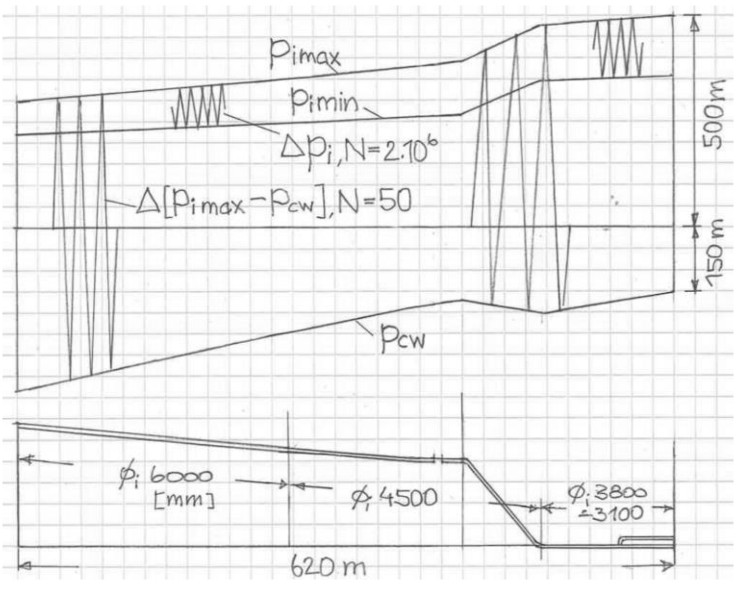

Fig.4: Example of cyclic loading conditions of a steel lining

These effects - mainly resulting from intensified operation- nowadays may lead to limiting design conditions for the linings and cause great demands on the detailing and fabrication of welds and structural parts like injection-nipples, openings, thrust-rings etc.

Fig. 4 illustrates the load conditions of a penstock recently under construction with linings in HSS 690. The load spectrum Δp_i has been based on an operating time of 100 years including pumping and the pressure variation Δp_i results in about 28% of the maximum hydrodynamic pressure. The variation $\Delta[p_{imax} - p_{cw}]$ is rather large too, due to the high crack-water level.

The specification of the load spectrum is usually provided by the hydro-power company of the plant since it is in close context with the planned service life of the penstock. In the given case it was composed of a mixture of expected operating sequences over 100 years and then increased with a factor of 1,2 on Δp_i and 5 on the number of cycles; - just for understanding, the latter means that the spectrum-length is increased by $5^{1/3}$.This approach is not a standard in Austria but it seems reasonable in view of a longstanding use of penstocks.

The design of these linings illustrated that a large part of them is dominated by the buckling phenomenon so that the general stress level under internal pressure is rather moderate there (see Fig.5). Nonetheless, the cyclic loads result in a high utilisation level at points of stress raisers like welds and local structural parts mainly resulting from grouting. The utilisation factors – both of fatigue and cyclic plasticity- may increase there up to 95%, which leads to the conclusion that the cyclic stress states surpass the static ones. This means that – in view of linings with higher utilisation under internal pressure - high attention must be paid to the cyclic material behaviour of HS-steels.

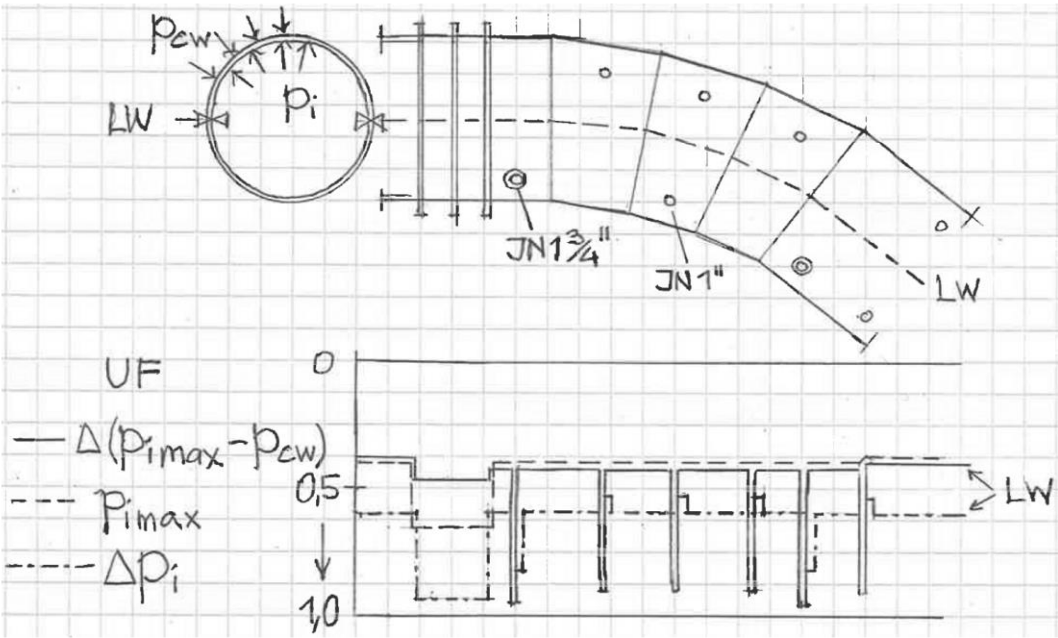

Fig.5: Example of a liner section under cyclic load, - utilisation factors UF

The above findings –as already mentioned above- are the result of the stress concentrations arising at local parts in the liner. Fig.6 demonstrates just some examples of stress concentration factors SCF, which may appear in such details in a large range of magnitude. These SCF mainly affect both the phenomena of fatigue and cyclic plasticity while ultimate stress design usually based on the area replacement method is not decisive in ordinary cases.

Cyclic plasticity is the limit state, which assures that incremental strain accumulation is avoided, and it is understood by the term “Shakedown”. It is the condition that after the first cycle of load, where some plastic strain occurs, the component behaviour is purely elastic in all following cycles. The target of it is avoiding any kind of plastic strain accumulation, which can lead to incremental collapse. For elastic-perfectly plastic material in a uniaxial stress state the maximum allowable elastic stress range is $2xf_y$, which is called shakedown-factor of 2,0 (Fig.7a). The actual shakedown factor for a general component is below this limit and depends on both the geometry and the type of loading [3]. Fig.7b illustrates the condition for a biaxial stress state of a cylindrical vessel under radial line-load [4] leading to the shakedown factor of 1,75.

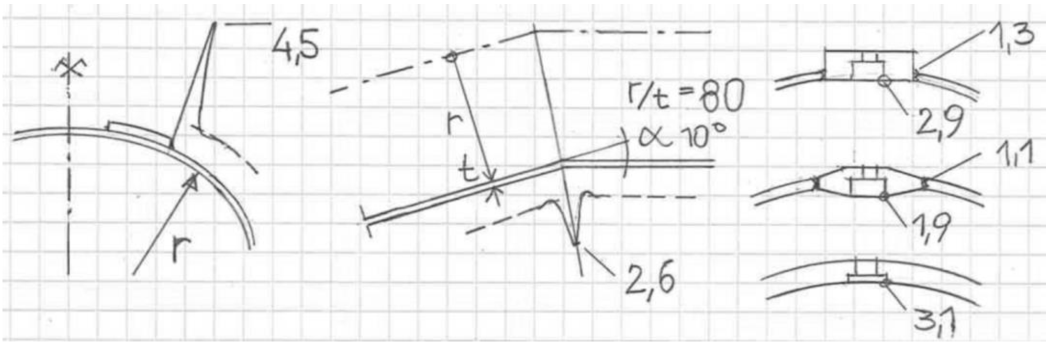

Fig.6: Stress concentration factors SCF for local structural parts

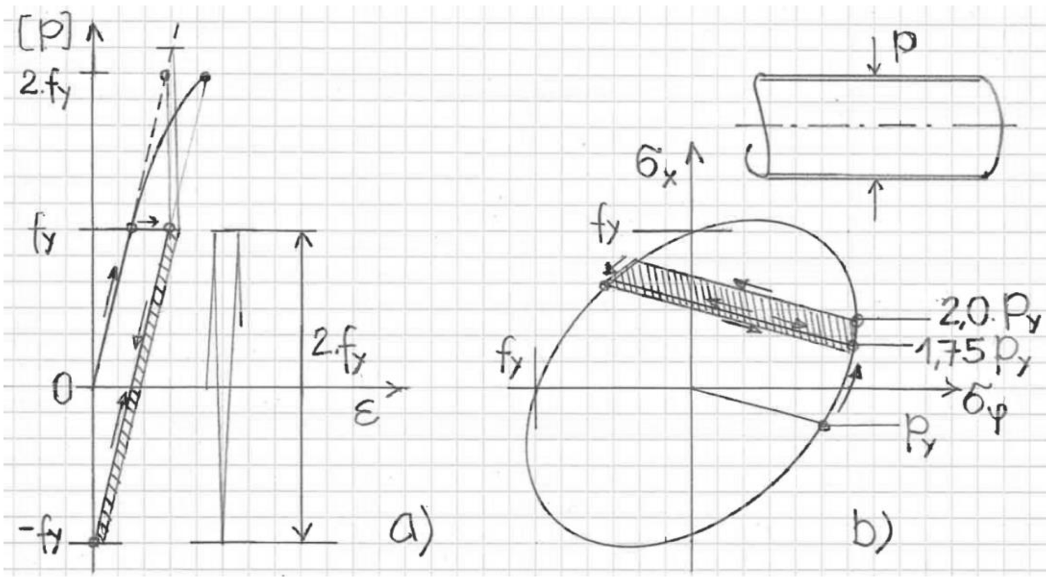

Fig.7: Shakedown for uniaxial (a) and biaxial (b) stress states

An example of nozzles in cylindrical vessels under cyclic internal pressure shows the progress of plastic strains in form of test results (Fig.8). When a cyclic pressure of 1,7xf_y is applied, the incremental strain reduces to zero after 20 cycles. If the pressure is increased to 1,82xf_y, small values of (constant) plastic strain still occur after 45 test cycles, which creates the case when progressive plastification occurs [3].

Some standards like the BS5500 for pressure vessels use a method for the shakedown factor, which is linked with the SCF of the component and leads to lower factors than 2,0, e.g. to 1,67 for the SCF=2. The Eurocode 3-1-6 for shell structures defines the shakedown by the factor of 2,0, which in light of the above results does not well fit to the to shell-type components of liners. For design purposes of HSS-liners a shakedown limit of 1,2xf_y has presently been fixed, which is conservatively derived from 1,6xf_y divided by a safety factor of 1,35, - the latter, to cover unknown effects of high steel grades, since relevant shakedown tests for HSS are not available so far. This limitation may later be raised when deeper insight into the behaviour of HSS is available. Experimental investigations would therefore be required.

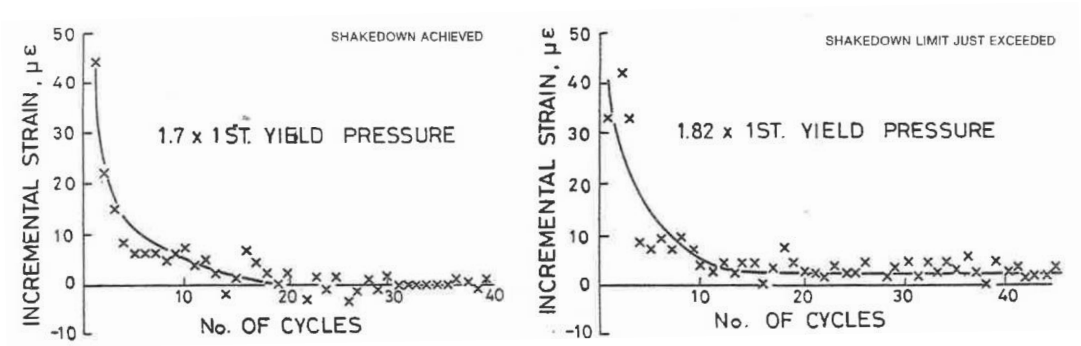

Fig.8: Incremental strains at crotch of a nozzle during shakedown tests [3]

The design limits for fatigue may be taken from the Eurocode 3-1-9 or from the IIW-Recommendations [5], which are identical for nominal stress design. For structural hot spot design however, the rules in [5] are more advanced and should therefore be applied where required. For certain structural details of liners specific solutions are missing in the above codes, like for welds at transitions of different wall thickness or intersections of longitudinal and circumferential welds at rings (see detail A in Fig.9). For the fatigue design of nipples or openings for grouting, which are the main stress raisers in liners, recommendations have already been elaborated [6].

Another structural part creating high utility are thrust rings, as shown in the example of Fig. 5. Some remarks are given in the following, since just few specific investigations of thrust rings are available so far. The design problem splits firstly into the load introduction of the thrust-force into the concrete and into the rock mass respectively and secondly into the fatigue design of the steel structure itself. The former has been elaborated recently [7] including rules for the elastic spring constants of the rings in axial direction. The latter comprises the calculation of the thrust forces subdivided into the individual rings and then the diverse fatigue checks at the different weld details shown in Fig 9. The individual thrust forces may be determined on basis of a bar with axial springs, however the shell-behaviour in form of the Poisson-effect due to internal pressure variation must be included because of its significant influence. It is interesting to see that – contrary to expectations - not the first ring but the last one –depending on the Poisson-effect - may take the highest percentage of the force as given in case of the example in Fig.9a. The diverse fatigue checks at the welds are indicated in Fig.9b – in particular the check at position A, where the longitudinal weld LW crosses the transverse circumferential weld of the ring. Although longitudinal welds are usually ground flush it should be investigated if the detail may be assumed comparable with that of the transverse-welded attachment on a plane plate.

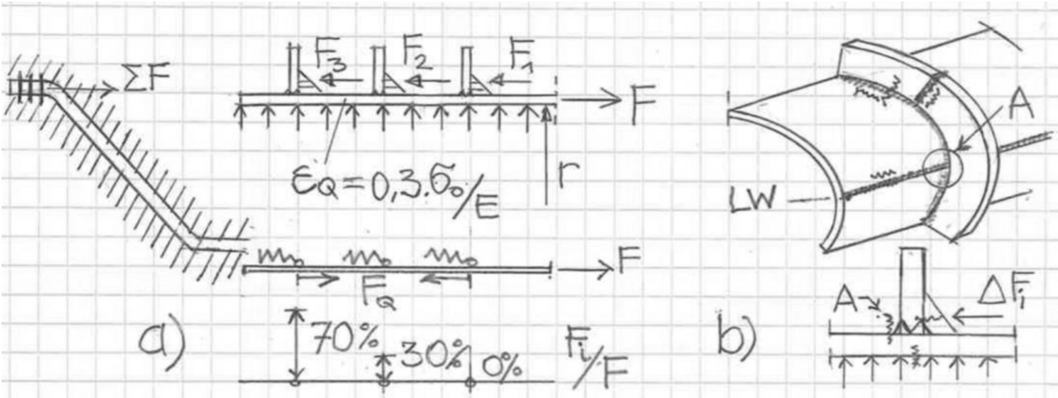

Fig.9: Thrust rings: calculation of force distribution (a) and points of relevant fatigue checks (b)

SUMMARY

The new developments presented in the paper comprise two aspects of design of Pressure shafts with high strength steel liners in context with the planning of new shafts or the experience from recently erected ones.

The first one is a consolidated design concept aimed at the ultimate load resistance of steel liners of pressure shafts, which includes an enhanced rock participation in the cracked state of the rock mass. Thereby, the limiting condition is the radial deformation of the soffit, which is restricted by the phenomenon of crack bridging of the steel; - whereby the latter may make high demands on the ductility parameters of HSS. Further, an amended safety concept has been proposed with individual factors for the rock and the steel liner. It on the one hand presents a mechanically consistent approach and on the other may also help to reduce the amount of steel.

The second part deals with the effects of cyclic loading on the design and detailing of the steel liner. It illustrates the design for the limit state of cyclic plasticity (shakedown) and its influence on the utilization of the steel liner. It further indicates that experimental investigation of the cyclic behavior of HSS is needed in order to define a sound shakedown limit for HSS.

Similarly, the effects of fatigue on the utilization at points of local structural parts have been adressed here illustrating their strong impact on the service life of the plant. Also shown is the need to investigate shell-specific details of steel liners, which are not covered by the standardized details of steel structures or pressure vessels so far.

1. INTRODUCTION

The recent development of high strength weldable steels has enlarged the range of design alternatives for the optimization of high-head steel-lined pressure tunnels and shafts in the hydropower industry. With the liberalization of the European energy market and increasing contribution of new renewable volatile energies in the electricity grid, storage hydropower and pumped-storage plants are subject to more severe operation conditions than before, resulting in frequent transients. Whilst the use of high strength steel allows the design of thinner steel liners, welded high strength steel do not provide higher fatigue resistance than lower steel grades, and may be subject to the risk of cold cracking [1]. Fatigue behavior may become the leading limit state criterion [2].

The research project presented hereafter aimed at: (i) improving the comprehension of the mechanical behavior of steel-lined pressure tunnels and shafts (presented in the Section 2 herein); and (ii) developing a framework for probabilistic fatigue crack growth and fracture assessment of cracks in the weld material of longitudinal butt welded joints, considering all possible steel grades for high-head hydropower schemes (presented in Section 3 of this paper).

The influence of anisotropic rock behavior and geometrical imperfections at the longitudinal joints on the structural stresses was studied by means of the finite element method (FEM) accounting for the interaction with the backfill concrete-rock multilayer system [3-4]. Parametric correction factors were derived to estimate structural stresses in steel liners with ease in practice. Stress intensity factors (SIF) for axial cracks in the weld material of the longitudinal joints were also obtained by means of computational Linear Elastic Fracture Mechanics (LEFM). The use of the previously developed parametric equations in the classical formulas for SIF in cracked plated structures was validated [5].

Finally, a probabilistic model (the Monte Carlo simulation procedure) for fatigue crack growth assessment was developed in the framework of LEFM and the Paris-Erdogan law. A week-long normalized loading spectrum derived from prototype measurements on an alpine pumped-storage hydropower plant in Switzerland was used [6]. This approach provides relative and quantitative results through parametric studies, giving new insights on the fatigue behavior of steel liners containing cracks in the weld material of the longitudinal joints.

2. STRESS INTENSITY FOR CRACKS IN THE WELD MATERIAL

2.1. GENERAL FORMULATION OF STRESS INTENSITY FACTOR IN PLATED STRUCTURES

Parametric equations for axial semi-axial surface cracks in cylinders are available in literature (vide [7]). However these solutions either cannot account for geometrical imperfections, or require the stress distribution on the crack face. Given the slenderness of the steel liners of pressure shafts, solutions for semi-elliptical surface cracks in plated structures can be considered as follows, according to Newman [8]:

$$K_I = M_w[M_m(\sigma_m + p_{cr}) + M_b\sigma_b]\sqrt{\pi a/Q} \qquad [1]$$

where: σ_m and σ_b are the membrane and bending stresses, respectively; p_{cr} is the pressure applied on the crack face (for a surface crack at the internal surface of a steel liner, the internal water pressure); M_m and M_b are the shape correction factors applied to the membrane and bending stresses, respectively; M_w is the weld shape correction factor; a is the minor semi-axis for an elliptical crack (e.g., crack depth for a semi-elliptical surface crack); and Q is the flaw shape parameter.

In the case of steel-lined pressure shafts, the complex interaction between all geometrical imperfections and the contact between the steel liner and the concrete-rock system have never been studied, particularly in anisotropic rock. Those specific features of these complex structures may greatly influence the input of Eq. [1], such as the membrane and bending stresses σ_m and σ_b.

2.2. INFLUENCE OF ANISOTROPIC ROCK BEHAVIOR ON THE NOMINAL STRESS

2.2.1. Conceptual model

The conceptual model for the calculation of stresses in steel line pressure shafts is presented in Fig. 1.

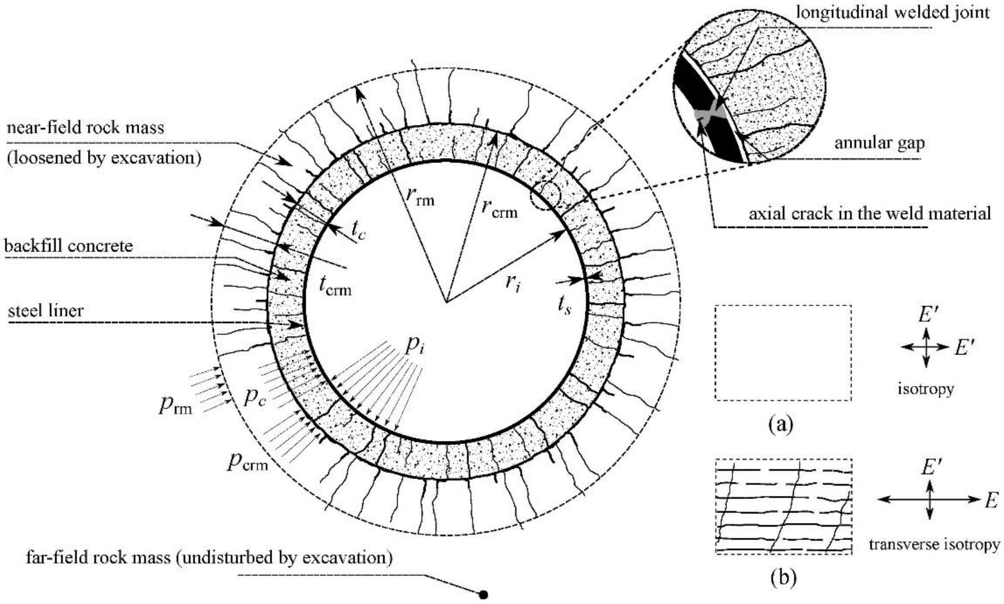

Fig. 1
Conceptual model (cross-section) of a steel-lined pressure shaft in different rock masses, with an emphasis on a longitudinal surface crack at the longitudinal weld (modified after [2])

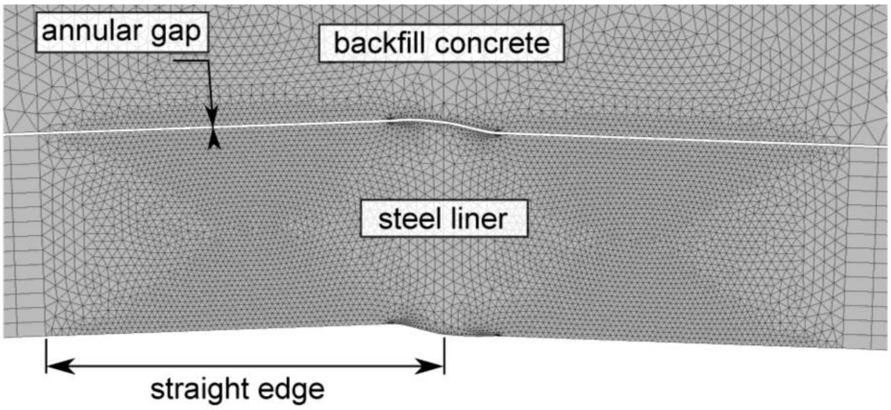
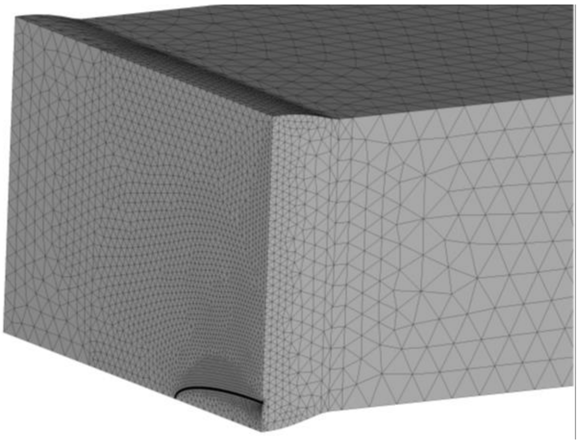
(a) Finite element model to study the influence of anisotropic rock



(b) Finite element model to study the influence of geometrical imperfections



(c) Finite element model to study stress intensity factors

Fig. 2
Finite element models developed to investigate the mechanical behavior of steel-lined pressure shafts
Modèles éléments finis développés dans le but d'étudier le comportement mécanique des puits blindé en charge

In this multilayer system, five layers are generally distinguished as presented in Fig. 1. A detailed description of these layers can be found, e.g., in [3]. In isotropic rock (vide (a) in Fig. 1), the system is axisymmetric, and stresses and displacements can be computed via an analytical solution [3].

2.2.2. Correction of the isotropic formulation

Pachoud and Schleiss [3] have studied systematically the influence of anisotropic rock behavior on the maximum stresses in the steel liner by means of the FEM (vide Fig. 2(a)). The particular case of transverse isotropy (e.g., foliated rock with a plane of isotropy parallel to the main foliation, see Fig. 1) was considered within ranges found in situ. It was found that such anisotropy mainly influences the nominal stress in the steel liner. The authors developed correction factors to be included in the analytical solution in isotropic rock allowing to determine the maximum stress in the steel liner considering the anisotropy [2,3,9].

2.3. INFLUENCE OF GEOMETRICAL IMPERFECTIONS ON THE STRESS CONCENTRATION FACTOR AT THE LONGITUDINAL WELDS

Geometrical imperfections are expected to produce bending stresses σ_b at the longitudinal butt welded joints. The effects of the geometrical imperfections presented in Fig. 3 have been studied by Pachoud [9] by means of the FEM (vide Fig. 1(b)), partly based in the descriptions provided in the C.E.C.T. recommendations [10].

Pachoud [9] has shown that the embedment removed the effect of out-of-roundness, whilst the roof-topping ("peaking") and the misalignment effects remain, barely influenced by the contact with the concrete-rock system. It was also shown that the stress concentration factors (SCF) at the longitudinal welds can be computed using SCF formulas for plated structures and shells [9,11].

2.4. ESTIMATION OF THE STRESS INTENSITY FACTOR FOR CRACKS IN THE LONGITUDINAL WELDS

The SIF for semi-elliptical surface at the longitudinal welds of steel liners (vide Fig. 4) was studied by means of the FEM (vide Fig. 2(c)) and the LEFM by Pachoud et al. [5]. It was shown that the previously published analytical/empirical solutions for cracks in plated structures can be used in the case of steel liners of pressure shafts, using the SCF studied by the authors [2,3,9]. The influence of the weld shape was also studied, and an empirical solution for M_w was proposed [5].

3. FATIGUE CRACK PROPAGATION

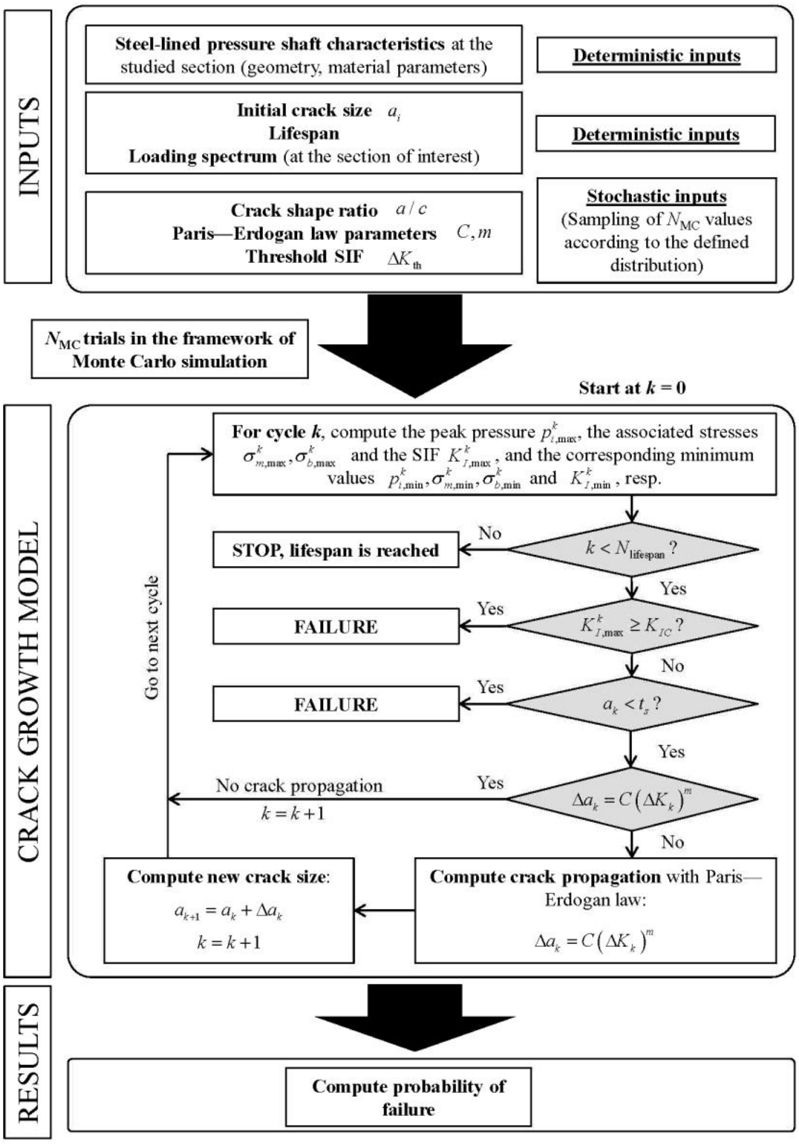

Fig. 5
Flowchart of the proposed Monte Carlo simulation procedure (modified after [2])
Fluxogramme de la procédure de Monte Carlo proposée (modifiée et étendue d'après [2])

3.5. LOADING SPECTRUM

Hachem and Schleiss [12] have measured transients generated within the course of one week of normal operation of an alpine pumped-storage scheme in

Switzerland, equipped with horizontal axis ternary groups with single-stage pumps and Francis turbines. These data were filtered and assembled by Hachem and Giovanola [6]. Pachoud [9] analyzed these data using the Rainflow Counting technique and derived a loading spectrum, which was then normalized with respect to the mean pressure $p_{i,mean}$. The normalized spectrum was used and scaled up for fatigue crack propagation in steel-lined pressure shafts cases.

3.6. PROBABILISTIC MODEL FOR FATIGUE CRACK GROWTH AND FRACTURE

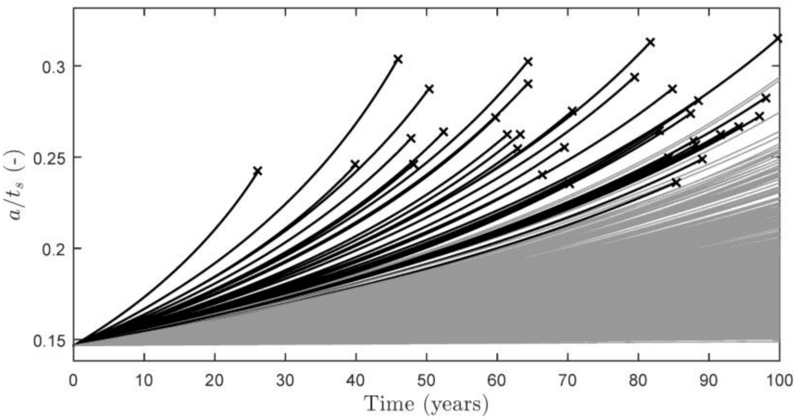

Fig. 6
Semi-elliptical surface crack growth as a function of time (x = failure) from the probabilistic model (1000 trials, in aggressive environment)
Propagation de fissures semi-elliptiques en fonction du temps (x = rupture), issue du modèle probabiliste (échantillon de 1000 valeurs, environnement agressif)

Pachoud [9] developed a probabilistic model for fatigue crack growth and fracture of initial axial cracks in the weld material of longitudinal butt welded joints of steel liners of pressure shafts. This model was implemented in the scope of the Monte Carlo simulation procedure, considering the well-known Paris-Erdogan law. The flowchart of the procedure is presented in Fig. 5. The complete and detailed methodology to compute pressures, stresses and SIF at each loading cycle is presented in [2] in the scope of a deterministic approach. More details on the probabilistic approach are presented in [9].

An example of result that can be obtained with the proposed approach is shown in Fig. 6, for only 1000 trials for the sake of presentation herein (mean static pressure of the load spectrum $p_{i,mean}$=15 MPa; steel liner thickness t_s=27.3 mm; initial crack depth a_i=4 mm; steel yield strength f_y=960 MPa, safety factor SF=1.8 on the yield strength for the design; elastic modulus of the isotropic rock E=5.0 GPa). The same procedure can be used to obtain the probability of failure of the steel lining within a given timespan and to determine the acceptable undetected initial crack sizes in the steel liner, for different steel grades options.

4. ACKNOWLEDGEMENTS

This study is part of *HydroNet 2: Modern methodologies for design, manufacturing and operation of hydropower plants*, a research project funded by the Swiss Competence Center Energy and Mobility (CCEM-CH). Additional support was obtained from the Swiss Committee on Dams (SwissCOD) and the Swiss Competence Center for Energy Research—Supply of Electricity (SCCER-SoE).

SUMMARY

This paper presents a novel contribution for the design of steel lined pressure tunnels and shafts considering (i) the influence of anisotropic behavior of rock as well as (ii) the geometrical imperfections and flaws at welds on the fatigue resistance of the steel liners. This issue is of utmost interest for high-head hydropower plants, in particular when considering the use of high-strength steels and low overburden. For fatigue assessment, a probabilistic model for steel liner crack growth and fracture in the steel liner was developed by using a set of new parametric equations for stress concentration at welds and stress intensity factors for cracks. The application of this model is illustrated in the paper for a case study subjected to dynamic loading. The probabilistic model allows to determine the acceptable undetected initial crack sizes in the steel liner depending on the choice of the steel grade, which is crucial for engineering practice using high-strength steels for pressure tunnels and shafts.

L'article présente une nouvelle contribution à la conception et au dimensionnement de galeries et de puits blindés, en tenant compte de l'influence (i) de l'anisotropie du massif rocheux et (ii) des imperfections géométriques du blindage et des défauts aux soudures, dans la résistance des blindages à la fatigue. Ce sujet est important pour les aménagements hydroélectriques à haute chute, en particulier ceux avec des structures blindées avec des aciers à haute limite de résistance ou avec un faible recouvrement rocheux. Pour l'analyse de la résistance à la fatigue l'article propose un modèle probabiliste basé sur un nouveau jeu d'équations paramétriques pour les concentrations de contraintes dans les blindages et pour l'intensité des contraintes aux fissures. L'application du modèle est illustrée pour un cas d'étude soumis à un chargement dynamique. Le modèle probabiliste permet d'obtenir les dimensions initiales maximales des fissures non-détectées selon le type d'acier, ce qui est primordial pour le choix en pratique du type d'acier à haute résistance pour les galeries et puits blindés.

During pressure test of a manifold of a brand new huge hydro power penstock fabricated from advanced high strength steel a catastrophic fracture appeared by breaking the circumferential weld of the closure head before reaching the design pressure. By analysis of the reasons of this event severe embrittlement of weld metal has been detected by observing intergranular fracture surface and toughness testing of the weld metal. Further investigations revealed that the embrittlement was caused by unqualified post weld heat treatment (PWHT) during fabrication, characterized by extremely low cooling rate of 15°C/h from holding temperature at 570°C. Temper embrittlement has been found as root cause for the embrittlement. For assuring safe service conditions all PWHT treated welds has completely been removed and re-welded. This was possible because of full access to the manifold welds in the tunnel. Further investigations revealed that many welds present in the inclined shaft has also been PWHT treated by application of the slow cooling rate. In these welds also severe embrittlement has been observed. The welded shells present in the inclined shaft has already been fixed in the mountain by concrete. That fore re-welding could not be applied because of water intake after removal of the existing welds. Therefore, consequently the fabrication of a new penstock in a newly drilled tunnel had to be considered, taking into account costs and schedule consequences.

Various possibilities has been studied to solve that severe problem. Reversible temper embrittlement treatment (RTE), a short time heat treatment at a

peak temperature around 600°C, was found as method to recover the toughness of the embrittled welds. Intensive investigations has been performed to realize this idea in the project. Electrical mat heating was selected and carefully qualified to be applied in the shaft.

The procedure of application of electrical mat heating on brittle welds in the penstock is discussed in this contribution. By qualified controlled application of electrical mat heating in the shaft, rehabilitation of the brittleness in the existing welds could successfully be achieved. The penstock after finishing this procedure has successfully been commissioned and could start service operation. (1)

The results of the industrial application of RTE treatment performed are doubtless very successful and reproducible. Basic scientific investigations to explain the surprising positive effect of RTE treatment on the recovery of the toughness of temper embrittled weld deposit have been performed. By application of Atom Probe investigations, the effect of embrittlement observed as well the surprising effect of de-embrittlement by RTE application could be explained. (2) (3)

1. INTRODUCTION

With the increasing demand for energy and dynamic distribution of electric power the requirements on power plants are rising. This means for penstocks of pumped storage hydro power stations an increasing amount of load cycles per year. For penstocks of welded pipes the welding seams demand attention because of possible deviation of the idealized geometry and microstructure. This paper deals with the influence of fabrication on the stress situation and its influence on penstock life time.

2. MOTIVATION

The penstock of the hydro power station described in this paper covers a water head of 600 m. The inner diameter of the penstock has a constant value of 3700 mm, the wall thickness starts at 12 mm near the basin and ends with 36 mm at the foot of the mountain. The materials used for the penstock are steels grades S355J2, S500QL and S690QL according to the increasing hydrostatic pressure.
The projected term is 80 years, the combination of high stress fluctuations and existing cold cracks leads to high cycle fatigue damage, which caused leakage after 5 years of service. To investigate this case, studies initiated between the operator of the hydro power station, a consultancy and engineering company and several institutes of the Graz University of Technology.

3. PRELIMINARY WORK FOR A FATIGUE CALCULATION

The aim of a fatigue calculation is the estimation of the achieved damage respectively remaining lifetime or a forecast of lifetime respectively expectation of loadcycles of a mechanical part.

The resources needed to achieve this aim are the “as-built” geometry of the part, the resulting stresses in combination with the loads and load cases and the material parameters.

3.1. GEOMETRY

The quality of a welding seam depends on the mechanical preparation of the plate (chamfer, rolling …) the welding process applied, and in addition, the remaining geometry (Fig. 1) of the welding seam, defined by misalignment d1, roof topping d2 and notch radius. These items have high influence on the resulting stress under service conditions. The notch factor depends on the notch radius and is the quotient of notch stress to nominal stress. Fig. 2 depicts as an example the influence of misalignment, peaking (outward known as roof topping and inward) and notch radius on the local stress situation of a weld seam. With a standard geometry of a welding seam, the nominal stress is about 2.2-times magnified (Fig. 2, a). A moderate roof topping raises the notch factor up to nearly 2.4 (Fig. 2, b). A combination of misalignment and roof topping increases the notch factor up to 3.1 (Fig. 2, c). Fig. 2, d shows the measured geometry of a sample with a quite smooth notch radius and thus a low notch factor of about 1.8.

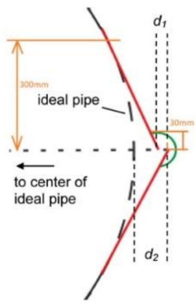

Fig. 1
Geometry of welding seam

To gain all the information needed, the process to generate the geometry for the penstock is split up into two parts. The first part is the overall geometry used in the global fe (finite element) model, the second part is the detailed geometry used for selected local fe models of the longitudinal welding seams. The local models are based on data gained during the laser measurement performed by the Institute of Engineering Geodesy and Measurement Systems (IGMS) of TU Graz [1].

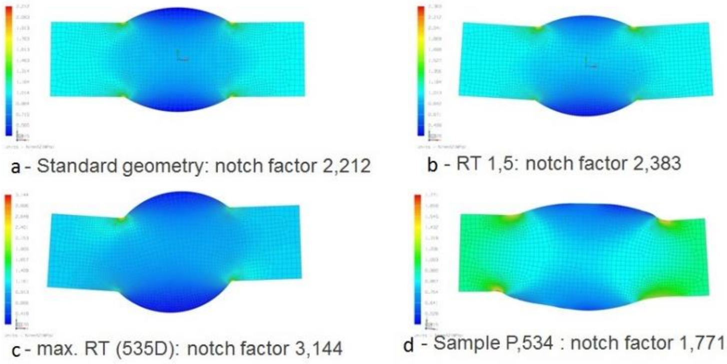

Fig. 2
Influence of the geometry on the local stress

3.1.1. *Global Model*

The global model developed covers the total penstock length of roughly 1000 meters (300 shells), considering its geometry of length, altitude, angle, plate thickness, supports and basements. The result of the global model is the stress caused by the hydrostatic pressure acting along the penstock with idealized plate thickness and without welding seams. The global model of the penstock is built as a 3D CAD model consisting of the penstock and the supports. All parts are meshed with linear 2D quad elements. The wall thickness changes according to the build penstock and the material is steel with a linear elastic behaviour.

3.1.2. *Misalignment and roof topping*

The actual measured geometries of the longitudinal welding seams are compared to the CECT values, which represent the specified allowable geometric deviation at this installation. As an example, Fig. 3 shows the measured misalignment and roof topping of the penstock.

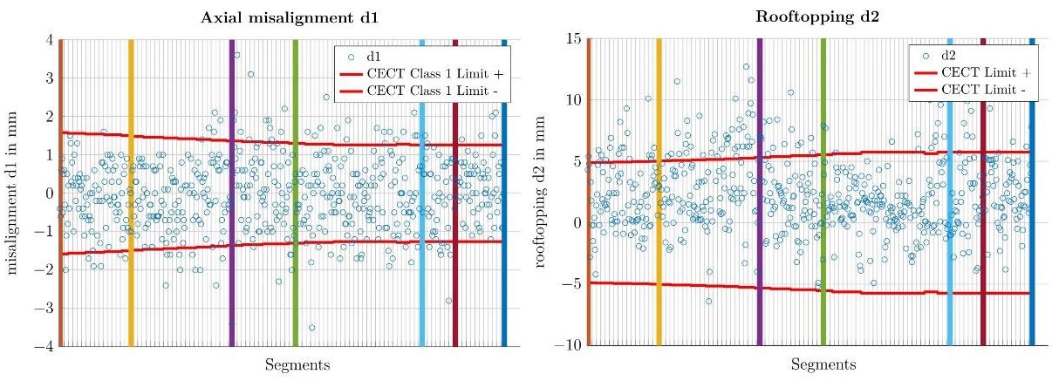

Fig. 3
Measured data of misalignmentd1 and roof topping d2 of the penstock segments

3.1.3. *Km factor*

At the beginning of the project, the question arised how to select the locations for the selection of local models. It was a common consent, that high values of misalignment and roof topping at the longitudinal welding seams results in high stresses The influence of misalignment and roof topping and their combination was calculated by application of the K_m factor [2] which describes the influence of the macro geometry of a welding seam on the stresses.

The measured and prepared data from IGMS (Fig. 3) have been evaluated and used in Eq. [1] to [4]. This allows on generating an overview of the influence of geometry along the entire penstock. The next step was a combination of K_m with the circumferential stress from the global model, which will give a first idea of the "structural stress" along the penstock.

$$K_{m,ax,mis} = 1 + \frac{6.d1}{t_1(1-\upsilon^2)} \cdot \frac{t_1^n}{t_1^n - t_2^n} \qquad K_m \text{ for axial misalignment} \qquad [1]$$

$$K_{m,ang,mis} = 1 + \frac{3.d2}{t(1-\upsilon^2)} \frac{\tanh\left(\frac{\beta}{2}\right)}{\frac{\beta}{2}} \qquad K_m \text{ for roof topping} \qquad [2]$$

$$\beta = \frac{2.l}{t}\sqrt{3(1-\upsilon^2)\frac{\sigma}{E}} \qquad [3]$$

$$K_m = 1 + \left(K_{m,ax,mis} - 1\right) + \left(K_{m,ang,mis} - 1\right) \qquad [4]$$

d1	…	misalignment	d2	…	roof topping
β	…	geometry parameter	t1	…	thickness of plate 1
t2	…	thickness of plate 2	v	…	poisson's ratio (0.3)
E	…	Young's modulus	n	…	factor for longitudinal joints (0.6)

3.1.4. *Local Models*

The local models are necessary for the fatigue calculation and therefore to obtain a forecast of the residual lifetime. The combination of stress from the global model and the calculated K_m from the measurement results in a "structural stress" at the welding seam. The notch stress is in addition to the misalignment, roof topping and plate thickness an important factor for local stress value and therefore for the fatigue calculation.

Based on the imported local models to CAD the geometry of the notch is defined and the notch radius could be derived. For the simulation it is necessary to use a half cross section of the penstock. A part of this cross section is covered by the measurement, the other parts of the geometry are build up by assumptions.

1. The absent part of the diameter of the penstock has an idealized geometry and corresponds with the delivered drafts.

2. The wall thickness is idealized and corresponds with the delivered information.

3. During the measurement campaign, only the outside surface of the penstock has been measured. There is no information about the geometry inside. That's why the geometry of the welding seam inside the penstock, used in the local models, can't be the exact geometry.

4. The grinded welding seams are idealized with a smooth transition from the wall to the grinded part without edges, scratches or cracks.

3.1.5. *Influence of weld notch radius*

The actual existing weld geometry of the penstock investigated can be rated, by the used actual welding procedure, as relatively smooth. For quantification of the influence of notch radius, the stress rising factor K_t is introduced. The maximum stress $\sigma_{max,static}$ (Eq. [5]) in the notch radius for hydrostatic pressure in the penstock is a combination of

- circumferential stress caused by hydrostatic pressure
- misalignment and roof topping and their influence factor K_m
- notch radius at the welding seam and the influence factor K_t

$$\sigma_{max,static} = K_m . K_t . \sigma_{hydrostatic} \qquad [5]$$

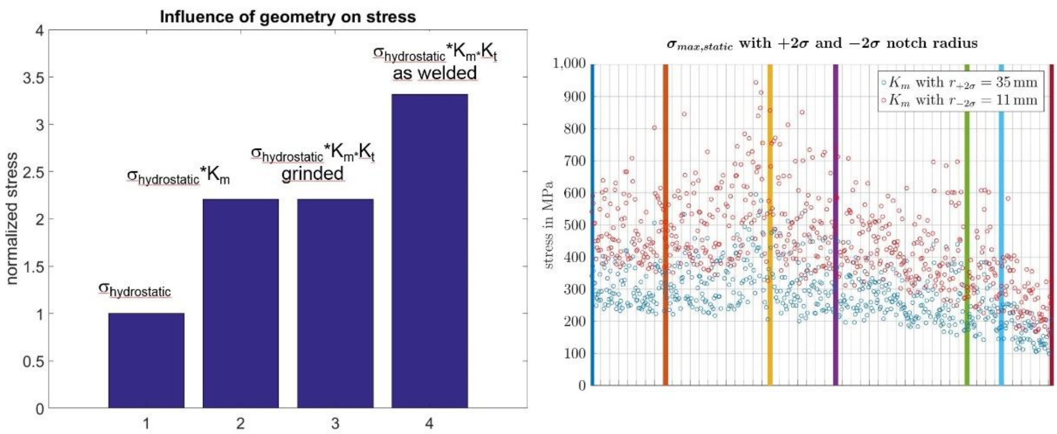

Fig. 4

a.) Comparison of the influence of geometry on stress and the calculated b) frequency bandwith of stresses along the penstock segments

The notch radii used for calculation of the selected local models have been derived from the geometric data. For this selected positions a statistical analysis has been made. The standard deviation (± 1σ and ± 2σ) of the notch radius from the local models is made by statistical analysis. The factor K_t is used to describe the additional effect of notch radius on the acting stresses in the weld region (Fig. 4, a). It was tried to perform a combination of K_m and K_t for r_μ , $r_{\pm1\sigma}$ and $r_{\pm2\sigma}$ which results in an overview of possible stresses $\sigma_{max,static}$ for all measured locations (Fig.

4, b). The estimated minimum stress along the penstock segments is about 100 MPa, the maximum stress about 950MPa.

3.2. MATERIAL

High strength steels promise higher fatigue strengths and gently inclined gradients compared to the standard steel SN-curves. On the other hand, high strength steels are more sensitive on notches, cracks and residual stresses. The penstock is fabricated with three different steel grades: S355J2, S500QL and S690QT The steel S355J2 steel is well known and the static and dynamic data are based on the data from FKM [4] and IIW [3]. At the beginning of the project, it was decided to use for the S500QL the same material data as for the S355J2. For S690QT less valuable data are available in the literature, so own SN-curves have been established. Because of the expected high stresses and strains in the welding seam notches an elastic-plastic material law have been used for the simulations. For the S355J2 the elastic-plastic material law is used which is delivered by the simulation software, for grade S690QL the data have been used from a former project.

4. RESULTS FE SIMULATION

4.1. RESULTS GLOBAL MODEL

The results from the global model are necessary for developing the local models. These stresses are similar to the results at the same location of a former project. The circumferential stress along the penstock is used for the local model calculations. With this stress distribution, the “structural stress” in combination with K_m has been calculated. It is also an indicator for the mean stress in the penstock wall for local models.

4.2. RESULTS LOCAL MODEL

The result of simulation are stresses and deformations of the penstock at the positions in the selected shells of the penstock. Fig. 5 presents an example of the influence of notch radius, roof topping and misalignment on the stress distribution represented by equivalent von Mises stress Fig. 5, a and examples of the influence of different extensive shapes of geometric discontinuities on the deformation of the pipe in an oversubscribed presentation Fig. 5, b. When evaluating these results it can be concluded, that across the local models calculated no commonly valid representative behaviour of the welds can be derived. The local deformation, and as a conclusion the stress distribution varies as a function of misalignment, roof topping, and notch radii in the measured position. In addition, it has to be considered because of the fact that the real geometry of the weld inside the pipe could not be measured. So, for the calculation the outside was "mirrored" to the inside and is therefore not quantitatively represented.

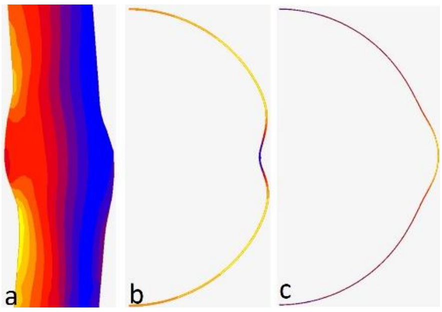

Fig. 5

a.) notch stress at local model with a maximum of 590 MPa at the welding notch
Examples of deformation (oversubscribed) of the penstock with hydrostatic pressure and positive b) and negative c) roof topping

5. FATIGUE CALCULATION

The fatigue calculation is based on fluctuation data, SN-curves, geometric measurement of the penstock and the FE simulation of local models. The whole fatigue calculation was performed by using MATLAB R2015b and the WAFO toolbox [5]. For the fatigue calculation the knowledge of the resulting stresses, allowable stresses and the load cases are essential. The resulting stresses are derived from the local models. The allowable stresses applied, are taken from the own test results and from [3]. The load cases and load cycles (fluctuation data) are provided by the operator of the power station (history of operations of the pump-turbine).

5.1 FLUCTUATION DATA

The fluctuation data consists of the loadcases and the amount of the loadcycles. The loadcases are separated in turbine and pump operations and the loadcycles are separated in different time periods. Each loadcycle consists of sinusoidal pressure fluctuations. The four main loadcases are separated into stop and shut down (trip) for each turbine and pump mode. For the loadcases fluctuation measurements exists from the pressure and strain fluctuations of the penstock.

The measured strain fluctuation has been converted to stress which have been combined with stress caused by hydrostatic pressure.

5.2 CALCULATION OF DAMAGE AND RESIDUAL LIFETIME

In a first step, the damage is calculated for one load cycle per load case. In the next step the damage for one load cycle is multiplied by the number of load cycles per time period. This was performed for all load cases and time periods. The sum of this damage per load cycles and different time periods represents the whole damage at the selected locations. Fig. 6 shows the wide scatter band of the remaining lifetime at selected positions along the penstock. The result covers a remaining lifetime starting with about 3 years up to several hundred years. As it can be revealed from measuring of misalignment and roof topping a wide scatter band of K_m factor in the shells is present. It can be concluded that the wide scatter of $\sigma_{max,static}$ acting in the shells (Fig. 4) including the strong influence of notch radius might confirm that a wide range of scatter of residual lifetime of the single shells have to be expected. To show the improvement of grinding a second fatigue calculation was made for 3 positions. Removing the notch radius increases the remaining lifetime clearly (Fig. 6).

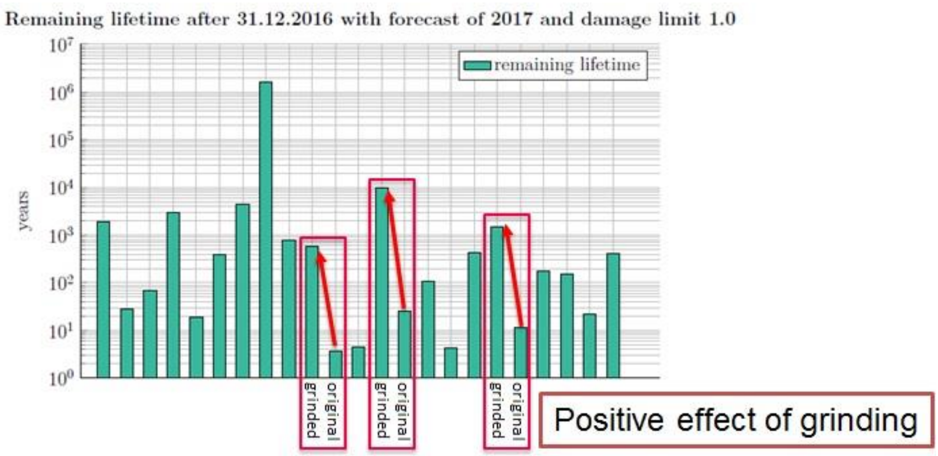

Fig. 6
Calculated remaining lifetime for selected local models

6 IMPROVING THE LIFE TIME BY MECHANICAL TREATMENT (GRINDING)

The question was if it is possible to determine those locations of the more than 600 measured positions which exceed the damage sum of D = 1.0 in 70 years if they are grinded during year 2017. The local models show detailed points of the fatigue calculation (Fig. 6) but it is not legitimate to conclude from the results of the local models from 23 positions to the complete longitudinal welding seam of the penstock. For this fatigue calculation, the damage sum consists of the damage accumulated until year 2016 and the approach for 70 years of the damage if all locations are grinded during year 2017. The calculations had shown that the number of shells which exceeds damage $D \geq 1$ is increasing when the notch radius became smaller than $r_{-1\sigma}$ = 17 mm (Table 1). Grinding and polishing of surfaces principally reduce the probability of fatigue crack initiation because of eliminating of local stress risers caused by microscopic roughness or notches. From this results the dominating influence of notch radius in addition on the existing geometric situation, represented by K_m factor is confirmed. Having the same K_m factor, the damage is dramatically in- respectively the residual lifetime is decreasing by smaller notch radii. Furthermore, it cannot be excluded, that within the entire length of welds outside and unknown weld length inside the pipe, positions exists with even smaller notch radii, which can increase the damage substantially. This observation explain clearly that the negative influence of notches will be eliminated by grinding of all welds.

Table 1
Number of shells, which probably exceed the damage limit in 70 years

notch radius	$D \geq 1$	$0.5 \leq D \geq 1$
$r_{+2\sigma}$ = 35mm	1	8
$r_{+1\sigma}$ = 29mm	1	8
r_{μ} = 23mm	1	8
$r_{-1\sigma}$ = 17mm	9	17
$r_{-2\sigma}$ = 11mm	44	47

SUMMARY

The result of this study clearly confirms that geometric deviations of welded pipes like roof topping, misalignment cause serious increasing of acting stresses in penstocks of pumping storage power plants, which can cause serious reduction of expected lifetime of the installation. In addition remaining notches caused by the welding procedure increase dramatically the local stress situation which additionally to roof topping and misalignment increase fatigue caused damage. For existing plants the removal of local notches by grinding can effectively reduce the sensitivity to fatigue damaging. In any case safe service behaviour can only be achieved by controlled fabrication processes considering prevention of geometric deviations roof topping and misalignment and providing of notch free surfaces on the pipes by application of grinding or polishing.

Les résultats de cette étude confirment clairement que les déviations géométriques des tubes soudés en acier comme l'effet de toit, le désalignement engendrent une augmentation importante des contraintes agissant sur les conduites forcées des stations de pompage-turbinage, ce qui peut entraîner une réduction importante de la durée de vie prévue de l'installation. En outre, les entailles existantes dues au procédé de soudage amplifient considérablement le niveau de la contrainte locale qui, en plus de l'effet de et du désalignement, augmente le dommage causé par la fatigue. Pour les sites existants, l'élimination des entailles locales par arasage peut réduire efficacement la sensibilité au dommage par fatigue. Dans tous les cas, une exploitation fiable et sûr ne peut être obtenu que par des procédés de fabrication contrôlés, en tenant compte de la prévention des déviations géométriques, d'effet de toit et des désalignements et de l'obtention de surfaces exemptes d'entailles ou autres discontinuités géométriques par meulage ou polissage.

ATOM PROBE INVESTIGATIONS ON TEMPER EMBRITTLEMENT AND REVERSIBLE TEMPER EMBRITTLEMENT IN S 690 STEEL WELD METAL, TO EXPLAIN SUCCESSFUL REHABILITATION OF BRITTLE PENSTOCK WELDS

Em.Univ.-Prof. Dipl.-Ing. Dr.mont. Horst CERJAK

AUSTRIA

During the hydrostatic pressure test of a penstock, in a brand new large pumped-storage hydropower plant, a spectacular brittle fracture of a closure head occurred. The embrittlement was located in the manifold weld seams as well as in the post weld heat treated welds of the completed penstock.

The reason for the failure was temper embrittlement (TE), produced by a low cooling rate during the post weld heat treatment, having a strong influence on the toughness of the weld material. Our investigations were focused on one side in the clarification of the failure cause and on the other side to clarify why by application of a short time heat treatment (starting at 10 seconds at 600° C) the toughness of the embritteled weld material significantly recovered - effect of reversible temper embrittlement (RTE).

In order to understand the mechanism of RTE, high resolution analytics as Atom Probe Tomography (APT) were applied. The investigations reveal phosphorus segregation in the high angle grain boundaries of the temper embrittlement material, see Fig. 1. When RTE treatment for few seconds was applied, phosphorus segregation in the grain boundaries disappears keeping the concentration of the other alloying elements unchanged.

The mechanism of this behavior could be explained by referring the Mc Lean [1] based grain boundary equilibrium segregation of phosphorous. Grain boundary impurities, as can be phosphorus, can produce embrittlement in steels which can be explained by electronic models based on quantum mechanical cluster calculations. The impurity is electronegative with respect to the metal and draw charge from the metal onto themselves. As result, less charge is available to participate in the metal–metal bonds and they are weakened. By the application of a RTE treatment around 600°C, diffusion of the impurities elements occurs faster because segregation starts at lower temperatures (around 550°C) [2]. During RTE treatment, the diffusion is much faster, producing the fast recovery of toughness.

The brittleness occurred in the post weld heat treated penstock welding`s could be recovered by site by application of qualified local electrical mat heating [3].

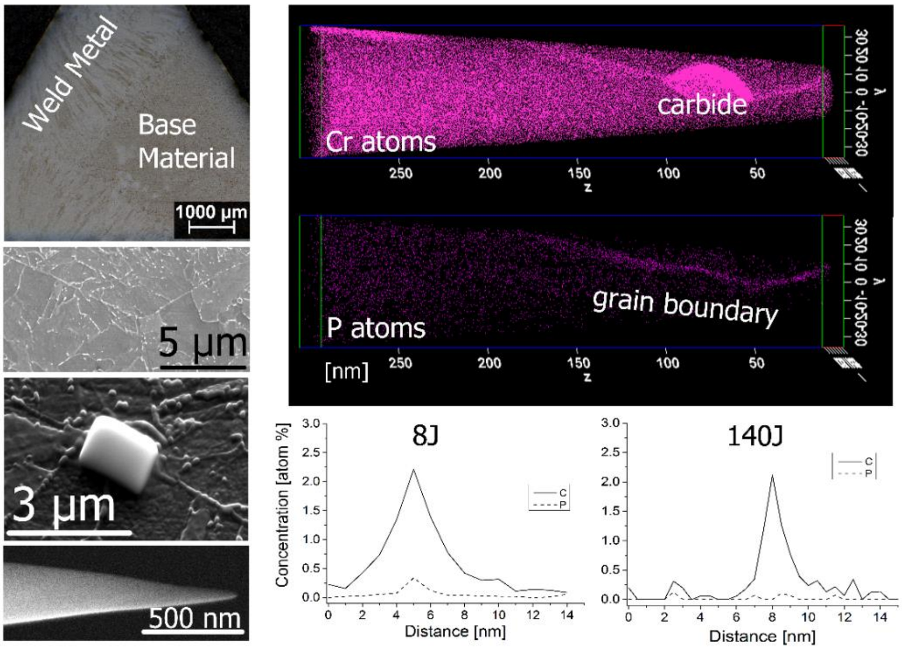

Fig. 1 shows the specimen preparation of a high angle grain boundary tip for atom probe tomography analysis. The results reveal segregation of phosphor at the high angle grain boundaries in the temper embritteled specimens (8J). The RTE specimens (140J) show phosphor free grains.

1. MAIN FEATURES OF RUDBAR LORESTAN DAM PROJECT

1.1 THE RUDBAR LORESTAN DAM PROJECT

The Rudbar Lorestan dam project shown in Fig. 1, located in a narrow canyon, comprises (i) a 156 m high earth core rockfill dam with a crest length of 185 m, (ii) two ungated tunnel spillways, with a length of 631 m and a total discharge capacity of 3342 m^3/s, and (iii) two bottom outlets. The dam body has a volume of 4.36 Mm^3 and was completed in 2016. The reservoir volume and surface area are 228 Mm^3 and 4.1 km^2, respectively. The power intake structure is at the right abutment near the dam. Twin penstocks, each about 2.2 km long, cross a long bend of the Rudbar River to serve a surface powerhouse. The head of the project is 430 m and the installed capacity of the two Francis turbines is 460 MW.

The main challenging features of this project are the location of the dam in a very narrow gorge, the high seismicity of the dam site and the presence of discontinuities and faults in the footprint of the dam.

Fig. 1
View of downstream face of Rudbar Lorestan rockfill dam with two spillway tunnels on left bank and two bottom outlets

1.2 MULTIPLE SEISMIC HAZARDS AT DAM SITE

The main seismic hazards of the Rudbar Lorestan dam site are:

(1) Ground shaking causing inelastic deformations in dam body;
(2) Movements at discontinuities in footprint of the dam that can cause distortions in the dam body and offsets in the filters;
(3) Mass movements (rockfalls, landslides) causing damage to dam crest, power intake structure and bottom outlet, block intake of bottom outlet, or causing impulse waves in the reservoir and overtopping of the dam crest; and
(4) Reservoir-triggered seismicity (RTS) [3] and [7].

There are other seismic hazards, which can affect large dam projects as discussed in [5] and [6].

Ground shaking: Ground shaking is the main seismic hazard addressed in all design guidelines. The other hazards listed above may not be relevant for most dam sites, therefore, they are rarely included in seismic design guidelines and thus may be ignored or forgotten. The peak ground acceleration of the worst-case earthquake scenario at Rudbar Lorestan dam site, i.e. a magnitude 7.5

earthquake along a major fault at a distance of about 1.5 km from the dam site, was estimated as 0.74 g (horizontal component on outcropping rock).

Fault movements: Seismotectonic studies at the dam site revealed different faults and discontinuities in the footprint of the dam. The faults are not seismogenic but rather secondary or splay faults, where movements may occur during strong nearby earthquakes. The maximum observed single event fault movement was 1.2 m along a relatively short fault, which has created a cumulative dislocation of about 8 m. Some of the faults are sub-parallel with almost identical features as found during excavation of the dam foundation. There are other discontinuities in different directions, i.e. fissures, joints, bedding planes, shear zones, and faults, which could experience different degrees of block-type movements as the limestone rock is of brittle nature. As there was no suitable material in the faults, dating of the last fault movements was not possible. Because of the complexity of the seismotectonics at the dam site and the difficulties in estimating possible movements along the different discontinuities, maximum horizontal and vertical movements were assigned to the main faults and discontinuities. For the main faults the horizontal and vertical design displacements were specified as 2 m and 1 m, respectively. Smaller displacement values were assigned to the other discontinuities. However, the dam design was governed by the larger displacements. The unique feature is that there are several faults and discontinuities in the footprint of the dam with different orientation, which could experience movements during a strong earthquake. In the selection of the dam type and dam design, these movements played an important role. At the time of the design, it was not possible to exclude such displacements, therefore they had to be considered in the design.

Mass movements: At dam sites, mass movements (landslides and rockfalls) are the seismic hazards that are often underestimated. Depending on their consequences, the stability of the dam abutments and reservoir banks has to be checked for different types of design earthquakes. For example, if the intake of the bottom outlet will be blocked by debris, then the slope must be stable for the ground motion of the safety evaluation earthquake (SEE), which in the case of a deterministic worst-case earthquake scenario is equal to the ground motion of the maximum credible earthquake (MCE). For other slopes with no dam safety consequences, the slopes must be stable for smaller earthquakes, as for example, those specified in building codes.

Reservoir-triggered seismicity: If a large dam has been designed according to the current state-of-practice, which requires that the dam can safely withstand the ground motions caused by the SEE, it can also withstand the effects of the largest reservoir-triggered earthquake, as the maximum reservoir-triggered earthquake cannot be stronger than the SEE. Thus, RTS is not a safety problem for a well-designed dam or the people who could be at risk in the case of a dam failure. However, RTS may still be a problem for the buildings and structures in the dam and reservoir area, because in seismic building codes the ground motion parameters are given for return periods of 475 years, whereas for large storage dams the corresponding value is 10,000 years. In the great majority of RTS, the magnitudes are small and of no structural concern Up to now, the maximum magnitude of reservoir-triggered earthquakes is 6.3. As the correlation between the filling of the reservoir and the occurrence of a damaging earthquake in the reservoir region is extremely weak, severe doubts remain if some of the largest observed earthquakes are actually RTS events. Therefore, dam owners would object to the classification of strong earthquakes in the reservoir region of large storage dams as being triggered by the reservoir [3] and [7].

.

2. SEISMIC DESIGN ASPECTS OF RUDBAR LORESTAN DAM

2.1 CONCEPTUAL SEISMIC DESIGN GUIDELINES FOR EMBANKMENT DAMS

The seismic design of embankment dams is based on (i) conceptual criteria, which are mainly based on the observation of the behaviour of embankment dams during strong earthquakes and the behaviour of soils and rockfill under dynamic loadings, and (ii) the results of seismic analysis of dams subjected to different types of design earthquakes. Usually several earthquakes must be analyzed – at least three. As a basis for the dynamic analysis a static analysis that simulates the incremental construction of the dam body and the filling of the reservoir and if applicable a seepage analysis must be performed first before the earthquake ground motion can be applied. The basic conceptual criteria are as follows [1].

1) Foundations must be excavated to very dense materials or rock; alternatively, the loose foundation materials must be densified, or removed and replaced with highly compacted materials, to guard against liquefaction or strength loss.
2) Fill materials, which tend to build up significant pore water pressures during strong shaking must not be used.
3) All zones of the embankment must be thoroughly compacted to prevent excessive settlements during an earthquake.
4) All embankment dams, and especially homogeneous dams, must have high capacity internal drainage zones to intercept seepage from any transverse cracking caused by earthquakes, and to assure that embankment zones designed to be unsaturated remain so after any event that may have led to cracking.
5) Filters must be provided on fractured foundation rock to preclude piping of embankment material into the foundation.
6) Wide filter and drain zones must be used.
7) The upstream and/or downstream transition zones should be self-healing, and of such gradation as to also heal cracking within the core.
8) Sufficient freeboard should be provided in order to cover the settlement likely to occur during the earthquake and possible water waves in the reservoir due to mass movements etc.

9) Since cracking of the crest is possible, the crest width should be wider than normal to produce longer seepage paths through any transverse cracks that may develop during earthquakes.
10) One of the most dangerous consequences of the dynamic loading of an embankment dam is the liquefaction of foundations or embankment zones that contain saturated fine-grained cohesionless and/or uncompacted materials.

2.2 DAMS ON ACTIVE OR POTENTIALLY ACTIVE FAULTS OR DISCONTINUITIES

In designing dams for fault movements, the following situations have to be considered:

- active or potentially active fault passing through the dam foundation (footprint of dam),
- multiple faults passing through the dam foundation or fault with wide fractured zone, and
- dam located in the near-field of a major fault, which is capable of producing large magnitude earthquakes: if fault displacements spread as far as the dam site, they can cause movements along fractures or secondary faults in the dam foundation.

In [2] the following recommendations are given:

1) When a major active fault is crossing the dam foundation the site should be abandoned and a more appropriate site should be looked for.
2) In highly seismic areas it may not be possible to find any site without fault slip hazard: In such a case, concrete dams should be avoided and preference be given to a conservatively designed embankment dam, designed with ample filter and transition zones, on both sides of a rather wide core, displaying ductile properties. There is a considerable confidence that such a structure can withstand, without failure, significant fault offsets.
3) If the seismotectonic conditions at a dam site are not clear, then the engineer should avoid concrete dams and select a conservatively designed embankment dam.

In highly seismically active regions, such as the Zagros Mountain Range in Iran, most of the faults could be potentially active or could undergo some movements by nearby strong earthquakes. Therefore, conservatively designed rockfill dams with earth core might be the safest seismic solution.

2.3 GENERAL GUIDELINES FOR THE DESIGN OF DAMS ON FAULTS

The basic ingredients of an embankment dam, which can resist both differential ground movements and strong earthquake ground shaking, are the following [1] and [2]:

1) Impervious core made of ductile material with a high failure strain to minimize the propagation of the rupture zone; prevention of internal erosion if core is cracked;
2) Thick filter and transition zones: about 50% shall still be available after faulting and slip movements;
3) Wide dam crest;
4) Flat slopes;
5) Generous freeboard: to prevent overtopping due to possible impulse waves in reservoir and settlement of the dam crest; and
6) Material selection and compaction of rockfill.

Fig. 2
View of core, filter and transition zones near the left abutment (top left), 5 m wide contact clay zone and treatment of rock surface in the core zone by shotcrete (top right) and detail of widened fine sand filter at the right abutment (bottom)

The main concern of any embankment dam with impervious core is the erosion resistance of the core material. The filter and transition zones provide the first line of defense against cracks in the core, adequately graded, cohesionless transitions are provided. A leak can only get out of control if embankment distortions exceed the width of the thin sand filter.

In view of the high seismic hazard from ground shaking and fault movements in the footprint of the dam and in order to account for the possible arching due to the location of the dam the following design features of the dam were provided as shown in Fig. 2:

1) Large freeboard,
2) Thick filter zone consisting of fine sand filter, coarse sand filter and transition zone, each 5 m thick, located at upstream and downstream faces of the core, to control internal erosion from seepage through any cracked portions of the core
3) Widening of the fine sand filter from 5 m to 10 m at the downstream faces of the core near the abutments to prevent contact erosion due to seepage along the abutment, and
4) Provision of a 5 m wide plastic clay zone at the interface with the rock abutment, in order to minimize any arching effects in the core and to increase compressive stresses in all zones of the core.

Ultimately, the seismic safety depends on the quality of the work done by the contractor. Moreover, in the core high pore pressure were induced in the core during construction, which do not deviate much from the pore pressure due to the long-term seepage process. This will minimize any seepage movements in the core and can be considered as a special type of “pre-stressing”.

2.4 SEISMIC DESIGN AND PERFORMANCE CRITERIA OF DAM BODY

The following design earthquakes are specified for large dam projects according to ICOLD [4]:

(1) Safety Evaluation Earthquake (SEE): The SEE is the earthquake ground motion a dam must be able to resist without uncontrolled release of the reservoir. The SEE is the governing earthquake ground motion for the safety assessment and seismic design of the dam and safety-relevant components (spillway and low level outlets), which have to be functioning after the SEE.

(2) Operating Basis Earthquake (OBE): The OBE may be expected to occur during the lifetime of the dam. No damage or loss of service must happen. It has a probability of occurrence of about 50% during the service life of 100 years. The return period is taken as 145 years [4]. The OBE ground motion parameters are estimated based on a PSHA. The mean values of the ground motion parameters of the OBE can be taken.

The SEE ground motion parameters can be obtained from a probabilistic and/or a deterministic seismic hazard analysis, i.e.

- Maximum Credible Earthquake (MCE): The MCE is the event, which produces the largest ground motion expected at the dam site on the basis of the seismic history and the seismotectonic setup in the region. It is estimated based on deterministic earthquake scenarios. According to [4] the ground motion parameters of the MCE shall be taken as the 84 percentiles (mean plus one standard deviation).

- Maximum Design Earthquake (MDE): For large storage dams the return period of the MDE is taken as 10,000 years. The MDE ground motion parameters are determined based on a probabilistic seismic hazard analysis (PSHA). According to [4] the mean values of the ground motion parameters of the MDE shall be taken.

  The general performance criteria for large storage projects are as follows:

  (1) The dam must be able to safely retain the water in the reservoir during and after the SEE. No uncontrolled release of large quantities of water that may flood the downstream area is accepted, however inelastic deformations are accepted. The stability of the dam must be ensured.
  (2) It must be possible to control the reservoir level after the SEE.
  (3) It should be possible to lower the reservoir level after the SEE to carry out any repair works on the upstream face of the dam or to increase the safety of the dam in case of doubts about its seismic safety.

3. STABILITY OF RESERVOIR BANKS DURING FIRST IMPOUNDMENT

The slow sliding of a rock mass into the reservoir may rise the lake level. But in the case of a fast slip into the reservoir an impulse wave will be generated, which, depending on the geometry of the reservoir and the direction of the impulse direction of the sliding mass may cause damage along the shoreline and the dam. The most severe event would be an overtopping of the dam. Calculation methods to estimate the height of such waves are available. Landslides also reduce the active storage volume of the reservoir.

From a dam safety point of view, the slope stability in the narrow reservoir of the Rudbar Lorestan project is of great importance particularly in the area near the dam (up to about 2 km). Any instability of the slopes (rock, overburden or spoil materials) may create impulse waves in the reservoir.

Among several potential unstable zones in the area close to the dam, five potential sliding zones including two spoil areas plus three zones composed of overburden materials were identified prior to reservoir impounding. Another three Areas at greater distance from the dam were also considered, but due to the geometry of the reservoir, these slides could not generate waves that could overtop the dam.

For each unstable zone a simplified impulse wave analysis was carried out. The results showed that at the dam, the maximum wave run-up could reach up to 8.8 m above the reservoir normal water level. The freeboard provided for the dam is 9 m, which is higher than the maximum estimated wave run-up.

The total volume of the sliding mass of all identified zones located above the normal water level is about 4.5 Mm^3. A simultaneous failure of these slopes and the sliding into the reservoir would induce a change in the reservoir elevation of 0.85 m, which is negligible compared to the maximum height of impulse waves and the available freeboard of 9 m.

During the first filling of the reservoir, several sliding movements were observed. The largest slope movement occurred at the right reservoir bank at a distance of 7.1 km from the dam. The first signs of slope movements were detected on October 7, 2016. Two months later, a vertical escarpment with a height of up to 15 m was formed as shown in Fig. 3, when the reservoir reached the sill level of the free-flow spillway. In the following months, the reservoir level has decreased due to the start of operation of the first unit in the powerhouse. Since then, no further movements have occurred, although this slope remains unstable and further movements may develop if the reservoir level is increased or lowered. Heavy rainfall in winter and spring and strong earthquake are additional triggers of natural slopes or slopes partially submerged by the reservoir. The consequences of failure of this slope will be relatively small on the dam, due to the great distance to the dam and due to the geometry of the reservoir.

Fig. 3
Unstable mass with vertical scarp of up to 15 m triggered during reservoir impounding (distance to dam: approx. 7.1 km; volume: 1.5-2.5 Mm^3) (photo taken May 5, 2017)

Several other rock slope failures were observed on the right bank of the reservoir as shown in Fig. 4. These failures occurred relatively slowly and did not cause any impulse waves in the reservoir. Nevertheless, due to the steep slopes and the possibility of mass movements, the number of people staying at the upstream face of the dam, were requested to stay away from the reservoir.

Furthermore, due to water wave action several small slides developed in zones with loose material on both reservoir banks as shown in Fig. 5. Although there are several mass movements observed during impounding of the reservoir, none of them has created any impulse wave yet.

Fig. 4
Local failure of rock slopes during reservoir impounding (distance to dam: approx. 4.3 km; volume: 0.4 Mm^3)

Fig. 5
Local slides in loose material on left bank, caused by surface waves in reservoir

Besides mass movements into the reservoir, mass movements could be triggered by the operation of the spillway due to the wetting of loose overburden materials above the plunge pool or erosion of the relatively weak rock. Tests of the bottom outlets were carried out, while construction of the plunge pool was not yet completed. Such tests have caused substantial river bank erosion. But these phenomena are not related to the impounding of the reservoir.

Finally, due to the almost vertical rock abutments and the presence of loose rocks at high elevations, it is expected that extensive rockfalls could be triggered by strong earthquakes. These rockfalls are not considered as a threat to the dam body, but may prevent access to the dam, damage the road surface near the abutments and may damage the power intake structure, spillway chute and others. For that reason, rockfall protections have been provided in the portal areas of the surface penstocks and the two surge tanks. Stabilization of the loose rocks above the dam is very difficult.

Due to the high seismicity of the dam site, a microseismic monitoring system was installed, to monitor any signs of reservoir-triggered seismicity. The network consists of 7 stations at distances from 8-25 km of the dam site and cover the reservoir and the most important faults around the project. Up to now, the largest recorded magnitudes were less than 3 and no changes in seismicity patterns were observed.

4. CONCLUSIONS

In the seismic design of the Rudbar Lorestan rockfill dam the following items are of main concern:

(1) The seismic hazard is a multi-hazard for most dam projects. Ground shaking is the main hazard considered in all earthquake guidelines for dams and other structures.

(2) Movements of active faults in the footprint of a dam or movements at discontinuities (faults, joints, bedding planes), which can be activated during strong nearby earthquakes, are the most critical seismic hazards for most dams. A conservatively designed earth core rockfill dam with wide filter and transition zones is the only feasible solution for such sites.

(3) Due to the topography, geology and the rock properties, mass movements affect the reservoir, the dam body and all appurtenant structures as well as access roads. Slope stability problems have been observed during impounding of the Rudbar Lorestan reservoir. Many more mass movements will occur during strong earthquakes.

(4) Impounding of the reservoir has not caused any changes in the seismicity of the dam and reservoir region. Reservoir-triggered seismicity is monitored by a dedicated microseismic network.

(5) The Rudbar Lorestan earth core rockfill dam includes several advanced features such as (i) wide filter zones, which are widened towards the abutments (doubling of width of fine sand filter at the downstream side of the dam), (ii) a wide impermeable core with a plastic clay zone at the core-abutment contact, in order to minimize any tensile cracks in the core, and (iii) a generous freeboard to account for large seismic deformations of the dam and the run-up of impulse waves due to mass movements into the reservoir.

Up to now, the dam behavior has been as expected. Despite all the antiseismic design features provided by the consultant, we shall not forget that it is equally important that the dam contractor is doing a perfect job.

SUMMARY

The 156 m high Rudbar Lorestan earth core rockfill dam, located in a narrow canyon in the seismically very active Zagros Mountain Range in Iran, had to be designed against multiple seismic hazards including ground shaking, movements along discontinuities in the footprint of the dam caused by nearby strong earthquakes, and rockfalls. Furthermore, in view of the proximity of a large fault, reservoir-triggered seismicity may occur during impounding and the first years of operation of the reservoir. The main concerns in the dam design were the discontinuities formed by joints, bedding planes, fissures and faults although there exist no active faults in the dam foundation, which could produce large earthquakes. The special design features of the dam, to cope with movements along multi-directional discontinuities in the footprint of the dam and the deformations in the dam body due to ground shaking are discussed. Construction of the dam body was completed in 2016 and first reservoir impounding was done in early 2017.The possible hazards from the failure of steep slopes in the reservoir are presented. The different types of slope failures and wave erosion of the slopes, observed during the first impounding of the reservoir, are described. The volume of the largest activated slope is about 1.0-1.5 Mm^3. Further mass movements could be triggered in the future by earthquakes or heavy rainfalls.

1. INTRODUCTION

The earthfill dam of Vernago is located in the east portion of the Alps, in northern Italy, and intercepts the Senales River (tributary on the left of the Adige River), giving rise to an artificial reservoir which feeds the Naturno hydroelectric power plant, managed by Alperia Spa. The dam has about 55 m maximum height and its length at the top is about 480 m. In standard operation, a single drawdown and filling cycle of the reservoir takes place each year [1]. Consequently, the water level ranges from 8 to 48 m from the bottom of the dam.

The slope bounding on the rightside the reservoir of Vernago (Fig. 1a) showed slow and small movements associated with each drawdown-filling cycle, mainly occurring in the glacial deposit that hosts the experimentally observed sliding surface [1]. These monitored movements, first recorded during the early '70s, suggested the need of geophysical and geotechnical investigations.

Inclinometer measurements showed that the displacements generally increase during the slow reservoir drawdown [2],[3]. To reduce its strain rate and increase its safety, a stabilizing berm at the bottom of the slope was built (Fig. 1b). *Piezometer readings* revealed differences between the reservoir water level (r.w.l.) and the piezometric head (p.h.) within the upper portion of the slope, during operation; therefore, a transient seepage flow regime occurs [4],[5],[6],[7].

Regression analyses preliminarily allowed to identify the correlation between the cumulated measured displacements and the variation of the r.w.l.. The effectiveness of the stabilizing berm is confirmed by the reduction of the rate of displacement accumulation (Fig. 3) [1],[7].

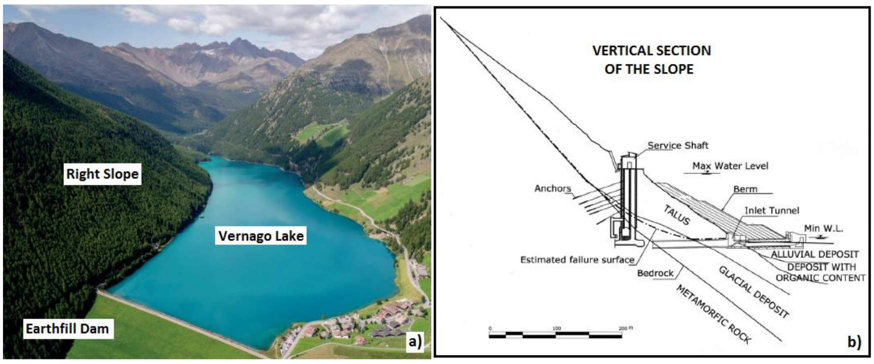

Fig. 1. a) Aerial view of the Vernago reservoir; b) Vertical section of the slope

2. REGRESSION ANALYSES OF INCLINOMETERS MEASURES

Slope displacements are monitored through several inclinometers [8],[9]; particularly, horizontal slope displacements refer to the T3, TM, TB, T4 inclinometers, located in front of the service shaft [9], at the elevation 1692 m a.s.l., and to the T5 and T6 inclinometers behind the shaft, at the elevation 1720 m a.s.l. (Fig. 2). In the period 1983-1999 the measures were not regularly recorded; few measures are thus available for the years 1987, 1990, 1991, 1993, 1995, 1996 and 1999. From 1999 until August 2015, the measurements were carried out every six-month, approximately; in the period of construction of the stabilizing berm (2000-2001), a greater frequency of measures was observed. From August 2015 until February 2016, due to a particular operation, the slope displacements were measured every 15 - 20 days.

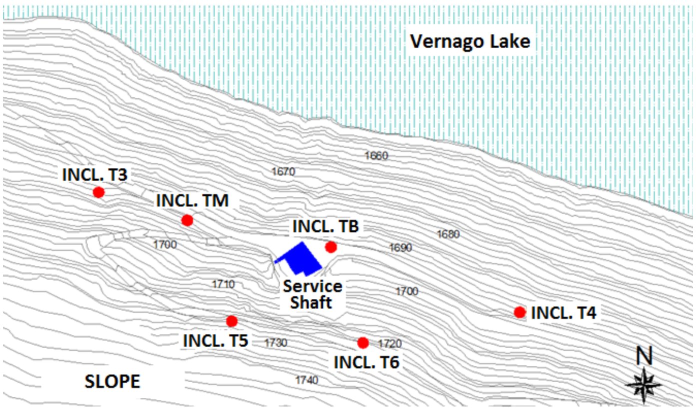

Fig. 2. Location of inclinometers

The measured slope displacements exhibit both reversible and non-reversible components [1],[7],[8],[9], the later generally increasing during the slow reservoir drawdown (Fig. 3); these movements are not uniformly distributed along the cross (towards the reservoir) and longitudinal directions.

To analytically describe the dependence of the slope movements on the variation in the reservoir water level (r.w.l.), regression analyses of the inclinometric measures have been carried out [7]. These analyses take into account the construction of the stabilizing berm, as well as the operation conditions (law of variation of r.w.l.). Therefore, the displacements (at the ground level) measured through the T3, T4, T5, T6 inclinometers have been distinguished during the following periods: *i)* 1982-1999 (before the construction of the berm); *ii)* 2009-2013 (after). The filling/drawdown cycles in these periods have been schematized to identify the governing hydraulic variables (e.g. H_{max} and H_{min}, that are the max and minimum reservoir water levels [m a.s.l.]; $\Delta T_{max,fill}$, the persistence period of H_{max} [days]; $\Delta t_{filling/drawdown}$, the duration of the filling/drawdown phase [days]; $v_{fill/dd}$, the rate of change in water level during the filling/drawdown phase [m/day]) on which the slope displacements could depend (Fig. 4). The following general relationship has been thus developed [7]:

$$s = C_0 + C_1 \cdot H_{max} + C_2 \cdot H_{min} + C_3 \cdot v_{fill/dd} + C_4 \cdot \Delta T_{max,fill} \qquad [1]$$

s [cm] being the horizontal displacement (h.d.) of the slope occurred from the initial time instant of the considered period (relative h.d.); C_0, C_1, C_2, C_3, C_4, the multiplier constants, derived from the regression analysis, related to the considered inclinometers (Table 1). The best agreement between the theoretical and measured displacements, for both periods (before and after the construction of the berm), is observed for the T4 and T6 inclinometers (Fig. 5).

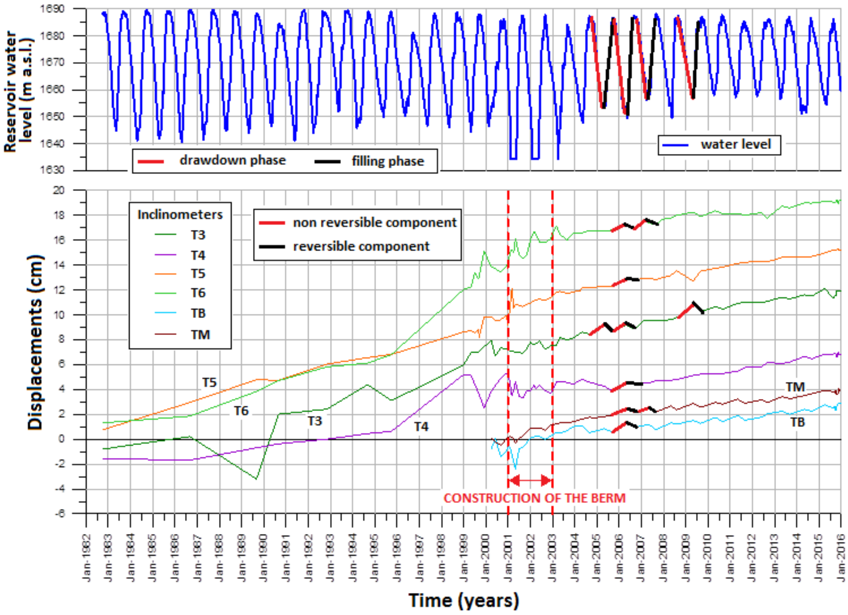

Fig. 3. Cumulated displacements measured through inclinometers

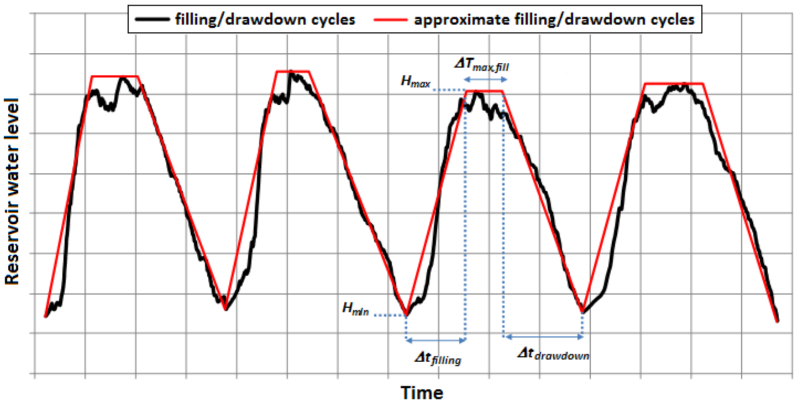

Fig. 4. Definition of the variables on which slope displacements depend.

The comparison between the relationships referred to the two considered periods show the effectiveness of the variation in the reservoir water level excursion (increase of H_{min} and decrease of H_{max}) and the construction of the berm (increase of effective normal stresses at the slope toe) in the reduction of the rate of the slope cumulated displacements (Fig. 6). Furthermore, the relationships obtained from the regression analyses (Table 1) of the slope displacements measured after the construction of the berm (2009-2013) have been applied to back analyze the displacements measured during filling/drawdown cycles (2006-2008), different from which previously considered [7].

Table1. Relationships from regression analyses for the T3, T4, T5, T6 inclinometers (R^2 = regression coefficient).

Period: 1982 - 1999 (before the construction of the berm)		
Incl.	**Relationship**	**R^2**
T3	$s = 479.8 - 0.75 \cdot H_{max} + 0.47 \cdot H_{min} + 14.0 \cdot v_{fill/dd} + 0.14 \cdot \Delta T_{max,fill}$	0.70
T4	$s = 783.4 - 0.46 \cdot H_{max} - 0.0003 \cdot H_{min} + 1.29 \cdot v_{fill/dd} - 0.013 \cdot \Delta T_{max,fill}$	0.96
T5	$s = 343.9 - 0.16 \cdot H_{max} - 0.044 \cdot H_{min} + 1.67 \cdot v_{fill/dd} - 0.010 \cdot \Delta T_{max,fill}$	0.97
T6	$s = 948.7 - 0.55 \cdot H_{max} - 0.01 \cdot H_{min} + 0.25 \cdot v_{fill/dd} - 0.013 \cdot \Delta T_{max,fill}$	0.90
Period: 2009 - 2013 (after the construction of the berm)		
Incl.	**Relationship**	**R^2**
T3	$s = -3.56 + 0.025 \cdot H_{max} - 0.023 \cdot H_{min} - 1.34 \cdot v_{fill/dd} + 0.0001 \cdot \Delta T_{max,fill}$	0.53
T4	$s = 94 - 0.037 \cdot H_{max} - 0.0187 \cdot H_{min} + 0.63 \cdot v_{fill/dd} + 0.002 \cdot \Delta T_{max,fill}$	0.86
T5	$s = 322 + 0.135 \cdot H_{max} - 0.332 \cdot H_{min} + 0.17 \cdot v_{fill/dd} + 0.00003 \cdot \Delta T_{max,fill}$	0.49
T6	$s = 265.2 + 0.008 \cdot H_{max} - 0.17 \cdot H_{min} - 1.62 \cdot v_{fill/dd} + 0.004 \cdot \Delta T_{max,fill}$	0.81

The appreciable agreement of the theoretical results with the in situ measures (Fig. 7) demonstrates the time cyclicity of the slope displacements.

Thus, the same relationships can be also applied to approximately estimate slope displacements evolutions following new operation procedures [7].

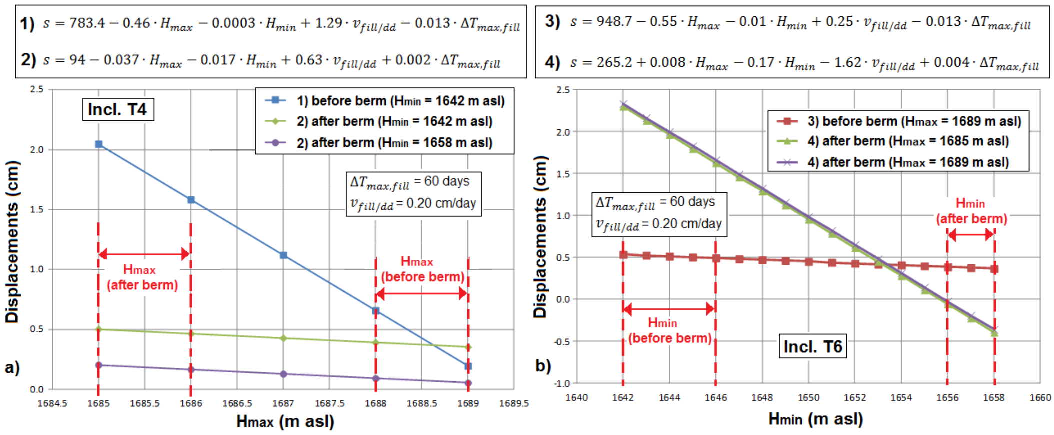

Fig. 5. Measured vs theoretical displacements, before and after the construction of the berm, for the a) T4 and b) T6 inclinometers, respectively

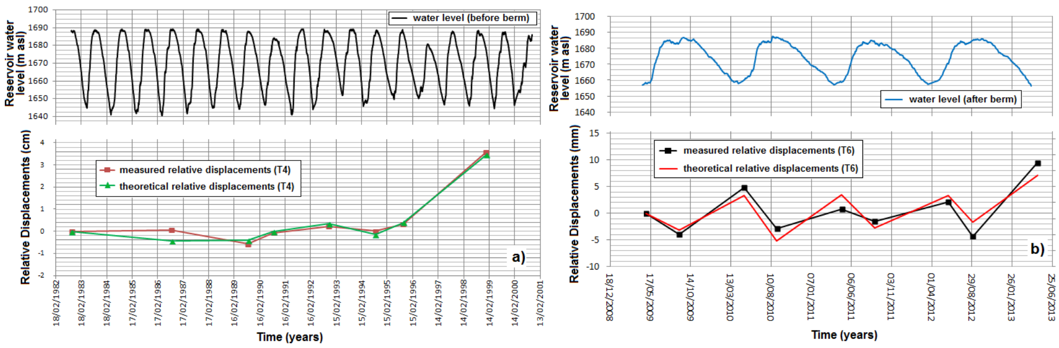

Fig. 6. Theoretical displacements for *a)* T4 and *b)* T6 inclinometers

3. COUPLED SEEPAGE AND STABILITY NUMERICAL ANALYSES

To measure the piezometric heads (p.h.) within the slope of the Vernago reservoir, 3 open standpipe piezometers and 8 Casagrande piezometers were installed [7],[8],[9].

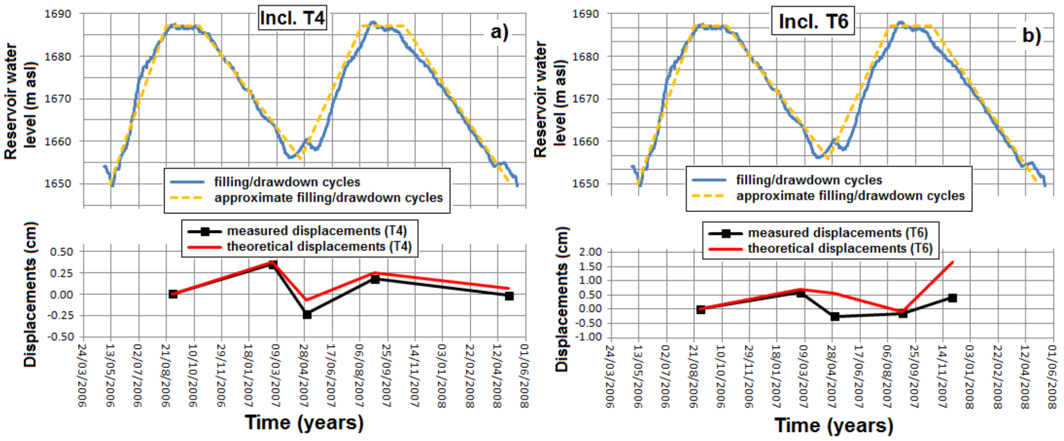

Fig. 7. Theoretical vs measured displacements for the period 2006-2008

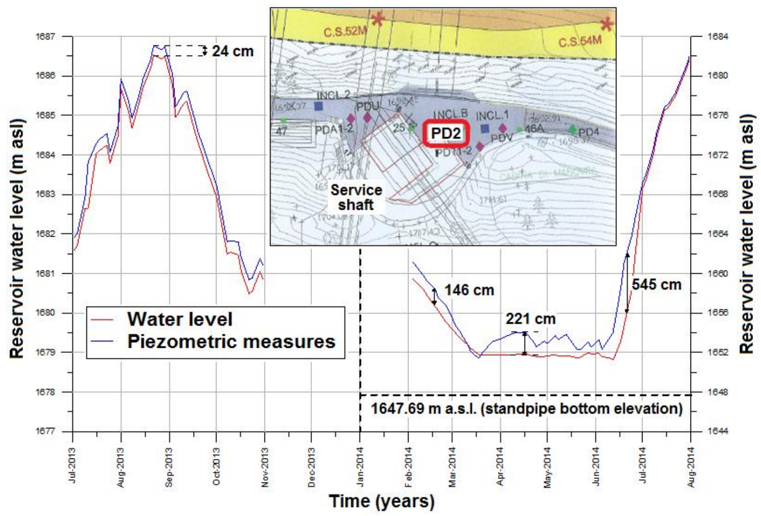

Fig. 8. Piezometric head measurements vs reservoir water level

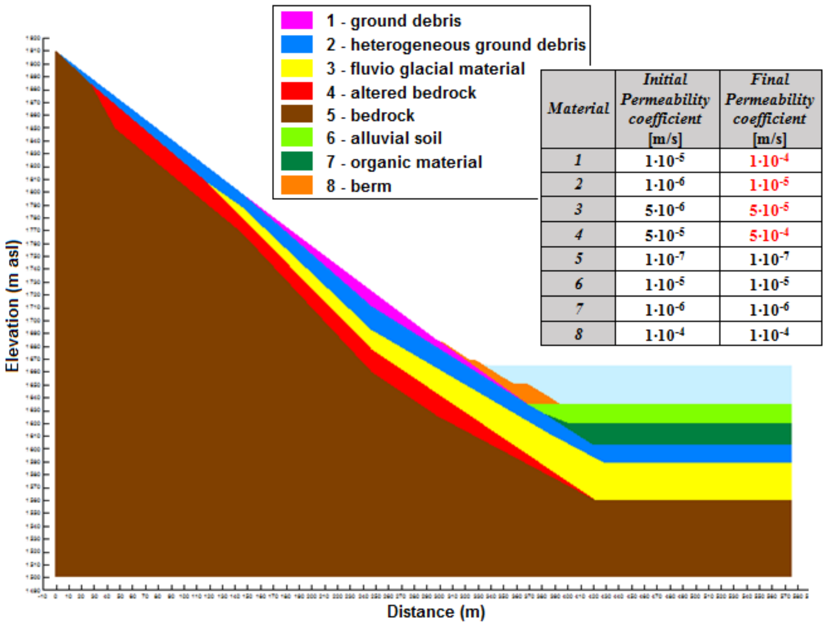
P.h. measurements through the PD2 open standpipe piezometer (located near the service shaft [9]) revealed differences (Δh) between the reservoir water level and the piezometric head within the upper portion of the slope subjected to movements during operations (Fig. 8). Particularly, the progressive saturation of the slope during the filling phase is slower than its desaturation during the drawdown phase: in particular, Δh is about 146 cm and 545 cm during the drawdown and filling phases, respectively (Fig. 8). This phenomenon influences the progressive change of the bulk unit weight of the soil during the unsteady seepage flow associated with the operation [2],[3],[7]. The coupled analyses of slope displacements and piezometric heads (p.h.) measures highlight *i)* the cyclicity of the slope movements, following the variation of the reservoir water levels; *ii)* the occurrence of unsteady state seepage flows; *iii)* the effectiveness of the berm in the reduction of movements by increasing the effective stresses.

The hydro-mechanical response of the slope has been thus investigated through coupled seepage (FE) and stability (LEM) analyses, carried by SEEP/W and SLOPE/W codes [1],[7]. The (initial) values of the permeability coefficients (deduced by previous geotechnical analyses [7],[8],[9]) has been progressively refined (through parametric simulations referred to the scheme in Fig. 9) to obtain the best fitting between the p.h. measurements and the computed (final) values of the piezometric heads. The agreement between the computed and measured (through PD1 piezometer) values of piezometric head (p.h.) can be observed in Fig. 10. The importance of the unsteady 2D seepage flow, affected by both horizontal and vertical components of the flow velocity vectors, inlet and outlet from the slope, is confirmed [7]. The inclinometric measures have also allowed to identify, for the reference slope cross-section (Fig. 9), the potential sliding surfaces (Fig. 11): the evolution of the slope safety factor, in dependence on the r.w.l. along time, has been determined (Fig. 12) [7]. Particularly, the safety factor generally reduces during the filling phase, reaching the unit value at the maximum water level (Fig. 12 a); its values *just below the unit value*, thus allowing slope movements, occur and persist during the most of the drawdown phase (Fig. 12b), according to the previously analyzed measures (Fig. 3).

For a careful comprehension of the hydro-mechanical behaviour of the slope, numerical models to simulate the recorded displacements have been previously developed [1],[7].



Material	*Initial Permeability coefficient* [m/s]	*Final Permeability coefficient* [m/s]

4	$5 \cdot 10^{-5}$	$5 \cdot 10^{-4}$
5	$1 \cdot 10^{-7}$	$1 \cdot 10^{-7}$
6	$1 \cdot 10^{-5}$	$1 \cdot 10^{-5}$
7	$1 \cdot 10^{-6}$	$1 \cdot 10^{-6}$
8	$1 \cdot 10^{-4}$	$1 \cdot 10^{-4}$

Fig. 9. Schematization of the slope of Vernago reservoir

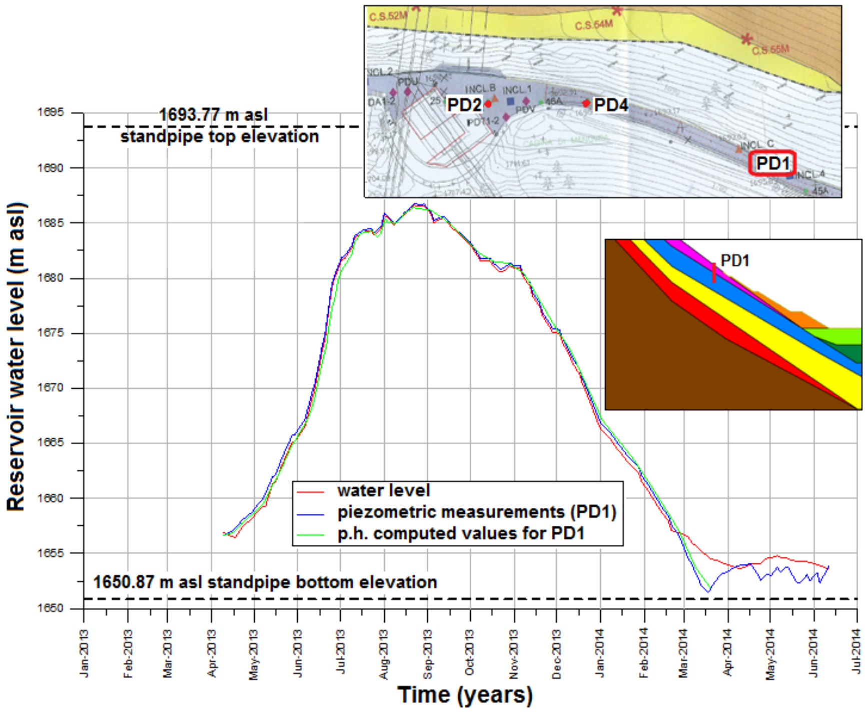

Fig. 10. Computed vs measured values of p.h. (PD1 open standpipe piezometer)

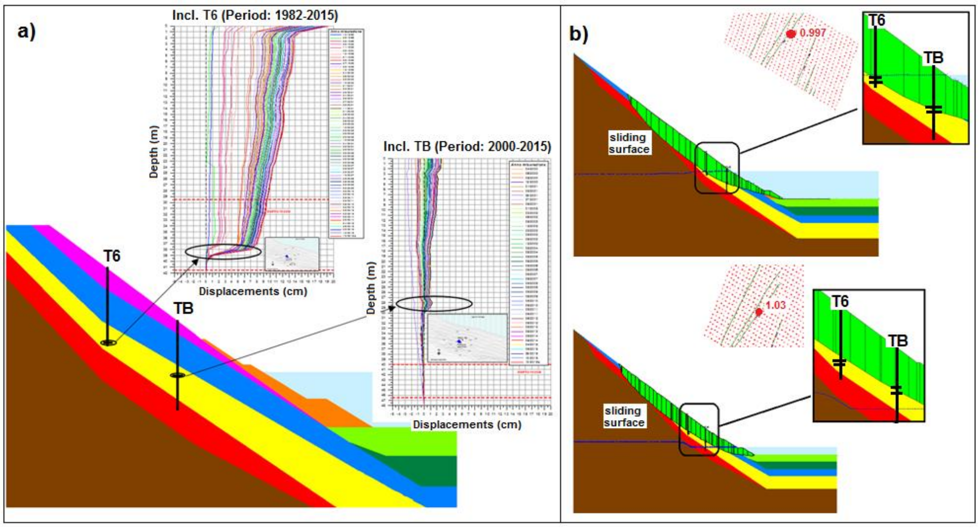

Fig. 11. a) Determination of sliding surface through inclinometric measurements; b) possible sliding surfaces from LEM analyses

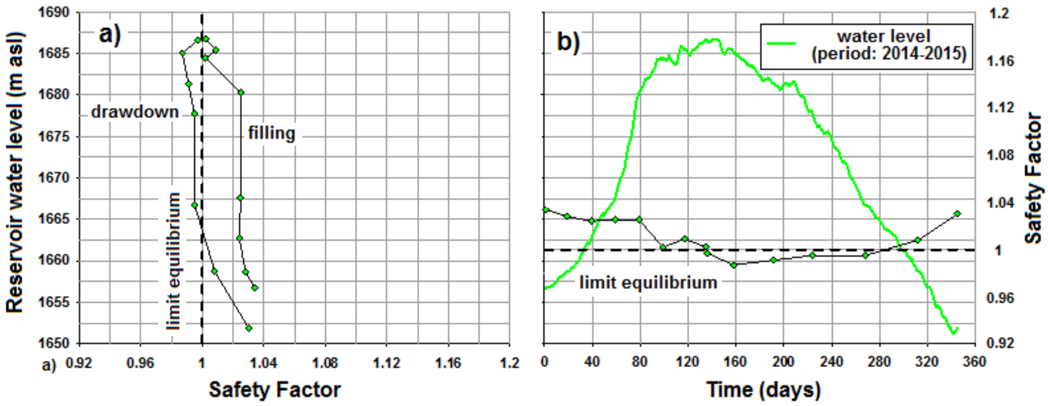

Fig. 12. a) Safety factor vs reservoir water level; b) safety factor vs time

Particular attention should be given to the mechanical characterization of the slope materials, specifically along the sliding surface [7]: due to the lack of specific experimental evidences on the validity of the rheological laws available in literature for the involved materials, specific calibration analyses, based on the interpretation of the available measured displacements, are needed [7]. To this purpose, advanced numerical simulations of the slope displacements are still in progress.

4. CONCLUDING REMARKS

The hydro-mechanical response of the slope of the Vernago reservoir has been firstly investigated through regression analyses of the displacements measured before and after the construction of the stabilizing berm. The obtained results highlighted the cyclicity of the slope displacements and the effectiveness of the berm in the reduction of movements. The obtained regression relationships may be applied to estimate slope displacements following new operation rules, according to the hydraulic variables H_{max}, H_{min} (max and minimum reservoir water levels), $\Delta T_{max,fill}$ (persistence of H_{max}), $v_{fill/dd}$ (rate of change in water level during the filling/drawdown phase). To better understand the hydro-mechanical response of the slope, according to the variation in the reservoir water level, coupled numerical unsteady seepage flow within (FE) and stability (LEM) simulations of the slope have been run. After a better characterization of the permeability coefficients (k) of the slope materials, through the best correspondence between those computed and measured piezometric heads, it has been clearly demonstrated that the hydraulic conditions within the slope don't correspond to hydrostatic conditions.

FE and LEM results coherently interpret the pore pressure and stress state evolution within the slope during the imposed operation conditions, both before and after the construction of the stabilizing berm. The hydromechanical response of the slope always depends on the operation conditions that, in turn, induce unsteady state seepage flows within the slope according to the filling and drawdown phases. Thus, the global stability of the slope strongly depends on the specific drawdown phase. In particular, its safety factor mainly reduces just below the unit value during the drawdown, confirming the observed displacements of the slope in the same phase.

SUMMARY

The slope bounding the reservoir of Vernago, in northern Italy, showed slow and small movements associated with the drawdown/filling cycles of the reservoir. Preliminary regression analyses of the measured displacements highlighted their cyclicity in time. Coupled transient seepage flow (FE) and stability (LEM) analyses have been also carried out. Numerical results coherently interpret the pore pressure and stress state evolution within the slope during the imposed operation conditions that induce unsteady state seepage flows on which in turn the hydromechanical response of the slope depends, according to the filling and drawdown phases.

ÉVOLUTION DE LA STABILITÉ DE LA PENTE DU RÉSERVOIR DE VERNAGO SOUS UNE VARIATION AU NIVEAU DE L'EAU, PENDANT LES OPÉRATIONS DE SOIXANTE ANS

RESUME

La pente qui borde le réservoir de Vernago, dans le nord de l'Italie, a montré des mouvements lents et faibles associés aux cycles de rabattement / remplissage du réservoir. Les analyses de régression préliminaire des déplacements mesurés ont mis en évidence leur cyclicité dans le temps. Des analyses de flux d'infiltration transitoire couplé (FE) et de stabilité (LEM) ont également été effectuées. Les résultats numériques interprètent de façon cohérente la pression interstitielle et l'évolution des contraintes dans la pente pendant les conditions de fonctionnement imposées qui induisent des flux d'infiltration instationnaires dont dépend la réponse hydromécanique de la pente, en fonction des phases de remplissage et de rabattement.

1. INTRODUCTION

[*] *titre de l'article complet*

The landslides of reservoir slopes may cause heavy casualties and loss of property. A large-scale high-speed landslide may cause high wave surge which may even endangers the safety of a waterpower project. Therefore, the stability of those slopes is an important subject in the design of a hydropower station. Landslides of reservoir slopes can occur during the operation of a reservoir (Jones et al.,1961；Schuster, 1979; Gutiérrez et al., 2010; Jiao et al., 2014; Da Huanga , et al., 2017). Statistics show that in general, approximately 50% of reservoir landslides occur during the first impoundment, with the others occurring during the first 3–5 years after the construction of the dam (Jones et al.,1961； Cojean and Cai, 2011). The raise in the water level during reservoir filling causes saturation of slope materials, reducing mechanical strength of soil and rock (Záruba and Mencl, 1982; Wang et al., 2007), and decreasing slope stability. The impact of water impoundment of a reservoir to the stability of a large scale accumulative body (ACC for short) slope is analyzed with an enhanced limit strength method based on a linear finite element stress analysis.

2. BRIEF INTRODUCTION OF THE RONG-SONG ACCUMULATIVE BODY

Rong-song ACC is located at the left bank of the Lan-cang River 5.5km away from a 315m high rockfill dam of the hydropower station in the south-west china. The photo of the ACC is shown in Figure 1. The elevation of the front of the ACC is 2654m and the height of the trailing edge is 3200m. It extends up to 3400m locally along a small gully. The length of it along the river is about 1.4km, the width vertical to the river is about 700m, and the natural slope is between 32 ° and 37 °. It is slightly steep near the riverbed which is at about 40 °. The total height of the ACC is up to about 750m. The slope is currently in a stable state and there is no signs of sliding. Groundwater can be divided into soil pore water which is stored at the Quaternary overburden soils and bedrock fissure water according to their presence conditions. Soil water is recharged mainly by atmospheric precipitation and the water content is dynamically unstable and changes with seasons. There is very few vegetation on the slope surface. The annual rainfall is much smaller than the evaporation. The bedrock fissure water is found in the fractures of the dacite, mainly receives the infiltration and precipitation recharge of the upper soil pore water. The depth of the groundwater at a surface level below 2800m exposed by drilling is 40m ~ 60m below the level. The groundwater in the middle and rear elevation above 2800m is not exposed in the ACC. After the reservoir is impounded, most of the accumulation is below the normal high water level of 2895m. The deposit below 2895m will be submerged during the impoundment of the reservoir, the stability of the accumulation will decrease. It may lose stability during the process of reservoir filling or operation, and the landslide wave surge is dangerous to the safety of the rockfill dam. Therefore, the analysis of the stability of the accumulation and its sliding mode is important to the design.

Fig.1 Phote of Rongsong accumulative body (oblique view from top to bottom)

2.1. TERRAIN GEOLOGY

The geological plane with 8 profile lines is shown in Figure 2. A typical profile R2-R2' is shown in Figure 3. The main body of the deposit was explored by drilling, adit and geophysical work. The ACC is composed of a gravel with fine soil layer with multi-layers gravel sandwiches and a gravel soil. Photo of materials at the surface and exposed by adit is shown in Figure 4. The deposit above 2800m is mainly gravel soils, forming oblique stratification of alternative distributed slope gravelly soil and crushed gravel as shown in Figure 4 (a). The cementation of slope gravel soil is good, and that of crushed gravel is slightly worse. It can be divided into two soil layers, including fine grained gravel soil $Q^{col+dl-2}$ and crushed gravel layer $Q^{col+dl-1}$. The thickness of a gravel soil layer ($Q^{col+dl-2}$) is 5 to 10m. The gravel grain content is about 50 ~ 60% with the size generally between 3 and 6 cm. With sandy soil packed between gravel grains, it is relatively dense and have some cementation. It is slightly loose at the slope surface. The soil can keep stable temporarily in a short time during tunnel excavation. The thickness of a crushed gravel layer ($Q^{col+dl-1}$) is 0.3 to 1.0m. The contact angle between layers is 27 ° to 32 °. Gravel diameter is generally 5 to 20cm, with a small amount of gravel grains which is 20 to 50cm in diameter locally. It is loose and poor cemented. When the adit is excavated to this layer, it is muddied. Deposit about 2800m below is early diluvial gravel soil, collapsing fragment stone terrace accumulation and accumulation of colluvial deposit fragment stone with small amount of alluvial sand gravel $Q^{col+dl+al}$. As shown in

Figure 4(b), particle size is mostly 5 to 20cm, there is about 1m diameter boulder locally. Several profiles shows that there is a small amount of sand and gravel Q^{dl+al} at the lower part of $Q^{col+dl+al}$ (Q^{dl+al} is not appear at R2-R2' as shown in Figure 3). The alluvial sand and gravel Q^{al} is located on the part of the riverbed and on the part of the old river bed on the slope in several profiles. There is gravel filled with gravel soil at the interface of bedrock and overburden as shown in Figure 4(c). Dacite rock is exposed at the front of the ACC along the river as shown in Figure 4(d).

At the bottom of the ACC, there is no obvious weakness in the contact interface between the bedrock and the overburden layer, the soil there is basically the same as that inside the ACC. The internal weakness of the ACC is mainly gravel layer $Q^{col+dl-1}$. Through field investigation, there are two possible types of failure mode in the ACC: (1) an circular sliding arc inside the ACC; (2) non-circular sliding mode including the overall stability failure sliding along the contact interface of the ACC and the bedrock, or a local non-circular sliding surface along the gravel layer within the ACC.

2.2. PHYSICAL AND MECHANIC PARAMETERS

Based on exploration and experiment, the bulk density and the Mohr-Coulomb strength parameters of soils are obtained as shown in table 1. In the stress calculation of the ACC, the adopted values of the elastic modulus and Poisson's ratio of all the deposit soils were 0.35GPa and 0.35 respectively. The bedrock is divided into three layers: strong weathering, weak weathering, and fresh rock mass. Their elastic modulus are 3, 7 and 15GPa respectively, and their Poisson's ratio are 0.3, 0.28 and 0.22 respectively.

Table 1 Bulk density and the Mohr-Coulomb strength parameters of soils

Soil name	Unit weight (kN/m^3)		Shear strength above water level		Submerged shear strength	
	Nature	Saturated	Cohesion (kPa)	Friction angle (°)	Cohesion (kPa)	friction angle (°)
Bedrock	26.5	27.0	900	45	900	45
$Q^{col+dl-1}$	22.0	23.0	5	34.2	0	28.8
$Q^{col+dl-2}$	21.0	22.5	50	33	25	28
$Q^{col+dl+al}$	21.5	22.5	20	35.7	10	30.5

3. STABILITY ANSLYSIS

The enhanced limit equilibrium method based on finite element stress is adopted. The combination of a finite element stress analysis with a limit equilibrium analysis provides greater certainty and flexibility regarding the internal distribution of stresses within the soil mass (Fredlund & Scoular, 1999). The normal force along any selected slip surface can be calculated from the stress distribution that has been calculated using a linear and non-linear stress analysis. The overall factor of safety for a slope, when the finite element method is used, can be defined as the available shear strength of the soil divided by the shear stress. The overall factor of safety is a combination of the local factors of safety within the slope. The resulting factor of safety retains the basic assumptions inherent to the limit equilibrium definition of the factor of safety. Optimization techniques should be used to find the critical slip surface of the slope.

3.1. STRESS INSIDE THE SLOPE

The finite element grid of profile R2-R2' is shown in Figure 5. The meshes in the overburden area are denser than that in the bedrock areas. The control length of a mesh side in the overburden areas is 3m. The elevation of the accumulation in the profile is 2689.5m to 3269.1m, with a height of 579.6m.

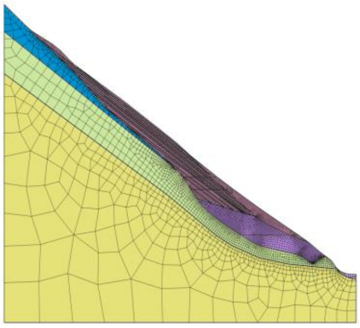

Fig.5 Finite element grid of profile R2-R2'

The steady seepage field with natural or varied water level during reservoir impoundment is calculated followed with the stress field calculation by the effective stress method. Due to the small amount of water influxion in the mountain side and the permeability coefficient of the accumulation material is large, so the phreatic line in the ACC is almost horizontal and flush with the reservoir water level during the reservoir impoundment.

Effective stresses of the slope were obtained by a linear stress analysis. The normal stresses at natural water level(2654m) and at the normal storage water level (2895m) are shown in Figure 6 and 7 respectively. The horizontal normal stress is tensile in the middle and upper part of the ACC (above elevation 2950m), while the actual stress in the ACC should not be tensile because it will crack when tensile stress occurs. The vertical normal stress is directly proportional to the depth of the deposit, which is agree with the actual situation. There is of course a certain difference between the obtained stress and the actual situation of the ACC with a linear stress analysis.

Compared with the natural state, the vertical normal stress in the ACC below elevation 2895m in the normal water level condition is basically reduced by the ratio of the buoyancy and the natural density.

3.2. CIRCULAR SLIDING MODE

Firstly, the factor of safety (FOS) of an arc sliding mode is studied. The position of an slip arc is defined by the position of the two intersection of the arc and the slope surface lines, a sliding into point and a sliding out point, and the arch height. 201 points were evenly arranged on the slope surface according to the distance as sliding into or out points. The FOS of each slip curve inside the overburden deposits with a chord not less than 20m and a arch not less than 5m is calculated. Firstly, the variable arch height is optimized. For a given pair of sliding into and out points, the search of the critical slip arc is a single variable optimization problem for arch height and the golden section method was adopted. Thus, the FOS of the critical slip arc of all pairs of sliding into and out points can be obtained. With the elevations of the sliding into and out points as the vertical and horizontal coordinates respectively, a contour map of the FOS of circular arc sliding mode can be plotted.

FOS contour map of profile R2 - R2' at the natural water level (2654m) is shown in Figure 8. The minimum FOS of arcs sliding from the upper part of the ACC and sliding out from the lower middle part is within 1.08, and the FOS increases with the distance deviation of the pair of sliding into and out points from this area.

As shown in Figure 9, when the water level rises to a higher level, the FOS of sliding arc with a sliding out point below that level decreases. At water level 2744.8m, the range of sliding out point with FOS lower than 1.08 extends to the bottom of the slope. At water level 2815 m, there is area with FOS less than 1.0, the sliding into point position is between 2950m and 3180m, and the sliding out point is located at the bottom of the slope. At water level 2863.8m, the FOS decreases further. At water level 2895m, the range with FOS less than 0.9 appears. Water level rising reduces the FOS of sliding arc with a sliding out point below the water level, but almost have no effect on the FOS of sliding arc above the water level.

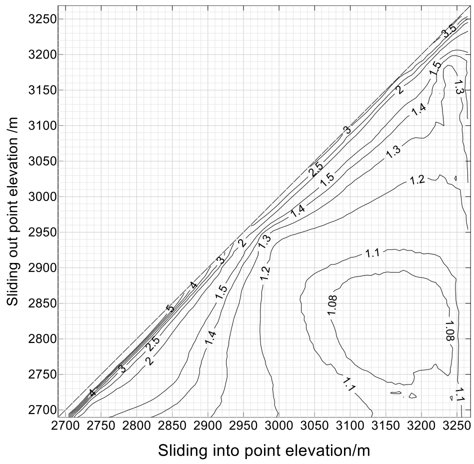

Fig.8 FOS contour map of circular sliding mode at the nature water level

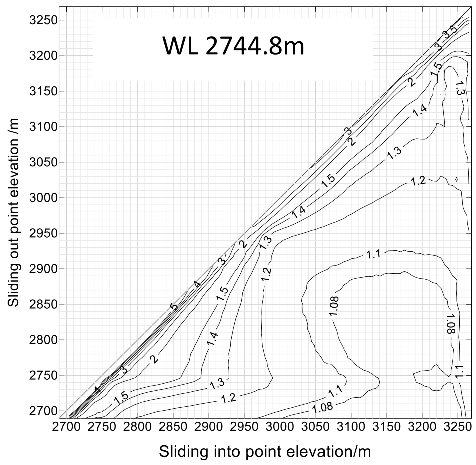
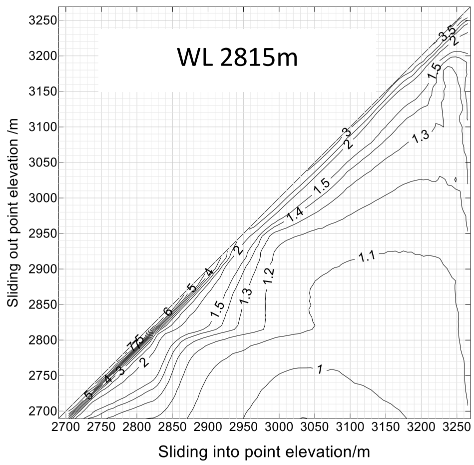
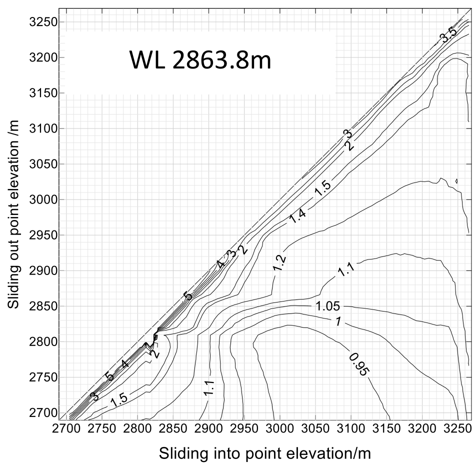


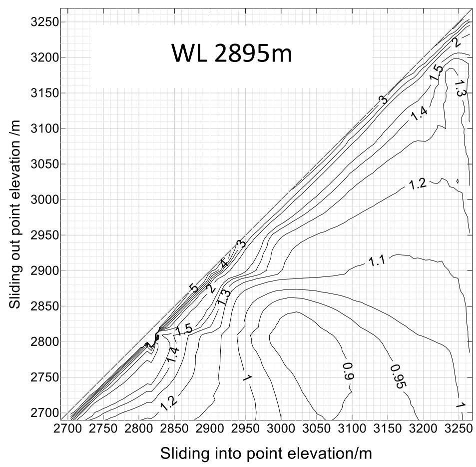
(a) Water level 2744.8m



(b) Water level 2815m



(c) Water level 2863.8m



(d) Water level 2895m

Fig.9 FOS contour map of circular sliding mode during impoundment

Figure 10 shows the critical circular slip arcs and their FOS at each water level. The FOS decreases with the water level, and the FOS decreases by 0.205, from 1.065 in the natural state to 0.860 at the normal storage water level 2895m. Because the FOS is decreased to less than 1.0, the slope may sliding during the impoundment of the reservoir.

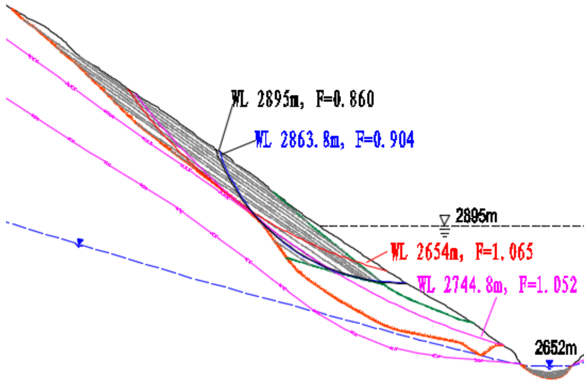


Fig.10 The critical slip circular arc and FOS at each water level

3.3. NON CIRCULAR SLIDING MODE

The non-circular sliding mode along one of the gravel layer in the upper part of the ACC is a typical sliding mode. The FOS of the critical sliding curve in the natural condition (WL 2654m) is 1.033. The position of the critical sliding curve along a gravel layer and the FOS doesn't change during the impoundment.

The FOS of the ACC as a whole sliding along the interface of bedrock and overburden is 1.12 in the natural condition. It decreases with the water level. The FOS at the normal storage water level 2895m decreases to 0.996 which is 0.12 less than that in the natural condition. The FOS of the ACC as a whole at a high water level during the impoundment is less than that of a circular arc sliding mode.

The stability situation of the other seven profiles are similar to profile R2-R2'. On the whole, the present situation of Rong-song ACC is stable. The possible sliding modes are circular slip mode and non-circular mode. The sliding probability along a circular arc and along a gravel layer are quite equal in natural condition. As the water level rises, the probability of circular sliding mode becomes higher than that of a non-circular sliding mode along a gravel sandwich layer or along the interface of the bedrock and overburden.

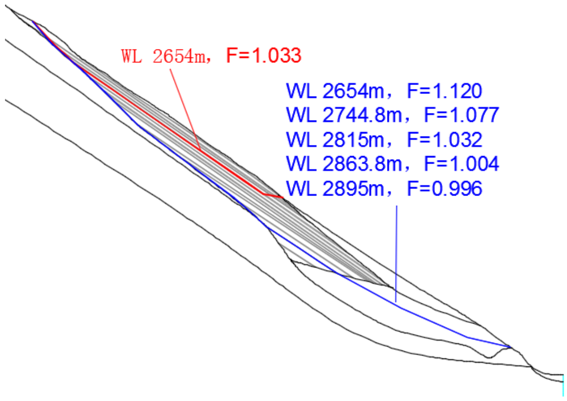

Fig.11 FOS of non circular slip arc at each water level

4. SUMMARY AND CONCLUSION

Based on the finite element stress, the stability of the Rong-song accumulative body in the natural state and during the reservoir impoundment is analyzed. There are two possible sliding modes for the instability accumulative body: the first is the circular arc sliding mode; The other is a non-circular sliding mode along the bedrock and overburden interface or along a sandwich gravel layer in the upper part of the ACC (accumulation body).

The ACC is stable in the natural state. As the water level rises during the reservoir impoundment, the lower part of the ACC will be submerged in the reservoir water. Due to the changes of the effective stresses and the reduction of the strength parameters of soils while it is submerged, the FOS of the ACC decreases with the reservoir water level.

The FOS of both the slip along the interface of the bedrock and overburden and along a critical circular arc decreases to less than 1.0 during the reservoir impoundment. The FOS of a critical circular arc is falling faster than that of the non-circular sliding mode. In the process of water storage, the accumulative body is most likely to lose stability in a circular sliding mode.

Manager Asia Pacific Zone, THE REINFORCED EARTH COMPANY (AUSTRALIA)

1. INTRODUCTION

The current limitations to space and access to permitting approvals has reduced construction of new dams in several parts of the world, particularly those located in or near densely populated areas. Upgrades to capacity and supplemental structures, including spillways and outlet structures, have resulted in turning toward technologies such as Mechanically Stabilized Earth (MSE) to maintain existing plan areas, while allowing vertical construction means to achieve increased water holding volumes and continued stability. This paper will provide an overview of MSE technology used in in the raising of earth dams and dam restoration. In addition to its cost efficiency, MSE wall systems such as Reinforced Earth® provide uniform distribution of loads throughout its mass and increases the overall stability of the resulting composite earth dam. Two separate general types of reinforcement materials, steel and polymeric, will be addressed as to design considerations for safe and expanded performance of earth dam structures. This paper will in turn be supplemented by two case studies representing each of the general reinforcement types to show the viability of each system for dam upgrades.

2. MSE STRUCTURES FOR DAM UPGRADE APPLICATIONS

2.1 BACKGROUND ON TECHNOLOGY

MSE technology as now used in civil engineering in the modern era was first developed by Henri Vidal, a French architect, in the early 1960s. It is more widely associated with road transportation construction on such applications as retaining and bridge abutment walls, but the breadth of MSE technology encompasses industrial, mining, waterway, military and railway support just to name a few of the applications where the technology has spread.

MSE structures are typically composed of precast concrete facing panels joined by reinforcing strips or grids (either steel or geosynthetic) within a granular select fill matrix (Fig. 1). The frictional bond between the backfill and the reinforcements is permanent and predictable and there is a reliable mechanical connection between reinforcements and facing panels. As a retaining structure, MSE represents a unique, composite construction having great strength and stability, a limited footprint and the ability to distribute loads uniformly, even on poor or sensitive foundation soils.

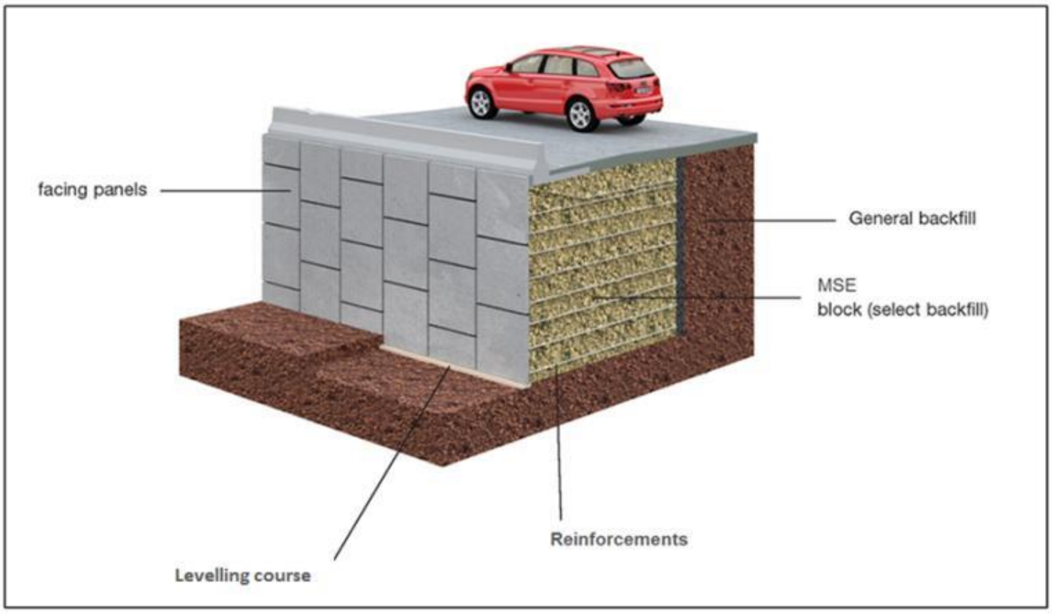

Fig. 1
Typical MSE Wall Components

The advent of MSE technology for use in waterway structures eventually resulted in its development for dam applications. In the mid-1980s, MSE walls were first used to construct new earth dams. One of the earliest dams that was constructed using the technology was Taylor Dam completed in 1984 (Fig. 2). The dam built across the White River in Rangeley, Colorado (USA) was approximately

22.6 m tall and was essentially developed as a core to save on the plan area, thus reducing project costs by approximately US $1 million dollars. Phreatic and drawdown considerations were incorporated, along with special toe stabilization support and incorporation of spillway and piping inclusions. Galvanized steel reinforcing strips were used within the MSE volume.

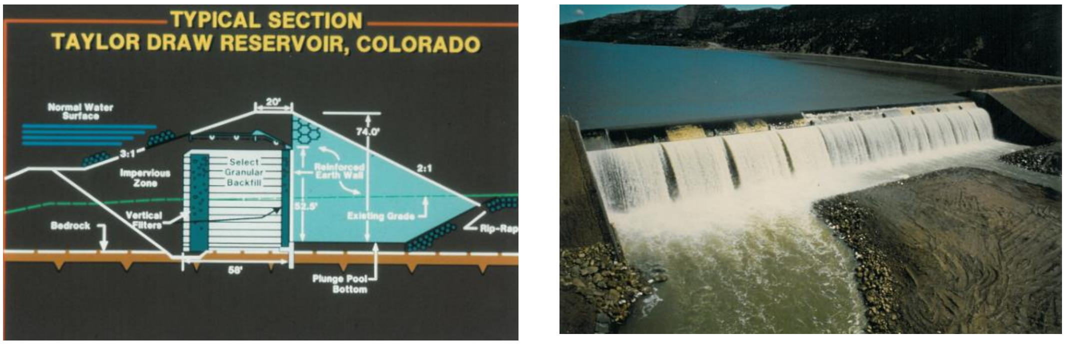

Fig. 2
Taylor Dam

Soon after completion of initial full scale dam projects, use of MSE technology turned to upgrades in existing earth dams to increase reservoir volume and improve embankment stability. One such example was the 60-year-old earth dam at Lake Sherbourne in Montana (USA). The 26m tall earth dam was topped by a 6m tall back-to-back MSE wall that increased the reservoir capacity by 200 m^3 at a cost savings of 35%. The use of MSE technology also had the additional benefit of preventing overloading of the foundation soils.

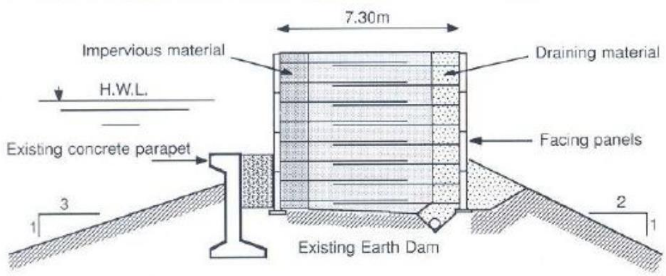

Fig. 3
Lake Sherbourne

Use of MSE technology in dam improvements continues today with less focus on newly established earthen dams (though still a most viable technology consideration). The earliest versions of MSE technology relied on galvanized steel reinforcements; however, geosynthetic strips have become recent reinforcement alternatives where elevated salts in the backfill and/or retained water make considerations for long term metal losses a factor in design and performance. Design and construction differences do exist in selection of reinforcement types, so an early assessment of project physical features needs to be confirmed during development and planning at the outset.

2.2 DESIGN CONSIDERATIONS

Earth dams using MSE technology, whether as new or upgraded structures, have a number of design considerations to be evaluated. These include internal reinforcement pullout and tension considerations typical of MSE walls along with impermeable barriers, drainage and filter features. External stability with respect to prevention of sliding and global stability that is also typical of MSE design, must more closely evaluate erosion and external protection along with through-spillway features.

2.2.1 *REINFORCEMENT AND FACING*

The use of discrete galvanized steel or geosynthetic strips are the dominant reinforcement types used internationally for MSE walls in water-related applications. A predictable metal loss rate for the metallic strips is possible thanks to the interaction between the hot dip galvanization and the underlying carbon steel during the life of the structure. Geosynthetic strips on the other hand depend on the durability and long term plastic deformation of the polymer type used in the reinforcement. In most cases the design life for critical MSE structures is assessed within a range of 75 to 120 years depending on the criticality of the structure involved.

The facing for permanent MSE walls in dam applications is usually precast panels in the range of 1.5 to 3m length and 1 to 2m height, though wire faced walls are sometimes used or panels tailored to resist unique conditions such as shipping or unusual impact loads. In relationship to the face dimensions of the panels, the thickness of the precast units is relatively thin (panel thicknesses as small as 140mm are not unusual with or without concrete reinforcement). Galvanized steel connectors are embedded or polymer recesses are cast into the precast concrete facings to offer mechanical anchoring of galvanized steel or geosynthetic strip reinforcements, respectively.

2.2.2 *BACKFILL*

The largest material component of a MSE structure is the select backfill used to construct it. Good design practice requires the use of materials that ensure adequate frictional interaction with the reinforcements within the resistant zone of the MSE structure (approximately 0.3H behind the wall face, where H is the wall height). Codes for MSE structures usually allow default friction values of 34º to 36º for backfill when less than 15% low plasticity fines are considered.

At the same time, the backfill near the face(s) of the MSE structure must incorporate zones of impermeable backfill backed by adequate drainage means to address rapid drawdown and other variations in internal water level (a central impermeable core may be considered in back-to-back walls where there is horizontal space between reinforced sections). Drainage can be achieved with backfill materials containing less than 5% fines (< 74µm), which is consistent with a permeability coefficient that should exceed 10^{-3}cm/sec. Higher fines in the impermeable zone or backfills treated with soil cement may be considered in dam-related structures. Grain size compatibility is needed to prevent piping and loss of fines between zones. Maintaining vertical impermeable and drainage zones poses potential construction difficulties, which is why use of geomembranes to accommodate water retention and permeable geosynthetics to promote drainage have been incorporated into MSE water retention structures.

The durability of galvanized steel in MSE applications is dictated by the backfill where it is embedded during its intended design life. Electrochemical conditions for the select fill in galvanized steel reinforcements follow guidelines in local codes for resistivity, pH and salts (typically chlorides and sulfates). Geosynthetic strips have separate durability conditions to be met including pH, temperature/creep resistance, construction survivability and chemical/biological degradation. Polymers commonly used in geosynthetic strips for MSE applications are coated high tenacity and molecular weight - polyester (PET) or polyvinyl alcohol (PVA). Though either galvanized steel or geosynthetic strips may be used in submerged freshwater MSE applications, only geosynthetic reinforcements are commonly used in saltwater exposure conditions.

2.2.3 *DRAINAGE, FILTERS AND EXTERNAL STABILITY*

As has been addressed briefly in the foregoing sections, the basic elements typical of all MSE walls must be further modified to address functional components that verify internal and external stability of the dams using the technology. Since the basis and analysis of the functions are specific to the dam upgrade being considered, Table 1 has been provided as an overview and further details are left to two case examples provided hereafter.

Components	Function
Foundation load-bearing soil	Support the dam embankment; distribute MSE bearing pressure per Meyerhof Method Resist geotechnical destabilization phenomena (sliding, settlement, bearing pressure, overturning and deep circular rupture), Resist water flow and internal erosion, prevent particle migration
Dam embankment or mass core	Ensure stability Limit the flow towards the other embankment components Prevent particle migration
Central core between MSE zones or immediate backface impermeable zone	Ensure the structure's watertightness Composed by low permeability materials (such as clays or compacted silts) *This function can be ensured by the MSE mass block in some cases (e.g., cement treated soils) or use of geomembranes*
Filters	Prevent leakage of materials in order to maintain the watertightness and structural integrity by resisting to internal erosion Prevent particle migration at the interface of granular elements. The main use is geotextiles
Drains	Monitor the occurrence of overpressure phenomena, swelling/shrinking events and destabilization Positive discharge of water seepage Additional design for internal or deep drainage
Berms	<u>Watercourse side</u>: used as protection system or as an element to add stability and watertightness (by decreasing the hydraulic gradient) <u>Protected Zone side</u>: used in order to provide stability and/or filtration, to control internal erosion and/or under pressure of the foundation ("sand boil", which can lead to liquefaction)
External protections	Protection by grass vegetation or hard shell Riprap, concrete artificial blocks (tetrapod) or dressed stones' riprap or masonry.

Table 1 MSE Dam Functional Components

3. PROJECT CASE STUDIES

3.1 CHAFFEY DAM, TAMWORTH, NSW, AUSTRALIA

Chaffey Dam is a 54m high and 430m long clay cored, rockfill embankment with a combined Morning Glory (MG) Spillway and outlet works. Construction began in 1976 and the dam was commissioned in 1979 with storage capacity of 62 gigalitres at full supply level (FSL). The dam is located 43 km south-east of Tamworth on the Peel River in New south Wales and provides town, industrial and irrigation water supplies, flood mitigation and drought security to the Tamworth Region. The dam, as it was originally constructed, had an inadequate flood capacity of 1:50,000 AEP and the crest was raised in 2004/5 by 1.8m using a precast concrete wall on the upstream edge improving the capacity to 1:98,000 AEP. However, Chaffey Dam is classified by the NSW Dam Safety committee as an Extreme Consequence Category dam and consequently the State Water Corporation decided to improve the flood capacity to the full Probable Maximum Flood and to augment its storage to 100 gigalitres. A detailed study in 2006-7 recommended the combined measures of forming an auxiliary spillway through the left abutment, raising the dam crest by 8.4m and raising the bellmouth of the MG spillway by 6.5m.

The raising of the crest to RL 541.6m and the increase in the FSL to 525.1m was predicted to induce settlement in the crest in the order of 100mm, and downstream deflection in the order of 20mm to 50mm so a camber allowance of 100mm was introduced. The PMF loading was predicted to induce crest deflection at the top of the structure in the order of 300mm to 350mm. The raising of the dam crest was detailed as two Mechanically Stabilized Earth (MSE) retaining walls, constructed 7.35 meters high, back to back, to RL 539.75 and topped with a precast concrete parapet 1.8 meters high to RL 541.8. The bearing pressure below the MSE block was estimated to be a maximum 270 kPa at the downstream toe for the PMF load condition, which controlled the design.

The MSE walls were designed by The Reinforced Earth Company (RECO) in accordance with NSW Roads and Maritime Services QA Specification R57 “Design of Reinforced Soil walls” with modular precast concrete facing panels and galvanized steel reinforcing strips for a design life of 100 years. Whilst both steel and polyester reinforcing strips were considered, steel was ultimately preferred due to concerns about possible damage to the polyester strips from the compacted gravel backfill.

Design load cases considered both dry and saturated MSE blocks for the PMF event using factored ultimate limit state (ULS) design loads that are calculated by moment equilibrium equations and assuming a Meyerhof vertical stress distribution. To satisfy R57 design requirements, an overdesign factor of 1.0 must be achieved. Earthquake load cases considered included the Operating Basis Earthquake (0.21g horizontal and 0.15g vertical accelerations) and Maximum Design Earthquake (0.99g horizontal and 0.73g vertical accelerations). Following pseudo-static analysis to determine the likely failure mode, an elastic finite element analysis using backfill stiffness varying from 50MPa to 200MPa predicted that the maximum likely movement of the MSE block could be in the order of 80-100mm under an MDE event.

The upstream facing panel joints were sealed with an impermeable membrane and the MSE block was constructed in zones which varied from a silty, sandy gravel (Zone 4) at the upstream face and above the existing dam's clay core, to a well graded gravel (Zone 4A) above the existing fine filter, to coarse gravel (Zone 4B) above the existing coarse filter (Fig. 4). Construction of the project was completed in December 2015.

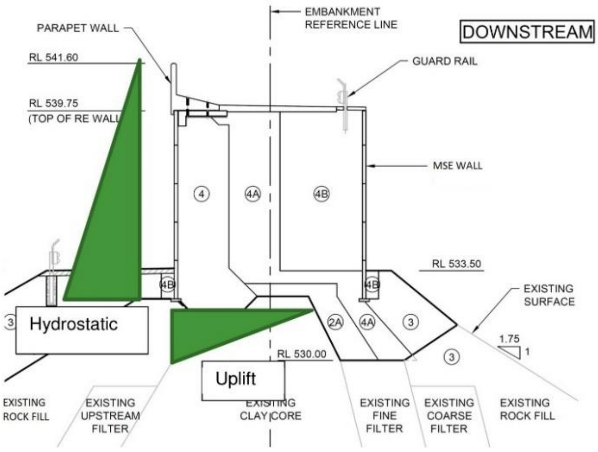

Fig. 4
Water Pressure Diagram for PMF Loading Case (Consultant Design Report)

3.2 LOS VAQUEROS DAM, CALIFORNIA (USA)

Los Vaqueros Dam was originally built in 1998 to create the Los Vaqueros Reservoir to improve the quality and amount of water available to the Contra Costa Water District (CCWD). In 2011, CCWD expanded the reservoir from 123,000 million liter (ML) (100,000 acre-ft) to 197,000 ML (160,000 acre-ft) in capacity by raising the dam height by 10.4m (34 ft).

The principal elements of the project were to excavate the crest of the existing dam by 14.3m (47 ft) and then to add 24.7m (81 ft) to the dam height, making a total dam height increase of 10.4m (34 ft), as shown in Figure 5. Approximately one million cubic meters of additional engineered embankment fill was placed; coming from borrow areas located near the dam.

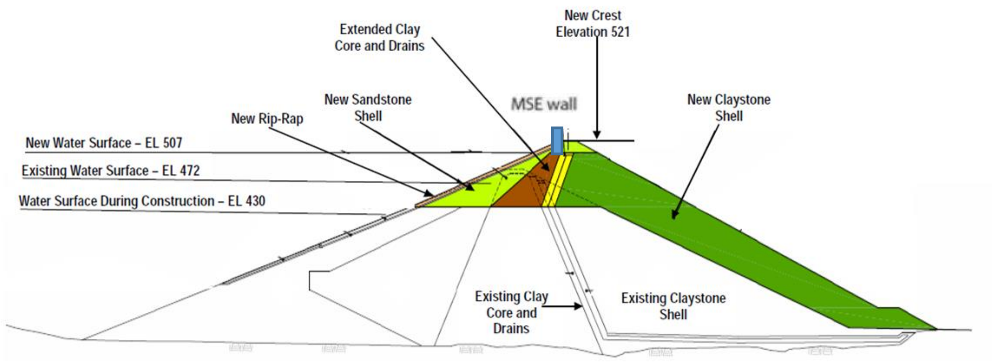

Fig. 5
Section of Dam Expansion

The project site was within a relatively high seismicity zone with a specified ground acceleration coefficient of 0.50g. Two MSE structures with a maximum height of 15m (49 ft) were utilized to widen the roadway at the crest of the dam on the upstream side. The other two structures were used on the downstream side. The upstream walls were located within the phreatic zone and subjected to submerged design conditions with one meter (3 ft) of rapid drawdown.

Design was performed on the basis of AASHTO codes modified to address special criteria related to PET geosynthetic strips and dam functionality. The MSE walls were founded on competent compacted shell-sandstone material that was also a part of the dam embankment. The bearing capacity was adequate to support the MSE wall with narrower base width at some sections of upstream walls. The final vertical plumbness of the walls was measured to be within 38mm (1.5 inches) in 3m (10 ft) of vertical distance. No movements were detected after the construction of the walls (Figure 6).

Fig. 6
Completed Los Vaqueros Dam Expansion

CONCLUSIONS

The use of MSE walls in upgrades to existing dams allows expansion to capacity while combining a more limited plan area and loading scheme with relative economy. Selection of reinforcements for the MSE walls depends upon the salts content of the retained backfill and water, but on the whole, either galvanized steel or geosynthetic reinforcements can perform equally well with the material considerations taken into account during design and construction. MSE walls are a well understood and mature technology that should be considered for their reliability, stability and flexibility, particularly in the face of seismic conditions.

SUMMARY

The first Mechanically Stabilized Earth (MSE) walls for dam applications were constructed using Reinforced Earth® in 1973, soon after development of the MSE technology by Henri Vidal in the late 1960s. Since these first structures, MSE walls have been used around the world to meet the challenges represented by a variety of waterway structures that include dams and dam upgrades. With time, the technology has evolved primarily in the type of reinforcements used to meet the site conditions imposed by geotechnical and hydraulic conditions. Case studies are provided to represent the primary applications of galvanized steel and geosynthetic reinforcements used in MSE walls for dam upgrades.

Les premières parois mécaniquement stabilisées (MSE) pour les barrages ont été construites en utilisant Reinforced Earth® en 1973, peu après le développement de la technologie MSE par Henri Vidal à la fin des années 1960. Depuis ces premières structures, les murs MSE ont été utilisés dans le monde entier pour relever les défis représentés par une variété de structures de voies navigables qui incluent des barrages et des améliorations de barrage. Avec le temps, la technologie a principalement évolué dans le type de renforcement utilisé pour répondre aux conditions du site imposées par les conditions géotechniques et hydrauliques. Des études de cas sont fournies pour représenter les principales applications de l'acier galvanisé et des renforts géosynthétiques utilisés dans les murs MSE pour la modernisation des barrages.

STUDY OF RESERVOIR RIM SLOPE STABILITY DUE TO OPERATION OF SUSU DAM

Ahmad FADHLI MAMAT

Project Leader, TNB RESEARCH SDN BHD

MALAYSIA

1. INTRODUCTION

Susu Dam is part of the Ulu Jelai Hydroelectric Project undertaken by the national power company (TNB) which could generate 372MW. Its main dam, with a height of 88m, is located in Cameron Highlands, about 200km north of Kuala Lumpur. This reservoir is one of the dams in Malaysia with major fluctuation during its operation. Leryar Village, which is a settlement for about 400 aborigines, is located on the bank and a rim slope failure could be catastrophic to the community. As such, this study investigates the landslide hazards due to the fluctuation of Susu reservoir and rainfall infiltration, by conducting soil investigation, hazard mapping and advanced laboratory tests.

2. METHODS

Rainfall data for the past 30 years were analyzed so that the intensity and duration of a rainfall event with a return period of 1:10 years could be estimated. Field assessments and GIS analyses were conducted so that hazard maps could be produced using methods proposed by Anbalagan (1992). Advanced lab tests, i.e. permeability, CU, CD and SWRC, were carried out to obtain the hydraulic and mechanical properties of the top soil layer, in the saturated and unsaturated states. The hydraulic conductivity relationship and the shear strength contribution with increase in suction were then deduced using methods proposed by Van Genuthen (1980), Freudland & Morgenstern (1977) and Ho & Freudland (1982).

3. RESULTS

Results of Factor of Safety (FOS) from slope stability analyses using this method differs greatly from the methods normally used by practitioners. Conventional methods would conclude that the slopes are sufficiently stable with FOS values of at least 1.47, while this method, which involved rigorous testing and numerical modeling, resulted in FOS as low as 0.37. It is also noted that hazard maps produced using a qualitative and probabilistic approach agrees well with the FOS of the specific slopes, which is quantitative and deterministic.

4. CONCLUSION

This study exhibits the need to conduct extensive soil tests and apply the latest theories in soil mechanics to obtain reliable FOS for shallow failures involving transient flow conditions, such as rapid drawdown and rainfall infiltration. It also suggests that qualitative hazard assessment could be used as a precursor to advanced soil tests and numerical modeling, which are costly.

1. INTRODUCTION

The observational method applied to monitoring slope stability in dams and reservoirs aims to provide substantial information for a proper risk management, during the construction and operation of these critical infrastructures.

This paper proposes to describe, explore and discuss the advantages and limitations of the data obtained by geological in situ inspections, classical geotechnical monitoring techniques (such as inclinometers, piezometers, etc.) and geodetic surveying techniques applied in large areas, together with the use of remote sensing techniques, like InSAR. This combination allows the information to be maximized in terms of areal coverage, accuracy and data integration.

In the case study presented, this analysis proved to be a great help to decision making in the context of a hydropower reservoir in Portugal owned by EDP, with a capacity of 106 hm3 and an area of 421 ha, created by a dam 110 meters high and 275 meters long at the crest, which has associated a powerhouse with a generation capacity of 263 MW.

2. MONITORING PROGRAMME FOR SURVEYING SLOPE STABILITY

The program for monitoring the slope stability of the reservoir included, locally, the installation and reading of several inclinometers and also the observation of several particular slopes whose safety can be compromised for geotechnical reasons and/or for their specific characteristics.

Dam monitoring includes the installation of topographical prisms over the dam body and also several topographic references that help the stability of the system in terms of precision and accuracy. Those reference prisms are also installed in the slopes, so in areas of potential movement. The use of other systems that can help to monitor these references and correct the final real displacement is also of interest.

InSAR remote sensing monitoring was analyzed in order to verify if this technique could be applied to:

- obtain displacement information over the remote slopes where there is no option to install in-situ devices,
- check if the reference prisms are in moving areas,
- obtain a general overview of the stability of the slopes and also helps to optimize the installation and readings of other geotechnical instruments.

Figure 1
Results obtained for slope monitoring with InSAR technology. Displacement map with general overview on the area (left) and results showing motion on the slopes close to the dam body (right).

1. INTRODUCTION

Jatigede Dam is the second largest storage dam in Indonesia that reaches almost 1 billion m^3. Completed in 2016, this dam is located in Cimanuk River, Jatigede Subdistrict, Sumedang District of West Java Province, Jatigede Dam is a center core rockfill dam with 114 m height and 1,715 m length. The main purposes of Jatigede Dam are to fulfill 90,000 ha irrigation area, 3,500 l/s of

Cirebon and Indramayu water supply, 2 x 55 MW of hydropower, and flood control of 14,000 Ha area around Cimanuk River.
The dam site area generally has an intensive and complex tectonic geological structure. The existence of this complex structure causes the dam site area be vulnerable of landslide. Downstream of the left and right slope of the dam and the upper left bank of main cofferdam are the landslide locations. Geological structure and high rainfall intensity are the main factors that cause the landslide.
During the construction phase of Jatigede Dam, it was discovered that some landslides were in motion around the main dam area particularly at the downstream left bank in Cipinang and at the right bank in Eretan. These landslides disrupted the work progress thus leading to initiation of several countermeasures. While the landslide at the right bank had been taken care of succesfully, the one occurs at the downstream left bank is still in progress of stabilization up to date.

2. GEOLOGICAL REVIEW

2.1. LOCAL GEOLOGY

The left saddle bedrock is formed by a mixture of sand-stone and clay-stone with thickness ranging between 10 to 40 centimetres, grey to yellowish grey in color, friable, slaking, and moderately weathered. This bedrock formation is classified as folded breccia. The upper part has weathered and mixes up with yellow to reddish brown soft soil.
The river bedrock consists of sedimentary rocks and rigid breccia formation utilized as the main dam's footing. There is also an evidence of fault in the riverbed as indicated in geological maps. In general, the bedrock on both left and right banks is formed by volcanic breccia of Lower Halang formation.
Within the bedrock of the right bank, the Lower Halang volcanic breccia starts to shift to the Upper Halang clay-stone. This transition manifests in the form of fault with angle of strike/dip N242^{0}E/82^0, inclined to the west with angle of N124^{0}E/64^0. This bedrock formation is more than five hundred metres spanning to the upstream and downstream of the main dam.

2.2. LANDSLIDES ZONE

Landslides area on the left bank is estimated about twenty hectares. The sliding crown is situated close by the sand sieving plant, spans toward the edge of river body in the east. The sliding border is easily recognized due to trapped topographical surface and highly steep slope (approximately 60^0 – 70^0).

Its bedrock formation is the lowest layer of Lower Halang breccia. The upper layers consist of Upper Halang flakish clay-stone and folded breccia, with the latter being white to brownish yellow in color, relatively permeable (permeability coefficient of 10^{-4} cm/s).

A layer of old unconsolidated volcanic sediment is situated above the aforementioned folded breccia. The sequential upper layer is filled by a mixture of solid aggregrates and residual soil with 10^{-4} cm/s permeability coefficient. The debris is a mixture of weathered soil layer and old volcanic breccia layer, permeable and unconsolidated.

The landslide at the right bank consists of rock and soil fragments, permeable and consolidated, which is a suitable indication for instability during or even after construction phase. Result of geology investigation gives a clear picture of quarter volcanic layer slides over the claystone layer, on which the claystone is indicated as heavily weathered and extremely soft, black in color. Geologic characteristic shows the volcanic quarter debris is a mixture of rock fragments and silty clay, with thickness between 8 up to 14 meter from top soil.

Ground water level is at the depth of 15 meter, adjacent to the landslide’s crown, 5 meter downstream

3. FACTORS OF LANDSLIDES

According to the national standard issued by Ministry of Public Works and Housing namely SNI 03-1962-1990 regarding the Planning on Landslides Countermeasures, the general driving forces for any landslides are identified from the source of disturbance, whether internal or external.

3.1. External Disturbance

(1) Overburden due to human activities, such as buildings or soil dumping on top of banks.
(2) Loss of lateral support, might be induced by bank erosion (natural cause or sand mining).
(3) Lack of vegetation cover leading to gully erosion.

3.2. Internal Disturbance

(1) Increase of soil mass due to over-saturation.
(2) Groundwater table raises up causing a higher pore pressure, which in turn lowers the friction among soil particles.
(3) Swelling on some certain clay soil.

In the case of Jatigede Dam, a heavy rainfall was accounted as external factor causing oversaturation in the soil, then the soil become an overburden toward itself with a higher pore pressure.

A similar phenomenon is expected to reoccur with a higher severity during the initial impondin. Thus, it is necessary for an intensive monitoring to be carried out during this phase.

3.3. LANDSLIDE SURVAILLANCE

3.3.1. Left Bank Landslide

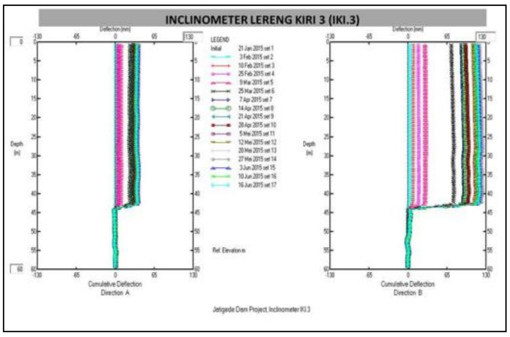
A. Inclinometer Reading

After the completion of bored piles line A, B, and C, inclinometer IKI-1 was installed at the center of landslide direction which was giving a reading with no signs of movement. In contrast, the inclinometer IKI-2 which was installed at the edge of the upper part landslide showed an eight millimeter movement at the depth of 16 meter. According to technical discussion on this matter, held in Bandung in June 2014, it had been then decided to install additional bored piles and inclinometers namely bored piles line D and IKI-3 and IKI-4, which were completed in August 2014. From these additional installations, another movements were detected (IKI-3 at the depth of 43 m; IKI-4 at the depth of 16 m and 24 m), thus leading to three more bored piles installation at the base of landslide (line E, F, G) which is still in progress.

Sliding movement showed by IKI-4 is situated on an exposed clay-stone with steep slope, with a creep movement and is calssified as translation sliding.

Reading of IKI-3 shows a deep slide at the depth of 43 m on the transition between breccia tuffs (semi-impermeable with coefficient 10^{-4} cm/s) and clay-stone (coefficient 10^{-6} cm/s) layers, therefore it is estimated that this transition layer is responsible as the sliding plane. This plane's slope, indicated as translation sliding, is in alignment with the top soil surface layer with slope of 5^0 – 10^0.

Inclinometers and Piezometers placement layout on the left bank is shown in figures below. Visual results of inclinometers display the rate of movement from IKI-3 (1.4 mm/day) and IKI-4 (1.5 mm/day), which are according to SNI 03-1962-1990 classified as creep movements (less than 4 mm/day).



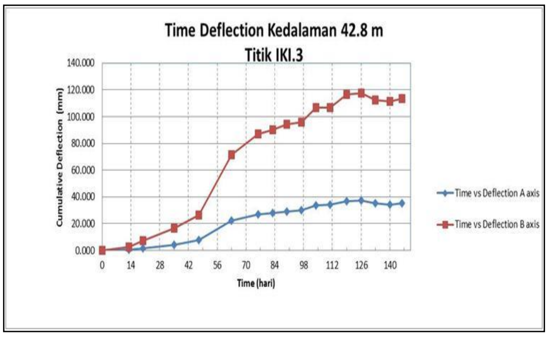


Figure 1.
Inclinometer Reading IKI-3 at Left Bank

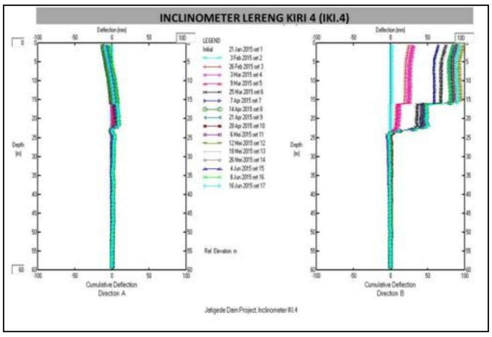
Inclinometer IKI-3 at Left Bank, Landslide Motions in Time



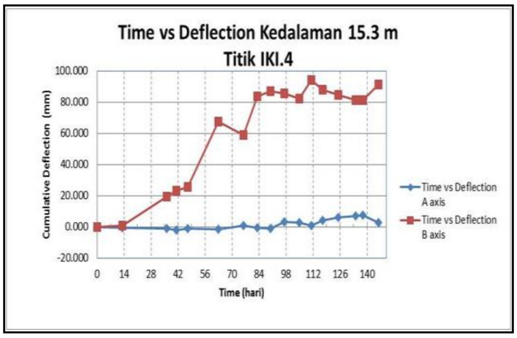


Figure 3.
Inclinometer IKI-4 at Left Bank

Figure 4.
Inclinometer IKI-4 at Left Bank, Landslide Motions in Time

B. Robotic Monitoring System Reading

At the left landslide zone, the result of robotic monitoring system shows that all observatory prisms tend to move toward the old river body (right side) by 18 mm in 2 months. This magnitude is considered to be relatively small in accordance with the inclinometer reading during period of March – May 2015 (Figure 7).

3.3.2. Right Bank Landslide

At the right landslide zone, the reading from observatory prisms shows tendency of movement toward the left direction with a relatively low magnitude (0 – 4 mm) (Figure 8).

Observatory Prisms on landslides around Jatigede Dam

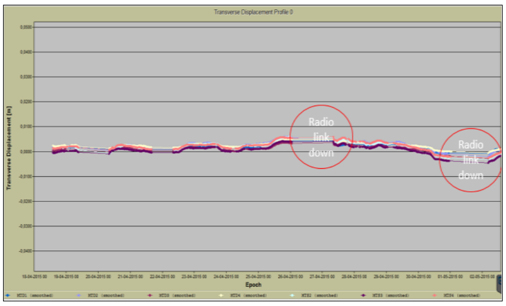

Figure 7.
Transversal Displacement of Left MTL (March-May 2015)

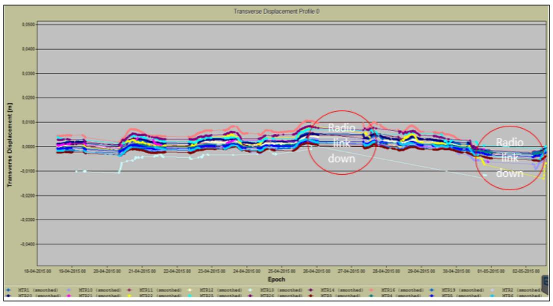

Figure 8.
Transversal Displacement of Right MTR (March-May 2015)

4. PROPOSED OF COUNTERMEASURES

Some countermeasures to prevent potential landslides has been prepared and constructed, they are:

1) Reduce the driving force

(a) Reduce static force:
- Reduce slope steepness (accomplished)
- Terraces construction at the upstream of bored piles line (accomplished)

(b) Minimize contact with surface run-off and groundwater:
- Rearrange drainage network (on progress)

2) Anchor Placement and Improvement of Sustaining Force

(a) Arrange bored piles lines along the bank (on progress, with some part has already accomplished).

(b) Construct a counterweight at the toe of the left bank (dependant on short-term monitoring result).

3) Various Improvement Activities

(a) Subsurface drainange system (horizontal-pipe drain).

(b) Robotic surface-coordinate monitoring (accomplished).

(c) Inclinometer installation (on progress).
(d) Installation of additional piezometers (on progress).
(e) Observation wells probing at the landslides site.
(f) Periodic observation and evaluation to determine the necessity of long-term countermeasures.
(g) Calculation of a three-dimensional mathematic model on the correlation of landslides and main dam.

5. CONCLUSION

Constructed countermeasures has showed that:

- Right Bank landslide had been taken care of successfully, and recent visual inspection and instrumental observation show no evidence of any significant displacements.
- Left bank landslide has undergone a similar treatment method assuming 12 to 14 meter depth of sliding plane. However, inclinometers reading shows indication of another movements at the depth of 43 m (IKI-3) and 16 – 24 m (IKI-4) with the rate of 1.4 mm/day, thus classified as a creep movement.
- These sliding movements are highly correlated to rainfall intensity.

However some recommendation countermeasures are still needed to make sure the stabilility dute to landslide potential areas, such as:

1) Complementary constructions in order to mitigate the additions of impending loads due to external disturbance as follows :
   (a) Deeper additional bored piles (in progress) or soil nailing at the toe of left bank.
   (b) Construction of counterweight at the toe of left bank which supports the right bank.
   (c) Continuation of subsurface drainage with horizontal pipes to lower groundwater leverl.
   (d) Continuation of surface drainage with Y-drains (bee hives construction) to reduce the rainfall effect.
2) Intensive monitoring and evaluation on both visual inspections and instrumental readings.
3) Reservoir imponding to be carried out thoroughly and gradually. Construction of point 1) could be implemented during or after the initial imponding.
4) Establish a discrete monitoring and evaluation task force, solely responsible during initial imponding phase.

6. ACKNOWLEDGEMENT

The authors would like to thank to Cimanuk Cisanggarung River Basin Unit for the authorization to publish the main result of the present study.

ABSTRACT

One of the challenges in engineering world is investigation on seismic behavior of earthdams during an earthquake. The complexity of this issue is lack of adequate information about the impact of the earthquake on earthdams behavior. Many scientists presented an important research in this area. Dam stability during the earthquake is one of considerable factors which can be estimated by various parameters. In this paper, as a reliable parameter, safety factor is estimated using finite element method in PLAXIS 2D software. In this paper, reservoir water level is considered as a noticeable parameter which affects on stability of earthdam and safety factor during an earthquake. For this purpose, two different water levels, %30 and %70 of earthdam height, is assumed for reservoir. Also, in order to consider effects of earthquake, a magnitude MW 6.8 earthquake is applied to model. Angle of internal friction of earthdam materials is 30 to 35 Degree and the side slopes are 1:2.7. Additionally, as isotropy has no enormous impact on results, isotropic materials are assumed for earthdam. Analysis results indicate reservoir water level increasing from %30 to %70 of earthdam height has direct impact on safety factor reduction up to %8.

KEYWORDS

Earthdam, reservoir level, finite element method, seismic performance, safety factor

1. 1.INTRODUCTIONS

It has been a long time since the construction of earth dams was used to control and store water. One of the issues that is important in earth dams is the seismic behavior of earth dams due to landslide of neighboring areas or earthquakes. Mostly failure due to an earthquake was not in areas where the dams are concentrated; however, to investigate this comment a few practical experiences are available. Earthquake-related failures can be sub-categorized and for each group the stability prediction can be considered:

- The earthquake shake causes cracks in the upper parts of the dam and these cracks may happen exclusively in the core and water can flow from cracks and if there are no precautionary measures, the piping will eventually lead to the destruction of the dam.
- The earthquake shake causes the body or foundation to subsidence, therefore the dam’s crest moves. As a result of the free height reduction, the water flows above the dam and the dam will destroy.
- The reservoir shake causes the formation of oscillary waves which are large and slow at the surface of the water. If there is not enough free height, the water inside reservoir passes the crest of dam toward downstream and possibly destroys the dam.
- Slopes of dam in the both sides might reach to failure due to earthquake and the dam can be destroyed from the both sides. One of the attractive factors is the stability of dams. To measure the stability of dams, various parameters can be used which one of the most accurate and reliable is the Safety factor.

Shong-Loong Chen et al. [4] entitled the effect of upward water level on dynamic response of embankment dams conducted a dynamic survey on embankment dams according to seismic conditions of Taiwan in DIANA-SWANDYNEII with different water levels and numerical simulations. In this paper, the penetration and dynamic stability of embankment dams making by three different types of soil such as clay, silt and silty sand have been examined. Results obtained from dynamic survey on five different water levels indicate that areas above foundation line and membrane part of upstream silty link to dam height have seep ability; moreover, pore water pressure makes rapidly and increase in medium of upstream silty part. Also, results indicate that pore water pressure in more than one third of upward out membrane mostly be negative until water height reaches to 0.75% of the dam height which is indicative of area stability and any seepage is impossible in this passive time.

Yu-xin Jie et al. [5] in a study examined penetration, seepage and also stress and strain on different water levels in embankment dams. In this research, in order to perform numerical simulation for filling water in a rock embankment dam, a simple approach has been used for analysis of unsaturated soil stabilization. In addition to stress and movement in dam, pore water pressure and phreatic line have simultaneously obtained. Results indicate that according to simultaneous effect between deformation and pore water pressure, progress of phreatic line in body and core of dam is faster than analysis of unsaturated penetration and seepage without simultaneous effect of deformation. Changes of pore water pressure is not only related to unsaturated penetration due to water surface changes, but also related to cavity due to deformation.

2. MATERIAL AND METHODS

In order to examine the dynamic behavior of embankment dams, a model was designed and safety factor for two cases of friction internal angles of 30 and 35 degrees in top and bottom levels of reservoir was investigated. For this purpose, a dam with 70 meters height, sides slope 1:2.5 and 9 meters length of crest was assumed. Clay soil was used for a core and a sand for drainage and also a foundation consist of clayey-sand. The dam has also a cutoff consist of grout (Figure 1), and then was meshed by the program (see Figure 2).

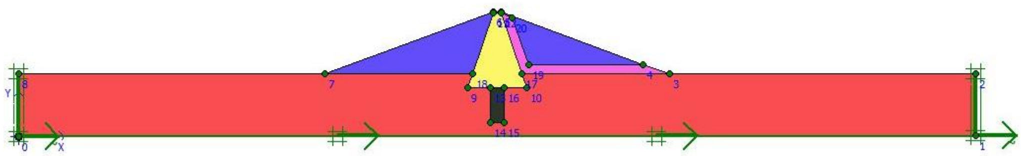

Fig. 1. soils cluster

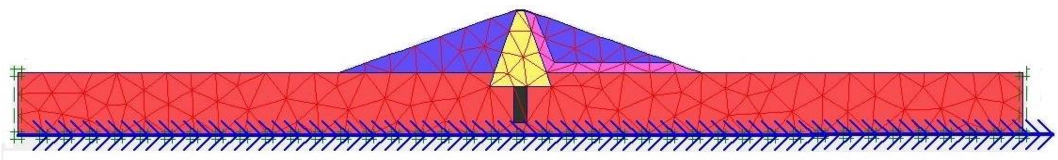

Fig. 2. mesh formation

2.1. SOIL DATA

In this model, five soil specimens (grouted ground to seal the foundation by, clay soil for core, sand and gravel for soil draining, clayey sand for soil of and at last, silty sand for dam surface) ware used which properties of each of them separately shown in Table 1.

Table 1. soils specifications

Soil	E(KN/m^2)	C(KN/m^2)	Φ	K(m/day)
Silty Sand	5500	30	35	0.2
Clay	2500	60	30	0.001
Clayey sand	3500	1	33	0.4
sand	30000	1	35	10
Grout	4000	1	33	0.05

the information above and also initial values of computations can be extracted by Allpile [1]program, Advance Soil Mechanic written by Das[6] and Foundation Analysis and Design written by Bowles[2] and other parameters can be computed. The table in this guideline and books has been taken for helping in selection of soils property.

Penetration of some soils has been mentioned in book of Advance Soil Mechanic from which can used for selecting the most appropriate soil. Test standard method for standard penetration test [3]and sampling soils by split rib tube (two scales sampling). This test method describes way of going forward two scales tubular sampling for obtaining definite soil specimen and measuring soil strength against sampling penetration, and generally it has been known as Standard Penetration Test (SPT).This standard do not express all safety cases related to its application, consumer of this standard account to provide appropriate health and safe instructions and define applicability of equality limitations before using. Values which is expressed in inches-pounds units as standard. This test provides both a sample in order to detection and appropriate experimental tests related to the soil, and another sample that it may lead to much touched shear deformations. This test has been widely used in exploratory geotechnical projects. There are any local and widely propagated relationships which number of SPT impact or N related to engineering behavior of earth works and foundations. Also, elasticity modulus of some soils can be determined by Foundation Design and Analysis book which is taken in the following using SPT.

Table 2. modulus of elasticity specifications

Soil	Es(kN/m^2)
Sand	Es=500(N+15) Es=18000+750N Es=(15200 to 22000)ln N
Clayey sand	Es=320(N+15)
Silty sand	Es=300(N+6)
Gravelly sand	Es=1200(N+6)

2.2. EARTHQUAKE DATA

Magnitude (Richter) and amplitude logarithmic measuring of earthquake is in conjunction with released energy as earthquake waves in earthquake center. Earthquake magnitude do not have top and bottom limits; however, the most and least earthquake magnitude are 9.5 and -3.5. In this logarithmic scale, shallow earthquakes have been shown that elastic wave of earthquake with magnitude 6 Richter, has an energy about 30 times energy of an earthquakes with magnitude 5 Richter, and also more than 900 times one with magnitude 4 Richter and so on. Different factors are effective on determination of earthquake power including focus depth, distance of earthquake center to measure station, frequency of sampled energy and pattern of earthquake propagation (angle variety in vibration amplitude).

According to the statistics of earthquakes occurred in California[7], America between 1898 to 1989, at least 23 earthquakes with magnitudes between 6.5 to 7.2 are reported and also, so other earthquakes observed in less or more magnitudes. Measurement is done by the shaking caused by earthquake in any time. In whole, in three past decades in California, the scales which have had more strong shaking and acceleration during earthquake, have been measured by organization of coastal and geodetic of America. On the base of statistics, earthquakes are differed on different cases. Thus herein, an earthquake with the following characteristics has been considered which these cases can be accounted in possibility occurrence in an acceptable range among earthquakes which may cause damage. Earthquake characteristics used in this analysis, have been taken in Table 3 and also, acceleration in cm/s2, velocity in cm/s and displacement in cm versus time observed in the following Figures.

Table 3. Earthquake specifications

Earthquake magnitude	6.8	Mw
The distance from the epicenter	77.7	Km
Peak value	-2.4	Cm
Sample rate	200	Hz
Acceleration	52.5	cm/s^2
Velocity	3.12	cm/s

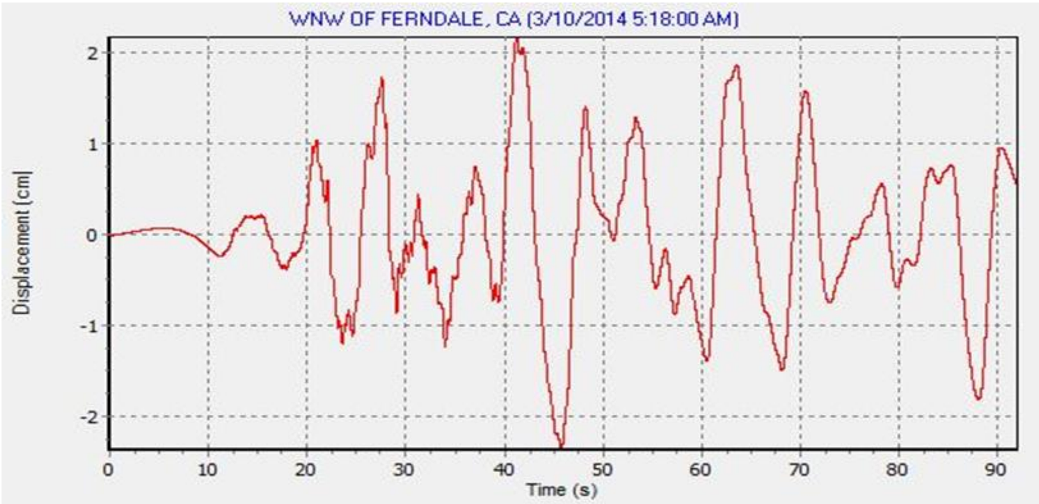

Fig. 3. Earthquake Displacement-Time diagram

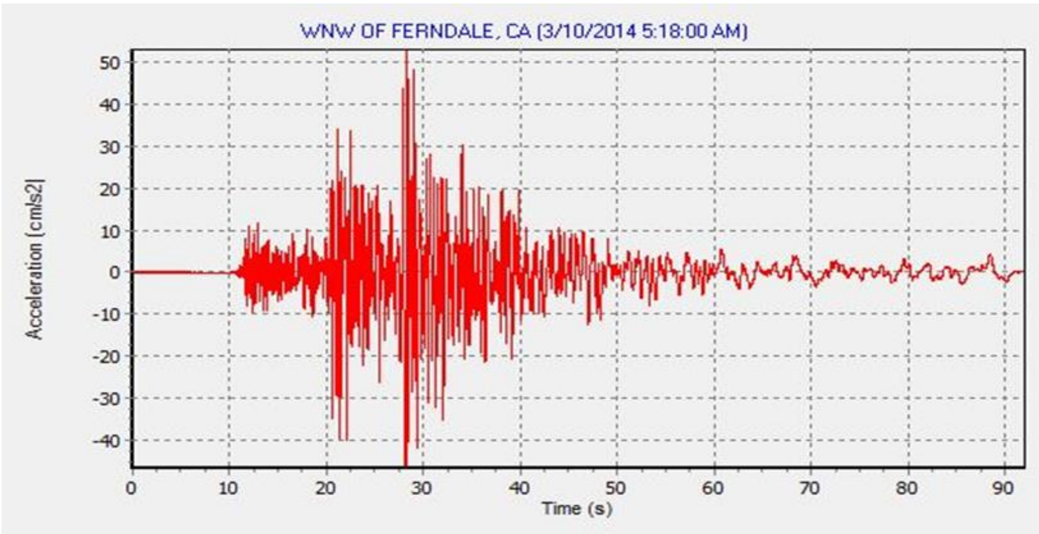

Fig. 4. Earthquake Acceleration-Time diagram

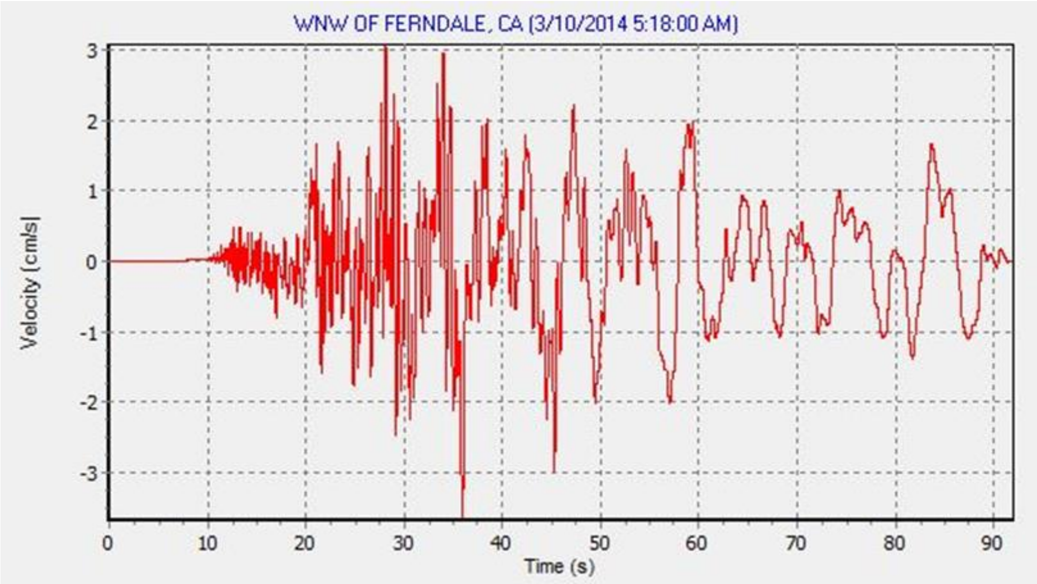

Fig. 5. Earthquake Velocity-Time diagram

3. RESULTS AND DISCUSSION

After modeling and applying initial conditions, seismic conditions of dam were considered according to two levels of water reservoir (30% and 70% of reservoir volume). These investigations were conducted in two different levels of water reservoir and each level by 3 times repetition. In the following, computation charts of safety factor were taken for different water levels with separation of reservoir water height that would be analyzed.

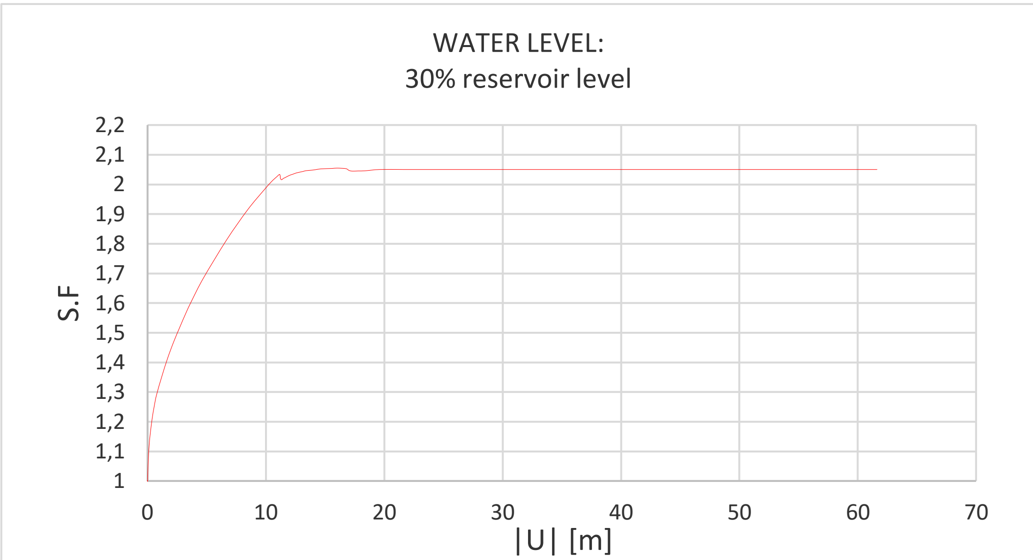

Fig. 6. Safety factor diagram-30% reservoir level

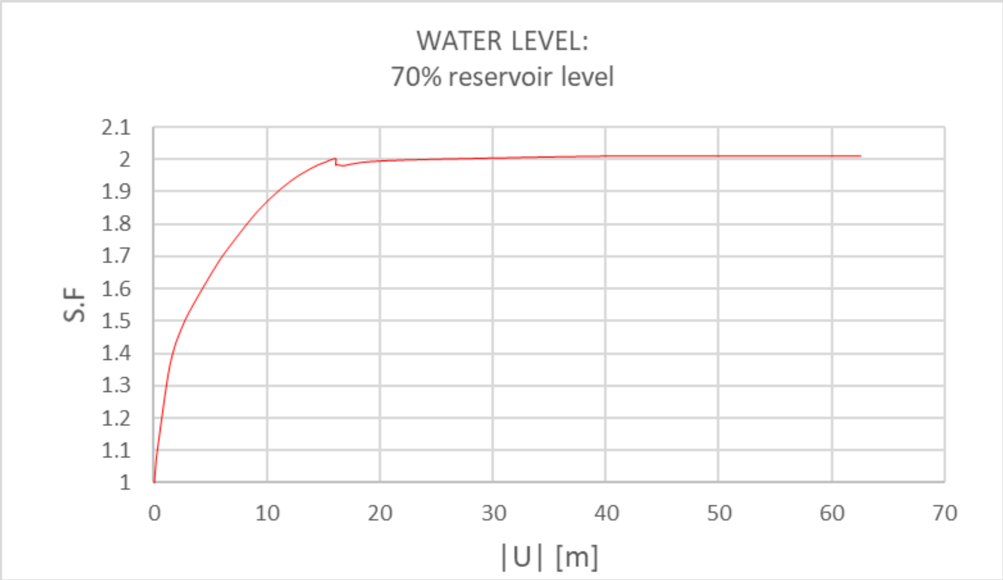

Fig. 7. Safety factor diagram-70% reservoir level

As it is observed in above charts, increasing water surface from 10% to 90% of reservoir height cause decreasing factor of safety.

4. CONCLUSION

Figures 6 and 7 indicates FS for two water levels. As it as it is obvious in these charts, curves slope reduced from level 30% to 70%. By drawing a tangent line between them to find safety factor, it's value becomes smaller. This means that, seismic stability of embankment dam is reduced by increasing water level of reservoir.

the Results indicate that FS is reduced by increasing upward water level of dam; if water level is increased from 30% to 70% of upward water level, this reduction would be about 8%.

1. INTRODUCTION

The three reservoirs are all situated on the Citarum, West Java. The Ir. H. Djuanda reservoir, which already exists since 1967 is the most downstream one. The next upstream reservoir is Cirata which is expected to become operational by 1987. The Saguling reservoir is the most upstream one and will start its operation in the most upstream one and will start its operation in the course of 1985. Downstream of Ir. H. Djuanda reservoir two weirs across the Citarum divert water into three main canals; the west tarum canal, the East tarum canal and the north tarum canal.

More than 20 million people are depend on Citarum with three reservoirs for irrigation (240,000 ha), water supply for domestic, municipal and industry (800 million m^3/year), Electricity (3,200 MW), flood control and environment water, therefore optimize operation three reservoirs is necessary for maximizes dependable water to meet several needs with existing limitation. Reservoirs can be operated by means of rule curves. These curves relate storage and time, several curves can be applied at the same time. Depending on the position of the release for the next periods are taken. The linier or dynamic programming method is a famous and classic method to optimize a reservoir system, and it was therefore chosen for application here. With this method it is possible to decide under uncertainly with in the most optimal “path” of reservoir level.

For the integrated hydro-power optimization from the three reservoirs cannot be special for the power production, caused by the multipurpose dam in downstream which fulfill water requirements and the system as a whole has to be operated such that flood control is maximal. Ad hoc adjustments are made during emergency situations on daily or even shorter basis. The rule curves produced had been optimized with respect to power production in the system. At the same time monthly target storage was derived with respect to flood protection and water supply for all purposes. Different purposes and various operators on managing reservoir operation induce conflict of interests. Optimization method cannot always be applied considering the complexity of constraints that must be adopted. To overcome the limitation of the method, the policies are brought about in the form of coordination forum. Optimization is conducted by simulation and sometimes without optimizing the hydropower production.

2. EXISTING INFRASTRUCTURE DAM IN CITARUM

The Jatiluhur project conceived in 1957 to supplement the run-of-river technical irrigation systems on the basin was completed in 1981. It is the largest contiguous irrigation system in Indonesia and is major rice production area. It comprises of the main Ir. H. Djuanda reservoir (estimated net capacity 1,860 M m3 in 1997), the associated Jatiluhur dam, hydro-electric power station (150 MW) and a conveyance system that provides irrigation to about 240,000 ha in West Java through the West Tarum Canal (WTC) system, East Tarum Canal (ETC) system and the North Tarum Canal (NTC) system. In addition, the project provides domestic, municipal and industrial (DMI) raw water supply to DKI Jakarta metropolitan area, to a number of urban center such as Bekasi, Karawang etc., and to industries along the corridor from Jakarta to Cirebon, including the region around Purwakarta. The Project also provides flushing water to Cirebon, including the region around Purwakarta. The project also provides flushing water flush rivers in DKI Jakarta metropolitan area during the dry season.

During the 1980’s the State electric Corporation (PLN) constructed two hydro-power projects upstream of the Ir. H. Djuanda reservoir. These are the Saguling Dam (750 MW) completed in 1985 and the Cirata Dam (500 MW) completed in 1988. The capacity of the Ciarata hydro-power station is currently being increased by 500 MW. The Saguling (estimated net capacity 620 M m3) and Cirata (estimated net capacity 800 M m3) reservoirs further regulate the flow in the Citarum and thus enable an increase in the utilization of the water resources of the basin. These reservoirs are operated by the State Electricity Company (PLN) instead of the Jasa Tirta II Public Corporation (PJT-II) with the generation of firm peak power as their main objective. The salient data of the Citarum cascade dams and hydropower plants is shown as “Table 1, 2 and 3”.

Table 1.
Data of Citarum Cascade Reservoirs

	Saguling	Cirata	Ir. H. Djuanda
Operational	1985	1988	1967
Dam Data			
Type	Rock fill dam with clay core	Rock fill dam with concrete face	Rock fill dam with inclined clay core
Height	99 m	125 m	105
Crest length	301 m	453.5 m	1220 m
Crest elevation	650.20 m	225.0 m	114.5 m

Table 2.
Data of Citarum Hydropower Plants

	Saguling	Cirata	Ir. H. Djuanda
Tail level (m)	252	103	27.0
Head loss (m)	28.4	4.0	1.0
Spillway characteristics	Gated spillway	Gated spillway	Ungated (ogee) spillway
Installed capacity (max. power, MW)	750	1000	187.5
Number of turbines	4 units	8 units	6 units
Type of turbines	Francis	Francis	Francis

Table 3.
Data of Specific Citarum Reservoir

	Saguling	Cirata	Jatiluhur
Full supply level	643 m	220 m	107 m
Dead storage level	623 m	205 m	56 m*)
Minimum power level	-	-	75 m
Maximum storage	880 x 10^6 m^3	1,973 x 10^6 m^3	2,970 x 10^6 m^3
Minimum storage	271 x 10^6 m^3	1,177 x 10^6 m^3	599 x 10^6 m^3 **)
Surface area at max operating level	49 km^2	62 km^2	83 km^2***)

In order to operate the whole cascade reservoir consistently, a special working group committee consisting of representatives from Jasa Tirta II Public Corporation, Electrical State Company, Research Institute of Water Resources keeps monthly meetings.

3. CITARUM WATER AVAILABILITY AND DEMAND

The Citarum river originates from mountainous area of Bandung region and flows northward to Java Sea through central portion of West Java Province. Bandung City, the capital of the West Java Province with inhabitants of 6,578,829 is located in the mouth of Saguling Reservoir. Topographically, the Citarum catchment upstream of Jatiluhur is characterized by a ring of high mountain ridges around a slightly undulating plain. Saguling dam is located in the upstream ridge while Cirata and Jatiluhur are in the downstream ridge. The seasonal variation in river runoff closely follows the rainfall distribution, marked by a distinct dry and wet season. The dry season fall in April – September and rainy season fall in October – March. The season not always like this, but depended from condition of season every year. Rainfall in the basin varies from about 4,000 mm/year in the mountainous areas in the upper catchment to about 1,500 mm/year along the coast.

Citarum River basin is covering an area of about 12,000 km^2 with the average annual flow of 12.95 billion m^3, out of which 6.0 billion m^3 flows in Citarum River and 6.95 billion m^3 flows in the other rivers in the basin. By employing water resources infrastructures in basin the water that could be regulated is about 7.65 billion m^3 per annum and the rest is wasted flows to the sea. The utilization of water by far is goes to irrigation of 6.0 billion m^3 equal to 88%, and to domestics, municipalities, and industries of 800 million m^3 equal to 12%.

At the present time the water demands on the Citarum cascade are mainly on Djuanda reservoirs as far DMI and irrigation water are concerned, of which irrigation water is by far the biggest (80%). This means that the actual demand has to be met in Djuanda. Of course, some demands are on Saguling and Cirata as well, but they are not consumptive. Water used for the generation of hydro-power and up in Djuanda reservoir, where it can be used for all other demands.

In the as “Table 4”, total water demands are shown for 2017 in as far they have been used by the preparation of the annual operational plan for the Citarum reservoir cascade, compared with irrigation water demands for a dry, normal and wet year, from Djuanda only, i.e, unregulated flows of the rivers intercepted by the West Tarum Canal, North Tarum Canal, East Tarum Canal system have already been taken into account. Although the demands are to be met by the reservoir system as whole, the location of the demands is from Djuanda Reservoir.

Table 4.
Water demands (m3/sec) from Ir. H. Djuanda Djuanda Reservoir in 2017 according the Annual Operational Plan for the Citarum Reservoir Cascade.

Condition / **Month**	**Dry year**	**Wet Year**	**Normal Year**
Jan	116,8	82,4	83,7
Feb	88,3	79,1	79,1
Mar	109,6	90,3	90,3
April	137,3	103,8	105,5
May	183,4	119,1	143,2
June	247,0	167,9	220,9
July	255,5	203,5	242,5
Aug	154,5	133,3	149,7
Sept	72,7	54,6	68,6
Oct	165,8	126,9	156,0
Nov	189,0	107,5	152,7
Dec	162,1	94,2	115,8
Average	156,8	113,5	134,0

The demand of the system can be generalized into three parts: (i) irrigation water supply to the North, East, and West Tarum areas, (ii) raw water supply to drinking water treatment plants for the districts and municipalities in the corridor of the canals including Jakarta, and (iii) to industrial zone along the corridor from Capital District of Jakarta to Indramayu, including the region around Bekasi, Karawang, Purwakarta, Subang district. These demands can partially be satisfied by rivers which are intersecting the main canals. The balance has to come from the Citarum, which are the greatest part of the intake requirements at the diversion weirs has to come from the Jatiluhur reservoir. As the biggest consumer and the largest contiguous irrigation area, irrigation water supply should be arranged into several crop plantation schedule. To cope with the available water resources, the irrigation plan is prepared as major input for Citarum cascade reservoirs operation.

The methodology to develop normal system operations in a multipurpose reservoir, include development of optimal end-of-month storage which maximize the expected value of selected primary objective function for the system, subject to satisfying other system objectives based on the specification of target performance levels. The domestic, municipal, and industry water demands (DMI) and irrigation water requirement as calculated from the previous procedure become an input to the reservoir operation model and synchronized with hydro-power to evaluate reservoir rule curves. Based on this model, an annual operational plan for Citarum cascade reservoirs is made using expected demands, statistical inflows based on dry, wet, normal years (each month). In this plan, the total energy of the system is maximised subject to a number of conditions:

- The demands at Jatiluhur reservoir should at least be met.
- The upper and lower rule curves for the reservoirs should be observed as much as possible.
- At the end of the year (or planning period) certain reservoir levels should be met.
- The maximum water level at the end of rainy season.
- To provide two times of yearly flood intercept and retain falling water and to control the flood periodically which released from Cirata reservoir (peak load).
- In order to prevent individual reservoir levels from changing to much from month to month, the relative net. storage of each reservoir with respect to the total net storage in the system should be kept constant.

For the preparation of the annual operation plan by working group for the monthly meeting, historical inflows since 1988 when the complete cascade was in operation are used by analyses Log Normal type 3 (LN-3). For Saguling, the inflows are derived from observations at Nanjung and intermediate inflows from reservoir balance calculations at Saguling. For Cirata and Djuanda historical inflows are calculated from reservoir balance calculations only. A problem with these calculations is that they notoriously inaccurate and difficult to check. Improvement by installing good automatic hydrometric stations just of each reservoir is therefore highly recommended.

Definition of wet and dry, and the way to calculate this is not universal. For instance NEDECO, 1985 uses a definition based on annual totals, but adjusted over the months by 2 two methods:

- Dry or wet year is defined according to the total annual flows. Monthly flows are distributed proportionally to the total annual flows.
- Dry or wet year is defined according to the total annual flow. Wet period monthly flows are distributed proportionally to the total wet period flow, while the remainder is distributed over the dry months.

Dry is defined as annual total 80% of the observation exceeded, wet as 20% exceeded (statistically known as the 80- and 20- percentile respectively). No underlying spastically distribution is used. If long historical records are used, additional years of data do not influence the picture very much. Based on any of the two approaches mentioned, additional very dry and very wet years can be defined. The biggest problem is, of course, to determine whether the present month belongs to a dry, normal or wet year.

4. RESERVOIR CASCADE OPERATION

4.1. RESERVOIR OPERATION CONCEPT

The Citarum cascade reservoirs have a combined effective volume of 3,276 x 10^6 m^3 which is approximately 57% of annual mean run off of Citarum, indicating that the system was not designed to provide carry-over storage during year-long periods. Using non-shared optimised reservoir operation, the total water released of the Citarum cascade reservoirs can reach 5,531 x 10^6 m^3, which is nearly 100% of water resources potential has been controlled. The water resources potential in the Citarum river is around 6 x 10^9 m^3 annually. The biggest consumer so far is irrigation which uses up about 87% of total regulated water from Ir. H. Djuanda reservoir and other rivers in the system.

The present cascade operation is based on the guidelines produced by PLN-P2B in 1991. First an annual operational plan is made using expected demands, statistical inflows based on dry, wet and normal years (by each month). This plan forms the basis of the reservoir operation. It result in a recommended rule curve for the year under consideration actual operation is adjusted during monthly consultative meetings group Citarum Basin. Ad hoc adjustments are made during emergency situations on a daily or even shorter basis. In this plan the upper two reservoirs are operated for power production, while the bottom reservoir, Ir. H. Djuanda, has to meet the water supply requirements. The systems as a whole has to be operated such that flood control is maximal

Main difficult with this way of operations are ; (1) the established of upper and lower rule curves, (2) how to adjust in an optimum manner if the actual situation differs from the planned one, (3) how to decide on the actual situation with the respect to very dry, dry, normal, wet or very wet situation, and (4) how to forecast inflows into the reservoir.

Apart from these major issues, other difficulties arise from:

- Maintenance (e.g. power plant units cannot be used, water levels are restricted due to maintenance of the dams, intake gates, etc)
- Water quality aspects (e.g. extra water for dilution is required to offset over-feeding of fish farms)
- Certain high water level are desired for recreational purposes.

In the following, a procedure will be sown, to derive an annual plan in a relatively simple and very flexible manner using a spreadsheet and its standards (non) liner optimization solver add-in.

The reservoir cascade ha a combined net storage capacity of 2800 Mm3, where net storage is defined as the storage between the spillway crest level and minimum storage level. The later level is the minimum operating level for hydro-power generation. For Saguling, Cirata and Ir. H. Djuanda these level and storages have been taken as “Table 5”.

Table 5.
Data of Water Level Citarum Cascade Dams

	Saguling		Cirata		Ir. H. Djuanda		Total Cascade
	(m +MSL)	(Mm3)	(m +MSL)	(Mm3)	(m +MSL)	(Mm3)	
Maximum Level	643	889	220	1,977	107	2,458	5,324
Min. Storage	623	272	205	1,177	75	599	2,048
Net Storage (Mm3)	617		800		1,859		3,276
Net storage (%)	18.8 %		24.4 %		56.8 %		100.0 %

The Citarum basin at Jatiluhur os about 5,750 Mm3. Thus the combined net storage capacity is about 49% of the MAR, indicating that the system was not designed to provide carry-over storage during year long drought periods. This typical for a reservoir in Java where there are very pronounced dry and wet season.

Before the construction of Saguling and Cirata, the multipurpose Ir. H. Djuanda reservoir, operated by PJT II, had to meet the following water supply objectives, ordered by priority based on the Water Resources Law No. 7/2004 as follow:

- Requirement of human life (drinking water, sanitation etc)
- Domestic, Municipal and Industry
- Irrigation
- Generation of (peak) hydro-power

Apart from these objectives, there is a standing operational obligation with respect to flood control. The following remarks can be made on the list.

4.2. CONCEPT THE RULE CURVES

Reservoirs can be operated by means of rule curves. These curves relate storage and time (month). Several curves can be applied at the same time. Depending on the position of the actual storage at a certain moment, decision on the release for the next period are taken. Quite often two rule curves are in uses; an upper rule curve and a lower rule curve. If the reservoir storage at the start of a month is greater than the storage indicated by the upper rule curve an above target amount of water is released from the reservoir in order to come back of the curve. In this way one can be observe the required storage capacity for floods, or spill can be prevented later on by routing an additional amount of water through the turbines. If the reservoir level drops below the lower curve water conservation measures have to take, which can be: (1) reduce the power target, (2) reduce the release target. Because above target releases for water supply do not yield any extra benefits, one can only prevent spill by producing more electricity.

If the upper rule curves is not meant to prevent spill or to provide storage for floods, a different decision may be assigned to it. This could be the case if the curve is used to maximize the average power output. In that case one may decide to release the expected average inflow plus the difference in storage which is indicated by the (gradient) rule curves. The function of the lower curve is mainly to prevent a great failures, either in irrigation or in power and to replace it by a controlled reduction in output. The number of organized failures through is greater that if nothing is done at all.

4.3. OPTIMAL INTEGRATED OPERATION

This method derived for a truly integral operation of the three reservoir together. For this purpose an optimization model has been developed which is based on the dynamic programming method. Three features of the model however have to be mentioned here.

- The dynamic programming model can only solve the problem for a set of discrete storages into which the reservoirs are schematized. The answer produced by the model is expressed as required storages at every time step, which always are one of the set of discrete stages. It is clear that by increasing the number of discretization a more precise answer is obtained. It must however be stressed here that the computational effort involved, is a quadratic function of the number of stages. In the present model, the number of stages is limited to 10. In some cases this even proved to be unpractical. The calculations were then first executed roughly with smaller number of stages. Then the 10 stages were introduced, but allowing only a limited range around the first solution.
- Secondly the optimization is only possible when a set of values, which are attributed to outflows and power productions are available. The problems are solved by using factious values. They do not represent real values in rupiahs but express more the priorities of several goals. The object is to find an operation which protects irrigation and urban water supply, and taking that into account maximizes the energy and power output. Producing power does yield a higher income at increase levels. In general 1,000 points per MW continuous production are allocated. The gain in power is of a much lower order of magnitude than the loss which is involved in not giving the release target. In this way, a solution which does not match the release target is highly improbable.
- The model is able to solve the operational problem for a dry, average wet year of for a combination of all three. The last method computes at every moment the benefits in a wet, average and dry case and combines the benefits according to the ration 3:4:3. This, because its is assumed that a 90% dry year and a 90% wet year each represent 30% of all possibilities and the average 40%. This is very roughly what is called “stochastic” dynamic programming. It would be better even to use all historical inflow data and to

compute the value in each case. The final value attributed to a certain decision is then just the average benefit. In the practical situation, such a model would be useless due to the core capacities of the minicomputer and because computer times were already very extensive (12 hours for a full calculation).

The optimal operational patches found in this way were tested with the simulation model. This verification was necessary to see whether violations of the criteria do occur. In that case adaption's of the optimal lines have to be made. This difference may occur due to the different set of flow data which are used in both models.

4.4. PRESENT ANNUAL OPERATIONAL PLAN PREPARATION

Each year, the representative of State electricity Company (PLN), Research Institute of Water Resources and PJT II prepare an operational plan for monthly meeting. It is based on the predicted Domestic, Municipal, Industry and irrigation demands, existing reservoir levels and expected inflows, and evaporation and tries to optimize the total power output of the system by varying the monthly outflows of the individual reservoirs. This is done on a monthly basis by hand.

A few other principles (constrains) are adhered to as well; (1) spilling is not allowed, (2) the ending reservoir water level is the same, or higher than the starting water level, (3) the principle of shared in each month is kept constant, at 21,12 %, 28,94 % and 49,94 % for Saguling, Cirata and Djuanda respectively.

In regular (at least monthly) consultative meeting of during the year this plan then is revised according to the real situation.

5. CONCLUSION

The three reservoirs are all situated on the Citarum River, West java, The Ir. H. Djuanda reservoir is the most downstream one, the next upstream reservoir is Cirata and the Saguling reservoir is the most upstream one. Downstream of Ir. H. Djuanda reservoir two weirs across the Citarum divert water into the three main canal.

Reservoirs can be operated by means of rule curves. These curves relate storage and time, several curves can be applied at the same time. Depending on the position of the release for the next periods are taken. The linear programming method is a famous and classic method to optimize a reservoir system, and it was therefore chosen for application here. With this method it is possible to decide under uncertainly with in the most optimal "path" of reservoir level.

Analysis and optimization of the annual operation plan by spreadsheet is both very flexible and easy to do with the built in solver. From the annual operation plan analysis by spreadsheet, it has been shown that operational principles have a large influence on the generation of (firm) power. In particular, a marked difference in result exists between so-called shared and non shared operation. Existing rule curves have not been updated in accordance with the latest flow figures. Similarly, elevation area capacity data for the three reservoirs are not recent. At least not for Ir. H. Djuanda. Local flow are determined by indirect reservoir balance calculations. Flow forecasting is not used for reservoir operation.

1. INTRODUCTION

The drawdown is one of the most dangerous conditions for the upstream slope. During the investment of the dams, rapid reduction of the water level is necessary when a defect threatens its stability, or when needed absorbing the flood wave or in case of dam rehabilitation in a short period.

The stability analysis of the upstream shell of the dam during rapid reduction has a significant impact. The reduction rate of 0.1 m / day is common, 0.5 m / day is large and the reduction of 1 m / day and above is a special rate [1]. The porous water pressure in the upstream shell remains for a period of time with high values [2] [3]. Dissipation of the porous water pressure is related to soil characteristics of the up-stream side (Permeability, mechanical and physical properties) [4] [5] [6]. It has been shown that high permeability soils respond hydraulically quickly where water is released from pores (consolidation process), while the low permeability soils need a long period of time to get the water out [7] [8]. In this paper, the rapid reduction of the Bradon dam reservoir was studied taking into account the slope properties for several types of soil (14 types), which could formed the upper shell with different properties, the amount and the time of reduction using Geo-Studio package [9] [10] [11]. Computed safety factors for each type of soil have been compared with the permissible safety factor values shown in "Table 1".

Table 1
Minimum safety of factors for slope stability [12]

Upstream slope	First full state (steady state)	1.3-1.5
	Rapid discharge (transient state)	1.2-1.3
Downstream slope	First full state (steady state)	1.5
	Earthquake and full reservoir	1.2

2. RESEARCH METHODS

2.1. COMPUTATION THEORY

To study the leakage in saturated and unsaturated media, a Darcy law is adopted [11] which is given according to the following equation "Eq. [1]" :

$$q = k * I \qquad [1]$$

Where: q - specific discharge, k- hydraulic conductivity, I – hydraulic gradient. Where the hydraulic conductivity takes a constant value of saturated soil. The only difference is that under conditions of unsaturated flow the hydraulic conductivity is no longer constant but varies with changes in water content and indirectly varies with changes in pore water pressure.

The governing differential equation used in the formulation of seep/w is:

$$\frac{\partial}{\partial x}(k_x \frac{\partial H}{\partial x}) + \frac{\partial}{\partial y}(k_y \frac{\partial H}{\partial y}) + Q = \frac{\partial \theta}{\partial t} \qquad [2]$$

Where: H - total head, kx - hydraulic conductivity in the x-direction,
ky - hydraulic conductivity in the y-direction, Q - applied boundary flow,
ϴ - volumetric water content, t – time.

Under steady-state conditions, the flux entering and leaving an elemental volume is the same at all times, the right side of the equation consequently vanishes and the equation reduces to the form:

$$\frac{\partial}{\partial x}(k_x \frac{\partial H}{\partial x}) + \frac{\partial}{\partial y}(k_y \frac{\partial H}{\partial y}) + Q = 0 \qquad [3]$$

Changes in volumetric water content are dependent on changes in the stress state and the properties of the soil. Seep/w program is formulated for conditions of constant total stress that, there is no loading or unloading of the soil mass. The second assumption is that the pore-air pressure remains constant at atmospheric pressure during transient processes.

A change in volumetric water content can be related to a change in pore-water pressure by the equation:

$$\partial\theta = m_w \partial u_w \qquad [4]$$

Where: mw - the slope of the water content function. The total hydraulic head is defined as:

$$H = \frac{u_w}{\gamma_w} + y \qquad [5]$$

Where: u_w - Pore-water pressure, γ_w - Unit weight of water, y - Elevation,

"Eq. [5]" can be rearranged as: u_w = (H - y) [6]

Substituting "Eq. [6]" into "Eq. [4]" then the result in equation 3 leading to the following expression:

$$\frac{\partial}{\partial x}(k_x \frac{\partial H}{\partial x}) + \frac{\partial}{\partial y}(k_y \frac{\partial H}{\partial y}) + Q = m_w \gamma_w \frac{\partial (H - y)}{\partial t} \qquad [7]$$

Since the elevation is constant, the derivative of y with respect to time disappears, leaving the following governing differential equation:

$$\frac{\partial}{\partial x}(k_x \frac{\partial H}{\partial x}) + \frac{\partial}{\partial y}(k_y \frac{\partial H}{\partial y}) + Q = m_w \gamma_w \frac{\partial H}{\partial t} \qquad [8]$$

The finite element equation that follows from applying the Galerkin method of weighed residual to the governing differential [11] equation is:

$$\int_v [B]^T [C]\cdot[B]\cdot\partial v\cdot(H) + \int_v \lambda \langle N\rangle^T \langle N\rangle \cdot \partial(v)\cdot(H),t = q\int_A \langle N\rangle^T \partial A \qquad [9]$$

Where: [B] = gradient matrix, [C] = element hydraulic conductivity matrix
{H} = vector of nodal heads, <N>T<N> = [M] = mass matrix
(H),t = change in head with time, q = unit flux across the side of an element

Slope/w uses the theory of limit equilibrium of forces and moments to compute the factor of safety. A factor of safety is defined as that factor by which the shear strength of the soil must be reduced in order to bring the mass of soil into a state of limiting equilibrium along a selected slip surface. For an effective stress analysis, the shear strength is defined as:

$$S = C' + (\sigma_n - u) tg\phi' \qquad [10]$$

Where: S - Shear strength, C'- Effective cohesion, ϕ' - Effective angle of internal friction, σ_n - Total normal stress, u - Pore-water pressure.

2.2. COMPUTATION MODEL:

The Bradon dam is located in the northwestern part of the Syrian Arab Republic, at the top of the northern Great River, 64 km from Latakia city. The dam is an earth-rock fill dam with a central clay core, tow filter zones and rock fill shoulders. The normal water level behind the dam is 193.8 m, the high is 62.5 m, the length is 806 m, and the width is 366 m at the base and 12 m at the top. The surface area of the reservoir is 5.3 km^2, the maximum storage level of 193.8 m, and a maximum storage volume of 164.5 Mm3. "Figure 1" shows the cross-section at the maximum height.

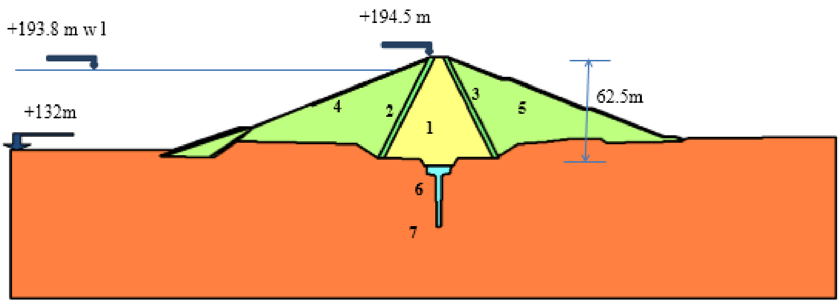

Fig. 1
Cross-section of the dam, 1 - central core, 2-3 filters, 4 - downstream shell, 5 - upstream shell, 6 - injection Curtain, 7 – foundation.

The Material properties of the dam, core and foundation are shown in "Table 2".

Table 2
The Material Properties of dam, core and foundation materials

Soil number	Soil location	ɣd (t/m3)	porosity n	Cohesion coefficient C (Kpa)	Angle of friction ϕ	Permeability coefficient (m/day)
1	Central core (clay)	1.76	0.562	64	30	Kc=0.00059
2-3	Filters	1.8	0.38	0	25	-
4-5	Downstream and upstream shell	2.1	0.33	30	38.5	10
6	Injection Curtain					
7	Foundation	2.68	-	120	31	0.3

3. RESULTS AND DISCUSSION

3.1. Seepage Analysis:

The seep/w program was used to analyze seepage in complex and simple models according to the finite element method with two-dimensional flow. The leakage line within the body of the dam calculated first as steady state in case of maximum level of storage for each type of studied soils shown in "Table 3". The leakage line was used as a boundary condition for rapid drawdown (transient seepage). The scenarios of rapid discharge were studied to determine the effect of water drop from 193.8 m to 167 m in linear form, for two cases of discharge programs as shown in "Figure 2". The first case through the irrigation outlet of 25 m3/s, it will take 58 days. And the second case through the transforming tunnel of 500 m3/s, it will take 3 days.

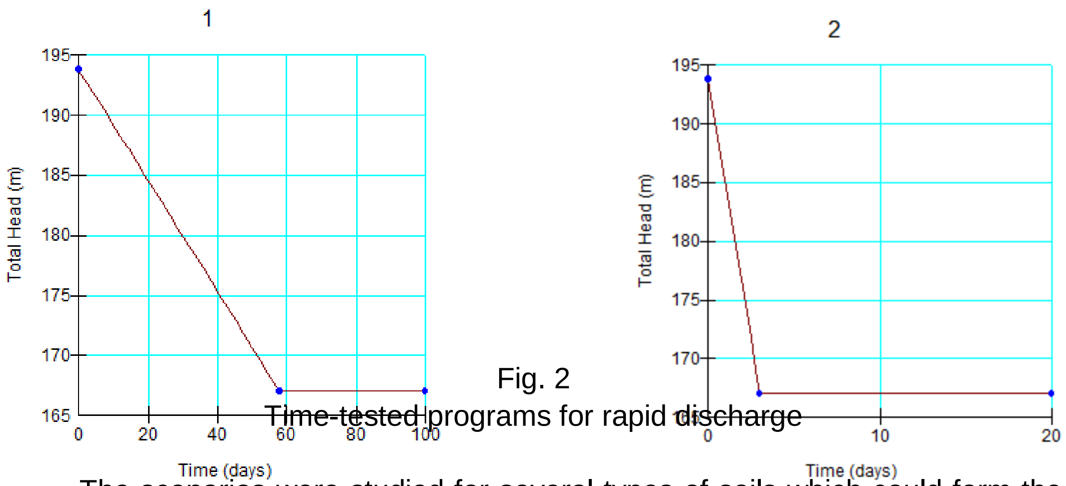

Fig. 2
Time-tested programs for rapid discharge

The scenarios were studied for several types of soils which could form the slopes according to "Table 3", Ks - is the hydraulic conductivity factor of the soil, and Kc - The hydraulic conductivity factor of the core.

Table 3
Studied soil samples

Soil type	Permeability Coefficient Ks (m/day)
gravel-pebble(Bradon state)	10
Gravel	8.64
Sand	4.66
Uniform Fine Sand #1	1.8576
Embankment (Silty clay)	0.1
Uniform Fine Sand #2	0.0976
Silt #2	0.0864
Silt Loam	0.0605
Sandy Loam	0.0506
Silty Sand	0.0432

Sandy Silty Clay	0.0121
Silty Clay	0.0026
Very Fine Sand	0.0017
Clay (Core soil)	Kc=0.00059

The leakage curves change during rapid drawdown were calculated using seep/w program for all types of soil mentioned above "Figures 3 and 4" show some of them for two cases of discharging.

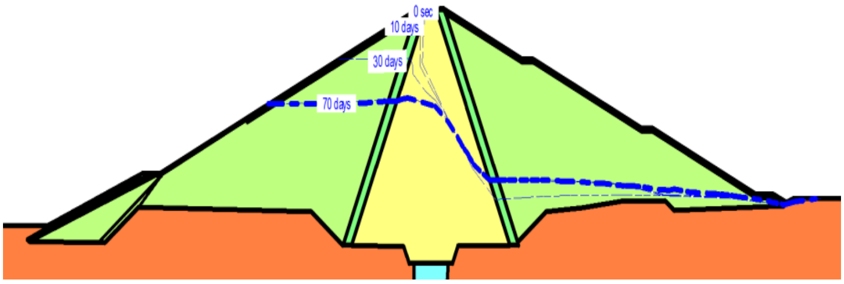

Fig. 3
Curves of leakage in case of discharge through
Irrigation outlet. Soil type (gravel-pebble)

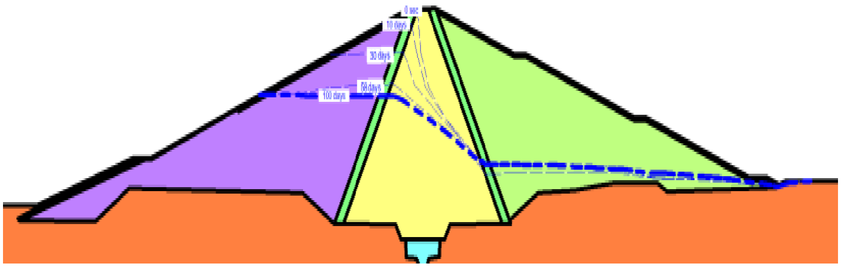

Fig. 4
Curves of leakage in case of discharge through
transforming tunnel. Soil type (Uniform Fine Sand #1)

3.2. STABILITY ANALYSIS:

The stability of the upstream shell was studied using the slope/w program, which uses several methods for analyzing and calculating the safety factor. These methods are Bishop, Phellinus, Janbu, Ordinary-Morgenstern-Price and others. The safety factors were obtained from the Morgenstern-Price method, which takes into account the balance of forces and moments [13].

The safety factor of the upstream slope and the critical slip surface for all types of soil have been calculated, under influence of the applied boundary conditions, "Figures 5 and 6" show some results in two cases of discharge. And "Table 4" and "Table 5" show the values of the minimum safety factors.

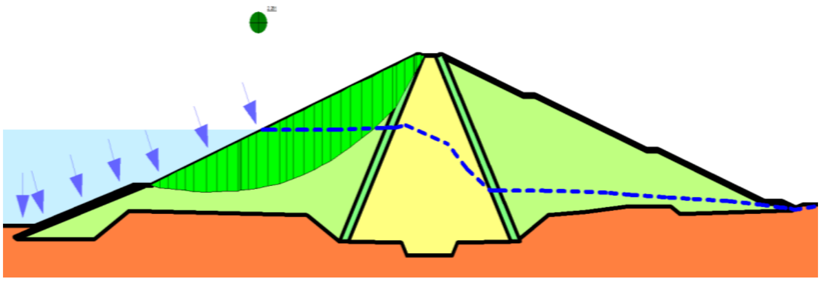

Fig. 5
Upstream slope safety factor in case of discharge through Irrigation outlet. Soil type (gravel-pebble)

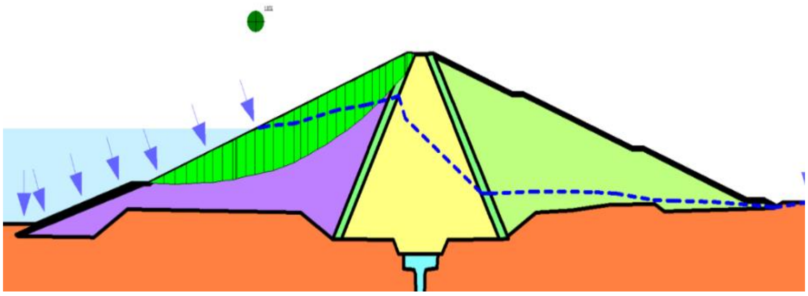

Fig. 6
Upstream slope safety factor in case of discharge through transforming tunnel. Soil type (gravel)

3.3. ANALYSIS THE EFFECT OF THE RATIO (KS/KC) CHANGES

The ratio between the permeability of the upstream shell (ks) and the permeability of soil core (kc) within the dam body has effected on the stability of the upstream shell. The variation was studied according to soil types and the ratio (ks/kc) were calculated. The obtained results shown in "Table 4" for the first case of discharge through the irrigation outlet, the discharge rate is 0.5 m/day, and in "Table 5" for the second case of discharge through the transforming tunnel, the discharge rate is 8.93 m/day.

Table 4
Minimum safety factor in the case of the first discharge program

Soil type	Safety factor	the ratio ks/kc	The range
gravel-pebble (Bradon dam state)	2.25	16949.15	>10000
gravel	1.729	14644.07	
Sand	1.595	7898.305	>1000

Silty Clay	0.679	4.40678	<10
Very Fine Sand	0.235	2.881356	
Clay (Core soil)	1.782	1	1

3.4. CONCLUSIONS

1- Using some types of soil causes a collapse of the upstream slope according to the dimensions and slope of the cross-section of the Bradon dam, i.e. the suitable soil type can be chosen from the design stage, which does not cause danger in the conditions of rapid drawdown.
2- The safety factor values in the second discharge program are lower than the safety factors in the first discharge program, i.e. that the greater of water reduction, the lower safety factors.

3- For the studied soils, the ratio $K_S/K_C = 165$ is the interval value between stable and unstable soils in the first case of discharge, and for the second case of discharge, the ratio is $K_S/K_C = 7898$.

SUMMARY

The aim of this study is to determine the effect of the rapid drawdown of the Bradon dam reservoir on the upstream shell stability for two different discharges scenarios and different types of available soils in situ.

The dam to be considered is 62.5 m high and the width is 366 m at the base and 12 m at the top. The dam consists of a central clay core, tow filter zones and rock fill shoulders. The normal water level behind the dam is 193.8 m high.

Various scenarios for rapid discharge cases were studied to determine the safety factor of water drop from 193.8 m to 167 m in linear form for two discharge cases. The first case is through the irrigation outlet 25 m^3/s and the second is through a tunnel transforming 500 m^3/s.

The obtained results show that the stability of the upper slope change under considered boundary conditions according to the soil type. And the appropriate type of soil can be chosen from the design stage. Also, the effect of the ratio between the permeability of the upper slope and the permeability of the clay core (ks/kc) was calculated, the results show for the studied soils in the first case of discharge that the ratio (ks/kc)=165 is interval value between stable and unstable soils. While for the second case of discharge, the ratio is (ks/kc) =7898.

KEY WORDS: Rock fill dam, safety factor, stability, transient seepage, Bradon dam.

SOMMAIRE

Le but de cette étude est de déterminer l'effet du rabattement rapide du réservoir du barrage de Bradon sur la stabilité de la coquille en amont pour deux scénarios de décharge différents et différents types de sols disponibles in situ.

Le barrage à considérer a une hauteur de 62,5 m, et une largeur de 366 m à la base et de 12 m au sommet. Le barrage se compose d'un noyau d'argile central, de zones de filtre de remorquage et d'épaulements de remplissage rocheux. Le niveau d'eau normal derrière le barrage est de 193.8 m de hauteur.

Différents scénarios de décharges rapides ont été étudiés pour déterminer le facteur de sécurité de la chute d'eau de 193.8 m à 167 m sous forme linéaire pour deux cas de décharge. Le premier cas est à travers la sortie de l'irrigation 25 m^3/s et le second est à travers un tunnel transformant 500 m^3/s.

Les résultats obtenus montrent que la stabilité de la pente supérieure change dans des conditions aux limites déterminées en fonction du type de sol. Et le type de sol approprié peut être choisi dès la conception. Aussi, l'effet du rapport entre la perméabilité de la pente supérieure et la perméabilité du noyau argileux (ks/kc) a été calculé, les résultats montrent pour les sols étudiés dans le premier cas de décharge que le rapport (ks/kc) =165 est la valeur d'intervalle entre les sols stables et instables. Alors que pour le second cas de décharge, le rapport est (ks/kc) = 7898.

MOTS CLÉS: Barrage de remplissage rocheux, facteur de sécurité, stabilité, infiltration transitoire, barrage de Bradon.

Abstract

The aim of the present research is the evaluating of Limit Equilibrium method to assess factor of safety under seismic load in earth dam using physical small-scale modeling. For this purpose, numerical analysis to evaluate slope stability under vertical peak ground acceleration (PGA) was carried out using Geostudio program. In parallel, small-scale physical modeling (1/100) was tested using vibrator table device in order to observe slope stability in induced dam by seismic motion. As result, the weak performance was obtained for assessing factor of safety under seismic load using Limit equilibrium method (LEM). Based on Physical modeling, damage with respect to longitudinal cracks was dramatically observed at upstream and crest during seismic motion while the simulated models were safe under same acceleration. Consequently, the good agreement was found between modeling tests and lesson learned from literature. Finally, due to predict dam safety along seismic motion using LEM, design acceleration of the dam site should be increasingly applied using (PGA+ 0.2g) for simulation.

Keywords: Factor of safety**,** Vibrator table, Acceleration, Physical modeling, Limit Equilibrium

1. Introduction

Due to slope stability in the field of geotechnical engineering, determination of the critical slip surface to compute factor of safety is one of the main concerns in the earthquake engineering. In this case, slope stabilization methods are based on specific skills that must be exactly understood and realistically simulated. This analyze significantly depends on many main factors such applied loads, foundation properties and soil behavior. However, factor of safety is the essential function to establish a safe and economical design. In this context, the limit equilibrium method (LEM) was presented using circular slip line (Fellenius 1936, Bishop 1955 and Spencer, 1967), which can be appreciated. After that, several attempts were also recommended based on general slide line (Janbu, 1973; Morgenstern and Price, 1965). After that, an additional equation of vertical force equilibrium was individually taken into account for each slice (Sarma, 1973 and 1979). In recent decades, Finite-Element Method (FEM) has been developed based on displacement, in particular used to evaluate safety regarding the shear strength reduction" SSR or "phi-c reduction" techniques (Huang et al, 2009; Baker, 2006). Some combined methods based on probabilistic approaches of slope analysis and design with an aid of LEM and FEM (El-Ramly et al, 2002; Li et al, 1987 and Griffiths et al, 2004) were also presented. Furthermore, an artificial neural network (ANN) was carried out using optimization techniques to compute factor of safety (Cho, 2009). Moreover, Two-stepped self-optimizing method was performed using genetic algorithm (GA) with structure evolution and parameter optimization (Yang et al, 2004). According to report from case studies, the underwater slide during the San Fernando earthquake (1971) was observed in Lower San Fernando dam. Fortunately, the dam barely avoided collapse, thereby preventing a potential disaster of flooding of the heavily populated areas below the dam. Two decades later in 1994, the Los Angeles Dam concrete face rock-fill dam (CFRD) was confronted by Northridge earthquake. The Northridge earthquake was almost equal in magnitude to the previous San Fernando earthquake. Ground shaking was very strong, with amplitudes among the highest ever recorded but consistent with the USGS estimates. Yet the dam showed only minor deformation and superficial cracking. Despite the intense shaking, the crest of the dam moved only 1 inch sideways and settled only 3.5 inches. In 2008 by earthquake 7.9 magnitude, the longitudinal crack was found in Fengshou reservoir dam. However, numerical analysis to evaluate dam behavior during seismic motion was commonly used (Parish et al, 2009; Berhe et al, 2010; Xia et al, 2010; Kong et al, 2010; Bayraktar et al, 2011; Risheng et al, 2006; Gordan et al, 2013). There are two reasons for using numerical method in this context such the lack of monitoring data and technology development. In the last decade, shaking table and centrifuge based on small-scale physical modeling were commonly used to evaluate dam behavior during the seismic motion (Matsumaru et al, 2008; Namdar et al, 2010; Wang et al, 2011). In the present paper, the performance of slope stability under severe seismic motion for homogenized earth dam is the main purpose of study. For this purpose, two physical small-scale models with different slope constructed for vibrating on top of the vibrator table. In parallel, factor of safety was computed using numerical analysis based on limit equilibrium method. Based on comparing result in both cases as mentioned earlier, the performance of Limit Equilibrium method under seismic load will be discussed.

2.0 Background of limit equilibrium method (LEM-slices)

Based on limit equilibrium method (LEM) with respect to slices from potential slip surface, Fellenius and Bishop's methods are the simplest and most applicable in the geotechnical engineering. As shown in Figure 1, the soil mass above a failure surface divided into slices with vertical sections. Each portion was taken as having a straight-line base, denoting mutual support between the slices. Based on Fellenius approach, the forces acting between each pair of slices (E, X) are neglected, so only the forces acting on the base of each slice (W, N and S) are left for consideration (Yu, 1998). Factor of safety (FOS) is the suitable relation between opposing and toppling moments. It can be computed according to the center point of an assumed slip circle. The final formulation of the safety factor has comprised only resisting and sliding forces (S, T).

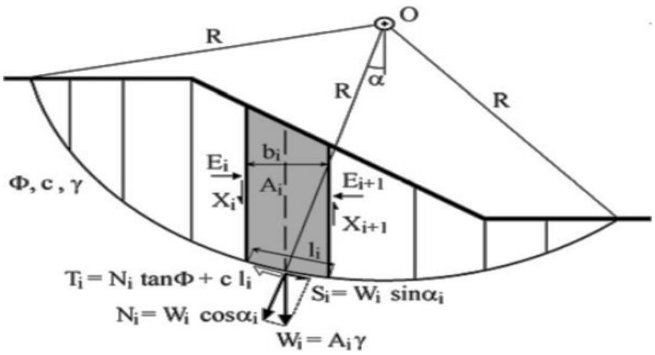

Figure 1: The idea of slice method and definition factor of safety (See Eq.2)

In Bishop's method, apart from the total moments' equilibrium conditions, an additional equation of vertical force equilibrium was taken into account individually for each slice. Such consideration leads to an implicit formulation of the safety factor that needs an iterative procedure (Zhu et al, 2003).

$$\Sigma H = 0,\ \Sigma V = 0 \text{ and } \Sigma M = 0 \tag{1}$$

$$F_S = \frac{\Sigma_i [c b_{i+} (w_i + x_i - x_{i+1}) \tan\phi] \frac{\sec\alpha_i}{1 + (\tan\alpha_i \tan\phi)/F_S}}{\Sigma_i S_i} \tag{2}$$

However, the general equilibrium equations as mentioned below should be persuaded (See Eq.1). Finally, the Bishop's method explained in Eq.2.

3.0 Method of research

Two types of tests such as soil mechanic and physical modeling test were carried out in this study. Soil properties were collected based on British standard test (BS). The physical small-scale modeling was performed using vibrator table. For this purpose, two models with sinusoidal motion were vibrated. For numerical analysis, Geostodio 2007 (Slope /W) was utilized for evaluations factor of safety based on limit equilibrium method. Figure 2 shows the research flowchart.

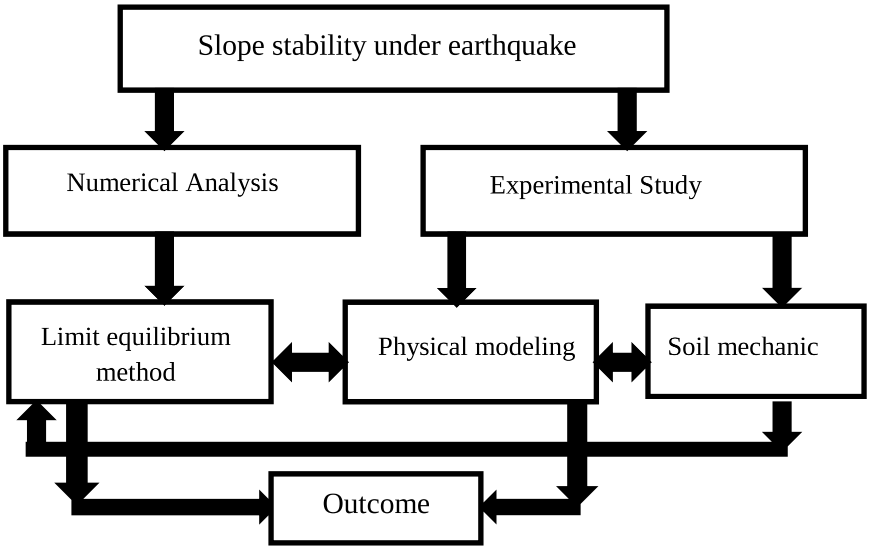

Figure 2: Flowchart

3.1 Soil mechanic laboratory tests

Due to collect soil physical properties, soil mechanic tests were completely carried out using British Standard (BS). Table 1 presents the physical properties for river sand with 75% relative density (dense sand). Physical characteristics of the tropical laterite soil were presented in Table 2. It is important noting that river sand and tropical laterite soil were respectively utilized in the foundation and dam body for small-scale models.

Table 1: Characteristics of sands

Engineering and physical properties	Content
Specific gravity	2.574
Maximum dry density (gr/cm^3)	1.721
Minimum dry density (gr/cm^3)	1.366
Maximum size (mm)	2.00
Minimum size (mm)	0.075
Uniformity Coefficient (C_u)	4.375
Coefficient of curvature (C_c)	2.725
Relative density %	75

Table 2: Characteristics of the laterite soil

Characteristics of the laterite soil	Content
Specific gravity	2.40
Liquid limit, LL (%)	75
Plastic limit, PL (%)	41
Plasticity index, PI (%)	34
BS classification	MH
Maximum dry density (g cm-3)	1.33

Optimum moisture content (%)	35
Unconfined compressive strength (KPa)	306.26
Cohesion (KPa)	25.18
Angle of internal friction (Degree)	30.00
Secant modulus elasticity (KPa)	15283.72
Coefficient of Volume Compressibility (m_v, m2/MN)	0.1055
Coefficient of Consolidation (cv, m2/yr)	44.16
Permeability (cm/seconds)	1.29E-5

Figure 3 and 4 show the distribution of the particle size for both type of soil as mentioned earlier. The determination of particle size distribution was tested based on BS 1377-2 1990. As seen, maximum size was 2.00 mm and minimum size was 0.75mm.

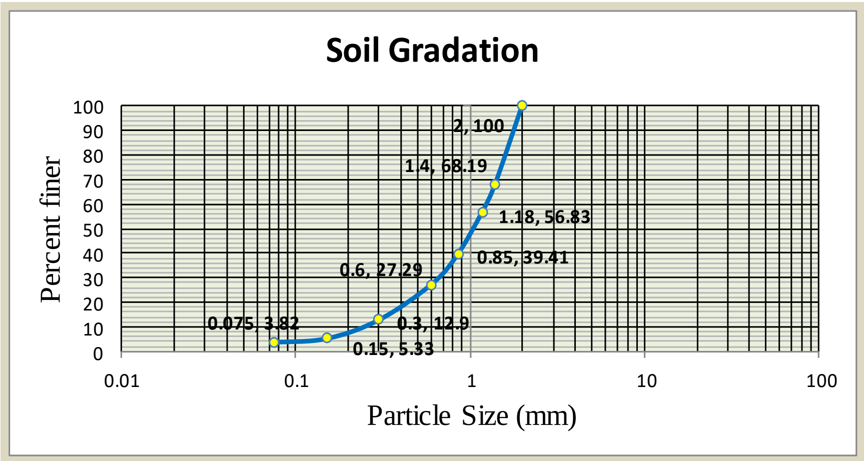

Figure 3: Laterite soil gradation

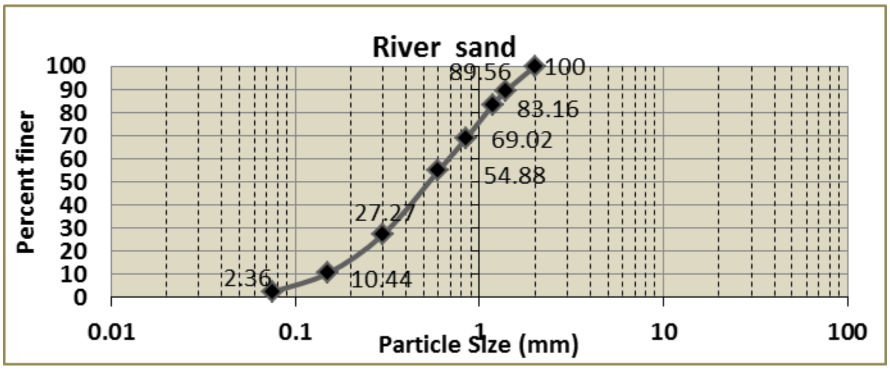

Figure 4: River sand gradation

3.2 Small-Scale physical modeling

Small-scale model is explained in the present section. In terms of utilizing apparatus for this study, some devices were applied such as vibrator table, displacement transducer, and data logger. In terms of dynamic loading, sinusoidal motion was used for evaluating slope stability for small-scale modeling (1/100).

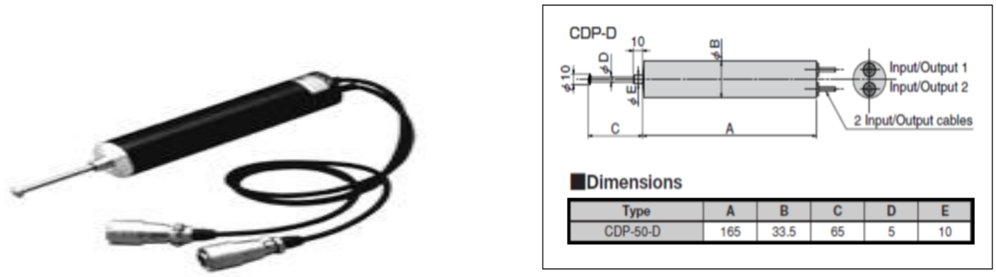
3.2.1 Vibrator table

Vibrating table 24-9112 (CN-166) was used in this study, as shown in Figure 3. The vibrating desk was cushioned steel and semi noiseless electromagnetic vibrator with 3600 vpm operating frequency. In addition, it was a separate controller to vary vibrator amplitude in case of frequency capacity limit to 100 Hz. Table capacities was equal to 750 lbs (340 kg). Double amplitude range was located at 0.002 inch (0.05 mm) to 0.015 inch (0.38mm). Actuator was an electromagnetic vibrator over 100 lbs (45.30kg). The table was square shape 30 inch (762 mm). The table thickness was 33.3mm of steel. In terms of weight, it was net 555 lbs (252 kg) and shipping 605 lbs (274 kg). Figure 5 illustrates the vibrator table that used in this study, as shown actuator is in the vertical direction.

Figure 5: Vibrator Table

3.2.2 Displacement transducer and data logger

Displacement transducer CDP-D was applied with dual isolated ports (I/O). By using transducer, one set of cables for input and output were connected to the analog measuring instrument and other set to the digital measuring instrument. With two different types of measuring equipment connected to this transducer, simultaneous measurements can be made without interference. Figure 6-a shows the displacement transducer which was used in this study. Besides, Figure 6-b shows the dimension detail for CDP-100 to measure displacement at both edges of the crest in small-scale modeling.



Type	A	B	C	D	E
CDP-50-D	165	33.5	65	5	10

Figure 6: a) Displacement transducer, CDP-100 **b**) Dimension of displacement transducer

In terms of data record, data logger or data recorder is the electronic device. It can record data over time or in relation to location either with a built in instrument or sensor or via external instruments and sensors. Figure 7 illustrates the data logger that used in this study.

Figure 7: Data logger, UCAM-70A

Based on device ability, results were printed during the duration of vibration. After that, results were classified by using Excel program. It should be noting that, both transducers as mentioned previously were connected to this data logger (UCAM-70A) in order to record vertical displacement during the vibration. In addition, the sub step of vibration period was equal two seconds based on device ability with respect to print.

3.2.3 Sinusoidal vibrate loading

There is a mathematical relationship between frequency, displacement, velocity, and acceleration for sinusoidal motion in order to consider the peak value. This relationship is such that if any two of the four variables are known, the other two can be calculated. all equations with respect to required combination are presented in Table 3. In addition, Table 4 illustrates distribution of displacement and acceleration based on different frequency. As seen, the amplitude of frequency is between 5 to 30 hertz. Also in this Table, it is obvious that, displacement and acceleration were increased while frequency was increased. It is important to note that, G in these formulas is not the acceleration of gravity. It is a constant for calculation within different systems. Respectively, for metric, imperial and Si G is 9.80665m/s², 386.0885827 in/s² and is 1.00 m/s².

Table 3: Equations for sinusoidal motion, Displacement (D), Velocity (V), Acceleration (A), and Frequency (F)

Displacement (D)	Velocity (V)	Acceleration (A)	Frequency (F)
$\frac{V}{\pi F}$	πFD	$\frac{2\pi^2 F^2 D}{G}$	$\sqrt{\frac{GA}{2\pi^2 D}}$
$\frac{GA}{2\pi^2 F^2}$	$\frac{GA}{2\pi F}$	$\frac{2\pi FV}{G}$	$\frac{V}{\pi D}$
$\frac{2V^2}{GA}$	$\sqrt{\frac{GAD}{2}}$	$\frac{2V^2}{GD}$	$\frac{GA}{2\pi V}$

Table 4: Distribution of acceleration using different frequency in vibrator table

Frequency (Hz)	5	10	15	20	25	30
Displacement (mm)	0.06875	0.083	0.0995	0.116	0.1325	0.149
Acceleration (Gn)	0.003341	0.01668	0.045	0.0933	0.166	0.269
Acceleration	0.034g	0.17g	0.46g	0.95g	1.69g	2.74g

Since the motion is sinusoidal, the displacement, velocity, and acceleration are changing sinusoidal. However, they are not in the same phase. The phase relationship between displacement, velocity, and acceleration is that such that velocity is 90° out of phase with acceleration and displacement is 180° out of phase with acceleration. In other words, when displacement is at a maximum, velocity is at a minimum, and acceleration is at a maximum. It should be noting that, 1 g_n = 9.80665 m/s² = 32.174 ft/s² = 386.0886 in/s².

3.2.4 Scaling laws

In case of using scale parameter, the scale factor according to Eq.2 was used in this study.

$$x^* = \frac{x_m}{x_p} \tag{3}$$

The subscript m represents "model" and the subscript p represents "prototype" and x^* represents the scale factor for the quantity x (Garnier et al, 2007).

The reason for spinning a model on a centrifuge is to enable small-scale models to feel the same effective stresses as a full-scale prototype. This goal can be stated mathematically as

$$\sigma'^* = \frac{\sigma'_m}{\sigma'_p} = 1 \tag{4}$$

Where the asterisk represents the scaling factor for the quantity, σ'_m is the effective stress in the model and σ'_p is the effective stress in the prototype.

In soil mechanics the vertical effective stress, σ' for example, is typically calculated by

$$\sigma' = \sigma^t - u \tag{5}$$

Where σ^t and u are total stress and pore pressure, respectively. For a uniform layer with no pore pressure, the total vertical stress at a depth H may be calculated by:

$$\sigma^t = \rho g H \tag{6}$$

Where ρ represents the density of the layer and g represents gravity. In the conventional form of centrifuge modeling (Garnier et al, 2007), it is typical that the same materials are used in the model and prototype; therefore the densities are the same in model and prototype, i.e.

$$\rho^* = 1 \tag{7}$$

Furthermore, in conventional centrifuge modeling all lengths are scaled by the same factor L^*. To produce the same stress in the model as in the prototype, we thus require

$$\rho^* g^* H^* = 1 \; g^* L^* = 1 \tag{8}$$

This may be rewritten as

$$g^* = \frac{1}{L^*} \tag{9}$$

The above scaling law states that if lengths in the model are reduced by some factor, n, then gravitational accelerations must be increased by the same factor, n in order to preserve equal stresses in model and prototype.

3.2.5 Dynamic problems

For dynamic problems where gravity and accelerations are important, all accelerations must scale as gravity is scaled, i.e.

$$a^* = g^* = \frac{1}{L^*} \tag{10}$$

Since acceleration has units of $\frac{L}{T^2}$, it is required that

$$a^* = \frac{L^*}{T^2} \tag{11}$$

Hence it is required that: $\frac{1}{L^*} = \frac{L^*}{T^2}$, or

$$T^* = L^* \tag{12}$$

Frequency has units of inverse of time, velocity has units of length per time, so for dynamic problems we also obtain

$$f^* = \frac{1}{L^*} \tag{13}$$

$$v^* = \frac{L^*}{T^*} = 1 \tag{14}$$

For model tests involving dynamics, the conflict in time scale factors may be resolved by scaling the permeability of the soil (Garnier et al, 2007).

3.2.6 Model introducing

In this study, two small-scale models vibrated in the vertical direction, as shown in Figure 8 and 9. In Figure 8, slope covers 0.785 vertical and 1.00 horizontal. The width of the crest is 10.00 meter. Both slopes and crest width were changed in Figure 9, as seen in the second model.

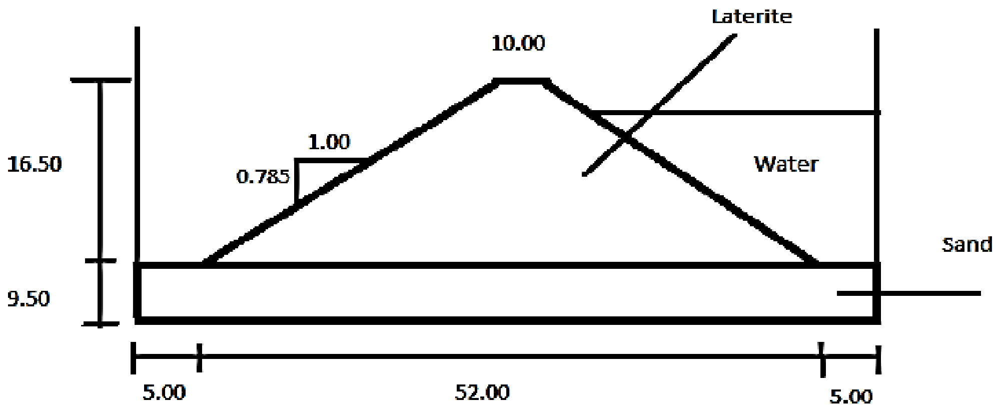


Figure 8: First physical small modeling; (S=1/100)

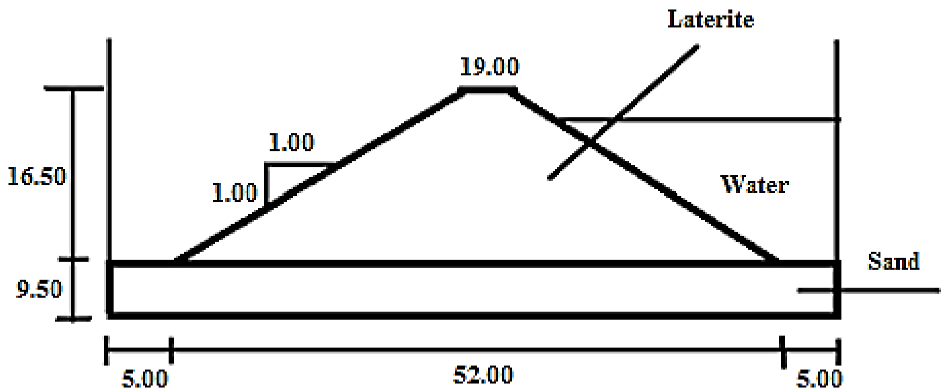

Figure 9: Second physical small-scale modeling; (S=1/100)

In models, both slope for upstream and downstream are same. In the second model, the crest width is 19.00 meter in order to make sharp slope. For both models, river sand (75%RD) was used in the foundation.

4. Results and analysis

Figure 10 show that, both points are at uplift position. In order to hydrodynamic pressure during the vibration, vertical displacement at upstream is larger than downstream. It can be respectively seen that, maximum displacement for downstream and upstream are 0.29 mm and 0.48 mm. However, the displacement peak is respectively occurred after 62 and 90 second. In addition, the fixed trend after peak was shown by both distributions.

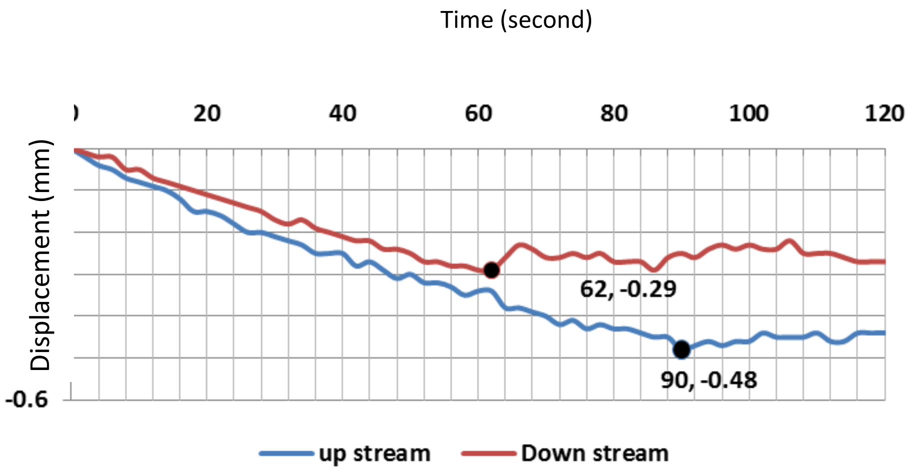

Figure 10: Vertical displacement distribution at the middle of crest length, first model

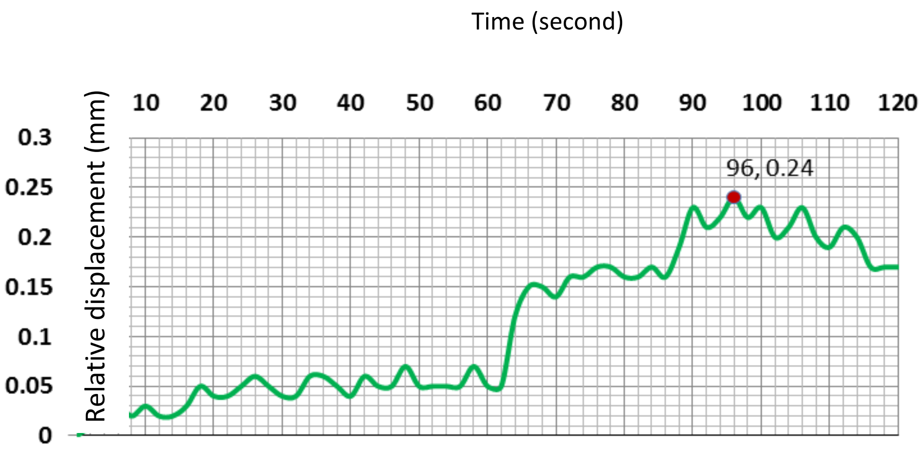

Figure 11: Relative displacement at the middle of crest length, first model

Moreover, in terms of relative displacement at the crest, Figure 11 shows that, maximum value is 0.24 mm at 96 seconds. It worth noting that, relative displacement was increased before than 60 seconds by 0.07 mm. In fact, dam performance is reliable for half time of vibration, because the maximum value is observed after three-fourth of duration. Furthermore, Figure 12 shows small-scale model before than vibration in the first situation. It can be seen that, two LVDT are installed at the middle of dam crest.

Figure 12: First small scale mode on vibrator table

Figure 13: Upstream damage after reservoir with vibration at resonance condition

In terms of damage observation, Figure 13 shows model at the end of vibration, after reservoir drainage. It can be observed that, there is some longitudinal crack in the upstream. In particular, most of them are located at one-fourth of dam height near to the crest, as shown with some lines such as A, B, C and D. Moreover, line-E shows longitudinal crack at the middle of upstream surface. It is also worth noting that, the maximum length of crack is exhibited by Line-c, as can be seen in Figure 14. Significantly, it was near to the middle of length crest.

Figure 14: Longitude crack at line-c

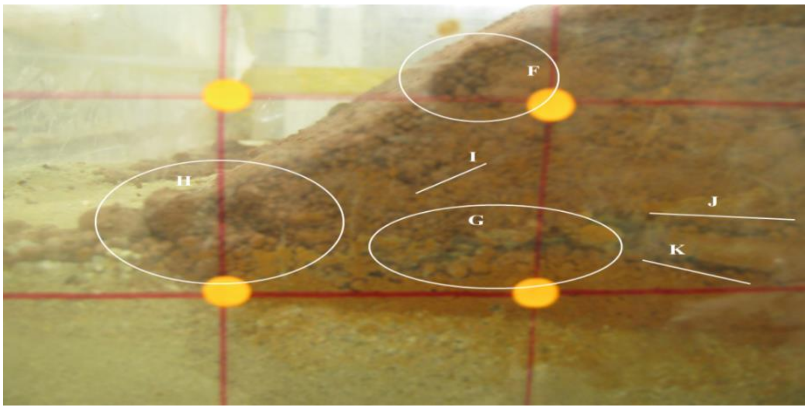

Figure 15: Transverse crack at downstream-toe

Furthermore, Figure 15 shows transverse crack in the downstream-toe. However, cracks are dramatically developed in this location. This area is restricted by four yellow circles with respect to network index for this photo, as shown by one-fourth of dam height near to foundation.

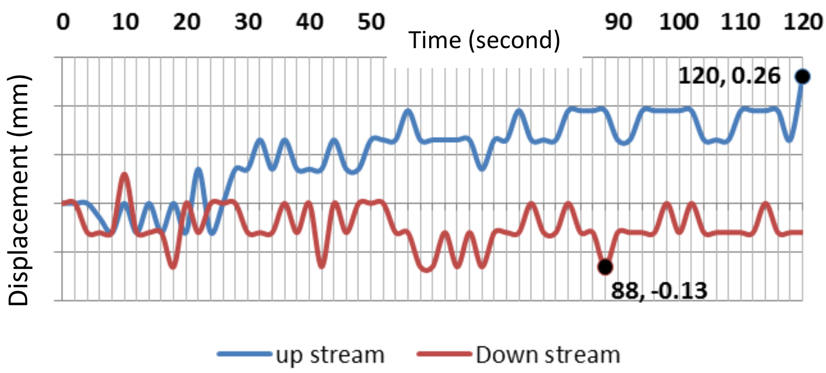

Figure 16: Vertical displacement distribution at the middle of crest length, third model

In terms of slope stability, the crest width in third small scale model is enhanced. Based on results, Figure 16 shows displacement distribution at the middle length of crest. Displacements at upstream and downstream are shown by different behavior, as can be seen that, the maximum values are respectively located at the end of vibration and 88 seconds. It means that, the edge of crest at upstream was in settlement while it was uplift at downstream, reversely. Also, in compare of maximum displacement at both edges of crest, the double ratio in upstream is observed. Furthermore, Figure 17 shows distribution of relative displacement at the middle length of crest in third physical modeling. It can be seen that, maximum value is occurred at the end of vibration with 0.32 mm, but this value also at the 88 seconds has been repeated.

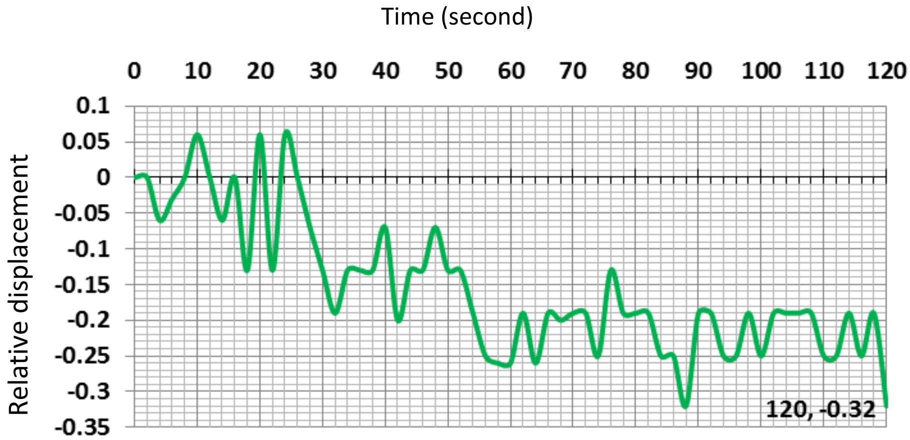

Figure 17: Relative displacement at the middle of crest length, third model

Figure 18 shows third model physical small scale. It can be observed that, dam is constructed on the river sand before reservoir. However, the upstream is located at right side. Also, some stud with different color at upstream (red color) and downstream (green color) in order to better identification of damage location are installed.

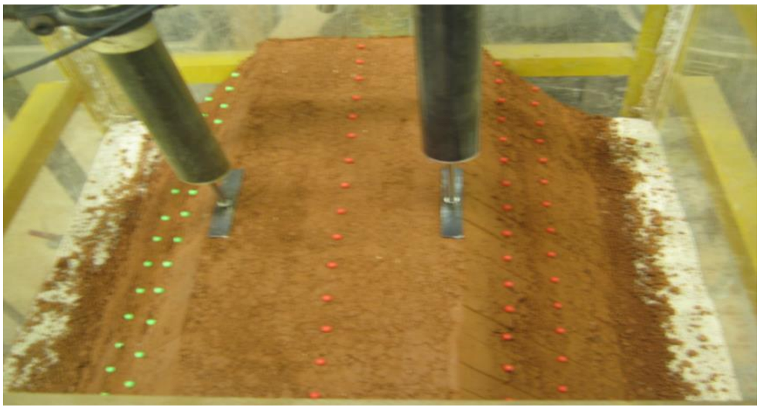

Figure 18: Second model view, upstream at right side

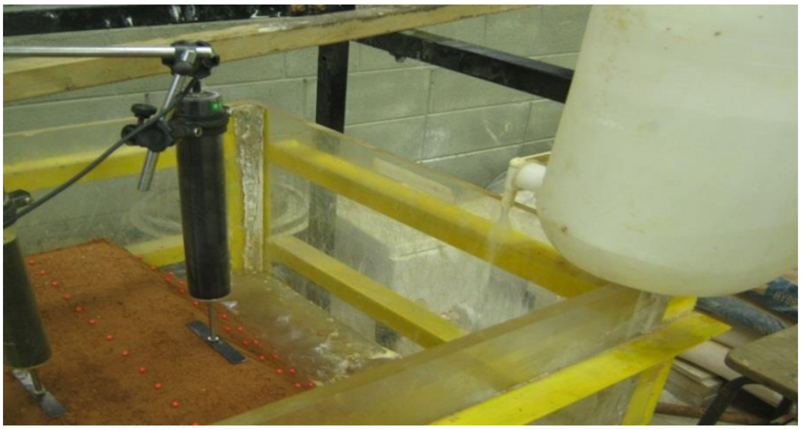

Figure 19: Third model view with reservoir

Also, Figure 19 shows model during tank process. It should be noted that, the rate of filling was very slowly. After vibration, damage location in this model shown by Figures 20 and 21.

Figure 20: Damage at upstream, middle to left side, near to abutment

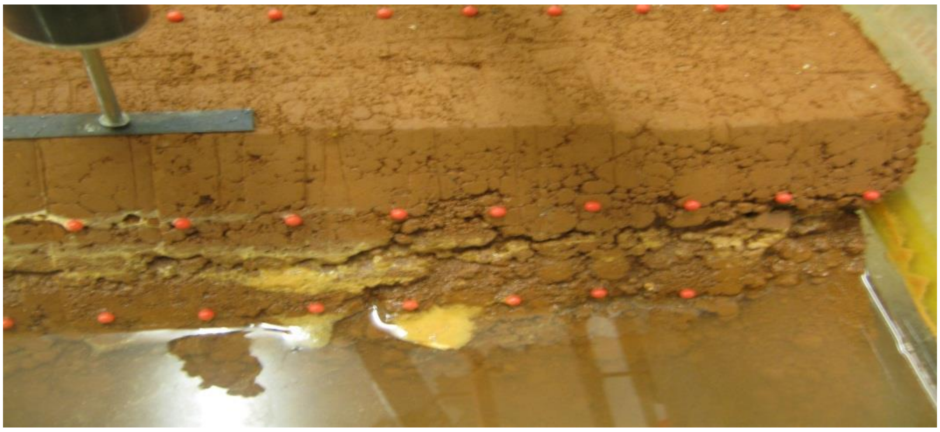

Figure 21: Damage at upstream, middle to right side, near to abutment

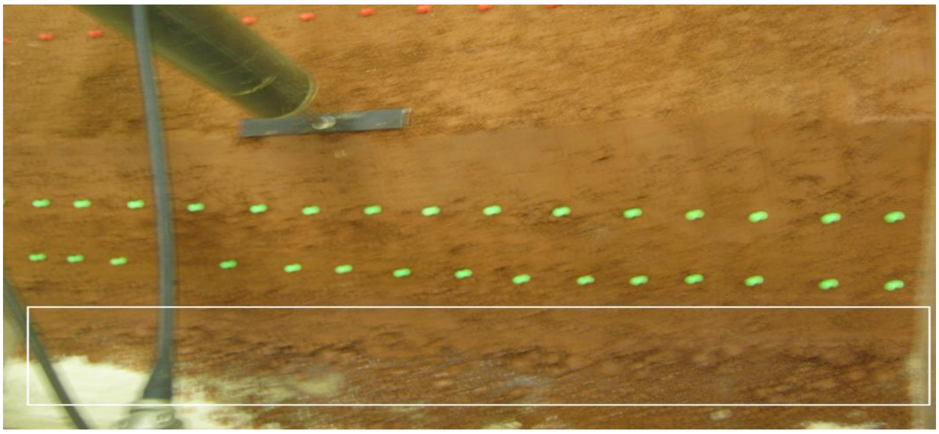

Figure 22: Damage at downstream, total length of the toe

The significant damage at upstream are occurred at hydrodynamic pressure level between half of upstream surface and freeboard. In particular, the huge damage with respect to intensity at area near to both abutments was observed. In parallel, Figure 22 shows damage at downstream of dam, as can be observed by white rectangular. The damage location at downstream was at toe area in total length.

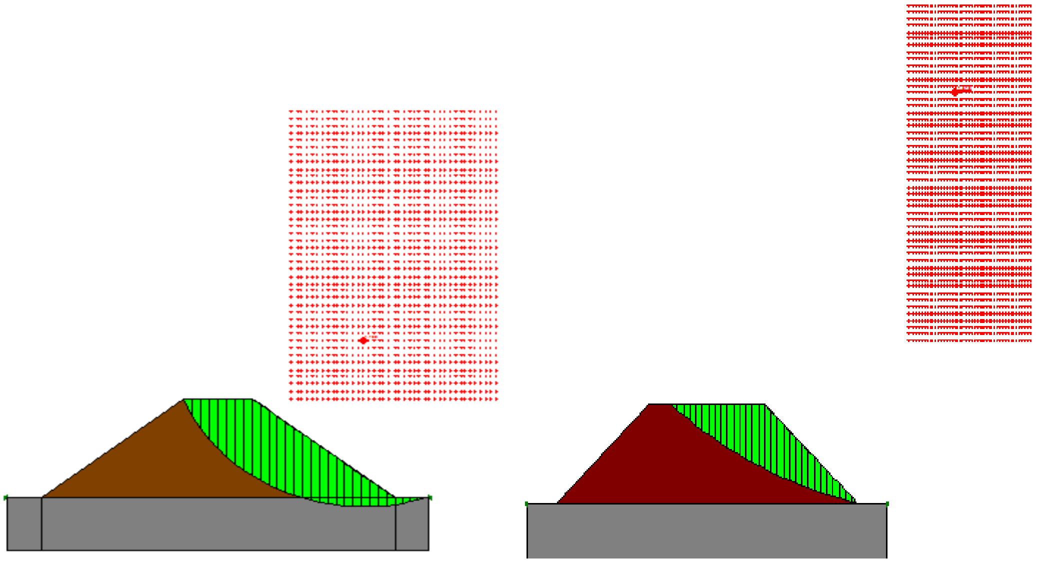
Factor of safety for models

To evaluate factor of safety based on vibration, models have been simulated using Geostudio 2007 in the present study. In this case, seismic load in ranges of 0.05g to 0.4g was used. Table 5 compares the factor of safety based on different peak ground acceleration in both models. Static safety presented using acceleration equal zero. As seen, factor of safety are respectively 1.199 and 1.31 for both models in the static position.

Table 5: Factor of safety for different seismic load in models

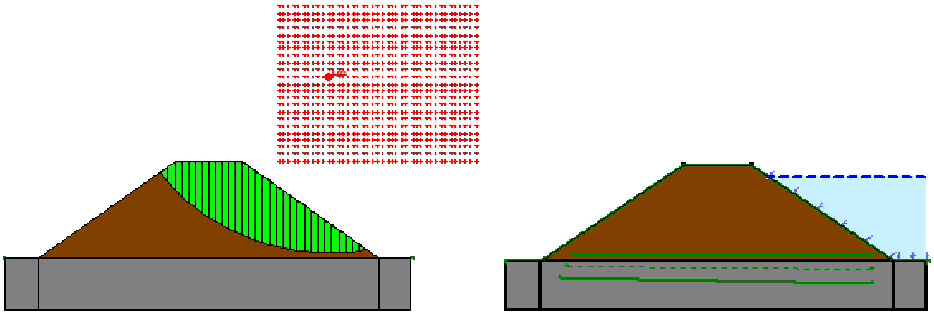
Model	FOS								
	0	0.05g	0.1g	0.15g	0.2g	0.25g	0.3g	0.35g	0.4g
First	1.199	1.141	1.109	1.08	1.037	0.996	0.958	0.922	0.889
Second	1.31	1.247	1.191	1.139	1.092	1.048	1.008	0.97	0.936

Figure 23 shows the safety map for both models as mentioned earlier. However, factor of safety is bigger in the second model. As seen in this Figure, critical slip was occurred at slope for second model while it was expanded towards foundation, as observed in the first model. It can be concluded that increasing of the crest width can be led to increase factor of safety in static situation. In order to effect of peak ground acceleration on the factor of safety, this value was less than one for 0.25g in the first model while it is unsafe for 0.35g in the second model. It should be noting that, both physical models have been vibrated using 10 Hz (0.17g), and should safe without any damage with respect to Table 5. In reality, models are safe under simulations using Limit equilibrium method but unsafe under sinusoidal motion using vibrator table. It means that, dam performance is very complex during vibration. In fact, Finite-element method should be applied to assess the accurate results. Therefore, more peak ground acceleration (PGA+0.2) is the best suggestion for using limit equilibrium method. For example, factor of safety for one case study using limit equilibrium method is the main purpose when site background is 0.15g; therefore, we suggest using 0.35g instead of 0.20g.



a) b)

Figure 23: Factor of safety in static situation, a) First model b) Second model



a) b)

Figure 24: Factor of safety in dynamic condition, a) Safety map b) model with tank

As a mentioned, critical slip surface was expanded in the static situation for first model. Figure 24 shows that, this condition was changed for seismic loading. Also in Figure 25, this position was similar to static state as explained earlier for second model. Finally, Limit equilibrium method was the weak prediction of safety in dam under dynamic loading. The location of damage was at upstream under seismic motion in physical small-scale modeling, when it was safe according to results from numerical analysis.

Figure 25: Factor of safety in dynamic condition, a) Safety map b) Second model with tank

5.0 Conclusion

In this study, earth dam safety using physical small-scale modeling and numerical analysis was carried out. As concluded, Limit equilibrium method was the weak assessment for factor of safety under seismic load. Damage during seismic vibration observed using Physical modeling while models as simulated were safe under same acceleration. It is the best recommendation to compute factor of safety using limit equilibrium method that acceleration of the dam site should be increased (PGA+0.2).

6.0 Acknowledgment

This study is made possible by the support of the International Doctorate Fellowship of Universiti Teknologi Malaysia, and it is very much appreciated.

FLOOD WAVE ANALYSIS OF EMBANKMENT DAM FAILURE BY USING 2D MODELS

Michael BERGER, René DÜNKNER

Institute of Hydraulic Engineering and Water Resources Management, Research Center of Hydraulic Engineering, VIENNA UNIVERSITY OF TECHNOLOGY

AUSTRIA

1. INTRODUCTION

Despite a very careful planning and construction as well as a meticulous surveillance, the risk of a dam failure cannot be neglected completely. According to [1], the two most common modes of failure for embankment dams are overtopping and piping. In order to estimate the consequences for a dam break scenario (loss of life, economic consequences), a flood wave analysis is mandatory. The present paper deals with the topic of flood wave analysis due to embankment dam failure by using 2D models. Key parts of this work are the estimation of the failure hydrographs on the one hand and the flood routing for different failure scenarios on the other hand.

2. INVESTIGATED CASE STUDIES

The following chapter summarizes the characteristic features of the two investigated case studies. Beside the specification of the embankment dams, a general description of the investigated downstream area is presented. Based on airborne LIDAR data, a 3D point cloud is used to generate a geometrical model of the area studied, in order to build the basis for hydraulic model.

2.1. CASE STUDY 1 – FLOOD RETENTION BASIN IN LOWLAND AREA

The embankment of the flood retention basin is a homogeneous earth-fill dam with a maximum height of 12,0 m, a crest length of about 115 m and slopes of 1:3 for both upstream and downstream face. According to the design criteria of retaining a 100-year flood, a retention volume of $V_{ret,100} \approx 2{,}5 \cdot 10^5\ m^3$ can be determined. During this flood event, a maximum discharge of the bottom outlet of $Q_{ret,100} = 8{,}2\ m^3/s$ will run off to the downstream area. For a 5000-year safety flood, the maximum reservoir volume of the basin can be calculated to $V_{ret,5000} \approx 3{,}3 \cdot 10^5\ m^3$. For this extreme scenario, a maximum discharge of $Q_{5000} = 61{,}1\ m^3/s$ can be stated for both the bottom outlet and the emergency spillway. The investigated downstream area of the basin is located in a lowland region. The total length of the hydraulic model is about 23,57 km, with an average bottom slope of 0,7 % (see Fig. 1). The meandering main channel often leads through woodlands and is surrounded by hedgerows over long distances. Furthermore, the channel runs through several culverts in order to cross some main streets of the region.

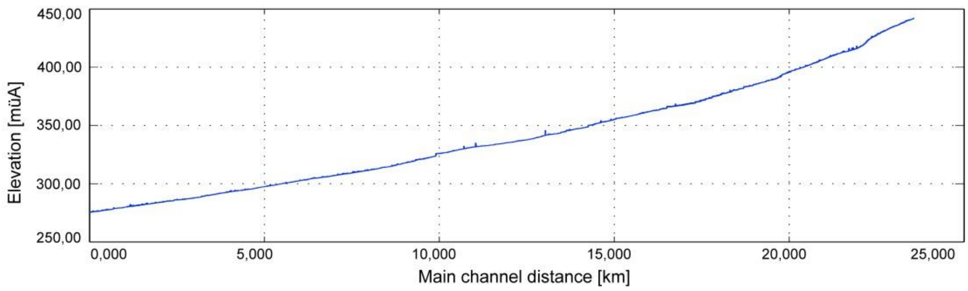

Fig. 1
Longitudinal section of the main channel – case study 1

2.2. CASE STUDY 2 – RESERVOIR IN ALPINE AREA

The second case study deals with the failure of a permanently impounded reservoir in an alpine region. With a maximum height of 92 m, a crest length of 275 m and slopes of 1:1,4 for the upstream, respectively 1:1,5 for the downstream face, the dam retains a volume of $V_{MOL} \approx 8{,}2 \cdot 10^6\ m^3$ for maximum operation level. For a 5000-year safety flood, the reservoir volume results to $V_{SHQ} \approx 9{,}0 \cdot 10^6\ m^3$. The corresponding water level in the reservoir for this scenario is about 1,5 m above the maximum operation level. The additional freeboard to the dam crest are another 1,5 m. The investigated downstream area of the dam is generally located in the Austrian Central Alps and can be subdivided into two main parts. The first upper part reaches over 5,5 km from the dam site, through a steep and narrow side valley to the 17,0 km long main valley (see Fig. 2).

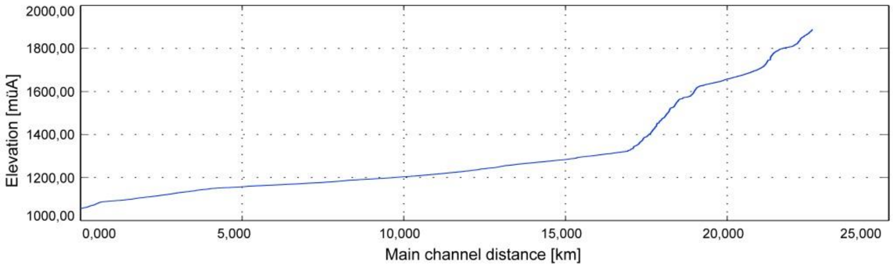

Fig. 2
Longitudinal section of the main channel – case study 2

3. THEORETICAL BACKGROUND AND GOVERNING EQUATIONS

The following chapter deals with the governing equations both of the breach outflow hydrographs and the 2D hydraulic model of the downstream area of the dam.

3.1. BREACH OUTFLOW

As a basis for the flood wave analysis, the discharge curve of the failure event has to be determined. The widespread approaches like those of Pierce [2] or Froehlich [3] provide only a peak outflow and are not immediately applicable for a transient flood wave analysis.

The DEICH parameter program developed by Broich [4] provides a transient failure hydrograph for both overtopping and piping failure of the embankment dam. The program assumes a trapezoidal initial breach cross section with a horizontal breach bed and a constant lateral inclination of the breach slopes (see Fig. 3). In order to calculate the enlargement of the breach, DEICH draws on standard empirical sediment transport formulae like those of Meyer-Peter and Müller [5] or Smart and Jaeggi [6]. Furthermore, the program uses an explicit algorithm for the calculation of water level, breach outflow and breach widening. The water level in the reservoir is either determined by the water level line or calculated using the volume balance. The outflow is calculated using the weir formula of Poleni-Weissbach.

In both case studies, DEICH is used to generate different outflow hydrographs. In addition, the empirical approaches of Rüdisser and Pierce are also used, in order to get an extended range of possible failure hydrographs. The peak discharge of both Ruedisser [7] and Pierce [2] follows Eq. 1.

$$\mathrm{Q_{Pierce}} = 0{,}0176(\mathrm{VH})^{0{,}606} \qquad \mathrm{Q_{Rüdisser}} = 0{,}0328(\mathrm{VH})^{0{,}625} \qquad [1]$$

where *V* describes the stored water volume and *H* the height of the dam.

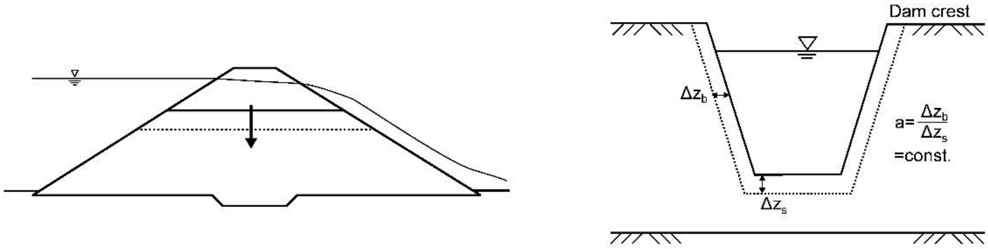

Fig. 3
Longitudinal and transversal development of a dam breach

3.2. FLOOD WAVE ANALYSIS

The 2D hydraulic calculations of the dam break scenario performed with HEC-RAS are based on a relationship of two basic equations. These are the Navier-Stokes and the Saint-Venant equations. As a simplification, an incompressible fluid, a consistent density of the fluid as well as a hydrostatic pressure and an averaged Reynolds number are assumed. Furthermore it is assumed, that the surface propagation of the water is much larger than its vertical spread. This assumption leads to low vertical velocities as well as a hydrostatic pressure in the fluid. Subsequently, the differential form of the Saint-Venant equations can be derived. In shallow water, the terms of the barotropic pressure gradient and soil friction are the dominant factors in the momentum equations. The terms of discontinuity, advection and viscosity can be neglected. The momentum equation is needed for the approximation of the two-dimensional form of the diffusive wave equation. Combining the momentum equation with mass conservation, the Diffusive Wave equation represents an equation system of the Saint-Venant equations that is easy to solve.

In order to reduce computation time, a sub-grid bathymetry method is used [8]. The basic idea here is, that a coarser calculation mesh is used for the hydraulic calculations. In post-processing, the results of the gross discretization with the information (exact altitude, storage area of the area element) of the finer discretization are revised. Assuming an incompressible fluid, the unsteady differential form of the mass conservation (continuity) equation takes the following form:

$$\frac{\delta H}{\delta t} + \frac{\delta(hu)}{\delta x} + \frac{\delta(hv)}{\delta y} + q = 0 \qquad [2]$$

In vector form, the mass conservation equation takes the following form:

$$\frac{\delta H}{\delta t} + \nabla \cdot hV + q = 0 \qquad [3]$$

Due to the significantly larger horizontal spread, compared to vertical water depth, the vertical velocity in the fluid is very low. In the Navier-Stokes momentum equation, the pressure in the fluid is assumed to be hydrostatic. As a result of the absence of baroclinic pressure gradients, atmospheric pressure, strong wind forces and pressure changes resulting from the vertical velocity component can be safely neglected in both mass and momentum equations. The 2-dimensional Saint-Venant equations take the following form:

$$\frac{\delta u}{\delta t} + u\frac{\delta u}{\delta x} + v\frac{\delta u}{\delta y} = -g\frac{\delta H}{\delta x} + v_t\left(\frac{\delta^2 u}{\delta x^2} + \frac{\delta^2 u}{\delta y^2}\right) - c_{fu} + f_v \qquad [4]$$

and

$$\frac{\delta v}{\delta t} + u\frac{\delta v}{\delta x} + v\frac{\delta v}{\delta y} = -g\frac{\delta H}{\delta y} + v_t\left(\frac{\delta^2 v}{\delta x^2} + \frac{\delta^2 v}{\delta y^2}\right) - c_{fu} + f_v \qquad [5]$$

In order to get a more compact and easily readable equation, the momentum equations can also be written in vector form:

$$\frac{\delta V}{\delta t} + V \cdot \nabla V = -g\nabla H + v_t\nabla^2 V - c_f V + fk \times V \qquad [6]$$

Starting from left to right, the following terms are shown: unsteady acceleration, convective acceleration, pressure term, turbulent diffusion, bottom friction term and Coriolis term. On closer inspection, it can be seen that at low water depth, the bottom friction term becomes decisive. For this reason, Eq. [6] for dry cells is limited to *V=0* and thus represents a special case.

The diffusive wave equation can be used under the previous conditions instead of the momentum conservation equations. The sub-grid bathymetry method also serves as a simplification of the numerical solution. The calculation is simplified insofar as the determination of the hydraulic radius *R=R(H)* and the wetted surface *A=A(H)* are outsourced as cell functions of the water level *H*. The simplifications and neglects for shallow waters also apply here. The simplified form of the momentum equation takes the following form:

$$\frac{n^2|V|V}{(R(H))^{4/3}} = -\nabla H \qquad [7]$$

Dividing both sides of the equation by the square root of their norm, the equation can be rearranged into the more classical form:

$$V = \frac{-(R(H))^{2/3}}{n}\frac{\nabla H}{|\nabla H|^{1/2}} \qquad [8]$$

By inserting the diffusive wave equation from Eq. [8] into the mass conservation equation Eq. [3], the classical differential form of the diffusive wave approximation of the Saint-Venant Equations can be obtained.

$$\frac{\delta H}{\delta t} - \nabla \cdot \beta \nabla H + q = 0 \qquad [10]$$

with

$$\beta = \frac{(R(H))^{5/3}}{n|\nabla H|^{1/2}} \qquad [11]$$

4. ESTIMATION OF THE FAILURE HYDROGRAPHS

With reference to the introduced approaches for estimating the breach outflow in case of a dam break (see chapter 3.1), a range of failure hydrographs for each of the case studies is generated.

4.1. CASE STUDY 1 – FLOOD RETENTION BASIN IN LOWLAND AREA

Different flood waves are used, in order to investigate the influence of peak discharge and wave run time on the flooded downstream area (see Fig. 4). With a peak discharge of about $Q_{HQ5000\ Rüdisser} = 574\ m^3/s$, the flood wave estimated with the approach of Rüdisser superposed with a 5000 years flood reaches this point 5 minutes after the break. In comparison to that, the wave following the approach Broich Smart shows a peak discharge of $Q_{Broich\ Smart} = 138\ m^3/s$ by reaching this value 27 minutes after the initial breaching.

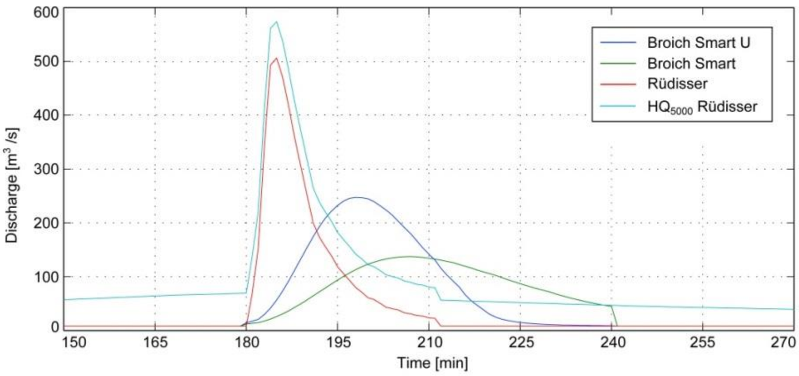

Fig. 4
Investigated failure hydrographs of case study 1

4.2. CASE STUDY 2 – RESERVOIR IN ALPINE AREA

The investigated failure hydrographs of case study 2 are based on different storage levels in the reservoir. The peak values of the discharge differ between $Q_{Broich\,Smart} = 1265\,m^3/s$ and $Q_{Pierce} = 3010\,m^3/s$. The timespans between the initial breaching and the peak discharge range between 25 and 45 minutes (see Fig. 5).

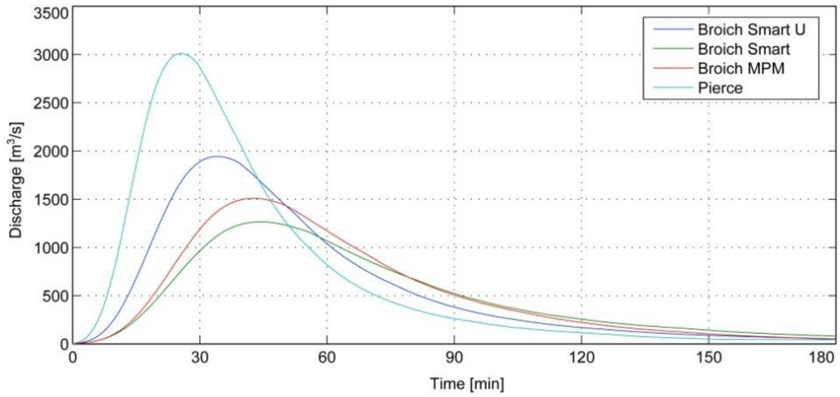

Fig. 5
Investigated failure hydrographs of case study 2

5. RESULTS OF THE FLOOD WAVE ANALYSIS

In the following chapter, an overview of the gained results of the flood wave analysis is presented. More detailed results and information can be found in [9] or [10].

5.1. CASE STUDY 1 – FLOOD RETENTION BASIN IN LOWLAND AREA

Due to the mainly flat investigation area as well as the several culverts, situated along the main channel, a strong retention character of the downstream region can be observed. Evaluating the first flood marker PP1, situated about 1,5 km downstream of the retention basin, a significant accordance to the input data of the failure hydrographs can be observed (see Fig. 6 – left). Along the section between the flood markers PP1 and PP2, two bridges cross the main channel and generate smaller flood retention area before the culverts. By studying Fig. 6 – right, a significant damping of the hydrographs can be noticed. Evaluating the further flood markers in the area studied, a continuing and reinforcing effect of flood retention can be observed.

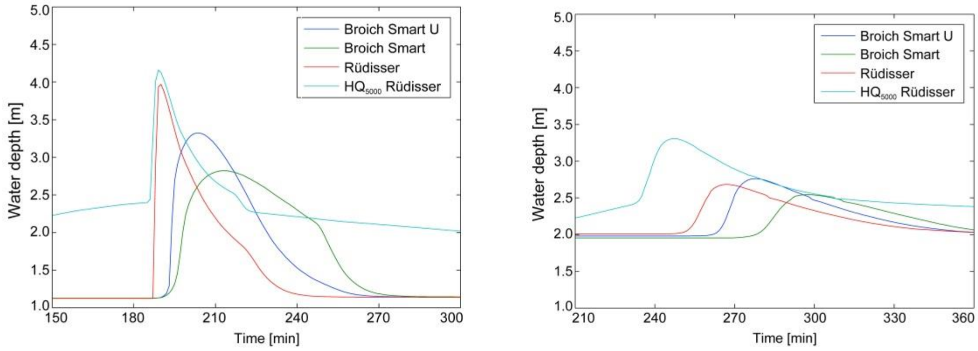

Fig. 6
Flood markers PP1 (km 22,000) and PP2 (km 16,800) in the investigation area of case study 1

The water depths of the flooded area strongly vary as a function of the respective failure hydrograph. Those failure scenarios with a higher peak discharge show higher flood levels as well as higher flow velocities in the area studied. Fig. 6 show water depths (left) and velocities (right) of the surrounding area of PP2. Due to the bridge crossing the main channel, a natural retention basin is build, which leads to higher water levels in the upstream and higher velocities in the downstream region.

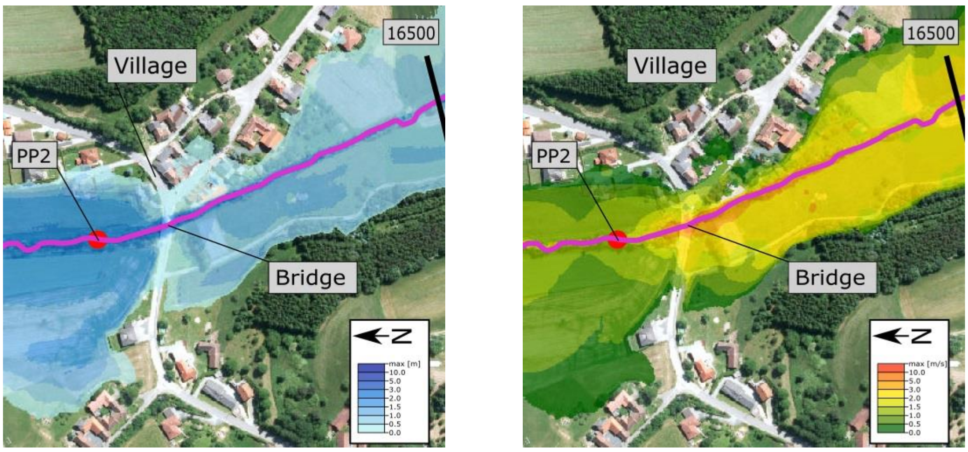

Fig. 6
Water depths and flow velocities around PP2 (16,800) in the investigation area of case study 1

5.2. CASE STUDY 2 – RESERVOIR IN ALPINE AREA

Along the first about 5,7 km long (km 22,650 – km 17,000), mostly steep and narrow part of the area studied, nearly no considerable flooding can be observed. The subsequent and more flat main valley (see also Fig. 2) allows an extensive propagation by effecting larger settlement areas. A significant retention of the flood waves can be observed. Furthermore, a correlation between the peak value of the failure hydrograph and the arrival time of the flood wave as well as the resulting flood levels can be noticed. By studying the flood markers along the area studied (see Fig. 7), a most sudden impact of the flood wave can be observed.

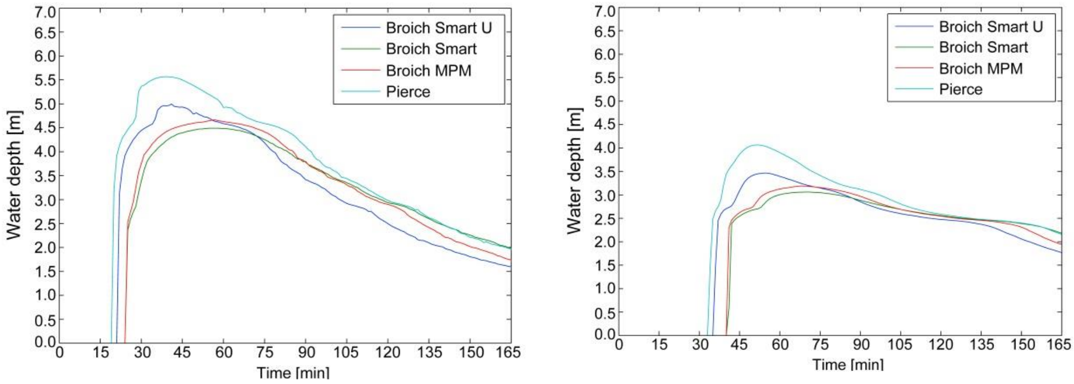

Fig. 7
Flood markers PP2 (km 15,000) and PP4 (km 9,000) in the investigation area of case study 2

The flood regime along the main valley is characterized by a rail embankment following the main channel and several underpasses. These underpasses mainly influence the flooding of certain villages. In some cases, an overtopping of the rail embankment can be observed as well (see Fig 8).

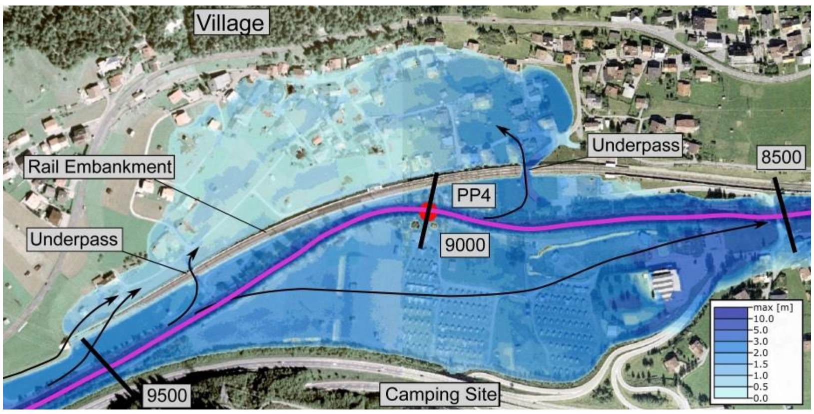

Fig. 8
Water depths around PP4 (km 9,000) in the investigation area of case study 2

Flow velocities around 15 m/s in the main channel and 5-10 m/s in the surrounding area can be noticed (see Fig. 9).

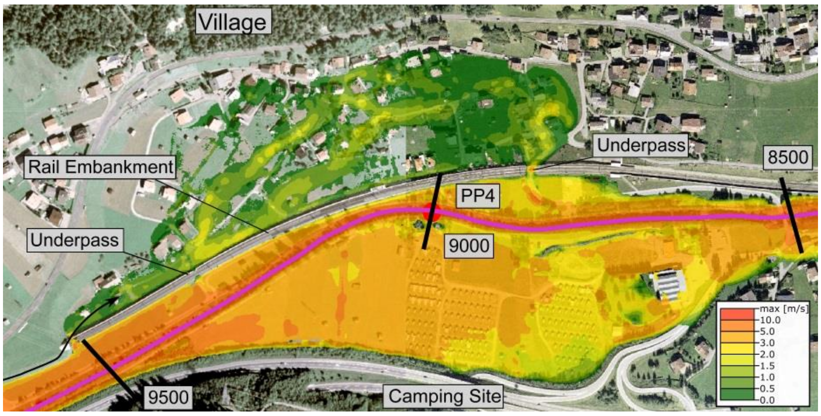

Fig. 9
Flow velocities around PP4 (km 9,000) in the investigation area of case study 2

SUMMARY

In order to estimate the possible consequences for a dam break scenario, a flood wave analysis is wisely required. Especially for embankment dams, the investigations should contain a study of potential failure hydrographs. By using different approaches for calculating the breach outflow on the basis of variable storage levels in the reservoir, it is possible to obtain a range of outflow hydrographs as a mandatory input data for the flood wave analysis.

Using 2D hydraulic models for this analysis allow to investigate the flood regime in detailed way. On the basis of airborne LIDAR data, geometric boundary conditions, such as culverts or underpasses in the area studied, can be implemented into the model in an easy way. Due to the influence of these geometric boundaries on the flooding, a special focus has to be set on the accurate modelling of the investigation area.

SWITZERLAND

RISK MANAGEMENT FOR THE LAGO BIANCO RESERVOIR IN CASE THE CAMBRENA GLACIER RUPTURES*

Johannes MAIER

Alexandra BECKSTEIN

Georges R. DARBRE

Supervision of Dams, SWISS FEDERAL OFFICE OF ENERGY, BERNE

SWITZERLAND

1. INTRODUCTION

The average annual temperature in Switzerland has increased by 2°C since the start of measurements in 1864. This increase is almost twice as high as for other land areas in the northern hemisphere. Today, the zero degree line in Switzerland is about 350 m higher than 60 years ago. Mainly because of these rising temperatures the alpine glaciers are melting.

In 2015, it was discovered that the retreating Cambrena glacier in southwestern Switzerland had introduced a new risk to the Lago Bianco reservoir: A melting glacier tongue is slowly retreating into a steep rock step and therefore losing its support at the front end and on both sides. According to the glacier specialists, there is a danger for a rupture of up to 1.5×10^6 m^3 of ice. The ice rupture could generate a flood wave in the reservoir and cause a sudden dam breach. Therefore, the owner of the Lago Bianco reservoir Repower AG had to add this new danger into his risk management.

2. LAGO BIANCO RESERVOIR

The Lago Bianco reservoir (see fig. 1) is located just west of the Bernina pass in southwestern Switzerland, only a few kilometers from the boarder to Italy. The reservoir is part of the water divide between the Mediterranean Sea and the Black Sea. The highest peaks of the eastern Alps (with altitudes around 4'000 m a.s.l.) flank the western side of the reservoir. The narrow gauge Bernina railway follows the eastern reservoir shore; the northeastern corner of the reservoir is close to the Bernina highway. Both traffic lines are all-the-year open, except winter days with

* *Gestion du risque au réservoir de Lago Bianco en cas de rupture du glacier de Cambrena*

high avalanche risk. The water stored in the reservoir is used in several power stations to produce electricity.

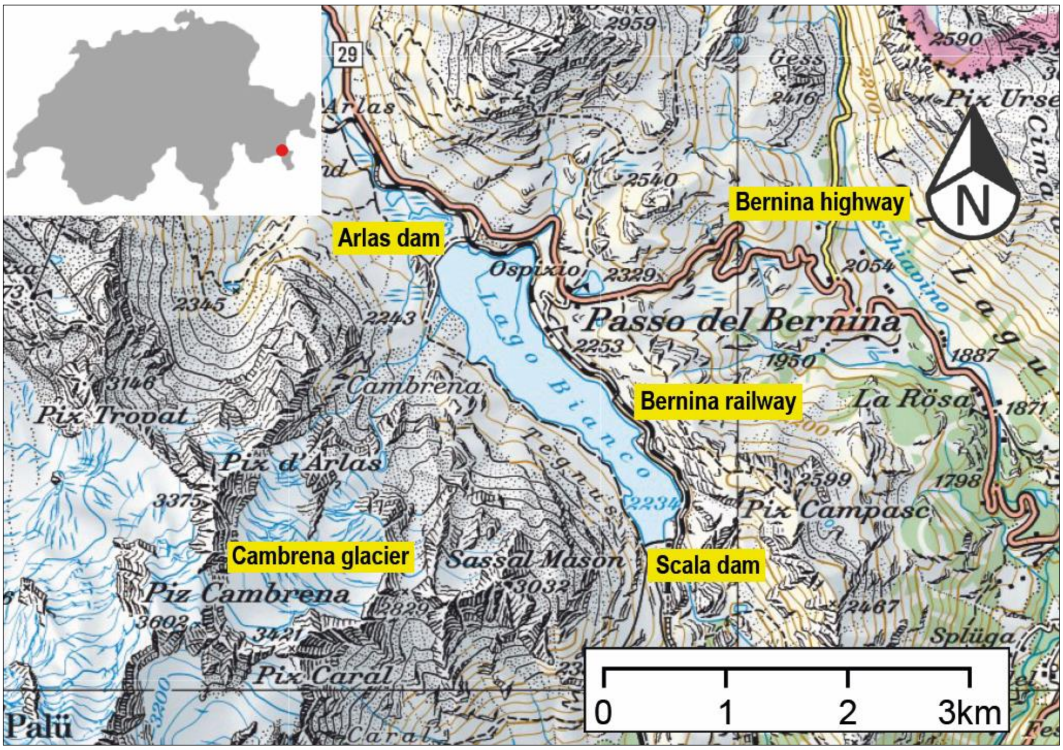

Fig. 1: Location of the Lago Bianco reservoir in southwestern Switzerland.
Img. 1 : Situation du réservoir de Lago Bianco au sud-est de la Suisse.

The two dams of the Lago Bianco reservoir, the Arlas gravity dam in the north and the Scala arch-gravity dam in the south, were originally built in 1910–12 with cyclopean concrete. The impounding of the reservoir connected two natural lakes. In 1941/42 the height of the two dams was increased by adding at the crest 4 m of concrete and so enlarging the reservoir capacity. Later on this additional concrete started to show signs of alkali aggregate reaction; furthermore, only an incomplete connection between the original and the additional concrete was discovered at the Scala dam. To solve these problems an extensive renovation of the two dams took place in 2000/01. The eastern two-thirds of the Arlas gravity dam were totally demolished and rebuilt with regular concrete above the old foundation. The demolition waste together with fresh rock material was used to cover the western third of the dam. The Scala arch-gravity dam got a shotcrete cover and PP-Dam sealing on the upstream face, a drainage and inspection gallery at the upstream foot, a new concrete crest and a systematic anchoring on the downstream face. Fig. 2 shows the actual cross sections of the Arlas and Scala dams.

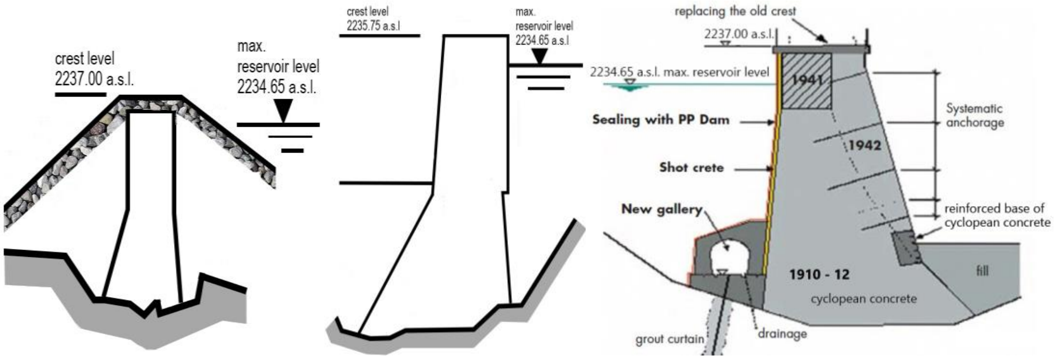

Fig. 2: Cross sections of the western part of the Arlas dam (left), the eastern part of the Arlas dam (middle) and the Scala dam (right).
Img. 2 : Coupe transversale de la partie ouest du barrage d'Arlas (à gauche), de la partie est du barrage d'Arlas (au centre) et du barrage de Scala (à droite).

The following list summarizes the characteristics of the Lago Bianco reservoir:

- Catchment area 10.85 km^2 (currently 15 % covered by glaciers)
- Reservoir area 1.43 km^2
- Reservoir volume 18.6×10^6 m^3
- Maximum reservoir level 2'234.65 m a.s.l.
- Length of Arlas dam 290 m
- Height of Arlas dam 15 m
- Crest level of Arlas dam 2'235.75 m a.s.l. (western part 2'237.00 m a.s.l.)
- Length of Scala dam 190 m
- Height of Scala dam 26 m
- Crest level of Scala dam 2'237.00 m a.s.l.

All dam outlets are located in the Scala dam. The bottom outlet has a maximum capacity of 6.0 m^3/s; the intermediate outlet with a base level of 2'231.40 m a.s.l. allows a maximum discharge of 24.0 m^3/s. Flood waters are controlled with a 37 m long overflow section, its crest is at the maximum reservoir level 2'234.65 m a.s.l. The turbination capacity amounts to 4.4 m^3/s and 0.75 m^3/s can be pumped from the reservoir below. Today, the Lago Bianco reservoir is used as a seasonal water storage with maximum level in autumn and minimum level in spring.

The regular surveillance of the Lago Bianco reservoir consists of visual inspections and measurements carried out by personnel of the reservoir owner. They are also responsible for the annual tests of the outlets with mechanical gates. Once a year a dam engineer carries out his inspection. He is also the author of the annual report about the condition and behavior of the reservoir and its two dams. Every fifth year a geodetic measurement and an in-depth safety review by a dam expert and a geology expert take place. All reports are submitted to the Supervision of Dams Section of the Swiss Federal Office of Energy. The responsible supervisor reviews these reports and carries out his own inspections at least every third year. The Supervision of Dams Section is also present at the site inspections of the experts.

3. RETREAT OF CAMBRENA GLACIER

During project work for the development of the current seasonal reservoir into a high capacity pumped storage facility it was detected that there is a risk of a rupture of the southern tongue of the Cambrena glacier. The reservoir owner asked glacier specialists from the ETH Zurich to study the situation and give their advice. Their findings [1] can be summarized as follows:

- **Actual situation:** The Cambrena glacier covers a surface of about 1.37 km^2 and has a volume of 50×10^6 m^3. The current lower end of the southern glacier tongue is at an altitude of 2'520 m a.s.l. Due to the strong glacier retreat a lake has developed in front of it. The terrain behind the end of the glacier gets steeper and steeper over a distance of 550 m until a flattening starts at an altitude of 2'820 m a.s.l. The inclination below the steep part is at 24°, in the steep part it is at 35°.
- **Prognosis of glacier melting:** Fig. 3 shows the result of model calculations for the ice volume of the Cambrena glacier from 1900 until 2100. Between 1985 and 2008 the volume loss amounts to 40×10^6 m^3 of ice. Furthermore, the diagram shows that the Cambrena glacier is expected to disappear totally between 2050 and 2080. Fig. 4 presents the prognosis of the surface covered by the glacier between 2010 and 2050. Around 2025 the glacier will have retreated above the steep part.

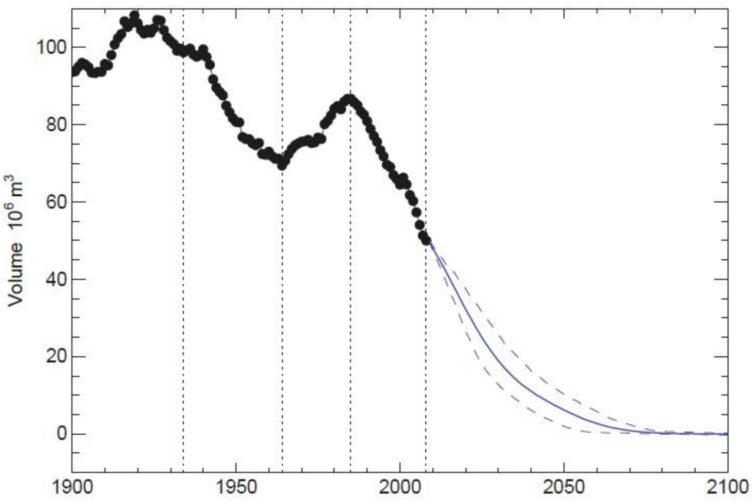

Fig. 3: Changes in the ice volume of the Cambrena glacier between 1900 and 2100 (the potential future changes are given by an average value and a band width from 10 scenarios; the vertical dotted lines indicate dates with known extent of the glacier surface) [1].

Img. 3 : Changements de volume de la glace du glacier de Cambrena entre 1900 et 2100 (les potentiels changements futurs sont obtenus avec une valeur moyenne ainsi qu'une variation de volume tirée de 10 scénarios ; les lignes pointillées verticales indiquent les dates avec la mesure connue de la surface du glacier) [1].

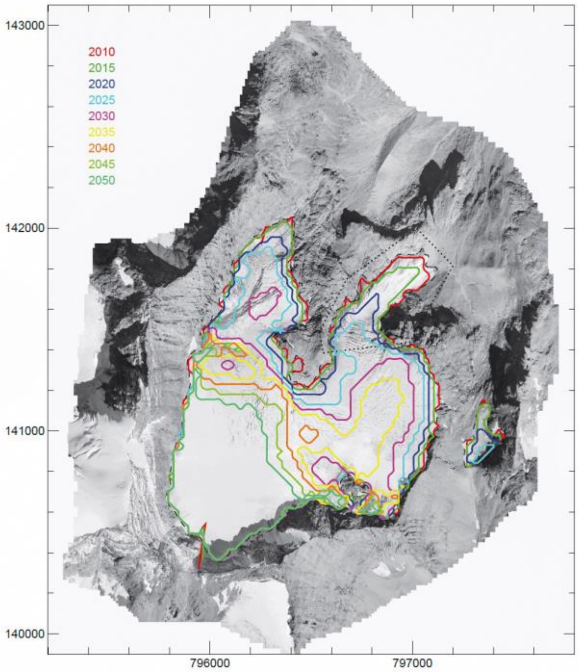

Fig. 4: Prognosis of the surface of the Cambrena glacier until 2050 (the base photo shows the situation in 2008) [1].
Img. 4 : Pronostic de la surface du glacier de Cambrera jusqu'en 2050 (la photo de base montre la situation en 2008) [1].

- **Threat of glacier tongue rupture:** Currently the glacier tongue is stabilized by its lowest part with the inclination 24° and the contact at its bottom and the two sides. As soon as the glacier tongue retreats into the steeper part with the inclination 35° and gets thinner on both sides, the ice is only stabilized by the contact to the terrain at its bottom (see fig. 5) and a risk of sudden ice rupture emerges. According to studies at other glaciers, a rupture requires a water flow between the glacier and the terrain surface. Therefore, such events usually occur with alpine glaciers in the months of July to October.

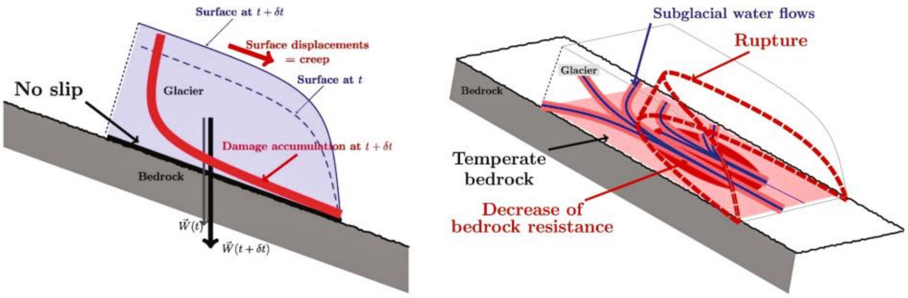

Fig. 5: Displacement of a glacier frozen to the bedrock (left); rupture of a glacier due to subglacial water flow on the temperate bedrock (right) [2].
Img. 5 : Déplacement d'un glacier gelé sur un socle rocheux (à gauche); décrochement d'un glacier en raison de flux d'eau sous-glaciaire sur le socle rocheux tempéré (à droite) [2].

4. RUPTURE OF CAMBRENA GLACIER TONGUE, ICE AVALANCHE AND IMPULSE FLOOD WAVE IN THE LAGO BIANCO RESERVOIR

The report of the glacier specialists [1] gives a forecast on the decrease of the ice volume in the steep part with time (see fig. 6): In 2015 the potential rupture volume equals to 1.5×10^6 m^3, this corresponds to the worst-case scenario to be taken into account in the risk management of the Lago Bianco reservoir. By 2020, the potential rupture volume will diminish below 0.5×10^6 m^3 of ice.

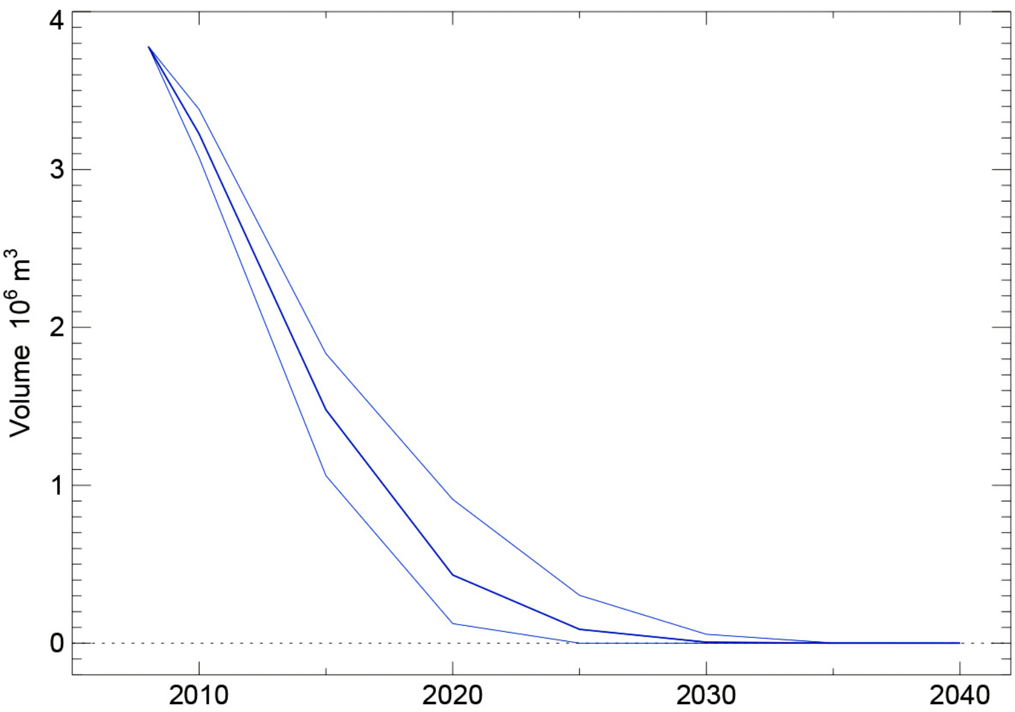

Fig. 6: Prognosis of the decrease of the ice volume in the steep part of the southern tongue of the Cambrena glacier (an average value and a band width from 10 scenarios are shown) [1].

Img. 6 : Pronostic de la diminution du volume de glace dans la partie raide de la langue glaciaire sud du glacier de Cambrena (une valeur moyenne ainsi qu'une variation de volume tirée de 10 scénarios sont représentées) [1].

The ruptured ice would move as an avalanche towards the Lago Bianco reservoir. The report [3] presents the calculations carried out by avalanche specialists with the computer program RAMMS [4]. The calculation results show that the ice rupture volume in the worst-case scenario of 1.5×10^6 m^3 gives an avalanche with a volume of 1.8×10^6 m^3, which reaches the reservoir with a speed of 10–20 m/s, a flow height of 5–10 m and a volume of approximately 0.25×10^6 m^3 (see fig. 7). The avalanche produced by an ice rupture volume of 0.5×10^6 m^3 reaches the reservoir with a volume of a few thousand m^3 and can be neglected.

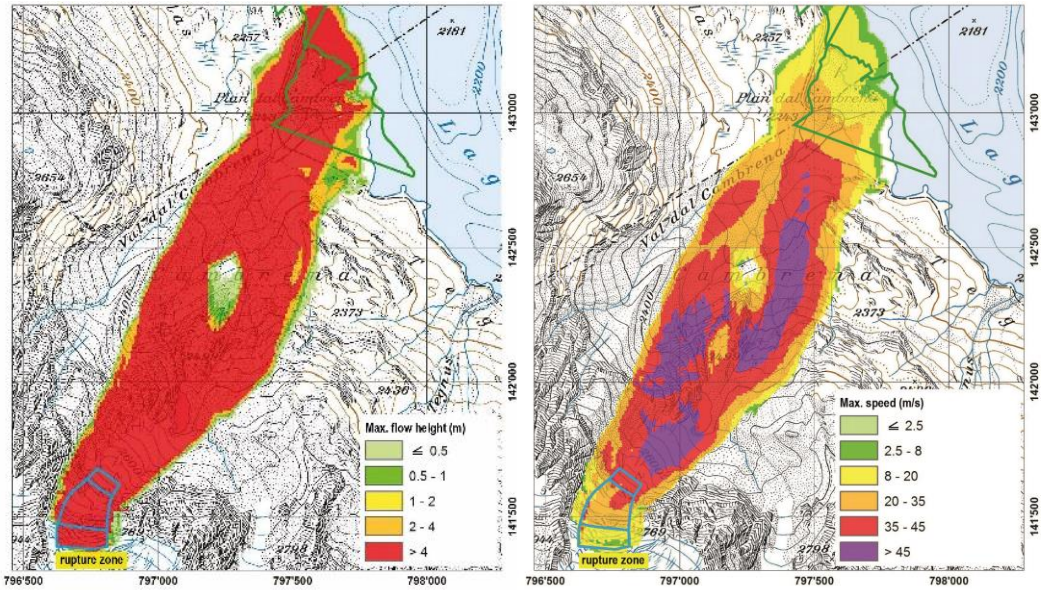

Fig. 7: Maximum flow height (left) and speed (right) according to the RAMMS calculations for the ice avalanche produced by the worst-case glacier rupture of 1.5×10^6 m^3 [3].

Img. 7 : Hauteur (à gauche) et vitesse (à droite) maximum de l'avalanche calculées selon la méthode RAMMS lors de la rupture du glacier pour le cas extrême de 1.5×10^6 m^3 [3].

Based on the results of the avalanche calculations the dam expert responsible for the Lago Bianco reservoir conducted impulse flood wave calculations [5] with a spreadsheet program developed at the demand of the Swiss Federal Office of Energy at the ETH Zurich [6]. For the worst-case ice rupture and the maximum reservoir level of 2'234.65 m a.s.l. the calculations for the Arlas dam give the following results:

- Wave height 1.5–4.5 m
- Overtopping volume 200–4'000 m^3 (minimum freeboard of 1.1 m taken into account)

The overtopping volume is rather small. It would only cause minor damages downstream of the Arlas dam. On the other hand, the flood wave reaches well above the danger level (= crest level of the eastern part of the dam at 2'235.75 m a.s.l.) and therefore puts the stability of the dam at risk.

The impulse flood wave can only reach the substantially more distant Scala dam after reflection. Thus, the wave height will be much smaller and pass the dam by the overflow section. The substantial freeboard of 2.35 m from the maximum reservoir level up to the crest level at 2'237.00 m a.s.l. (= danger level) is expected to guarantee the integrity of the Scala dam.

5. ICE FLOW SPEED AS EARLY INDICATOR OF GLACIER RUPTURE

Experiences with several glacier ruptures have demonstrated, that the ice flow speed is a good early indicator for a situation becoming dangerous [1, 2]. Fig. 8 presents the flow speed of the tongue of the Allalin glacier in the Saas valley in the southern Swiss Alps for the years 1965 to 1967. The two decreasing curves from 1965 were measured after the rupture of more than 2×10^6 m^3 ice on August 30th 1965, which killed 88 people on the construction site of the Mattmark dam. The curves from 1966 and 1967 show speed increases by a factor of 10 or more from a few decimeters/day to several meters/day. Important is also the fact that the increase periods lasted many days or weeks.

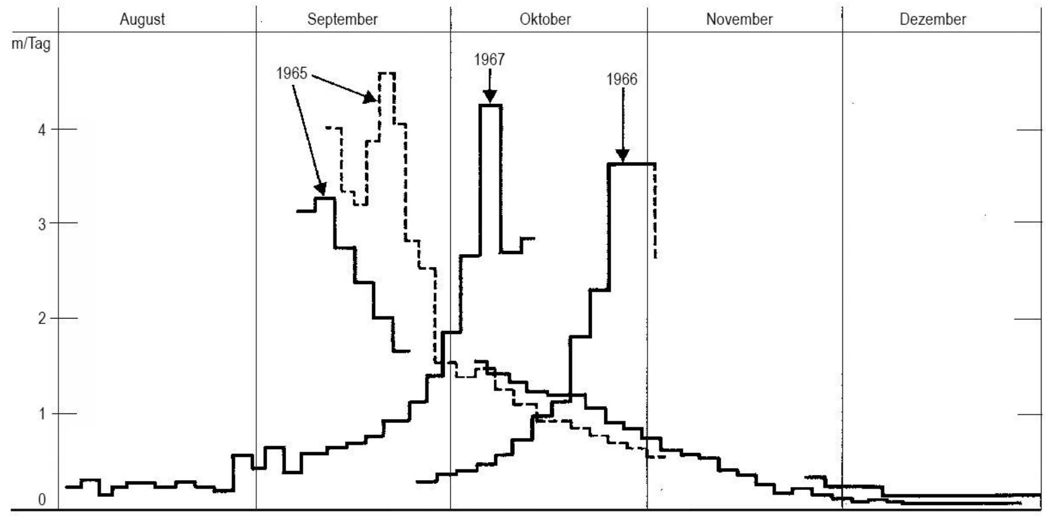

Fig. 8: Flow speed of the Allalin glacier in the southern Swiss Alps for the years 1965 to 1967 [1].

Img. 8 : Vitesse de déplacement du glacier d'Allalin dans le sud des Alpes suisses durant les années 1965 à 1967 [1].

Based on the findings given above, the ETH Zurich glacier specialists recommended in the case of the Cambrena glacier the installation of an automatic photographic camera with energy supply from a photovoltaic panel and mobile phone data transmission to follow the ice flow speed on a daily basis. The camera (see fig. 9) was installed in July 2015 at a cost of about 30'000 CHF (≈ 25'000 EUR) [7]. The annual costs amount to 12'500 CHF (≈ 10'500 EUR) and include the analysis of the daily pictures by the glacier specialists. Fig. 10 shows as an example the ice flow speed calculated from the camera pictures for two different periods of the year 2016.

Ice flow speeds between 0.04 and 0.12 m/d, averaged over periods of several days, were measured for the steep part of the southern tongue of the Cambrena glacier during the year 2016.

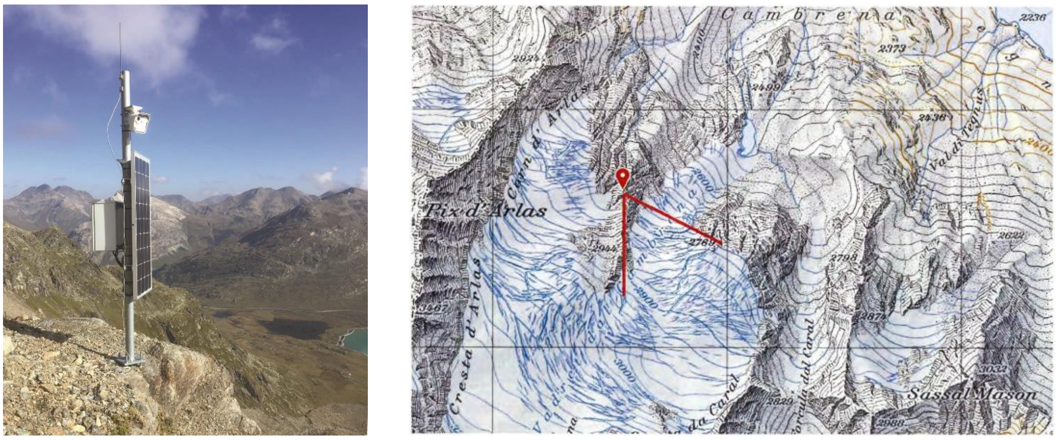

Fig. 9: Automatic camera with photovoltaic energy supply and mobile phone data transmission for the surveillance of the Cambrena glacier (left) [2]; camera position and view angle over southern glacier tongue (right) [7].

6. EMERGENCY PREPAREDNESS PLAN

Emergency preparedness plans for reservoirs and their dams use five danger levels [8, 9], as it is common for different risks in Switzerland:

- Danger level 1 = normal situation → regular surveillance and maintenance
- Danger level 2 = moderate danger → preparation of emergency organization
- Danger level 3 = serious danger → emergency organization in action
- Danger level 4 = high danger → preparation of alarm of population
- Danger level 5 = very high danger → alarm and evacuation of population

At a meeting with the owner of the Lago Bianco reservoir, the ETH Zurich glacier specialists, the dam engineer, the dam expert and the geology expert the supervision of dams authority assigned danger level 2 for the Lago Bianco reservoir. Thereafter, the reservoir owner developed a special emergency preparedness plan for a rupture of the Cambrena glacier tongue [10]. This plan uses two basic elements:

- Continuous surveillance of the Cambrena glacier to measure the ice flow speed.
- Lowering of the Lago Bianco reservoir in case of a high ice flow speed to a level, which still guarantees the stability of the Arlas dam.

Based on the calculations presented in the preceding chapter 4 the safe reservoir level was determined by the dam expert for the worst-case glacier rupture of 1.5×10^6 m^3 of ice to be 2’232.15 m a.s.l., i. e. 2.50 m below the maximum reservoir level. The time needed for this lowering plays a key role in the emergency preparedness plan. With an inflow of 1.0 m^3/s to the reservoir, the available outlets (see chapter 2) give the following times for reaching the safe level:

- Turbination only: 10.9 days
- Bottom outlet only: 7.4 days
- Intermediate outlet only: 2.6 days

The use of the intermediate outlet at maximum capacity would cause substantial damage downstream of the Scala dam. To reduce this, the reservoir owner has decided to open the intermediate outlet stepwise as long as the danger does not reach level 4. Therefore, the lowering of the reservoir level including a preparation period of 24 hours is prolonged to 100 hours ≈ 4 days. This agrees with the statement of the glacier specialists, that the increase period of the ice flow speed lasts many days or weeks before it comes to a glacier rupture. In case of danger levels 4 and 5, an immediate full opening of all outlets down to the safe level is intended.

Based on the previous statements the following conditions and procedures were established for the danger levels 2 to 5 (see fig. 11):

- **Danger level 2:** The reservoir may be operated over its full range. The glacier specialists of the ETH Zurich check the ice flow speed, during the critical time of the year on a daily basis. The operation center of the reservoir owner is active on a 24 hours and 7 days basis.
- **Danger level 3:** A reported glacier flow speed ≥ 2.5 pixel/day (≈ 0.5 m/d) and a reservoir level > 2'232.15 m a.s.l. (= safe level) triggers danger level 3. Between June 1st and November 30th, a camera blackout of 5 days and a reservoir level > 2'232.15 m a.s.l. would also lead to danger level 3. Immediately, the reservoir owner informs the emergency center of the police about the new danger level and sends personnel to the reservoir. After a 24 hours preparation period, the lowering of the reservoir with a stepwise opening of the intermediate outlet starts.
- **Danger level 4:** A reported glacier flow speed ≥ 5 pixel/day (≈ 1.0 m /d) and a reservoir level > 2'232.15 m a.s.l. (= safe level) triggers danger level 4. Immediately, the reservoir owner informs the emergency center of the police about the new danger level and the intermediate outlet is totally opened; if possible, the bottom outlet and the turbines are additionally used with maximum capacity. The water alarm center at the Lago Bianco reservoir is now permanently manned. The police closes down both railway and highway over the Bernina pass.
- **Danger level 5:** A glacier flow speed ≥ 5 pixel/day (≈ 1.0 m/d) continuously reported over 5 days and a reservoir level > 2'232.15 m a.s.l. (= safe level) triggers danger level 5. Immediately, the water alarm is activated and the Swiss civil protection sirens alarm the population to evacuate the possible flooding area of an Arlas dam breach. The reservoir owner informs the emergency center of the police about the new danger level and the activation of the water alarm. The lowering of the reservoir continues with the totally opened intermediate outlet and if possible with the full capacity of the bottom outlet and the turbines.

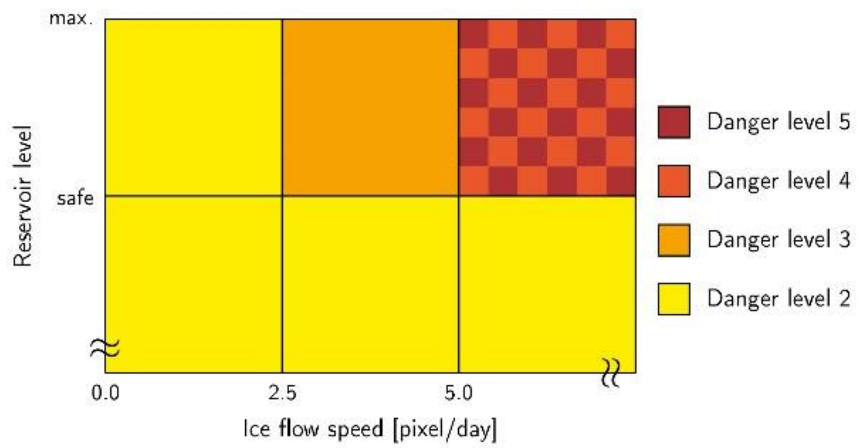

Fig. 11: Emergency levels 2 to 5 as a function of the ice flow speed of the Cambrena glacier and the water level in the Lago Bianco reservoir.

Img. 11 : Niveaux d'urgence 2 à 5 en fonction de la vitesse de déplacement de la glace du glacier de Cambrena et du niveau d'eau dans le réservoir de Lago Bianco.

7. ADJUSTMENTS TO THE EMERGENCY PREPAREDNESS PLAN

The measuring of the actual ice thickness allows a more precise estimate of the possible ice rupture volume. In May 2017, a first such measurement was carried out [2]. Fig. 12 presents the glacier profiles measured with a helicopter-based radar system. The measurements showed ice thicknesses between 40 and 60 m. Repetitions of these measurements are planned in the coming years until the Cambrena glacier has retreated out of the steep zone.

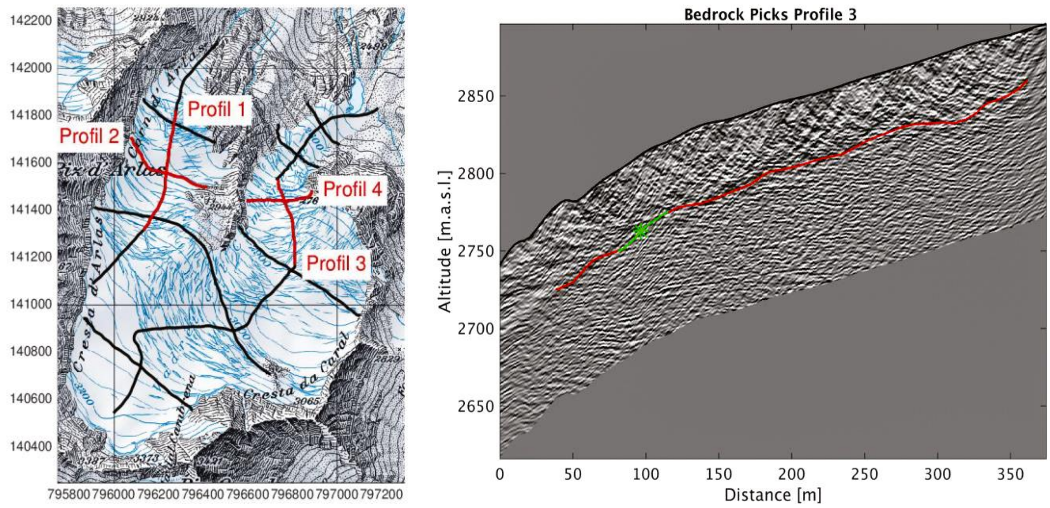

Fig. 12: Profiles for the thickness measurements on the Cambrena glacier carried out in May 2017 (left); results for profile 3 with red line showing the bedrock altitude (right) [2].

Img. 12 : Profils des mesures d'épaisseur sur le glacier de Cambrena en mai 2017 (à gauche) ; résultats du profil 3 au moyen d'une ligne rouge indiquant l'altitude du socle rocheux (à droite) [2].

As soon as a new estimate of the possible rupture volume becomes available, the calculations of the ice avalanche and the impulse flood wave can be repeated. Eventually the results will allow for an adjustment of the safe level of the Lago Bianco reservoir. This would permit a slower reservoir lowering process with less damage downstream of the Scala dam.

ACKNOWLEDGEMENTS

The authors want to express their thankfulness for the support given by R. Vassella and C. Pelazzi from Repower AG, R. Baumann from Rebau Engineering AG, K. Steiger and W. Schmutz.

SUMMARY

In 2015 it was discovered that the retreating Cambrena glacier had introduced a new risk to the Lago Bianco reservoir in southwestern Switzerland. The melting southern glacier tongue could eventually lose its support, rupture off, move as an ice avalanche down to the reservoir and initiate an impulse flood wave with danger of a breach of one of the reservoirs two dams. Therefore, the owner of

the Lago Bianco reservoir Repower AG established a special emergency preparedness plan. It is based on two elements:

- Continuous surveillance of the Cambrena glacier by an automatic photographic camera to measure the ice flow speed.
- Lowering of the Lago Bianco reservoir in case of a high ice flow speed to a level, which still guarantees the stability of the dam.

If the ice flow speed increases faster than predicted before the safe reservoir level is reached, the emergency service of the Swiss civil protection will alarm the population in the danger zone to evacuate and close down both railway and highway passing by the reservoir.

SERVER DESIGN STANDARDS OF RESERVOIR FAILURE ALERT SYSTEM

Baeg LEE, Byoung-Han CHOI

Researcher of Region & Infrastructure Research Group, RURAL RESEARCH INSTITUTE, KRC

KOREA

1. INTRODUCTION

In recent years, a great number of reservoir failures have been reported in many countries including Korea. Especially, the large increase in hydrologic variables due to meteorological variability & climate change and the rapid progress of facility aging are factors that threaten the stability of reservoirs. The lack of flood control capacity due to the hydrologic variables which have increased from the stage of design and the loss of function due to aging are directly linked to reservoir overflows and structure failures & damage. In addition, the increased number of residents due to the development of downstream areas is directly related to massive casualties and property damages. Therefore, along with the existing safety evaluation, a failure alert system that detects and controls early signs of failure and damage in real time, considering various risk factors and uncertainties, is desperately needed.

In order to propose server design standards for the Reservoir Failure Alert System, similar cases in Korea were analyzed and pros and cons were examined. Design standards have been established after considering them. The server design standards set goals in each of the four aspects: database (DB) design, hardware (H/W) configuration, software (S/W) configuration, and framework (F/W) configuration. Sever design standards are proposed to achieve each goal.

2. SERVER DESIGN STANDARD ESTABLISHMENT METHODS

2.1. RESERVOIR STATUS AND TARGETS

Over the past 100 years, rainfall intensity has decreased by 18%, while precipitation has increased by 17% (KMA, 2004). The increase in hydrologic variables due to climate change along with the aging of reservoirs are factors that threaten the stability of reservoirs. According to the "Statistical Yearbook of Land and Water Development for Agriculture (2014)", there are 17,427 reservoirs designated as agricultural irrigation facilities, and about 51% of them are over 70 years old.

According to the Rearrangement of Agricultural and Fishing Villages Act (MAFRA, 2016), domestic reservoirs are classified into Level 1 of 1,197 and Level 2 of 16,203, and subject to safety management according to the safety grade (Table 1) (Choi and Lee, 2015). In the case of Level 1 reservoirs (reservoirs with a capacity of 300,000 tons or more), they are checked for safety inspection and precision safety diagnosis according to the system. However, Level 2 reservoirs (reservoirs with a capacity of 300,000 tons or less) can receive safety inspections only on a quarterly basis, and if there is a sign of abnormality, precision safety diagnosis can be requested.

Table 1 Classification of state evaluation of structures

Safety grade	Condition of Structures
A	Excellent condition of structure
B	Mostly excellent condition of structure
C	Normal condition without difficulties in the safety management
D	Condition requiring partial repair and reinforcement
E	Condition requiring urgent repair and reinforcement

Among domestic reservoirs, the reservoirs which are actually subject to failure, are small and medium reservoirs with reservoir capacity between 200,000 and 300,000 tons. There are 884 such reservoirs scattered throughout the country. It also shows that the safety grade does not guarantee the actual safety of reservoir. In this reality, the configuration of the failure alert system should be constructed and operated for small and medium reservoirs, which are vulnerable due to poor management, by counteracting the aging of facilities, the rapid increase in hydrologic variables due to climate change, and the increased number of residents due to the development of reservoir downstream areas, in order to minimize damage on humans and properties.

2.2. STRUCTURAL HEALTH MONITORING

Structural health monitoring is a technique to diagnose the exact state of a structure by collecting and analyzing the responses of the structure from the sensors installed in the structure. It began in the aerospace industry and has expanded into many areas.

Real-time integrated disaster management is possible if the structural (or facility) health monitoring methodology is applied to social infrastructures such as reservoirs (dams). This benefit should be introduced into the Reservoir Safety Management System; such a system enables to minimize damages by identifying and remediating risks before a disaster occurs, and minimize damages on humans and properties by forecasting to the public in case of failure (Choi et al., 2014).

2.3. RESERVOIR MONITORING REGULATIONS

According to Article 3 Paragraph 3 of the ʹReservoir and Dam Safety Control and Disaster Prevention Actʹ (MPSS, 2014), reservoirs and dam caretakers shall install various monitoring facilities or observation facilities for reservoirs and dams designated as dangerous, and keep & manage records through monitoring and observation. According to Article 15 of the ʹNational Disaster Management Standardsʹ (2010), in the case of reservoirs which are under control of local governments, the competent disaster management authority shall collect and analyze risk factors present in the area and detect the likelihood of disaster in advance, according to the content of the disaster health monitoring. The authority shall then establish a disaster health monitoring plan in order to support decision making by making reviews on installing a sensor system, collecting and analysing data, issuing a forecast or warning in accordance with monitoring, and establishing measures to minimize damage.

2.4. ALERT SYSTEM CONFIGURATION DESIGN GOALS

The C/S (Client-Server system) has the advantages of relatively short development period due to simple design application in handling calls to business logic and operating data service results, but it also has the disadvantages that client processing performance becomes degraded when dealing a rapid change of work and a large amount of data, the software is difficult to manage, and the scalability and flexibility of the system are difficult to achieve. Therefore, this alert system is aimed to be developed as a web system to respond actively to various sensors, business logic and changes of user's work, and to improve system utilization by reducing logic changes and client maintenance with minimal interface change.

3. CASE STUDY AND ANALYSIS

Similar cases related to domestic failure alert include the "Ubiquitous Sensor Network (USN) Reservoir Failure Forecasting and Warning System", an information pilot project of Korea Rural Community Corporation, the "Disaster Prevention Monitoring System", the "USN Steep Slope Failure Forecasting and Warning System " of the Ministry of Public Safety and Security, and the "Waterfront Structure Integrated Safety Management System" of Korea Water Resources Corporation (K-water).

3.1. USN RESERVOIR FAILURE FORECASTING AND WARNING SYSTEM

In the case of the USN Reservoir Failure Forecasting and Warning System, the monitored values collected from the sensors are managed by single tables, and the monitored data manages the correction values of the monitored data with meta information of monitored items, length, conversion formulas, etc. in the "Sensor Information" table. It also manages reference values for real-time forecasting and warning by managing the per-sensor-related risk criteria in separate tables (Fig. 1). The DB is a meta information management, which has a design structure in which a table change can be applied even if other kinds of sensors are added in the future.

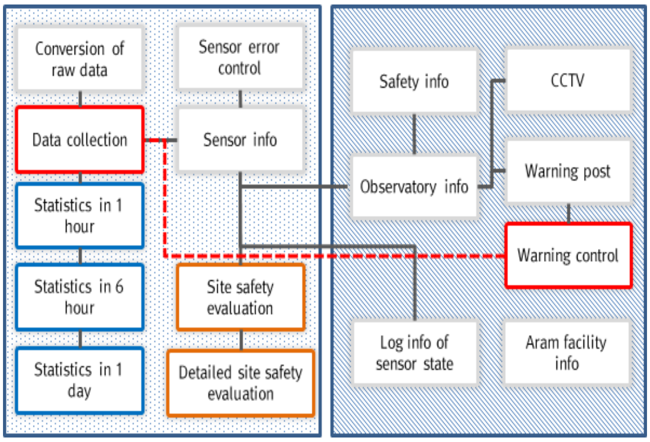

Fig. 1 DB Structure of Forecasting and Warning System for Reservoir

The configuration of H/W, S/W and F/W of the USN Reservoir Failure Forecasting and Warning System is in pilot operation constructed as follows. Sensors installed in reservoirs are connected to the data loggers by wire, and data collected by the sensors are delivered to the branch offices through the internet network. Monitored information gathered at the branch offices is used to search for forecasting and warning status and monitored values in real time through the monitoring system of the branch offices. The monitored data is sent through an external commercial network to the integrated monitoring system of the Rural Research Institute (Fig. 2). Due to this system configuration, the types of services between the branch offices and the Rural Research Institute Headquarters are different, requiring double management in maintenance and operation. In addition, there is a possibility of error in ensuring the consistency of data, and the data loggers may be dependent on a specific company and may be impossible to be upgraded in the future.

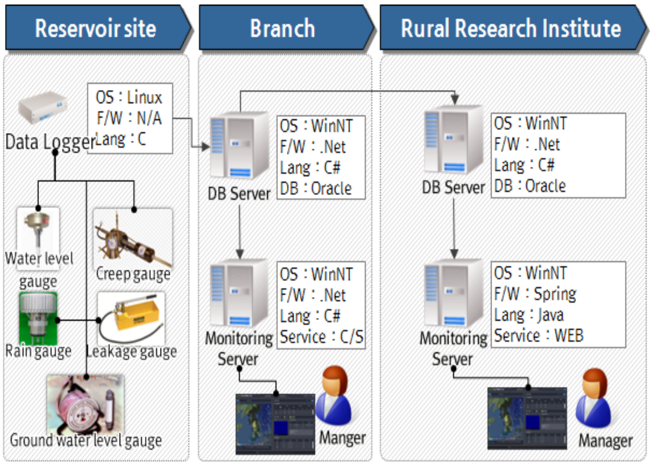

Fig. 2 System Structure of Reservoir Forecasting and Warning System

3.2. DISASTER PREVENTION MONITORING SYSTEM

The disaster prevention monitoring system is constructed for the reservoirs, which are more than 15m high and with a storage capacity of more than one million tons of water, among Level 1 reservoirs. It is a system which automatically collects and manages data from the installed sensors and manages the monitored values collected from the sensors by making separate tables for each gauge. It also provides scalability by generating up to 150 data table columns in case a sensor type is changed. The threshold value for each sensor is also managed as a separate table, and the reference values for real-time warning are stored and used for warning management (Fig. 3). The implications are as follows: "When a new sensor is added, a table for storing data of a new sensor must be newly created, and a screen for displaying the stored data must be newly developed. This limits the scalability."

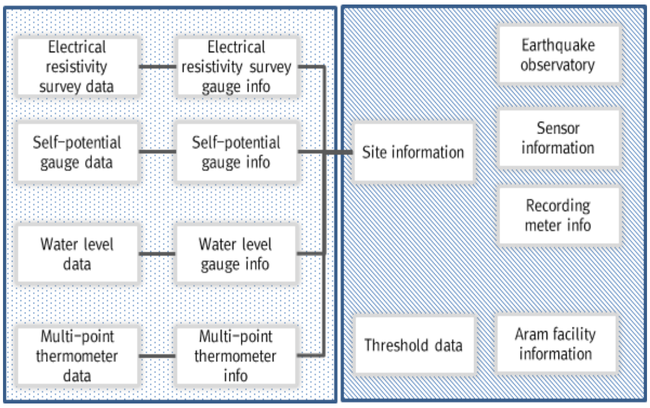

Fig. 3 DB Structure of Disaster Prevention Monitoring System

The configuration of H/W, S/W, and F/W of the disaster prevention monitoring system is as follows. The Rural Research Institute collects and manages the data of reservoirs directly, and the sensors installed in the reservoirs are communicated and monitored in a manner provided by the manufacturer. The central monitoring system is composed of the collection server, the DB server, and the monitoring server. The monitoring server uses the WEB server (server for static data processing) and the WAS (Web Application Server) server (server for dynamic data processing) without distinguishing them. In addition, the reservoirs equipped with an electrical resistivity sensor and a seismic accelerometer have installed and is currently operating a virtual private network (VPN) solution in order to achieve data security (Fig. 4).

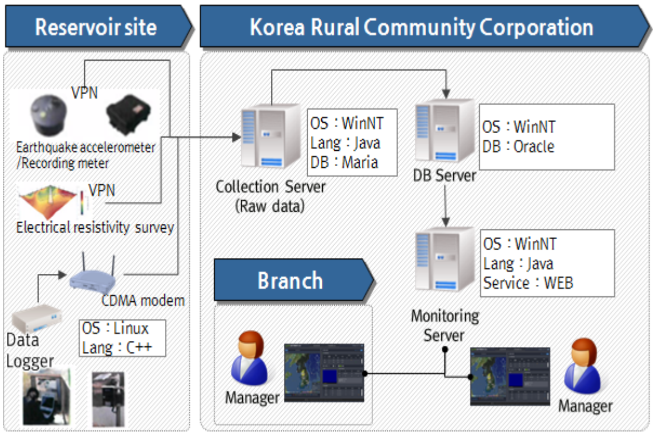

Fig. 4 System Structure of Disaster Prevention Monitoring System

3.3. USN STEEP SLOPE FAILURE FORECASTING AND WARING SYSTME

The USN Steep Slope Failure Forecasting and Warning System of the Ministry of Public Safety and Security is a pilot system constructed and operated in six districts up to the 3rd project from 2013, targeting the steep slope danger zones managed by local governments. It is a system which identifies risk of steep slopes with monitored data and makes a forecast and warning at the site. However, as of 2016, it has been merged with the National Disaster Management System (NDMS), and its programs have been revised mainly to focus on steep slope status management and monitored data retrieval rather than the forecasting and warning function. Accordingly, it is being operated with the tables for managing the established values for forecasting and warning removed, so that the function of the forecasting and warning system is lost (Fig. 5).

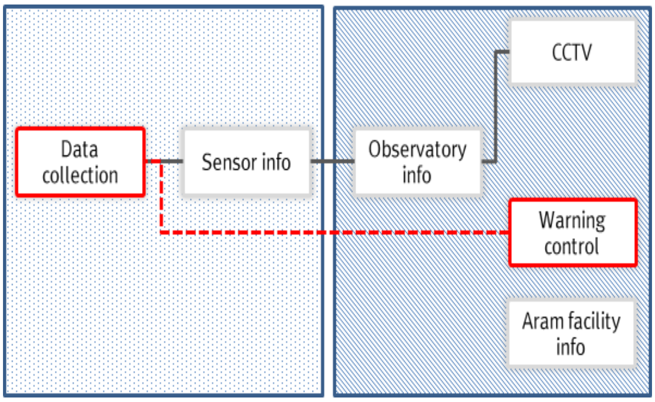

Fig. 5 DB Structure of Forecasting and Warning System for steep slope

The system configuration of H/W, S/W, and F/W of the USN Steep Slope Forecasting and Warning System is constructed as follows. The sensors installed in steep slopes are connected to the data loggers by wire. Collected data of the sensors are compiled into Si/Gun/Gu through internet. The monitored information collected in Si/Gun/Gu is transmitted to the NDMS system of the Ministry of Public Safety and Security via the administrative network. The monitored values are then monitored through the steep slope monitoring system of the NDMS (Fig. 6).

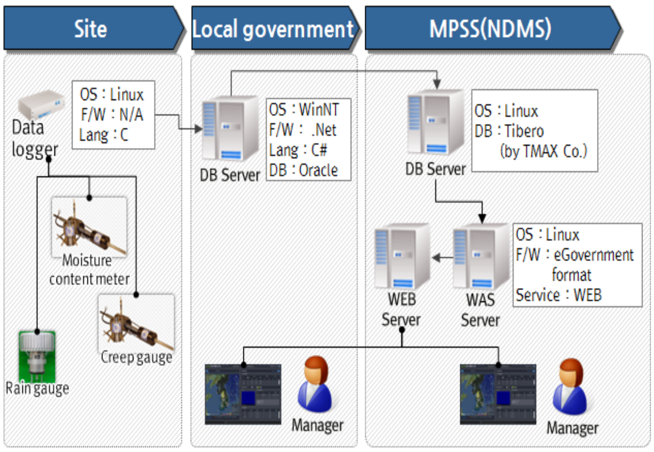

Fig. 6 System Structure of Forecasting and Warning System for steep slope

The H/W, S/W, and F/W that make up the system are installed in the G-Cloud environment of the National Computing and Information Service located in Daejeon. For this reason, they are being developed and operated as the Linux- and Java-based e-government framework that is established as the standard in e-government. All systems are made redundant, which are composed of a non-disruptive system in case of failure.

The integrated safety management platform based on the disaster scenario of Korea Water Resources Corporation is designed to standardize and store the monitored values of five items per sensor in single measurement tables, and issue a warning after comparing the stored data values with the values of the safety evaluation table of river water level and earthquake monitoring (Fig. 7). A system for the pilot service is currently under construction and will be launched in 2017. The safety evaluation values are managed based on river water level and earthquake monitoring values. A notable point is that it manages the SOP (Standard Operating Procedure) response status in the system by managing the SOP DB in case of a disaster.

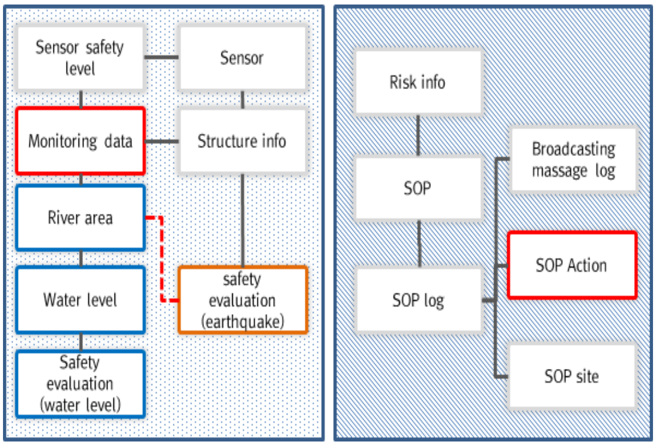

Fig. 7 DB Structure of Integrated Waterfront Infrastructure Safety Management System

The structure of H/W, S/W, and F/W of the integrated safety management platform based on the disaster scenario of Korea Water Resources Corporation (K-water) is composed of the following structure. Sensors installed in the Test Bed are connected with the data loggers. Monitored data is collected in the collection server of Korea Water Resources Corporation (K-water) through the CDMA wireless internet network. The monitoring system then monitors monitored values and safety assessment.

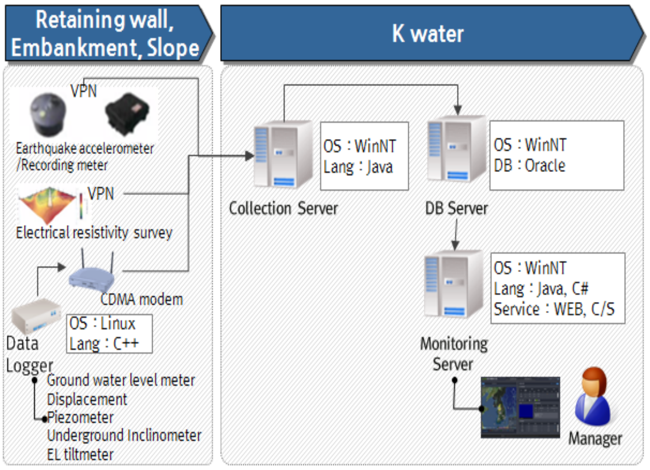

Fig. 8 System Structure of Integrated Water Infrastructure Safety Management System

The structure of H/W, S/W, and F/W of the integrated safety management platform based on the disaster scenario of Korea Water Resources Corporation (K-water) is composed of the following structure. Sensors installed in the Test Bed are connected with the data loggers. Monitored data is collected in the collection server of Korea Water Resources Corporation (K-water) through the CDMA wireless internet network. The monitoring system then monitors monitored values and safety assessment.

The H/W, S/W, and F/W that make up the system configuration are installed in Korea Water Resources Corporation (K-water). As the system is configured for a trial service, it is not redundant. It is based on the WinNT server, and the programs in use are mixed with C# and JAVA (Fig. 8). For S/W, the DB is configured with Oracle and the WAS with Tmax's JEUS product. In case of expansion of the system in the future, it is expected that the cost of introducing S/W will be increased. In addition, the transmission programs for each sensor use the program of the supplier, and the program for each function is not standardized and developed as WEB, C/S, single application or other ways. Therefore, it is considered that standardization work of the frameworks and programs should be carried out in various parts in case of dissemination after the test operation.

3.5. CASE ANALYSIS RESULTS

From a result of the analysis of similar cases, four programming languages such as C, C#, C++, and JAVA are being used as the development languages. When the development languages used in the data logger, the collection server, and the monitoring server are different, the maintenance cost for each program increases. In addition, as there are not enough people who can use four languages at the same time, there is a difficulty that programmers who can use each programming language must be secured separately.

The IoT framework is widely used for data analysis and communication. This framework is mainly based on Open Source. In the Reservoir Failure Alert System, the IoT framework can be used for the data logger that transmits the data collected by sensors to the collection server. If the data logger is constructed of a proprietary program of the development company, there will be problems due to dependency on the specific company in the future maintenance and expansion.

Oracle, Maria, and Tibero are used for the DB server management programs, and many commercial products and open source solutions exist today. The use of commercial products implies additional costs of program purchase, installation and operation.

The table configuration of the DB server is configured in various ways according to the structure of the system. Two representative methods are used: the method which is intuitive but lacks scalability by organizing tables by sensor type; and the method of considering scalability by managing single table configurations and alert reference values in separate tables.

The WAS server is a software to save the program and compute dynamic data during the time of the WEB service. It is not applied in most cases, but it is a necessary solution to distribute the system load for ensuring efficiency and performance when the number of users increases.

The processed sensor data is displayed to the C/S or the WEB system via the WEB server to be delivered to users. The C/S has the disadvantages of software management difficulties and difficulty in securing system scalability and flexibility.

Table 2 Purpose of H/W structure

Item	Purpose
Data Logger	To collect data from installed sensors in site
Collection Server	To collect data from Data Logger and send to DB Server
DB Server	To save observed data in the format of raw, statistic, backup, and processed
WAS Server	To access sensor data and to drive alert program
WEB Server	To save/service HTM and, image file

Table 2 shows the H/W and configuration purposes to be achieved in the failure alert system. The collection server, the DB server, the WAS server, and the WEB server must be configured independently to ensure efficiency and performance when the number of users increases. When constructing S/W, it is necessary to consider that the maintenance cost increases when a commercial S/W is introduced, and the program redevelopment cost occurs when the DB management system is changed. Since the monitored data volume is not vast, Open S/W must be configured as a basis. When configuring F/W, it must be configured in such a way that the transmission method for each sensor be unified, and could be integrated into the e-government framework, so as not to be dependent on the sensor and data logger vendor's program.

4. SERVER DESIGN STANDARD SUGGESTIONS

The analysis of the designs and operation status of similar cases and pre-installed systems led to the drafting of standards from the following three perspectives.

1. To integrate the Reservoir Forecasting and Warning System composed of two sides – sites and users & managers – into a single system
2. To introduce and operate a framework for monitored data collection and transmission, suitable for the failure alert system to remove the dependency to the sensor and data logger vendor.
3. To select the DB design considering convenience and extensibility in similar cases and pre-built system

In order to implement the above design standards, optimal solutions should be selected by examining the status of H/W in each programming language, in the DB server, in the WAS server and in the WEB server, and comparing with the existing frameworks and solutions used as the standards of electronic government businesses. The functional comparison between solutions is pointless in nature as there is currently a small variation in performances and functions for each solution. Therefore, the solutions are chosen considering both popularity and cost savings.

4.1. DEVELOPMENT LANGUAGE SELECTION

Currently, JAVA has been designated as the standard programming language for e-government projects. Looking at the global programming language share of August 2016, the most popular programming language used is JavaScript followed by Python, Java, and C (Nunns, 2016). Because the languages defined as the standards by the e-government among the four languages are Java and JavaScript, they have been selected as the standards in the reservoir alert system.

4.2. DATA LOGGER FRAMEWORK SELECTION

If the framework of data logger is built on the development company's own program, there will be problems caused by the dependency on the specific company in maintenance and expansion. In order to prevent these problems, basically public frameworks that are widely used around the world are applied and functions specialized for the reservoir alert system are built together. Docker and Apache Spark rank first and second in the global framework interest of 2016 (Nunns, 2016). In the case of Docker, there is a lot of interest but the cases of actually being applied to the field is still lacking. Therefore, Apache Spark, which is widely used as a core framework for other commercial solutions, is chosen to be used in the data logger framework of the reservoir alert system.

4.3. DB SERVER SOLUTION SELECTION

The DB server is used to store and manage data. It stores monitored information of sensors for the Reservoir Failure Alert System. Although many commercial products and open source solutions exist, open source solutions are chosen in terms of cost saving because there is a small variation in performance and function. Currently, CUBRID, MariaDB, MongoDB, and MySQL are used. CUBRID is a free open source option specifically optimized for web applications, and has the advantage that its complex web services can handle large amounts of data and generate simultaneous requests of large amounts of data (Champagne, 2016). Thanks to these advantages, the standards of the domestic e-government system recommends CUBRID, a domestic open source DB solution. Therefore, it is selected as the standard in the Reservoir Failure Alert System as well.

4.4. DB TABLE DESIGN SELECTION

DB table is composed of a single table with the monitored values collected from the sensors. It enables the management of reference values for the real-time alert by managing risk criteria per sensor in a separate table (Fig 9).

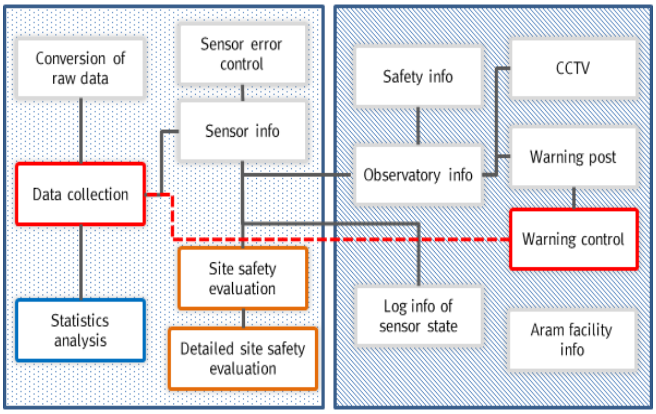

Fig. 9 Proposal of DB Table Design

Since extensibility needs to be considered for the DB table, the DB table is structured as follows. The transmission format of the monitored data of each sensor is standardized to organize the data into 4 kinds and the measurement value columns of the monitored data storage table are limited to four (Fig. 10 (a)). It is reflected in the design in order to operate the system regardless of the sensor manufacturer, by conforming to the standard data format even if a sensor is added in the future. The DB is a meta information management which has a design structure adjustable to a table change, even if other kinds of sensors are added in the future.

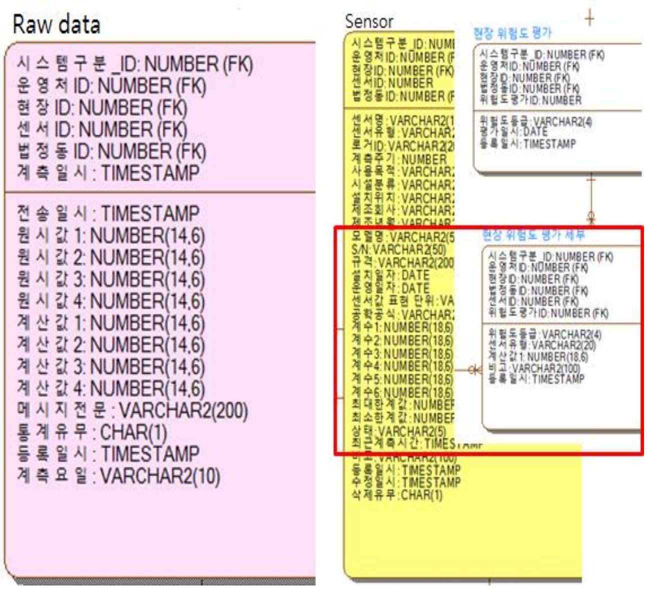

Fig. 10 Proposal of DB Table Design; (a) Raw Data table structure (left), (b) Basic and correction data table structure (right)

The table columns of the DB are constructed considering the inclusion of the following: the general information of sensors, such as sensor type, model name, manufacturer, warranty period, and image storing column, as well as engineering formulas and coefficient values for correcting the monitored values of sensors, such as engineering formulas, coefficients, minimum limit value, and maximum limit value (Fig 10(b)). Even if sensors of the same nature are used, the methods of correcting deviation of measurement values are different according to the sensor manufacturer. Therefore, columns are used to reflect the measures for securing future scalability in the DB design. Furthermore, it is necessary to construct a table that can set the threshold separately for each sensor installed, and to use it as a reference value.

4.5. WAS SERVER SOLUTION SELECTION

The WAS server is a software that processes business logic like calculating and storing data by storing the program during the time of the WEB service, and is a solution located between the WEB server and the DB server. Currently, commercial products and open source solutions are being used as the WAS server. Typical WAS platforms used in 2016 include IBM WebSphere, Oracle WebLogic, RedHat JBoss, and open source Tocat. The domestic product is Tmax's JEUS product (Kharkovsk, 2016). IBM's WebSphere product offers many features, but not all of these features are necessary. The reservoir alert system intended to be built is fully operational with RedHat's Jboss solution, which is based on open source. It is also a recommended standard for the e-government system. Therefore, Jboss solution is selected for the above reasons.

4.6. WEB SERVER SOLUTION SELECTION

The WEB server is a software that is used to store and serve HTML documents, images and files during the time of the WEB service, and is located at the front of WEB service. Currently, commercial products and open source solutions are being used as the WEB server. In terms of worldwide share of Web servers in 2016, the open source Apache solution accounts for 45%, followed by Microsoft's IIS, a commercial solution (Netcraft, 2016). The open-source Apache is currently being recommended as the e-government standard. Therefore, the Apache solution is chosen as the standard of the reservoir alert system as well.

4.7. DRAFT OF RESERVOIR FAILURE ALERT SYSTEM DESIGN STANDARDS

Table 3 Selected S/W for alert system

Item	S/W	Reason
Development language	JAVA	- WEB program standard - e-Government standard framework
Operating system	Linux	- Open source so low application cost - To work in low H/W spec
Communication F/W	Apache spark	- Open source so no application cost - IoT real time data collection and analysis
DB	Cubrid	- Open source so no application cost - DB of eGovernment standard
WAS Server	JBOSS	- Open source so low application cost - WAS S/W of e-Government standard
WEB Server	Apache	- Open source so low application cost - WEB S/W of e-Government standard

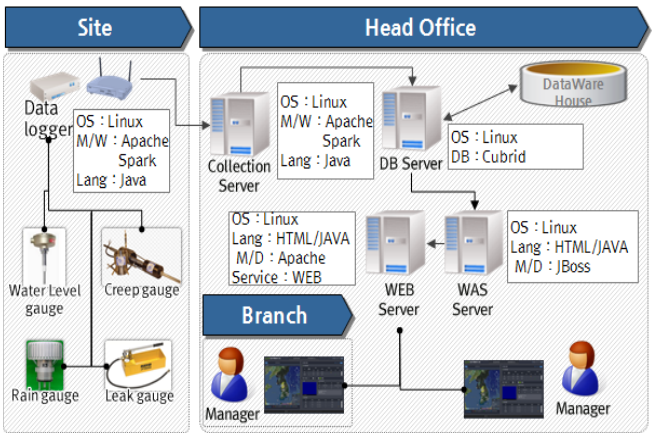

Fig. 11 Proposal of Server H/W, S/W, and F/W design

The H/W and S/W introduced to establish the system design standards are structured using the G-Cloud construction and operation environment of the National Computing and Information Service located in Daejeon as a reference, which is currently being used as the standard of the e-government system. The H/W configuration of the introduced WEB, WAS, and DB server use the introduced H/W that supports the open O/S Linux as the standard, and the basic O/S is based on the Open S/W Linux. Table 3 shows the results and the server design is constructed as shown in Fig 11. DB table is structured as a single table, and since extensibility has to be considered, measurement value columns of the monitored data storage table are limited to four. In addition, for a stable service, all the system configurations are made redundant from collection to display for non-disruptive service as a principle.

5. CONCLUSION

In order to present the server design standards (draft) in this study, the analysis of similar cases and the e-government standard frame were comprehensively considered to derive the directions of the system as follows:

First, Java and JavaScript are chosen as the standard languages, taking into consideration the unification of development language, program share, and the e-government standard framework.

Second, Apache Spark is chosen as the data logger solution in order to avoid problems caused by dependency on specific companies, and to fit the e-government standard frame.

Third, CUBRID is selected as the DB solution because it is an open source program good for cost saving and fits the e-government standard framework.

Fourth, The DB table consists of single tables of collected measurement values, the risk standards for each sensor is managed in a separate table, and the DB adopts the table methods that can manage with the meta information.

Fifth, RedHat's JBoss solution based on open source is selected as the WAS server to handle business logic.

Sixth, the Apache solution is chosen as the standard of the WEB server solution to be strong in security and minimize maintenance cost according to the e-government standard framework.

SLOPE MONITORING BY DISTRIBUTED FIBER-OPTIC SENSING: PROJECT EXAMPLES, RESULTS AND LIMITATIONS

Michael ITEN & Frank FISCHLI

Marmota Engineering AG, ZURICH

SWITZERLAND

1. INTRODUCTION

Reservoir slopes, dams and hydropower infrastructure, such as water pipelines or transportation ways, often lay within areas of potential soil movements. These areas, affected by unstable slopes and differential settlements, mostly have a large aerial extension, which makes it particularly difficult to identify the critical zones. Distributed fiber-optic sensors, that are capable of providing monitoring data for thousands of individual sections along a sensor of up to several kilometers of length, can reveal possible threats over a large area.

The authors have wide experience with soil- and rock-embedded fiber-optic sensing solutions for landslide and infrastructure monitoring, particularly:

- Pipeline monitoring in creeping landslides;
- Dam stability monitoring by borehole-embedded sensors;
- Landslide site investigation by horizontal and vertical sensors;
- Possible substitution of inclinometers by fiber-optic sensors.

Besides detailed project examples and monitoring data of these projects, the challenges and limitations of the fiber-optic methods are discussed. In addition, a short introduction into the most prominent distributed fiber-optic strain sensing technologies is provided.

2. METHODOLOGY

2.1. DISTRIBUTED FIBER-OPTIC SENSING TECHNOLOGIES

A distributed sensing system means that sensor data is continuously (distributed) obtained over the full length of a sensor cable. This can be idealized as a gapless array of numerous point sensors aligned one after another. Continuous strain along optical fibers can be measured by several techniques based on the Brillouin scattering effect: spontaneous Brillouin scattering occurs when a light pulse guided through a silica fiber is backscattered by a nonlinear interaction with thermally excited acoustic waves. The scattered light undergoes a frequency shift, which is directly related to the strain and temperature in the medium. Thus, in addition to the strain sensor cable, a loose fiber must be placed for temperature compensation. The backscatter is recorded in the time domain to obtain information of the scattering location along the fiber. The frequency shift of the signal is analyzed and converted into strain and temperature data.

When using spontaneous Brillouin scattering (Brillouin Optical Time Domain Reflectometry - BOTDR), the signal is weak and thus, frequency shift information not very accurate as well as possible distance of signal transfer is limited. In the more refined stimulated Brillouin setup (e.g. Brillouin Optical Time Domain Analysis - BOTDA), two counter-propagating light waves at different frequencies interact via stimulated acoustic waves [1]. The interaction results in an energy transfer and thus, amplifies the signal, which leads to higher accuracy of the measured strain as well as longer sensor lengths. With BOTDA technology, the strain measured is an average value over the spatial resolution (typically 1 m), which corresponds directly to the wavelength of the light pulse sent down the fiber. The readout resolution is about 2 $\mu\varepsilon$ and the maximum sensing distance is > 30 km.

Distributed strain measurement technologies can also be based on Rayleigh scattering. Commercially available Rayleigh technology is currently limited to 70 m sensing length and due to this limitation, it has not been used in the monitoring projects below.

2.2. MONITORING CONCEPTS

The different sensing concepts can mainly be divided in terms of the angle between movement and sensor direction and type of movement which is to be detected (see Figure 1). A distributed fiber-optic sensor measures strain and or temperature changes along its longitudinal direction. Therefore, the most obvious application is a situation in which the main movement acts in the direction of the installed sensor (e.g. in vertically installed sensors in boreholes or piles for load monitoring). In many cases however, the direction of movement is not parallel to the installed sensor, since such installation is not possible, or the exact location of the movement is not known and needs to be detected. Applications where the sensor is subjected to angled movements can be used for qualitative assessments of movements and for quantitative analysis by adopting a suitable model for the data interpretation.

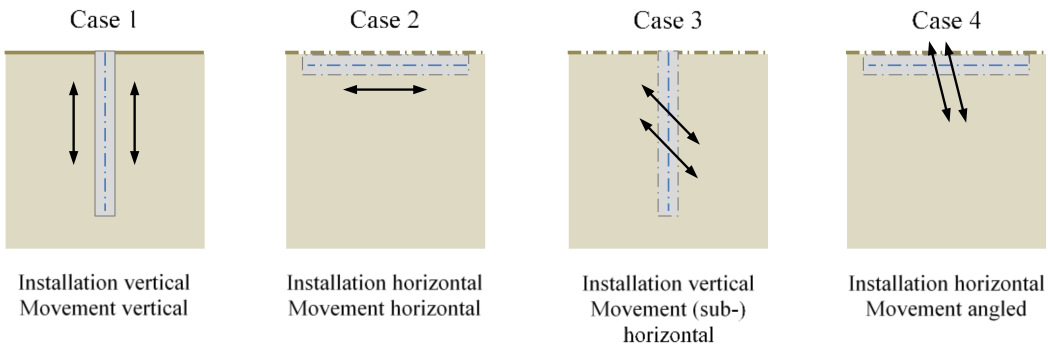

Fig. 1
Schematic layout of the different sensing cases (blue dotted line shows sensor).

2.3. DATA INTERPRETATION FOR ONE LONGITUDINAL SENSOR

In Figure 2a, a movement of point B induces strain in the sensor section AB (of length equal to the spatial resolution of the applied measurement technology). Thus, for a measured strain ε in the fiber sensor, L_0 changes to L_n. This means, that the new location of B is anywhere on the circle with center A and radius L_n. In the case were the movement angle can be sufficiently well estimated, a good quantitative assessment is possible. This is especially true for movements at angles β below 85° and above 95° to the sensor axis. Figure 2b shows the movement that can be detected over the typical spatial resolution of 1 m with a typical measurement resolution of 2 με.

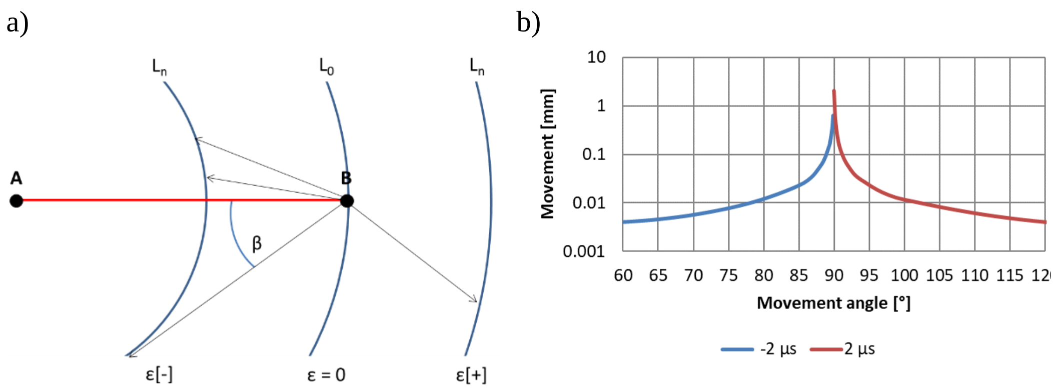

Fig. 2
(a) Possible movements of point B for a given measured strain with unknown movement angle β; (b) influence of movement angle for the data interpretation.

2.4. DATA INTERPRETATION FOR THREE OR MORE LONGITUDINAL SENSORS OVER THE CROSS SECTION

As shown in Figure 3 below, it is possible to arrange several longitudinal sensors over the cross section of a circular structure. A movement of point F then induces strains in the sensor sections AB and CD. Assuming the cross section stays planar and the geometry does not change, the movement of point F can be calculated as well as its movement angle. An advantage is also that this model does not need a temperature compensation but is self-compensating.

It must be noted that for both concepts shown above (one or three and more longitudinal sensors), it is necessary to know at least one point along the structure in its absolute coordinates. Preferably, this is obtained geodetically.

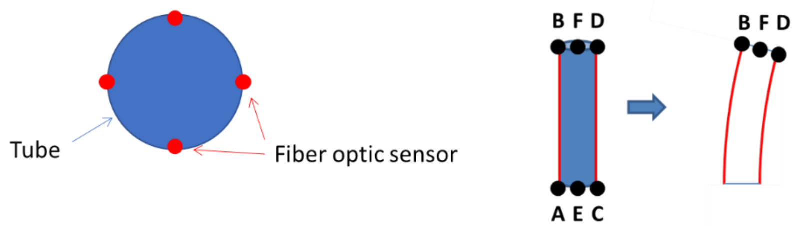

Fig. 3
Arrangement of four longitudinal sensors over the cross section of a tube.

3. PROJECT EXAMPLES

3.1. SUCCESSFUL APPLICATIONS

Possible applications for geotechnical monitoring using fiber-optic sensors are numerous and soil-embedment of sensors has been studied by the authors for years (e.g. [2]). In order to bring it to a successful practical implementation, the concepts have to satisfy certain requirements: sufficient reliability for a given task, practical applicability, acceptance by infrastructure experts/decision makers and commercial effectiveness. In the next paragraphs selected successful applications that have been awarded as commercial projects (i.e. the authors have been contracted by private or public entities to carry out the job) are shown.

3.2. LANDSLIDE SITE INVESTIGATION

Unstable reservoir slopes can endanger the reservoir itself as well as constructions on them. However, the extent of the landslides and its boundaries may not be sufficiently known from surface observation only. Distributed fiber-optic sensors can help to localize the shear zones and quantify their extent, as well as specify the moving areas. To localize shear zones, sensors can be placed vertically into boreholes (c.f. Figure 1 Case 1) or horizontally, directly into the soil or into roads (c.f. Figure 1 Case 2). Several landslide site investigation projects have been carried out in the Swiss Alps from 2006 to 2016:

In the mountain resort of St. Moritz, which is partly built on a creeping landslide, selected roads and boreholes have been instrumented with the goal of identifying if constructions will be on stable or moving ground. For example, a horizontal sensor was embedded in a road (Figure 4a) ahead of the construction of a new water reservoir. Another sensor was installed vertically in a borehole (Figure 4b) to detect possible sliding surfaces and its depths. A fiber-optic sensor was chosen over an inclinometer since it was more economical and faster to detect, and the main interest was the sliding surfaces depth. Only of secondary interest was the magnitude and the direction of the movement. The depth of the borehole was 42 m which coincides with the stable rock surface. Thus, a deeper sliding surface could be excluded. After a measurement period of only 3 months, one sliding surface could already be detected at 35 m depth within the overlaying soil layer (Figure 4c). The magnitude of displacement (approx. 4 mm) was estimated assuming a movement in direction of the dip at 80° to the sensor axis. The identification of this sliding layer was significant for the new building construction measures that were applicable according to the construction regulations.

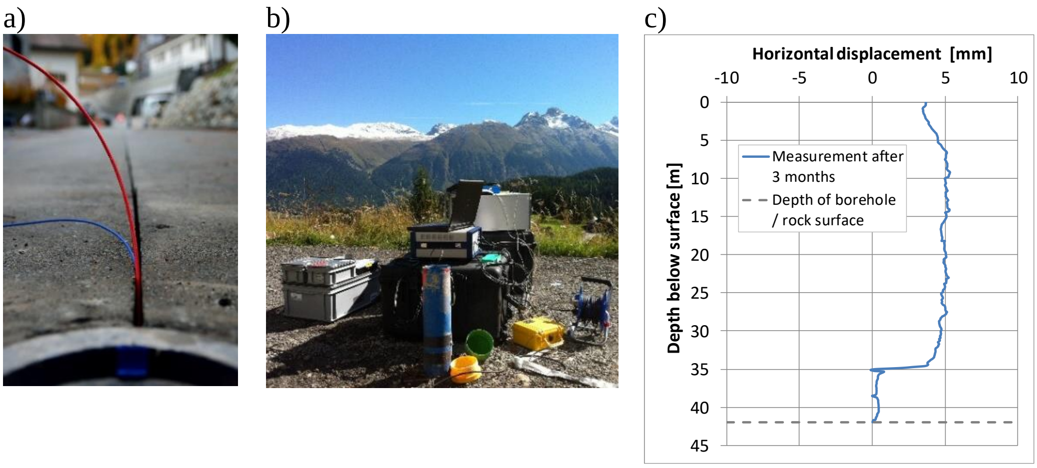

Fig. 4
Strain sensors for the detection of landslide boundaries: (a) embedded into a road; (b) vertical sensor embedded into a borehole; (c) results of borehole measurements.

Below the small town of Brienzauls, which apparently lies on a rather fast creeping landslide, a 125 m deep borehole was instrumented (Figure 5a). The objectives of the installation were to detect the presumably several sliding layers and quantify the magnitude of displacements. The usage of distributed fiber-optic sensors was ideal for this application as the depth and numbers of the sliding surface was unknown. In addition, the sensors could be assembled with high flexibility to adjust for the reached borehole depth. The results of the horizontal movements calculated from strain measurements and combined with the geodetic measurements at the borehole head are shown in Figure 5b. Different sliding surfaces could be detected. Further, it can be observed that the geodetically measured displacements do not only accumulate over the depth of the borehole but also below. It is assumed that more sliding layers exist in greater depths. This first installation provides a deeper insight in the behavior of the unstable slope and now serves as a basis to more extensive instrumentation and deeper boreholes.

a) b)

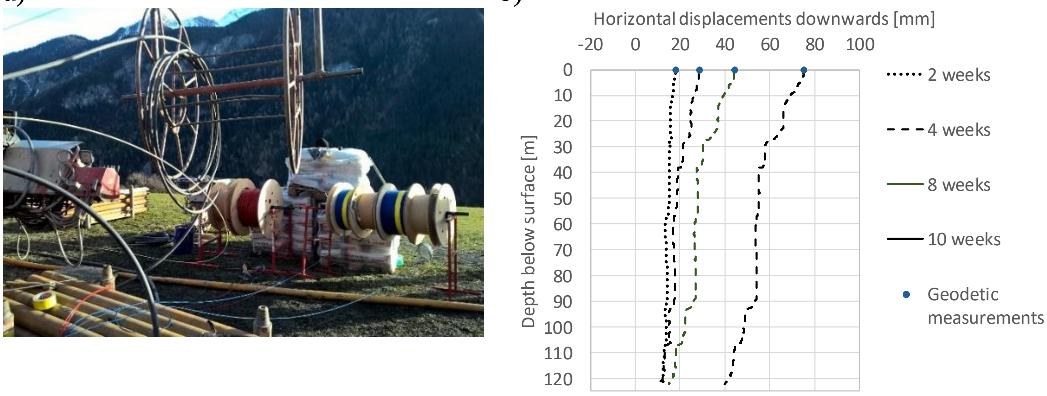

Fig. 5
(a) Installation of strained temperature sensors in the borehole; (b) horizontal displacements over the depth of the borehole.

3.3. Pipeline monitoring in creeping landslides

The headrace pipe of a newly built hydropower plant crosses steep slopes in a mountain area close to the small village of Tschiertschen, Switzerland (Figure 6a). The slopes within the first pipeline kilometer are known to be unstable, however the exact locations and the extent of the movements were not known. The use of conventional monitoring techniques (e.g. geodetic measurement or radar) was not optimal due to the changing vegetation (forest and fields) and the large extension of the endangered area. Therefore, it was decided to install a distributed fiber-optic measurement system running parallel to the pipe (Figure 6b) allowing for gapless monitoring. The cables were embedded into soil, starting from a service building at the water intake from where also the measurements are carried out.

The measurements are reported as strain along the sensor and thus in the direction of the pipeline. For example, Figure 7a shows the strain data for a two year period. Qualitatively, stable ground can be read out from the smooth strain sections (i.e. 150 m to 280 m, 470 m to 650 m, 730 m to 830 m). Strain peaks indicate shear zones (i.e. around 720 m and 950 m) and a large creeping zone can be evaluated from 850 to 1000 m (unstable strain profile). Further details are highlighted in Figures 7b and 7c. The most probable interpretation of the compression in Figure 7b is a shearing movement angled to the pipeline. The magnitude of the movement can be calculated by assuming a movement parallel to the surface with a direction of the dip at an angle of 75 to 82 ° to the pipeline. Having a maximum strain of roughly 0.35%, this results in a movement of 4 mm to 40 mm. In Figure 7c, two elongation peaks are combined with a compression in between. The section lies in a concave part of the slope and can be interpreted as a sliding within the concave part. This results in compression in the center and extension at the outer ends.

Similar monitoring systems were successfully installed in further projects during 2015 and 2016 for hydropower and gas pipelines. Monitoring is ongoing.

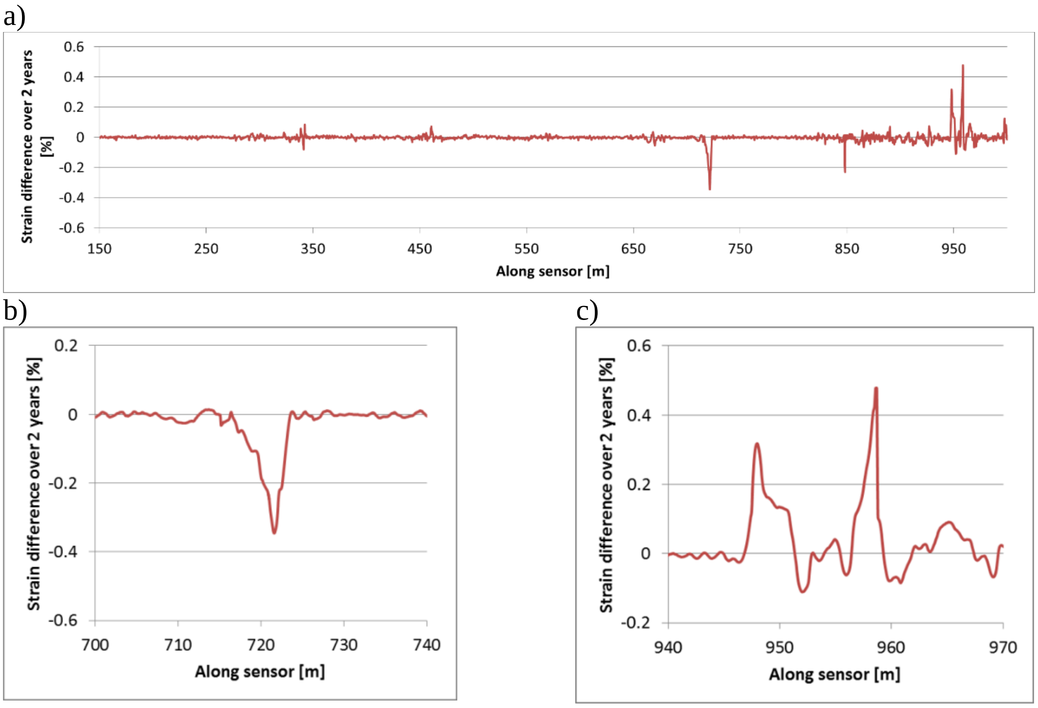

Fig. 7

Field data for pipeline monitoring over a roughly two year period: (a) over the first kilometer; (b) around 720 m; (c) around 950 m.

3.4. DAM STABILITY MONITORING

For mining repositories, the material is often disposed of in tailings. Such tailings dams can grow up to a height of 100 m and more, thus loading the ground below significantly up to its limit. Settlement as well as sub-surface monitoring by inclinometers are the main methods to detect a sliding surface development. Since borehole-embedded distributed fiber-optic sensors may offer a more efficient alternative, a trial was performed in two 150 m deep boreholes between 2014 and 2017 in a mine in Poland. In Figure 8, the results of one installation, which consists of four longitudinal sensors fixed to the outside of an inclinometer tube (c.f. 2.4) are displayed. This installation allowed to measure and compare the fiber-optic setup and the inclinometer simultaneously. The main shear surface at 80 m elevation is well recognized by both methods as well as the general amplitude of the movements. Below the main shear surface, the absolute data varies significantly.

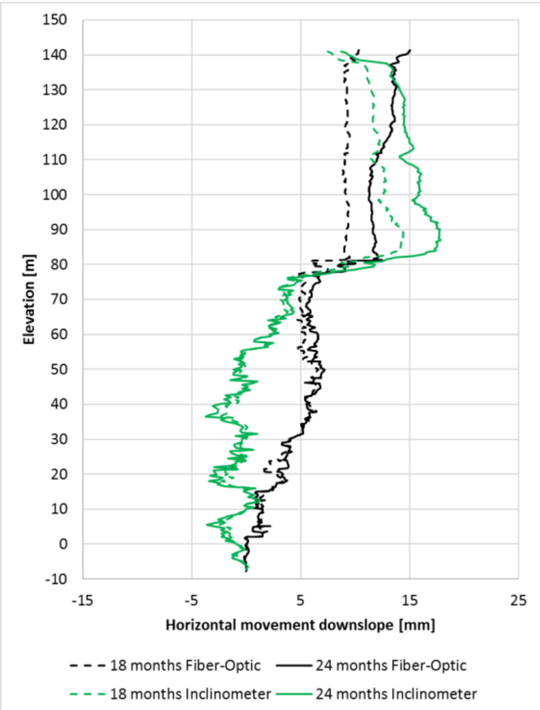

Fig. 8
Comparison of the movements measured by inclinometer and fiber-optic sensors.

4. DISSCUSSION AND CONCLUSIONS

4.1. MONITORING RESULTS AND LIMITATIONS

For one-dimensional problems, where the main strain vector is in the direction of the sensor axis, accurate results of good quality can be obtained straightforward. When the movement is not in the direction of the sensor axis, which is the case for most projects, the interpretation is more challenging. The angle of movement direction (in relation to the sensor axis) plays a major role for the accurate interpretation of the measured strain. The strong dependency of a fixed measured strain value (e.g. 2 με) interpreted into movement is shown in Figure 2b. Particularly at angles between 85° and 95°, quantitative interpretation is prone to large uncertainties. Additional difficulties for quantitative interpretation arise for cases where changing angles are expected, either over time or over distance or even both. Despite the difficulties in movement quantification, especially in the following situations good results are possible:

a) Only qualitative interpretation expected: detection and localization of shear zones (strain peaks), moving grounds (unstable strain profile) and stable ground (smooth strain profile). This can be seen for example in Figure 7a.

b) Strain profiles in boreholes: qualitative information about shear zones, moving and stable ground. By measuring the borehole head and or estimating the movement angle, the horizontal movement over depth can be estimated and a good idea of quantitative behavior is obtained. Yet, it is important to distinct between this kind of instrumentation and inclinometers: not the same results are produced, and this shall not be expected or promised for such instrumentation.

c) Pipeline monitoring: since the sensor axis is in the direction of the pipeline axis, the actual impact of a movement on the pipeline can be measured. The amount of the movement is not the major interest, but more the effect of the movement on the pipeline strain.

4.2. CONCLUSIONS

From the theory outlined and the projects shown in this paper, the following main conclusions can be drawn:

1) Well-funded monitoring results were obtained and compared with data obtained by third parties (e.g. geodetic measurements). Due to the high sensitivity of the fiber-optic sensors (resolution of 2 με) as well as the possibility to place the sensors as close to the location where measurements are desired (e.g. inside the soil, not only on the surface), movements are often much quicker detected as compared to other methods. Thus, additional time for decision making and reaction is gained.
2) The equipping of soil (horizontal and vertical) with only one longitudinal sensor is a simple and efficient method. Especially when it comes to assessing the effect of a movement for a one-dimensional structure (pipeline), the detection and quantification of the extent of shear zones, as well as the order of magnitude of the movement of individual ground layers. The installation is straightforward and cost-efficient, even for large size projects.
3) For boreholes, one must be aware, however, that this is not a one to one substitution of an inclinometer. Nevertheless, depending on the project,

it may as well provide more than sufficient information about the ground behavior. And in contrary to the inclinometer this information can be obtained by a moderate installation and readout effort. In general, the authors see a large potential for the instrumentation of boreholes. The main challenge is not on the technical side, but rather in convincing the engineers that often, full inclinometer information is not required.

4) For most cases, the main priority should be the qualitative assessement since it is rather difficult to obtain quantitative results.

SUMMARY

Reservoir slopes, dams and hydropower infrastructure, such as water pipelines or transportation ways, lay often within areas of potential soil movements. These areas affected by unstable slopes and differential settlements mostly have a large extension, which makes it particularly difficult to identify the critical zones. Distributed fiber-optic sensors that are capable of providing monitoring data for thousands of individual sections along a sensor of up to several kilometers of length can reveal the possible threats over a large area. The authors have wide experience with soil- and rock-embedded distributed fiber-optic sensing solutions for landslide and infrastructure monitoring and share their particular experience in this paper. Besides detailed project examples and monitoring data, the challenges and limitations of the fiber-optic methods are discussed.

Les pentes du réservoir, les barrages ainsi que les infrastructures hydroélectriques, se trouvent souvent dans des zones de mouvements potentiels du sol. Ces zones ont pour la plupart une extension importante, ce qui rend particulièrement difficile l'identification des zones critiques. Des capteurs à fibre optique distribués pouvant atteindre plusieurs kilomètres de longueur peuvent révéler les menaces possibles sur une grande surface. Les auteurs aimeraient partager leur expérience avec des solutions de détection à fibres optiques distribuées enrobées de terre pour la surveillance des glissements de terrain.

ABSTRACT

This paper is focused on the use of InSAR (Synthetic Aperture Radar Interferometry) and PhotoMonitoring^{TM} techniques for dams and reservoir slopes monitoring.

The technological and scientific advances in the field of remote sensing have allowed the spread of different technologies that currently represent powerful tools for the surficial monitoring of ground and infrastructures. This paper allows to circulate and to make known the capabilities of these technologies for dams monitoring applications. In particular, Terrestrial and Satellite SAR interferometric techniques and the innovative remote sensing approach called PhotoMonitoring^{TM}, are introduced highlighting their potential and the possible applications for dams and reservoir slopes monitoring. Furthermore, two example of applications based on Terrestrial and Satellite SAR interferometric techniques have been described.

1. INTRODUCTION

Remote sensing techniques can be a powerful tool for structural health assessment of dams and for reservoir slopes monitoring. The evolution of traditional technologies and the development of emerging technologies (e.g., satellite and terrestrial radar technologies and PhotoMonitoring^{TM}) offer a wide spectrum of monitoring solutions. These technologies find application during different stages of the life cycle of a dam (e.g., design, construction, operation and maintenance) and can be applied effectively in several crucial operations, such as (i) dam reservoir site selection, (ii) reservoir catchment management, (iii) detection and control of geohazard-prone areas, (iv) structural health monitoring (SHM) of dams, (v) risk management and risk-informed decision-making.

Over the last decades, several monitoring approaches have been adopted, ranging from visual inspection to instrumental continuous monitoring [1-4]. At this regard, Satellite and Terrestrial SAR Interferometry can be an effective tools for the engineers in charge of SHM [5,6], representing a unique solution in the monitoring of structures, such as the capability to provide information about the ongoing and past deformations with millimeter accuracy.

As regards the radar-based technologies, satellite and terrestrial SAR (Synthetic Aperture Radar) interferometry represents one of the most advanced and effective techniques for monitoring deformation of both ground and man-made structures.

The main strengths of satellite SAR interferometry are the capability of monitoring large areas with high accuracy and the ability to perform historical analyses (thanks to archive satellite SAR images available from 1992). These characteristics allow to observe and measure reservoir slopes and to detect potentially unstable slopes at reservoir scale, in order to undertake the appropriate risk management strategies.

Terrestrial SAR interferometry, on the other hand, thanks to its high sampling frequency of data collection (in the order of few minutes or even seconds) and its high accuracy of displacement measurement (up to decimal millimeter order), has proven to be effective for local-scale, real-time slopes and structures monitoring, currently considered a proper technology for early warning purposes.

In addition to radar-based technologies, cutting-edge solutions like the PhotoMonitoring^{TM} are now available for dams and reservoir slopes monitoring. The concept PhotoMonitoring^{TM} refers to different image processing techniques, used for geotechnical and structural monitoring purposes. Among these techniques are included the digital image correlation (DIC), the change detection and the 3D photogrammetry.

In the following paragraphs, the description of the techniques and an overview of some projects carried out by NHAZCA S.r.l. using terrestrial and satellite SAR interferometry and PhotoMonitoring^{TM} techniques are presented.

2. TERRESTRIAL SAR INTERFEROMETRY

2.1. BASIC PRINCIPLES AND APPLICATIONS

Terrestrial SAR Interferometry (TInSAR) is an all-time (night and day), all-weather, non-contact, high-accuracy and fully remote sensing technique based on an active radar sensor that emits microwaves and receives the return of scattering objects. The final output is a 2D displacement map of the investigated scenario along the instrumental Line of sight (LOS), i.e., the path between the sensor and the target. In addition, for every measurement point characterized by high backscattering features, it is possible to obtain the time series of displacement.

The SAR principle is achieved by moving the sensors along a rail and by combining the backscattered signals using focusing algorithms, that allow to obtain high resolution 2D images in range (sensor-target direction) and cross-range (orthogonal to the range; [7]) directions. The length of the rail determines the cross-range resolution of the acquired images (i.e., the longer the rail, the higher the cross-range resolution), while the distance between the instrument and the observed scenario determines the range resolution [8].

By the comparison of the phase value of SAR images collected at different times, sub-millimeter accuracy measurements can be obtained (interferometric principle). According to the site-specific conditions, the system's accuracy can range between some tenths of a millimeter, in the optimal monitoring conditions (very high signal to noise ratio values), to some millimeters (Figure 1).

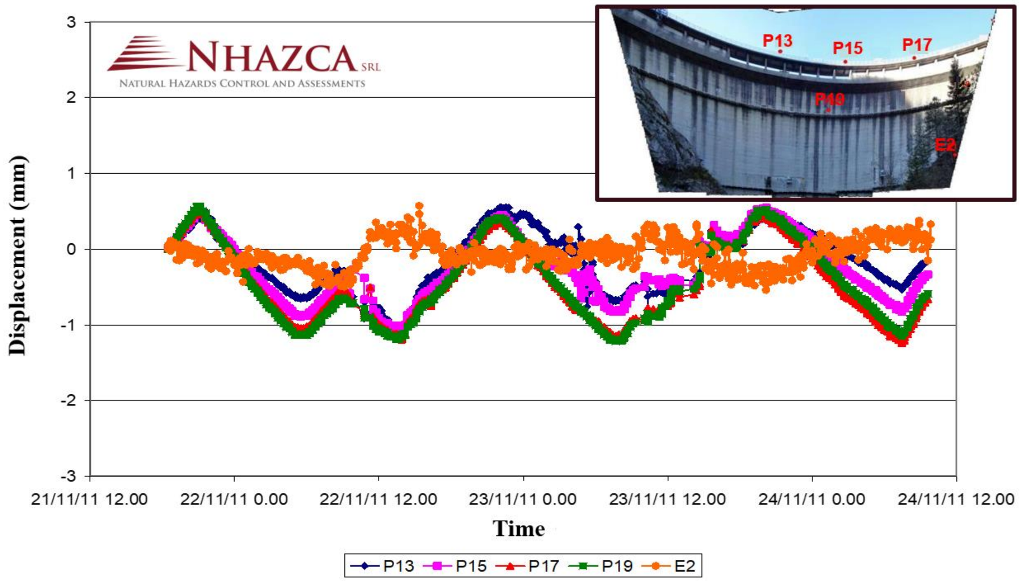

Figure 1. Example of time series of displacement (in millimeters) obtained with TInSAR in correspondence of a concrete arch dam in Northern Italy. The high accuracy of the collected displacements (up to a few hundredths of a millimeter) allowed to capture the thermal deformation behavior of the concrete dam.

Thanks to the active nature of the sensor, the TInSAR instrument does not need artificial reflectors, allowing to monitor the deformational behavior of ground and structure/infrastructure from a completely remote point of view. However, in particular conditions, artificial reflectors on the ground (i.e., the so-called corner reflectors) would allow to improve the data accuracy and the density of measurement points.

The high data sampling frequency (up to 30 seconds), the high spatial resolution, the continuous monitoring capabilities (both in time and in space) and the high accuracy in terms of displacement monitoring, make TInSAR a suitable instrument for different applications and purposes such as [9]:

- knowledge monitoring, to characterize and assess the processes under investigation in ordinary operational conditions;
- control monitoring, to quantitatively check the evolution of known issues;
- emergency monitoring, in order to provide alert in case the risk become unacceptable.

An example of application of the TInSAR technique for the monitoring of the right flank of an earth dam is reported in paragraph 2.2.

2.2. TINSAR MONITORING OF AN EARTH DAM

In the frame of the engineering works for the stabilization of the right flank of an earth dam in Central Italy, a continuous 24/7 TInSAR monitoring has been setup. The activity has been performed for the following purposes: i) early warning for the safety of workers and ii) improvement of knowledge about the deformational behavior of the slope, also thanks to the correlation of TInSAR data with weather data and information from other monitoring instruments.

The measurements have been acquired in continuous, with a sampling period of few minutes. The data have been pre-processed on site through suitable algorithms and then transferred to the NHAZCA monitoring center, where they have been processed using a semi-automatic software. A phase of automatic image processing and internal alarms notification was performed to guarantee the early warning purposes. In case defined thresholds were exceeded, after the data validation performed by an expert user, the alarm procedure is activated.

During the 2 years of monitoring, localized surface displacements have been observed in the central part of the slope (Figure 2). In particular, more than 300 mm of displacements have been detected on the right flank of the earth dam. However, the deformations were ascribed to anthropic work activities and shallow debris movements correlated with rainfalls that did not cause concerns among the decision makers.

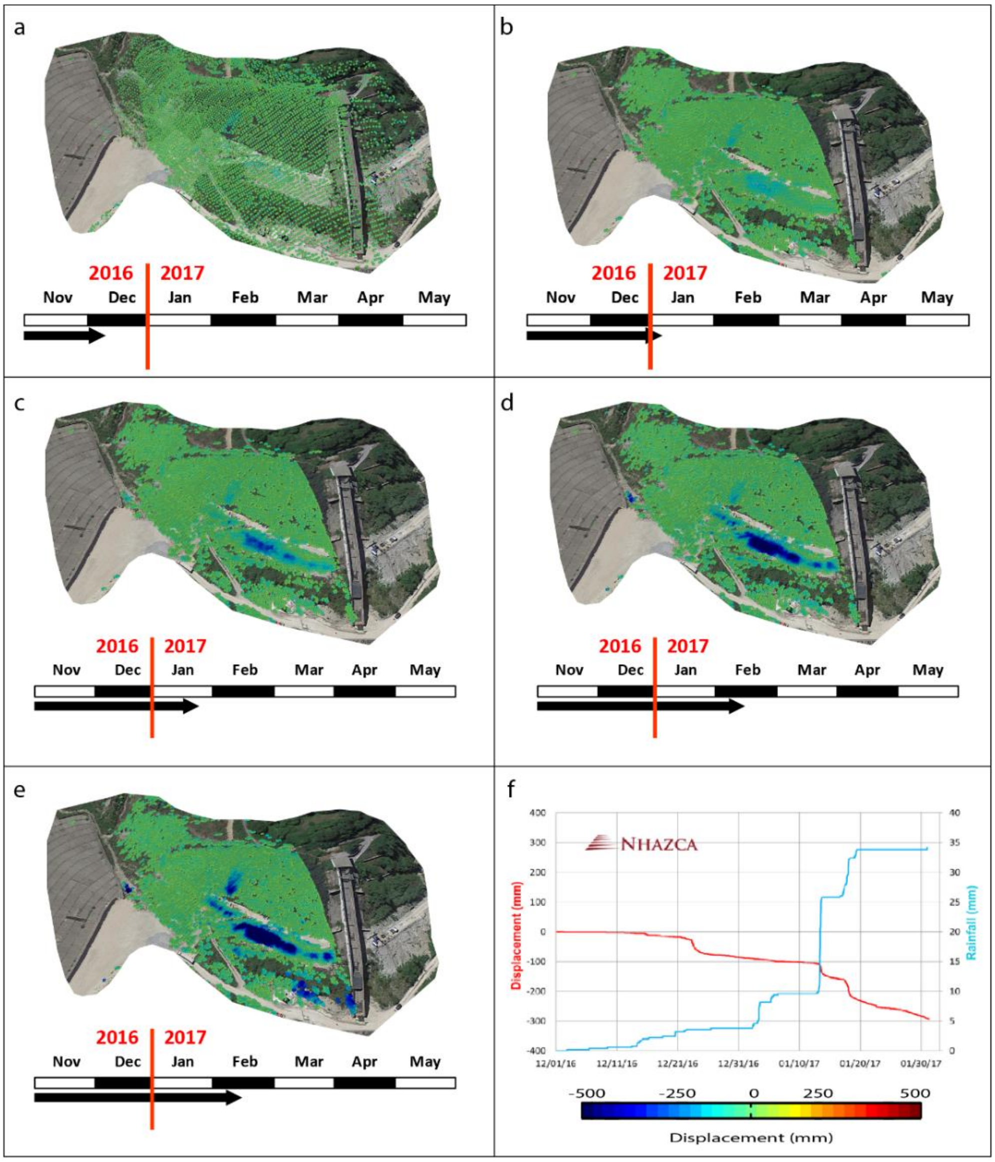

Figure 2. a - e) TInSAR multi-temporal deformation maps in tridimensional view; f) time series of displacement of one of the measured point inside the moving area and the relation between rainfall and displacements can be observed. The color of the points indicates the intensity and the direction of displacements. Specifically, negative values (light blue to dark blue) are points with deformation direction towards the sensor, while positive values (yellow to red) refer to points moving away to the sensor. Green points are considered stable.

3. SATELLITE SAR INTERFEROMETRY

3.1. REPEAT PASS SATELLITE SAR INTERFEROMETRY

Satellite Synthetic Aperture Radar (SAR) Interferometry has proved its capability in monitoring the ground and structures deformation with high accuracy

[10-14]. With respect to other traditional methods, this technology can work at all-time, with all-weather conditions and it is suitable for both wide areas and site-specific applications. A further relevant characteristic of Satellite SAR Interferometry is the possibility to retrieve information on the deformation history of the area of interest, looking back in time using the SAR data archives of the Spatial Agencies. In fact, the first global systematic acquisition of SAR imagery started in the early 1990s, with ERS-1 and -2 satellites (European Space Agency). Since then, images have been collected in several parts of the world with revisit times of the order of some days (for examples the Envisat-ASAR sensor had a revisit time of 35 days, while the recent Sentinel-1 constellation has a revisit time of only 6 days).

A SAR image consists of a matrix of resolution cells (i.e., pixels) that contain the information about the satellite-target distance. Surficial deformations can be investigated through to the Differential InSAR (DInSAR) methodology, that is based on the phase difference between two SAR images collected in different times (computing in the so-called interferogram), allowing to estimate the displacement occurred between the two acquisitions. In order to overcome the major limitations of the DInSAR technique, like the influence of the atmospheric phase screen (APS), long time series of SAR images are used in the Advanced Differential InSAR (A-DInSAR) technique. This latter take advantage of several SAR images collected in the same area over time to perform deformation measurements [10, 11]. A-DInSAR methodology allows to obtain the displacement-time information of natural targets on the ground, which are measured along the satellite Line of Sight (LOS).

The Persistent Scatterers Interferometry (PSI) is one of the most effective A-DInSAR techniques, based on the analysis of specific targets on the Earth's surface (called Persistent Scatterers, PSs) characterized by long time-coherent behavior [10, 12].

The main outputs of a PSI analysis are: i) the trend of deformation during the investigated time period; ii) the time series of displacement, with an accuracy up to few millimeters; iii) the height of the target on the ground; iv) cyclic (non-linear) deformation due to several factors (e.g., temperature variations).

3.2. A-DInSAR historical analysis of 2 rock-fill dams

A preliminary site-specific PSI analysis has been carried out for two rock-fill dams in USA (Figure 3a, b). The two reservoirs serve as terminal basins for the water supply of Colorado Springs and surrounding municipalities.

The A-DInSAR historical analysis has been performed using a stack of 114 high-resolution COSMO-SkyMed (form Italian Space Agency, ASI) scenes collected in the time span ranges between 2011 and 2016, in the ascending geometry of acquisition.

The multi-image processing technique allowed the analysis of the past deformational behavior of the dam bodies. The velocity measurements have been obtained with millimeter accuracy in the LOS direction (the average velocity map is showed in Figure 3c). The measurement points in correspondence of the dam flanks show a general stability, while constrained ground deformations have been observed in the lower portion of the dam '*b'* in Figure 3c, where linear deformation behavior has been observed during the 5 years monitoring period, with an average velocity trend ranging between 3 and 7 mm/year.

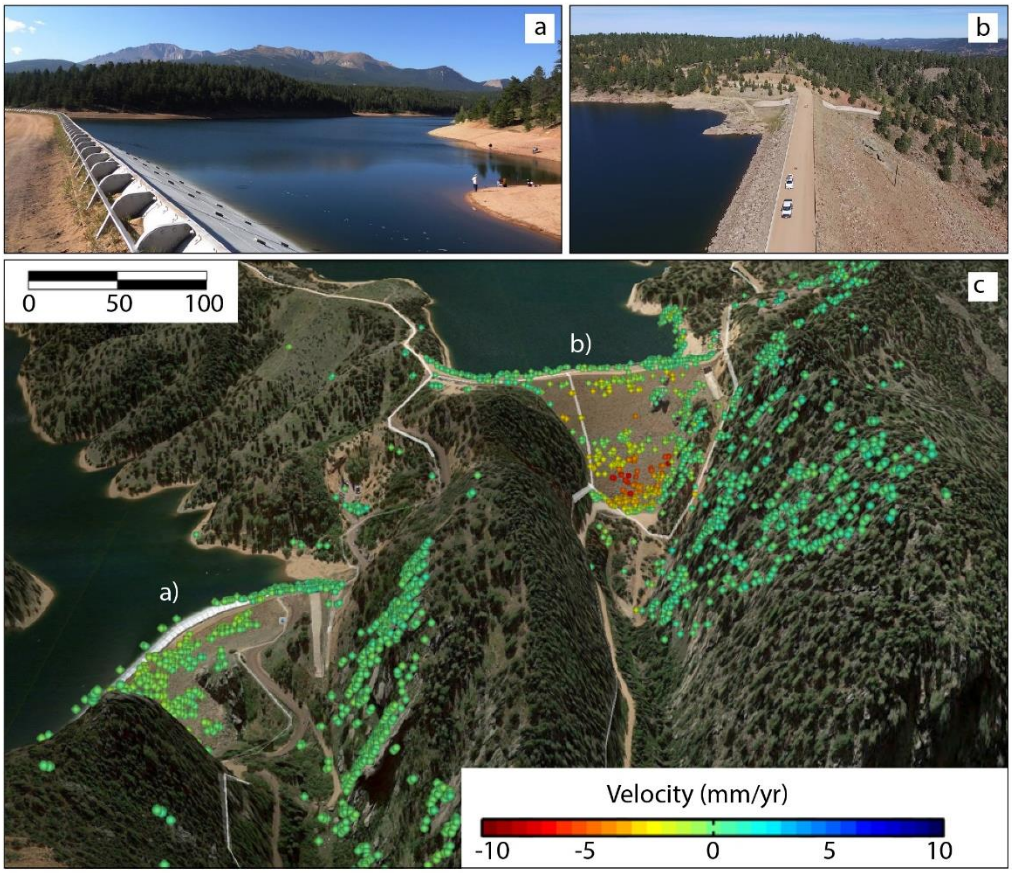

Figure 3. The two dams under investigation (a, b) and A-DInSAR results (c). For every measurement point, it is possible to observe the displacement rate in mm/year. Negative values (yellow to red) are points with deformation rate away from the satellite, while positive values (light blue to dark blue) are points that move towards the sensor. Green points are stable. (COSMO-SkyMed Product - ©ASI - Agenzia Spaziale Italiana – (2017). All rights reserved).

4. PHOTOMONITORING™: AN INNOVATIVE MONITORING SOLUTION

In addition to radar-based technologies, cutting-edge solutions are now available for dams and reservoir slopes deformation analyses. PhotoMonitoring™ is one of the most innovative remote sensing solutions, useful for geotechnical and structural monitoring.

The increasing number of satellite-based, airborne and ground-based optical and radar sensors, have greatly increased the potential of PhotoMonitoring™ for engineering applications. Ranging from very high resolution (VHR) optical and/or multispectral cameras to low-cost and low resolution sensors, today an incredible amount of source of information can be exploited using the PhotoMonitoring™ approaches.

The approach of PhotoMonitoring™ is based on the integration of different remote sensing measurement techniques that allow to identify, analyze and quantify the surface changes/variations over time by processing two or several optical or multispectral images (e.g., satellite, aerial imagery or simple photos), collected at different times over the same area (www.photomonitoring.com).

Specifically, Change Detection (CD), Digital Image Correlation (DIC) and 3D Photogrammetry techniques can be combined, also with other remote or contact instruments for dams and reservoir slopes monitoring. In fact, it is possible to retrieve quantitative and qualitative measurement of surface changes on the investigated object (e.g., the surface of a concrete or earth dam, unstable reservoir slopes) with both Change Detection and Digital Image Correlation techniques. If Change Detection technique allows to identify, describe and quantify any changes of the area of interest, Digital Image Correlation technique allows the measurement of "full-field" deformation on the surface of investigated area. This is possible through the correlation of co-registered images, collected at different time intervals [15-19] (Figure 4).

The great adaptability of the technique makes PhotoMonitoring™ appropriate for several kinds of dam related applications. PhotoMonitoring™ can be an effective solution at different scales of investigation, from the single crack measurement to the reservoir scale.

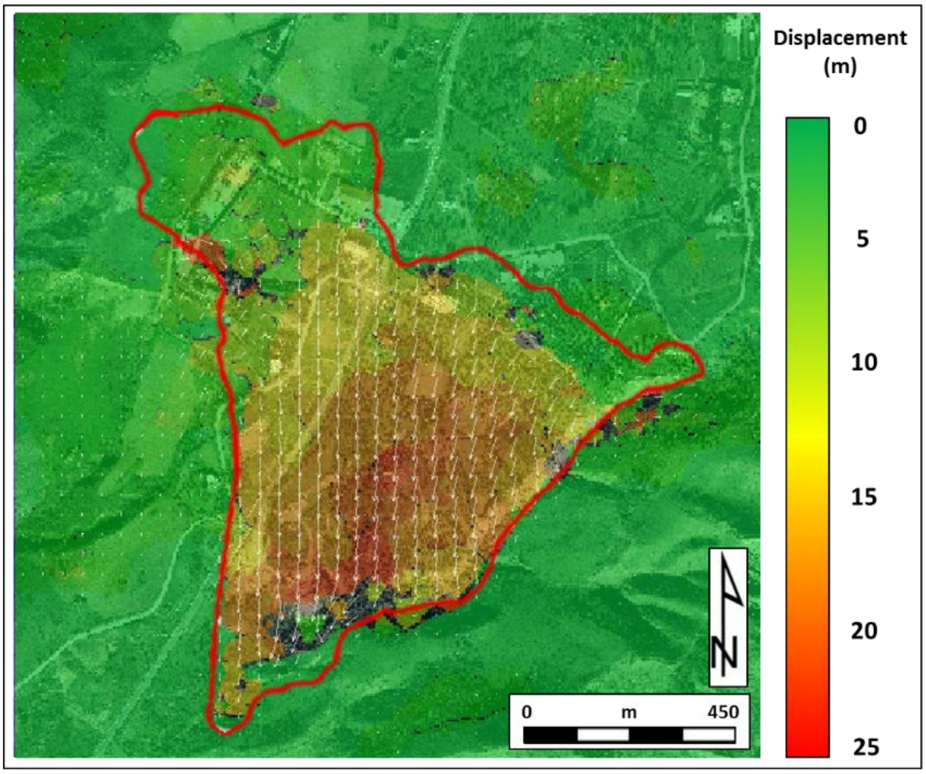

Figure 4. Example of 2D displacement map retrieved by DIC analysis performed on very high-resolution optical imagery. Here it is reported the displacement related to a large earth-slide, occurred in Italy. The landslide boundary is highlighted in red, while the displacement field is highlighted with white arrows.

In fact, satellite multispectral and/or radar images can be exploited with PhotoMonitoring™ approach for big scale application in order to investigate the stability of reservoir slopes and identifying insights of slope instability processes, thanks to the application of semi-automatic digital image analysis techniques. At the same time, terrestrial instrument based on the acquisition and processing with CD and DIC techniques of high-resolution photos can be installed for local-scale analysis, in order to monitor the 2D displacement field of the dam body or of a slope of interest. The accuracy in displacement measurement strictly depends on the kind of sensor used, the distance between the target and the collecting instrumentation and the environmental features, reaching a theoretical accuracy of 1/10 of pixel [20-24]. The terrestrial instrument, known as Virtual Digital Extensometer (VDE), can be completely managed from a remote location, allowing considerable advantages during emergency scenarios, where a quickly monitoring service is required and when traditional geological, geotechnical and structural monitoring techniques (such as inclinometers, strain gauges, crack-meter, etc.) cannot be applied avoiding risks and logistical problems.

3D Photogrammetry technique allows the reconstruction of 3D digital models, by using optical images with a high percentage of overlapping and through the implementation of Structure from Motion (SfM) algorithms. This latter can be the most suitable solution to have a comprehensive three-dimensional overview of the dam of interest [25-28]. As reported also in Buffi et al. (2017) [25], the 3D Photogrammetry technique, integrated with an UAV-based platform (Unmanned Aerial Vehicle) and traditional topographic techniques, can be the most suitable solution for the reconstruction of a 3D model of a dam. In addition, through the digital analysis of the three-dimensional model, it is possible to perform an accurate virtual inspection of the dam, even in correspondence of inaccessible or dangerous dam sectors.

5. CONCLUSIONS

This paper showed the potential of three different remote sensing monitoring solution for dams surveillance: Terrestrial SAR Interferometry (TInSAR), Satellite SAR Interferometry and PhotoMonitoring™.

The main capabilities of TInSAR (i.e., the high sampling frequency and the high accuracy of measurements) make it possible to use the technique to improve the knowledge about a deformation process, to control it over time and for emergency applications.

Satellite SAR Interferometry, and in particular, A-DInSAR technique, allows to perform both wide areas investigation and local scale analysis with high accuracy in terms of displacement measurements. The large-scale analysis can be very useful in order to investigate the state of activity of reservoir slopes, possibly detecting deformation anomalies where to focus the attention, allowing decision makers to plan further investigations. On the other hand, site-specific investigations can be carried out on localized area or structure, allowing to characterize and monitor the possible occurrence of deformations. The peculiarity of satellite InSAR is the possibility to perform historical analyses, exploring the deformation processes occurred in the past in order to improve the know-how about the investigated phenomena.

The PhotoMonitoring™ is an emerging group of technologies, which can be effectively used for long term monitoring surveys but also for quick analyses, taking advantage of the relatively low-cost of the technology.

In conclusion, the aforementioned remote sensing technologies represent powerful tools for several applications at different stages of the life cycle of a dam (design, construction and operation), such as: the reservoir catchment management, the structural and health monitoring of dams, geo-hazard monitoring and risk management.

1-INTRODUCTION

Among various engineering projects, dams construction and their industry involves major challenges. Since 1980 construction of earth and rock fill dams are more common than other type of dams. The reasons for this common usage are: the method of construction is based on ordinary technology with utilization of cheap raw soil materials, subsurface materials and does not depend on particular valley shape. Also, geometric design of embankment dams depends on barrowed soil materials, subsurface conditions and type of construction. Consequently feasible design can cause significant reduction on construction time, materials and costs. One of the main important factors for the failure of earth dams is the slope stability analysis in their body and abutments. In order to prevent the dam failure, it is essential to control the stability in the earth dam.

In this paper, software analysis results consisting of slope stability analysis at different loading conditions of dam performance within its effective life, analysis of seepage from Gambiri diversion dam earth dyke body and foundation, are presented, based on which, geometric design of Gambiri diversion dam parts is performed.

The Gambiri diversion dam site is located in Kunar province, eastern Afghanistan, near Asadabad city as shown in “Fig. 1”. The site location in the global coordinates system is defined with X =680248 and Y =3842647. The Gambiri diversion dam is an earth dam with a clay core and elevation from river bed is 10.5 meters.

Fig. 1
Location of the Gambiri diversion dam site in the eastern Afghanistan.

In order to identify and develop geological units within the project, geological map has been prepared based on field studies “Fig. 2”. According to the map, four sedimentary units with one hard formation of metamorphic rocks are observed within the project area. The sedimentary units include Quartenary sediments within the project area, deposited in the river-bed. Based on field surveys and the results of geotechnical studies, the Kunar River-bed sediments are mostly of rounded coarse aggregates in sizes of cobble, gravel, sand and small percentage of fines. From lithological point of view, some pieces of granite and gneiss stone are observed in these deposits. The Quartenary units overly the metamorphic unit in the diversion dam area. Metamorphic rocks are related to an early Proterozoic metamorphism (marked with X1gm sign).

No outcrops of this unit are observed around diversion dam site. The results of geophysical studies indicate that the depth to bedrock below earth surface at the diversion dam site is about 120 meters.

Dam site geological map

2- ANALYSIS METHOD

In order to achieve the objectives of this study, Slope/W software [1] is used. This program can calculate the safety factor (FOS) using Bishop [2], Janbu [3], Morgenstern-Price [4] and Spencer [5] methods. SLOPE/W is one component in a complete suite of geotechnical products called Geo-Slope, one of whose powerful features of the integrated approach is that it opens the door to types of analyses of a much wider and more complex spectrum of problems, including the use of finite element computed pore-water pressures and stresses in a stability analysis [6]. Slope/W can effectively analyze both simple and complex problems for a variety of slip surface shapes, pore-water pressure conditions, soil properties, analysis methods and loading conditions. In the present study, Morgenstern-Price method for slope stability analysis is used, which has more accuracy than modified Bishop Method while its difference with this method is negligible.

Minimum safety factor recommended for stability analysis in different loading conditions are given in “Table 1”. This table is prepared according to U.S. Army Corps of Engineers [7]. In slope stability analysis, failure safety factors calculated by limit equilibrium methods in different conditions of construction and operation are compared with allowable amounts recommended by references for downstream and upstream slopes [8].

Table 1.
Recommended safety factors for stability analysis at different conditions of diversion dam earth dyke

State	Situations	Minimum Safety Factor allowed	Explanations
1	End of Construction	1.3	Upstream & Downstream Slope
2	Seepage from partially full Reservoir	1.5	Upstream Slope
3	Water Rapid drawdown from Normal Level	1.2	Upstream Slope
4	Steady seepage from Normal Level	1.5	Downstream Slope
5	States 1.2 and 4 with Earthquake	1.0	Earthquake Coefficient

In the slope stability of upstream and downstream slopes of an earth-fill dam, stability analysis is generally performed in the following states:

- During or at the end of construction
- Operation state (steady seepage) and full reservoir (maximum water level)
- Each of above states in earthquake conditions
- Reservoir rapid drawdown

Considering each of these states, depends on the conditions of construction and operation stages. Important forces in slope stability analyses include water load and earthquake. In SLOPE/W software, excess pore pressure for different parts of materials can be defined. Pore pressure in soil resulted from construction can be defined as a percentage of vertical stress. In the current methods, pore pressure ratio (ru)is used instead of pore pressure (Uw). Usually according to experiences, ru is considered as 0.1 to 0.5. Pore pressure ratio (ru) is defined by [Eq. 1].

$$r_U = \frac{U_w}{\gamma z} \qquad [1]$$

In which U_w is pore pressure, γ is soil specific gravity and z is the depth of study point. Earthquake effects can be simulated by pseudo-static method. Pseudo-static slope stability analysis is done by introduction of a horizontal earthquake coefficient (static acceleration as in seismic studies). Earthquake force is considered as a percentage of weight of each segment in this method.

In order to select pseudo-static acceleration, references suggest a ratio of 0.27 - 0.5 of peak seismic acceleration [9].

So for selection of final seismic acceleration, "Eq. [2]" is used:

$$K_h = 0.5 \frac{PGAH}{g} \qquad [2]$$

In this relation, PGAH is the horizontal peak seismic acceleration. On this basis, seismic coefficients 0.14g and 0.18g are used for DBE seismic level (for end of construction and seepage from half full reservoir) and MDE seismic level (for other loading cases), respectively.

3- STABILITY ANALYSIS OF EARTH DYKE BODY SLOPES

All of the cross sections of an earth dam must be sufficiently stable in different loading conditions, to consider it safe and stable. Stability analysis of the critical cross section is done by investigation of foundation and abutments conditions. On this basis, body height and crest width of the maximum cross section are considered as 10.5 and 5 meters respectively.

3.1 ENGINEERING CHARACTERISTICS OF EARTH DYKE FOUNDATION AND BODY MATERIALS

In this analysis, dyke foundation is assumed to consist of two major layers:

- Upper alluvial layer consisting of sand and gravel with average density and a thickness of about 10 m
- Lower dense layer of sandy gravel with thickness about 60 m

Shear strength parameters used in the stability analyses for different parts of body and foundation are presented in "Table 2".

Table 2
Strength parameters of the different parts of body and foundation of earth dyke of Gambiri diversion dam

Materials	γwet (KN/m3)	γsat (KN/m3)	Internal Friction Angle (Degree)	Cohesion (KN/m2)
Upper Foundation (0-10m)	-	20	33	0
Lower dense Foundation (10-70m)	-	22	40	0
Rip Rap	22	22.5	40	0
Mixed Materials of Dyke Body (UU Parameters)	20.5	20	33	5
Mixed Materials of Dyke Body (Total Parameters)			25.4	10
Mixed Materials of Dyke Body (Effective Parameters)			29.2	6
Filter	19.5	20.5	30	0
Drain	20	20.5	31	0

3.2 ANALYSIS CONDITIONS

With attention to prior comments and according to construction and operation conditions, stability analyses of earth dyke were performed as below.

3.3 END OF EMBANKMENT CONSTRUCTION (EARTH DYKE)

In this state, embankment (earth dyke) construction is assumed to have been terminated but pore pressures due to dam construction still exist. Both upstream and downstream slopes are subject to instability. Critical condition is when the pore pressure in low permeable parts of embankment (earth dyke) is in maximum. To take pore pressures into account, stability analyses are performed by use of total stress parameters from UU triaxial test.

For relevant pseudo-static analysis, because of rather short duration of this state compared to dam life, using MDE seismic level is conservative. So DBE seismic level and acceleration of 0.14g is selected.

3.4 SEEPAGE FROM PARTIALLY FULL RESERVOIR

Here, half of the reservoir is assumed to be full and upstream slope is prone to instability. In this state, parameters of materials are selected from CD (drained) triaxial tests. Subjects mentioned about pseudo-static analysis at the end of construction, are universal in this condition too. So by DBE seismic level and prior comments acceleration 0.14 g is selected.

3.5 RAPID DRAWDOWN

Rapid drawdown happens when it is required to discharge reservoir water in a short time. It can cause upstream slope instability. Upstream slope stability in this condition is usually related to permeability of shell. Occurrence probability of this state in the diversion dams is too low.

In this state, parameters of low permeable materials are selected from CU triaxial test. This state is analyzed by assuming water in the maximum and normal levels.

3.6 STEADY SEEPAGE

In this state, downstream slope is subject to instability due to seepage forces. In this state parameters of materials are selected from CD triaxial test (like "seepage from partially full reservoir" condition). In this report steady seepage state is analyzed considering reservoir water in the maximum and normal levels. In the pseudo-static analysis using MDE seismic level and prior comments acceleration 0.18 g is selected.

Summary of results has been presented in "Fig. 3 to 6".

4- CONCLUSION

In the present study Slope/W software is used under different conditions to evaluate slope stability. Analyzes for each state and each slope with Morgenstern-Price methods is calculated that the minimum safety factor in each of this method, be considered as a safety factor (FOS) of slope stability. Stability analyses has done based on common finite element method at different loading conditions, and the results showed that dam body has no specific problem in terms of stability.

Based on the results from all slope stability analyses performed on critical section of Gambiri earth dyke in different loading conditions (static and pseudo-static analysis), it is observed that dyke body with upstream slope of 1:3 (vertical: horizontal) and downstream slope of 1: 2.5 (vertical: horizontal) is always stable.

EXTENDED ABSTRACT

The dam basin and the area around it could affected by important geological phenomena such as slope instability, erosion and sedimentation. Recently, a new methodology for the mapping of intertidal for the mapping of intertidal zone in estuarine, based on the use of Synthetic Aperture Radar (SAR) images [1]. This result makes the use of SAR images an interesting alternative for the mapping of small changes of terrain morphology due to erosion and sedimentation. The intensity variations in a SAR image are related to the surface roughness and dielectric proprieties as well as to the polarimetric proprieties and the local incidence angle of SAR acquisition. Geometrical distortions such as foreshortening, layover and shadowing strongly affect the amplitude of SAR images in mountainous regions and even in areas with a moderate topography. A water basin appears as a dark patch on a SAR image as a result of the surface

specular reflection. The exposed terrain surface behaves as a diffuse reflector due the terrain roughness. This property of SAR image intensity allows to identify the waterline and distinguish between the dam lake and the terrain surface around it. The waterline of dam basin changes in time according to the water level. As a consequence, if the time series of water levels is known, the temporal evolution of the waterline can be observed and the land/water separation used to generate the DEM of the dam basin. The precision of terrain morphology estimation depends on the precision of water level measurements. The proposed algorithm is based on the assumption that soil moisture and roughness have different temporal scales. The idea of this work is to use the temporal changes of water level in the dam basin to map the terrain morphology of the whole area covered by water during the maximum extension of the lake. This would allow to identify areas in the dam basin where soil accumulated due to sedimentation or affected by soil depletion due to erosion and so to estimate the seasonal variation of useful water volume of the dam. Furthermore, this would also help to map the lake shoreline variations due to erosion as a function of the water level. The result depends on the spatial resolution of SAR images and the wavelength of the SAR sensor. The spatial resolution provides the precision of the waterline identification and so the spatial resolution of the DEM. The wavelength directly affects the scattering properties of terrain and water surfaces and so the capability to distinguish between water and land which at the basis of the proposed methodology. Furthermore, the application of the methodology depends also on the exposure of the dam basin with respect to the line-of-sight of current spaceborne SAR sensors which are always moving along a polar orbit. It could happen that portions of the lake cannot be observable on SAR images, especially in mountain areas, due to shadow effects. In this work we used X-band CosmoSkyMed to map the terrain morphology of the earth-filled dams of the Consorzio di Bonifica di Capitanata, located in the Apulia region, southern Italy.

SUMMARY

A methodology to measure displacement of earth-filled dams by means of Synhetic Aperture Radar (SAR) interferometry is described. The methodology is applied on both ground-based and spaceborne SAR data.

1. INTRODUCTION

The mechanical parameters of earth dams is one of the key issues of geotechnical problems. Parameter back-analysis using internal or external monitoring data has been proven to be an efficient way to solve this problem. In fact, based on the identified parameters, the stability and security analysis can be investigated using the finite element method (FEM). However, traditional internal or external monitoring methods have limitations in efficiency, long-term monitoring and spatial coverage. The internal monitoring methods include e.g. tension wire alignment, hydraulic overflow settlement gauges, extensometers. However, these internal monitoring methods do not meet the safety monitoring requirements of large dams in terms of efficiency and long-term observations because of their low coverage and durability, and labour-intensive monitoring needs. Traditionally, external monitoring methods include levelling or Global Position System (GPS) measurements, but they are rarely used in back-analysis because of their low coverage. Therefore, the external monitoring results from the InSAR observation can be used as a integration for traditional monitoring methods to analyse the parameters of the dam. In this work we present the results which have been obtained within the AIM-DAMS project for the monitoring of earth-filled dams. The project has been funded by the Apulia Innovation Agency. Both Ground-Based and Spaceborne SAR systems have been used. Ground-based radar interferometry has provided deformation measurements of earth-filled dams of the Consorzio di Bonifica di Capitanata, located in the Apulia region, southern Italy. Earth dams have similar scattering properties as landslides for which the Ground-Based Synthetic Aperture Radar (GBSAR) technique has been so far extensively applied to study terrain displacements [1]. In this work, SAR and Real Aperture Radar (RAR) configurations are used for the measurement of earth dam surface deformations. A methodology is described for the acquisition of SAR data and the rendering of results. The geometrical correction factor needed to transform the Line-Of-Sight (LOS) deformation measurements of GBSAR into an estimate of the horizontal deformation vector of the dam surface is derived. Furthermore, a methodology for the acquisition of RAR data and the representation of deformation temporal profiles and vibration frequency spectrum of dam concrete structures is presented. For this study, a ku-band ground-based radar equipped with horn antennas having different radiation patterns have been used. Spaceborne radar interferometry provided maps of vertical deformation of the dam crown. X-band CosmoSkyMed SAR images have been processed using the Persistent Scatterer technique. This technique uses a time series of SAR images acquired over the the same region. Examples of application of single couples of SAR images to the measurements of vertical deformations of dams have been already published in the literature [2].

2. MONITORED DAMS

Four earth-filled dams were monitored, all located in the Apulia and Campania regions, southern Italy and managed by the Consorzio di Bonifica di Capitanata. The four dams are:

1) Occhito, on the Fortore river. It has been built between 1958 and 1966 and started to operate in 1972. It has one of the largest dam basins in Europe. The dam is located on the northern part of the Apulia region, in the districts of Carlantino and Celenza Valfortore, on the border between Apulia, Campania and Molise regions;
2) Capaccio, on the Celone river. It has been built between 1992 and 1997 and started to operate in 2000. It is located in the district of Lucera, on the northern part of the Apulia region;
3) Marana Capacciotti, on the Ofanto river. It has been built between 1969 and 1976, and started to operate in 1987. It is located 13.5 km south-west of the Cerignola city, on the northern part of the Apulia region, precisely;
4) San Pietro, on the Osento river. It has been built between 1958 and 1966, and started to operate in 1972. It is located in Aquilonia district, on the western part of the Campania region, on the border with the Basilicata region.

Figure 1 displays the Google© snapshots of the four dams with the installation sites of SAR acquisitions to derive the displacement maps of dam surfaces.

3. SYNTHETIC APERTURE RADAR INTERFEROMETRY

A Synthetic Aperture Radar (SAR) is an active microwave sensor used to produce 2D microwave images of the observed scene [1][2]. The main advantage of microwave images is their capability to observe a scene without the need of solar illumination and in any weather condition. The SAR interferometry (InSAR) technique consists in processing two SAR images of the same scene obtained either from two slightly displaced positions or from the same position. The acquisition geometry is typical of repeat-pass space SAR interferometry, while the second geometry is common in ground-based SAR interferometry.

Differencing the phase of two coherent complex-valued SAR images provides information on displacement phenomena of terrain or structures. Using data of both current and past spaceborne SAR missions, it is possible to monitor current displacement and to study displacement phenomena occurred or started in the recent past. The SAR interferometry provides only the Line-of-Sight component of the real displacement, i.e. the component along the radar line of sight. For this reason, the displacements measured by spaceborne SAR sensors are mainly related to a vertical movement of the observed scene, being the sensors looking downward with a look angle variable depending on the acquisition configuration. The technique of Ground-Based Synthetic Aperture Radar (GBSAR) intterferometry uses a frequency band 16.70–16.78 GHz. The working range distance to the study area ranges from about less than 100 m up to more than 7000 m.

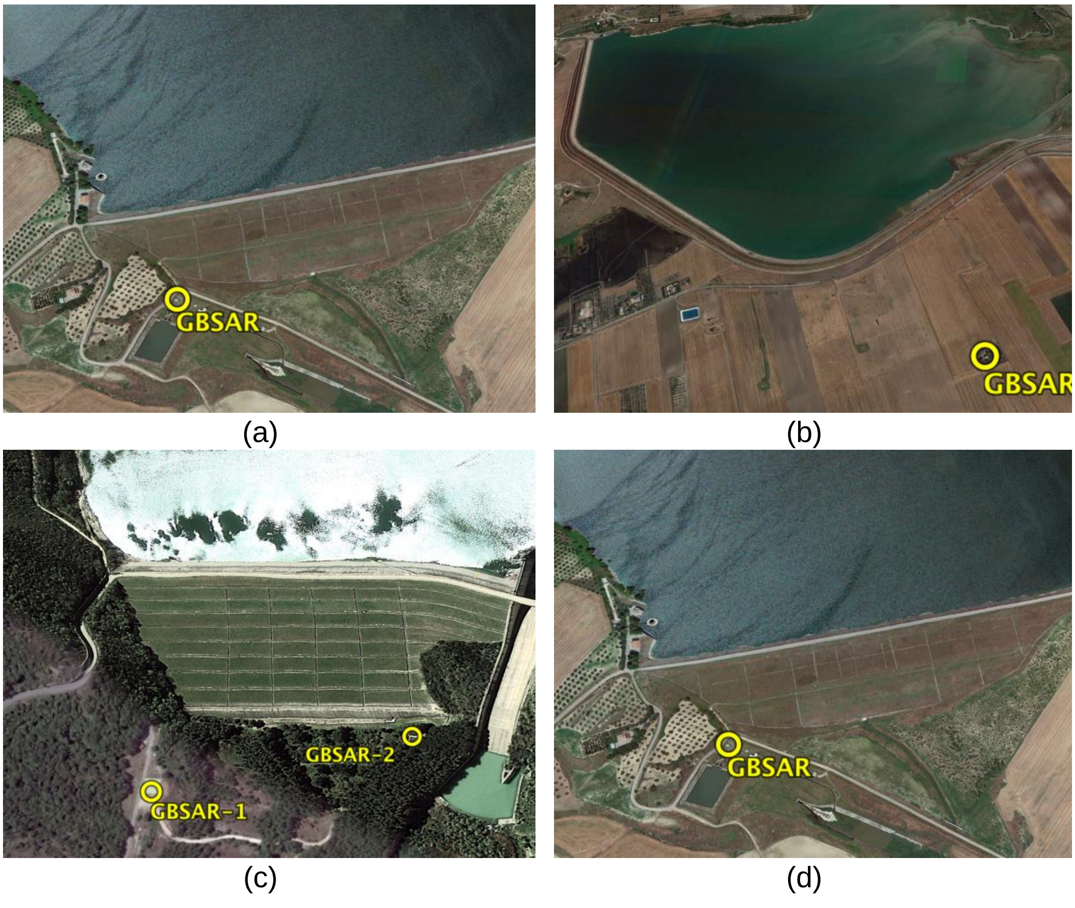

Fig. 1. From the top-left to the bottom-right, Google© snapshots of Marana-Capacciotti dam on the Ofanto river, Cerignola; Capaccio dam on the Celone stream, Lucera; Occhito dam on the Fortore river, Carlantino and San Pietro dam on the Osento stream, Aquilonia. The GBSAR installation sites are also shown. (after Di Pasquale et al. [1]).

The scene is mapped in terms of range and azimuth distances, where the azimuth direction is set by the orientation of the rail. The advantage of GBSAR interferometry with respect to many traditional techniques is its capability to provide areal information on the displacement field rather than measurements of displacements in only a few points. The precision of SAR interferometry measurements of displacements are in the order of a fraction of centimeter for spaceborne SAR sensors, and of a fraction of millimeter for GBSAR interferometry, depending on the temporal coherence of the scene, depending on the landcover characteristics. The accuracy mainly depends on the correction of phase delays due to microwave propagation in atmosphere.

4. RESULTS

In this section we present a few results which were obtained by SAR interferometry, processing both spaceborne and ground-based SAR data. The use of spaceborne SAR data is an effective tool to vertical displacements due to subsidence phenomena. In this case, GBSAR sensors cannot be effectively used since the fraction (LOS component) of a vertical movement they can measure is very small. For the observation of horizontal displacements of the dam surface,spaceborne SAR sensors are most appropriate and for this reason a GBSAR system was used. For the sake of brevity, we present only the results referred to the Occhito dam. More results can be found in Di Pasquale et al. [1]. Concerning spaceborne SAR interferometry, a set of twenty Cosmo-Sky-Med X-band SAR images was processed. Images were acquired over the area around the Occhito dam. Images were acquired between 7 August 2013 and 3 March 2014. Each image was characterized by a 3m spatial resolution. Figure 2 shows a portion of the CSK amplitude image with the Occhito lake and details of the dam, which is located at the bottom of the lake image. It can be observed how the structures of the crown and down-stream surface of the dam can be easily identified.

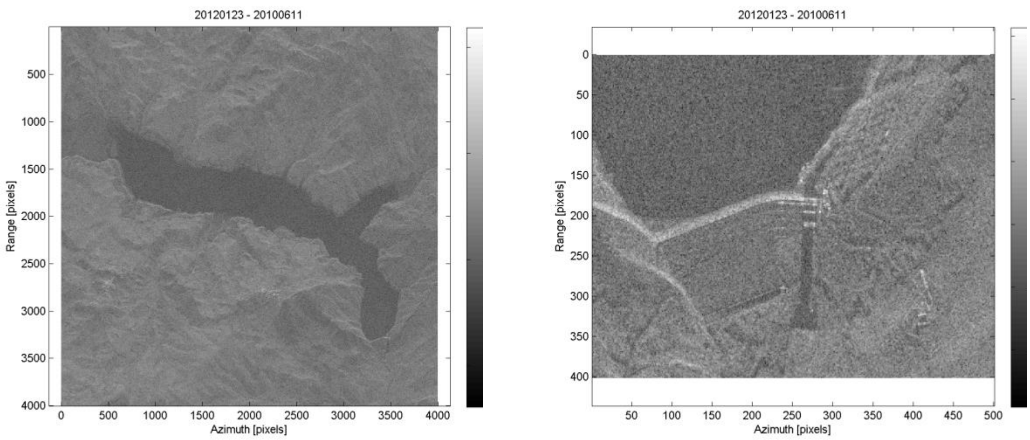

Fig. 2: Occhito lake and detail of the dam as observed by spaceborne CSK SAR image (after Mascolo et al. [3]).

A Persistent Scatterer (PS) analysis has been done to measure the mean displacement of the of both the crown and the whole down-stream surface of the dam. Figure 3 display the maps of mean displacement velocity and the corresponding precision.

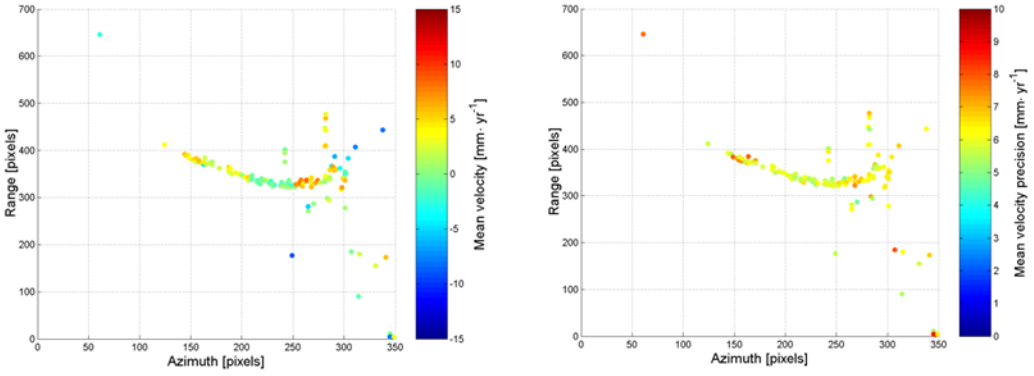

Fig. 3: Mean dispalcement velocity and precision. Maps are referred to the Occhito dam (see Fig. 2)

Concerning ground-based SAR interferometry, tour data acquisition campaigns were carried out at the Occhito dam from 27 May 2014 tto 3 March 2014. Two different acquisitions sites were selected on the right and left of the downstream side the dam. Figure 4 reports the portions of the dam observed by the two GBSAR positions and the corresponding displacement maps, obtained using a temporal baseline of about six months. The results of this work show the information that a ku-band ground-based and X-band spaceborne SAR data can provide time series of displacement maps with high spatial resolution and time sampling frequency. Besides being useful to define to monitoring protocols of earth-filled dams, the information provided by SAR interferometry could be used to perform back analyses also when other monitoring data are not available, and to implement a calibration procedure to set up a reliable numerical model.

5. ACKNOWLEDGMENTS

Cosmo-Sky-Med SAR data have been provided within the project COSMO-SkyMed/RADARSAT-2 AO “Pilot project for the multifrequency and multiplatform InSAR slope stability monitoring of earth dams: merging spaceborne C and X-band and ground-based Ku-band SAR images”.

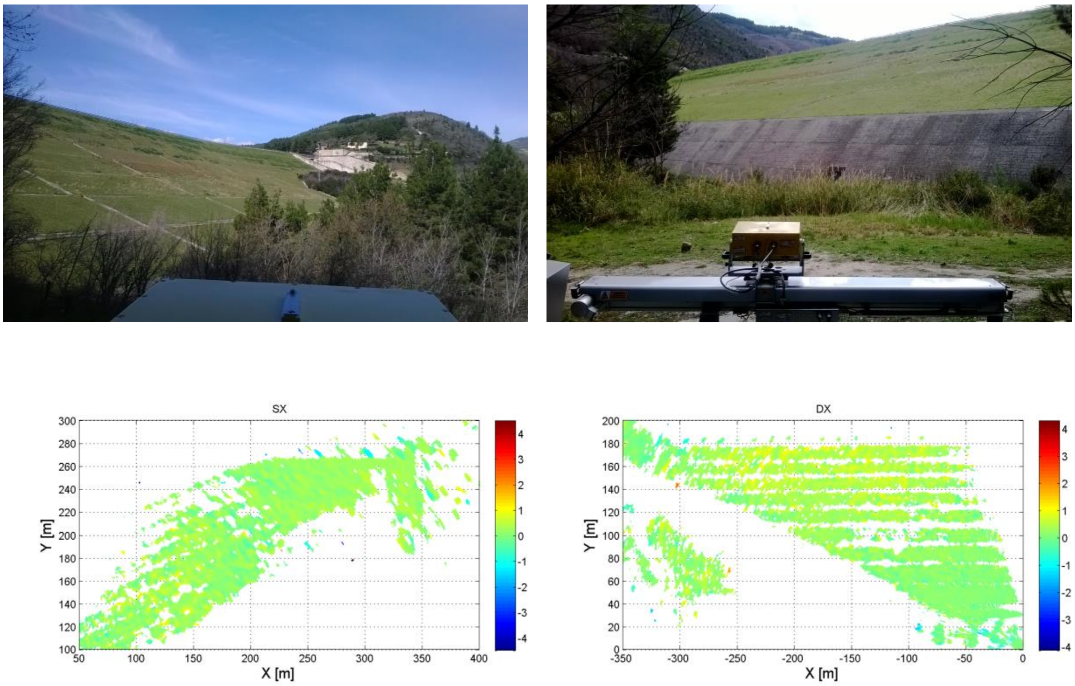

Fig. 4. Occhito dam, Carlantino. From the top to the bottom, photo of the dam as observed from the GBSAR position and displacement map. Data have collected by two GBSAR systems installed on the left (SX) and right (DX) downstream sides of the dam (see also Fig. 1). (after Di Pasquale et al. [1]).

ABSTRACT

The rate of dam construction has been rapidly increasing in the last two centuries especially embankment dams. This may be attributed to the increase of water scarcity all over the world. Embankment dams represent the major portion of dams in the world. It represents about 80% of dams in the United States. One of the major risks that are associated with dam construction is dam failure. Dam failure is a catastrophic event where both peak flow and volume significantly affect downstream property and could result in loss of life. The amount of the affected property and loss of life depend on the inundated area and the degree of inundation, which are in turn a function of the reservoir size and other breach parameters. Because of the high risk associated with dam failure, especially for large dams, international standards recommend performing a dam break analysis during the design stage, in which the designer should study the effect of dam failure on the downstream region. So, it is very important to accurately represent the

breach process and its final opening dimensions to mitigate flood hazards due to dam failure. Several studies were conducted to predict dam breach parameters. This paper presents a critical review of the available studies.

A comparison between the available equations for prediction of dam breach parameters is conducted to select the best equations for each breach parameter using the breach parameters of about 1400 dam failure events. The comparison between the existing equations is based on the coefficient of determination (R^2) and Root Mean Squared Error (RMSE). So, the equation which has the minimum RMSE and the maximum R^2 will be described as the best equation for this parameter. Also, the available equations is sorted from the best to the worst based on the same two evaluation factors.

Applying the comparison criteria, **Fehler! Verweisquelle konnte nicht gefunden werden.** (see fullpaper) presents the sorting of the existing prediction equations from the best to the worst equation based on R^2 and RMSE.

Based on the comparison and its results (presented in **Fehler! Verweisquelle konnte nicht gefunden werden.**- see fullpaper), it is found that Soliman 2015 equations for H_f and B_{avg} prediction are the best equations followed by Elsayed 2018 equations for the same two parameters. Regarding T_f, Elsyaed 2018 is classified as the best equation based on R^2 while Von Thun & Gillette, 1990 is classified as the best equation based on RMSE and both are followed by Soliman 2015 equation.

Additionally, it is very clear from the above table that the prediction equations for T_f are uncertain as all of them have very low values for coefficient of determination (R^2). So, additional investigation and analysis should be conducted in future to find a better equation for formation time prediction.

1. INTRODUCTION

Assessment of slopes’ stability is an important part of site investigations for hydraulic projects, especially in mountainous regions. Necessity of such investigation directly at the dam site is obvious. The 1963 Vajont disaster highlighted their importance at and above the reservoirs’ rims to avoid collapse of large rock masses in the water body. However, quite adverse effects for hydraulic structures might be produced by powerful outburst floods caused by breach of naturally dammed lakes in the catchment area, upstream from the reservoir. While most of such floods occur due to breach of the moraine and glacier lakes, the most hazardous are associated with the breach of large rockslide dams that could create lakes comparable or exceeding reservoirs’ flood-control storage.

Several examples of powerful outburst floods after breach of the historical and prehistoric rockslide dams and their effects will be presented, demonstrating what could occur downstream in the valley. Extreme level of the potential threat associated with such phenomena shows that adverse effects of the river-damming rockslide must be taken into consideration not only if such blockage already exist in the catchment area but also if it can be anticipated there during the dam's lifetime [1]. It is exemplified by case studies from the Pamir and Himalayas, in the Vakhsh and the Siang (Brahmaputra) River basins correspondingly, where large hydraulic schemes are under construction or planned in future.

2. HISTORICAL AND PREHISTORIC OUTBURST FLOODS CAUSED BY CATASTROPHIC BREACH OF LARGE ROCKSLIDE DAMS

Breach of large rockslide-dammed lake could produce flood with peak discharge exceeding those caused by hydro-meteorological processes significantly. It can be exemplified by historical events and by prehistoric case studies, which parameters can be derived from the geomorphic observations.

2.1. HISTORICAL DISASTERS

In 1786 breach of seismically induced rockslide dam in the Dadu River in Sichuan, China, claimed about 100 000 lives, thus being the most disastrous catastrophe associated with a single slope failure [2, 3]. In 1841 and in 1885 catastrophic outburst floods affected Indus River valley at a distance exceeding 420 km where water raised up to 25 m [4, 5]. In 1914 breach of the prehistoric rockslide dam in the Rio Barrankos valley, in Argentina, and release of about 1.5 km^3 of water resulted in outburst flood that devastated Rio Colorado valley for about 1000 km long passage up to Atlantic Ocean [6]. Powerful outburst flood with 100 m high surge wave just downstream from the 220 m high Bairaman landslide dam occurred in 1985 in Papua New Guinea [7]. In 2000 breach of the rockslide dam in the Yigong River valley – the left tributary of the Tsangpo-Siang-Brahmaputra River in Tibet, China and release of about 2 km^3 of water stored behind the 55 m high dam (level of the artificially excavated spillway) resulted in ~120 000 m^3/s peak discharge that was recorded 17 km downstream from the dam. In India, more than 400 km downstream, it was about 44,200 m^3/s [8, 9].

2.2. EVIDENCE OF THE PREHISTORIC OUTBURST FLOODS

Similar catastrophic phenomena occurred in most of mountainous regions in the past as well. The disastrous potential of such events can be exemplified by the extraordinary prehistoric outburst flood with estimated peak discharge up to 400 000 – 500 000 m^3/s, which traces were found in the Sarydjaz-Aksu River valley in Xingiang (China) [10]. Flood was caused by the breach of a gigantic, 300-350 m high dam formed by the rockslide about 900×10^6 m^3 in volume (41.764° N, 79.526° E). The dammed lake was approximately 31 km long and could store up to 2.2 – 2.5 km^3 of water. Due to color contrast of rockslide debris and the terraces downstream, the distinct traces of the outburst flood indicate that the surge wave immediately downstream from the breached dam was up to 120 m above the riverbed and ~700 m wide (Fig. 1). About 16-20 km downstream, after passing a narrow gorge, this flood left the amygdaliform branching ravines on the 50-60 m high right bank terrace (Fig. 2). Farther downstream this extraordinary flood spread over the 630 km^2 older alluvial fan formed by the Sarydjaz-Aksu River at the feet of the Tien Shan Mountains [10].

3. POTENTIAL BLOCKAGES IN THE VAKHSH CATCHMENT AREAS UPSTREAM FROM THE ROGUN RESERVOIR

Case studies described above strengthen the concern on what might occur if similar blockage would originate in the catchment areas of the existing or proposed hydraulic schemes with large reservoirs.

Several potentially hazardous sites where large lakes can be dammed either by surging glaciers or by rockslides were identified in the Muksu and the Obi-Khingou River valleys draining northern parts of the Pamir mountains, upstream from the 330 m high rock-filled Rogun dam that is under construction now, far away from its reservoir (Fig. 3). Size of the potential slope failures and of the dams that can be created were estimated according to expert judgment. Taking in mind that, due to lack of the detailed information, no quantitative assessment of slopes' and blockages' stability is possible at present, we considered the most conservative scenarios: failure of the entire slope with real evidence of instability (fractures, scarps, etc.) followed by the dammed lake impoundment up to the blockage crest level and its catastrophic breach due to overtopping.

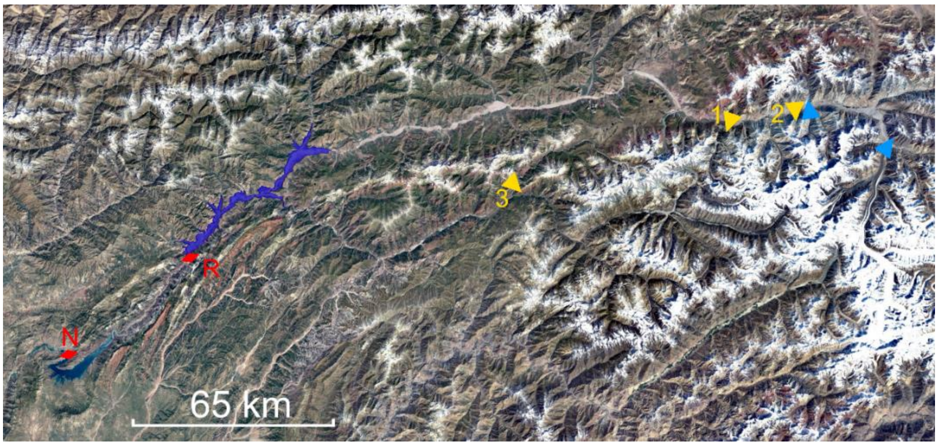

Fig. 3
Location of sites in Vakhsh River catchment where large-scale river damming is anticipated. R - Rogun dam and future reservoir at normal water level; N – Nurek dam and reservoir; blue triangles – possible glacier dams; numbered orange triangles – possible rockslide dams; Google Earth image as a background

3.1. MUKSU RIVER VALLEY

Analysis of the potential damming sites in the Muksu River valley allowed estimating potential amount of water that could be stored upstream of the anticipated blockages that could be formed by catastrophic collapse of the entire slopes affected by visible slope deformations in case of landslide damming, or by intensive and rapid glacial surges. The largest possible lake about 0.19 km^3 in volume could be formed 200 km upstream from the Rogun dam by the ca. 100 m high rockslide dam (1 on Fig. 3). According to calculations, surge wave that can originate after its breach with the initial peak discharge of ca. 13×10^4 m^3/s could be up to 50 m high. It will reach the tail part of the Rogun reservoir in ca. 14 hours being 10 m high with peak discharge of about 5700 m^3/s. Large reservoir with an area of ca. 150 km^2 at its full level will accommodate the entire outburst flood, so that reservoir level will increase less than for 1.5 m that will not produce any threat to the rock-fill dam.

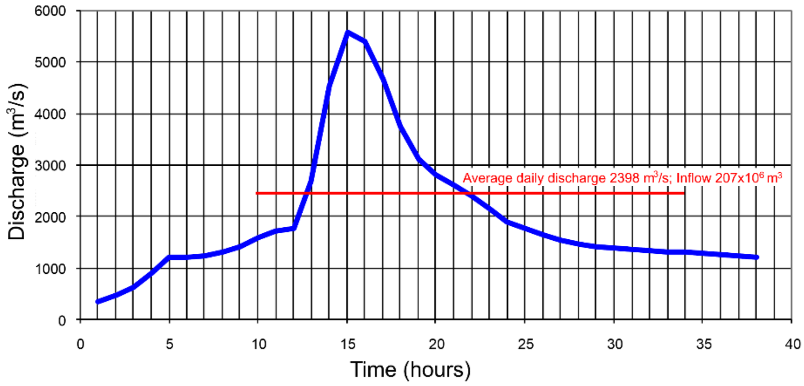

Fig. 4

The Muksu outburst flood hydrograph at the entrance of the Rogun reservoir

3.2. Obi-Khingou River valley

The largest potential river-damming landslide in the Vakhsh River catchment was found in the Obi-Khingou River basin, at the mouth of its right tributary – the Ragnow River, at 38.921° N, 70.964° E, about 140 km upstream from the Rodun dam (No 3 on Fig. 3). More than 1 km-high right bank of the valley is affected by recent landslide and by numerous downslope and upslope-facing fractures. The most distant one at 3100 m a.s.l. is about 800 m far from the crown of the recent slope failure at 2850 m a.s.l. (Fig. 5). Slope is composed of folded Upper Cretaceous sedimentary rocks (limestone, sandstone, siltstone and gypsum) with relatively low strength striking along the slope and dipping 40-45° in the slope. Nevertheless, intensive fracturing visible on Fig. 5 allows assumption that this slope could fail in one large event forming the ~260 m high dam ca. 3×10^8 m^3 in volume (Fig. 6). Such a dam can impound a lake up to ~412×10^6 m^3 in volume – about 2 times larger than in the Muksu River case describe above.

Its catastrophic breach caused by overtopping could result in outburst flood with the initial peak discharge up to 350-500×10^3 m^3/s. On its' 100 km long way to the Rogun reservoir along the Obi-Khingou River valley with wider trough-like upper part and V-shape canyon in the lower reaches (see Fig. 3), flood will transform significantly and would reach the tail part of the Rogun Reservoir in ca. 1 hour being about 20-25 m high with peak discharge of ca. 30×10^3 m^3/s (Fig. 7). Even if the impounded dammed lake will be emptied completely, the Rogun

Reservoir level will raise for ca. 2.5 m only, less than the PMF headwater level. The most adverse effect of such flood could be the caused by waves that might originate in the reservoir. Their propagation along the reservoir and height at the dam site could be assessed by the numerical of physical modeling. However, considering that on its way such wave should split up- and downward the reservoir it is unlikely that at the dam site it would exceed the wind wave of 1% probability.

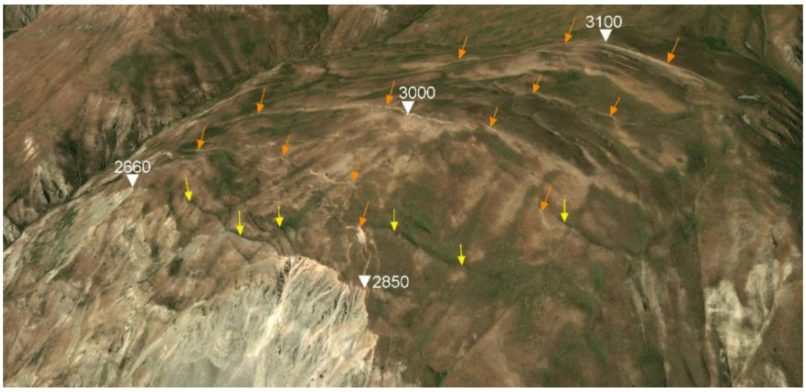

Fig. 5

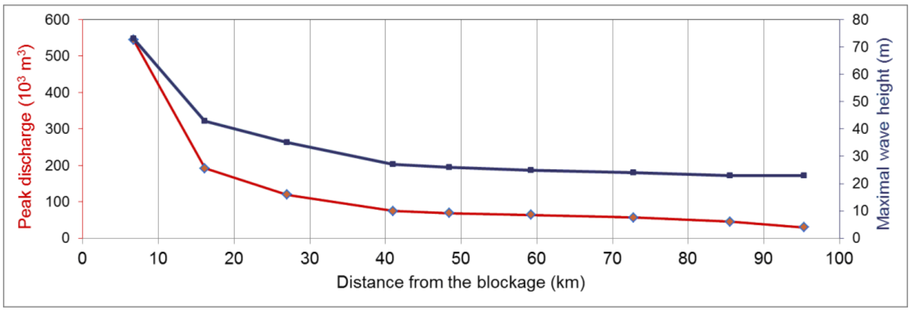

Fig. 7
Variation of peak discarge (red line) and of the maximal wave height (blue line) along the Obi-Khingou River valley from the Ragnow-mouth rockslide dam up to the entrance in the Rogun reservoir

4. POTENTIAL BLOCKAGE IN THE SIANG (BRAHMAPUTRA) RIVER BASIN

Similar analysis was performed in the Siang (Brahmaputra) River basin, whose upper part is in China and the lower one – in India. At least twice, in 1900 and in 2000 this valley was affected by the disastrous outburst floods that originated in the Yigong River valley – the large left tributary of the Brahmaputra (Fig. 8) [8, 9]. River damming was caused by rock avalanches that originated in the upper reaches of the Zhamu Creek and, after passing about 10 km, blocked the Yigong River by the dams up to 50-70 m high. As we mentioned above, in 2000 release of about 2 km^3 of water resulted in 44,200 m^3/s peak discharge in India, more than 400 km downstream. It can be assumed that steep walls in the Zhamu Creek head still have the potential of similar failures in future.

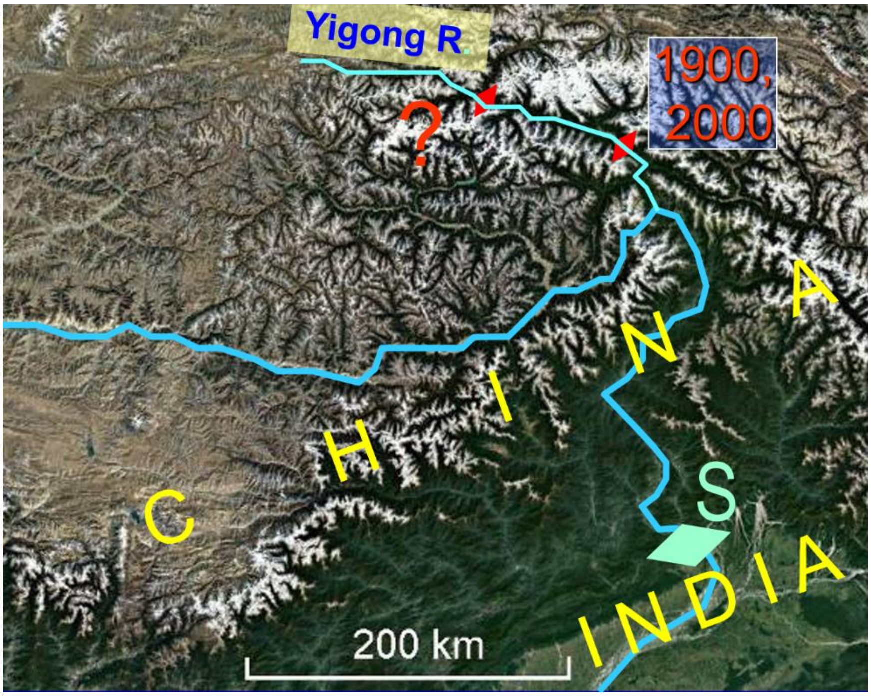

Fig. 8
Location of the potential river-damming sites in the Brahmaputra River basin (red diamond symbols): that marked by 1900, 2000 – where Zhamu Creek rock avalanches occurred; ? – the assumed rockslide site shown on Fig 9; S – location of the Siang hydraulic scheme(s) in India

However, analysis of space images revealed possibility of the, potentially, much more hazardous phenomenon that might occur in the same Yigong valley about 100 km upstream from the 1900 and 2000 dams' site at 30.448° N, 94.075° E (see Fig. 8). Here, few kilometers downstream from the Jangba village, the 1500 m high right-bank slope demonstrate distinct evidence of the ongoing large-scale instability – arcuate step on top and numerous rock falls starting at the central part of the slope and at the bounds of this slope section (Fig. 9). It differs significantly from all surrounding slopes and looks as if the entire 600-800 m high upper part of this slope is affected by the deep-seated gravitational slope deformation. Much wider upstream section of river valley demonstrate evidence of both recent and, likely, older impoundments and could store large amount of water – up to ca. 6 km^3 in case of river damming.

Possible volume of the hypothetical slope failure and of the blockage was estimated, based on expert judgment, as ca. 207-230 million m^3 (volume of the blockage is slightly larger than that of the collapsed rock mass, considering its inevitable softening). Such a large failure, if it would occur as a single event, could form a dam up to 300-350 m high (Fig. 9). Similar shape of the headscarp was observed, for example, at the Lower Aral rockslide in Central Tien Shan [10].

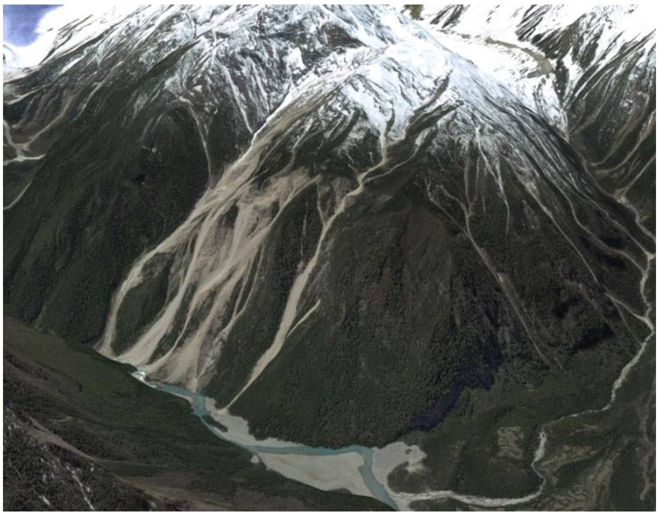

Fig. 9
3D Google Earth view of the rockslide-prone site on the right bank of the Yigong River valley with evidence of the ongoing deformations

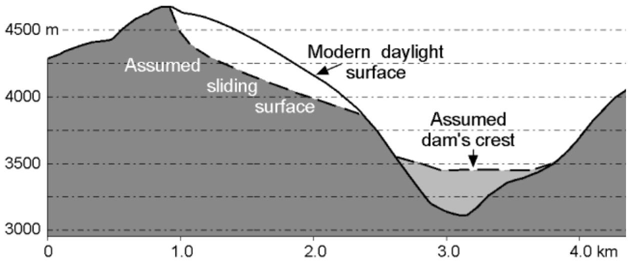

Fig. 10
Schematic cross-section of the anticipated Jangba rockslide dam

Parameters of possible outburst flood could be estimated based either on the model calculations or on the analogues some of which were presented above in Section 2. Preliminary calculations provided the assumed peak discharge of the outburst surge wave of about 600-800x10^3 m^3/s. Such enormous estimate, however, seems to be reliable, considering 400-500x10^3 m^3/s peak discharge of the outburst surge wave at the Sarydjaz-Aksu site (see Fig. 1) caused by the release of about 2 km^3 of water only, and 120x10^3 m^3/s discharge recoded 17 km downstream from the breached dam about 55 m high only (the level of the excavated spillway canal) that had stored about 1.5 km^3 of water and ca. 100 m high surge wave observed during breach of the 210 m high dam and release of 50 million m^3 of water on the 1985 Bairaman case [7].

In the lower reaches of the valley, in India, after passing through the ~500 km long gorge, peak discharge of such a flood could exceed 50,000 m^3/s and a flood wave could be up to 50 m high.

5. CONCLUSIONS

The extreme potential hazards provided by hypothetical outburst floods that might occur in the Vakhsh and the Siang River basins, along with the data on similar disastrous phenomena that had occurred in the past all over the world, highlights the necessity to investigate possibility of large-scale rockslide damming in the catchment areas of large hydraulic schemes in mountainous regions.

Though outburst floods anticipated in the Vakhsh River basin should not produce disastrous effects for the Rogun dam, they might cause flooding on the way and along the reservoir banks posing a threat to local communities and infrastructure. Potential hazard of river blocking in the Yigong River valley seems to be much higher.

Identification of such potentially hazardous sites based on the analysis of the remote sending data should be followed by their more detail study and monitoring aimed not to miss occurrence of such a slope failure. Fixing of river-blocking slope failures in the catchment areas allows taking timely actions to mitigate or avoid most adverse effects of the disastrous outburst floods and to protect hydraulic structures located downstream.

SUMMARY

The necessity of identification of sites in the catchment areas upstream from reservoirs, where large-scale river damming rockslides following by powerful outburst floods might be anticipated, is exemplified by case studies from the Vakhsh and the Siang (Brahmaputra) River basins, where large hydraulic schemes are under construction or are planned in future.

RÉSUMÉ

Des exemples des bassins de rivières Vakhsh et Siang (Brahmapoutre), en aval de laquelles est prévue la construction de grandes ouvrages hidrauliques, on démontre la nécessité d'identifier en amont au sein du bassin d'alimentation les zones dans lesquelles peuvent se former des débris de terre et les glissements de terrain avec la formation de barrages, percée qui peut provoquer des inondations (faire face à la formation des crues).

1. INTRODUCTION

Slow moving landslides pose a risk to the environment and often cause severe damages to infrastructures. In this contribution, the influences of water level changes in a storage basin of a pumped-storage power plant on the movement behaviour of a slow moving landslide are investigated. After a short introduction of the site, results of pore water pressure measurements and displacement measurements are presented. The measurements showed excess pore water pressures at the slope toe. Furthermore, a clear relationship between storage operation, excess pore water pressures at the slope toe and movement rates of the landslide could be derived from the measurements. Based on numerical back-calculations, the reasons for the measured excess pore water pressures at the slope toe are discussed. The quantitative influence of the storage operation on the slope movements is estimated from the results of a fully coupled flow-deformation analysis (finite element analysis). Furthermore, the influence of other factors (creep behaviour and precipitation) on the slope movements is shown by numerical back-calculations.

2. SLOW MOVING LANDSLIDE NEXT TO WATER STORAGE BASIN

2.1. SITE DESCRIPTION

The pumped-storage power plant with the associated water storage basin is located in the Central Eastern Alps. The volume of the storage basin is roughly 300,000 m³. Due to the operation of the power plant, the water level in the storage basin changes up to three times a day with a maximum change in water level of approximately 7 m.

The dimensions of the landslide are 220 x 270 m. The main sliding surfaces in the lower part of the slope were detected by inclinometer measurements between 20 and 40 m below ground surface. The average inclination of the slope is 30°. The average movement rate of the landslide is 4-5 cm/year. Fig. 1 shows a plan view and a side view of the landslide and the storage basin. Furthermore, the positions of the installed measurement equipment are indicated in Fig. 1.

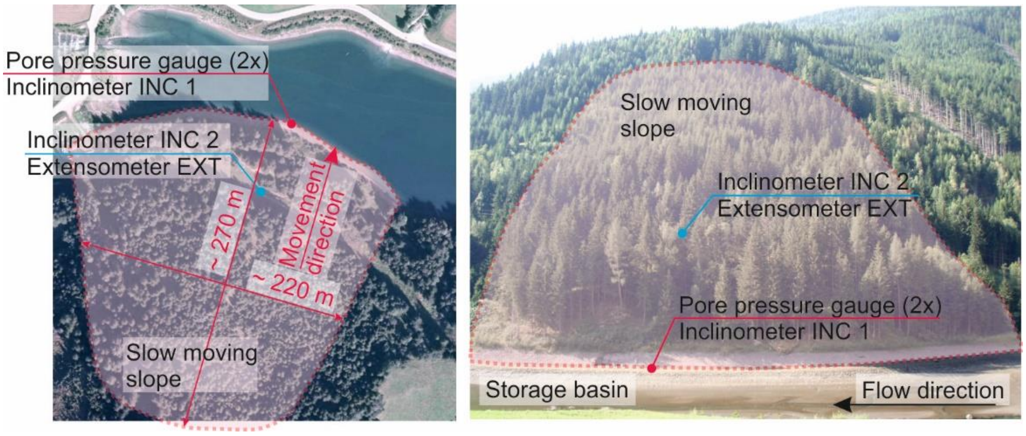

Fig. 1
Plan view and side view of water storage basin and slow moving slope [1]

The material of the slow moving landslide mainly consists of weathered and sheared rock. Beneath the slope toe and the water storage basin the subsurface explorations showed lacustrine fine sediments with an increasing fine content with depth, mainly consisting of silt.

2.2. MEASUREMENT RESULTS

To monitor the slope movements and the pore water conditions at the slope toe, a comprehensive measurement system was installed. The positions of the measurement devices are marked in Fig. 1. In addition to the indicated devices, the entire slope is equipped with geodetic measurement points.

In the following, selected results from the on-site measurements are presented.

2.2.1. Pore water pressure measurements

Two pore water pressure gauges were installed at the slope toe of the landslide. Pore water pressure gauge PPG 1 is installed at a depth of 21 m below ground surface. PPG 2 is installed at 33 m below ground surface.

Fig. 3 shows the absolute pressure height at the position of the measurement devices and in the storage basin for one week. Furthermore, the resulting excess pore water pressures are plotted in Fig. 3. According to Fig. 3, high and fast water level changes lead to high excess pore water pressures at the slope toe as shown in the first part of the plotted period. In contrast, small water level changes, which occur in the second part of the plotted week, lead to small excess pore water pressures.

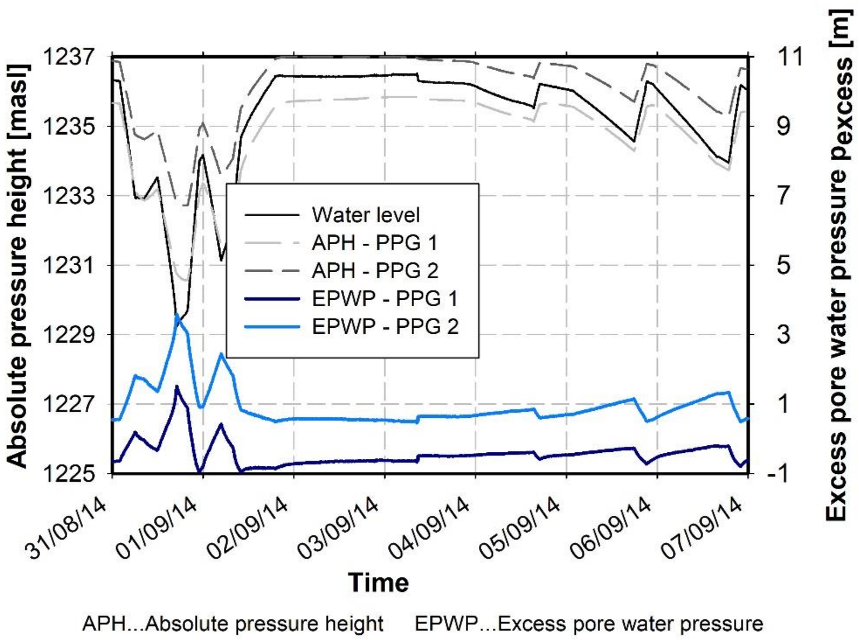

Fig. 3
Absolute pressure height and excess pore water pressures at slope toe from 31/08/2014 until 07/09/2014 [2]

Two important conclusions can be derived from the pore water pressure measurements. First, excess pore water pressures are present at the slope toe of the slow moving landslide and second, the magnitude of the excess pore water pressures depends on the storage operation.

2.2.2. Deformation measurements

In addition to the conventional inclinometer measurements, the two inclinometers were equipped with in-place inclinometers to investigate the relationship between storage operation and movement behaviour at the slope toe.

Fig. 4 and 5 show comparisons of the water level changes in the storage basin with selected deformation measurements.

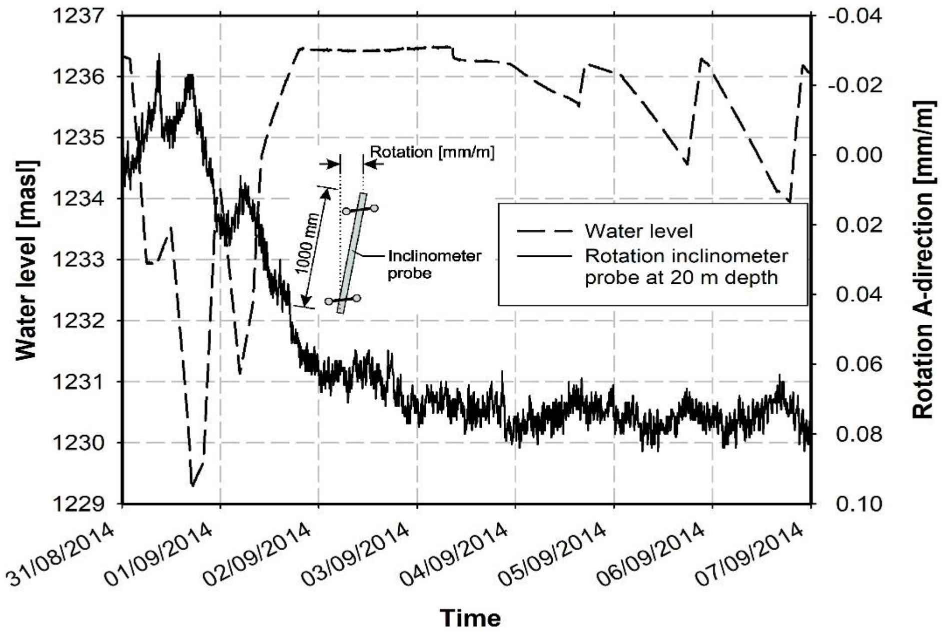

Fig. 4

Rotation of inclinometer probe at 20 m depth in inclinometer INC 1 and water level in water storage basin [2]

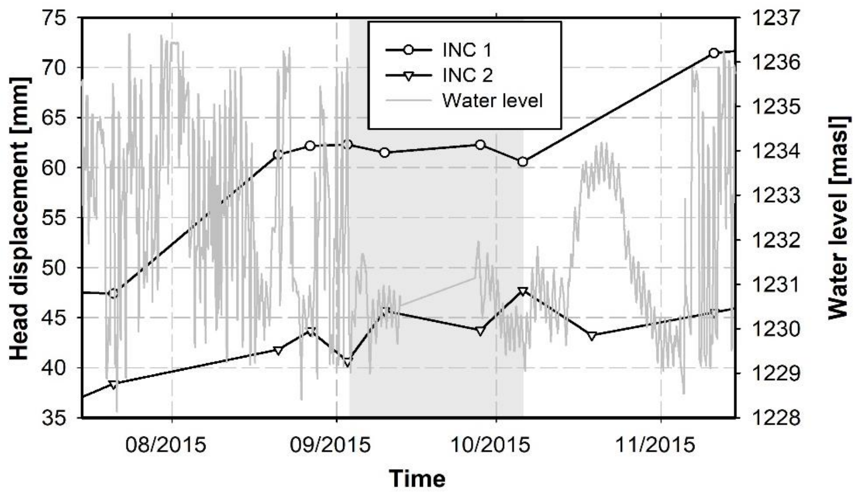

Fig. 5

Head displacements of inclinometers and water level in water storage basin [2]

In Fig. 4 the rotation of one inclinometer probe at a depth of 20 m (position of main sliding surface) at the slope toe is plotted. As shown in Fig. 4, the first high and fast water level changes lead to high deformation rates. During the days with small water level changes the deformation rate is significantly reduced. The head displacements of inclinometer INC 1 and INC 2, as plotted in Fig. 5, show almost no displacements during the period without water level changes. Based on the two presented comparisons between storage operation and deformation measurements a clear relationship between the two measurement quantities can be derived.

2.2.3. Summary of measurement results

In summary, the measurement results indicate a relationship between water level changes in the storage basin, excess pore water pressures at the slope toe and movement rates at the slope toe. The geodetic measurements revealed a small influence of the precipitation on the movement behaviour in the middle and upper part of the landslide. To determine the actual influence of different factors (creep behaviour, precipitation and water level changes) on the slope deformations, numerical back-calculations, which consider all these factors are performed. The results are presented in the following.

3. NUMERICAL BACK-CALCULATIONS

The numerical back-calculations concerning the pore water pressures at the slope toe and the slope deformations were performed with the FE-software Plaxis 2D 2016 [3]. The FE-model is shown in Fig. 6.

The FE-model incorporates the real water level changes from the storage basin and the precipitation and evaporation corresponding to the specific site. The precipitation was measured on site. The potential evaporation was estimated according to Thornthwaite [4]. The influences of the soil suction on the evaporation [5] and the transpiration were neglected due to the lack of measurement data. Furthermore, the lacustrine fine sediments at the slope toe (layers Fine sand, silty and Silt, fine sandy, clayey) were modelled with the Soft Soil Creep model [6] to model the creep behaviour of these soil layers.

To achieve appropriate initial conditions concerning the stress state and the hydraulic conditions, the geological history was modelled in a simplified way. Afterwards, one year with characteristic precipitation and water level changes was simulated [2].

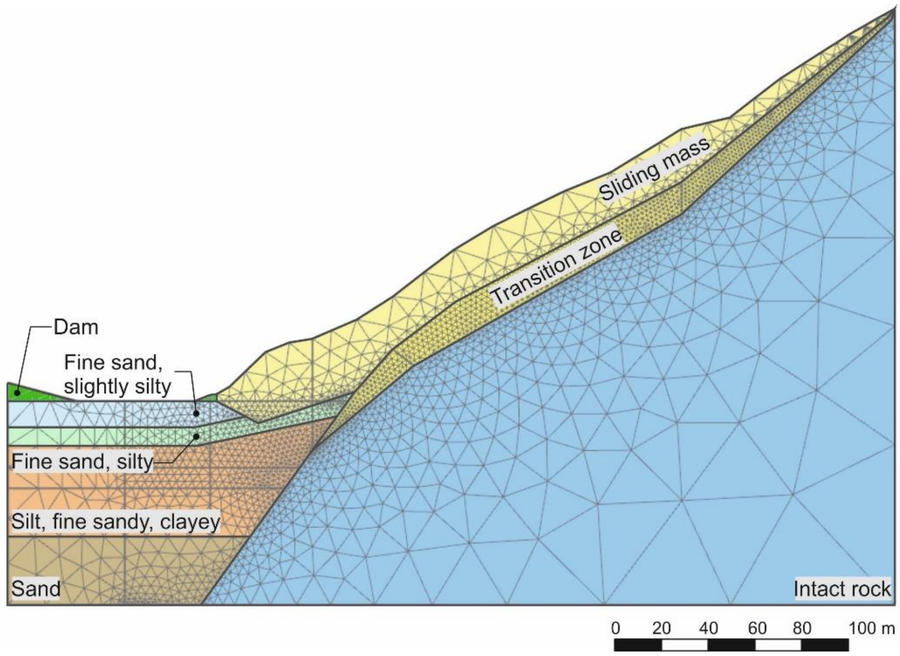

Fig. 6
FE-model for numerical back-calculations [2]

3.1. BACK-CALCULATION OF PORE WATER PRESSURES AT SLOPE TOE

The back-calculation of the pore water pressures was performed for several periods with different types of water level changes. Fig. 7 shows a comparison of the measured and calculated excess pore water pressures for the two installed pore water pressure gauges PPG 1 (21 m) and PPG 2 (33 m). Furthermore, the water level in the storage basin is plotted in the following graph.

From the comparison in Fig. 7 it can be seen that a good agreement between calculations and measurements could be achieved. Based on the numerical results, the reasons for the high excess pore water pressures at the slope toe can be investigated. For this, the groundwater head in the FE-model after the water level lowering in the storage basin on 16/09/2014 is shown in Fig. 8. As can be seen from this figure, in the majority of the subsoil the groundwater head is higher than the water level in the storage basin. I.e. positive excess pore water pressures are present in the model. In addition, the principal stresses in the area of the pore water pressure gauges are shown in Fig. 8. A rotation of the principal stresses is apparent. This clearly shows the influence of the slope on the stress state in this area. It can therefore be assumed that during the water level lowering the mechanisms, that typically occur during rapid drawdowns, lead to the excess pore water pressures in the subsoil. This is reasonable due to the high velocity of the water level changes and the low soil permeability of the lacustrine fine sediments. The mechanisms of rapid drawdowns have been discussed thoroughly in recent literature (e.g. [7], [8], [9] and [2]). Furthermore, the almost constant water level in the slope influences the pore water pressures at the position of the measurement devices as shown by the equipotential lines turned to the left. This also leads to excess pore water pressures in the monitored area.

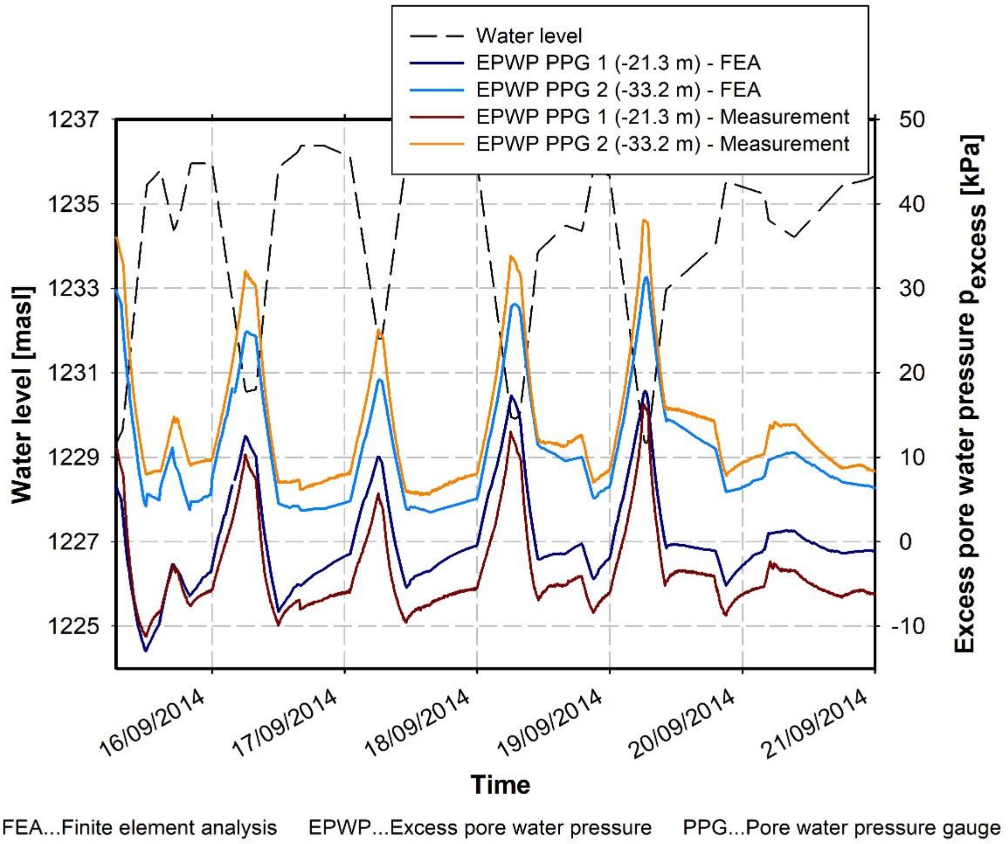

Fig. 7
Back-calculated excess pore water pressures [2]

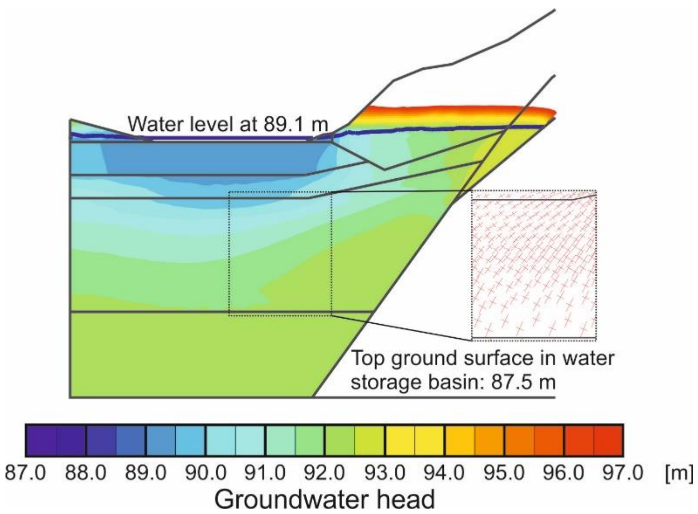

Fig. 8
Groundwater head after water level lowering on 16/09/2014 [2]

Based on the comparison of the measurement results and the calculation results and the analysis of the numerical results, it can be confirmed that the fast water level changes in the storage basin lead to excess pore water pressures at the slope toe.

3.2. BACK-CALCULATION OF SLOPE DEFORMATIONS

To estimate the quantitative contribution of the different influencing factors on the total displacements, consecutive calculation phases were performed. In each phase a new influencing factor was considered. The slope deformations due to the different influencing factors were analysed in different nodes at the slope. Fig. 9 exemplarily shows the results for node E in the middle of the slope. The difference between two time-displacement curves is the influence of each additionally considered factor as indicated by the label of the curves.

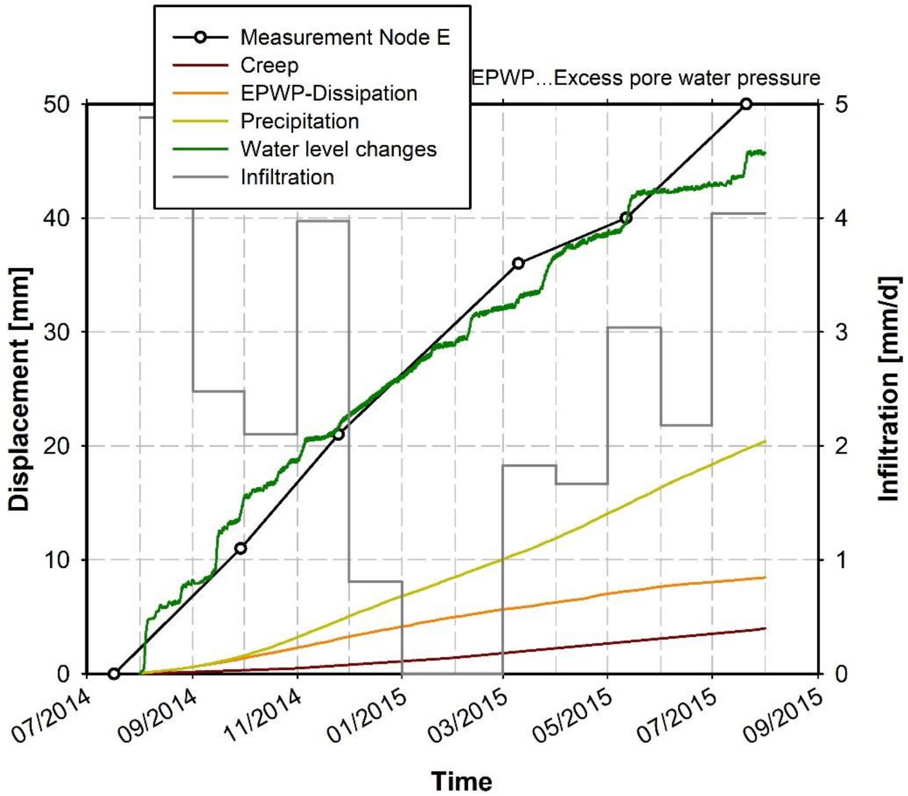

Fig. 9
Displacements at node E (in the middle of the slope) for different influencing factors [2]

A comparison between the on-site measurements in the area of node E and the total displacements from the calculation again indicate a good agreement. According to Fig. 9 the displacements are mainly due to the water level changes in the storage basin but creep behaviour and precipitation add to the displacements. The displacements based on the dissipation of the excess pore water pressures is due to numerical reasons and can be neglected for further discussions.

The analysis as shown in Fig. 9 was performed for several nodes at the slope. This showed that the influence of the creep behaviour of the lacustrine fine sediments on the deformations decreases with the increasing distance up from the slope toe. The influence of precipitation and evaporation is increasing in the middle and upper part of the slope and the influence of the water level changes on the slope deformations is almost constant over the entire slope.

Based on the back-calculations of the slope deformations it can be stated that the water level changes are the main reason for the slope movements. However, slope movements would also occur without the storage operation but the magnitude of the deformations would be smaller.

SUMMARY

Measurements on a slope next to a storage basin of a pumped-storage power plant indicated slope movements which are connected to the storage operation. Furthermore, excess pore water pressures were measured at the slope toe.

Based on numerical back-calculations in combination with the available on-white measurements the reasons for the excess pore water pressures at the slope toe could be identified. It could be also shown that the water level changes in the storage basin are the main reason for the slope movements. However, precipitation and creep behaviour of the lacustrine fine sediments at the slope toe also lead to deformations. I.e. without the storage operation the slope deformations would be smaller but they would be not zero.

The insights from the on-site measurements and the numerical back-calculations enable the definition of alarm values with regard to the slope deformations and an efficient design of appropriate remediation measures.

1. INTRODUCTION

The landslide induced impulse wave (LIIW) in reservoirs might result in tragic disasters. After the Huangtian LIIW event in 2009 at the Xiaowan Reservoir, the LIIW becomes a major concern to some of hydropower projects on the Lancang River, southwest of China. As most reservoirs in these projects located in narrow valleys, the estimation of LIIW damage in those channel-type reservoirs is very important.

Existing theories for LIIW are often generalized from wave flume and wave basin experiments, which assume that the wave generation direction is (partly) the same as the wave propagation direction. However, the LIIW in channel-type reservoirs is far more complex due to its distinguishing energy transport and dissipation mechanisms. The nearfield dissipation in the channel-type reservoir is very strong while the far field dissipation is limited because the wave propagation direction is generally the same as the channel stream direction. In this study, a novel numerical model, which characterizes both above two stages, is developed for LIIW in channel-type reservoirs and applied in engineering practices.

2. METHODS

The numerical model is constituted of two parts, the nearfield model and the far field model. In the nearfield model, the water is modelled with the Naiver-Stokes equation while the landslide is modelled with elasto-plastic model. The model is solved with the Smoothed Particle Hydrodynamics (SPH) method. And the far field model solves the 2D shallow water equation with adaptive mesh technique to simulate the wave propagation. These two models are connected unidirectionally using wave height matching technique.

The model is validated against several laboratory experiments and the results are promising. Both the deformation of the landslide and the initial wave could be reproduced reasonably and only a few artificial parameter is necessary.

3. RESULTS & CONCLUSION

The model is applied in the engineering design of a huge hydropower project on the upstream of the Lancang River. A slope, which locates at about ten kilometers upstream from the dam, is considered to be unstable during the attack of the extreme event. With prescribed slide surface from FEA simulation, the large deformation of the slide during both the slope failure and the impact process is well characterized.

The results show that while the initial wave generated in the impact process is huge, the wave propagated to the downstream is limited. This simulation shows the ability of the proposed model and also the unique characteristic of LIIW in channel-type reservoirs.

1. INTRODUCTION

Despite the most careful surveillance and construction measures, the risk of failure of an embankment dam cannot be completely eliminated. The probability of failure has been quantified as $8*10^{-5}$ for embankments with at least five years of service. The consequences of such a catastrophic event could be severe. [1]

According to ICOLD data, the two most common causes of failure are overtopping and piping. [2] According to [3] in most failure events, overtopping and piping occur in combination. Whereas piping may be the initial cause of many embankment dam failures, the worst case would be a collapse of the piping tunnel, which causes lowering of the dam crest and eventually leads to overtopping.

Existing models for hydrograph prediction display a wide range of results. The complex processes and interdependency of parameters and boundary conditions of the breaching process of overtopped embankment dams are not yet fully understood. In order to contribute to the understanding of the influence of several parameters and boundary conditions on the breach outflow hydrograph, it is necessary to conduct and analyze model test series.

2. EXPERIMENTAL METHODS

To investigate the significance of several parameters and boundary conditions on the breach outflow hydrograph of overtopped embankment dams with falling water reservoir level and no additional inflow into the reservoir, two experimental studies were conducted in the laboratory of the Institute of Hydraulic Engineering and Water Resources Management, Vienna University of Technology [4], [5].

2.1. General setup

Experiments were performed as three-dimensional full models and three-dimensional half models to observe the breach processing through a transparent sidewall. Both studies refer to similar geometry values with a dam height h_D = 0.31 m, crest width b_C = 0.02 m, upstream and downstream slope m_u = m_d = 1:2 and a channel width at the dam b_D = 1 m (half model) to 2 m (full model). The depth of the triangular shaped initial breach varied from d_B = 0.01 to 0.05 m. The reservoir had a volume of V_R = 1 to 4 m³ (referring to the full model) with the maximum water level at breach initiation h_W = 0.30 m. (Fig. 1) [5].

To analyze potential effects caused by the sidewall, additional full model tests were performed. [5] For the full models, the half models were mirrored at the transparent sidewall, with an initial breach in the center of the channel, b_D = 2 m and V_R = 4 m³.

Fig. 1 Model test rig and measurement scheme

Fig. 1 displays a scheme of the model test rig and the measurement system. All heights are defined relative to the reference datum at the top of the dam platform.

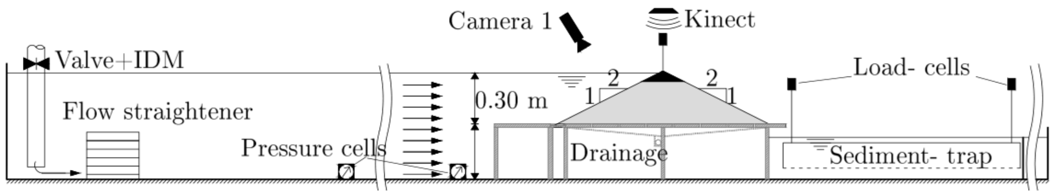

Fig. 1 Model test rig and measurement scheme

Tests were performed by constantly filling the reservoir until reaching the maximum water level h_W. The inflow was halted and simultaneously the initial breach was created by sudden pulling of a triangular shaped prism. The dam platform was pervious through a bottom drainage, which could be optionally closed for the performance of undrained tests.

Fig. 1 contains a scheme of the installed measurement devices in the test rig. Hydrograph recording as well as drainage water measurement was performed by pressure cells, according to the falling reservoir level and the reservoir characteristic by the relation $Q(t) = dV/dt$. Breach processing could be registered by three video cameras through a transparent sidewall in the breach cross section and at the upstream slope of the embankment dam. The third camera was situated in a Microsoft Kinect module, 3 m above the dam crest. This optical device contains also an infrared sensor to capture the three-dimensional shape of the breached embankment and is described in [4] and [5] (Fig. 2).

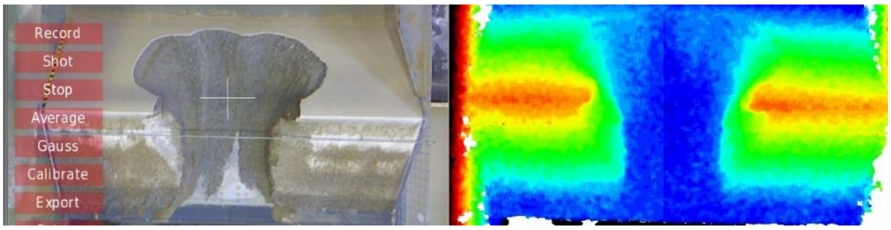

Fig. 2 Three-dimensional in situ breach recording

During breach formation shell erosion could be measured by a submerged sediment trap with load cells, which was installed downstream of the dam platform.

2.2. Parameters investigated

The first study [4] dealt with the influence of reservoir size- and shape. Therefore, the effects of three different reservoir volumes (1, 2 and 4 m^3- referring to the full model) as well as a linear rectangular cross section reservoir and a nonlinear triangular cross section reservoir were investigated.

The second study [5] analyzed the effects of three different grain size distributions (nonuniform, d_m = 1.1 to 3.1 mm), an upstream impervious blanket, three initial breach depths (0.01, 0.03 and 0.05 m) as well as model effects due to sidewall, drainage and scalability. In order to reduce the seepage that occurred by using coarse and high permeable shell material, a membrane coating, like an upstream dam sealing blanket, was developed, which enabled impounding, by heaving no significant effect on the breaching process. In addition, a model family with a scale factor of λ = 2 was created. Most experiments were performed three times for each parameter.

3. MAIN RESULTS

3.1. Significance of the parameters investigated

The most significant influence on the hydrograph could be observed by varying the reservoir size, followed by the reservoir shape. By doubling the reservoir volume, an average increase of the peak hydrograph value of approx. 70% was measured. Compared to a reservoir with a rectangular shape and linear characteristic, the nonlinear triangular shaped reservoir caused a rising of the peak hydrograph about approx. 40 to 60% [4].

Using different shell material had a significant effect on the hydrograph as well, but it was lesser and also dependent on the reservoir size. The coarse material (d_m = 3.1 mm) possessed the highest peak value, with a reservoir volume of 4 m³, about approx. 36% higher, than the fine grained material (d_m = 1.1 mm). With a reservoir volume of 2 m³, the difference was approx. 50% [5]. Regarding material properties, no cohesion or apparent cohesion is to be expected.

Steeper slopes in the breach cross section using finer materials were observed by [6] (d_m = 0.19 to 0.64 mm) and [7] (d_m = 0.21 mm). This effect can be explained by apparent cohesion. According to [6] or [8] the breaching process with material d < 1 mm is controlled by apparent cohesion whereas the erosion of coarser material is controlled by shear stress. However, in the current study, the slopes in the cross section were almost parallel. Just the time and the speed of the breach development differed with each material. Therefore, the nonuniform coarse material eroded faster with a higher peak erosion during the decisive phase of breaching. Yet towards the end of the breaching process, with decreasing flow intensity, the order of the erosion rates changed and subsequently the erosion of the coarse material ceased first. This could also be observed in the two-dimensional pre tests [5].

Applying an upstream impervious blanket led to higher erosion rates and therefore greater destruction of the embankment shell. The peak hydrograph increase was about approx. 30% compared to similar embankments with no impervious blanket.

The variation of the initial breach depth had no significant effect on the peak hydrograph value, but the process was delayed at the beginning. The time of peak discharge after breach initiation was increased with a smaller initial breach depth.

Model effects due to the sidewall could not be detected, undrained tests using coarse material showed a peak hydrograph increase of approx. 4% compared to fully drained tests.

3.2. SCALABILITY

The ideal Froude scaling could be affected by viscosity *v*, surface tension *σ* or material cohesion *c*. To neglect the effect of viscosity and surface tension, the flow must be fully turbulent. Viscosity effects can be neglected for flow *depth > 5* cm *w*as stated by [9]. Concerning the shell material, the sedimentation Reynolds number $Re^* = v_c^* d/\nu$ with $v_c^* = (gR_h I_0)^{0.5}$ as the critical shear stress velocity v_c^*, the hydraulic perimeter R_h and the energy gradient I_0, should not fall below 200 [10]. Regarding the material properties and the flow conditions in the current studies, especially in the decisive phase during peak hydrograph occurrence, scaling should be possible according to Froude's similarity law.

The test results fit very well to the scaled peak values $Q_P = Q * \lambda^{2.5}$ with a scale factor $\lambda = 2$ [5].

4. HYDROGRAPH PREDICTION MODEL

4.1. GENERAL AND IMPULSE

The processes that control breach development and eventually the outflow hydrograph depend on numerous parameters and boundary conditions. Their complex relations are not yet fully understood and are also the subject of the research studies presented in this paper.

The essential geometrical parameters are the dam height h_D, upstream and downstream slope m_u, m_d and crest width b_c. Main hydraulic factors are considered as water level h_W, reservoir volume V_R, Reservoir shape n and a potential influence of the downstream water level h_d. Geotechnical parameters are mentioned as shell material properties - represented as the medium grain size diameter d_m dam type, impervious blankets etc. x ([6], modified).

According to [11] effects of m_d are negligible as well as the influence of b_C [12].

With the assumption of a full reservoir at the start of the breach initiation (dam height $h_D \approx$ reservoir water level h_W) and no influence from a downstream water level, a global length scale $h = h_W \approx h_D$ is introduced for the normalization of the parameters displayed in this paper referring to dimensions as flow rate, volume, length and time [6]. - Eq. [1]

$$Q^* = \frac{Q}{\left(g h_W^5\right)^{0,5}} = f\left(\frac{V}{h_w^3}, \frac{d_m}{h_w}, n, x\right) \qquad [1]$$

Existing hydrograph predicting models can be divided into empirical and process-based physical models. Empirical models are usually based on the analyses of historical failure events or large scale field tests. Input parameters are commonly the dam height h_D and the reservoir volume V_R, with the breach hydrograph peak Q_P as target value.

Process-based physical models are commonly based on assumed simplified breaching approaches (e.g. the enlargement of a trapezoidal or rectangular breach cross section) or calculating a breach shape by considering material parameters and slope failure mechanism. Therefore, the breach formation is predominantly controlled by erosion, calculated with standard empirical sediment transport formulae, whereas breach outflow is assessed by the assumption of a broad crested weir. However, the use of the sediment transport equations is bound to the limits of input parameters for each test series these formulae are based on. With the assumption of stationary flow conditions, the maximum permitted energy gradient is e.g. 2% (Meyer- Peter and Mueller) and 20% (Rickenmann). There is also a narrow range of input parameters regarding the sediment. For example grain size diameter is restricted from 0.2 to 2 mm (van Rijn) or 2 to 10.5 mm (Smart and Jaeggi). A large selection of empirical and physical methods was presented by [13]. Thresholds for selected commonly used sediment transport equations have been summarized by [5].

Using flood wave prediction models in engineering practice in order to fulfill government requirements related to safety issues, it is necessary to set equal standards. The application of process-based models is required to define parameter values which impact on the high complex processes is currently not fully understood. Within the possible range of feasible values, with some models it is possible to “design” a flood wave, rather than calculate it. Empirical models are strongly dependent on their often inhomogeneous and scarce database; the results of commonly used equations display a large range [5].

In order to evaluate several methods for flood routing due to embankment dam failure of reservoir basins for snowmaking, the Austrian Federal Ministry of Sustainability and Tourism initiated a workshop for the creation of guidelines. Selected empirical models as well as one-dimensional analytical and two-dimensional numerical process-based models were examined with realistic input data from prototypes. The calculations display a wide range of results, with peak hydrograph differences up to 1500%. The selection of the transport formulae as well as the variation of material parameters and hydraulic coefficients were highly significant [14].

Therefore, the model described in this paper was intended to be a simple approach for an applied hydrograph prediction model, which was initially designed for a common standard of supply reservoirs for snowmaking in Austria.

4.2. MODEL CHARACTERISTICS

From the previously described test series [4], [5], three different V_R/h_W - ratio, with each two different settings, representing the reservoir shape, the spectrum of different shell materials and an upstream impervious blanket, could be obtained. Fig. 3 shows the results of this tests as a matrix of dimensionless peak hydrograph values Q_P* (Eq. [1]).

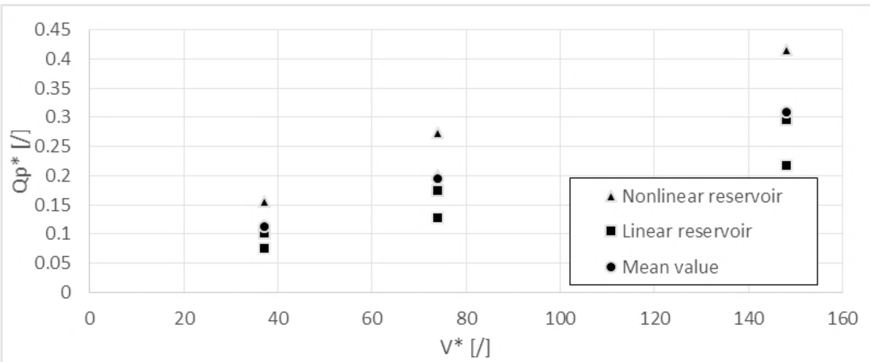

Fig. 3 Dimensionless peak hydrograph values from test series

[15] conducted model test series with numerous different reservoir sizes, simulated with reservoir inflow during the breach process. The results coincide well with the studies from Vienna University of Technology. With the calibrated equation of [15], for the calculation of the peak hydrograph using reservoir surface area and

maximum water level, the previous described spectrum of the matrix could be extended (Fig. 4).

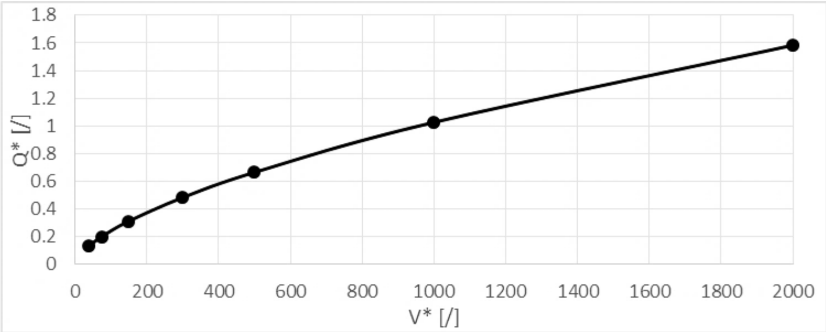

Fig. 4 Extended matrix according to [15]

Eq. [2] presents a fitting equation for the presented matrix calculating the peak outflow by using dimensional parameters based on reservoir volume V_R and maximum water level h_W.

$$Q_{max} = 0.0415 * (V_R * h_W)^{0.626} \qquad [2]$$

For engineering practice and the requirement of non-steady runoff simulations, the hydrograph profile is decisive. In the first step, the peak hydrograph value was calculated as described above. The second step generates the hydrograph profile.

By analyzing the runoff hydrographs of the test series, several characteristics could be observed, despite the variation of reservoir volume, impervious blanket and shell material properties. Peak hydrograph value always occurred with approx. 80% remaining reservoir volume in linear and approx. 70% in nonlinear characteristic reservoirs. The profile shapes were quite similar as well, with a characteristic steep ascent to the peak value, followed by a less steep decent and an asymptotic approach to zero. The dam body remaining, retaining approx. 5 to 15% of the initial reservoir volume could be noted. With these assumptions and boundary conditions, the outflow hydrograph can be generated iteratively with a fixed characteristic profile, whereas the peak value occurs at 75% remaining reservoir volume and a total outflow of 90%. Defining variances, different scenarios can be generated (Fig. 5).

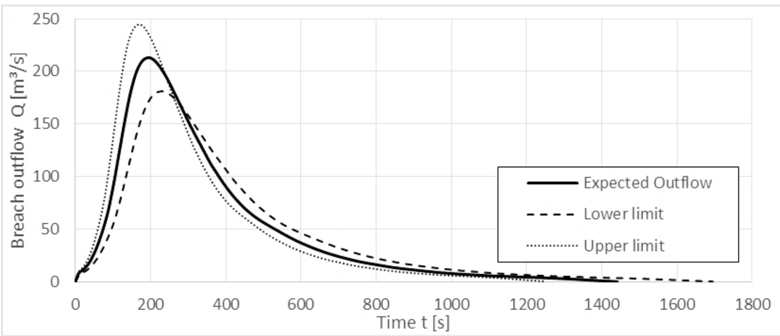

Fig. 5 Breach outflow hydrograph example - Variance + - 15%

4.3. COMPARISON WITH HISTORICAL FAILURE EVENTS

Fig. 6 presents the peak hydrograph values of different embankment dam configurations (water level h_W from 5 to 25 m, reservoir volume V_R from 5,000 to 20,000,000 m³ and a constant, realistic grain size distribution) from selected empirical equations [16], [17], [18] and the process based model DEICH [19], compared to the model presented in this paper. The hollow circles represent the database of [18] from historical failure events.

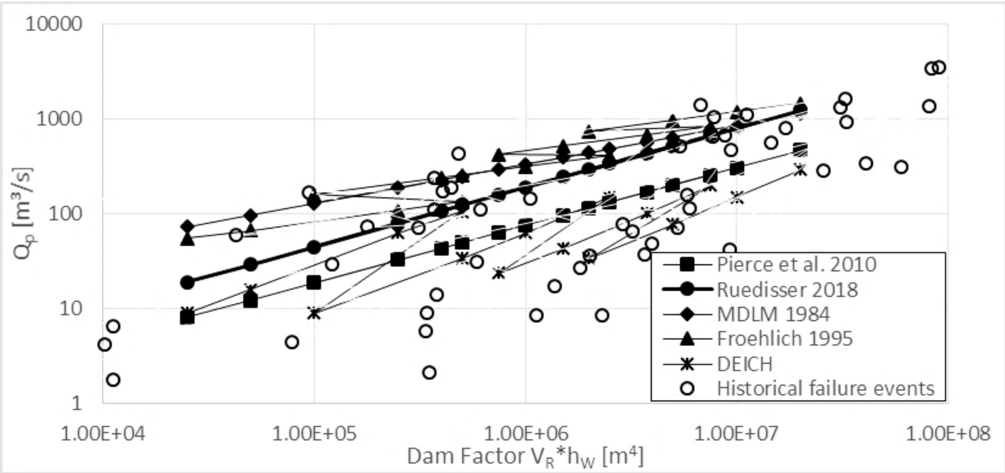

Fig. 6 Peak hydrograph prediction and historical failure events

For smaller structures with a rather small reservoir volume, the available data is quite limited. Filtering the Database of [16], for V* < 340 (see Eq. 1) and a Dam Factor $V_R * h_W < 3 * 10^8$, the results are in a plausible range compared to the historical failure events (Fig. 7).

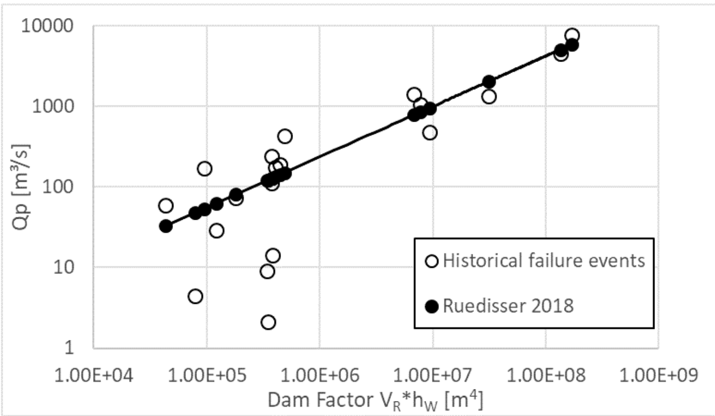

Fig. 7 Peak hydrograph and filtered database V* < 340

SUMMARY

In order to contribute to the understanding of the significance of several parameters and boundary conditions on the breach outflow hydrograph of overtopped embankment dams under falling water level and no reservoir inflow, two studies with three-dimensional experiments have been conducted at Vienna University of Technology. The parameters investigated were the influence of reservoir size and shape, different grain size distributions of the shell material, an upstream dam blanket, the significance of the initial breach depth as well as scalability and model effects. The most influential parameters are reservoir size, followed by shape. Shell material and an upstream impervious blanket do have a clear effect on breach processing, but the effect is not dominant. Further, the results cannot be comprehended with process-based models using sediment transport formulae from river engineering. The hydraulic and geotechnical conditions are outside the thresholds of the equations. Based on the results obtained from the studies, a simple approach for breach outflow hydrograph prediction, especially for embankments with comparatively smaller reservoir volume, is presented.

1. INTRODUCTION

Drought is a temporary period of deficiency in precipitation relative to normal conditions that may induce insufficiency to meet the water demands of human activities. The amount of precipitation during the three months of summer is fifty to sixty percent of the annual precipitation in the central and southern parts of the Korean Peninsula. Thus, relatively small amounts of precipitation on wet periods for one or two consecutive years cause shortage of water supply. There has been a drought every five to seven years in the Nakdong River basin of the Korean Peninsula. A severe drought in 2014 led to set systematic operation rules of limited water supply from multipurpose dams in the Nakdong River basin against drought occurrence. The rules, however, have been modified to fit the actual situation of water supply, and thus alternative researches and developments have been still needed. The contents of this study on water supply operation rules of the dams include the derivation results of hedging rules for single reservoir operation and the decision results of parameters on additional water supply from upstream dams to lessen water supply shortage at downstream control points.

Korean government have constructed several multipurpose dams in the Nakdong River basin and each dam has its own purpose on water supply and flood control. A discrete hedging rule having several hedging phases can be effective method for water supply operation of a reservoir against drought periods [1]. We present briefly the derivation results of the discrete hedging rules of the five major dams for water supply operation in the section 2. The rules for independent operation of the reservoirs, however, do not always ensure a stable supply of water against different future time series of drought inflow to the dam. If the other dams may supplement the water supply shortage from a dam, overall water supply of the

* *PROCÉDÉ DE SIMULATION DE SYSTÈME DE RÉSERVOIR PERMETTANT D'ÉVITER UN DÉFICIT D'ALIMENTATION EN EAU AUX POINTS DE CONTRÔLE EN AVAL EN UTILISANT UNE MÉTHODE HEURISTIQUE*

reservoir system will be more stable. Applying the discrete hedging rules mentioned above, we made a method of reservoir system operation to lessen water supply deficit at the downstream control points. The parameters needed for the reservoir system operation are additional water supply amounts from the upstream reservoirs and minimum reserve volumes of the upstream reservoirs above the trigger volumes of the first hedging phase. We describe the formulation of the method of reservoir system operation including parameters mentioned above in the section 3. We show the heuristic search results of the parameters and reservoir system simulation results in the section 4.

2. HEDGING RULES OF INDEPENDENT OPERATION OF A RESERVOIR

Jin et al. [2] developed the discrete hedging rules of water supply for the five dams: Andong, Imha, Hapcheon, Namgang, and Miryang. The rules depend on current reservoir storage without incorporation of the future reservoir inflow. A time interval of water supply from a dam is defined as follows: the first and second periods of a month have ten days; the third period has the remaining days of the month. That time division method about ten days comes from oriental calendar. We pronounce the unit of the time interval as / sun / and name it 'sun.' A time interval has four trigger volumes of hedging phases. A hedging phase includes 36 trigger volumes that form a line for the whole year. The application of a mixed integer programming module results in four hedging rule curves of each dam. The objective function of the optimization model is Eq. [1]:

$$Maximize \quad \sum_{t=1}^{T} y_{1,t} - \omega \sum_{p=1}^{12} \left(V_{1,p} + V_{2,p} + V_{3,p} + V_{4,p} + V_5 \right) \qquad [1]$$

where $y_{1,t}$ = 1 if full demand is available during a period t or 0, otherwise; ω = a weight value; T= the whole period of reservoir simulation; p is 1 to 36; $V_{1,p}$, $V_{2,p}$, $V_{3,p}$, and $V_{4,p}$, are trigger volumes of concern, caution, alert, and severe phases, respectively; and $V_{5,p}$ = the reservoir storage of low water level. Jin et al. [2] describe the twenty-five constraint equations.

Fig. 1 shows the derived hedging rule curves of four dams. Fig. 1 includes the Box-whisker plots drawn by monthly historical records of reservoir storage. The hedging rule curve values in summer are relatively larger than those of the other seasons are for Andong, Imha, and Hapcheon dams. It means that refrained release and higher storage status in summer and wet season may guarantee stable water supply until the end of dry seasons of the next year. The watershed area of Namgang dam is 2285 km^2 and the storage capacity is 309.2 million m^3 and somewhat small. The design water supply of Namgang dam is small compared to the inflow, which results in different hedging rule curves from the other curves. The case of Miryang dam is similar to Namgang dam and is omitted here.

3. RESERVOIR SYSTEM OPERATION METHODOLOGY

3.1. RESERVOIR SYSTEM OPERATION RULE

The five reservoirs form a system of reservoirs (Fig. 2). If the water supply shortage from a dam may be supplemented by the other dams, overall water supply of the reservoir system will be more stable. An upstream dam has water supply contracts with several demand centers near downstream control points. For example, Andong reservoir has water supply contracts with the downstream demand centers near control points 1 and 3. The rule of reservoir system operation is as follows and Fig. 3 describes it. If a water supply amount is less than the contract amount at a control point, some upstream reservoirs may supply additional water to lessen water supply shortage at the downstream control point. Sufficient storage is the condition that upstream reservoirs provide extra water. If reservoir storage is not sufficient, the reservoir supply water independently.

Schéma du système de réservoir

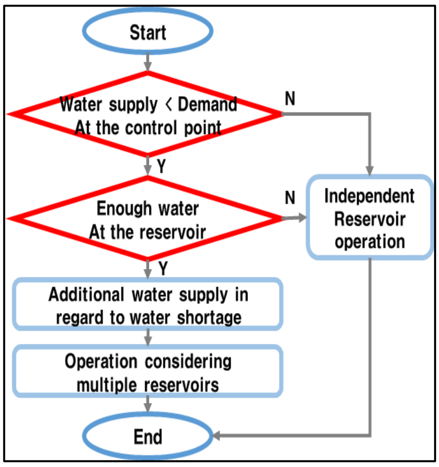

Fig. 3
Flow chart for the reservoir system operation rule to lessen water shortage at downstream control points [2]
Organigramme de la règle d'exploitation du système de réservoir pour réduire la pénurie d'eau aux points de contrôle en aval

3.2. OPTIMIZATION PROBLEM

The decision variables needed for the reservoir system operation are additional water supply amounts from the upstream reservoirs and minimum reserve volumes of the upstream reservoirs above the trigger volumes of the first hedging phase. The objective function is Eq. 2 that minimizes the total sum of water shortages at the control points over the whole simulation period and the weighted total number of times during which water supply failed at each dam:

$$Minimize \quad Z = \left(\sum_{cp=1}^{3}\sum_{t=1}^{T} Deficit_{cp,t}\right) + \left(\omega \sum_{r=1}^{5}\sum_{t=1}^{T} Fail_{r,t}\right) \qquad [2]$$

where *cp* is control point; *T* is the total number of periods for reservoir system optimization; *t* is the period; $Deficit_{cp,t}$ is water supply deficit during a period at a control point; $Fail_{r,t}$ = 1 if water supply is failed during period *t* or 0, otherwise; ω is a weight value that is big to minimize water supply failures.

3.3. DYNAMICALLY DIMENSIONED SEARCH METHOD

The optimization problem has sixteen decision variables mentioned in the previous section. We applied a heuristic search method to decide the decision variable values. Using 2 to 80 dimensional test functions, Kang [3] evaluated three types of heuristic techniques: a genetic algorithm; shuffled complex evolution [4]; and a dynamically dimensioned search method [5]. He concluded the dynamically dimensioned search method is superior to the other two in converging performance to a global optimum. We applied a dynamically dimensioned search method to the optimization problem based on the evaluation results for the three heuristic search methods. The dynamically dimensioned search method uses search strategies that perform searches globally at the initial iteration stage and locally at the post-repeating stage, regardless of the maximum number of iterations.

4. SEARCH AND RESERVOIR SYSTEM OPERATION RESULTS

4.1. SEARCH RESULTS OF OPTIMIZATION MODEL

The total number of iterations for one search run was 0.2 million. Optimization run was carried out once more with the first answers as the initial values. Fig. 4 illustrates the convergence of the objective function in the optimization process. Although it is difficult to distinguish visually, the value of the objective function decreases slightly after the sixth search iteration.

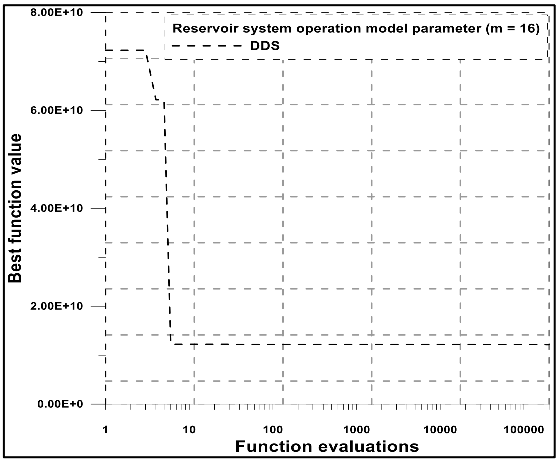

Fig. 4
Convergence of the objective function value [2]
La convergence de la valeur de la fonction objective

Tables 1 and 2 show the search results of the decision variables. Table 1 shows the priority and additional water supply proportion of the downstream water supply shortage for each dam by control point. The Andong reservoir additionally releases seven percent of the water supply shortage in the control point 1 that is relatively small amount. Regarding the lack of water supply at the control point 2, the priority of additional release of Namgang reservoir is highest and the proportion of additional release for the lack of water supply is the largest. For the Namhangang reservoir, available water is quite large due to its large basin area and high inflow. Due to these characteristics, the Namgang reservoir can be considered to have a relatively large storage margin for additional release against the shortage of downstream water supply. As the water supply volume of Hapcheon reservoir is relatively larger than the inflow and storage capacity of the reservoir, it is deemed that the proportion of additional releases was found to be small. Table 2 shows the search results for minimum water reserve above the trigger volume of concern stage to supply water additionally.

Table 1
Optimized results of additional water supply for the downstream water supply shortage [2]

Control point	Dam	Optimization results	
		Priority	Additional water supply proportion of the downstream water supply shortage (%)
1	Andong	1	7
	Imha	2	99
2	Andong	2	85
	Imha	3	70
	Hapcheon	4	7
	Namgang	1	99
3	Andong	1	56
	Imha	2	61
	Hapcheon	3	53
	Namgang	4	99
	Milyang	5	59

Table 2
Minimum reserve volume above the trigger volume of concern stage [2]

Dam	Minimum reserve volume (m^3)
Andong	19,196,600
Imha	7,608,200
Hapcheon	8,894,950
Namgang	27,252,100
Milyang	35,588,100

4.2. RESULTS OF MITIGATION OF WATER SUPPLY SHORTAGE AT CONTROL POINTS

The results of reservoir system operation using determined variable values were compared with the results of the independent reservoir operations. The operation period of the reservoirs is 2006 to 2016. Fig. 5 shows the reservoir storages and water supply amounts excluding the spillway releases: only the results of Andong and Namgang reservoirs are shown by page limitation. The design water supply amounts are provided when the reservoir storage volumes are on the normal status beyond hedging phases. The water supply is rationed when the reservoir storage volumes are under hedging phases. Fig. 6 indicates the shortage of water supply at control points 1 and 2. Table 3 shows the total deficit of water supply, the maximum deficit of water supply, the number of rationing, and the reliability of each control point. Due to additional release of the Andong reservoir for control point 1, the reservoir water level reached low water level, resulting in a complete failure of water supply for ten days (Fig. 5(a)). As for control point 2, the total water supply deficit was reduced 91 % over the independent operation of the reservoirs due to the effects of additional releases from the Namgang reservoir (Table 3). Additional releases of upstream reservoirs into the downstream regions are considered effective in the total deficit of water supply, but may cause increased water supply deficit for short periods during a severe drought. Therefore, further research is needed to limit the search ranges of additional water supply amounts from upstream reservoirs to prevent adverse effects of reservoir system operations.

The number of rationing	210	149	31	239	150	31
Reliability	0.47	0.62	0.92	0.40	0.62	0.92

5. CONCLUSIONS

Dynamically dimensioned search methods are excellent search techniques that can find a solution of a complex optimization problem near to a global optimum. We applied a dynamically dimensioned search method to an optimization problem of a reservoir system operation under the discrete hedging rules of independent water supply operation of the five reservoirs in the Nakdong River basin. The downstream tributaries are not included in the reservoir system. The decision variables are additional water supply amounts from the upstream reservoirs and minimum reserve volumes of the upstream reservoirs above the trigger volumes of the first hedging phase. Results of the reservoir system operation using searched values of decision variables are as follows. Additional releases of upstream reservoirs into the downstream regions are considered effective in the total deficit of water supply, but may cause increased water supply deficit for short periods during a severe drought. Thus, further researches are needed to limit the search ranges of the additional water supply amounts from the upstream reservoirs to suppress the increase of the maximum deficits of water supply resulted from the independent operation of the reservoirs.

SUMMARY

A discrete hedging rule having several hedging phases can be effective method for water supply operation of a reservoir against drought periods. Hedging rule curves for five multipurpose dams were determined independently by applying a mixed integer programming module in the Nakong River basin, the Republic of Korea. The derived hedging rule curves reveals the following: refrained release and higher storage status in wet season may guarantee stable water supply until the end of dry seasons of the next year; the Namgang reservoir needs little hedging operation due to the relatively large reservoir inflow and small amount of design water supply. Applying the discrete hedging rules derived above, we made a method of reservoir system operation to lessen water supply deficit at the downstream control points. The parameters needed for the reservoir system operation are additional water supply amounts from the upstream reservoirs and minimum reserve volumes of the upstream reservoirs above the trigger volumes of the first hedging phase. We decided the sixteen parameters by applying a dynamically dimensioned search method. The reservoir system operation showed that additional releases from upstream reservoirs into the downstream regions are considered effective in the total deficit of water supply, but may cause increased maximum deficit of water supply for short periods during a severe drought.

RÉSUMÉ

Une règle de couverture discrète comportant plusieurs phases de couverture peut être une méthode efficace pour l'alimentation en eau d'un réservoir contre les périodes de sécheresse. Les courbes des règles de couverture pour cinq barrages polyvalents ont été déterminées indépendamment en appliquant un module de programmation mixte dans le bassin de la rivière Nakong, en République de Corée. Les courbes dérivées de la règle de couverture révèlent ce qui suit: le rejet et le stockage plus élevé en saison humide peuvent garantir un approvisionnement en eau stable jusqu'à la fin des saisons sèches de l'année suivante; le réservoir Namgang a besoin de peu d'opérations de couverture en raison de l'afflux relativement important du réservoir et de la faible quantité d'eau de conception. En appliquant les règles de couverture discrètes dérivées ci-dessus, nous avons fait une méthode de fonctionnement du système de réservoir pour réduire le déficit d'approvisionnement en eau aux points de contrôle en aval. Les paramètres nécessaires pour le fonctionnement du système de réservoir sont des quantités d'eau supplémentaires provenant des réservoirs en amont et des volumes de réserve minimums des réservoirs en amont au-dessus des volumes de déclenchement de la première phase de couverture. Nous avons décidé les seize paramètres en appliquant une méthode de recherche dimensionnée dynamiquement. L'exploitation du système de réservoir a montré que des rejets supplémentaires provenant des réservoirs en amont dans les régions en aval sont considérés comme efficaces dans le déficit total d'approvisionnement en eau, mais peuvent causer un déficit maximal d'approvisionnement en eau pendant de courtes périodes.

1. INTRODUCTION

Nowadays lack of space is an important factor connected to economic development and the extent of damage (magnitude) from natural disasters. According to United Nation reports, 90% of all natural disaster is somehow connected or better triggered by weather and climate changes. Floods account almost 47% of all weather related disasters. The intensity of events and disaster extent increases and the extent of damage is almost directly commensurate with intensity of settlement and land use.

Apparat from flooding, heavy rain is closely connected to another major type of natural disaster – Landslides. When the mases slide down to the bottom of the valley and block the river course – we speak of the landslide dams. Landslide dams are an old phenomenon – many glacial and other lakes are a still an existing proof. The event is quite rare. However, due climate changes and due to rapid urbanization presents a significant threat. This type of dam may not be a long lasting structure - they may last for a few hours or for thousands of years. Furthermore, it is difficult to assess the condition and predict the breaching mechanisms, since usually there is no time to make complex analysis. Flush flood or debris flow caused by brake of this type of dams is even more dangerous, than the breaching of regular dams, because the breach happens quickly and the flow is strong and destructive.

In the paper we will present several such past events in Europe and worldwide and touch the question what we could learn from historical event.

INDONESIA

Geology and Geotechnical Condition from Geological Mapping, Core Drilling, and Geophysical at Masang II Hydropower Project, West Sumatera, Indonesia

Jodi Prakoso Basuki [1)]
Kiki Lukman Nulhakim [1)]

[1)] Geologist at PT. Kwarsa Hexagon. He has been involved in feasibility studies of hydropower projects in Indonesia or other geotechnical project to give the geology and geotechnical recomendation

Introduction

Masang II project is one of the hydropower projects to develop in Agam District, West Sumatra Province. To realize this project, a weir will be build on the Sianok River. Water that diverted from weir, will be used utilized for hydro power plant (hydropower) with a capacity of 2x26 MW. The Masang II hydropower project is located on the Sianok River that flows from south to north, which empties into the Masang River on the border of Agam and Pasaman districts. Seeing the area supported by the topographic condition of the region, the Sianok River has considerable potential to develop into a hydropower energy source (hydropower). The aim of this paper is to know geology and geotechnical condition at project location.

Based on the Regional Geology Map of Padang, Sumatera (Kastowo, Gerhard, Gafoer, and Amin; 1996) 1: 250.000 scale published by Geological Agency, West of Sumatera consists of 3 rock group Pre Tertiery Rock Unit, Tertiery Rock Unit, and Quaternary Rock Unit. In general, the stratigraphy of the project site is composed of tuff and metamorphic rock. The major geological structure in and around the Masang II site is the Sumatran Fault Zone (SFZ), one of the most active zones in Indonesia. It affects the condition of bearing capacity at project location.

Method

The method that used in this project is literature review of project location, field surveys include surface geological mapping, geotechnical and geophysical investigation, consisting of core drilling and seismic refraction have been performed along with soil/rock laboratory tests and analysis.

Regional Geology

Physiographically project location is belong into Mountain Barisan Block with characteiristic by a series of NW – SE Block Mountain, The Sumatran Fault Zone, locally Block Faulting and Active Volcanos.

Based on the Regional Geology Map of Padang, Sumatera (Kastowo, Gerhard, Gafoer, and Amin; 1996) project location consist of Permian Limestone Rocks (Pl), Ultrabasic Rock (Kub), Early Tertiary Andesite (Ta), Andesite of Maninjau Caldera (Qamj), and Pumiceous Tuff and Andesite (Qpt) (Fig. 1). Regional tectonic of project location according to Barber et. Al, (2005), activities of the Sumatera Fault is continued until now. Mechanism of movement is strike slip dextral fault, is related to subduction zone fom Indo-Australian Plate that subducted into under Eurasian Plate at west Sumatera Island.

Fig. 1

Regional Geology Map of Padang, Sumatera (Kastowo, Gerhard, Gafoer, and Amin; 1996)

Investigation Result

a. Geological Mapping of Project Area

Stratigraphy of the project site from old to young: Pre Tertiary Metamorphic Polimic Fragment Rock Unit and Quartenary Pumiceous Tuff Rock Unit. Pre Tertiary Metamorphic Polimic Fragment Rock Unit consists of many types of rocks that are mixed in a matrix, it is predicted that these units are formed in the subduction zone resulting many various types of rocks. Types of rock in this unit are calcarenite, calcipulverite, metalimestone, serpentinite, schist mica, conglomerate-breccia, and diorit as fragment. Quartenary Pumiceous Tuff Rock Unit is located at the top of the hill. The outcrop was very weathered and became rice field area and plantation. The thickness of this outcrop is 1-20 meters and can be found at side of the road.

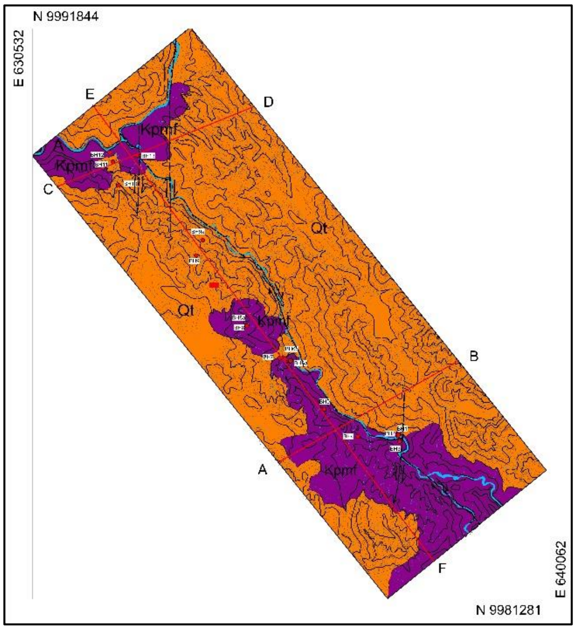

Fig. 2
Geological Map of Project Area

b. Core Drilling

There are 15 (fifteen) points of core drilling and in-situ testing from weir until power house. The result of core drilling show many various of metamorphic rocks.

Weir

Based on the geological mapping at the weir area is composed of metalimestone. At the surface metalimestone outcrop show the cracked structure and jointed. Metalimestone is predicted a part of fragment from melange zone. Meanwhile, based on the result of core drilling at weir site (BH1, BH2, and BH3), top layer (fluvial deposit) is composed by sandy clay-silty clay contain boulder. Below of top layer, generally composed by metalimestone with high fractured and cracked with thickness is about 20 meters.

Connecting Culvert

At connecting culvert there is cores drilling that is BH-4. These location core drilling at Jorong Bamban with long of the connecting culvert is 881 m. Based on the results of geological mapping of the surface can be seen that the connecting culvert composed by serpentinite and metalimestone. At the surface metalimestone outcrop show cracked structure and fractured. Serpentinite is found at Intermiten River and around the serpentinite outcrop is found polimic metamorphic rock and gneiss. But this metalimestone and serpentinite predicted part of fragment from melange zone.

Connecting Tunnel

At the connecting tunnel, there is core-drilling BH5. From geological mapping, the connecting tunnel composed by serpentinite and metalimestone. At the surface metalimestone outcrop show cracked structure and fractured. Metalimestone and serpentinite is predicted a part of mélange. Top soil layer (sandy clay) with the thick of 0.8 meter and below of this layer is metalimestone with thick of 39.2m. The condition of metalimestone layer is fracture. That indicated at BH-05 is fault zone and it is an aimpact from sumateran fault.

Intermediet Pond

In the intermediate pond area, there are three (3) boreholes BH-06A (right abutment), BH-06B (as dam), and BH-07 (left abutment). Based on the results of geological mapping this area is composed by metalimestone and tuff. At the surface metalimestone outcrop show cracked structure and jointed, but this metalimestone predicted a part of fragment from melange zone.

Headrace Tunnel

At the Headrace tunnel have 3 point of core drilling (BH-8, BH-8a & BH-9). Top soil of the borehole BH-8 & BH-8a are composed by sandy clay-clayey sand with thick of 3.4 meter. Below this layer composed by Phyllite, Schist Mica, Schist & Sand (mélange deposite) with the depth of 3.4-75 meters. Basement layer (phyllite) is found from the depth of 75-90 meters. Headrace tunnel is past of mélange deposite and basement layer.

Around headrace tunnel found outcrop like schist and phyllite with high fractured. It indicated around headrace tunnel has affected by geological structure. Beside that, core samples at BH-08, BH-08a, and BH-09 is fractured and jointed. It can predicted that an impact of sumateran fault zone and must be aware when buikd the tunnel.

Surge Tank

At the surgetank is represented by the results of observations on the BH-10. Top soils of the borehole BH-10 are composed by soft clay sand with thick of 3.6 meter. Below this layer composed by Sand, Breccia and Serpentinite (mélange deposite) with the depth of 3.6-78 meters. Basement layer (phyllite) is found from the depth of 78-80 meters.

Penstock

Stratigraphy at penstock is represented by the result of observation on the BH-11. Top soils of the borehole BH-11 are composed by sand and silty clay. Silty clay are dominated at the bottom of the layer. From top layer to bottom hardness of the soil rise up.

Power House

Core drilling at the Power House area is BH-12, Soil layer (silty Clay – Clayey Sand contain of Boulder) at the depth of 0 – 4.8 m. Intercalation of Metalimestone and Slate layer below the soil layer.

c. Seismic Refraction

Seismic refraction was held by using air gun as source of vibration at tunnel area. The vibration will be recieved by geophone with interval 10 meters. One shoot of this air gun can reach 500 meter of distance. Seismic activity is performed along the tunnel area from BH-4 until BH10 where at that bore hole are the tunnel area. Total range of distance seismic refraction is 7,5 km with 16 hole and 15 line.

The result of this seismic refraction data can intepreted layer from top to bottom with >350 meter of depth based on velocity value. This data can help to intepreted layer of the project area from velocity. However, this data must be correlation with borehole data to make intepretaion correctly. Based on this seismic data, project area divided into 3 layers, that is top soil/tuff, mélange deposit, and basement. All of this layer have different characteristic from velocity in the field. Top soil have velocity 200-600 m/s, mélange deposit have velocity 600-3000 m/s, and Basement have velocity >3000 m/s.

Geology and Geotechnical Condition

From geological mapping, core drilling, and seismic refraction data can be combined to interpretation geology condition from the surface and subfurface. After combined the data can interpreted that the project area consist of three layers that are soil/tuff, melange complex, and basement.

After combined from three data (geological mapping, core drilling, and seismic refraction), can be interpreted the geological section. Soil/tuff is at the top of the layer and consist of many kind of soil result from weathering of tuff. This layer have small velocity value (vp) that is 200-600 m/s. Melange complex is at the bottom of soil/tuff layer where at this layer consist of many rock type and mixed into a layer. Melange complex consist of diorite, basalt, andesite, metamorphic rock like mica schist, slate, gneiss, metalimestone, and phyllite. This layer have velocity value (vp) 600-3000 m/s. Basement layer is bottom of the layer and just consist of phyllite. This layer have velocity value (vp) >3000 m/s.

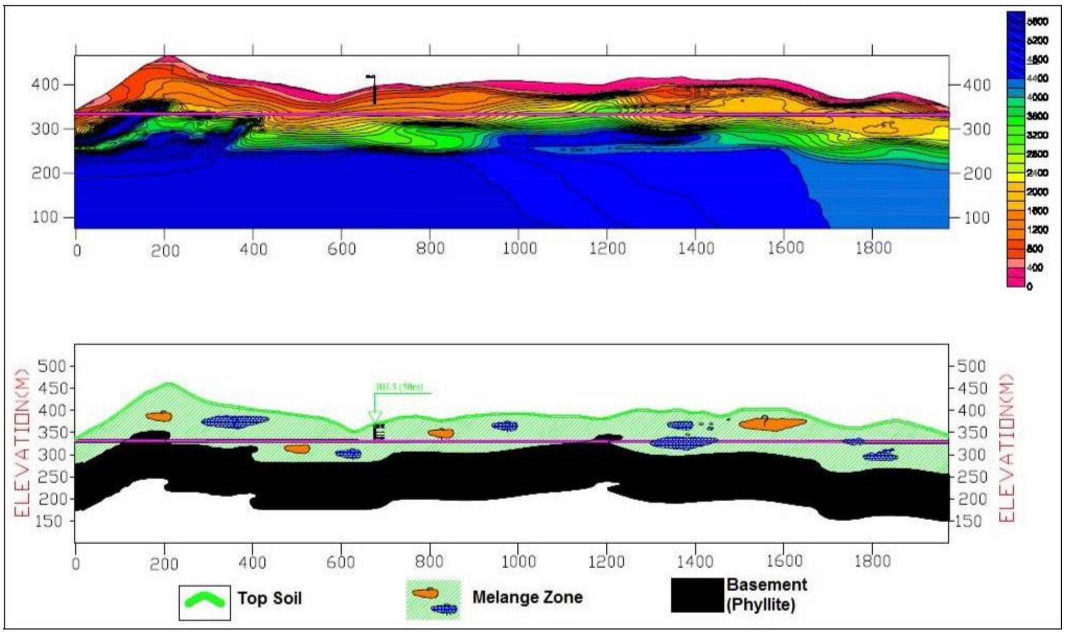

Fig. 3
Corelation between Seismic Refraction and Borehole at Connecting Tunnel

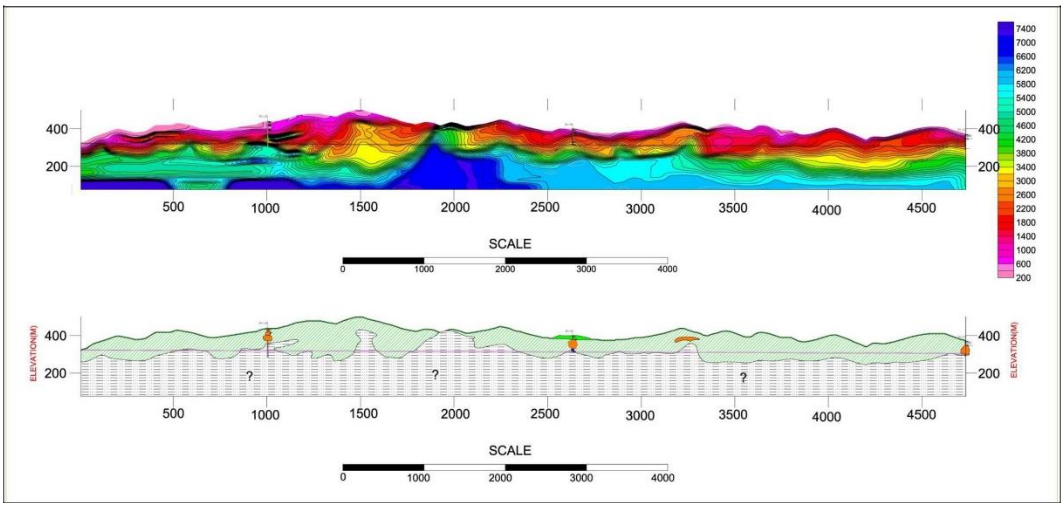

Fig. 4
Corelation between Seismic Refraction and Borehole at Headrace Tunnel

Geotechnical condition of the project area can be intepreted from core drilling and seismic refraction. Core drilling at the weir site can not be SPT test because the lithological is rock. At the depth of 5.8-15.7m is unstable based on SPT test where the SPT of the soil is 2-4 blows/feet. Meanwhile at the bottom of the weir site bearing capacity is good because bottom of the weir site is metalimestone. Although the bearing capacity of rock is high (Qa>68 ton/m2), but the rock conditions are fractured and cracked so it is grouting is recommended for this layer.

Due to metalimestone is fractured and cracked, possibly could be happen seepage at the weir site.

Foundation of Connecting Culvert is at the top soil and mélange deposite layer. The top soil consists of clayey sand and Sand. Bearing capacity of top soil layer with the depth of 0-12m about 6,8 – 21,8 ton/m2. Melange deposite layer have bearing capacity about > 68 ton/m2. Foundation of connecting culvert, where is at the top soil layer is not good, so pile foundation is recommended for it.

Foundation of dam site is at the mélange deposite layer. The mélange layer is consist of clayey sand weathered from tuff, silty clay contain diorite and metalimestone gravel, and clay contain metalimestone gravel. Based on core drilling result permeability test and bearing capacity analysis, intermediate pond no need to conducted grouting.

Foundation of headrace tunnel is at melange zone and basement. The melange layer is consist of various of rock like schist, metalimestone, breksi, and serpentinit. Bearing capacity at this layer is heterogeneus, in one place is stable but in other place is unstable. From RMR class, we can know that at melange zone is very unstable. At basement rock, bearing capacity is stable because at basement is very compact rock.

S14	115	Phyllite	2800-3200	Very blocky and seamy (V)	2.26	2.3	20.3	20.98	20
S15	1431	Metalimestone, Clayey Sand, Phyllite, Schist Mica, Schist, Sand, Breccia	600-2800	Completely crushed but chemically intact (VI)	1.53	2.3	15.2	22.32	30

Foundation of Penstock from BH-11 is recommended at the Hard Silty Clay – Clayey Sand layer (5-20 m depth) with the bearing capacity, Qall > 68 ton/m^2, which cutting the soil layer (0 – 5 m depth). From CPT's data, Dense or Cemented Sand layer at the depth between 2 – 8.2 m. Foundation of Penstock is recommended at this layer.

Foundation of Power House is recommended at the Metalimestone and Slate Intercalation layer (4.8 – 30m depth) with the bearing capacity, Qall > 68 ton/m^2, which cutting the soil layer (0 – 4.8m depth).

Summary

Masang project area consist of 3 layers that are soil/tuff layer, melange complex layer (consist of schist, phyllite, diorite, metalimestone, and serpentinite), and phyllite basement. This three layer have different bearing capacity value because affected to rock condition and hardness of the layer. Soil/tuff layer have small bearing capacity value because this layer is soft and easily to weathered. Melange complex is very heterogeneous condidtion, it can be stable but it can be stable, but the bearing capacity value is more higher than soil/tuff layer. Basement layer have high bearing capacity value is affected from the rock condition of basement rock is very compact and homogen.

1. INTRODUCTION

Several mountain slopes of the Alpine valleys, where many Italian large dams are located, are characterized by hazardous instability phenomena that might give rise to rock-fall that could impact on the above infrastructures. In order to plan adequate mitigation and protection works for the safety of the dams, the first step is the assessing of the consequences that potential events of rock-fall could cause on the structures.

This paper presents the numerical modeling of a massive boulder falling from the left bank of the reservoir and impacting on Place Moulin arch-gravity dam. The most hazardous instability phenomena provided by recent geological surveys were considered to characterize the volume and the trajectory of the boulder. The main consequences that the dam could suffer are described in terms of structural damage.

2. INSTABILITY PHENOMENA OF THE LEFT SLOPE OF THE RESERVOIR OF PLACE MOULIN

The dam of Place Moulin, located in the Municipality of Bionaz in Valpelline, in the Italian Region of Valle D'Aosta, is a concrete arch-gravity structure built between 1955 and 1965 (Fig. 1). The reservoir has a total volume of 105 Mm^3 that feeds the power station of Valpelline.

Fig. 1
Downstream view of the dam of Place Moulin

The dam is 155 m high, with a crest length of 678 m and a thickness varying from 6,44 m at the crest and 41,94 m at the base. The dam volume is 1,51 Mm^3.

The instability phenomena that occurred and might still take place on the rocky slope of the orographic left bank of the reservoir of Place Moulin were thoroughly investigated during some geological surveys [1][2]. The outcomes of these studies allowed to characterize the structural and geomorphologic setting of the left slope and to identify which potential kinematic mechanisms could directly threaten the dam.

First of all, the boulders that could detach, fall off and roll down along the left slope, will not exceed a volume of 10 m^3 because of the strong fractured state of the in situ rock. The rock-fall hazard simulations highlighted that the first part of the left side of the dam crest, 30÷50 m long, has a 15÷60% probability to be threatened; the hazardous conditions progressively decrease moving towards the center of the crest and they become nearly negligible for a distance exceeding 80 m from the left abutment. The trajectories and the impact points of the main boulders are mapped in Fig. 2 while the features of the most hazardous conditions for the dam are listed in Table 1.

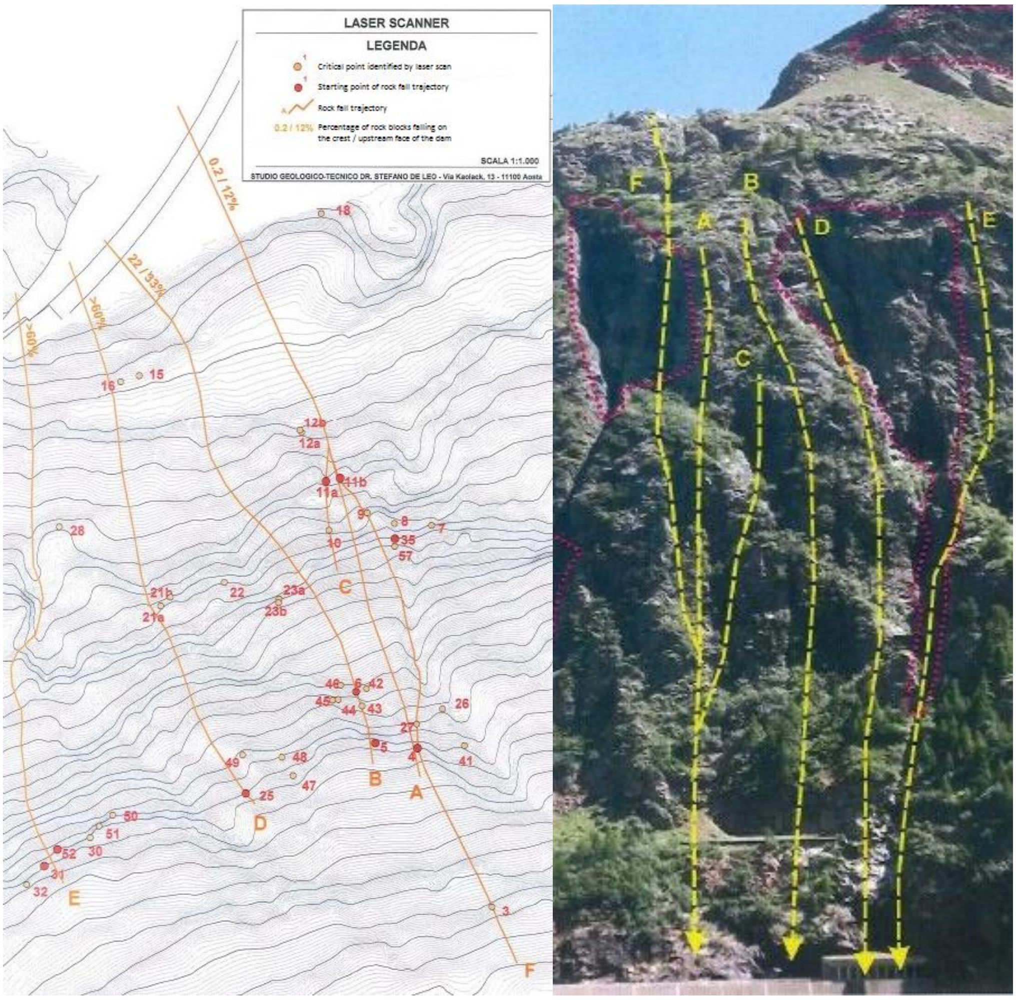

Fig. 2
Trajectories of the main boulders that could impact on the left side of the dam

Table 1
Features of the main boulder trajectories

Number of the hazardous conditions	Boulder volume [m^3]	Boulder mass [kg]	Outcrop volume [m^3]	Maximum kinetic energy [kJ]
1	9,0	24.750	483,0	24.360
2	6,9	19.000	17,2	20.500
3	8,9	24.500	34,2	23.800
4	7,1	19.500	360,0	29.972
5	5,2	14.300	12,0	24.250

Bearing in mind these results, the hazardous condition number 4 in Table 1 was selected to carry out the numerical simulations of the impact of the boulder on the dam because this situation is characterized by the highest kinetic energy and by the highest probability of occurrence.

3. THE FINITE ELEMENT MODEL

3.1. GEOMETRY AND CONTACT SURFACES

The three dimensional Finite Element model of the dam was generated on the basis of the design drawings [3]. Considering the large size of the dam with respect to both the impact zone and the boulder dimension, only half dam was modelled together with an extended part of the foundation (Fig. 3). This choice was endorsed by a preliminary analysis that modelled the whole dam with a coarse mesh; the related results have shown that the effects of the impact are restricted to the left part of the concrete structure, towards the abutment. For sake of simplicity, the numerical simulations have taken into account only a single boulder with a volume of 7,1 m^3, assuming a spherical shape (Fig. 3, bottom-right picture).

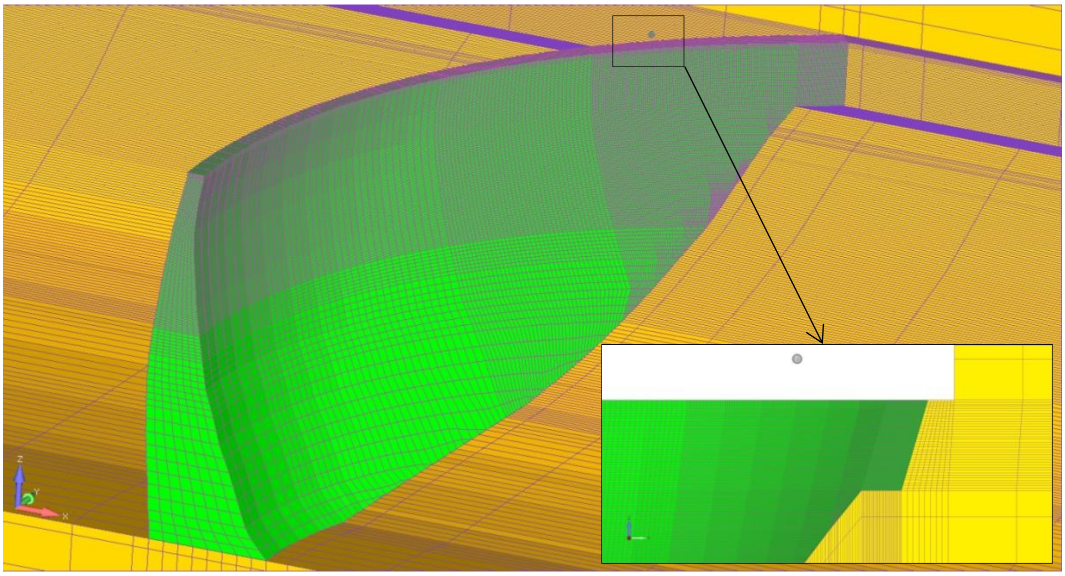

Fig. 3
Finite Element model of the half dam, the foundation and the boulder (in the bottom-right picture a zoomed downstream view of the left part of the dam with the starting position of the boulder)

In order to reduce the computational time of each simulation, the mesh was progressively refined along the following directions: starting from the main vertical section towards the left abutment, and moving from the foundation towards the crest of the dam. The resulting model has nevertheless more than 210.000 nodes and nearly 184.000 finite elements, because the impact zone requires to be really well refined. The nodes laying on the base and vertical sides of the foundation were constrained; on the main vertical section of the dam symmetric boundary conditions were assigned to take into account the stiffness of the right part, not included in the model. The dam body was assumed monolithic, and there is also continuity between the dam and the foundation.

In order to model the interaction between the boulder and the dam, two contact surfaces were included: the former completely covers the outer surface of the boulder, the latter partially covers the crest and the upstream face of the left part of the dam.

3.2. IMPACT POINTS ON THE DAM

The numerical simulations have taken into account the following three different impact points on the dam:

A. The upstream edge of the crest, 50 m far from the left abutment
B. The midpoint of the crest thickness, 50 m far from the left abutment
C. The upstream face, 50 m far from the left abutment and 10 m below the crest level

In Table 2 the impact velocity, the kinetic energy, the incidence angle from the vertical axis, and the direction cosines of the falling trajectory are listed.

Table 2
Features of the analyzed falling trajectories

Case study	Impact velocity [m/s]	Impact kinetic energy [kJ]	Incidence angle [°]	Direction cosines		
A	52,91	27.331	50°÷55°	0,259	-0,721	-0,643
B	52,91	27.331	50°÷55°	0,259	-0,721	-0,643
C	55,51	30.083	25°÷30°	0,143	-0,397	-0,906

The incidence angle in the horizontal plane was maintained constant for all the three cases.

3.3. CONSTITUTIVE MODELS AND RELATED MATERIAL PARAMETERS

In order to simulate the impact phase, non-linear constitutive models were used because the material strength is overcome both in the concrete of the dam and into the boulder, with the exception of the foundation assumed as elastic, being rather far from the impact zone.

The parameters of all materials are summarized in Table 3 while some details of the related constitutive models, adopted to simulate their mechanical behaviour, are reported in the following paragraphs.

Table 3
Material parameters [3][4][5]

Material parameter	Foundation	Dam	Boulder
Young modulus	75.600 MPa	34.000 MPa	75.600 MPa
Poisson coefficient	0,220	0,166	0,220
Density	2.750 kg/m3	2.450 kg/m3	2.750 kg/m3
Compression strength	-	42,4 MPa	-
Tension strength	-	3,2 MPa	0,8 MPa

3.3.1. Dam

The concrete behaviour of the dam was modelled by means of the Concrete Damage Plasticity Model (CDP) provided in ABAQUS [6][7][8]. The main failure mechanisms of concrete are cracking in tension and crushing in compression. The CDP model aims to capture the effects of irreversible damage associated with these failure mechanisms, taking into account:

- different yield strengths in tension and compression, with the initial yield stress in compression being a factor of 10 than the initial yield stress in tension
- softening behavior in tension and initial hardening followed by softening in compression (Fig. 4)
- different degradation of the elastic stiffness in tension and compression, according to the following stress-strain relations under uniaxial tension and compression loading:

$$\sigma_t = (1 - d_t) E_0 \left(\varepsilon_t - \varepsilon_t^{pl}\right) \qquad [1]$$

$$\sigma_c = (1 - d_c) E_0 \left(\varepsilon_c - \varepsilon_c^{pl}\right) \qquad [2]$$

The unloading response of concrete from any point on the strain softening branch of the stress-strain curves is weakened being the elastic stiffness degraded. This degradation is characterized by two scalar damage variables, d_t (DAMAGET) and d_c (DAMAGEC), which are assumed to be functions of the plastic strain, ε_{pl}. The damage variables can take values from 0, representing the undamaged material, to 1 which denotes total loss of strength.

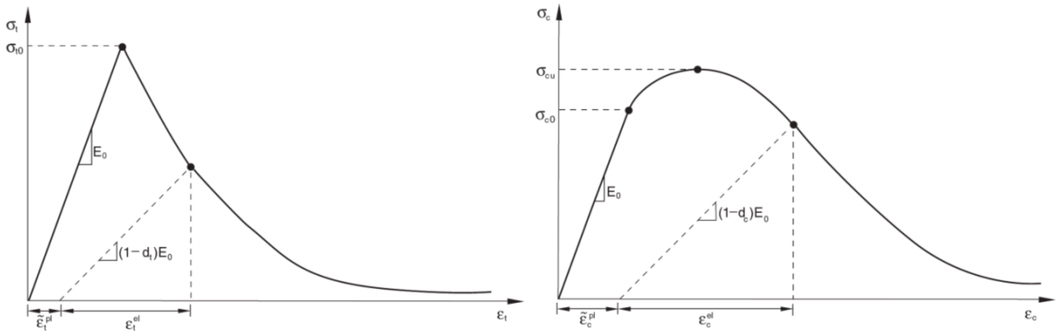

Fig. 4

Response of concrete to uniaxial loading in tension (left) and compression (right)

3.3.2. Boulder

The mechanical behaviour of the boulder was modelled by means of the Brittle Cracking (BC) Model provided in ABAQUS [6] which is designed for applications in which the tensile cracking is the dominant failure mode. A crack initiation is detected by a simple Rankine criterion which states that a crack forms when the maximum principal tensile stress exceeds the tensile strength of the brittle material. Although crack detection is purely based on Mode I fracture, post cracked behaviour includes both Mode I (opening mode) and Mode II (in plane shear/sliding mode) failures (Fig. 5). During the numerical analyses, the BC model allows removal of elements based on the Rankine criterion.

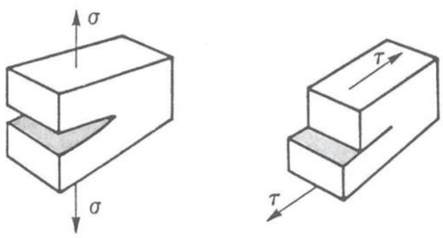

Fig. 5

Mode I – opening (left) and Mode II – in plane sliding (right) in fracture mechanics

In order to avoid mesh sensitivity into the results, the post failure stress is specified as a tabular function of displacement across the crack, u^{ck}, defining thus the energy required to open a unit area of crack in Mode I as a material parameter (Fig. 6, left).

Considering that the cracked shear modulus decreases as the crack opens, a shear retention model is adopted in which the post cracked shear modulus G_c is defined as a fraction of the uncracked shear modulus G. The shear retention factor ρ is defined as a function of the opening strain across the crack, e^{ck} (Fig. 6, right):

$$G_c = \rho\left(e_{nn}^{ck}\right) G \qquad [3]$$

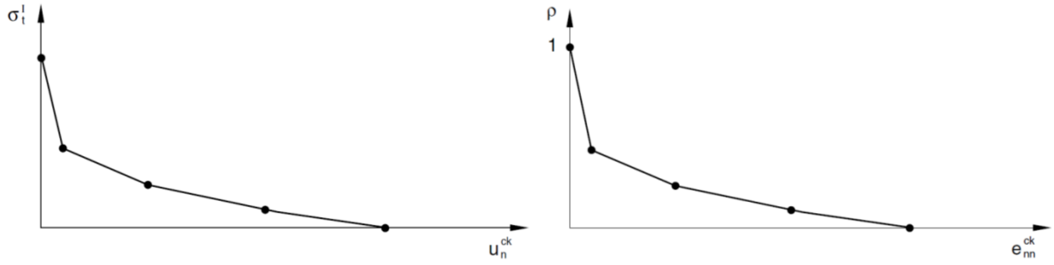

Fig. 6
Post failure stress-displacement curve (left) and shear retention model (right)

4. SENSITIVITY ANALYSES ON THE BOULDER FAILURE PARAMETERS

The boulder is composed of metamorphic rocks, characterized by marked schistosity and fracturing. The choice of the strength parameters related to this type of rock is indeed important because they define how much energy the boulder could dissipate during impact breaking into several pieces. The energy dissipated by the boulder increases with its brittle behaviour, and at the same time a major shattering of the boulder corresponds to a lower damage of the dam.

Sensitivity analyses were thus carried out to assess how the compression and tension damage varies on the dam body changing the brittle behaviour of the boulder in terms of deformation at the formation of cracks and at failure (Table 4).

Table 4
Failure parameters of the boulder used in the sensitivity analyses

Material parameter	Case 1	Case 2	Case 3
Deformation at the formation of cracks	0,0250	0,0070	0,0015
Failure deformation	0,0400	0,0090	0,0030

Making reference to the case study in which the boulder impacts against the midpoint of the crest thickness (Case B in Table 2), the results in terms of the tension damage parameter value show that the damage of the concrete is little influenced by the level of shattering of the boulder (Fig. 7). In the first case the boulder remains almost undamaged after the impact while in the last case it shatters almost completely.

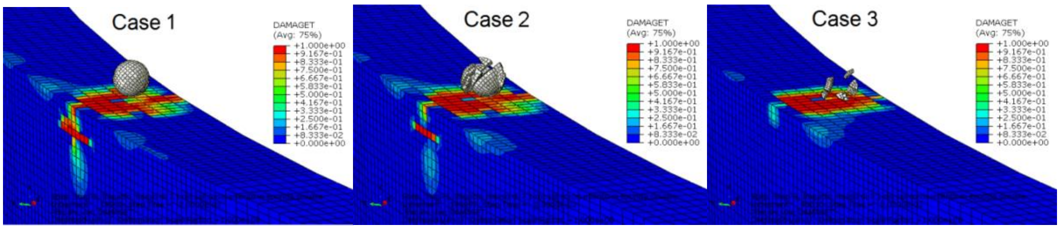

Fig. 7
Contour of the DAMAGET parameter – results of the sensitivity analyses

5. RESULTS OF THE IMPACT ANALYSES

In all the three case studies the impact analyses, carried out with ABAQUS/Explicit, shows that the compression damage on the concrete dam is limited to the impact area, and it is quite negligible for Case C as the boulder hits almost tangentially the upstream face of the dam. The tension damage is significant in the first two cases but not in the last one (Fig. 8 and Fig. 9).

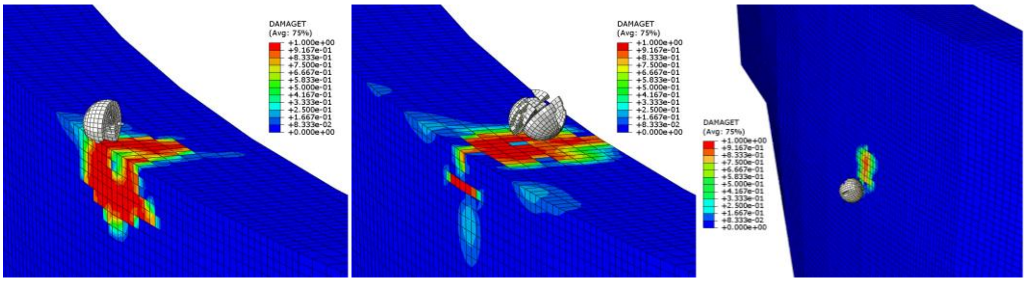

Fig. 8
Contour of the DAMAGET parameter on the crown and upstream face (Case study A - left, Case study B - centre, and Case study C - right)

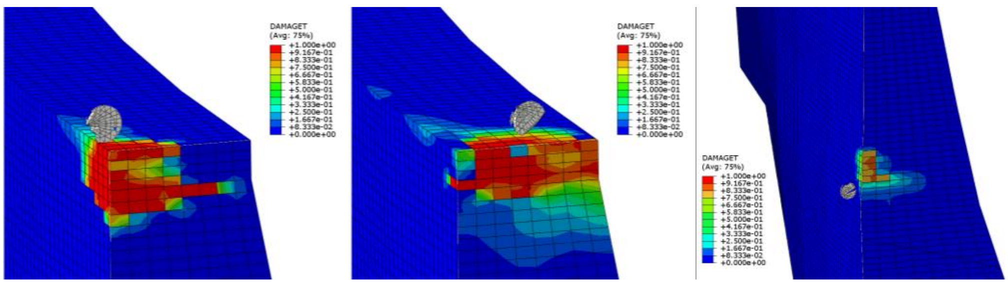

Fig. 9
Contour of the DAMAGET parameter in a vertical section of the dam (Case study A - left, Case study B - centre, and Case study C - right)

The most damaged conditions in tension are related to Case B since the formation of cracks extends down the dam nearly 2,5 m from the crest level and propagates along the whole thickness of the structure. In Case A the tension damage extends more along the vertical direction with respect to Case B, about 4,0 m from the crest level, but it does not affect the entire dam thickness.

6. CONCLUSION

The results of the impact analyses show that the boulder causes damages in tension on the concrete dam of Place Moulin because of the high kinetic energy. Being the slope rather steep, in fact, the boulder attains high velocities at the end of its falling path. The impact effects on the crest of the dam are higher than those occurring on the upstream face. Anyway, in each analysis the damaged zone in tension is quite localized.

On the contrary, in all cases the damage in compression is rather negligible being almost localised on the impact area. As expected, the static analysis, carried out after the impact simulation, has shown that the damaged zones do not affect the whole structural behaviour of the dam. These results will support the dam owner to select the most adequate mitigation works to guarantee the safety of the structure.

EXPERIMENTAL STUDY ON OVERTOPPING BREACHING PROCESS OF EARTH DAM AND PEAK DISCHARGE

Duan Wengang, Huang Guobing, LiLi

Engineer of Hydraulic Department, CHANGJIANG RIVER SCIENTIFIC RESEARCH INSTITUTE

CHINA

1 INTRODUCTION

The pattern of dam break is important for the study of the dam failure, which decides how long the whole dam failure lasts, the level of the peak discharge and the damage to the downstream areas. The break pattern closely relates to the dam type. Generally, the sudden break happens on the concrete gravity dam and arch dam, while the gradual break mostly turns up on the earth dam. For the different way of overtopping flow, the density of fill and gradation composition of the dam’s constructional material, the breaching process of earth dam is also distinctly different. Combining the indoor earth dam overtopping erosion experiment , the study tries to preliminarily explore the erosion process of earth dam, and makes further efforts to disclose the relationship between the breaching process and the peak discharge.

2 STUDY METHODS

2.1 Experimental Layout

The experimental flume is 25 meters long and 1.2 meters high with a 6-meter-wide reservoir on upstream(Figure 1). The profile of the flume on downstream is 2 meters wide. The reservoir on upstream is simulated with a certain volume of capacity which has a maximum capacity of 80m3.

The geometric profile of the experimental dam body is shown in Figure 2 with 100cm high(H), 1:1.5 slope of upstream, 1:3 slope of downstream, 20cm top width(b), 470cm bottom width(B).

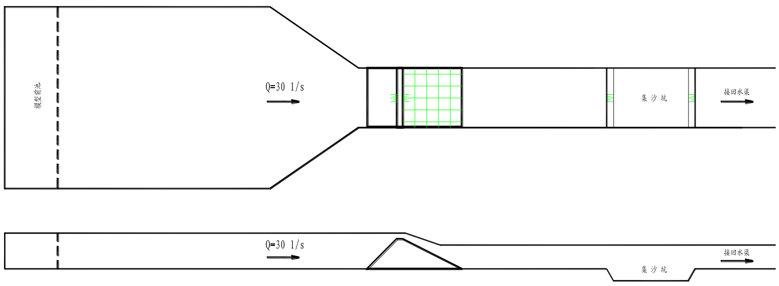

Figure 1 Sketch of experimental flume

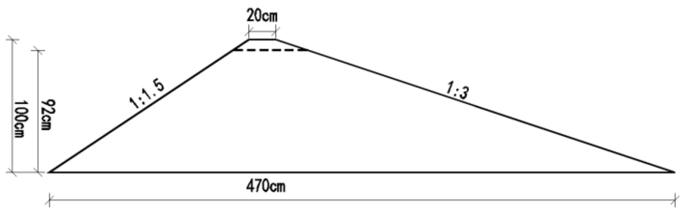

Figure 2 Sketch of experimental earth dam

2.2 Measure System

The test measure system uses many measure technology (upstream, downstream, inside and outside of the dam, multiple tools). The measured points and means are as follow: ①Real-time water level: 4 points being laid along the upstream and downstream, the dynamic process line of the water level is being recorded by the pressure sensor and DASP acquisition system;② Breach discharge: It is speculated from the the water level and reservoir capacity curve of the upsteam;③ The velocity of the breach flow: Being located on the breach part, it is dynamically measured by the electromagnetic flow velocity;④The breach shape: The vertical erosion incision is dynamically recorded by embedded light erosion catcher, while horizontal extension is observed by the grid technologies(A grid of 20cm×40cm being drawn on the downstream slope), also 2 HD cameras installed along the up and down stream of the dam to record the breach process which is analysed by the image technology.

In order to monitoring the developmental process of dam erosion process, and ensuring the layout and the size of the catchers have no impact on dam failure, 7 light erosion catchers are embeded into the dam before the experiments which is a light sphere with a diameter from 3cm to 5 cm and with different color and number on outside, so the catchers can be easily washed out by the flow and be catched. Just like in Figure 3, they are numbered from 1 to 7 according to the elevation and profile of the embeded catchers. In the experiment, when the breach erosion goes to the location of the light erosion catcher, it is washed out by the flow that is exactly recorded by the HD camera. All above indicates that the instantaneous erosion of the dam has developed to the site and shows this method is useful and feasible and easy to operate.

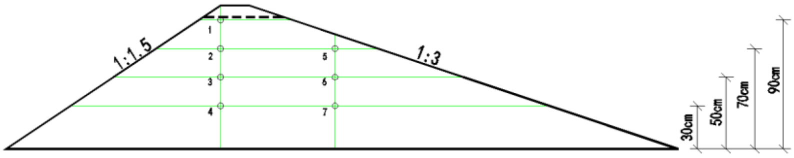

Figure 3　Sketch of embedded erosion catchers

2.3 Experimental Project

In the experiment, flow of the upstream reservoir is constant at Q=30L/S. There are 2 kinds of the designed dam crest for the contrast experiment: one kind has no direct flow channel and the elevation of the crest is same (100cm); the other one has direct flow channel whose profile is designed to be trapezoid with a bottom width of 6 cm (b=6cm), a depth of 8cm (h=8cm), (that is to say the elevation of the direct flow channel is 92cm). The constructional material of the dam is cohesionless and wide gradation sandy gravel whose particle size is from 0.005mm to 40mm. The compact degree of the experimental gravel material is different. One is naturally stacked in which the gravel is in loose state; the other one is　artificially tamped with water in which the gravel is close-grained.

In order to prevent the damage of the penetration before the overtopping break, one or two layers of the waterproof film are embedded around the dam. In the constraint condition of no affection on the dam break, fragment overlapping arrangement is used on the emplacement of the film.

3 RESULTS AND DISCUSSION

3.1 Overtopping Breaching Process of Earth Dam

Depending on the way of the overtopping flow, the density of fill and gradation composition of the dam’s constructional material, overtopping erosion process can be classified into 3 types such as layer-by-layer erosion, entire overtopping erosion and headcut erosion. Mostly, the entire overtopping erosion happens, when there is no direct flow channel on the crest of the dam and the elevation of the crest is the same; with a direct flow channel in the crest also the gravel of the dam’s constructional material being loose, generally the layer-by-layer erosion happens; otherwise with a direct flow channel in the crest and the gravel of the dam’s constructional material being compact, the headcut erosion shows up.

3.1.1 Layer-by-layer Erosion

The process of layer-by-layer erosion is shown in Fig.4 and Fig.5. Generally speaking, the erosion process of the dam is relatively even in which the erosion area gradually develops from Ⅰ→Ⅱ→Ⅲ→Ⅳ→Ⅴ. Firstly, the overtopping flow from the direct flow channel and form a distinct erosion gully. With the erosion gully continuing deeper and wider, the dam slope of the downstream is constantly slower. Then the erosion is gradually close layer-by-layer to the main area of the dam and the dam is constantly incised along with the slower the slope of the dam and the wider the extention of the breach. At last, the main dam is eroded entirely.

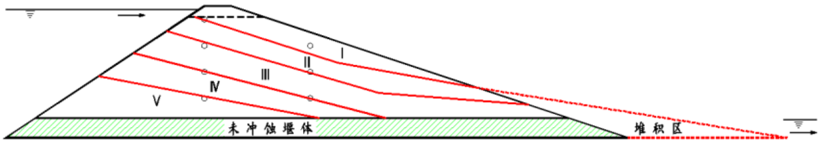

Figure 4 Sketch of layer-by-layer dam erosion

Figure 5 Test ptoto of layer-by-layer dam erosion

3.1.2 Entire Overtopping Erosion

The process of the entire overtopping erosion is shown in Fig.6 and Fig.7. Generally speaking, the erosion process is similar with the one of the layer-by-layer erosion in which the erosion area gradually develops from I to V. The entire overtopping flow form the crest of the dam. Firstly, the small flows just like the thin sheets whose erosion ability gradually enhances as the increasing speed of the small flows discharging along the downstream slope to erode the small particles of the dam’s surface. With the erosion closing the dam’s main area layer by layer, the slope of the dam becomes slower and slower until the main dam is eroded entirely at last.

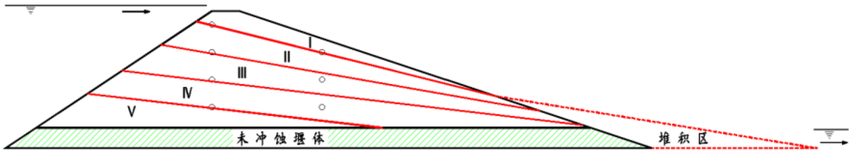

Figure 6 Sketch of entire Overtopping dam erosion

Figure 7　Test photo of entire Overtopping dam erosion

3.1.3 Headcut Erosion

The process of headcut erosion is shown in Fig.8 and Fig.9 which is very uneven. In the first half part of the dam break, the erosion mainly happens in the slope of the downstream. After the headcut waterfull flow being formed, the breach discharge is controlled by the width, the height and the shape of the breach on the dam's upstream (The entrance of the weir forms "control profile"). The breach flow increases slowly, also the water level declines slowly. The headcut becomes higher and higher for the scouring erosion with the slope on the both sides increasly deep. The experiment finds that the scouring process can be divided into 4 stages which are as follows：① The erosion gully formation stage in the surface of the downstream slope: the erosion of the dam occurs in the surface of the downstream slope, and the process is slowly progressive; the discharge and the speed of the breach flow are even and small, and the water level of the reservoir laying on up steam is slowly rising.②"The multilevel drop sill" erosion stage of in the surface of the downstream slope: in this stage the erosion also mainly happens in the surface of the downstream slope, and the erosion ability of the overtopping flow is gradually enhancing; With the flow and the speed of the breach rising slowly, the water level of the reservoir laying on upstream begins to decline slowly after it reaching the maximum value. ③ "the waterfall flow" rapid erosion and break stage of the dam: in this stage, the dam break has developed to the upper edge of the dam crest, and the erosion ability is mostly powerful with a dramatic dam collapse process; rising rapidly, the discharge and the speed of the breach flow reach the peak in this stage, and the water level of the reservoir laying on up steam drops rapidly.④ the stable stage of the dam break: the indexes of the breach flow factors(the water level of the breach on upstream, the discharge and the speed of the flow and so on) begins to drop slowly after reaching the maximum value, and the erosion ability of the flow becomes weak gradually, then erosion process of the dam slows down and eventrually stabilizes, that is to say, the dam discharges the flow which comes from the upstream.

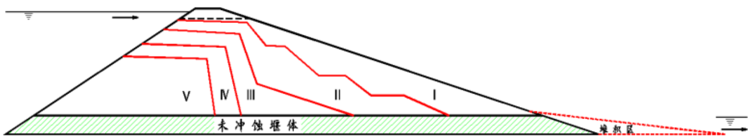

Figure 8　Sketch of headcut erosion

Figure 9 Test photo of headcut erosion

3.2 Peak discharge of dam break

3.2.1 Layer-by-layer erosion

The discharge change process in the layer-by-layer dam erosion is shown in Fig.10. The water level of the reservoir laying on upstream reaches the maximum value of 97.7cm after rising slowly (t=156s, the relevation of the bottom of the direct flow channel is 92cm), which indicates that the instantaneous discharge just reaches to 30 l/s from upstream. Then the breach flow increases rapidly to the maximum value Q=459l/s at 240s which indicates that the water level drops acutely very much and the water level of the downstream reaches the maximum value later. After that, the water level of the reservoir and the breach flow decline step by step. When t within 420s, the observation is end and the water level of the reservoir declines to 35.6m along with the discharge of 41l/s just a little bit more to the flow from upstream which shows the erosion tends to be balanced.

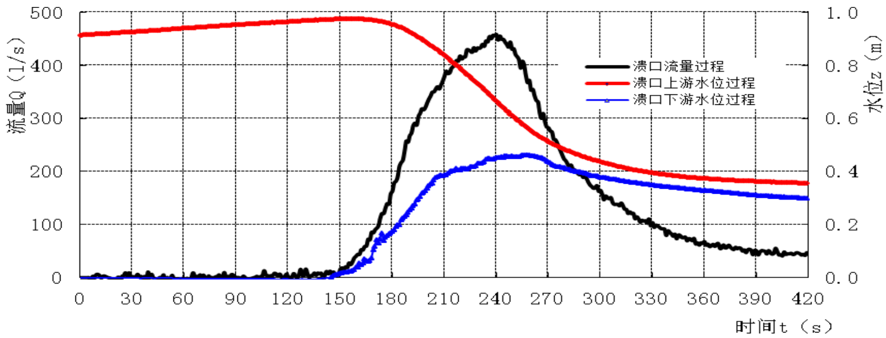

Figure 10 Water level and discharge process lines of layer-by-layer dam erosion

3.2.2 Entire overtopping erosion

The change process of the flow and the water level in the entire overtopping erosion experiment of dam break is shown in Fig.11. The water level of the reservoir laying on upstream reaches the maximum value of 102.1cm after rising slowly(t=100s, the relevation of the dam crest is 100cm), then the breach flow climbs up quickly which comes to the maximum value of Q=526l/s when t within 165s. Later, the water level of the reservoir and the the breach flow decline step by step. When t=360s, the observation is over and the water level of the reservoir declines to 41.5cm along with the discharge of 39l/s just a little bit more to the flow from upstream which shows the erosion tends to be balanced.

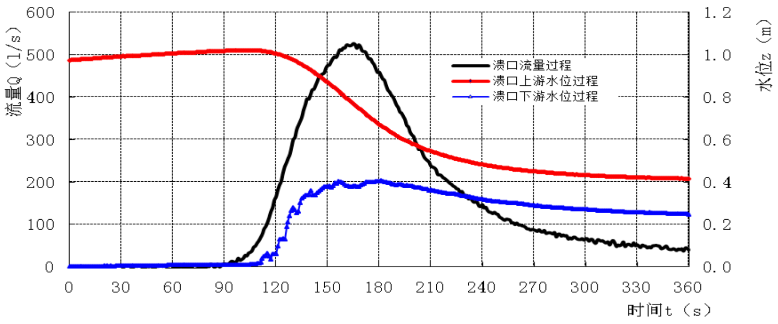

Figure 11　Water level and discharge process lines of entire overtopping erosion

3.2.3 Headcut erosion

The change process of the flow and the water level in the headcut waterfall flow erosion experiment of dam break is shown in Fig.12. The water level of the reservoir laying on upstream reaches the maximum value of 97.7cm after rising slowly(t=154s, the relevation of the dam bottom is 92cm), then the volume of the breach flow maganifis gradually　and the water level of the reservoir lying on the upstream drops slowly which falls to 89.5cm when t=250s. Later, the breach discharge climbs up rapidly which comes to the maximum value of Q=654l/s when t=289s; at the same time, the water level of the reservoir drops quickly which declines to 43.2m when t=330s. After that, the water level of the reservoir and the breach flow decline slowly, and when t=480s, the observation is finished and the water level of the reservoir declines to 29.4cm along with the discharge of 40l/s just a little bit more to the flow from up stream which shows the erosion tends to be balanced.

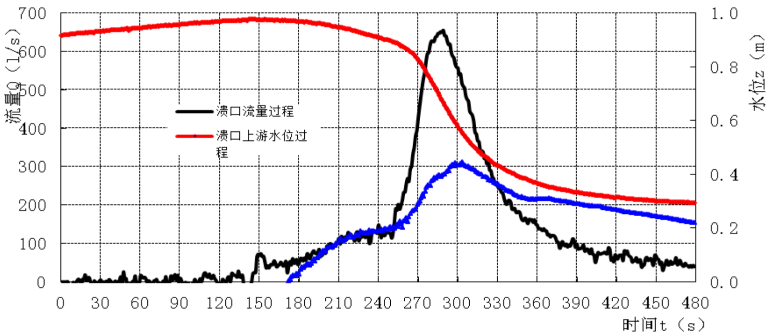

Figure 12　Water level and discharge process lines of headcut erosion

3.3 Analysis and Discussion

For the comparation and the analysis, the hydraulic parameters of the above 3 kinds of the erosion process are list in the table 1.

Table 1 Hydraulic parameter peak value of different breaching process

Breaching process	upstream water level Z_{max}（cm）	Breaching discharge Q_{max}（L/s）	Water level maximum fall in 30s ΔZ（cm）	Main dam breaching t（s）
layer-by-layer erosion	97.7	459	17.3	90
entire overtopping erosion	102.1	526	19.9	90
headcut erosion	97.7	654	24.8	60

The table 1 shows that the breach process of the layer-by-layer erosion and the entire overtopping erosion takes more time(about 90s), in which the water level of the reservoir lying on upstream declines no so much acutely, at the maximum water level fall in 30 second, with respective drop of 17.3cm and 19.9cm and a flat peak of the process line to recording the breach discharge. Because of direct flow channel on the dam crest, in the process of entire overtopping erosion, the water level of the reservoir furthest reachs to 102.1cm and the peak discharge is measured as Q=526l/s, while in the process of layer-by-layer erosion, the maximum reservoir water level is 97.7cm and the peak discharge is measured as Q=459l/s.

The break process of the headcut erosion takes a shorter time(about 60s), the water level of the reservoir lying upstream falls dramaticly with a tip and thin peak of the process line. When the headcut develops to some extend, the breach collaps suddenly both in horizontal and vertical direction with the instant increase of the discharge and the sudden drop of the upstream water level, at the maximum water level fall in 30 second, with a drop of 24.8cm. In the experiment, the maximum reservoir water level of the upstream is 97.7cmm, but the peak discharge is measured as Q=654l/s which is 40% more to the one measured in the type of the layer-by-layer erosion. It can be seen that even if the profile of the dam and the maximum water level of upstream are the same, the peak discharge distinctly differs because of the different erosion process of dam break.

4 CONCLUSIONS

A series of indoor flume experiments have been done on earth dam (1 meter height)constructed by wide gradation and cohesionless materials. Dam erosion process and hydraulic parameter changing process have been measured in the condition of flood overtopping. The result of the experiment indicates that depending on the way of the overtopping flow, the density of fill and gradation composition of the dam’s constructional material, the overtopping erosion process can be classified into 3 types such as layer-by-layer erosion, entire overtopping erosion and headcut erosion. There is a very close relationship between the peak discharge and the breaching process. The quicker of dam-break happens, the bigger the peak discharge is. In the same situation, the peak discharge of headcut erosion increases 40% to the one of layer-by-layer erosion.

It should be noted that the experiment is operated under the specific simulation and boundary conditions, while the process and the modality of the break may be different from the reality which may lead to the difference between the peak discharge in experiment and the one in reality.

Rockfill materials are used in construction projects such as dam construction, road construction and so on. Due to the increasing use of these materials, experiments and studies have also been carried out on this material and usually, these studies have been carried out on strong rockfill materials. Today, the use of soft and weak rockfill materials has expanded because the economic and environmental issues. and still no comprehensive studies have been conducted on soft rockfill materials and need more information on the behavior of these materials in different conditions. With considering that the dimensions of the usable rockfill material may be much larger than the dimensions of the laboratory equipment. Therefore, it is always a matter of scaling and matching the results of the laboratory and the field from the important items of rockfill materials. In this research, the behavior of weak rockfill materials has been investigated in different conditions.

KEY WORDS

Particle Breakage, Weak Rockfill Material

1. PREFACE

In recent decades, hundreds of dams over 100 m high have been built in world to produce clean and renewable energy. More and more soft rocks have increasingly been used in the construction of dams because of their easy availability and environmental considerations. These marginal materials traditionally would not be used owing to their unfavorable engineering properties that is, low strength, high compressibility, and proneness to material degradation with time. Therefore, the use of soft rocks excavated on site as rockfill materials for high rockfill dams is still a controversial issue, as weathering takes place when the rock is exposed to an environment in which variations in air, temperature, and water content are involved. Compared with conventional rockfill materials such as fragments of hard rock, soft rocks are more sensitive to weathering, with temperature and drying/wetting variations. As there are limited applications of soft rocks used in rockfill dams, the long-term behavior of the compacted soft rocks is of great concern and is not yet well understood.

2. INTRODUCTION

2.1. SOFT ROCKFILL MATERIAL

A rockfill dam is an embankment dam which relies on rockfill as its major structural element. Among the major advantages of rockfill dam construction are the following: a wide variety of sites and foundations are suitable, cheap natural construction materials can be found in local quarries since even weak rock is usable. All kinds of rock (igneous, sedimentary and metamorphic) are used for compacted rockfill [1].

The Table 1 show the strength of various rock types used in rockfill material [2].

Table 1: Strength classification of rocks [2]

Class	Description	Uniaxial Compressive Strength(MN/ m^2)
A	Very high strength	Over 200
B	High strength	100 – 200
C	Medium strength	50 – 100
D	Low strength	25 – 50
E	Very low strength	Less than 25

Rocks in class C, D, E would probably form ‘weak’ rockfills [2].

2.2. PARTICLE BREAKAGE

Particle breakage index that quantifies the degree of particle breakage, can reflect the degree of particle crushing of material. Particle breakage index can be divided into different categories. The methods for measuring the level of crushing in granular materials are based on the variation of the gradation curve or the retention curve. One of the first measures was proposed by Marsal et al. [3] using the retention curve. In this case the difference between the percentages of retained mass at initial (f_0(D)) and final (f_u(D)) stages in a test is calculated for each sieve. The amount of crushing is given by the sum of positive difference values and it is equal to parameter B_g, or:

$$B_g = \frac{1}{2}\int_{D_m}^{D_M} \left| f_0(D) - f_f(D) \right| dD \qquad (1)$$

The procedure is illustrated in Figure 1. The factor B_g is a simple factor describing the amount of crushed material and has been currently used by engineers in soil mechanics practice.

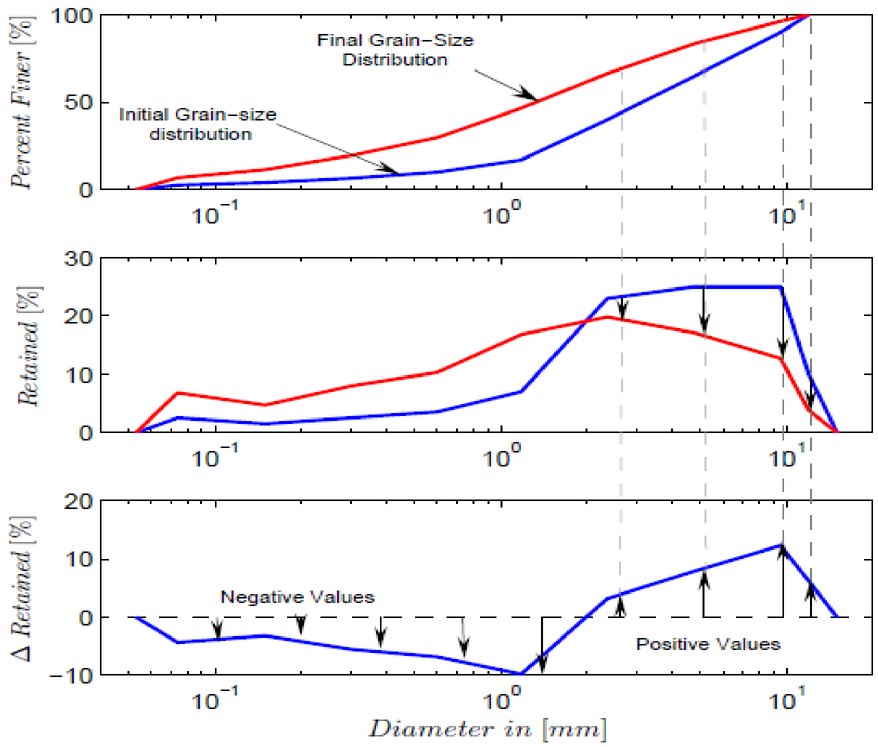

Figure 1. Calculus of Marsal's breakage index

2.3. Medium-Scale Oedometer Apparatus

To carry out experiments on studied rockfill materials, a Medium-scale oedometer apparatus is used. In Figure 2 illustrate an overview of the apparatus. The specimen cell contains a stainless steel material of 15 cm in diameter and 25 cm in height [4].

Figure 2. Large-scale oedometer apparatus

2.4. NOHOB STORAGE DAM

Nohob Dam, is located on Qazvin province, 35 km southwest of Takestan city, 1 kilometer downstream the Nohob village. Nohob dam is under construction. The Nohob storage dam specification presented in Table 2 [5].

Table 2: Nohob dam specification [5]

Type of dam	Earthfill dam with clay core
Dam height	46 m
Crest length	2156 m
Crest width	10 m
Reservoir capacity	120 Mm^3
Year of construction	2012

In Figure 3, the dam site is specified.

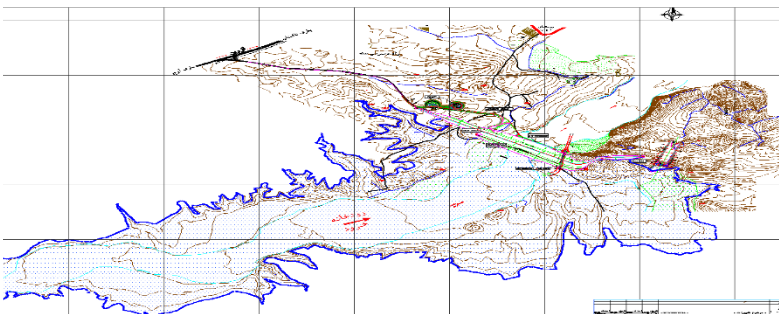

Figure 3. Nohob dam site [5]

3. METHODOLOGY AND TEST PROCEDURE

To select weak rockfill materials, Iran Water Resources Management Company was visited and information about dams in the construction stage was received and reviews were conducted on different dams. Due to the fact that most of the rockfill dams materials that in construction stage were in high strength class. Then we were visited the Nohob dam that was under construction and rockfill material in overflow excavation section that was thrown away and it was not used in the construction of the dam.

Then the rocks are sampled in different sections of the overflow excavation and uniaxial compressive strength[6] test was performed on them. The results are presented in the Table 3.

Table 3: Overflow rock specification

Sampling location	uniaxial compressive strength(MPa)
1	23.5
2	45.5
3	80.4
4	26.3

With given the strength achieved by the rock materials, sample No.1& 2 was selected which is placed in class C&D of table 1. Then materials was sampled for grading. In Figure 4 shows the sampling site.

Figure 4. Dam overflow location

Then with according the grain size distribution curves from other dam that constructed with quarried rockfill material, grain size distribution curve was selected and in Figure 4 is shown. As respects the diameter of the test cell is 15 cm and the maximum ratio is $\frac{D}{d}$ = 6 that the D is the diameter of the test cell and d is the maximum grain size of sample. Modeled rockfill materials for $d_{max} = 25.4\ mm$ were obtained using parallel gradation technique that illustrated in Figure 5.

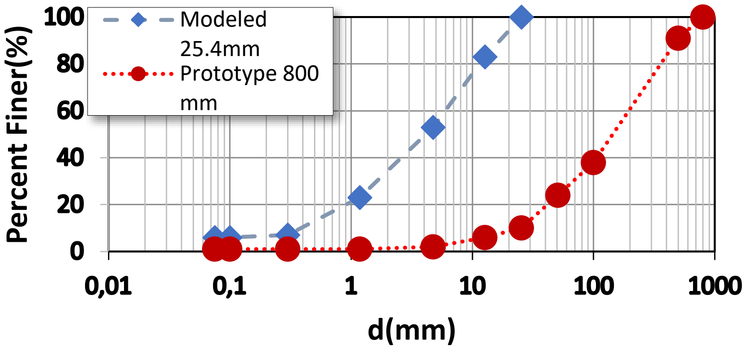

Figure 5. Grain size distribution curves

Then with according to the standard test methods for maximum index density and unit weight of soils using a vibratory table (ASTM D4253) [7] and standard test methods for minimum index density and unit weight of soils and calculation relative density (ASTM D4254) [8], these methods were used to determine γ_d. The RD mold with a volume of 14,070 mL is filled completely with a graded rockfill material Minimum dry density ($(\gamma_d)_{min}$) is determined as the ratio of total weight of the material filled in the mold to the total volume of the mold occupied by the material. To determine the maximum dry density ($(\gamma_d)_{max}$), the mold fitted to the 75 cm * 75 cm table with a motor is vibrated for 12 min and the volume change of the material in the mold is recorded. Then the $(\gamma_d)_{max}$ is determined as the ratio of total weight of the material in the mold to the total volume of the mold occupied by the material. Using $(\gamma_d)_{min}$ and $(\gamma_d)_{max}$, the specimen density is determined using Eq. (2) corresponding to RD of 87%.

$$\mathrm{RD} = \frac{\frac{1}{(\gamma_d)_{min}} - \frac{1}{\gamma_d}}{\frac{1}{(\gamma_d)_{min}} - \frac{1}{(\gamma_d)_{max}}} * 100\% \tag{2}$$

where γ_d is the dry density in a given condition. $(\gamma_d)_{max}$ and $(\gamma_d)_{min}$ were determind and the results are presented in Table 4.

Table 4: Material unit weight

Material	γ_d $(^{Kg}/_{m^3})$	
	Max	Min
1	1585	1470
2	2207	2055

In preparing the specimen, a lubricant was first laid on the inner side of the container to reduce side friction. The materials was compacted in five lifts in the container. The water content of the compacted specimen was less than 1% for dry specimens and the water content of the compacted specimen was 20% for wet specimens . The maximum particle size was about the half the thickness of each lift.

Volumetric (vertical) deformations of the specimen were monitored by a linear variable differential transducer (LVDT) in all the tests. Stresses mentioned in this paper mean the vertical stress applied on the specimen.

Conventional oedometer tests were performed on the rockfill. The purpose of the tests was to quantitatively evaluate the particle breakage during compaction of specimen and in the oedometer test. After each test, a grain size distribution curve was obtained. In figure 5 shows step to do the experiment.

Figure 6. Oedometer Apparatus

4. TEST RESULTS

The oedometer tests were performed under normal stresses are presented in Table 5 for two types of materials..

Table 5: Normal stresses in specimen

Day	Stress(kpa)	
	Material 1	Material 2
425	310	425
850	620	850
1275	930	1275
1700	1240	1700
2125	1550	2125
2550	1860	2550
2975	2170	2975

4.1. MATERIAL 1

The material 1 consisted of rock fragments with sharp edges. It was prone to particle breakage induced by high levels of stress or stress concentration on the edges (Marshal, 1967)[3]. vertical strain occurred in the Oedometer test at the vertical stress owing to compression and particle breakage of the material. Fig 7 interprets the vertical strain, ε.

The deformation of the rockfill was considered to include a transient phase that occurred instantaneously upon applying the load and time-dependent deformation. As seen in Fig 8, the deformation developed quickly and was mostly completed within the first loading step.

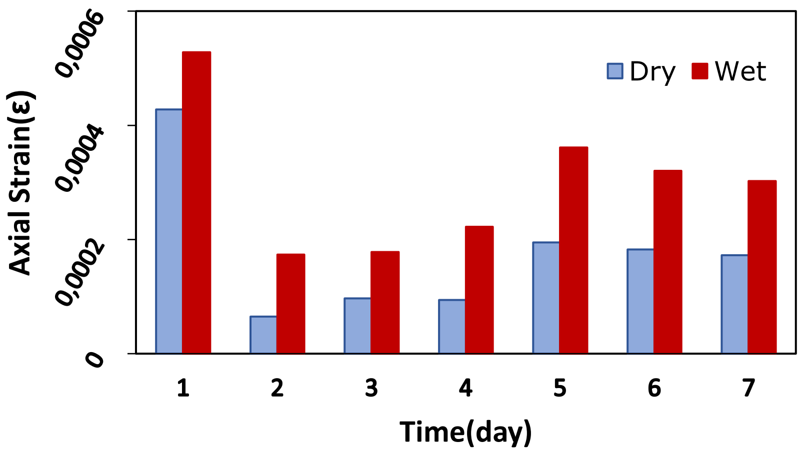

Figure 7. Axial strain in dry and wet specimens in material No.1

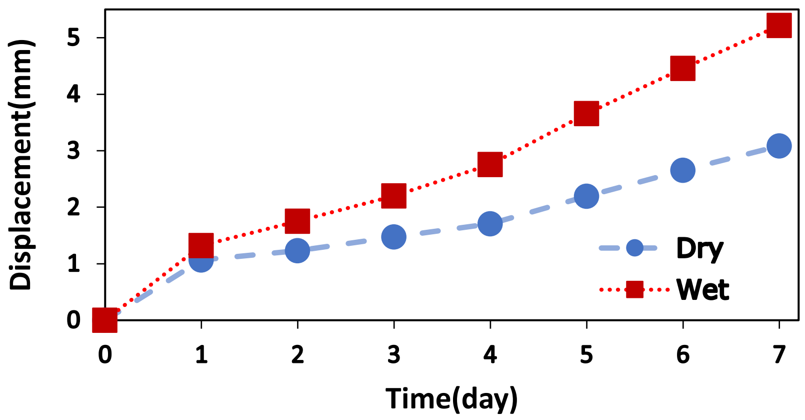

Figure 8. Total displacement in dry and wet specimens in material No.1

4.2. MATERIAL 2

The material 2 consisted of rock fragments with sharp edges. It was prone to particle breakage induced by high levels of stress or stress concentration on the edges (Marshal, 1967)[3]. vertical strain occurred in the Oedometer test at the vertical stress owing to compression and particle breakage of the material. Fig 9 interprets the vertical strain, ε.

The deformation of the rockfill was considered to include a transient phase that occurred instantaneously upon applying the load and time-dependent deformation. As seen in Fig 10, the deformation developed quickly and was mostly completed within the first loading step.

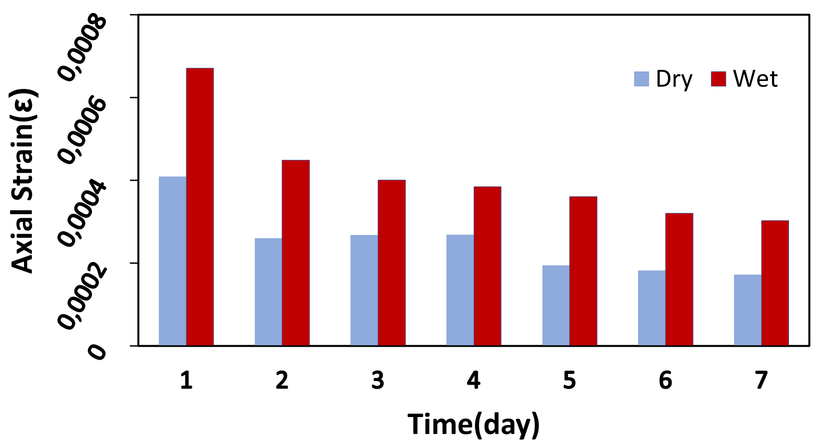

Figure 9. Axial strain in dry and wet specimens in material No.2

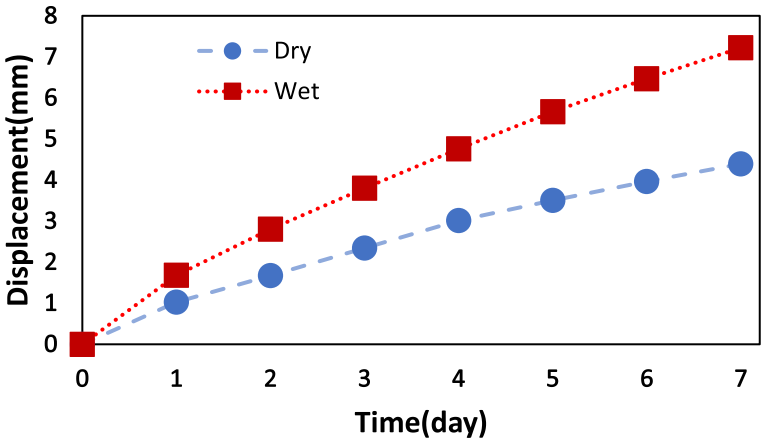

Figure 10. Total displacement in dry and wet specimens in material No.2

5. CONCLUSIONS

This paper describes a study of deformation of soft rockfill material subjected to stresses in dry and wet conditions. Based on the study, the following conclusions were drawn:

1) In the wet condition, the axial strain and displacement are more than dry condition.
2) In the initial steps of loading, the axial strain and displacement are greater than the end steps.

This research and experiment is ongoing and the more complete results will be provided in the next articles due to the experiment with other rockfill materials and variation test conditions.

ACKNOWLEDGMENT

We thank Mr. Mousavi and Mr. Keshavarz from Qazvin Regional Water Authority that provided information and cooperation on material sampling for this study.
