SYMPOSIUM HYDRO ENGINEERING - FOREWORD

The ATCOLD Symposium Hydro Engineering will pave the way for presentations and discussions on specific issues of hydraulic structures serving for energy from renewable resources, irrigation, drinking water supply and flood protection. Hydro Engineering requires a wide range of knowledge and expertise. Therefore, many specific disciplines are involved. Research effort is needed to give answers effectively to challenges during project realization, operation and maintenance. Problem solutions should be sustainable and economically feasible in a wide range. To present and discuss specific issues in the field of hydro power production, this Symposium Hydro Engineering focus on the following topics:

- Climate Changes Reservoir Operation
- Permission and Safety Assessment
- Dam and Foundation Sealing
- Caverns and Power Water Ways
- Stability of Reservoir Slopes

Additionally, two special seminars will be held about the following topics:

- Oroville Dam Spillway Incident
- High Strength Steel in Hydro Power Plants

To allow ICOLD Technical Committee’s to present and discuss their work, in parallel to the Symposium Hydro Engineering “Technical Committee Workshops” are organized. Especially Workshops are organized by the following Technical Committees:

- Resettlement due to Reservoirs, Embankment Dams and Dam Safety
- Joint Workshop

  A - Committee on Computational Aspects of Analysis & Design of Dams
  B - Committee on Seismic Aspects of Dam Design

As green meeting, we provide one printed book of extended abstracts containing, the contents of the contributions and on 2 pages the abstract version of the contributions. Full papers are published electronically and are available for downloading.

We thank all the authors for their efforts and contributions to the Symposium. Based on reviews and authors preferences we selected 240 papers and posters from 55 countries for presentations in parallel sessions and during poster presentations.

We would like to express our deepest gratitude towards all the members of the review panel for their effort, and to the organizing committee members especially - Harald Breinhälter, Josef Schneider, Franz-Georg Pikl, Shervin Shahriari and Edwin Staudacher.

CAPITALIZATION OF BENCHMARK WORKSHOPS RESULTS SINCE BERGAMO 1991

Guido MAZZA'

Chairman of ICOLD Committee A "Computational Aspects of Analysis and Design of Dams, RICERCA SUL SISTEMA ENERGETICO RSE S.P.A.

ITALY

EXTENDED ABSTRACT

Policies on energy and water resources all around the world poses an increasing demand of clean energy and sustainable water resources. These needs require both refurbishment programs of many old dams in those countries where dam construction dates back at the beginning of the industrialization process, such as Europe and USA, and the construction of new infrastructures where the need of water resources and renewable energy is more pressing.

ICOLD in 1988 decided to appoint the Committee *Computational Aspects of Analysis and Design of Dams* with the aim to contribute to the diffusion of computer software in the field of dam engineering and to fill the gap existing between the specialists of mathematical modelling and dam designers, authorities, and managers. As a matter of fact, numerical modelling represents nowadays a key tool for dam engineers to perform efficiently the design making process, the construction stage as well as the whole operational dam life until the possible decommissioning phase. The activities of the Committee have contributed to make fully accepted the numerical models in the engineering practice.

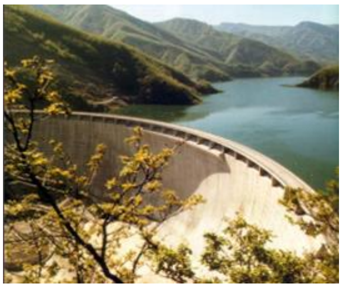
Today and future activities of the Committee are oriented towards:

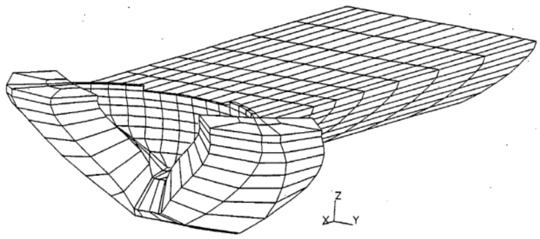
- ✓ creating a stronger link between the observed dam behavior and the modelling process with the aim to contribute to the preservation and maintenance of existing dams;

- ✓ promoting mathematical modelling improvements to approach safety-related problems that cannot at present be properly analyzed;
- ✓ issuing guidelines to be used for educational purposes in the current practice. The Committee is strongly committed to contribute in the process of a suitable transfer of experience, skill and knowledge across generations.

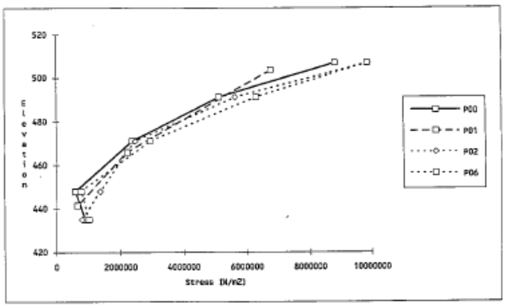
The work done by the Committee during its long activity has given rise to the issuing of three Technical Bulletins (N. 94, *Computer software for dams. Validation*, 1994; N. 122, *Computational procedures for dam engineering*, 2001; N. 155, *Guidelines for use of numerical models in dam engineering*, 2013).

Moreover, the Committee has promoted the organization of benchmark-workshops (BWs), with the aim to guide dam engineers in the correct use of computer programs. The benchmarking program started in Bergamo (Italy) in 1991 and continued up to 2017 with the 14th workshop held in Stockholm.

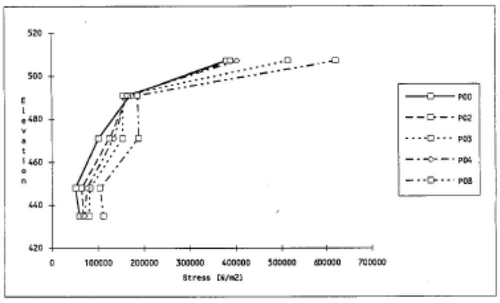




FLEXIBLE FOUNDATION AND INCOMPRESSIBLE FLUID
MAX ABS PRINCIPAL STRESSES P1 AND THEIR TIME OF OCCURRENCE
CENTRAL CANTILEVER



RIGID FOUNDATION AND COMPRESSIBLE FLUID
MAX ABS PRINCIPAL STRESSES P1 AND THEIR TIME OF OCCURRENCE
CENTRAL CANTILEVER



Bergamo (Italy), 1991-1992. Seismic analysis of Talvacchia dam: the dam seen from the left abutment; the FE model; some results of the seismic analyses

The benchmarking activity represents a reference for the whole dam community, and in particular for young engineers engaged in the challenging task of dam safety assessment and design. To facilitate the accessibility and a critical review of the proceedings related to the 14 BWs held so far, a capitalization activity of the tremendous amount of data at disposal has been recently started.

The preparation of a new Bulletin to provide a synthesis of the BWs results and comments on the progresses achieved on the numerical modelling methods and the strategies to be used to tackle most of the dam engineering problems is foreseen for the end of 2019.

50 YEARS OF COMMITTEE ON SEISMIC ASPECTS OF DAM DESIGN

Martin WIELAND

Chairman, ICOLD Committee on Seismic Aspects of Dam Design, POYRY SWITZERLAND LTD., ZURICH

SWITZERLAND

EXTENDED ABSTRACT

The Committee on Seismic Aspects of Dam Design is one of ICOLD's oldest technical committees, which at present comprises dam and earthquake experts from 34 different countries from all continents. The Committee was created in 1968 and will celebrate its 50^{th} anniversary in 2018. Guidelines on (i) different seismic hazards affecting storage dams, such as fault movements in the footprint of dams, and reservoir-triggered seismicity, (ii) seismic design criteria, (iii) dynamic analysis of dams, (iv) conceptual guidelines for earthquake-resistant design of dams and design of appurtenant structures, and (v) seismic monitoring and inspection of dams after earthquakes, have been published. These guidelines, listed below, represent the international state-of-the-art in the seismic design, construction and safety assessment of large storage dams, i.e.

Bulletin 52 (1986): Earthquake analysis procedures for dams,
Bulletin 112 (1998): Neotectonics and dams,
Bulletin 113 (1999): Seismic observation of dams,
Bulletin 120 (2001): Design features of dams to resist seismic ground motion,
Bulletin 123 (2002): Earthquake design and evaluation of structures appurtenant to dams,
Bulletin 137 (2011): Reservoirs and seismicity,
Bulletin 148 (2016): Selecting seismic parameters for large dams, and
Bulletin 166 (2016): Inspection of dams following earthquakes

Among these guidelines, Bulletin 137 provides information on reservoir-triggered seismicity (RTS), a hazard unique to large storage dams, which is often a key dam safety argument brought forward by opponents against new dams. For properly designed and constructed dams, RTS is not a new safety concern for dams. However, the publication with the greatest long-term impact on the seismic design and safety assessment of existing dams is Bulletin 148, which includes the concept of two earthquake levels for dams and safety-critical elements, i.e. the Operating Basis Earthquake (OBE) and the Safety Evaluation Earthquake (SEE). The safety-critical elements are the spillway and low level outlets, which are needed to control the reservoir level after the SEE or for lowering for repair works or for increasing the safety of a dam. This is new. Bulletin 120 complements Bulletin 148 as it includes conceptual features for the seismic design of dams, which are extremely important, as it is well known that it will be difficult to have a structure to perform well during an earthquake, when the basic seismic design concepts are not observed.

Dams were the first structures designed against earthquakes, on a worldwide basis, starting in the 1930s. At that time, the ground shaking was the main seismic hazard and was represented by a seismic coefficient of typically 0.1, almost irrespective of the seismic hazard at the dam site, which was often unknown. The seismic analysis was done with the pseudostatic method, ignoring the dynamic characteristics of dams. Because of its simplicity, this method is still in use today, although it has become clear that this method is obsolete following the observations made during the 1971 San Fernando earthquake. The pseudostatic method is also not compatible with current seismic guidelines (Bulletin 148) and, therefore, this obsolete method shall no longer be used for the safety checks of large storage dams. One of the main tasks of the Committee is to promote good practice in dam engineering, which includes the dissemination of the international state-of-the-art. Using the pseudostatic concept, the seismic load case was very seldom the governing one. This has changed by using today's rational concepts for seismic hazard analyses and dynamic analyses of dams. The earthquake load case has become the dominant one for most dams.

Since the formation of the seismic committee, the magnitude 8 Wenchuan earthquake of May 12, 2008 that occurred in Sichuan province, China, was the most important earthquake for dam engineers as it damaged some 1580 dams. Most of them were small earth dams, but also some large dams were damaged. The main lesson from this earthquake was that the seismic hazard is a multi-hazard. Thousands of mass movements occurred in the mountainous epicentral region. Mass movements that can be triggered by strong earthquakes are often ignored or the hazard is assessed using criteria, which are different from those used for the dam body. Based on the past experience, it is obvious that dams are not inherently safe and can be damaged by strong earthquakes. The most vulnerable dams are those, which are poorly constructed and/or designed. Still a lot of work is required in order to ensure that all dams comply with modern seismic safety criteria, which is the main concern of the Committee..

NUMERICAL METHODS APPLIED AND INTERPRETED FOR SAFE DAM BEHAVIOUR

Gerald ZENZ[1], Edwin STAUDACHER, Shervin SHAHRIARI

[1]*Institute of Hydraulic Engineering and Water Resources Management, GRAZ UNIVERSITY OF TECHNOLOGY*

AUSTRIA

1. INTRODUCTION

Dams are designed to serve in a secure and safe way to our society under any environmental and operational conditions throughout their lifetime. During design and construction models are needed to be set up to account for the safety approach. This models are based on practical experience gained from the performance of existing structures and rely on models we assume for possible failure modes. To set up and apply advanced numerical models and interpret their results a detailed discussion within the engineering community is need. To show the abilities and the meaningful interpretation of numerical investigations the "Technical Committee on Numerical Analysis and Design of Dams" organizes since 1991 benchmark workshops. These results are published in proceedings and concluded in ICOLD Bulletins. Herein a short summary of the content of investigations and a further step to disseminate the results is undertaken. It is to emphasize the requirement to develop a model about the system behavior of dams based on their foundation, reservoir slopes, catchment area and environment. Numerical models and the interpretation of the gained results are one essential part within this ICOLD network to guarantee for the safe dam operation.

International Benchmark Workshops on Numerical Analysis of Dams are intended to provide an in-depth examination of the computational methods and software used for dam analysis. It is an international forum to share the latest information regarding state-of-the-art software and techniques available for the analysis of dams' behavior. For the community of Dam Engineers, a possibility is given to discuss on assumptions, results and conclusions drawn by the help of numerical analyses. The Benchmarks are organized by members of the ICOLD "Technical Committee on Computational Aspects of Dam Analysis and Design". During a period now of 29 years the working group is active in discussing computational aspects and concluding the major results in Bulletins. However, the effort is based on the activities of their members, Vice-Chair and especially their Chair as these are from the beginning: Olgierd Zienkiewics, Michele Fanelli, Gabriella Giuseppetti, Alian Carrere, Ignacio Escuder and the current chair Guido Mazza.

The results and outcome of benchmarks workshops result in working group discussions; their work is being published in Bulletins ([1],[2],[3]). These Bulletins aims to offer a support to dam engineers to choose the most suitable computational strategies to cope with the engineering problems under examination in the best possible way having in mind potentialities and possible shortcomings.

SEISMIC ASPECTS IN THE DESIGN OF EMBANKMENT AND ROCKFILL DAMS

CAMILO MARULANDA

Technical Manager, INGETEC

COLOMBIA

EXTENDED ABSTRACT

Historically, embankment dams have usually performed well during earthquakes. However, earthquakes can undesirably affect embankment dams in different ways. One of the most obvious way is by causing instability or large deformations in the dam, due either to strong shaking, or to increases in pore pressure and resulting decreases in strength (caused by cyclic loading). One of the most well-known cases of liquefaction and instability of a dam during an earthquake, is the Lower San Fernando Dam, where a portion of the embankment liquefied during the 1971 San Fernando earthquake and slid, leaving only about 3 feet of freeboard remaining to contain the reservoir. Dams have also failed due to erosion through cracks caused by an earthquake. Consequently, earthquakes may induce instability in the slopes of the dam, differential settlements and cracks. The assessment of the behavior of an embankment dam under seismic loading typically includes the following aspects:

1. Identifying and characterizing potential sources of earthquake loading, whether known faults or historic seismicity not associated with known faults.

2. Determining the appropriate loadings to apply in the analyses.

3. Determining the properties of the embankment and foundation materials,

4. Analyzing the post-earthquake stability of the embankment, including the evaluation of a possible drastic loss of shear strength.

5. Estimating the extent of deformations resulting from earthquake shaking and reduction in material strengths.

6. Determining the potential for dam failure by the overtopping of deformed embankment, erosion through cracks in the embankment, or other possible failure mechanisms.

7. Evaluating other structures, such as spillway walls adjacent to the embankment, whose failure could cause failure of the embankment dam by allowing overtopping or by creating unfiltered exit points for internal erosion.

The presentation will focus on the different seismic aspects to consider in the design of an embankment dam and some of the available numerical methods to evaluate the different failure mechanisms of a dam under seismic conditions, including, stability of the dam, deformation prediction and liquefaction potential.

COLLAPSE OF AGRICULTURAL EARTH-DAMS BY A RECENT EARTHQUAKE AND ITS RECONSTRUCTION

Fumio TATSUOKA

Professor Emeritus, UNIVERSITY OF TOKYO and TOKYO UNIVERSITY OF SCIENCE

JAPAN

1. COLLAPSE AND RECONSTRUCTION OF IRRIGATION DAMS

A pair of old irrigation dams in Fukushima Prefecture collapsed by the 2011 Great East Japan Earthquake (Fig. 1a). The collapse was due to generally poor soil compaction and the use of inadequate soil type (sandy soil) in the top layer despite homogeneous type of the dam in addition to a prolonged strong seismic motion. The new dams (Fig. 1b) were constructed to be much more stable by the use of adequate type soils, good compaction and an adequate structure.

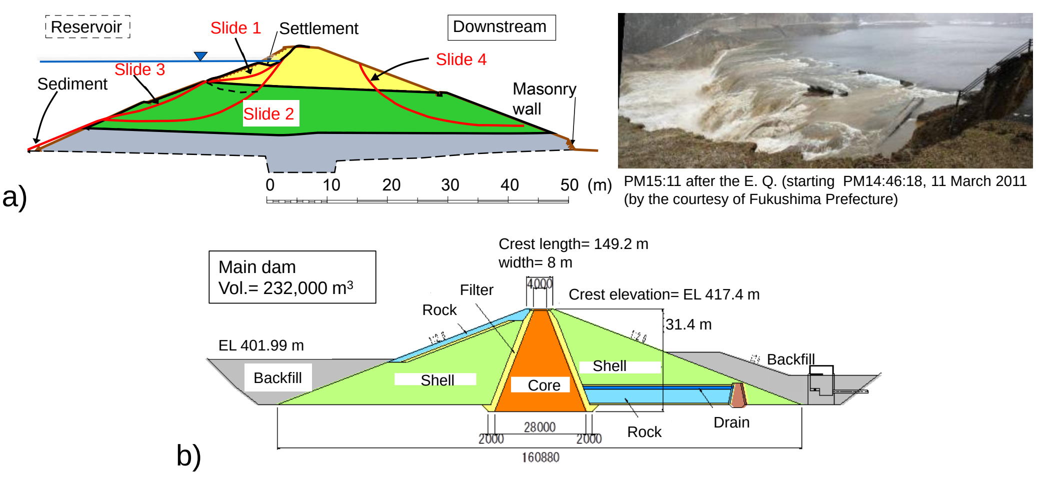

Fig. 1. Fujinuma dam, Fukushima Pref. Japan: a) collapsed; & b) reconstructed.

In soil compaction, the target values of dry density and water content were specified to be equal to the maximum dry density and the optimum water content by Standard Proctor while controlling the degree of saturation to become the optimum degree of saturation (i.e., $S_r= (S_r)_{opt}$) irrespective of variations in the soil type and compaction energy in actual compaction. When $S_r= (S_r)_{opt}$, the highest dry density (so, the highest shear strength and stiffness) and sufficiently low hydraulic conductivity of saturated soil is obtained under any given field condition.

2. STABILITY AND DEFORMATION ANALYSIS

The collapse was successfully simulated by simplified practical analysis incorporating the time histories of undrained stress-strain relation and peak strength of saturated soil that degrade by cyclic undrained loading during an earthquake (Figs. 2a & b). The residual slip evaluated by the Newmark method and the residual deformation outside the slip layer by pseudo-static FEM, both incorporating the time history of response acceleration, were summed up. No slip with very small residual deformation of the new dam by the seismic load by which the old dams collapsed was confirmed by analysis by this method. The effect of compaction on the dam stability is tremendous. Fig. 2c shows the average drained and undrained shear strengths mobilized along the critical slip circles in the top zone of the old and new main dams (as shown in Fig. 2a). With the new dam, the average degree of compaction (Standard Proctor) D_c is equal to 101 %, thus the undrained shear strength at the end of seismic loading is higher than the drained strength while substantially higher than the value at D_c= 87 % of the old dam.

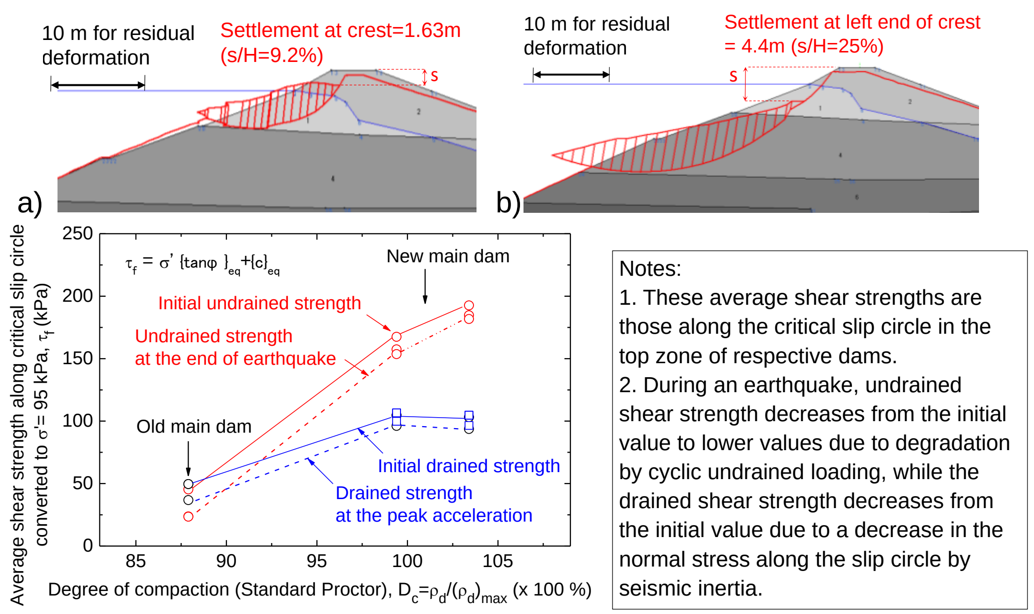

Fig. 2 a) & b) Residual deformation for two critical slip circles by numerical analysis of the old dam; & b) average shear strengths mobilized in the upper zone.

COMPARISON OF MEASURED AND ANALIZED SEISMIC BEHAVIOR OF CONCRETE DAMS AND EMBANKMENT DAM IN JAPAN

Hiroki SAKAMOTO

Koishiwaragawa Dam Construction Office, JAPAN WATER AGENCY

Hiroyuki SATO and Takashi SASAKI

National Institute for Land and Infrastructure Management, MINISTRY OF LAND, INFRASTRUCTUR, TRANSPORT AND TOURISUM

JAPAN

1. INTRODUCTION

Many earthquakes have hit Japan and informative data about seismic behavior has recorded at dams during large earthquakes [1]. The report shows some examples of dynamic analyses of existing dams with efforts in order to reproduce seismic performances exactly. In this abstracts, outlines of an arch dam case and an embankment dam case are briefly explained.

2. CASE OF ARCH DAM [2]

The earthquake record observed at the crest of Yagisawa Dam (dam height of 131m, Fig.1) in Chuetsu Earthquake (Oct.23, 2004) was 656cm/s^2. In the reproduction analysis, modification of the foundation - reservoir coupling conditions has been conducted as compared with generally used conditions in Japan. By using the modified analysis, reproduced behavior of the dam in the earthquake has higher precision than previous method as shown in Fig. 2.

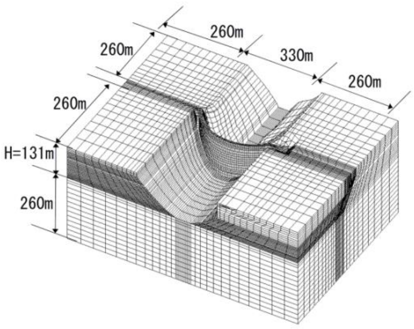

Fig. 1
Analysis Mode

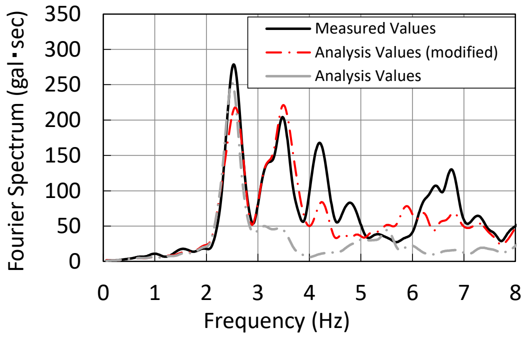

Fig. 2
Fourier Spectrum at Dam Crest
(Upstream-downstream direction)

3. CASE OF EMBANKMENT DAM [3]

Due to the Iwate-Miyagi Nairiku Earthquake in 2008, settlement without sliding deformation was observed at Isawa Dam (ECRD, Fig. 3). The dynamic strength tests for construction materials and deformation analysis using cumulative damage theory were conducted. Through the analysis, the settlement can be reproduced accurately and it is important to consider saturated/unsaturated conditions in dam body for accurate evaluation (see Fig. 4).

CURRENT CHALLENGES OF SEISMIC NUMERICAL MODELLING FOR DAMS: SOME ITALIAN EXPERIENCES

Massimo MEGHELLA

Member of ICOLD Committee A "Computational Aspects of Analysis and Design of Dams".
Sustainable Development and Energy Sources Department – Structures, RICERCA SUL SISTEMA ENERGETICO RSE S.P.A.

ITALY

EXTENDED ABSTRACT

The dynamic FEM analysis is currently the most effective tool to simulate the seismic response of dams. However, as the seismic forces increase up to the level of intensity typically corresponding to MCE, the complexity of the models and the computation time increase dramatically, having to take into account the non-linear behaviour of both materials and interfaces (joints and pre-existing cracks). At the same time, the overall models uncertainty increases, which in combination with the lack of information on the real response of dams when subjected to strong earthquakes, makes models calibration and subsequent seismic analysis a very challenging, expensive and often impractical task. To cope with that, RSE adopted and further developed, a simplified dynamic method - the Endurance Time Analysis method (ETA) - which allows drastic reductions of the computational effort, to analyze the non-linear response of several large concrete dams in Italy and to obtain their "capacity curves" ranging up to collapse. In such way, even if the overall model uncertainty is still not properly addressed and quantified, the comparison of such curves within the dams portfolio allowed to develop simplified "risk indexes" to rank their relevant seismic risk, so that resource allocation for safety assessment can be definitely optimized.

QUALIFICATION OF DYNAMIC ANALYSES OF DAMS AND THEIR EQUIPMENT---OUTCOME OF JCOLD-CBFR TECHNICAL EXCHANGE---

N. MATSUMOTO(1) & J. J. FRY(2)

(1) Managing director , JAPAN COMMISSION ON LARGE DAMS
(2) Dam expert, Centre d'ingénierie Hydraulique, EDF

JAPAN AND FRANCE

1. JCOLD-CFBR TECHNICAL EXCHANGE

The technical exchange between CFBR and Japan Commission on Large Dams (JCOLD) has been conducted for the qualification of seismic dam analyses in last five years since 2013. The first objective was the comparison between the new French legislation and the current Japanese legislation, discussion about their implementation, the performance of dams under strong motions and the feedback from such performance on dam modeling. The second objective was the validation of dynamic analysis by modeling the performance of some large dams under strong motions earthquakes. The third objective was the calibration of simplified methods according to the large seismic data gathered in Japan. Therefore, the analytical procedure ranges from simplified methods for providing preliminary assessment to sophisticated methods for simulating the nonlinear deformation of dams during large earthquakes. Analyses of appurtenant structures of dams are also included.

2. OUTCOME OF COLLABORATION

CFBR developed own analysis methods and focused on the verification of them through the reproduction simulations of various dam types using the seismic records that were monitored in large dams in Japan. The spillway gates in French dams were roughly assessed for the seismic capability by comparing the dimensional data with ones in Japan. JCOLD provided some cases of the reproduction simulations of the concrete gravity dam, the arch dam and the facing rockfill dams. In addition, state-of-the-art research on the seismic analysis method and material characteristics of a largely deformed rockfill dam due to the seismic impact was introduced. The technical discussion and exchange between CFBR and JCOLD resulted in creative outcomes involving the adequate verification of the methods and finding further technical issues addressed in the future. These results are disseminated to many dam engineers in five workshops and two international symposiums held in French and Japan. An e-book compiling the above technical activity as 36 technical papers will be issued this year as titled “Qualification of Seismic Dam Analyses and their equipment.”

The main topics of the book are the following:

a. Analysis on acceleration data of dams collected by JCOLD
b. Practical guide for selecting seismic parameters and numerical models
c. Material properties and performance of embankment dams ·
d. Performance and analysis of AFRD and CFRD
e. Qualification of simplified analysis of embankment dams
f. Qualification of detailed analysis of embankment
g. Dynamic modeling, experimental and in-situ results of concrete dams
h. Effects of radiative boundary conditions and spatial variability of the seismic ground motion
i. Dynamic behavior of concrete dam : lessons learned from the JCOLD database
j. Characterization of the dynamic behavior of an arch dam by means of forced vibration tests
k. Comparison between numerical analyses and seismic records on dams
l. Simplified analyses for gravity dam
m. Displacement-Based Seismic Assessment of Concrete Dams
n. Comparison of design criteria of gates between Japan and France
o. Analysis of gates compared to field measurements

OBSERVATIONS OF PERFORMANCE OF EARTHFILL EMBANKMENTS DURING RECENT EARTHQUAKES IN NEW ZEALAND

Trevor MATUSCHKA

Director, ENGINEERING GEOLOGY LIMITED

NEW ZEALAND

1. INTRODUCTION

Many earthfill embankment water storage dams have been constructed near Seddon, New Zealand since 2004 for the purposes of irrigating grapes. They range up to 26m in height. They were subject to very strong earthquake ground motion from earthquakes in 2013 and 2016. Peak horizontal ground accelerations of close to 0.75g were recorded at Seddon during the Mw6.6 Lake Grassmere earthquake (16 August 2013) and the Mw7.8 Kaikoura earthquake (14 November 2016). The performance of eleven water storage dams located near Seddon that were subjected to these two earthquakes is summarized. The embankments were generally designed in accordance with guidelines published by the New Zealand Society on Large Dams (NZSOLD).

2. OBSERVATIONS

Observations of embankment performance are summarized in Table 1. In general, there was minor to no damage to dams that were designed and constructed to modern standards. Some dams were affected more by the Lake Grassmere earthquake. This is explained by this earthquake being closer, even though the Kaikoura earthquake had a much longer duration of strong shaking.

Two dams (F and I) that had deficiencies and were damaged in the 2013 earthquake were repaired and subsequently performed much better in the 2016 earthquake. Seiches were noted in some reservoirs in the 2016 earthquake with heights estimated to be at least 1.2m and in one case overtopped a saddle dam.

Table 1
Summary of observations

Dam ID	H^1 (m)	Lake Grassmere Earthquake R_{rup}^2 (km)	Lake Grassmere Earthquake OBSERVATIONS	Kaikoura Earthquake R_{rup} (km)	Kaikoura Earthquake OBSERVATIONS
A	17	12.4	Movement of riprap, minor cracks	26	Minor movement of riprap
B	19	14.1	No damage	28	No damage
C	13	14.1	No damage	29	No damage
D	26	17.0	No damage	20	No damage
E	17	13.7	Deformation upstream shoulder, cracks in crest	20	Additional deformation and cracks
F	10	10.7	Deformation upstream shoulder, cracks in crest	22	No damage
G	15	11.4	No damage	22	No damage
H	6	4.1	No damage	20	No damage
I	12	7.0	Deformation of upstream shoulder, cracks in crest	22	Minor cracks
J	8	15.0	No damage	31	No damage
K	11	6.1	Not constructed	21	Minor cracks upstream side dam crest

[1]H = embankment height
[2]R_{rup} = closest distance to fault rupture

3. CONCLUSIONS

Earthfill embankments designed to modern standards and constructed to high standards can withstand very high levels of ground motion with minor damage. Embankments where the earthfill is not properly conditioned and poorly compacted can be expected to deform with the potential for significant longitudinal cracking and some potential for transverse cracking where the abutment profile is irregular or stepped.

LESSONS LEARNED FROM RECENT INTERNATIONAL WORKSHOPS ON SEISMIC NUMERICAL MODELLING FOR CONCRETE DAMS

Emmanuel ROBBE

Dam specialist, HYDRO ENGINEERING CENTER OF EDF

FRANCE

EXTENDED ABSTRACT

From 2013, the author participated to several workshop dedicated to the safety assessment of concrete dams under earthquakes:

- Several ICOLD benchmark on numerical analyses of arch dam:
    - Graz 2013 on the fluid-structure interaction effect on arch dam under earthquakes,
    - Lausanne 2015 on the safety assessment of Luzzone arch dam following the Swiss guidelines,
    - Stockholm 2017 with increasing complex numerical analyses on Janeh gravity-arch dam assessment under earthquake

- USSD workshops:
    - in 2016 for a blind prediction with numerical analyses of the recorded behavior of Monticello arch dam under M4.1 earthquake, 16km away from the dam
    - in 2017 on the seismic analyses of concrete dams

- Several workshop from 2013 to 2016 during the collaboration between Japanese and French committees on large dams, on seismic behavior of dams.

The presentation will summarized the main lessons learned by the author from theses workshops.

First, the numerical modeling of concrete dams under earthquakes will discussed: from commonly used simplified finite-element model using Westergaard added masses and massless foundation to more complex numerical analyses using advanced soil-fluid-structure interaction with fluid element and viscous-spring foundation boundaries for example. Comparisons of finite-element analyses with simplified and advanced methods will be presented.

Second, the qualification of the numerical methods with earthquakes records on dams will be discussed: devices to records and save dam's response under earthquake are now easily available and such data can be used to evaluate and improve numerical tools.

Finally, a software is currently under development by the author to go through the Japanese database of records on dams and foundation. Such tool might prove very useful to analyze the increasing number of dam's response under earthquake and to evaluate dynamic properties such as eigenfrequencies and damping values during earthquake.

SEISMIC HAZARD ANALYSIS OF HARD-ROCK DAM SITES

Kofi O. ADDO

Principal Engineer, British Columbia Hydro & Power Authority, Burnaby
Member, ICOLD Committee on Seismic Aspects of Dam Design

CANADA

EXTENDED ABSTRACT

Current ground motion models for western North America (WNA) characterize site effects based on scaling with respect to V_{S30}, the time-averaged shear wave velocity (V_S) in the uppermost 30 metres. The upper limit on this V_{S30}-scaling in these models is in the range of 1100 to 1500 m/s and reflects the paucity of earthquake recordings from rock sites with V_{S30} > 800 m/s. A review of earthquake recordings on hard-rock shows that shear wave velocity alone does not fully explain observed trends and that another characteristic of the rock, *kappa* (*k*), a measure of shallow crustal damping, is required to better capture or reproduce the observations in the data. In general, kappa decreases as V_{S30} increases but there is no explicit *kappa* scaling in available WNA ground motion models and hence *kappa* is not directly included in seismic hazard analysis

Most hard-rock sites in British Columbia are glaciated and have V_{S30} values higher than 800 m/s, sometimes as much as three times higher. Hence, until such time that the development of these models incorporates data from high V_{S30} sites, seismic hazard analysis for hard-rock sites has to be performed in two stages. First, a seismic hazard analysis is conducted for a reference rock with a known V_{S30} (usually < 800 m/s) and a known inherent *kappa*. Secondly, relative amplifications based on the site-specific V_{S30} and site-specific *kappa* are calculated and applied to the computed reference hazard to derive the site-specific seismic hazard. Figure 1 shows different response spectra (with kappa varying from .05 to .01 seconds) for a structure on a hard-rock site that needs to safely resist a M_w6.5

earthquake occurring about 25 km away. If the structure is a concrete dam or supports safety-critical electromechanical equipment sensitive to short period (< 0.2 to 0.3 seconds) shaking, then kappa largely controls the spectral accelerations in this range and the ground motion almost doubles or triples at certain periods. It is therefore imperative that dam owners and their engineers know the values of V_{s30} and *kappa* for their hard-rock dam sites in order to reduce the uncertainty in the ground motion estimates.

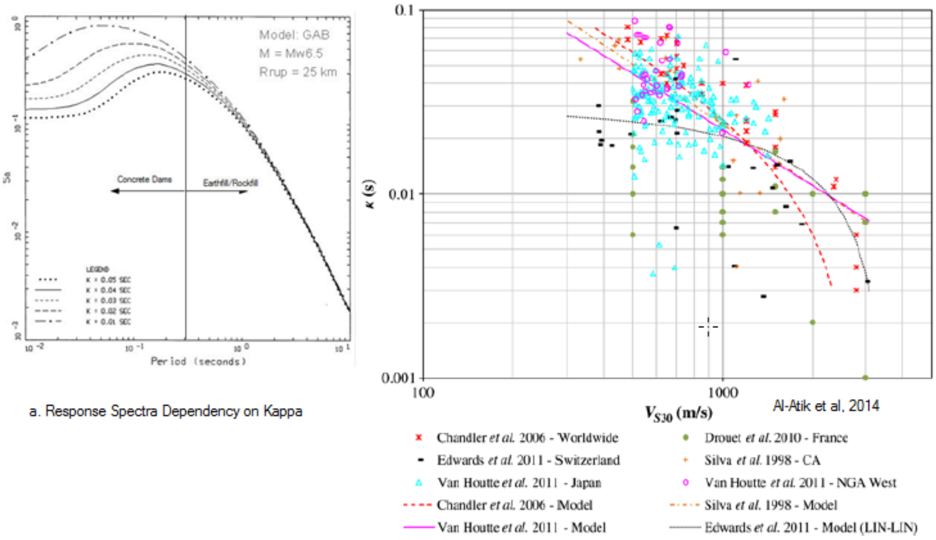

Figure 1 Response Spectra and Shear Wave Velocity Variation with Kappa

At BC Hydro, relative site amplifications based on site-specific properties are calculated and applied to probabilistic seismic hazard based on a reference rock with a V_{S30} of 760 m/s and a kappa of 0.040 seconds. Initial results show that empirical amplifications from field data are generally consistent with analytical amplifications using a hard-rock kappa of 0.015 seconds. The results also show that computed ground motions generally decrease with higher V_{S30} at all frequencies but tend to be significantly underestimated at high frequencies (> 5 Hz) if kappa and its uncertainty are not appropriately considered in the computation of the amplifications. This finding has significant loading implications for high frequency response dams and other safety-critical structures.

Also shown in Figure 1 is an approximate relationship between Kappa and Vs30 from available global data (Al Atik et al, 2014). Due to the poor correlation, it is preferable to obtain site-specific kappa values rather than rely on its dependency on Vs. To measure kappa, one needs to deploy an energy source powerful enough to excite the top 2-5 km of the earth's crust (which is impractical even if possible) or install strong motion accelerographs (SMAs) and patiently wait for an earthquake to occur. Kappa can then be estimated from the slope of the high frequency (5-20 Hz) portion of the Fourier amplitude spectrum (where it is linear in log-linear space) of an earthquake recording if the event hypocenter is within 50 km or so. Data from the SMAs, if remotely accessible, can also be used to timely inform decision-making on earthquake emergency response planning, further underscoring the importance and urgency of installing SMAs on 'significant' consequence dam sites.

1. INTRODUCTION

Oroville Dam is located on the Feather River in northern California (USA). At 234.7 m (770-ft) tall, this earth embankment is the tallest dam in the United States. With its 4.3 billion m3 (3.5 million acre-feet) of storage, Lake Oroville is the second largest reservoir in California, supplying water to cities as far south as Los Angeles. The Oroville Dam, reservoir (Lake Oroville), and hydropower plant facility is the flagship of the State Water Project (SWP), which is owned and operated by the State of California, Department of Water Resources (DWR).

The 2016-2017 Winter Storms brought record breaking precipitation to the Northern California Sierra mountains including the Feather River watershed. On February 7, 2017, the Oroville Dam's 54.5 m (179-ft) wide Flood Control Outlet (FCO) Spillway chute (Fig. 1) was releasing water to control the Lake Oroville reservoir level in accordance with the prescribed operations plan. During this operation, the FCO spillway suffered a catastrophic failure of the lower chute area eventually resulting in the loss of approximately 427 m (1400 ft) of the lower chute, including the scour of more than 1.2 million m^3 (1.6 million yd3 of soil and rock materials. On February 11, 2017, the Emergency Spillway (Fig. 1) was used for the first time since the project was completed in 1968. During this operation, significant erosion and scour caused by the Emergency Spillway overflow led authorities to fear for the safety of the spillway structures, resulting in the activation of the Emergency Action Plan and evacuation of about 188,000 persons from downstream communities.

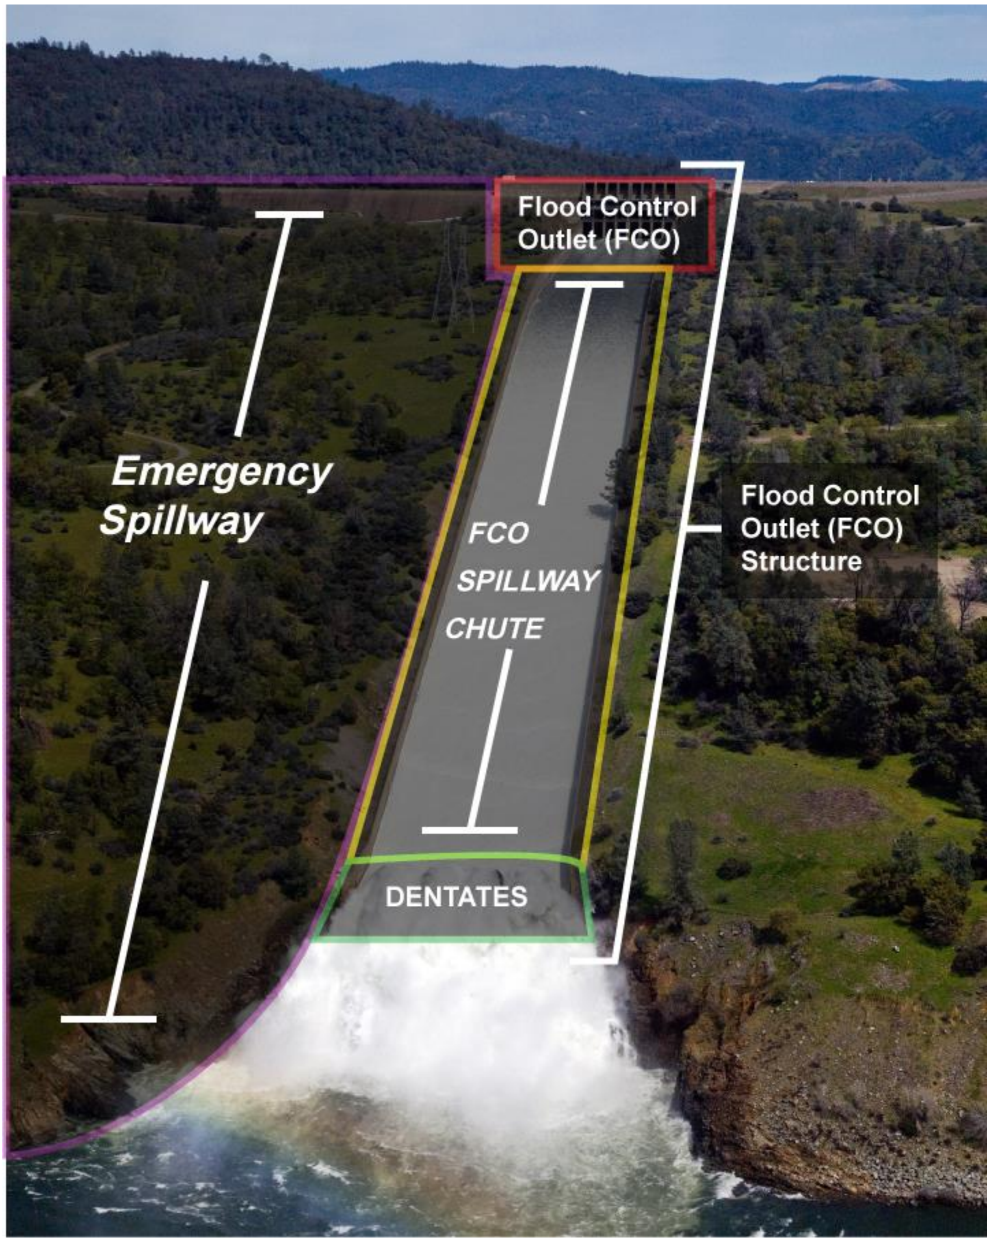

Fig. 1 Flood Control Outlet (FCO) Structure and
Emergency Spillway, March 2011

This paper is part of a series developed by the State of California, Department of Water Resources to present the results of warning and evacuation related research, conducted for the United States Army Corp of Engineers (USACE), on the Oroville Dam Spillway Incident. This investigation is part of the USACE effort to collect and analyze data on:

1) the timing of the decisions to order public evacuation warnings including the flow of information between engineers and engineering geologists monitoring the hazard and local officials,
2) the method and timing of the dissemination of those warnings including the diffusion or warning by various communication channels, and
3) the interpretation and response by the public to those warnings, including the timing of protective action decisions.

The findings from this effort will not only provide invaluable lessons learned that can improve emergency management for this type of rare event, but they will also be incorporated into the existing approaches used by USACE and others to better understand evacuations and how their effectiveness impacts the risk associated with flooding downstream from dams and levees.

2. BACKGROUND ON WARNING AND EVACUATION RESEARCH

2.1. PURPOSE OF RESEARCH EFFORT

Decisions within the USACE Dam and Levee Safety Programs follow a risk-informed management process where life safety is paramount. Understanding and making informed decisions related to life safety risk not only requires a clear understanding of the engineering aspects of our flood defense infrastructure, but also the human aspects. To that end, USACE engaged with well-respected social scientists in the areas of warning and evacuation to better understand how flood warnings spread through a community and what causes an individual to delay their decision to take a protective action based on those warnings. This understanding has not only allowed consequence specialists to better assess the existing life safety risk associated with flood defense, but also provide important insights regarding implementing or recommending efficient and effective risk reduction measures.

The research, by Dr. Dennis Mileti and Dr. John Sorensen, both renowned socials scientists in the areas of emergency warning and evacuation, covers the warning and protective action initiation timeline, which is composed of three distinct timeframes (illustrated in Fig. 2): warning delay time, warning diffusion time, and protective action initiation time. Their research, which is a culmination of existing social science research on the topic, details the primary factors that influence each aspect and provide guidance on how to develop inputs to our evacuation modeling tools. Additionally, they developed a facilitator guide that describes how to interview local emergency managers and gain an understanding of the existing evacuation potential in their area in the event of a major flood event.

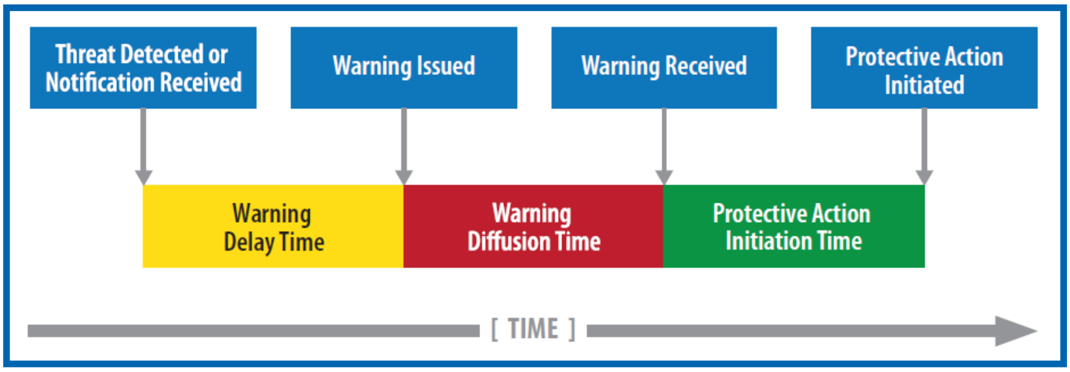

Fig. 2 Warning and Protective Action Initiation Timeline

Finally, and perhaps most importantly, they developed a document titled "A Guide to Public Alerts & Warnings for Dam and Levee Emergencies" [1]. The guidebook's purpose is to assist those involved with emergency management in issuing more timely and effective public alert and warning messages for flood emergencies. It is based on findings from decades of research on disaster warnings and presents best practices derived from these findings. While the guidebook is targeted toward dam and levee safety emergencies, it can be used to prepare a plan in such a way that allows successful implementation of emergency message communication for a wide range of emergency events.

2.2. Limitations of Existing Research

While the previous effort from Drs. Mileti and Sorensen was invaluable in providing a better understanding of the factors that influence the effectiveness of an evacuation, and established the basis for quantitative estimates for analyzing such an event, the research had gaps.

Specifically, they pointed out that research is needed to fill the warning issuance data gap. Due to the scarcity of data on warning issuance times and delays, there is a distinct need to increase the number of data points to gain a better grasp of the problem. Similarly, they stated that warning diffusion and protective action initiation models could be improved by collecting more, recent, and relevant empirical data on which to base the models.

2.3. Improving on Existing Research

Given the limitations of the previous research, USACE, with the assistance of Drs. Mileti and Sorensen, began monitoring the nation with the goal of gathering the necessary additional information when the next large-scale emergency evacuation inevitably occurred. On February 12, that scenario occurred downstream of Oroville Dam.

3. OROVILLE EVENT OVERVIEW

Based on discussions we had with locals in the Oroville area, it is clear that prior to February 2017, the public generally did not consider the consequences of an uncontrolled release of water from the Oroville Dam or its spillways. The dam was simply part of the landscape of the community that had remained virtually unchanged for nearly 50 years.

3.1. Event Initiation and Evolution

During the winter of 2016-2017, Northern California experienced its wettest winter in nearly a century. Record inflows from the Feather River into the Oroville Reservoir during the month of January caused employees of the California Department of Water Resources (DWR) to open the main spillway and release water at rates up to 560 m^3/s (20,000 ft^3/s). The release of water down the spillway was normal procedure during very wet rainy seasons and that rate of flow is far below the designed capacity of the spillway chute and downstream channel.

On the afternoon of February 6, in anticipation of increased inflow from an upcoming storm, the flow from the Flood Control Outlet (FCO) Spillway was increased to 1,550 m^3/s (55,000 ft^3/s). The following morning, an unusual flow pattern within the FCO Spillway chute caused DWR employees to close the FCO Spillway gates to allow for inspection. The halted water flow revealed a large area of concrete slab failure and foundation erosion beneath the spillway chute.

DWR began consulting with the Federal Energy Regulatory Commission (FERC) and other dam safety agencies the following day. Test flows were released down the damaged FCO Spillway to verify how much flow the spillway chute could bear. This information was important, as the area was still in the middle of a very wet season and it was likely the FCO Spillway would be needed again in the coming months. Further slab failure and foundation erosion within the spillway chute was carefully monitored and an emergency operations center (EOC) was established to oversee the spillway operations.

Even though the Butte County Sheriff's office and others received an electronic message from DWR to inform them that they were investigating the damage at the flood control outlet of Oroville Dam, it was through social media that the Sheriff learned of the hole in the FCO Spillway chute. After the initial communication issues were cleared up, the Sheriff remained in continuous contact with the EOC to ensure that public safety was the top priority. At this point, DWR officials presumed that the remaining storage area within the reservoir was sufficient to capture the expected flood flows from the rainfall during the rest of that week without causing any threat to the dam or the public. It was the goal of the dam operators to avoid using the emergency spillway while the flood flows were contained, but to be prepared in case using the Emergency Spillway became necessary. DWR and the Butte County Sheriff's Office kept the public informed through their respective social media platforms.

On February 9, rainfall in excess of 32.5 cm (12.8 in) over the Feather River Basin caused the inflows into Lake Oroville to exceed 5,380 m^3/s (190,000 ft^3/s). The peak inflow to the reservoir was significantly higher than originally forecasted. The following morning, dam operators raised flows through the main service spillway to 1,840 m^3/s (65,000 ft^3/s) and the hole within the spillway chute continued to expand and erode portions of the adjacent mountainside. DWR personnel decided to use the emergency spillway in an effort to minimize the increasing erosion at the main spillway. They reduced flow through the main service spillway to 1,550 m^3/s (55,000 ft^3/s) and water level within the reservoir continued to rise.

It is important to note that debris deposited in the river downstream of the dam from concrete slab failure and foundation erosion of the FCO Spillway chute raised the tailwater on the Edward Hyatt Power Plant and threatened to flood it out. DWR implemented emergency measures to flood proof the plant with the goal of preserving power and water supply capabilities post event. Without that effort, water supply for the region would have been in jeopardy. Although not an evacuation issue, it was foremost on the minds of the officials during that critical time.

The Emergency Spillway had not been used or tested since the dam was constructed. A large amount of erosion was expected in the Emergency Spillway and DWR employees prepared the face of the mountain by removing brush and trees in the areas where the water was likely to go, trying to limit further impact to the power plant. Due to the erosion concerns on the FCO Spillway chute and higher than anticipated inflows, the water level in Lake Oroville reached the Emergency Spillway crest early in the morning of February 11.

3.2. Determination of Critical Risk

On Sunday morning, February 12, after more than 24 hours of water flowing over the Emergency Spillway, work in the EOC was quiet. Water continued to spill over the Emergency Spillway at a rate that posed no direct threat to the downstream communities. Experts remained at the EOC and at the top of the dam communicating with each other by traveling back and forth or through text messaging with spotty cell reception. Later that morning, staff monitoring the situation at the dam noticed deep erosion rills cutting back toward the emergency spillway at a rate and size much larger than anticipated. At approximately 2:00 pm, the erosion began to concern engineering geologists about the safety of the Emergency Spillway.

If the erosion continued and reached the base of the Emergency Spillway, one of the concrete monoliths could be undermined and collapse. Engineers were concerned that a failure of one monolith could result in a domino effect, causing successive collapse of the adjacent monoliths. Engineering geologists estimated that the erosion would reach the base of the Emergency Spillway in two hours. Those monitoring the situation at the top of the dam discussed if the circumstances constituted an emergency declaration, and who had the power to make that decision.

Around the same time, at the Butte County Sheriff's Office, the Sheriff believed the entire incident was nearly complete and decided to head home for the rest of the day. Being unaware of the developing situation at the Emergency Spillway, the Sheriff stopped by the EOC to thank the people for their hard work.

Meanwhile, staff monitoring the Emergency Spillway brought photographs of the advancing erosion to the EOC and showed them to the Incident Commander. The Incident Commander received the photos at approximately 3:00 pm and received a briefing on the developing situation. He asked, "Does the Sheriff know about this?", unaware that the Sheriff had just arrived at the EOC and was standing behind him. Seeing the elevated concern, the Sheriff asked what would happen if the Emergency Spillway were to fail. DWR staff informed him that failure of the Emergency Spillway could result in a 9-10 m (30 ft) wave of water flowing from the breached spillway until the top 9-10 m (30 ft) of Lake Oroville had drained.

3.3. Decision to Evacuate

At 3:30 pm, several dam managers, engineering geologists, and the Butte County Sheriff were discussing how to address the situation developing at the Emergency Spillway. The dam managers decided to allow a flow of 2,830 m^3/s (100,000 ft^3/s) through the FCO Spillway chute to decrease the water level in the reservoir below the Emergency Spillway crest as quickly as possible. All acknowledge that this would cause additional erosion along the FCO Spillway chute, but would possibly alleviate the risk that the Emergency Spillway would fail.

During the discussion at the EOC, a DWR dam safety official entered the room and estimated that erosion was moving toward the Emergency Spillway at a rate of approximately 9-10 m (30 ft) per hour. At that moment, the erosion was approximately 9-10 m (30 ft) from the base of the Emergency Spillway. The official recommended an evacuation of the downstream communities in case the Emergency Spillway was to fail. Everyone present began talking loudly amongst themselves until the Sheriff took control of the room. He asked, “Can anyone here give me a reason not to evacuate?” The room went silent. He made the decision to evacuate at approximately 3:50 pm.

An Emergency Action Plan (EAP) had been prepared for Oroville Dam shortly after it was built. An inundation map plan that showed the areas that would be inundated if the entire dam were to fail was included as a part of the EAP. However, a map estimating the flood extents of an Emergency Spillway failure did not exist. The Sheriff, with the assistance of DWR dam safety officials, made a conservative estimate on the areas to evacuate within Butte County based on the available maps. The Sheriff also called the Sheriffs of Yuba and Sutter Counties located downstream. He quickly related that he was evacuating the potential inundation areas along the Feather River within Butte County and that they should do the same in their respective counties.

3.4. COMMUNICATION OF EVACUATION DECISION TO SAFETY OFFICIALS

DWR communicated with a variety of organizations about the situation at Oroville Dam beginning on February 8, 2017. They also distributed the following evacuation decision message to 161 organizational contacts, including safety and emergency managers (159 were reached), on February 12, 2017 at 4:10 pm. That message stated: “This is an evacuation order. Immediate evacuation from the low levels of Oroville and areas downstream is ordered. A hazardous situation is developing with the Oroville Dam auxiliary spillway. Operation of the auxiliary spillway had led to severe erosion that could lead to a failure of the structure. Failure of the auxiliary spillway structure will result in an uncontrolled release of floodwaters from Lake Oroville. In response to this developing situation, DWR is increasing water releases to 100,000 cubic feet per second. Immediate evacuation from low levels of Oroville and areas downstream is ordered. This is NOT A Drill. This is NOT A Drill. This is NOT A Drill.”

3.5. CHRONOLOGY OF FIRST PUBLIC EVACUATION MESSAGES

Five first public evacuation messages were subsequently issued to people in different at risk geo-political areas. These were: (1) Butte County, which contains the City of Oroville, (2) the National Weather Service to people in Butte, Sutter, and Yuba Counties, (3) Sutter County, (4) Yuba City, which is the largest city in Sutter County, and (5) Yuba County, which contains the City of Marysville. Fig. 3 illustrates the location of these communities in relation to Oroville Dam. We catalogued first evacuation messages for different subpopulations because their timing was central to our efforts to examine warning decision-making, diffusion, and protective action initiation. The five first public evacuation messages follow.

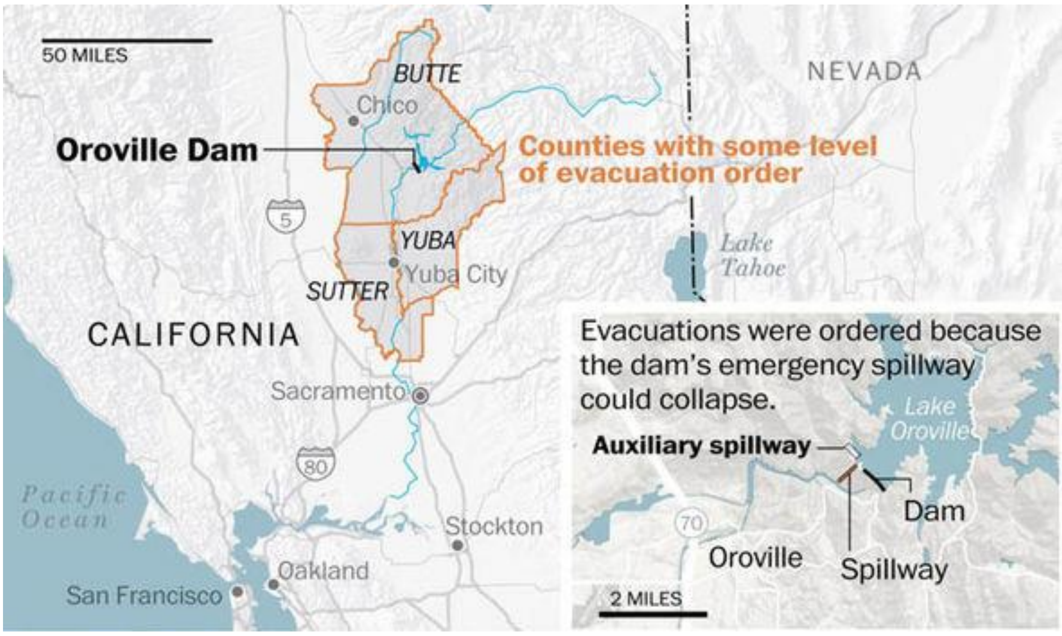

Fig. 3 Areas Receiving Evacuation Orders Downstream of Oroville Dam
(Source: United States Geological Service)

3.5.1. 4:21 pm: Butte County.

The Butte County Sheriff's Office sent the first public evacuation message to the public of Butte County at 4:21 pm on February 12, 2017. It stated the following. "This is an evacuation order. Immediate evacuation from the low levels of Oroville and areas downstream is ordered. A hazardous situation is developing with the Oroville Dam auxiliary spillway. Operation of the auxiliary spillway has lead to severe erosion that could lead to a failure of the structure. Failure of the auxiliary spillway structure will result in an uncontrolled release of floodwaters from Lake Oroville. In response to this developing situation, DWR is increasing water releases to 100,000 cubic feet per second. Immediate evacuation from the low levels of

Oroville and areas downstream is ordered. This is NOT A Drill. This is NOT A Drill. This is NOT A Drill.

This message was disseminated using social media, local radio and television, and the Blackboard notification system (described further in Section 4.2.1). The Sheriff also ordered the deputies in Butte County to go to the neighborhoods at risk and announce the evacuation order over the public address system in their police vehicles.

3.5.2. 4:35 pm: All Three Counties at Risk.

The National Weather Service in Sacramento released the following statement at 4:35 pm on February 12, 2017 via Wireless Emergency Alerts (WEA) to everyone in the entire three-county area at risk. "The National Weather Service in Sacramento has issued a Flash Flood Warning for a dam failure in south central Butte County in Northern California. Until 4:15pm PST Monday. At 4:19pm PST, dam operators reported a hazardous situation is developing with the Oroville Dam auxiliary spillway. Operation of the auxiliary spillway has led to severe erosion that could lead to a failure of the structure. Failure of the auxiliary spillway structure will result in an uncontrolled release of floodwaters from Lake Oroville. In response to this developing situation, DWR is increasing water releases to 100,000 cubic feet per second. Immediate evacuation from the low levels of Oroville areas downstream is ordered. From Oroville to Gridley...low level areas around the Feather River will experience rapid river rises. This is not a Drill. This is not a Drill. Repeat this is not a drill. Locations impacted include Oroville, Palermo, Gridley, Thermalito, South Oroville, Oroville Dam, Oroville East and Wyandotte. Turn around, don't drown when encountering flooded roads. Most flood deaths occur in vehicles. Move to higher ground now. Act quickly to protect your life."

3.5.3. 5:33 pm: Yuba County.

The Yuba County Office of Emergency Services issued the following warning message to people in Yuba County at 5:33 pm on February 12, 2017. "ALERT-ALERT-ALERT –- Yes, an evacuation has been ordered. All of Yuba County on the valley floor. The auxiliary spillway is close to failing. Please travel safely. Contact family and friends. Help the elderly. Take only routes to the east, south, or west. DO NOT TRAVEL NORTH TOWARD OROVILLE!!!!!" At 5:48 pm, the Marysville Police Department confirmed that a mandatory evacuation for the City of Marysville and Yuba County was in effect. Then at 6:08 pm it was stated that: "Evacuation for Yuba includes Hallwood, Marysville, Olivehurst/Linda and Plumas Lake due to potential failure of Oroville Dam spillway."

3.5.4. 6:03 pm: Sutter County.

At 6:03 pm on February 12, 2017, the Sutter County Office of Emergency Management issued the following message to people in Sutter County. “Immediate evacuation Live Oak, Yuba City, Nicholas and other communities along Feather River ordered. Evacuate on Highway 99/70 south of Highway 20 west. Do not evacuate north. A partial failure of the Oroville Dam is possible.” The county followed this first evacuation message to people in Sutter County with a subsequent message at 6:17 pm, which declared that the evacuation was ordered (or mandatory). “Immediate evacuation ordered for Live Oak, Yuba City, Nicolaus & all communities Feather River Yuba City basin. Evacuate West on Hwy 20 and/or South on Hwy 99 and Hwy 70 toward Sacramento.”

3.5.5. 6:49 pm: Yuba City.

Another public evacuation message was issued which targeted the people in Yuba City—located in Sutter County. It was distributed at 6:49 pm on February 12, 2017. It was the first message issued by city officials and it followed the mandatory evacuation message distributed by the county. It contained a voluntary evacuation recommendation, and was issued by local Yuba City government. It stated the following. “City of Yuba City strongly recommends an evacuation of all residents immediately. Travel options are as follows. South on Highway 99, West on Highway 20, Highway 99 South to Highway 113, or South on George Washington to Highway 113. Do not travel on Highway 20 or Bridge Street as the bridges are closed. Do not travel North.”

3.6. PUBLIC RESPONSE

At the writing of this paper, response to the public survey that we created to gather information on the response to the warnings described in previous sections was in its final stages. Some preliminary findings are described below, but these may change as the data undergo final analysis. Importantly, the survey was conducted on a representative sample of the entire population in the evacuation zone. Therefore, we have a statistical basis for generalizing the findings for people not in the sample.

3.6.1. Protective Action Initiation Response Rate

Preliminary analysis of public survey responses suggests just under 70% of the population in the targeted evacuation zone actually evacuated. Table 1 lists the reasons why people did not evacuate. The primary reason for non-evacuation (33%) was that even though they were in the evacuation zone, they felt that they would be above the flood elevation. In effect, they felt they were not asked to evacuate as the evacuation order was targeted to those in “low lying areas”. The next most common responses were that they did not think there would be a flood (19%) or that they were not in an area told to evacuate (14%). Another common response (13%) stated that traffic congestion kept them from evacuating, either they tried and turned around or saw the congestion on the news and stayed home.

Table 1
Reasons for Non-evacuation

NON-EVACUATION REASON	% of NON-EVACUEES
Not in area told to evacuate	14%
Not in low lying area or an area that would flood	33%
Stayed behind to protect my property	10%
Did not think there would be a flood	19%
Stayed behind to do my job	2%
Did not have the resources	6%
Physically unable to evacuate	3%
Other (Mostly traffic congestion related)	13%

3.6.2. Evacuation Timing

Preliminary data analysis suggests that about 10% evacuated prior to the first evacuation order (either due to concerns with the dam or left for other reasons and did not return). Approximately 40% of those that evacuated did so within 30 minutes of the first public evacuation order, which was issued at 4:21 PM on February 12. Approximately 70% evacuated within an hour of the first evacuation order, and 83% evacuated within 2 hours of the first evacuation order.

For those that evacuated, the amount of time they spent on the road was significant. On average, it took 3 hours for people to reach their destination. For context, most evacuees all traveled to destinations that would have normally taken less than 1 hour. Table 2 shows the breakdown of travel times.

Table 2
Evacuation Travel Times

TRAVEL TIME (HOURS)	% of EVACUEES
< ½ hour	14%
½ hour – 1 hour	33%
1-2 hours	10%
2-3 hours	19%
3-4 hours	2%
4-5 hours	6%
5-10 hours	3%
> 10 hours	13%

4. LESSONS LEARNED

The Oroville emergency evacuations provided some new lessons, and reinforced many existing lessons, for emergency managers. The list below is not meant to be exhaustive, but highlights some of the more important ones in the view of the authors. Many of the lessons reinforced by this event are describe by the authors in previous work [1].

4.1. Lack of Inundation Maps

Perhaps the most important lesson learned, or in this case reinforced, was the value of having inundation maps for a wide range of potential scenarios available for emergency managers at a moment's notice. As described above, the situation on February 12 was relatively calm leading up to the emergency, and nobody was concerned about a potential breach of the Emergency Spillway. Within a couple hours of recognizing erosion that could impact the stability of the Emergency Spillway, local emergency managers were sending out evacuation notices with little understanding of the area at risk. Their only available information was for a complete failure of the main dam embankment, which would have led to flows that would be orders of magnitude higher than were expected from breach of the Emergency Spillway. This short amount of time does not allow even the most experienced hydraulic engineers to model properly the scenario in question. Therefore, it is important to have inundation maps available covering a wide range of potential breach and non-breach scenarios as part of the EAP.

DWR was already aware of the need for additional maps for Oroville and other dams in their portfolio. They were already in the process of creating a library of inundation maps to cover a wider range of breach and non-breach scenarios. If this emergency had occurred just a few months later, these additional inundation maps would have been available, and the evacuation notice could have been targeted to more specific areas.

4.2. Mass Notification System

The notification system used by DWR emergency managers, known as Blackboard, and the large notification lists contained therein led to some unforeseen issues and confusion during the incident.

4.2.1. Blackboard

Blackboard is an automated mass notification system that has many capabilities, but in this case, was set up by DWR to sends messages to a roster of emergency management and response agencies via email and telephone. For telephone messages, it has the capacity to call three phone numbers at a time. It works sequentially through the notification list until all contacts have answered the phone, been left a voicemail, or did not answer after several attempts.

The fact that the system can only call three numbers at a time resulted in a significant delay in disseminating the evacuation notice to those relying on telephone messaging. The initial evacuation message that was sent via Blackboard at 4:10 pm did not reach all of the ~160 contacts on the notification list until 4:44 pm. The follow up message, which indicated that the Emergency Spillway could fail within the next 60 minutes and provided guidance on evacuation routes, was sent at 4:34 pm and was not completely disseminated until 5:10 pm. Because of this delay, many of the emergency management and law enforcement agencies on the notification list found out about the emergency and evacuation via social media prior to learning about it from the official Blackboard notification.

DWR had added various emergency managers to the Blackboard call down list over the years, without understanding the impact that all those additional numbers would have on the efficiency of the system. In that regard, it is important that dam operators or anyone relying on these automated systems to provide important emergency messages understand their limitations and test them regularly.

4.2.2. Message Specificity and Warning Templates

Another lesson that was reinforced through the Oroville emergency was the need for emergency messages, especially those ordering protective actions such as evacuations, to be as specific as possible. The initial message that was sent out started with "*This is an evacuation order. Immediate evacuation from the low* *levels of Oroville and areas downstream is ordered.*" This message went out to all emergency managers downstream of Oroville Dam, which includes the city of Sacramento and surrounding areas about 100 km (70 miles) downstream. Some emergency managers in those areas far downstream interpreted the message to mean they should be preparing to evacuate, when in reality the concern for them potentially being flooded was minimal. Emergency managers in those areas would have been better served if the initial message contained more specific information on the areas downstream from Oroville Dam that should evacuate. Emergency managers downstream but not at risk of flooding could have been preparing to receive evacuees rather than determining if they were really meant to be evacuating their communities.

This re-emphasizes the need for warning templates and examples. Example messages and templates serve a number of significant purposes for an emergency manager. First, it is not reasonable to expect that all emergency managers are familiar with the value of certain content (such as specificity of locations) or wording in messaging, so templates and examples provide an effective starting point. Second, messages cannot be written in advance for every emergency scenario. Message templates provide the capability to create specific event messages much more quickly. Example messages and templates are also useful to avoid hastily written content. Finally, example messages and templates provide emergency managers something to practice and hone their skills on.

4.3. Communication Issues

A widely recognized issue within the emergency management community is the need for trustworthy means of communication between the various agents during and emergency event. In the case of Oroville, communication between those monitoring the situation from the crest of the dam and the command center was strained due to lack of reception on the mobile phones used by those at the dam site. Calls rarely connected, and text messages were intermittent and lagged. This required those monitoring the site to take pictures and travel to the command center with the information so those managing the situation could have the necessary information. Hardened and redundant communications technologies such as satellite telephones and two-way radios can prevent these kinds of issues and lead to more efficient and effective emergency management.

4.4. Lack of Sleep

Admirably, DWR staff were dedicated to understanding and managing the emergency. From the initial discovery of damage on February 7 until the emergency evacuation on February 12 (and beyond), many of the engineers and project staff were on call, either in the local office, at the project, or in the emergency operations center nearly non-stop. Many of the senior engineers had little to no sleep in the days leading up to the evacuation. A multitude of scientific studies have shown that sleep deprivation makes it difficult to adapt to the unexpected. While the authors of this paper are not questioning the decision-making during the Oroville Dam Incident, emergency managers should take the opportunity to learn from this and implement procedures that require those faced with making potential life and death decisions to get a reasonable amount of sleep during prolonged emergencies such as this.

ACKNOWLEDGEMENTS

We would like to acknowledge the California Department of Water Resources (DWR), the United States Federal Energy Regulatory Commission (FERC), and the local emergency mangers in Butte County, Sutter County, Yolo County, and the cities of Marysville and Yuba City for answering all our questions about this emergency. Their open and honest responses provided invaluable information that will be used to better understand the flow of information during an emergency and improve emergency management going forward.

1. INTRODUCTION

Oroville Dam is located on the Feather River in northern California (USA). At 234.7 m (770-ft) tall, this earth embankment is the tallest dam in the United States. With its 4.3 billion m3 (3.5 million acre-feet) of storage, Lake Oroville is the second largest reservoir in California, supplying water to cities as far south as Los Angeles. The Oroville Dam, reservoir (Lake Oroville), and hydropower plant facility is the flagship of the State Water Project (SWP), which is owned and operated by the State of California, Department of Water Resources (DWR).

The 2016-2017 Winter Storms brought record breaking precipitation to the Northern California Sierra mountains including the Feather River watershed. On February 7, 2017, the Oroville Dam's 54.5 m (179-ft) wide Flood Control Outlet (FCO) Spillway chute (Fig. 1) was releasing water to control the Lake Oroville reservoir level in accordance with the prescribed operations plan. During this operation, the FCO spillway suffered a catastrophic failure of the lower chute area eventually resulting in the loss of approximately 427 m (1400 ft) of the lower chute, including the scour of more than 1.2 million m3 (1.6 million yd3 of soil and rock materials. On February 11, 2017, the Emergency Spillway (Fig. 1) was used for the first time since the project was completed in 1968. During this operation, significant erosion and scour caused by the Emergency Spillway overflow led authorities to fear for the safety of the spillway structures, resulting in the activation of the Emergency Action Plan and evacuation of about 188,000 persons from downstream communities.

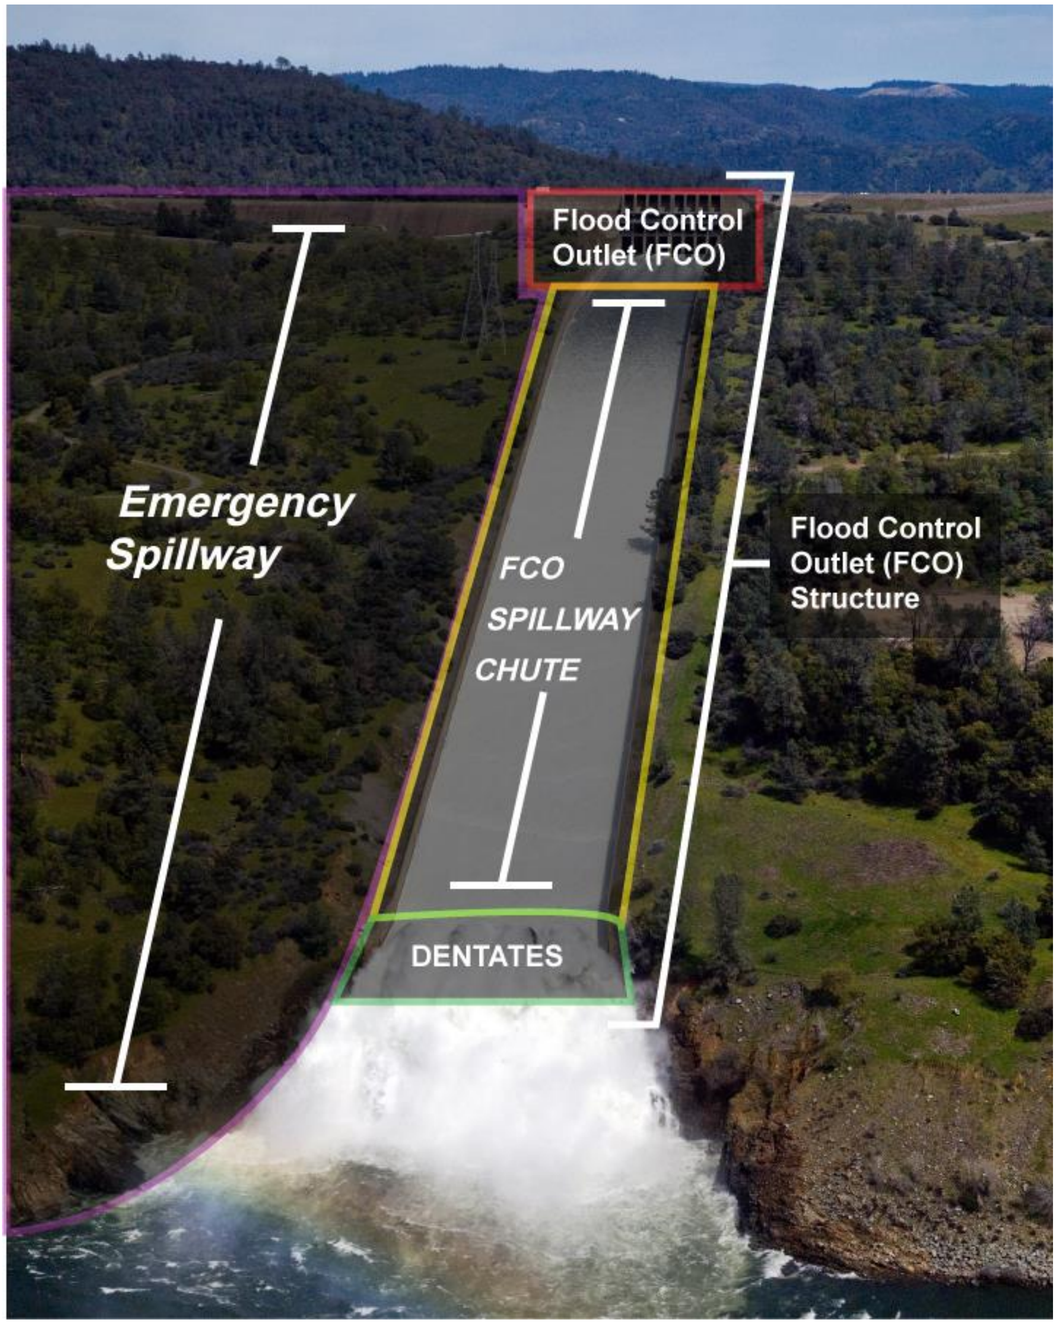

Fig. 1 Flood Control Outlet (FCO) Structure and Emergency Spillway, March 2011

This paper is part of a series to describe the Oroville Dam Spillway Incident Emergency Response and Recovery. This paper focuses on the implementation of the emergency response actions starting on February 7, 2017, and the actions taken in the days and weeks after failure of the concrete in the FCO Spillway chute. It provides detail of the incident as it unfolded, the decisions made to protect the public, the incident command system, and the situation that led to the evacuation.

2. OROVILLE DAM FACILITY

The Oroville Dam facility design was initially proposed in 1953 and was modified a number of times based on new requirements and scaled physical model studies, with construction being complete in 1968.

The Oroville Dam and its major appurtenant facilities consist of a main dam (Oroville Dam), two saddle dams (Bidwell Saddle Dam and Parish Saddle Dam), two spillways (FCO Spillway and Emergency Spillway), the Hyatt Powerplant (Powerplant), and the River Valve Outlet.

The main embankment is a zoned earthfill at 234.7 m (770 ft) high and a crest length of 2110 m (6920 ft). Bidwell Saddle Dam is located at the end of the Bidwell Bar Canyon arm of Lake Oroville and has two embankments. The combined length of the Bidwell Saddle Dam is 409 m (1340 ft) and the maximum embankment height is 14.3 M (47 ft). Parish Camp Saddle Dam is an embankment with a maximum height of 8.2 m (27 ft) and is 79.9 m (260 ft) long.

Oroville Dam's two spillways include a Flood Control Outlet (FCO) structure and an Emergency Spillway. They are configured as two separate structures right (north) of the main dam's right abutment. The function of the FCO structure is to provide flood protection to the downstream communities. Flows are regulated through the FCO structure, thus routing storms and river inflows through the reservoir storage. The FCO structure has three main components: a Flood Control Outlet, a 1310 m (4300 ft) long FCO Spillway chute, and an energy dissipater. The FCO structure was sized to control the "standard project flood" peak inflow of 12460 m^3/s (440,000 ft^3/s) without using the Emergency Spillway. During the standard project flood routing, the maximum flow through the FCO structure was set at 4248 m^3/s (150,000 ft^3/s) due to downstream levee capacity. This upper limit of release was set to protect local and downstream urban and agricultural areas from flooding. However, during the estimated Probable Maximum Flood (PMF) events, the FCO structure was designed to release a maximum of 8283 m^3/s (296,000 ft^3/s). The FCO Spillway chute is a rectangular, reinforced-concrete open-channel chute. The profile of this lined chute closely follows the original natural terrain. This minimized the excavation as well as the disturbances of the underlying rock due to blasting. The FCO Spillway chute was founded on varying degrees of weathered rock. Four dentate structures were placed at the end of the chute to dissipate excess energy. From the end of the dentates, the flow releases into the Feather River.

The purpose of the Emergency Spillway is to discharge extreme floods to prevent overtopping of the Oroville Dam embankment. The Emergency Spillway consists of two sections; an ogee section and a low-sill weir. The ogee section consists of multiple concrete monoliths founded on bedrock with varying heights. The tallest monolith has a height of about 15.9 m (50 ft) from the original ground and excavated into rock. The low-sill weir is a broad-crested concrete weir also founded on rock. The Emergency Spillway was sized such that during a PMF event, the spillway would be able to release a maximum flow of 10,506 m^3/s (371,016 ft^3/s) when the reservoir elevation is at 297.5 m (917 ft). The natural topography downstream of the Emergency Spillway was designed to convey the Emergency Spillway flows to the river. The area downstream of the Emergency Spillway was not cleared of vegetation because of the predicted infrequent use of the Emergency Spillway (once in 800 years), and for economic, cultural, and aesthetic reasons. Although the Emergency Spillway was designed to withstand extreme flows, some erosion of the hill slope and debris were expected if the Emergency Spillway was ever engaged. However, the actual weir was not anticipated to be endangered from erosion during flows, based on the original design.

Additional discussion and figures regarding the hydrologic and hydraulic information and data related to Oroville Dam and the Oroville Emergency Response and Recovery are provided in accompanying DWR papers noted earlier, and the references cited.

Two 6.7 m (22 ft) diameter penstock tunnels leading from the reservoir to three reversible pump turbines and three conventional turbines feed the Hyatt Powerplant. The maximum combined release capacity of the Hyatt Powerplant is 479.9 m^3/s (16,950 ft^3/s). The facility also includes a River Valve Outlet system. The River Valve Outlet is at the lowest elevation that accesses the reservoir with a modest maximum capacity of approximately 122 m^3/s (4300 ft^3/s). Water from the Hyatt Powerplant and the River Valve Outlet flows into diversion tunnels, which exit near the downstream toe of the dam and into the tailrace, which eventually leads back to the Feather River channel. Normal emergency drawdown of the reservoir is typically through the FCO Spillway and/or the Hyatt Powerplant. The River Valve Outlet is only used when the reservoir level is too low for the Hyatt Powerplant to efficiently operate.

3. CALIFORNIA'S EMERGENCY MANAGEMENT SYSTEM

3.1 California Emergency Management

California has faced many disasters and emergencies over the years. The State has developed a robust emergency management community and has been a national leader in developing regulations, plans, and policies. DWR is an integral part of California's system and has other responsibilities beyond the SWP, including providing support and technical assistance to local agencies during floods. California's emergency management system works in layers to streamline communication and ensure resources are being delivered to the highest priority emergencies statewide. The following is a brief overview of the emergency management practice that is used during emergency events, such as the Oroville Emergency Response.

3.1.1 California State Emergency Plan

The foundation for emergency management in California is the State Emergency Plan (SEP). This plan describes how responses to natural and/or human-caused emergencies should occur in the State. The plan describes: methods for conducting emergency operations, the process for rendering mutual aid, emergency services of government agencies, how resources are mobilized, how the public is informed, and how continuity of government is maintained during an emergency. The SEP also describes hazard mitigation (actions to reduce risk), as well as preparedness and recovery from disasters. The SEP is compatible with federal emergency planning concepts.

Key elements of the plan are used on a regular basis in response to different incidents and emergencies, such as statewide winter storms, wildfires, and the Oroville Emergency Response. The SEP, through its mutual aid and resource management systems, identified the state agency and department resources to be used to assist local governments in evacuating 188,000 people, providing meals and shelter for almost 10,000 people, and aided the sharing of information and coordination of activities from the field level to state government response.

3.1.2 The Standardized Emergency Management System

The Standardized Emergency Management System (SEMS) (Fig. 2) is the cornerstone of California's emergency response system and the fundamental construct of emergency management. California law requires SEMS for managing multiagency and multijurisdictional responses to emergencies. The system unifies all elements of California's emergency management community into a single integrated system. SEMS incorporates: 1) Incident Command System (ICS) - field-level emergency response system based on management by objectives; 2) Multi/Inter -agency coordination - affected agencies working together to coordinate allocations of resources and emergency response activities; 3) Mutual aid - system for obtaining additional emergency resources from non-affected jurisdictions; and 4) Operational Area Concept - County and its sub-divisions to coordinate damage information, resource requests and emergency response.

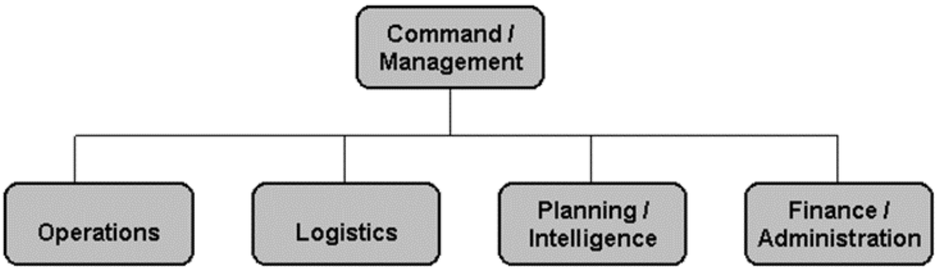

Fig. 2 - SEMS Organization Structure

3.1.3 STATE OPERATIONS CENTER

During major incidents, multiple emergencies can occur simultaneously. It is important that emergency responders communicate and coordinate throughout the various layers of government. At the highest level of emergency coordination in California is the State Operations Center (SOC) that is responsible for coordinating resource requests and resolving priority issues that arise at the regional level. The SOC is also responsible for coordinating with federal agencies. SOC operations are under the management of the California Governor's Office of Emergency Services. SOC responsibilities include, in part: 1) overall state coordinator in the event of simultaneous, multi-regional incidents; 2) monitors and facilitates inter-regional communications and coordination issues; 3) compiles, authenticates, and makes available summary disaster status information obtained from all sources, in the form of Situation Reports, to the Governor's Office, the legislature, State agency headquarters, media, and others as appropriate; 4) provides necessary coordination with and between established statewide mutual aid systems at the state headquarters level; 5) manages the state government emergency public information; and 6) supports the recovery process and assists State agencies and Regional Emergency Operations Centers (REOC) in developing and coordinating recovery action plans.

During the Oroville Dam Spillway Incident, the SOC and a REOC were activated to the highest level and were critical in addressing local and State agency needs. This system led the State response to assist many local agencies during the mass evacuation of about 188,000 people. It was critical to deploy a number of high-level DWR executives to the SOC to facilitate enhanced communication, situational awareness, and resource priority setting between the DWR Department Operations Center (DOC) and the Governor's Office.

3.1.4 Department of Water Resources Emergency Operations

In addition to many other responsibilities, the Department of Water Resources is responsible for protecting life and property from catastrophic events such as flood, drought, and dam or levee failures. When significant weather events are forecast, DWR is responsible for coordinating local, State, and Federal flood operations. DWR's first layer of emergency coordination is the Department Operation Center (DOC), which is responsible for coordinating all DWR emergencies and communicates directly with the SOC. DWR operates many potential emergency centers, including a State and Federal Flood Operation Center (FOC) to coordinate various flood-related emergencies. DWR's Project Operations Center is responsible for emergencies focused on State Water Project facilities. Similar to the State's Emergency Response plan, DWR and SWP have specific emergency response plans and emergency action plans that focus on their respective responsibilities and facilities.

3.1.5 Public Contract Code Section 10122(b)

In cases of failure or threat to a dam, reservoir, aqueduct, or other water facility or facility appurtenances, DWR has unique emergency construction authority. DWR must expedite processes and, in some cases, immediately implement work. This emergency authority pursuant to Public Contract Code Section 10122(b) is critical to DWR and SWP in safely and efficiently executing its mission.

4. THE OROVILLE DAM SPILLWAY INCIDENT

California receives most of its precipitation and largest storms during the winter months. Thus, large reservoirs, such as Lake Oroville, are needed to provide flood protection in the winter and then water supply for the summer months and carryover in anticipation of drought years. Beginning in January 2017, after 5 years of historic drought, above average rainfall and snowfall occurred throughout most of California.

Major reservoirs were operating based on regulatory flood control curves and were releasing flood flows by design.

Prior to February 7, 2017, DWR had already activated the Joint State-Federal Flood Operations Center (FOC) in Sacramento. This was due to heavy precipitation causing high water conditions in many California streams and rivers, resulting in elevated flood threats throughout California.

By February 7, over 145% of normal precipitation had occurred over the Feather River Basin. A purpose of the Oroville Dam facility is to manage flood flows by routing inflows through the reservoir and the FCO Spillway according to the prescribed operations plan and regulatory requirements. The FCO Spillway began releasing 850 m^3/s (30000 ft^3/s) on February 3 and then the release was increased to 1416 m^3/s (50000 ft^3/s) on February 6, 2017.

On February 7, and within standard operating criteria, FCO Spillway release was increased to 1530 m^3/s (54000 ft^3/s) due to forecasts predicting additional heavy precipitation. After the FCO Spillway flow was increased on February 7, unusual flow patterns and brown water were observed approximately half way down the chute. The FCO Spillway was immediately shut down to observe the chute condition (Fig. 3). Initial assessments of the FCO Spillway chute damage were made and additional technical resources were brought in to evaluate potential mitigation and protective measures that might be implemented. Forecasts were predicting significant reservoir inflows in the coming days. The emergency warranted that DWR activate the Oroville Dam Emergency Action Plan (EAP) to ensure that local, State, and Federal agencies were notified of the current incident.

Fig. 3 – Damage to FCO Spillway chute on February 7, 2017

Over the next hours and days, critical technical and regulatory teams arrived at the facility to assist with the assessment and development of mitigation measures, analyze risks, implement contingency plans, and update local agencies and the media. State and Federal regulatory agencies along with other specialized consultants were some of the first to arrive at the site to engage in these activities.

DWR's Oroville Field Division activated the Oroville Incident Command Team (OICT) in Oroville. The team began field-level emergency response activities, regular communications and coordination with the Project Operations Center (POC), and the DOC. The OICT first organized and developed staffing to assess the FCO Spillway and adjacent facilities, develop risk assessments, develop and implemented immediate mitigation measures, and communicate with partners, local agencies and officials, regulatory agencies, and other State and Federal agencies. The OICT was charged with managing all on-site emergency response activities with support from the DOC and the POC. All DWR resources were made available under a Department declared State Water Project Emergency.

The DOC management team was immediately set up and quickly addressed staffing and operational location questions/concerns. Full activation of the DOC was critical to coordinate, monitor, assess, plan, and respond to the very dynamic conditions at the Oroville Dam facility and the high-water conditions throughout the State. This was important to ensure that all DWR resources were tasked effectively and to ensure the public's safety.

DWR's Acting Director declared a Department Emergency on February 8, 2017, based on internal briefings and field verifications. These briefings provided extensive information regarding the status of the FCO Spillway chute damage, current and anticipated reservoir inflows, forecast reservoir elevations, and downstream infrastructure and potential threats to public safety. This declaration was done to ensure that all DWR resources were made available to respond to and recover from the incident. This declaration was critical to initiating the largest emergency response in DWR's history, and allowed re-tasking of DWR management and staff, consultants and contractors, and the use of emergency contracting for emergency services and resources not currently available.

The POC was also immediately activated in Sacramento to support the Oroville Dam Spillway Incident. The POC, in close coordination with the State Water Project Deputy Director and the DOC, was charged with providing State Water Project system-wide assessments, hydrology forecasts, reservoir routing, assessments of threats and response alternatives, cost forecasting, and executive briefings to DWR directorate and the State Operations Center (SOC). The POC was critical in managing the dynamic environment at the Oroville Dam facilities with close coordination with the Oroville Incident Command Team (OICT).

Figure 4 provides an organization chart for DWR's Emergency Operations Centers and the Incident Command Teams that were activated during the Oroville Emergency.

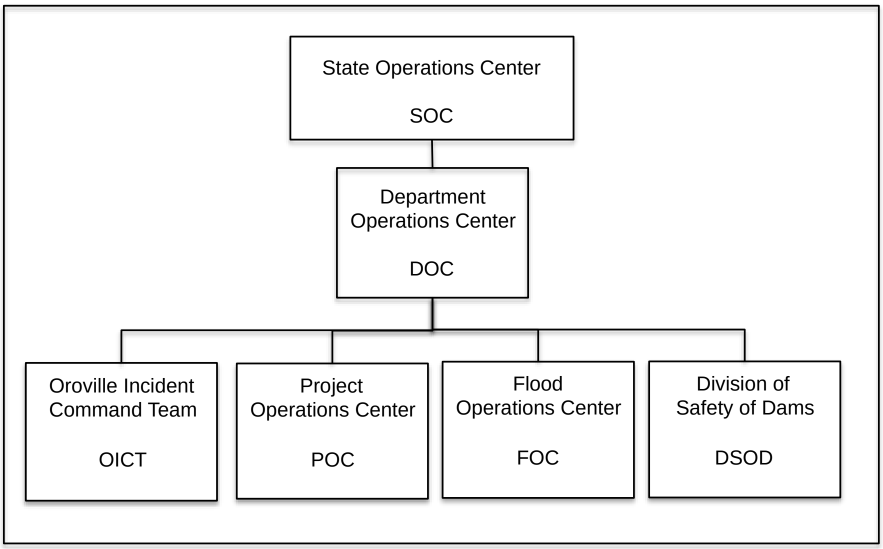

Fig. 4 Emergency Organizations for FCO Spillway Incident

On February 9, 2017, Butte County Sheriff Kory Honea contacted DWR's Acting Director to request direct communication with DWR during the emergency. The Acting Director traveled to Oroville Dam to assess the status of the FCO Spillway chute, related facilities, resource needs, and to ensure that the communication and organization concerns were being properly addressed. The Sheriff met with the Acting Director at the Incident Command Post (ICP) in Oroville and, in a short discussion, the Acting Director and the Sheriff quickly agreed to support each other and their respective missions, with the highest priority being public safety. This understanding and agreement was critical to the outcome of this extremely difficult and dynamic incident.

Organizations that are rarely involved in large emergencies do not have the real-world experience of emergencies, which cannot be fully replicated by training. This resulted in a limited number of experienced DWR staff that could fulfill critical EOC and ICT roles. During this period, it became clear that the ICT needed additional emergency management support, including emergency response personnel and emergency equipment. CalFire is the agency that routinely manages wildfire emergencies throughout the State of California and is very familiar with the incident command system. Therefore, CalFire was contacted at the Director level and was immediately activated to assist DWR in their ICT roles. A CalFire management team ramped up within a few hours and began setting up a CalFire incident command post. It was critical to quickly integrate the experienced CalFire management team into the DWR Oroville ICT to provide formal structure, communication and documentation process, and on-the-job training to existing and rotating DWR Oroville management and staff. Initial challenges included operational space, chain of command and control structure, internal and external communications, and developing a common understanding for the threats, risks, and potential response actions for a dam safety emergency compared to a wildfire emergency. DWR Executives, Oroville ICT, CalFire, and the Butte County Sheriff met as a team to address situational awareness, identify critical next steps, and lay out a short process to form a Unified Command Team. The Unified Command Team formed between DWR, CalFire, and the Butte County Sheriff was critical to quickly address the chain of command at the local level, reinforcement of the ICT with strong SEMS processes, procedures and roles, and improve internal and external communication with other EOCs, the media, and the public.

Another critical component of the Emergency Management Team was the regulators responsible for overseeing dam owners and the safety of dams. Oroville Dam is regulated by two entities: the State of California Department of Water Resources' Division of Safety of Dams (DSOD) and the Federal Energy Regulatory Commission (FERC). In California, the DSOD takes a prominent role in the regulation and oversight of dams that fall under their jurisdiction. DSOD regulates about 1,250 dams in California and makes regular inspections, construction inspections, and dam re-evaluations. FERC regulates dams associated with the generation of hydroelectric power that are issued a license under their jurisdiction. FERC regulates these dams to assist the licensee in ensuring and promoting dam safety and following Federal dam safety requirements as well as general compliance with license requirements. FERC regulates approximately 2,500 dams throughout the United States and performs regular dam safety inspections, reviews and approves of any new construction or modifications to existing dams, performs construction inspections, and often requires independent consultant reviews of high and significant hazard projects.

State and Federal laws mandate that both the FERC and DSOD play an independent role in dam safety, including during emergency responses such as Oroville. During the emergency, both DSOD and FERC were available on-site 24/7. They participated in briefings, meetings, technical evaluations and other activities to be fully informed of threats, risks and proposed mitigation measures. Many DWR decisions to address the emergency required the regulators to be aware of, consulted with or approve. The regulators maintained authority to allow or disallow proposed actions resulting from those decisions. Even though the regulators were cooperative and collaborative during the emergency, they maintained a high level of independent oversight of DWR. Transparency offered by the DWR and the availability of the regulators allowed the response and recovery process to proceed in an expeditious manner. The regulators therefore played a critical role in the emergency response..

The United States Army Corps of Engineers (USACE) was also added to the Unified Command Team for their expertise in emergency dam repairs and support for decisions on reservoir operations. Their expertise in the development of response alternatives, risk assessments, technical capabilities, and implementation of mitigation measures was critical to the emergency response.

The Unified Command Team proved very effective in addressing response conflicts, improving communication to the media and the public, setting global priorities, and maintaining safety and security. Daily briefings and in-person meetings and frequent telephone conferences were held to ensure that the Unified Command Team maintained common response objectives, threats to the infrastructure, personnel and the public were verified and understood, action plans were reviewed and a one-team, one-message environment was maintained.

Since February 7, 2017, over 950 DWR staff, working about 190,000 person hours, were activated to support the EOC and ICT response and recovery activities. Communication, command and control, and operational decisions continued to be a challenge and were a priority during the first 30 days or so. These challenges were addressed by: twice-daily status briefings, daily team meetings, written daily action plans, infrastructure condition verification by physical and remote monitoring, twice daily hydrology modeling, daily meetings with cooperators and contractors, and written daily reports submitted to the DOC and SOC.

5. BALANCING RISKS AND DECISIONS

5.1 Factors Considered

As the emergency system was being set up, the FCO Spillway was being assessed, resources were being drawn together, and critical decisions had to be made. After the initial assessment of the FCO Spillway chute damage was made, varying amounts of outflow were throttled through the FCO Spillway to determine what the impact might be on the damaged spillway. Over the next few days, varying test flows were released to assess the impact of the concrete chute failure on the ability to use the FCO Spillway to manage expected reservoir inflows. After considering a number of factors, including increasing reservoir inflows, increasing reservoir elevation, additional precipitation in the long-range forecasts, size and depth of the damaged chute area, inability to access the damage chute area, and no identified temporary repair options or protective measures available, it was decided that the FCO Spillway had to be used to manage reservoir inflows.

5.1.1 Decision Making Protocol

In any emergency, responders are faced with difficult decisions with limited information, assessments, and communication. There were a number of competing factors that made real time decision-making difficult during this emergency. Facing this dynamic incident, the DWR emergency response teams, regulators, consultants, and contractors and their supporting partners had to work together in ways that had not been accomplished in the past. An unfamiliar chain of command, changing command and control structures, critical specialists in remote locations, information and data limitations, safety and security, and the size and scope of the incident were some of the challenges. First and secondary potential impacts or damage to infrastructure and risks were continuously considered and reevaluated throughout the duration of the response to ensure public safety. Some of the early policy directives included transparency and communication with regulators, partners, local officials, responders, the public, and employees.

The DWR SEMS organization structure was the basis for decision-making during this incident. Daily and advance planning needed to consider response actions, all threats and risks, contingency plans, and mitigation measures. Due to the complexity of the organization, it was critical to remind the team that decisions needed to be made within the organizational structure. Due to the size of the emergency, limited data, competing priorities and/or regional impacts, conflicting recommendations were occasionally passed along to decision makers. These more difficult decisions were elevated up to the POC, DOC, and the Acting Director of DWR. The following sections provide some examples of competing priorities and reasoning for some of the difficult decisions that had to be addressed.

5.1.2 FCO Spillway Chute Condition

The concrete within the FCO Spillway chute was being damaged and displaced with increasing flows and time. Water flowing down the FCO Spillway chute lifted large slabs of concrete, sending them down to the Feather River channel below. Weathered rock and adverse foundation conditions near the original spillway chute failure site were factors in the significant erosion of the underlying foundation rock. As the rock eroded, additional concrete was damaged and displaced. The failure propagated at a rapid pace, both in the upstream and downstream directions. The integrity of the FCO structure at the top of the spillway was critical to the safety of the dam and the potential for an uncontrolled release of the reservoir. Decision makers were also guarding against additional eroded rock in the tailrace, causing backwater affects to the Hyatt Powerplant, and the loss of the transmission line, resulting in the loss of the ability to release water from the reservoir through Hyatt Powerplant.

5.1.3 Emergency Spillway

The Emergency Spillway was intended to protect the dam from overtopping and was not intended to be used during normal flood operations. If ever engaged, the hillside downstream of the control section was expected to experience significant erosion. In addition to surficial soil, further debris such as the trees that covered most of the hillside, would wash into the river channel and would compound issues with downstream structures. Therefore, the use of the Emergency Spillway during this emergency needed to be avoided if possible.

5.1.4 Weather, Forecasts and Modeling

One of the most important aspects of the incident was the long collaborative working relationship DWR has with its mission critical partners. The National Weather Service in Sacramento and the California Nevada River Forecast Center are co-located with DWR at a Joint State Federal Operations Center (JOC) in Sacramento. This is the only location in the nation from which both Federal and State agencies provide weather forecasting, river and reservoir modeling, reservoir operations management, and management of flood emergencies. Working side-by-side 24/7 lays the foundation for a “One Mission, One Message” approach..

During this incident, DWR and its Federal partners at JOC were responsible for monitoring and for analyzing weather forecasts, river and reservoir flood routings, and modeling of emergency response alternatives. Not only were emergency managers dependent on the weather forecasts, many local levee districts responsible for maintaining levees in the Sacramento Valley were working to assess downstream levee conditions, and to respond to potential levee threats resulting from the extreme weather and releases from the basin's reservoirs. Changing weather forecasts were immediately made available to the OICT, who had to quickly modify decisions due to changing weather conditions.

Having critical weather, modeling, and water managers in the same location and in close communication with the OICT allowed emergency response alternatives to be developed, assessed, vetted by the management team, and implemented in a timely manner.

5.1.5 Hyatt Powerplant

Protection of the Hyatt Powerplant and its connection to the State's electric power grid was one of the most difficult challenges that faced the DWR OICT. The loss of this facility would have been catastrophic to DWR and the Oroville Emergency Response and Recovery. Releasing sufficient water from the reservoir below the FCO Spillway's crest (sill) is virtually impossible without the use of Hyatt Powerplant. This would be critical to allow future repairs to the spillway. Secondly, local and State water supplies for agriculture and 25 million people could potentially be severely impacted for years ahead without the use of the Powerplant. There were two main issues associated with Hyatt Powerplant during the emergency: 1) high flows and debris in the tailrace caused backwater effects that limited the functionality of the Powerplant and caused flooding of the Powerplant; and 2) transmission towers, which secured power lines from the Powerplant, were located adjacent to the FCO Spillway chute and were in danger of collapse due to eroding the rock surrounding the two towers and loss of the tower foundations.

Due to the high water elevation in the Feather River channel from large spillway releases, compounded by the debris building up in the channel, the Powerplant had to be shut down. DWR OICT, pursuant to the facility Emergency Action Plan, and based upon previous experience during high FCO Spillway release events, were aware of potential damage due to backwater flooding of the Powerplant. Therefore, they immediately implemented a number of emergency mitigation measures. Waterproofing measures were continuously reassessed and additional improvements were made on an ongoing basis. These decisions were part of the daily action planning objectives implemented by the Hyatt Powerplant Operations Strike Team. Over time, additional risks were identified as the water elevation continued to increase on the downstream face of the Powerplant. As responder safety and maintaining waterproofing measures at the Powerplant were extremely critical, additional backup power supplies, pumps, and contract resources were stationed at the Powerplant. Around-the-clock monitoring, reassessment of water elevations, and mitigation measures were reported to the OICT Operations Chief.

As a result of these extreme efforts, the Hyatt Powerplant was successfully protected from the unprecedented high backwater caused by the incident.

The six turbines in the Hyatt Powerplant can only produce power when connected to the State's electric power grid. They also must be spinning and generating power in order to release water from the reservoir to the Feather River channel. The assessment of DWR's power lines and towers connecting the Powerplant to the power grid became a high priority since the loss of the power lines would prevent the ability to discharge up to 479.9 m^3/s (16500 ft^3/s) from the reservoir once the water dropped below the sill of the FCO. Monitoring and assessment teams became aware that continued erosion on the right (north) side of the FCO Spillway chute could compromise at least one of the transmission towers on the right side of the chute. The risk of losing this one tower was increasing and the impact could have resulted in the failure of numerous towers and power lines. This in turn increased the safety risks for responders and the possibility of losing the power grid connection to the powerplant for months, if not years. The OICT Commander ordered additional monitoring and risk assessments of this transmission tower as well as contingency and mitigation plans. It was determined that the tower power lines must be cut, and the tower removed to protect responders, prevent failure of multiple towers, and reduce the threat to the other high-voltage electric power in the area. These actions were approved by the OICT Commander, scheduled into working Actions Plans, coordinated with cooperating partners and the public, and then successfully implemented. Mitigations measures were then necessary to plan, design, and install shoe-fly power lines over the FCO Spillway chute away from the erosion threats. This process was completed with a high level of coordination with OICT Planning, Operations and Logistics teams, the FCO Spillway Strike Team, the Hyatt Powerplant Strike Team, the Emergency Spillway Strike Team, contractors, and the other power utility (Pacific Gas and Electric, PG&E). This work was successfully completed just as sufficient debris was removed from the Feather River channel to allow the water elevation to drop low enough for safe reoperation of the Hyatt Powerplant. This allowed DWR to begin releasing additional water from the reservoir and reduced the need to use the FCO Spillway for the remainder of the 2017 runoff season.

5.1.6 Electric Power Grid Considerations

An additional 230 kV electric power line, which is critical to California's electric power grid, crossed the Oroville Dam facility just downstream of the confluence of the FCO Spillway chute and the Feather River in the area of a large rock debris pile in the river channel. Debris removal was critical to getting the Powerplant back on line, but the use of tall equipment working in proximity to the transmission lines was an extremely high risk. Mitigation alternatives developed and implemented to protect the power lines and the electric power grid, which included flooding the barge and allowing it to sit lower in the water, drawing down the water elevation in the river channel, removing some of the excavator cabin and roll bar, and adjusting the schedule to move the excavator. These actions were extremely important to preventing a major secondary impact to the utility, the statewide electric power grid, and public safety.

5.2 Critical Decisions

There were continuous discussions by technical teams, OICT management, and DWR's Acting Director regarding "what if" scenarios, go/no go criteria for use of the FCO Spillway chute, reservoir inflow and releases, and forecasts of reservoir elevations. DWR's high priorities were responding to public safety, protection of the Hyatt Powerplant and power lines, continued use of the FCO Spillway chute, and avoidance of the use of the Emergency Spillway, if possible. Setting criteria for each of these priorities was very difficult and there was little room for error and little time for decisions. Monitoring and reevaluation of conditions and criteria for decision points was also difficult due to the nature of the changing conditions.

Considering the original weather forecasts, reservoir routing, current FCO Spillway chute and Feather River channel conditions, the expectation was to not allow Lake Oroville to exceed elevation 295.2 m (900 ft) or 0.3 m (1 ft) below the top of the Emergency Spillway crest. Thus, FCO Spillway releases were scheduled at 1,841 $m^3{}_{/s}$ (65,000 ft^3/s) February 10 at 1500 hours. DWR and its regulators were very concerned with the erosion of the FCO Spillway chute and the adjacent slopes. The erosion had not stabilized and there was concern that the foundation erosion and the concrete slab failure may migrate up the chute and threaten the operation of the FCO, leaving only the Emergency Spillway to manage the Feather River Basin's large runoff for the remainder of the record-breaking wet season. Due to concerns about additional erosion in and around the FCO Spillway chute and near the power lines and the closest tower, the FCO Spillway release was decreased to 1,559 m^3/s (55,000 ft^3/s)) late on February 10. This spillway release rate was selected to limit the degradation of the FCO Spillway chute, yet prevent the Emergency Spillway from being used.

On February 11, Lake Oroville inflows significantly exceeded the forecast. The storm had unexpectedly stalled over the Feather River Basin watershed, causing a peak inflow of 5,395 m^3/s (190,435 ft^3/s). This inflow exceeded DWR's original expectations by approximately 850 m^3/s (30,000 ft^3/s). At this point, greater FCO Spillway releases would be necessary to avoid flow over the Emergency Spillway. However, because of the concerns discussed above, the decision was made not to increase the flows through the FCO. In addition to the FCO Spillway safety concerns at Oroville Dam, downstream levee capacity concerns also played into making this decision. On February 11, water began flowing over the crest of the Emergency Spillway and revised monitoring and contingency plans were quickly developed. Personnel were continually reminded that decisions and actions must stay within the OICT command and control structure for consistency and full cooperation with all those involved with this incident. The OICT and regulatory agencies were also developing “what if” scenarios and working to reinforce the decision-making processes. Initially, erosion occurring downstream of the Emergency Spillway was within expected levels. . However, on February 12, significant erosion of the rock hillside was noted to be progressing more rapidly than anticipated to the point where it was considered a threat to the Emergency Spillway. This situation prompted an immediate meeting between the Butte County Sheriff, DWR’s Acting Director, OICT management, DSOD, and FERC. Suggestions, such as increasing the FCO Spillway release to 5949 m^3/s (210,000 ft^3/s) to stop flow over the Emergency Spillway, had to be rejected since that would exceed downstream levee capacities, causing flooding of downstream communities. Based on the best available data, including the FCO Spillway’s current condition, Powerplant flooding potential, the potential for erosion failure of the Emergency Spillway, and continual forecasts, the DWR’s Acting Director agreed to increase FCO Spillway releases to 2832 m^3/s (100,000 ft^3/s). With the flow through the FCO Spillway increased to 2832 m^3/s (100,000 ft^3/s) February 12 at 1800 hours, the flow over the Emergency Spillway stopped several hours later.

DWR maintained the FCO Spillway release at 2832 m^3/s (100,000 ft^3/s until February 16. On February 16, the Lake Oroville water elevation dropped low enough for the Butte County Sheriff to change the mandatory evacuation to an evacuation warning, allowing an estimated 188,000 people to return to their homes and businesses.

Emergency repairs were developed and implemented, using air and ground resources. It was critical to repair the erosion damage below the Emergency Spillway in case it had to be used again. These emergency repairs to the Emergency Spillway consisted of filling erosion voids and armoring the ground surface. However, they were viewed as temporary, based on limited information, planning, and design. Fortunately, the Oroville Emergency Recovery team was onsite 24/7 and was able to collect advance-planning data and information as the damaged area was being backfilled and armored. This response effort was extremely large, yet simple in approach and had no planned stopping point set. DWR Executive management, in close coordination with DSOD and FERC, addressed terminating the Emergency Spillway repairs based on available reservoir storage, forecast, and the amount of completed temporary repair work.

6. COMMUNICATION AND TRANSPARENCY

6.1 COMMUNICATION

As in every emergency, effective and timely communication is critical. DWR faced many challenges in this regard. Communicating technical and nontechnical information relating to changing weather conditions and forecasts, reservoir, dam and spillway conditions, dynamic situational awareness, and associated risks proved to be difficult.

DWR communication resources were limited and had little experience with emergency process and procedures. Under the Unified Command, CalFire brought significant emergency communication resources (people and equipment) and set the processes, procedures, and schedules in place. Call centers, standardized graphics and public messaging were key communication improvements. Integrating DWR and its contractors into the process provided effective on-the-job training. When CalFire demobilized out of the Oroville ICP, they left a much more effective emergency communication team.

Many communication tools and activities were used to inform the responders, partners, other agencies, the media and the public. Global phone lists, written communication plans, set briefing schedules for responders, cooperating partners, the media and the public, public web cameras, daily photographs and drone videos, improved websites and incident websites, radio and television interviews, and live streaming media briefings and public meetings were all used during the Oroville Emergency Response phase. These tools continue to be used and improved during the Emergency Recovery phase.

6.2 TRANSPARENCY

From the beginning, DWR's Acting Director instructed management and staff to be transparent in responding to and recovering from this incident. This proved difficult in the first few days due the changing conditions of the incident, integration of a number of agencies, implementing the command and control organization and magnitude of the emergency and had to be regularly reinforced over time. Due to the size, scope, and public safety concerns of the incident, a number of normal design and regulatory process and procedures had to be modified. DWR took a high intensity, short duration, and no-fail approach to design and implementation of both short-term repairs and long-term recovery actions. This had to be done with DSOD and FERC regulators in the room to facilitate expedited design review and necessary approvals. This is easy to say but was difficult to implement for the processes and procedures that typically take weeks, if not months or years to complete, coupled with limited available staff, location of key specialists, and required third-party oversight. A project of this size, scope, and schedule had never been completed before and required unprecedented commitment by DWR, consultants, DSOD, and FERC, as well as the Independent Board of Consultants and DWR's other partners.

Transparency was also an important concern to the local agencies and the public. DWR took many actions to improve transparency via its communication and outreach procedures. DWR also ensured that the regulatory agencies, the Independent Board of Consultants, the Independent Forensic Team, and the Butte County Sheriff had full access to the facility and its records. Special tours were provided to Federal, State, and local elected officials on a regular basis. Transparency will remain a critical element toward improving communication with regulatory agencies and the public. Dam owners and operators should review their plans, policies, and procedures in advance of an incident to address transparency in such communications.

Transparency was often in conflict with security concerns and the need to protect Critical Energy and Electric Infrastructure Information (CEII). Any time information was held back due to security concerns, there was potential for the public and media to become uncomfortable or alarmed by the lack of full disclosure.

7. EMERGENCY RECOVERY

As is standard practice in emergency management, immediately after the initial incident, DWR began pulling together the Oroville Emergency Recovery (OER) team. It was critical for DWR and its partners to recognize OER had to be quickly mobilized even as conditions and risks to the facility were changing. DWR maintained an emergency management approach during recovery to successfully meet its primary and secondary objectives: an operational FCO Spillway structure by November 1, 2017, and full recovery of the FCO Spillway chute and the Emergency Spillway by January 1, 2019, respectively. Additional discussion and figures regarding various aspects of the Oroville Emergency Recovery efforts are provided in the accompanying DWR papers.

8. LESSONS LEARNED

There have been many valuable lessons learned during this incident. Emergency management systems, polices, and procedures need to be in place and are an essential part of risk reduction programs. Integrating external emergency management partners into the response and recovery efforts under a unified command organization proved very successful. Partnering in advance of an incident with strategic emergency experts would improve response and recovery efforts. It is also critical to have State and Federal emergency management agencies fully onboard and engaged with a project’s EAP with annual training as well as functional exercises on a regular basis.

Having facility experts available and on-site during this incident was invaluable. Understanding details of siting, permitting, construction, maintenance, operations, and management of the facility were critical to assessing risks, mitigations, and potential response actions. Taking a new look at this information is critical to assessing risk and consequences. Fortunately, DWR had immediate access to consultant experts, who were familiar with the facility and the issues of concern. Dam owners should identify critical consultant resources prior to an incident as part of their risk reduction program.

Protection of CEII information is critical for national and economic security, as well as for public health and safety. However, protection of this information will likely be in conflict with efforts to increase communication and transparency. CEII policy review, following policy and third-party education, should reduce this conflict.

Finally, while the Oroville Dam facility is an amazing example of engineering for multiple benefits, this incident is an example of how critical infrastructure can have unanticipated impacts on those benefits and the costs to respond and recover from a major incident. This incident has refocused California on the need to improve infrastructure and ensure its safety and reliability. California has turned the corner on this conversation, and now it is time for action.

SUMMARY

The Oroville Spillway incident was unprecedented in many ways. This "no notice" event brought many difficult challenges and risks that needed to be assessed, verified and mitigated during an historic hydrologic setting. Public safety (responders and the public) has to be the highest priority at all times. The incident required the dam owner, to work side by side with regulators, subject matter experts and contractors in real time to respond and recover from this incident. Maintaining a high level of transparency with the regulators and the public throughout the response and recovery phases allowed decisions and actions to be taken to mitigate or eliminate risks to the public and infrastructure. DWR, FERC, USACE, Cal Fire, and Butte County Sheriff Office quickly and successfully integrated into a unified command organization structure. The California emergency management plans demonstrated that multiple agencies and their contractors could be activated and respond to major catastrophic events in a matter of hours. There are many lessons that can be learned from this event. A new look at infrastructure risk management, security, emergency action plans, emergency training and public education is required. This incident is also an example that large complex infrastructure projects can be designed and constructed in an expedited manner. To repair, replace or improve today's critical infrastructure in a timely manner, processes to complete projects must be streamlined.

This paper recognizes the hundreds of people who participated in this challenging emergency and in some cases at great personal risk to work for public safety.

1. INTRODUCTION

Oroville Dam is located on the Feather River in northern California (USA). At 234.7 m (770-ft) tall, this earth embankment is the tallest dam in the United States. With its 4.3 billion m3 (3.5 million acre-feet) of storage, Lake Oroville is the second largest reservoir in California, supplying water to cities as far south as Los Angeles. The Oroville Dam, reservoir (Lake Oroville), and hydropower plant facility is the flagship of the State Water Project (SWP), which is owned and operated by the State of California, Department of Water Resources (DWR).

** INCIDENT DE DÉVERSEMENT DE BARRAGE D'OROVILLE - CONCEPTION ET CONSTRUCTION DE RÉTABLISSEMENT RAPIDE DE PISTE POUR COMBLER LA SÉCURITÉ DES BARRAGES CRITIQUES*

The 2016-2017 Winter Storms brought record breaking precipitation to the Northern California Sierra mountains including the Feather River watershed. On February 7, 2017, the Oroville Dam's 54.5 m (179-ft) wide Flood Control Outlet (FCO) Spillway chute (Fig. 1) was releasing water to control the Lake Oroville reservoir level in accordance with the prescribed operations plan. During this operation, the FCO spillway suffered a catastrophic failure of the lower chute area eventually resulting in the loss of approximately 427 m (1400 ft) of the lower chute, including the scour of more than 1.2 million m3 (1.6 million yd3 of soil and rock materials. On February 11, 2017, the Emergency Spillway (Fig. 1) was used for the first time since the project was completed in 1968. During this operation, significant erosion and scour caused by the Emergency Spillway overflow led authorities to fear for the safety of the spillway structures, resulting in the activation of the Emergency Action Plan and evacuation of about 188,000 persons from downstream communities.

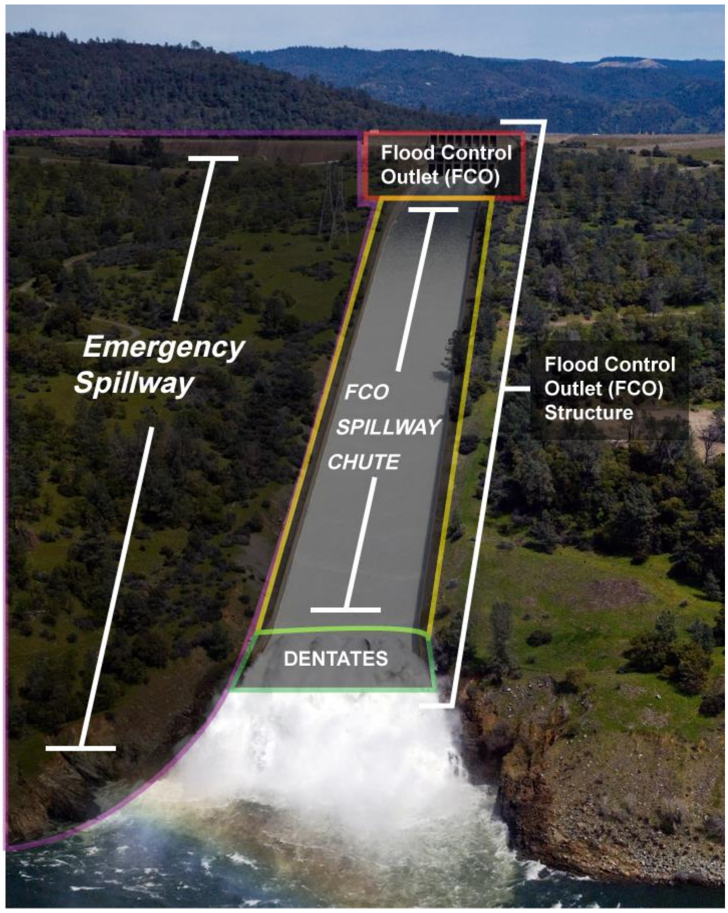

Fig. 1 Flood Control Outlet (FCO) Structure and Emergency Spillway, March 2011

This paper is part of a series developed by the State of California, Department of Water Resources (DWR) to describe the Oroville Spillway Incident Emergency Response and Recovery. This paper focuses on the design and construction processes employed in 2017 to safely allow the dam to pass expected flood flows during the 2017-2018 Winter Flood Season. The remainder of this paper is organized into the following sections:

- Meeting the Challenges for Spillway Recovery
- Design and Construction Processes
- Regulatory Review
- Reservoir Operations
- Meeting the Schedule
- Lessons Learned

2. MEETING THE CHALLENGES FOR SPILLWAY RECOVERY

2.1. THE CHALLENGES

The management of the Oroville Dam Spillway Incident in February 2017 and in the ensuing months was considered by DWR as the Oroville Emergency Response [1]. The restoration work following this initial effort was known as Oroville Emergency Recovery (OER). The charge for the OER was to restore adequate capacities for the FCO Spillway chute and the Emergency Spillway to safely pass potential flood events during the 2017-2018 Winter Flood Season, and thereafter. This charge presented enormous challenges, including:

- The need to complete repair and replacement designs in only weeks instead of the normal months or years,
- Insufficient qualified DWR staff available,
- Insufficient geologic information,
- The need to operate the damaged FCO Spillway chute through May 2017,
- Limited time for regulatory review and approval of designs,
- Insufficient time to construct complete repairs or replacements,
- Lack of a full understanding as to the causes of the incident, and
- Managing expectations and communicating accurate information to a concerned public and their elected representatives.

2.2. ASSEMBLING THE TEAM

For the Oroville Emergency Recovery, DWR quickly assembled the OER Spillways Task Force devoted to completing the FCO Spillway chute and Emergency Spillway recovery designs, administering construction contracts, and developing a revised reservoir operations plan. The team was composed of several experienced engineers from DWR's Division of Engineering, Project Operations Office, and other units from within DWR. However, there were insufficient staff available from within DWR to perform the necessary engineering work. As a result, DWR contracted with knowledgeable and experienced engineering professionals from a variety of sources including:

- Engineering consulting firms: GEI Consultants, HDR Engineering, Stantec, AECOM, David Ford Consulting Engineers, Northwest Hydraulic Consultants, Lettis Consultants International, Vali Cooper & Associates, and RMA Group.
- United States Army Corps of Engineers and United States Bureau of Reclamation.

In addition to the engineering professionals directly integrated into the OER team, several specialty consultants were added to the OER team to provide specific engineering services:

- Brierley Associates to provide expert peer review evaluations of rock slope stability and planned stabilization of eroded and over-steepened rock slopes along the FCO Spillway chute channel,
- BGC Engineering USA to provide scour evaluations of the rock materials on the Emergency Spillway,
- REVEY Associates, Inc. and EROCK Associates to provide engineering designs and oversight for explosive blasting excavation and demolition, and

Utah State University to provide physical hydraulic modeling for the redesign of the FCO chute. Over 100 individuals were eventually integrated into the OER team, with most initially assigned to work together in spaces provided in the California Natural Resources Building in Sacramento, California. Many members of the team were later relocated, as needed, to Oroville Dam during field investigations and during construction later in 2017. Team members commonly worked 12+ hours each day, 6 to 7 days a week. Key points in the timeline were as follows:

- Oroville Incident and Emergency: initiated February 7, 2017
- OER Design Phase: March – July 2017
- OER Mobilization Phase: April – May 2017
- OER Construction Phase 1: May – November 2017

2.3. Project Objectives

The original design intent of the FCO Spillway chute was to safely pass flood flows ranging up to about 7390 m^3/s (261,000 ft^3/s) without using the Emergency Spillway. During larger floods, the Emergency Spillway would also be used to pass flood flows for events up to the Probable Maximum Flood (PMF), a very rare event that had an average recurrence interval commonly on the order of 10,000 years. The total discharge from the FCO Spillway chute and the Emergency Spillway during the PMF event would be about 19000 m^3/s (671,000 ft^3/s), with the FCO Spillway chute being used to pass flows up to 8500 m^3/s (300,000 ft^3/s) and the Emergency Spillway being used to pass about 10500 m^3/s (371,000 ft^3). The purpose of being able to pass the PMF event is to prevent the embankment dam from being overtopped and failing during this extreme design event. Following the incident, the FCO Spillway lower chute was left badly damaged and the Emergency Spillway was found to be incapable of safely passing even 340 m^3/s (12,000 ft^3/s).

> The mission of OER was to develop and implement measures to:
> "Restore the Spillway Capacity to Ensure Public Safety in Advance of the 2017-18 Winter Flood Season."

It was recognized early on that the full restoration or replacement of the damaged areas would require multiple phases and years, in part because the first design and construction season in 2017 was extremely short – only about 8 months between March 1, 2017 and November 1, 2017, which was the assumed onset of the 2017-2018 Winter Flood Season. Accordingly, the first phase would include structural replacements, modifications, and other remedial measures to rebuild the existing spillway structures to safely pass water flows for the upcoming 2017-2018 Winter Flood Season. Later phases will increase the level of protection incrementally each year until the original design capacities are restored. Later phases are estimated to require as much as 5 to 10 years to complete. The specific design objectives for the 2017 construction season were set as follows:

- The reliable capacity of the relatively undamaged the FCO Spillway upper chute, approximately 488 m (1600 ft) in length between the upstream gated headworks and the main scour hole, would be restored to safely pass a peak discharge flow of 7600 m^3/s (270,000 ft^3/s).
- The capacity of the damaged FCO Spillway lower chute, approximately 427 m (1400 ft) in length, would be restored to safely pass a peak discharge flow of approximately 2800 m^3/s (100,000 ft^3/s), and up to 7600 m^3/s (270,000 ft^3/s) with potential damage.
- The capacity of the Emergency Spillway would be restored to safely pass a limited flow of up to 850 m^3/s (30,000 ft^3/s) without significant damage to the spillway monoliths and weir, but erosion further downslope would be expected.

These 2017 spillway design objectives are illustrated in Fig. 2 (flows shown in cubic feet per second – cfs).

Fig. 2 2017 Oroville Spillway Recovery design objectives projected onto an aerial view of the damaged spillways at Oroville Dam

2.4. EXPEDITED ALTERNATIVE ANALYSES

On March 6, 2017, less than one month after the beginning of the incident, an all-day alternatives workshop was conducted by DWR at the California Natural Resources Building in Sacramento. The purpose of the workshop was to develop reinforcement and replacement alternatives to restore the FCO Spillway chute and the Emergency Spillway to meet the 2017 design objectives by November 1, 2017. Several restoration concepts were proposed for the FCO Spillway chute and for the Emergency Spillway.

2.4.1. FCO Spillway Chute Alternatives

The FCO Spillway chute is a reinforced-concrete spillway approximately 54.5 m (179 ft) wide and 914 m (3000 ft) long. Alternatives for the relatively undamaged 488 m (1600 ft) long FCO Spillway upper chute above the scour holes included:

- Repair-in-place
- Remove and replace
- Construct new FCO Spillway upper chute

The 427 m (1400 ft) long FCO Spillway lower chute was heavily damaged by the incident. The damage included two deep scour holes as much as 30 m (100 ft) in depth, including a large scoured erosion channel to the left of the FCO Spillway lower chute, and severely distorted, broken concrete walls and invert slabs downstream of the scour holes (see Fig. 2 and 3).

Fig. 3 Aerial view of heavily damaged FCO Spillway lower chute (March 2017)

Alternatives for the heavily damaged FCO Spillway lower chute included:

- Remove, backfill, and replace
- Leave scour holes and erosion channel in place for spillway discharges and only armor sides and bottoms of eroded areas
- Construct bridge/aqueduct across scour holes
- Construct new FCO Spillway chute

These alternatives were further refined and evaluated by OER team in the days following the workshop. Some alternatives were modified or combined with others, while some were eliminated because they did not meet the project objectives, or were simply infeasible. A set of ranking criteria and weighting was developed to evaluate the alternatives. Following the evaluation and ranking of alternatives, the measures recommended for immediate implementation for the FCO Spillway chute were as follows:

- The entire FCO Spillway chute, including both the undamaged upper portion and the heavily damaged lower portion, should be completely removed and replaced with new reinforced-concrete walls and invert slabs constructed to modern spillway design standards.
- The removal and replacement of the upper chute should proceed by completing as much as could be done by November 1, 2017, in time for the 2017-2018 Winter Flood Season, with the remaining portion

of the upper chute replaced the following year, during the 2018 construction season.

- The eroded scour holes in the FCO Spillway lower chute should be filled with roller-compacted concrete (RCC) to restore the eroded spillway rock foundation (see Fig. 4). The damaged concrete chute walls and invert panels in the lower chute should also be removed, and new structural-concrete sections (chute slabs/panels and walls) should be constructed to modern standards for the entire lower chute. If the entire lower chute could not be restored by November 1, 2017, the construction work should be sequenced to defer backfilling of the initial scour hole in order to use the scour hole and the erosion channel to convey spillway discharges from the upper chute to the Feather River.

These measures were accepted by DWR management and an Independent Board of Consultants in mid-March 2017 and designs were initiated immediately. During the design and 2017 (Phase 1) construction phases, the limits for specific measures on both the upper and lower chutes were modified several times as a result of improved understandings of the work involved, various constraints, and what the construction contractors could accomplish during the very abbreviated 2017 construction season. The alternative measures finally adopted for repair and replacement of the upper and lower chutes, during the 2017 and 2018 construction seasons, are illustrated in Fig. 5 and Table 1.

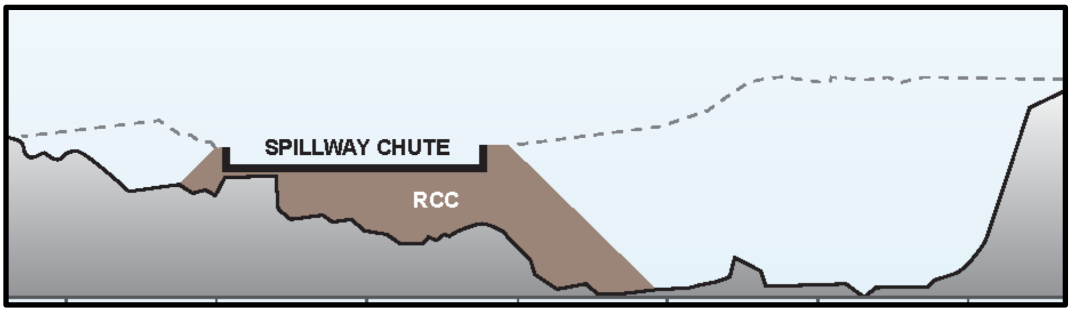

Fig. 4 Conceptual cross section for reconstructing the eroded the FCO Spillway lower chute using Roller Compacted Concrete in 2017

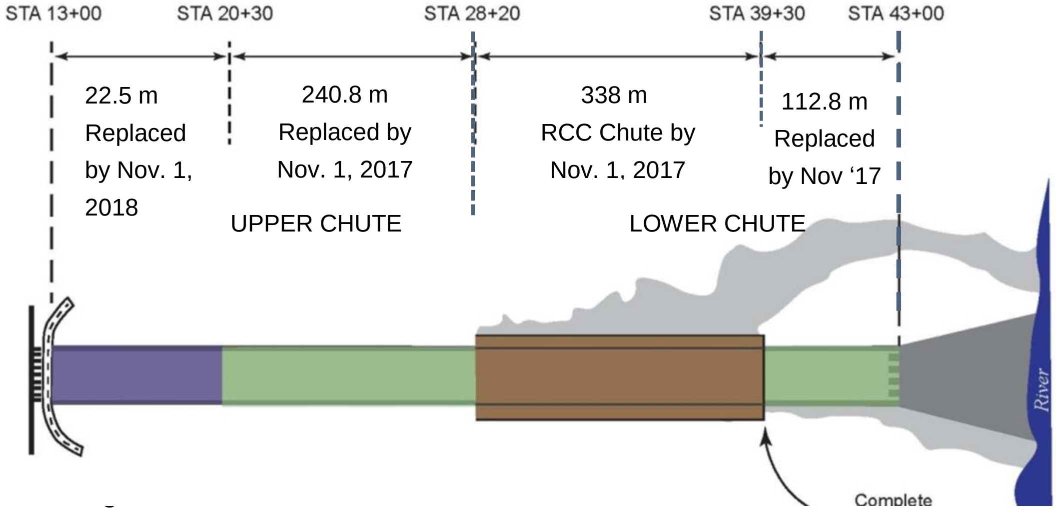

Fig. 5 Plan view of 2017 and 2018 repair/replacement alternative measures for the FCO Spillway chute

Table 1
2017 and 2018 Repair/Replacement Measures for the FCO Spillway chute

FCO Spillway Chute Reach	Stationing (feet)	Length (feet)	Length (meters)	2017 Construction	2018 Construction
Upper Chute	13+00 – 20+30	730	222	Minor repairs	Replacement
	20+30 – 28+20	790	241	Replacement	-
Lower Chute	28+20 – 39+30	1110	338	RCC Backfill	Structural concrete
	39+30 – 43+00	370	113	Replacement	-
Total	13+00 – 43+00	3000	914	Replacement	

2.4.2. Emergency Spillway Alternatives

The Emergency Spillway is an ungated monolith/weir structure that is approximately 527 m (1730 ft) wide at the weir crest. The left 283 m (930 ft) portion consists of concrete-gravity ogee monoliths/weir sections that were keyed into slightly-weathered rock. The structural heights of the monoliths range as high as 27 m (90 ft). The right 244 m (800 ft) portion is a cut section with a small 30 cm (1-ft) high concrete ogee weir. During the Oroville Spillway Incident, there was great concern that rapidly developing head-cutting erosion under a relatively small discharge of 340 m^3/s (12,000 ft^3/s) could quickly lead to destabilizing these monoliths/weir sections and result in an uncontrolled release of the reservoir (see Fig. 6). There had also been concern regarding the sliding stability of the larger monoliths during extreme flood events and seismic loadings.

Fig. 6 Aerial view of head-cutting erosion threatening the Emergency Spillway monoliths/weirs during the Feb. 12, 2017 spillway releases

Four alternatives were considered during the initial alternatives analysis phase for the Emergency Spillway. All four alternatives included: a buttress or a rock-anchoring system for the larger monoliths, replacement of the small 30 cm (1-ft) high weir on the right side of the Emergency Spillway, a concrete apron or splash pad for erosion protection over the rock surface for About 100 meters downstream of the monolith/weir sections, and a secant pile wall located at the downstream edge of the concrete apron to protect the apron from undermining by head-cutting erosion. The four alternatives were evaluated and ranked, using the same criteria that were used for the FCO Spillway chute alternatives, and the following measures were selected for the Emergency Spillway:

- An RCC buttress on the downstream side to reinforce the larger monoliths/weir sections (2018)
- A 2 m (6-ft) high concrete wall/weir crest to replace the small 30 cm (1-ft) high weir on the right side of the Emergency Spillway (2017)
- An RCC apron downstream of monoliths/weir sections (2018)
- A secant-pile wall at the downstream edge of the RCC apron (2017)

The selected measures for the Emergency Spillway's monoliths/weir sections are illustrated in Fig. 7. The 2-m-high concrete crest on the right side of the Emergency Spillway and the secant pile wall were to be constructed primarily in the 2017 construction season, but unlike the measures for the FCO Spillway chute, the completion of these features could extend a few months into the 2017-2018 Winter Flood Season if the FCO Spillway chute measures were completed by November 1, 2017. The RCC buttress and apron would be completed during the 2018 construction season.

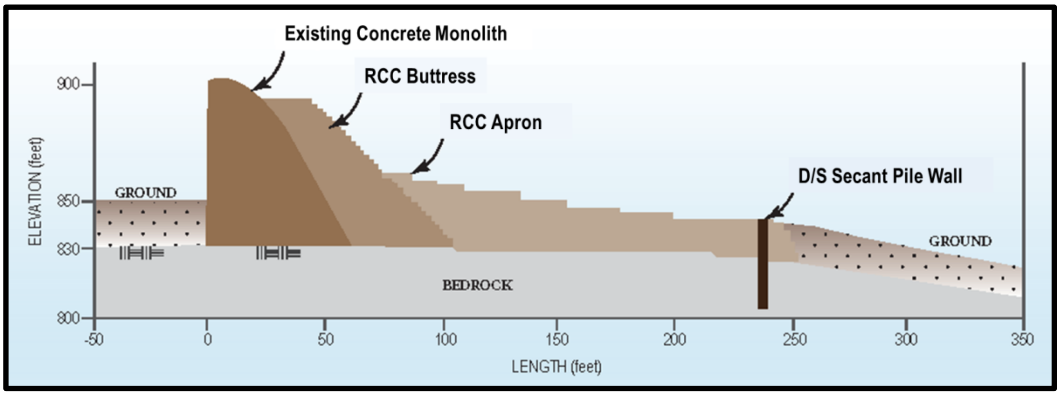

Fig. 7 2017 and 2018 repair/improvement monoliths/weir measures selected for Emergency Spillway

3. DESIGN AND CONSTRUCTION PROCESSES

3.1. CONSTRUCTION CONTRACTING APPROACHES

During the Emergency Response phase, several construction contracts had been awarded by DWR to help manage the emergency, including contracts to temporarily armor the Emergency Spillway and for dredging the Diversion Pool (Feather River) immediately below the FCO Spillway chute and dentates to remove eroded rock and concrete [1]. However, the restoration work under OER could not begin immediately after the incident occurred in February because: (1) the FCO Spillway chute had to be used intermittently between February and May to release the record reservoir inflows to avoid use of the eroded Emergency Spillway, thus preventing any work on this facility until late May; and (2) the designs for the various repair/replacement measures were not yet developed or approved by dam safety regulatory agencies. Yet there was a critical need to start recovery work as soon as possible given the very short 2017 construction season. As a result, DWR proceeded with the following approach:

- An initial construction contract (Specification No. 17-08) was advertised on March 21, 2017, and awarded to Teichert Construction on March 27 for a low-bid amount of $5.8 million. This first contract was used to construct access roads and staging areas that would be used later for the FCO Spillway chute recovery work. It was also used for the initial excavation work around the upper portions of the scour holes to help stabilize the slopes so that construction work could be safely done beneath the overly steep and unstable rock slopes. This work was defined by 28 contract drawings and 20 specification sections.

- The Oroville Emergency Recovery contract associated with the spillways (Specification No. 17-09) was advertised on March 31 and awarded to Kiewit Corporation on April 15 for a low-bid amount of $275 million. This was the main construction contract for completing the work identified to restore the spillway capacities in 2017 and 2018. The Contractor's bid was based on a 30-percent design with 108 contract drawings and 47 specification sections. The purpose for awarding the contract without a completed design was to have a contractor on board to begin mobilization and preliminary work as soon as possible, even though the designs were not completed and the FCO Spillway chute was still being operated intermittently until its final closure on May 19. The contractor was given a Notice to Begin Work on April 20, with 75-percent designs provided on May 18, Final designs provided on June 21, and Revised Final designs provided on July 20. The major elements of work in this contract included:

    - Slope stabilization
    - Demolition of reinforced-concrete chute walls and slabs
    - Foundation excavation
    - Foundation cleanup
    - Dental and leveling concrete construction
    - RCC construction (FCO Spillway chute)
    - FCO Spillway chute drains construction
    - Structural reinforced-concrete construction
    - Chute slab anchors construction
    - Crest concrete wall construction (right side of Emergency Spillway)
    - RCC buttress and apron construction (Emergency Spillway)
    - Secant pile wall construction (Emergency Spillway)

With the approaches described above, it was recognized that the original bid amount would likely increase, possibly by 50 to100 percent.

A formal, facilitated partnering process was agreed to between DWR and the contractor (Kiewit Construction/Corporation) for the Spillways, Oroville Emergency Recovery contract, as called for in the contract specifications. Following the Award of the Contract, the Partnering Team developed and signed a Partnering Charter on April 24 that laid out project and partnering goals. The Partnering Team had bi-weekly Executive Partnering sessions and quarterly team meetings to help foster a cooperative relationship. Surveys of the Partnering Team members were conducted every two weeks in advance of the Executive Partnering sessions that helped provide a pulse for the project and facilitated information exchanges and issue resolutions.

3.2. DESIGN APPROACHES

3.2.1. General Design Approach

Design work was completed by forming multi-disciplined sub-teams assigned to specific design tasks, such as determining slope stabilization methods, excavation depths, foundation objectives and treatments, underdrain designs, structural concrete designs, RCC designs, and secant pile wall designs. Leads and members of the sub-teams were organized beginning on March 6. Eventually, over 100 professionals were involved in developing over 50 design technical memorandums and contract plans and specifications. The work for the preliminary designs was generally completed in Sacramento, with final designs being completed by moving design team members to work on-site in Oroville. This latter work was facilitated by mobilizing over a dozen portable trailers with communication and computer equipment to a large parking area adjacent to the Emergency Spillway. This allowed the design groups to be co-located with the contractor's (Kiewit's) forces and to be on-site as the construction work was being done. This also helped obtain expedited dam safety regulatory approval as the designs were being finalized and the construction work was being completed, as dam safety regulatory staff (FERC, DSOD) were provided temporary office space in the trailers.

3.2.2. Geologic Investigations

During the original design, boreholes had been completed along the FCO Spillway chute alignment and along the monoliths/weir sections of the Emergency Spillway. There were also very detailed geologic maps of the FCO Spillway chute and the monolith foundations completed during original construction, but relatively little detailed geologic information was available on the Emergency Spillway area downstream of the monoliths/weir sections. Geologic investigations carried out in 2017 for the OER are described in detail in a companion paper [2]. The 2017 geologic explorations included the use of 10 drill rigs to complete over 104 new borings, install 26 piezometers, and install 15 inclinometers, all by the end of July 2017. In addition, 22 seismic refraction lines were completed, and extensive geologic mapping of exposed rock was carried out at both spillways.

The geologic investigations confirmed that the rock foundation at both spillways consisted generally of amphibolite with varying degrees of weathering. The degree of weathering ranged from intensely weathered or decomposed to fresh, with most of the surface exposures consisting of moderately-weathered rock. There were also numerous shears across both spillways, which significantly contributed to both slope instability and erosion problems. Along the FCO Spillway chute alignment, the vast majority of the intensely-weathered rock was found at the two scour holes, with almost all of this original foundation material having been eroded out during the 2017 incident. In general, the geologic maps created during original construction were found to be very accurate. The thicknesses of the concrete chute slabs in the FCO Spillway chute, however, were found to be generally much thicker than the nominal 38 cm (15 inch) minimum thickness specified during original design, with thicknesses ranging up to 2.1 m (7 ft) and an average concrete slab thickness on the order of about 1 m (3.5 ft). This larger thickness resulted in additional demolition and excavation in the removal of these concrete slabs, larger thicknesses of new leveling concrete, and deeper underdrains, extending to rock through the leveling concrete beneath the new structural concrete.

3.2.3. Hydraulic Analyses and Modeling

Hydrologic and hydraulic analyses, using 1D, 2D, and 3D analytical models and a physical model of the FCO Spillway chute constructed at Utah State University, were used to verify and improve the designs for both spillways. The details of these analyses are presented in a separate companion paper [3].

3.2.4. FCO Spillway Chute Structural Concrete Designs

The structural reinforced-concrete designs for new chute wall and slab sections were developed to meet modern spillway design standards and to address any potential areas for improvement identified in the original design. Presented in Table 2 is a list of potential design and/or construction areas for improvement identified by the OER and the Forensic Investigation Team appointed to provide an independent assessment of the potential causative factors that led to the incident. Also shown are the elements included in the new structural-concrete design intended to address these areas for improvement. Fig. 8 illustrates several of these elements.

3.2.5. Secant Pile Wall/RCC Designs for Emergency Spillway

During the final design of the interim measures for the Emergency Spillway, designers concluded that a capacity higher than the 850 m^3/s (30,000 ft^3/s) design objective for the upcoming 2017-2018 Winter Flood Season was needed. This was because it was recognized that a major modification or replacement would eventually be needed in order for the Emergency Spillway to safely pass its original rated design capacity of 10500 m^3/s (371,000 ft^3/s) for a PMF flood event. Further, it would likely require 5 to 10 years to implement such a major project. Consequently, the interim repairs/upgrades were needed to be able to convey flows that might reasonably be discharged through the Emergency Spillway during the next 5 to 10 years. While not established during the initial alternatives analyses, a target flow of 2800 m^3/s (100,000 ft^3/s) was later adopted during the final design phase as a design objective for the Emergency Spillway for the next 5 to 10 years.

Table 2
Design Measures Included in New FCO Spillway Chute Structural Concrete to Address Areas of Improvement Identified in the Original Design/Construction

Areas for Improvement Identified in Original Design/Construction	Design Measures in New FCO Spillway Chute Structural Concrete to Address Identified Areas for Improvement
Relatively thin concrete slab at 0.38 m (1.25 ft)	New concrete slab minimum 0.76 m (2.5 ft) thick
Only 1 layer of relatively light steel reinforcement	2 layers of robust steel reinforcement
No waterstops	Waterstops added at each transverse joint
Large variations in slab thickness	Use of thick (~1.5 m [5 ft]) layers of leveling concrete
Corrosion of reinforcing bars	Upper layer of steel reinforcement epoxy coated
Placement of underdrains within concrete slabs	Underdrains placed beneath concrete slabs
Collector pipes drain both underdrain and backfill	Separate collector pipes for underdrain and backfill
Brittle clay underdrain and collector drain pipes	PVC underdrain and collector drain pipes
0.15 m (6 in) I.D. perforated underdrain pipes too small	0.20 m (8 in) I.D. slotted PVC underdrain pipes used
No clean-outs for underdrain system	Clean-outs added for each underdrain pipe
Gravel envelope around drains not filter compatible	Granular filter material around new drain pipes
Presence of untreated erodible rock foundation	Intensely-weathered rock was over-excavated
Presence of untreated shears in rock foundation	Shear zones over-excavated and treated
Less rigorous foundation clean-up	Extremely rigorous foundation clean-up
Insufficient rock anchorage (only ~1.5 m [5 ft] deep)	Deeper rock anchors – 4.6 to 7.6 m (15 to 25 ft) deep
Potential corrosion of rock anchors	Rock anchors epoxy coated
Potential cavitation	Aeration added in Phase 1 spillway section [3]

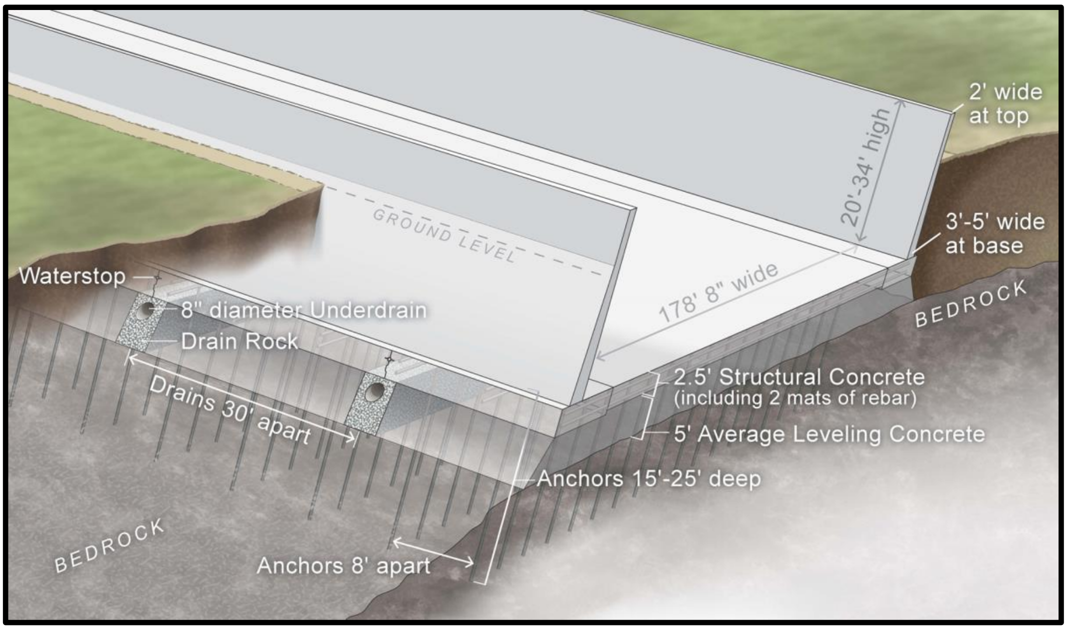

Fig. 8 Design measures included in 2017 structural concrete for FCO Spillway chute

The 3 m (10 ft) thick RCC apron was founded on rock, requiring substantial removal of surface soils, fills, and temporary armoring. The foundations for the RCC buttress and the 2-m-high concrete crest were specified to be of moderately-weathered rock, or better, and to be thoroughly cleaned.

The purpose of the downstream secant pile wall is to support and protect the RCC apron from head-cutting erosion. Using the results of the geologic explorations, an alignment was chosen for the secant pile wall approximately 227 m (746 ft) downstream of the existing monoliths/weir sections. Along this alignment, the depth to slightly weathered or fresh rock is only about 6 m (20 ft) or less. This allows for the bottoms of the piles to be keyed into slightly weathered or fresh rock to depths of at least 4.5 m (15 ft) or more, with total pile depths ranging between 11 and 20 m (35 and 65 ft). As shown in Fig. 9, the piles were designed to be a minimum 91 cm (3 ft) in diameter with centers spaced at 61 cm (2 ft), and to be constructed in 5-pile panels with a 30 cm (1 ft) gap between panels to allow for drainage and to avoid the buildup of groundwater pressure against the wall. Two of the five concrete secant piles in each 5-pile panel were reinforced, while the other three were unreinforced (see Fig. 9). A reinforced concrete grade beam will be constructed across the tops of the piles and anchored back into the RCC apron to a minimum distance of 40 feet (12 meters).

4. REGULATORY REVIEW

The declaration of State and Federal Emergencies for the Oroville Dam Spillway Incident greatly facilitated the regulatory permitting process, particularly environmental permitting. However, State and Federal laws also required that the California Division of Safety of Dams (DSOD) and the Federal Energy Regulatory Commission (FERC) review the safety of any dam modifications or repairs, including those for the spillways. Usually, the review and approval process requires months after designs or contract drawings and specifications are submitted for regulatory approval, time that the OER project did not have. The solution to this was to dedicate full-time DSOD and FERC staff to the OER project, both in Sacramento and Oroville. Both agencies were able to commit full-time staff to review the work of OER as it was being developed and implemented in the field. During the foundation excavation and treatments for the chute slabs on the FCO Spillway chute, the final inspection for each slab foundation was approved in the field not only by OER engineers and geologists, but also by an inspector from DSOD and an inspector from FERC, both assigned on-site. The dedication of regulatory staff to the project, while still retaining their independent regulatory function, greatly reduced the time required for regulatory review and approval, typically down to a matter of days or a week for each design review.

State and Federal laws also required that the spillway designs and construction be reviewed by an independent Board of Consultants to provide an independent expert peer review of the work. The members of the Board of Consultants nominated by DWR and approved by DSOD and FERC were:

- John Egbert, P.E.
- Kerry Cato, Ph.D., C.E.G.
- Eric Kollgaard, P.E.

- Faiz Makdisi, Ph.D., P.E., D.GE
- Paul Schweiger, P.E., P.Eng, CFM

The Board of Consultants held their first meeting on March 1-3, 2017, with the Spillway Recovery Team and dam safety regulators. Between March and December 2017, the Board of Consultants met 14 times to review the designs and to inspect construction in the field. The Board of Consultants completed written reports following each meeting, providing comments and recommendations to the Spillway Recovery Team, DSOD, and FERC, which DWR then made available to the media and the general public.

OER also participated in a Risk Assessment Workshop conducted by the United States Army Corps of Engineers in April 2017 and in a Potential Failure Mode Analysis workshop in May 2017 conducted by DWR. These two workshops focused on the safety of the FCO Spillway chute and the Emergency Spillway.

5. LAKE OROVILLE OPERATIONS

Following the 2017 incident, DWR used the damaged FCO Spillway chute intermittently between February and May 19, 2017, to pass reservoir inflows to avoid using the unreliable Emergency Spillway. On May 12, DWR completed a Near-Term Lake Oroville Operations Plan to support the final 2017 closure of the spillway (FCO) gates in the second half of May, and to use the Hyatt Powerplant releases to lower the reservoir to Elevation 214 m (700 ft) by November 1, 2017. The objective of this operations plan was to minimize the likelihood of using either spillway during the rest of the 2017 construction season, and to also minimize the need for using the Emergency Spillway at all during the 2017-2018 Winter Flood Season.

On October 16, 2017, DWR completed a Lake Oroville 2017/2018 Flood Control Season Operations Plan targeted to limit flows on the FCO Spillway chute and to prevent any flow through the Emergency Spillway. The 2017/2018 Plan was based on hydrologic and hydraulic analyses using historical precipitation, snowpack, and reservoir data. It was also developed to balance the competing needs of dam safety versus downstream flood safety. The 2017/2018 Plan incorporates a low initial reservoir elevation target to be held during the Winter Flood Season and uses reservoir set points where increasing releases would be made from the Hyatt Powerplant and the FCO Spillway chute to avoid the use of the Emergency Spillway. The 2017/2018 Plan allows the reservoir to pass the Standard Project Flood without releases on the Emergency Spillway and without a discharge greater than 2800 m^3/s (100,000 ft^3/s) on the FCO Spillway chute.

6. MEETING THE SCHEDULE

During the height of the 2017 construction season, the contractor (Kiewit) had as many as 750 craft workers on site. During this season, the following work was completed on the FCO Spillway chute before the November 1, 2017, deadline:

- 320,000 m^3 (420,000 yd^3) of excavation
- 265,000 m^3 (347,000 yd^3) of RCC construction
- 234 structural-concrete slabs and 78 reinforced-concrete walls constructed
- 32000 m^3 (42,000 yd^3) of leveling concrete constructed
- 23000 m^3 (30,000 yd^3) of structural concrete constructed

The progress of the work on the FCO Spillway chute is illustrated in Fig. 10, and the pertinent events for OER are highlighted in Table 3. Final placement of 2017 concrete on the FCO Spillway chute was made on November 1, 2017 (see Fig. 10), thus meeting the most important goal for the project.

Fig. 10 Aerial views of construction on FCO Spillway chute between May and November 2017

Table 3
Pertinent Events in Oroville Emergency Recovery (OER)

2017 Date	No. of Days	Event
Feb. 7	0	Initiation of Oroville Dam Spillway Incident
Feb. 12	5	Emergency declared, downstream areas evacuated
Feb. 23	16	OER Framework adopted
Mar. 1-3	22-24	First meeting of Board of Consultants
Mar. 6	27	OER leads organized, alternatives workshop
Mar. 15	36	Forensic Investigation Team selected

Mar. 27	48	Initial contract (Specification 17-08) awarded to Teichert Construction
Mar. 31	52	30% Design, Advertised Spillways, Spillways, Oroville Emergency Recovery Contract (Specification 17-09)
April 15	67	Spillways, Oroville Emergency Recovery Contract (Specification 17-09) awarded to Kiewit
April 18-20	70-72	USACE Risk Assessment Workshop
April 22	74	First blasting excavation to stabilize over-steepened slopes
May 2-4	84-86	COE Potential Failure Modes Analysis Workshop
May 18	100	75% Design, Plans and Specifications
May 19	101	Final Closure of FCO Gates on FCO for Spring 2017
June 21	134	Final Plans and Specifications issued for Review
July 13	156	DSOD approval of Final Plans and Specifications
July 13	156	First Secant Pile completed
July 15	158	FERC approval of Final Plans and Specifications
July 20	163	Revised Final Plans and Specifications issued
Aug. 17-18	191-192	Final Clean-up/First Placement of RCC in Main Scour Hole
Oct. 16	251	Lake Oroville 2017/2018 Flood Control Season Op. Plan completed
Nov. 1	267	Final concrete placement on FCO Spillway chute Phase 1 Recovery

7. LESSONS LEARNED

The expedited design and construction processes used in the urgent restoration of spillway capacity at Oroville Dam were unprecedented, and were only successful because of the commitment of everyone (owner, consultants, contractors, and regulators) to work together in partnership to ensure that the public was properly protected. Lessons learned during this project included housing all parties in one location, first in Sacramento and then at Oroville. The dedication of regulatory staff full-time to the project team and the timely comments and recommendations from the Board of Consultants were critically important in staying on schedule. The main contractor (Kiewit) maintained an extremely proactive and aggressive schedule throughout the construction period and quickly responded to scheduling issues whenever necessary to overcome the considerable construction challenges associated with the project.

SUMMARY

Following the February 7, 2017, Oroville Dam Spillway Incident, DWR formed the Oroville Emergency Recovery (OER) team to restore spillway capacity in advance of the 2017-2018 Winter Flood Season. The team worked under considerable pressure during the ongoing incident to quickly develop recovery plans for the two major areas of damage – the Flood Control Spillway and the Emergency Spillway. Using an expedited process that included integral coordination with state and federal dam safety regulators, a recovery design was developed and construction contracts were issued. The 2017 expedited design and construction processes used in the urgent restoration of spillway capacity were unprecedented, and were only successful because of the commitment of everyone involved to work together.

1. INTRODUCTION

Oroville Dam is located on the Feather River in northern California (USA). At 234.7 m (770-ft) tall, this earth embankment is the tallest dam in the United States. With its 4.3 billion m3 (3.5 million acre-feet) of storage, Lake Oroville is the second largest reservoir in California, supplying water to cities as far south as Los Angeles. The Oroville Dam, reservoir (Lake Oroville), and hydropower plant facility is the flagship of the State Water Project (SWP), which is owned and operated by the State of California, Department of Water Resources (DWR).

The 2016-2017 Winter Storms brought record breaking precipitation to the Northern California Sierra mountains including the Feather River watershed. On February 7, 2017, the Oroville Dam's 54.5 m (179-ft) wide Flood Control Outlet (FCO) Spillway chute (Fig. 1) was

* INCIDENT DE DRAINAGE DE BARRAGE D'OROVILLE - INFLUENCES DE BÉTON COMPACTÉES PAR ROULEAU SUR LES CARACTÉRISTIQUES DE CONCEPTION STRUCTURALE DE RÉCUPÉRATION

releasing water to control the Lake Oroville reservoir level in accordance with the prescribed operations plan. During this operation, the FCO spillway suffered a catastrophic failure of the lower chute area eventually resulting in the loss of approximately 427 m (1400 ft) of the lower chute, including the scour of more than 1.2 million m3 (1.6 million yd3 of soil and rock materials. On February 11, 2017, the Emergency Spillway (Fig. 1) was used for the first time since the project was completed in 1968. During this operation, significant erosion and scour caused by the Emergency Spillway overflow led authorities to fear for the safety of the spillway structures, resulting in the activation of the Emergency Action Plan and evacuation of about 188,000 persons from downstream communities.

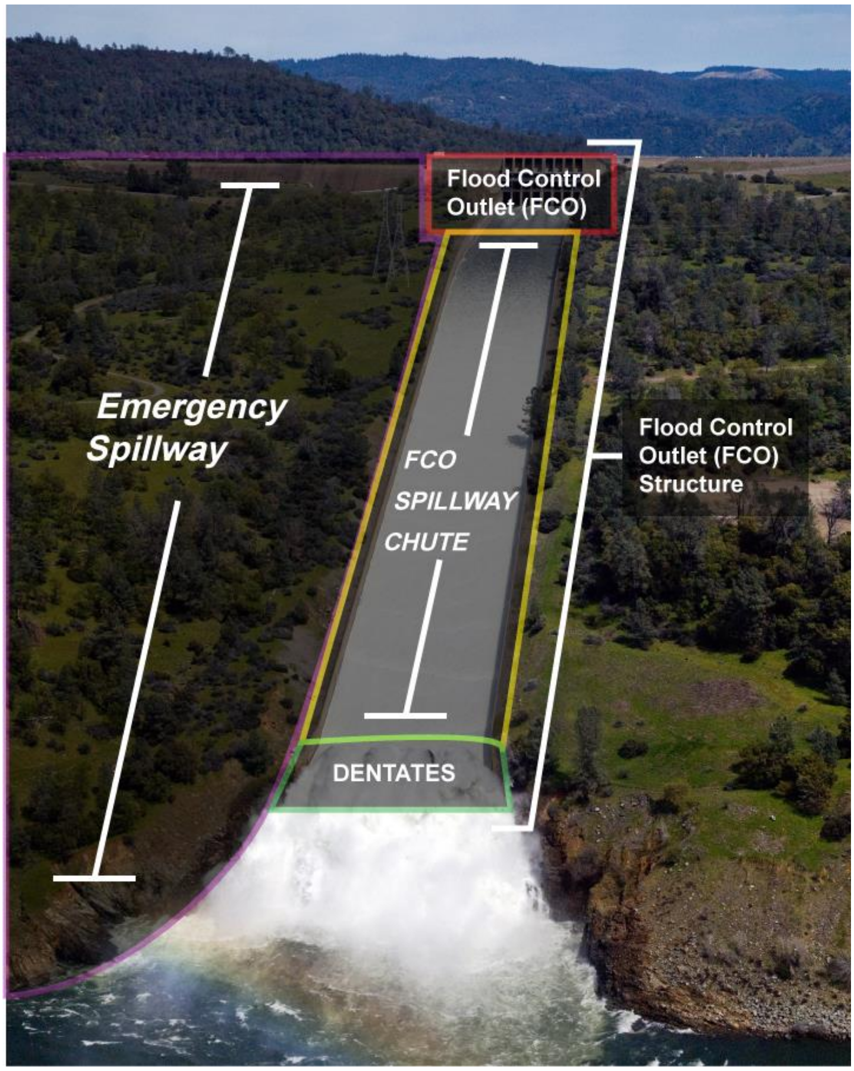

Fig. 1 Flood Control Outlet (FCO) Structure and Emergency Spillway, March 2011

This paper is part of a series developed by the State of California, Department of Water Resources (DWR) to describe the Oroville Dam Spillway Incident - Emergency Response and Recovery. including lessons learned and key design features to allow the Oroville Dam FCO Spillway chute to be able to pass expected annual flood flows by the next wet-year cycle, starting by November 1, 2017. This paper presents the roller-compacted-concrete portion of the reconstructed spillway design that was intended to be used for replacing the eroded foundation of the FCO Spillway chute and as a buttress and apron for the rehabilitated Emergency Spillway. Through a series of design and project management decisions, the roller-compacted concrete came to play a much more vital role in meeting the project objective of having a completed FCO Spillway chute by the November 1, 2017, deadline. This paper identifies and discusses specific dam safety risks and the evolution of the key structural design features that were developed to meet the project-specific design and public safety requirements, including critical reviews by state and federal regulatory authorities along with the independent Board of Consultants.

2. BACKGROUND

The Oroville Dam Spillway Incident of 2017 was one of the most serious dam safety occurrences in the United States in many years. As the tallest dam in the United States and the keystone of California's State Water Project, Oroville Dam and Lake Oroville stand as a steadfast monument to water resource development in the 20th Century. The Oroville Dam Spillway Incident has provided a testimony to the dedication of emergency response and dam safety professionals who came together to meet the challenges of a rapidly changing situation to assure the safety of the Oroville Dam and the public living downstream. Starting in Oroville, California, this incident will impact the dam safety profession around the world as the details of the incident, response, and recovery become fully known and realized.

The original mission of Oroville Dam and Lake Oroville as part of the California State Water Project (SWP), was originally conceived as the following [1]:

Oroville Dam and its appurtenances comprise a multipurpose project encompassing water conservation, power generation, flood control, recreation, and fish and wildlife enhancement. The Lake stores winter and spring runoff which is released into the Feather River as necessary, to supply project needs. The (United States) Federal Government shared in the cost of the Dam, which provides 750,000 acre-feet of flood control storage. The 15,805-acre surface of the Lake with a 167-mile shoreline provides water-oriented recreational opportunities.

An incident such as this at the Oroville Dam spillways has many facets from beginning to end, along with many lessons learned. Along with others in this series of papers developed for the U.S. Society on Dams [2, 3, 4, 5, 6], this paper presents important technical details from those directly involved in the groundbreaking Herculean effort to recover from the incident in an expedited manner to protect and serve the people of California. With strong leadership from the Oroville Dam owner, the California Department of Water Resources (DWR), the Oroville Emergency Recovery Spillways Task Force pulled in professional resources from industry, including consultants, independent experts, regulators, and contractors to make the seemingly impossible into a reality of success based on pure determination, hard work, commitment, and dedication to the single mission of recovery.

3. KEY RECOVERY STRUCTURAL DESIGN FEATURES

The Oroville Dam Spillway Incident created the need to address many areas of structural rehabilitation to facilitate the reconstruction of damaged or destroyed features of the Flood Control Outlet (FCO) Spillway chute and the Emergency Spillway. As detailed in the related situational development paper [2], the flood damage to both spillways was catastrophic. For the FCO Spillway chute, nearly 40% of the spillway chute was completely destroyed, scouring out an estimated 1.2 million m^3 (1.6 million yd^3) of material into the downstream Feather River channel, leaving a large hole in the foundation and a cavernous valley of eroded bedrock where once lay one of the largest spillways in the United States.

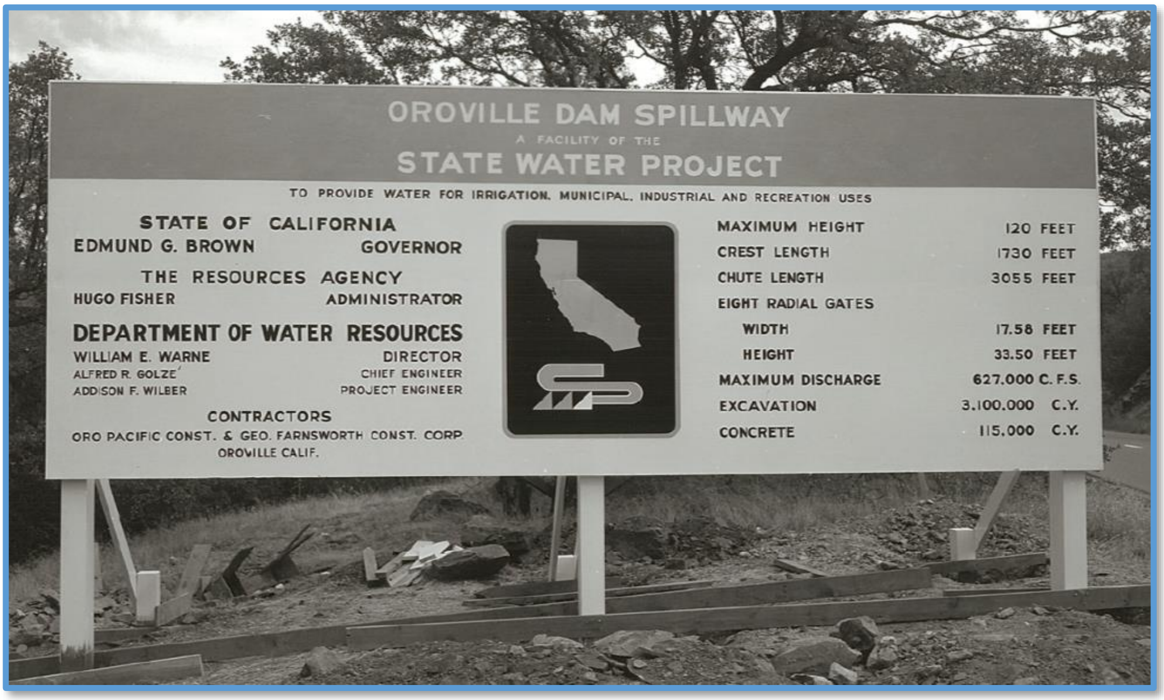

Fig. 2 Oroville Dam Project Sign

As shown in Fig. 2, the FCO Structure, with eight 10.21 m (33.5 ft) high radial gates, has a capacity of about 8380 m^3/s (296,000 ft^3/s), which has been restricted to 4200 m^3/s (150,000 ft^3/s) out of concern for downstream flooding. The FCO Spillway chute is 931 meters (3055 feet) long and 54.6 meters (179 feet) wide, with a steep 4:1 (horizontal:vertical) slope on the lower chute and a large energy-dissipating dentate structure at the terminal end. There is 170 meters (558 feet) of elevation change from the invert of the FCO gates to the normal water surface elevation of the diversion pool - the Feather River below the FCO Spillway chute, which is the tailwater for the powerhouse.

This paper focuses on describing the repair of the FCO Spillway chute, using roller-compacted concrete (RCC), as this work was a large part of the recovery effort during the first year following the 2017 incident. Repair and recovery of the FCO Spillway chute was given the highest priority by DWR management so that the spillway would be available for the next 2017-2018 Winter Flood Season. This led to the rapid development and evaluation of recovery concepts that were constantly evolving and changing based on weekly, if not daily, interactions with the design team professionals, federal and state regulators, and eventually the construction contractor. A critical aspect of all recovery concepts was to determine the maximum work that could be accomplished within the limited timeframe, resulting in an operational FCO Spillway chute by November 1, 2017.

Similarly, the recovery work at the Emergency Spillway was carried forward, considering what could be completed during the 2017 construction season and what work could be deprioritized until 2018. It was determined that a deep secant pile wall should be the highest priority in 2017 to address the serious headcutting observed during the original 2017 incident. Following completion of the secant pile wall, an RCC buttress to the ogee spillway and a large RCC apron would be constructed in 2018. Many of the RCC design features and lessons learned rebuilding the FCO Spillway chute have direct relevance to the upcoming Emergency Spillway work. The RCC mix design and construction processes are anticipated to be the same for both structures.

4. RCC AS A "FILL THE HOLE" SOLUTION AT THE FCO SPILLWAY CHUTE

Immediately following the incident, the Oroville Emergency Recovery (OER) Spillway Task Force was swiftly assembled. The OER Spillway Task Force developed a wide-ranging list of potential recovery approaches for both the FCO Spillway chute and Emergency Spillway. For the FCO Spillway chute, engineers were faced with a spillway chute that was abruptly terminated (by the foundation erosion and chute loss) at about the mid-point of its length, leaving an approximately 30.5 meter (100-foot) deep hole across the full width of the chute and extending beyond with extensive and irregular areas of exposed rock.

An assessment of alternatives to repair the FCO Spillway chute was developed by the OER Spillway Task Force. These alternative concepts were grouped in the following categories:

- "Use the Hole" – These concepts involved developing a long-term stilling basin out of the scoured hole and ending the spillway chute near the location remaining after the incident. It was determined that extensive design and modelling would be needed to assure that such a solution would be suitable for flows up to the spillway design flows anticipated under probable maximum flood (PMF) conditions. A key unknown here was whether the foundation rock would continue to erode under these higher flows and possibly endanger the main dam.

- "Bridge the Hole" – While minimizing the foundation contact and preparation, these concepts involved construction of a reinforced-concrete aqueduct bridge over the chasm to carry flows over the eroded area. Given the lack of precedent for this type of solution on such a large-capacity, high-discharge, high-velocity spillway, it was determined that extensive structural and physical modelling would probably be needed for such a critical structure. These concepts were ultimately deemed to be structurally too intense for the design and construction time available.
- "Fill the Hole" – These concepts centered on replacement of the eroded foundation of the FCO Spillway chute and utilizing the original spillway profile. There were two competing concepts for how this could be achieved:

    - "Fill the Hole with Rock" – This concept involved filling the eroded hole with large boulders and other rock that could be solidified using flowable concrete. This approach was discounted because of the high variability in the available rock on site and unknown imported rock materials. Again, extensive design and modelling seemed to be required for unknown material sources and material properties, including thermal effects.

- “Fill the Hole with RCC” – This concept, shown in Fig. 3, anticipated using horizontal lifts of RCC to fill a portion of the eroded hole sufficient to re-construct the FCO Spillway chute to the original geometry.

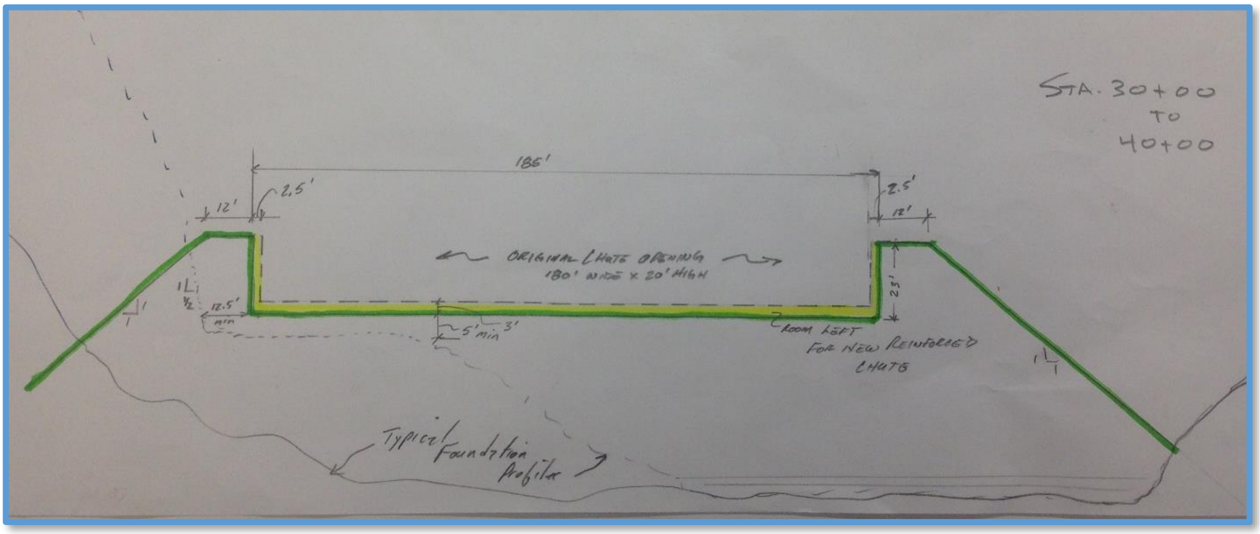

Fig. 3 Initial Sketch of RCC for "Fill the Hole" Solution

The following list of arguments, in support of the “Fill the Hole with RCC” approach, was presented to the OER Spillway Task Force, including regulatory agencies and the independent Board of Consultants for consideration:

1. The recommended alternative would provide the least risk to DWR by reconstructing the damaged portion of the FCO Spillway chute back to the original geometry with the foundation restored using RCC.
2. Reconstructing the FCO Spillway chute to its original geometry would have the least unknowns regarding hydraulic performance, which had already been studied, modeled, and proven through years of service, including:
   a) the least amount of additional field investigations or hydraulic modelling; and
   b) the avoidance of further negative impacts on flow patterns and debris in the diversion pool (Feather River) downstream of the spillways.
3. The use of RCC would allow the reuse of scoured rock debris recovered from Feather River as well as rock excavated from the chute foundation as concrete coarse and fine aggregates.
4. Reconstructing the FCO Spillway chute to its original design configuration would have the least environmental impact as no new areas will be permanently impacted.
5. The use of RCC for dams and spillways is mature in the dam engineering profession and construction industry and has been shown to be a highly efficient methodology for accelerated construction as opposed to conventional mass or reinforced concrete.
6. There have been several high-volume RCC projects for dams of this magnitude in the State of California over the last 10 years; thus, this RCC alternative will provide highly-reliable cost estimates and experienced contractors.

7. An assessment of the construction schedule showed that using RCC for foundation replacement would be a feasible solution for reconstruction of a usable FCO Spillway chute by November 1, 2017.
8. Should early storms arise in the fall of 2017, requiring the operation of the FCO Spillway chute before the scheduled completion on November 1st, the RCC should be resistant to scour up to moderate flows – about 1400 m^3/s (50,000 ft^3/s) or higher under temporary conditions.
9. The completed spillway modification project using RCC would have a positive appearance of a robust and complete solution that restores public confidence in the reliable operation of Oroville Dam.
10. The completed FCO Spillway chute, using RCC, would be a permanent solution capable of a design life of 100 years or more, capable of passing large flows up to the original design value of about 8400 m^3/s (296,000 ft^3/s)

Based on these initial benefits, the FCO recovery solution, using RCC foundation replacement in the scoured areas, was selected for preliminary design early in the evaluation process. With selection of RCC for the FCO Spillway chute, this decision led to the consideration of RCC for other aspects of the recovery design, including the Emergency Spillway buttress and spillway apron.

5. RCC PRELIMINARY DESIGN SOLUTION

The use of RCC for the FCO Spillway chute reconstruction was initially proposed as shown in Fig. 4, which included a conventional reinforced-concrete slab overlay as well as reinforced-concrete chute walls against RCC. In this initial concept, RCC was envisioned as the primary structural feature for the 6.1 meter (20 foot) high FCO Spillway chute walls with 0.76 meter (2.5 foot) thick reinforced-concrete vertical inside walls that were tied-back into the RCC.

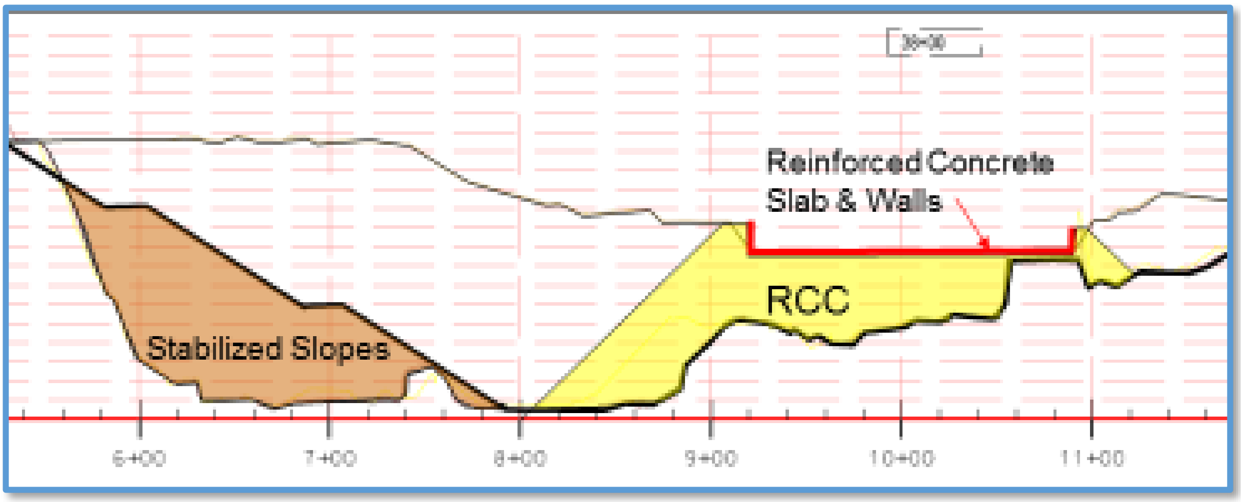

Fig. 4 Preliminary RCC Concept

The constructability of the initial concept envisioned that the RCC chute and walls would be constructed first, then the reinforced-concrete slabs and walls would be placed in sequence later within the same construction season. This concept, developed at the 30-percent design completion, was the basis for the original construction bid.

6. RCC AS FOUNDATION REPLACEMENT

The design process continued, following the initial construction bidding and award, as the overall completion moved forward. As the design progressed towards about 60% complete, a decision was made to modify the RCC portion of the chute to a foundation replacement only, which would provide a similar design approach, using reinforced-concrete for the chute slabs and cantilever retaining walls for the entire FCO Spillway chute. The construction contractor was confident that the RCC foundation replacement could be completed within the necessary timeframe, but indicated that the single-sided reinforced-concrete walls originally envisioned for the RCC portion could not be completed during the 2017 construction season.

As a result, an intermediate design modification of the RCC chute replacement was developed that included RCC as foundation replacement only so that the rebuilt chute would have similar reinforced-concrete slabs and cantilever retaining walls throughout the spillway. This 60% design concept is shown in Fig. 5.

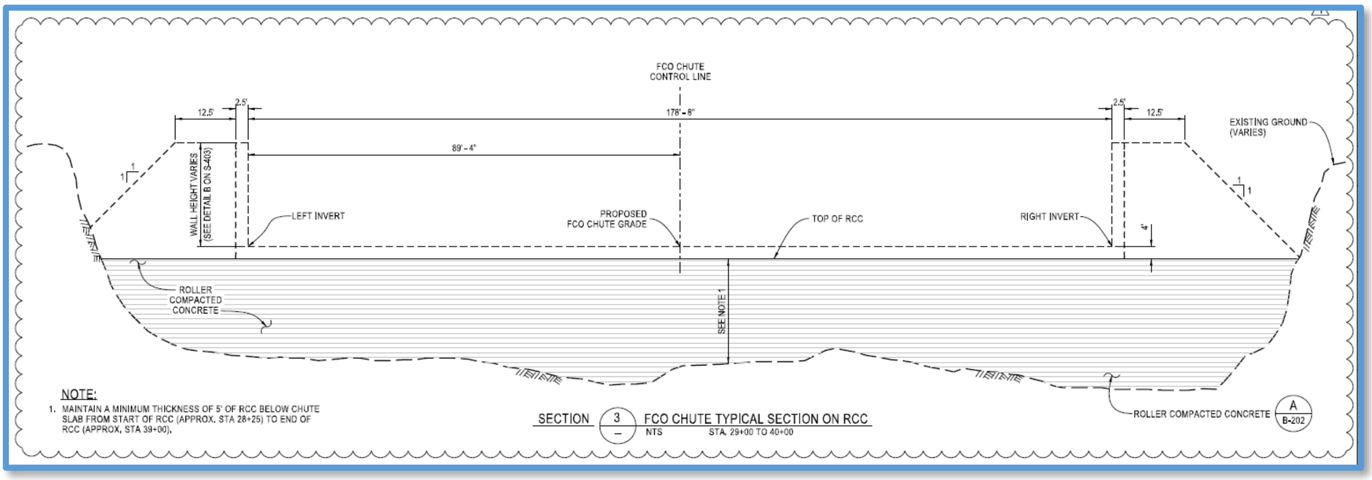

Fig. 5 Intermediate RCC Design Concept (60%)

The advantage of this concept was a simplified RCC construction process without the walls, resulting in a shorter RCC placement schedule. The challenge would be to get the RCC placed in time ahead of the reinforced-concrete work to allow that work to meet the critical November 1st completion date. There was some concern about the early strength of the RCC to allow proper anchoring of the chute slab. Early tests in the RCC Test Fill #1, however, showed that sufficient RCC strength would develop to allow proper anchorages.

7. INTERIM RCC FOUNDATION REPLACEMENT CONCEPT

The design and construction work continued to move together at a fast pace between April 15, 2017, when the construction contract was awarded and the anticipated start of field work on June 1, 2017, following final gate closure of the FCO Structure. During this time, the contractor was evaluating the post-incident condition of the foundation with regard to the clean-up needed for the RCC and conventional concrete work. In this same period, project geologists determined that a considerable volume of rock foundation under the remaining non-eroded FCO Spillway chute was unstable and needed to be removed before foundation clean-up could be started in the deepest upper hole"

In DWR's discussions with the contractor about the scope of work and schedule, it was determined that the November 1, 2017, completion target could not be met with a design concept that included both RCC foundation replacement and conventional reinforced-concrete slabs and walls. Therefore, an Interim RCC Foundation Replacement Concept was developed that restored the RCC walls, though at a lower level to allow up to 2800 m^3/s (100,000 ft^3/s) as a solution for an interim period only during the 2017-2018 Winter Flood Season. The plan was to shotcrete the inside of the RCC walls for the interim period, then remove the RCC walls in the 2018 construction season to allow completion of the reinforced-concrete slabs and walls as originally designed, as shown in Fig. 6.

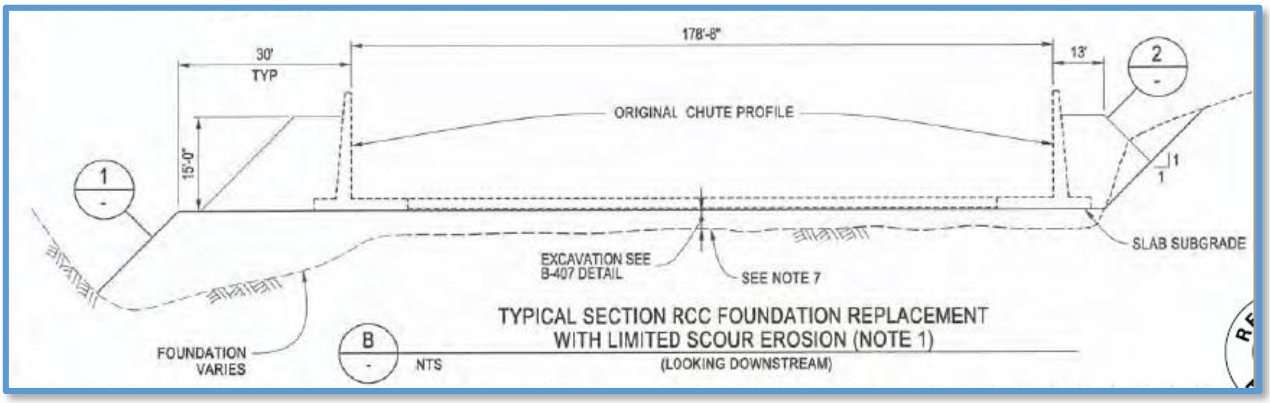

Figure 6 - Interim RCC Foundation Replacement Concept

The characteristics of the Interim RCC Foundation Replacement Concept are provided below:

- RCC is used as the foundation replacement material from Station 28+35 to 39+00.
- A minimum RCC thickness of 1.5 meters (5 feet) perpendicular to the chute slope is provided in the RCC area of the FCO Spillway chute (Sta. 28+35 to 39+00).
- The RCC foundation replacement is placed in horizontal layers below the planned final 4:1 finished grade of the reinforced-concrete spillway chute, creating a roughed-in 4:1 slope for the chute.
- A final 30 cm (12 inch) thick layer of RCC would be placed monolithically on a 4:1 slope using a higher-strength enriched RCC mix to provide a durable surface for the 2017-2018 Winter Flood Season, leaving the final RCC chute surface about 0.91 meter (3 feet) lower than the planned finished reinforced-concrete slab chute grade.
- At the upper end of the RCC (Sta. 28+35), a vertical 0.91-meter (3-foot) step from the FCO Spillway update chute finished reinforced concrete surface to the downstream RCC surface would be used as an aeration ramp with a vertical chimney section at each abutment to allow air to be incorporated into future flows.
- At the lower end of the RCC (Sta. 38+00 to 39+00), a 30.5 meter (100-foot) long transition section would slowly bring the RCC chute surface up flush with the finished FCO Spillway lower chute reinforced-concrete surface.
- Shorter 4.9 meter (16-foot) high RCC walls would be constructed with a similar design as the initial concept - a vertical inside face, 4 meters (12.5 feet) across the top and 1:1 side slopes on the outside faces], which is designed to accommodate a design flow of 2,800 m^3/s (100,000 ft^3/s).
- A minimum of 6 inches of the inner wall face would be constructed using reinforced shotcrete to provide a durable surface for the 2017-2018 Winter Flood Season.

The Interim RCC Foundation Replacement Concept described above was constructed during the 2017 construction season. As noted above, the Final Design solution for the RCC area of the FCO Spillway chute will include the following modifications during the 2018 construction season:

a. The RCC side walls above the 4:1 chute surface will be removed following the 2017-2018 Winter Flood Season so that new 6.1 meter (20-foot) high reinforced-concrete cantilever retaining walls can be added as the permanent chute walls.

b. Permanent reinforced-concrete slabs will be placed over the RCC, including drainage and anchor design features, for the remaining portions of the chute. Key aspects of this work will include roughening the RCC surface to allow a better connection to the new reinforced concrete.

8. RCC DESIGN

The initial estimated quantity of RCC was about 191,000 m^3 (250,000 yd^3), based on the initial topographic information from Station 29+00 to 39+00. This estimate was periodically revised during construction to account for changes in the foundation excavation, including the Arena Cut, which laid the upstream foundation area back to about Station 28+00 due to instabilities identified in the FCO Spillway upper chute foundation. Ultimately, the final RCC volume was about 268,000 m^3 (350,000 yd^3) that was placed during the 2017 construction season.

The technical specification for RCC features were developed based on recently-completed RCC projects in California by members of the OER Spillway Task Force. The project specifications also included technical requirements for crushing on-site rock for the RCC. Key aspects of the project specifications included the following features:

- RCC Mix Design
- Unformed RCC 1:1 Slope for the abutment sides
- Unformed RCC 4:1 Slope for the chute surface

Each of these features of the RCC design are discussed in the following sections.

RCC Mix Design: The intent for the RCC mix design was to use on-site materials for RCC aggregates, primarily rock eroded during the February 2017 incident that were later dredged from the Feather River. These eroded materials had been stockpiled in several areas around the project site. Initial investigations into the RCC mix design commenced shortly after the incident, using the dredged rock. These materials were crushed in several test programs, including preparation of RCC concrete cylinders. The results of these tests showed that an initial sorting process was necessary to remove fine-grained materials (silt, sand and gravel) finer than 1-inch in diameter. This provision was included in the final specification for the RCC Aggregates.

To simplify the preparation of RCC aggregates, the specification was developed using only two types of aggregates: coarse and fine. The coarse aggregate was specified as ASTM C 33, Size Number 357 [8] with a maximum aggregate size of 38 mm (1.5 inches). The fine (sand) aggregate was a custom blend, initially established in the following table. In addition, the sand equivalent value requirement was set to be no less than 35 when tested in accordance with ASTM D 2419.

Table 1
RCC Fine Sand Gradation

Sieve Size	INITIAL SPECIFICATION Percent Finer by Mass	FINAL SPECIFICATION Percent Finer by Mass
9.5 mm (3/8 inch)	100	100
4.75mm (No. 4)	95-100	90-100
2.36 mm (No. 8)	75-95	55-80
1.18 mm (No. 16)	55-80	35-60
600 □□□□No. 30)	35-60	25-45
300 □m□□No. 50)	24-40	15-35
150 □m□□No. 100)	12-28	10-25
75 □m□□No. 200)	8-18	8-18

The design intent of the RCC cementitious materials was to develop a mix that would attain an unconfined compressive strength of about 17 MPa (2,500 lb/in^2) at 90 to 120 days, which is expected to give about 27.6 MPa (4,000 lb/in^2) at one year. To meet this requirement, a target of 50 percent cement and 50 percent Class F Fly Ash was developed for initial mix design testing. The specification included a range of cement and fly ash components (by weight as shown in the table below) with a target mix at 103 kg of cement and 103 kg of fly ash per cubic meter (175 lb of cement and 175 lb of fly ash per cubic yard) to allow DWR the flexibility to modify the cementitious material content.

Table 2
RCC Material Specification

Location	Batch Proportions - kg/m^3 (lbs/yd^3)			Aggregate Size Range, Percent by Volume of the Total Aggregate	
	Cement	Fly Ash	Water	Group 1 38 mm-4.75 mm (1.5 in. to 1/4 in.)	Group 2 4.75 mm minus (No. 4 minus)
Gated Spillway Chute	59.3-118.7 (100-200)	59.3-118.7 (100-200)	112.7-127.5 (190-215)	60-64%	36-40%

RCC Full-Scale Trial Placement: An initial full-scale trial placement was conducted in June 2017 to validate contractor placement means and methods as well as for evaluating the production uniformity of the on-site RCC batch plant. Several key aspects of the construction were tested, including: general placement, Grout Enriched Vibratable RCC (GEVR), forming of 60 cm (2 foot) high steps, and placement of the 1:1 unformed slopes. During this trial placement, the base RCC mix for foundation replacement was finalized as 103/119 kg/m^3 (175/200 lb/yd^3) of cement/fly ash. The amount of water was tested to produce a VeBe time of 10 seconds (+/- 4 seconds) when tested in accordance with ASTM C 1170, Procedure B [12]. The trial placement was also used for physical testing as well, including trenching through fresh RCC (anticipated for the installation of foundation drains); installation of contraction joints; installation and testing of foundation anchors; and two types of demolition (blasting and hoe-ram).

Enriched RCC Mix Design: An enriched RCC overlay material was developed for use as a surficial wearing surface on the FCO Spillway chute surface between Stations 28+35 and 39+00, where the RCC would be exposed only for the 2017-2018 Winter Flood Season. This material was required to have an early strength higher than the base mix to allow flows on the FCO Spillway chute as early as November 1, 2017. Based on cylinder testing during the full-scale trial placement, the enriched RCC mix design was established as 178/103 kg/m^3 (300/175 lb/yd^3) of cement/fly ash, which was expected to produce RCC with an unconfined compressive strength of about 27.6 MPa (4,000 lb/in^2) at 28 days and about 41.4 to 51.2 MPa (6,000 to 8,000 lb/in^2) at one year.

Figure 7 Unformed 1:1 Slope of RCC Structure

Unformed RCC 1:1 Slopes: A key factor in the RCC design was construction simplicity in order to provide for timely future recovery at the Oroville Dam's spillways during the 2018 construction season. For the FCO Spillway chute, the outside slopes of the foundation replacement were designed to be unformed at a 1:1 slope (see Fig. 7) in order to expedite and simplify construction. The RCC structural section provides a stable and robust structure against static and dynamic loads, including potential overtopping of walls during the interim 2017-2018 Winter Flood Season (temporary RCC walls are shorter than the permanent reinforced-concrete walls). Unformed 1:1 RCC slopes have been used successfully at other RCC projects, including the foundation replacement shaping blocks at Olivenhain Dam (San Diego, California, 2004). This previous history of RCC construction gave credibility for the mix design to regulatory agencies and the OER's independent Board of Consultants.

Unformed RCC 4:1 Slopes: The preponderance of the FCO Spillway chute where RCC is placed as the foundation replacement material will have a spillway chute slope of 4:1. The placement of the final enriched layer of RCC on a 4:1 slope is an innovative method for this project as there are no known occurrences of RCC placement on 4:1 slopes anywhere in the World at the time this spillway design concept was developed. For the base RCC foundation replacement structure, the design intent included placement of RCC in horizontal lifts with a free-form 4:1 slope in the main chute area (see Fig. 8).

Figure 8- Free Form Construction of 4:1 Slope of RCC

As previously discussed, the FCO Spillway chute design included a final 30 cm (12-inch) thick lift of enriched RCC in the main chute placed on the 4:1 slope. A full-scale test program that included placing and compacting RCC on a 4:1 slope was successfully completed as shown in Fig. 9. This trial placement test was critical for confirming the placement procedures using heavy equipment on the steep slope as well as: confirming the placement method (efforts to get a smooth completed surface), the compaction process (number of passes to get required density), and RCC testing. The completed test fill was used to further test different concrete hardening compounds for possible use to further increase the durability of the exposed RCC material during the 2017-2018 Winter Flood Season. Based on the performance of the hardening

Figure 9 - Test Fill #2 for 4:1 Slope Placement

materials during the trial placement, it was decided to apply the hardener only in the area immediately downstream of the aeration ramp on the completed chute.

SUMMARY

In summary, the use of RCC for the foundation replacement provided a robust solution for the Oroville Emergency Recovery – Spillway Task Force. RCC was used to backfill the eroded bedrock chasm within the original damaged FCO Spillway chute area with a high-strength cementitious material, which provided support for the future reinforced-concrete spillway slabs and walls. The RCC was placed within the limited time window to construct an operational FCO Spillway chute for the 2017-2018 Winter Flood Season. Several aspects of this application of RCC were innovative, including the expedited time frame for design and construction; RCC placement on a 4:1 slope with sloping walls; use of an enriched RCC overlay for a robust surface on a high-capacity/high velocity chute spillway; and RCC placement in a challenging rock foundation, using a combination of vibratable RCC with and without mix enrichment with grout.

The RCC solution utilized the reuse of scoured rock debris, and had the least environmental impacts of the alternatives considered. It provided a robust bidding climate as a majority of the construction means and methods were well known in the dam construction industry. It provided a competitive bidding process, which resulted in a low unit bid price. RCC was placed continuously and rapidly to complete the FCO Spillway chute recovery within the limited time frame.

The contractor, Kiewit Corporation, was instrumental in the success of RCC with its commitment to a quality constructed product. The contractor’s willingness to experiment and come up with new ways to place RCC on a challenging foundation was instrumental in achieving the desired design intent. The speed of construction, economy of materials (including the reuse of scoured/eroded rock), innovative contractor placement methods, and material adaptability to variable foundation conditions made the use of RCC as foundation replacement in the FCO Spillway chute an ideal solution for Oroville Emergency Recovery.

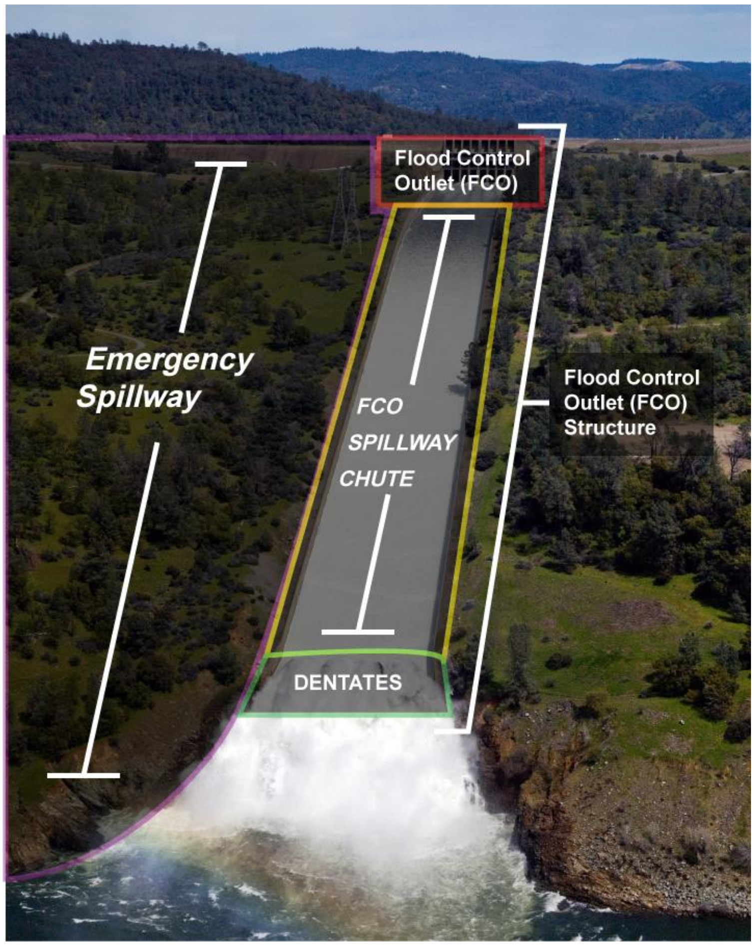
1. INTRODUCTION

Oroville Dam is located on the Feather River in northern California (USA). At 234.7 m (770-ft) tall, this earth embankment is the tallest dam in the United States. With its 4.3 billion m3 (3.5 million acre-feet) of storage, Lake Oroville is the second largest reservoir in California, supplying water to cities as far south as Los Angeles. The Oroville Dam, reservoir (Lake Oroville), and hydropower plant facility is the flagship of the State Water Project (SWP), which is owned and operated by the State of California, Department of Water Resources (DWR).

The 2016-2017 Winter Storms brought record breaking precipitation to the Northern California Sierra Mountains including the Feather River watershed. On February 7, 2017, the Oroville Dam's 54.5 m (179-ft) wide Flood Control Outlet (FCO) Spillway chute (Fig. 1) was releasing water to control the Lake Oroville reservoir level in accordance with the prescribed operations plan. During this operation, the FCO spillway suffered a catastrophic failure of the lower chute area eventually resulting in the loss of approximately 427 m (1400 ft) of the lower chute, including the scour of more than 1.2 million m3 (1.6 million yd3 of soil and rock materials. On February 11, 2017, the Emergency Spillway (Fig. 1) was used for the first time since the project was completed in 1968. During this operation, significant erosion and scour caused by the Emergency Spillway overflow led authorities to fear for the safety of the spillway structures, resulting in the activation of the Emergency Action Plan and evacuation of about 188,000 persons from



downstream communities.

Figure 1 - Flood Control Outlet (FCO) Structure and Emergency Spillway, March 2011

This paper is part of a series developed by the State of California, Department of Water Resources (DWR) to describe the Oroville Dam Spillway Incident - Emergency Response and Recovery. This paper focuses on the geologic conditions known prior to the incident and the subsequent development and execution of a geologic and geotechnical investigation program to support the Oroville Emergency Recovery (OER). The geologic materials at the Oroville Dam site are structurally complex, with numerous cross-cutting shear zones that make predicting ground conditions difficult. It was clear, however, that the geology, in particular the cross-cutting shears, controlled the performance of the FCO Spillway chute and Emergency Spillway during the incident, and controlled the designs developed during the OER phase.

The complex geology, coupled with the urgent time-frame in which to develop and implement a field and laboratory testing program, and then provide useful high-quality subsurface geologic and geotechnical information to the OER design team, was very challenging. Specific challenges ranged from resource management to assessing a wide range of conceptual and then preferred design components, field quality assurance and quality control (QA/QC), expedited data analysis, and interpretations needed to support development of time-critical project designs. These challenges are discussed in the following sections of the paper.

2. GEOLOGY

Oroville Dam is located in the northeastern portion of the Sacramento Valley in northern California in the western Sierra Nevada foothills within the Middle to Late Jurassic arc sequence [4]. The western-most portion of the foothills consist of the Foothills Metamorphic belt, which includes Jurassic-age ophiolitic rocks of the Smartville Complex. The predominant geologic formation where the Oroville Dam and spillways were constructed is an unnamed member of the Smartville Complex, which consists of strongly-foliated green-schist-facies mafic meta-volcanic rocks. The primary mineral assemblage of the on-site rocks consists of actinolite (amphibole) and plagioclase, and is generically referred to as amphibolite.

Site geologic studies completed prior to the dam’s construction included regional and site-specific geologic mapping, rock core drilling, packer testing, laboratory shear strength testing, surface geophysics, petrographic studies, exploratory tunnels, and other measures [5, 6]. These studies led to dam and spillway sites that were generally well-characterized, using the standards at the time for design and construction purposes.

The following subsections generally describe the geologic studies completed for design of the original FCO Spillway chute and Emergency Spillway, geologic observations and documentation created during the original construction of Oroville Dam, and geologic investigations performed between the original construction of the FCO Spillway chute and Emergency Spillway and the Oroville Dam Spillway Incident. This background information is presented to illustrate the detailed geologic and geotechnical information that was relied upon after the incident and during the subsequent development of the exploration program for the OER design efforts.

2.1. Geologic Investigations Pre-1960s Construction

The Oroville Dam site was well-studied prior to construction in the 1960s. Specifically related to the FCO Spillway chute and Emergency Spillway, 45 rock-core borings were drilled and logged, 11 P-wave surface geophysical profiles were imaged, and geologic mapping of natural outcrops was performed. In addition, 51 bulldozer trenches were excavated to estimate the thickness of overburden that could be removed without blasting and to help determine the rock's excavation characteristics. Most of these explorations were performed along the alignments of the FCO Spillway chute and the Emergency Spillway monolith/weir section.

The initial phase of rock-core borings was laid out along a preliminary FCO Spillway chute alignment that was later abandoned (Fig. 2). This preliminary alignment was also where most of the 51 bulldozer trenches were excavated. The rock-core borings ranged up to 29 m (95 ft) deep and were vertical to inclined. The associated boring logs documented the rock lithology, degree of weathering and fracturing, discontinuities and infilling, and descriptions of other relevant geologic features, and included packer test results and water levels where measured. High-quality photographs of the rock cores were also documented for most of the rock-core borings.

The results of the pre-1960s-construction site geologic studies indicated that un-rippable rock was present at relatively shallow depths – generally about 0.9 to 1.2 m (3 to 4 ft) below the surface [5]. Subsurface rock-core borings and P-wave geophysical lines were used to develop contour maps and profiles showing depths to sound rock. Sound rock included fresh and slightly weathered rock, and might be slightly to moderately fractured. These maps and profiles were used by the engineering geologists and design engineers to help establish the anticipated foundation rock quality at the invert excavations for both the FCO Spillway chute and the Emergency Spillway monolith foundations.

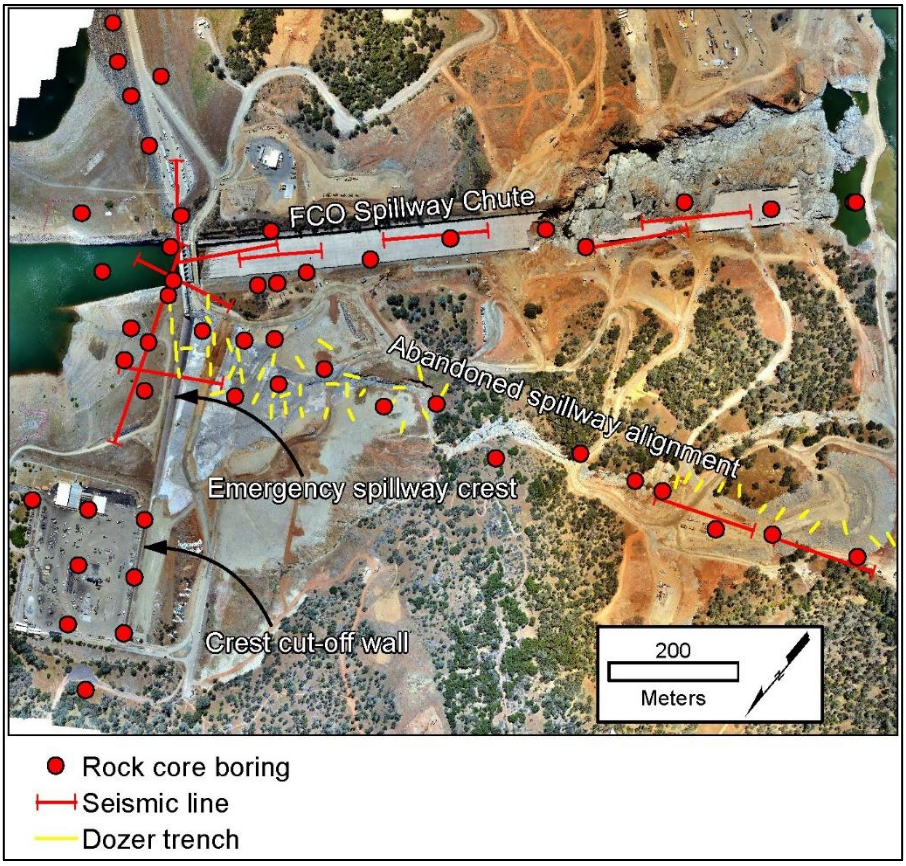


Figure 2 - Geologic explorations prior to original 1960s construction [5].

2.2. GEOLOGIC CONDITIONS DOCUMENTED DURING 1960S CONSTRUCTION

During construction of the FCO Spillway chute, DWR geologists created as-excavated geologic foundation maps (Fig. 3). These maps denoted the general rock weathering at the foundation invert as well as the location of shears and shear zones. Each shear or shear zone greater than 3 cm (0.1 ft) wide was assigned a unique sequential number with a relatively detailed description given in the construction geology documentation. The shear descriptions included the thickness, composition or mineral infilling (e.g., breccia versus clay-filled), and other pertinent information [6].

The Emergency Spillway includes an ungated monolith/weir structure that is approximately 527 m (1730 ft) wide at the weir crest. The left 283 m (930 ft) consists of concrete-gravity ogee monoliths/weir sections that were keyed into slightly-weathered rock. The heights of these monoliths range up to 27 m (90 ft). The right 244 m (800 ft) is in a rock cut with a small 0.3 m (1 ft) high concrete ogee weir. As-excavated foundation geology maps were similarly prepared during original construction to document the foundation rock at each concrete monolith of the Emergency Spillway, as well as the foundation rock conditions in the foundation of the concrete weir.

The detailed as-excavated foundation maps developed during original construction for both spillways were critical pieces of information used by OER to assess the geologic foundation conditions of the FCO Spillway chute where the initial failure occurred, and were used to estimate the headward erosion that could be expected based on the intersection of discontinuities in the foundation. These maps were also used to identify areas downstream of the Emergency Spillway monoliths that might be more susceptible to erosion under high water flows.

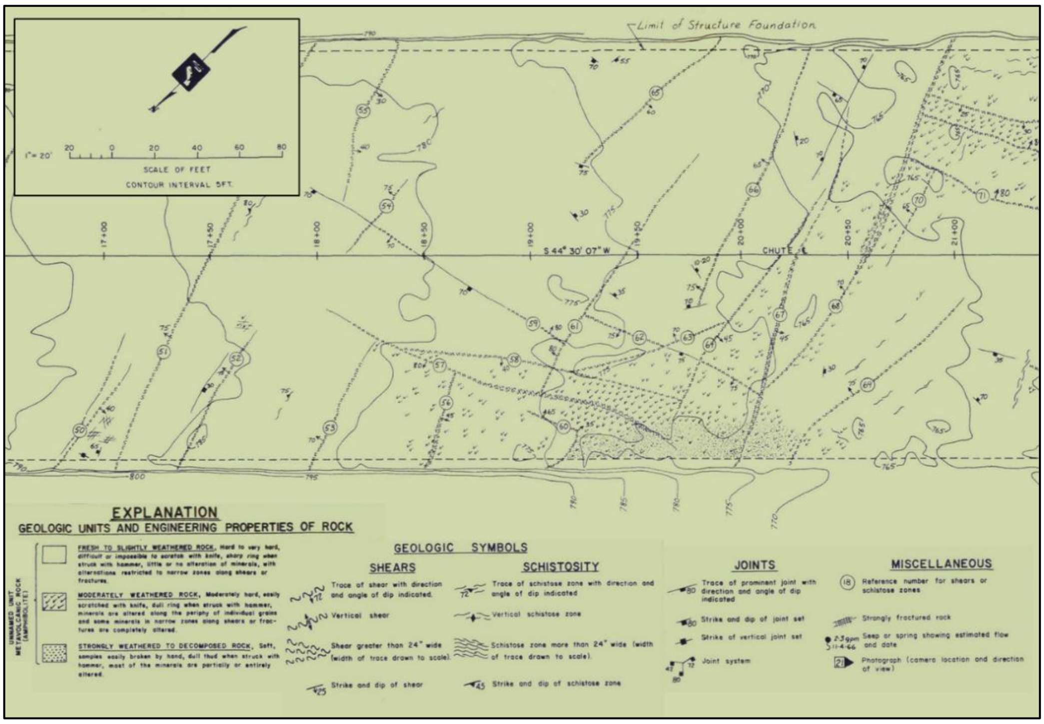

Figure 3 - Example of an as-excavated FCO Spillway chute foundation map [6]

In addition to the foundation geologic mapping during original construction in the 1960s, DWR geologists created foundation maps of areas-which-were and areas-which-were-not fully cleaned up. These clean-up maps documented the presence of fine-grained excavation debris that could remain in place in the FCO Spillway chute foundation. The design specified that the foundation provide at least 50 percent of the rock foundation to be completely cleaned of excavation debris, while the other 50 percent allowed some amount of clean-up debris to be left in place. These fine-grained materials, referred to on the clean-up maps as “compacted clayey fines”, were left in place and have been the source of some confusion. Recent investigations confirm that these materials were sourced from original construction debris.

2.3. Geologic Investigations Since 1960s Construction

Numerous geologic studies have been performed in and around Oroville Dam since original construction in the 1960s. However, only two were located in or near the FCO Spillway chute and the Emergency Spillway: (1) a landslide investigation was performed in 2004 near the FCO Spillway chute on the lower left slope near the Feather River [7]; and (2) a new boring with downhole shear wave velocity measurements was completed in 2016 downstream of the larger monoliths of the Emergency Spillway [8]. Another such boring was completed on the left abutment of the embankment dam at the same time.

In 2004, slope instability was observed about 30 m (100 ft) to the south of the FCO Spillway dentates. While there was no concern about the stability of the FCO Spillway chute, there was concern that a large block of soil and rock might slide into the Feather River channel, blocking the passage of water flowing from the Hyatt Power Plant. This questionable slope was located in an area where the 1960s dam contractor had wasted soil and rock materials at the completion of dam and spillway construction. Historical aerial photos and topographic maps were examined, and it was determined that the slope instability was localized to within the old waste/spoil areas, which were estimated to be relatively thin (less than about 5 m [16 ft]. Based on the work completed in 2004, DWR geologists concluded that it was highly unlikely a large rock or soil mass would fail and block the river channel. No remediation of the unstable materials was completed in this area.

One rock-core boring was drilled downstream of the Emergency Spillway in September 2016 as recommended by the 2014 Director's Safety Review Board for the Ninth Five Year Part 12D Safety Inspection Report for Oroville Dam [9]. The purpose of this boring was two-fold: (1) to obtain site-specific shear wave velocity (Vs30) data for the rock foundation; and (2) to install a piezometer to evaluate potential uplift pressures beneath the Emergency Spillway's concrete monolith structures. Unfortunately, during the Oroville Emergency Response in February 2017, this newly-installed open standpipe piezometer had to be destroyed, as the area was covered with grouted-riprap armoring for added protection prior to and following the initial spill at the Emergency Spillway.

3. DEVELOPMENT OF THE OROVILLE EMERGENCY RECOVERY EXPLORATION PLAN

The damaged FCO Spillway chute was operated intermittently between February 2017 and May 19, 2017 to release water from Lake Oroville. While one team of engineers, geologists, and construction specialists focused on ongoing operations, monitoring, and repairs through the remainder of the 2017 flood season as part of the Oroville Emergency Response phase, a second team of engineers, geologists, and construction specialists began to work on the design for the repairs that would begin in Spring 2017 under Oroville Emergency Recovery. The design work for the Oroville Emergency Recovery phase began in early-March 2017, less than a month after the initial incident. Regardless of the final condition of the structures after the operation of the FCO Spillway chute finally ceased in May 2017, it was rapidly determined that the foundations of the spillway structures needed to be further explored to better understand the site geologic conditions, provide parameters for the design team (e.g., range of rock shear strength, rock and dowel anchor designs, and filter compatibility), investigate the FCO Spillway chute that would likely remain in place, and to anticipate construction issues (e.g., rippability, areas prone to slope instability, and groundwater conditions interfering with excavations).

3.1. EXPLORATIONS TO UNDERSTAND GENERAL SITE GEOLOGIC CONDITIONS

The Oroville Dam site was one of the most studied dam sites of its time. That said, many of the eroded and scoured areas around both the FCO Spillway chute and the Emergency Spillway exposed fresh geology that clearly indicated the need for additional explorations to better understand and define the geologic site conditions.

The FCO Spillway chute failure initiated in a portion of the chute founded on intensely-weathered to decomposed amphibolite rock (Fig. 4). Within this initial scour hole, the depth of rock scoured out ranged up to 30 m (100 ft). Intermittent spillway discharges resulted in the creation of a large erosion channel leading away from this initial scour hole and running downslope to the left of the damaged FCO Spillway chute (Fig. 4). Within this left erosion channel, the near vertical eroded rock faces were as tall as 60 m (200 ft). The left side of the scour hole and erosion channel generally consisted of a thin veneer of soil or colluvium at the top, about 6.5 to 10 m (20 to 30 ft) of moderately-weathered amphibolite, with slightly-weathered amphibolite below (Fig. 4). There was no intensely weathered to decomposed rock observed in this left channel exposure. The zone of intensely weathered to decomposed rock previously mapped within the chute itself had been scoured away.

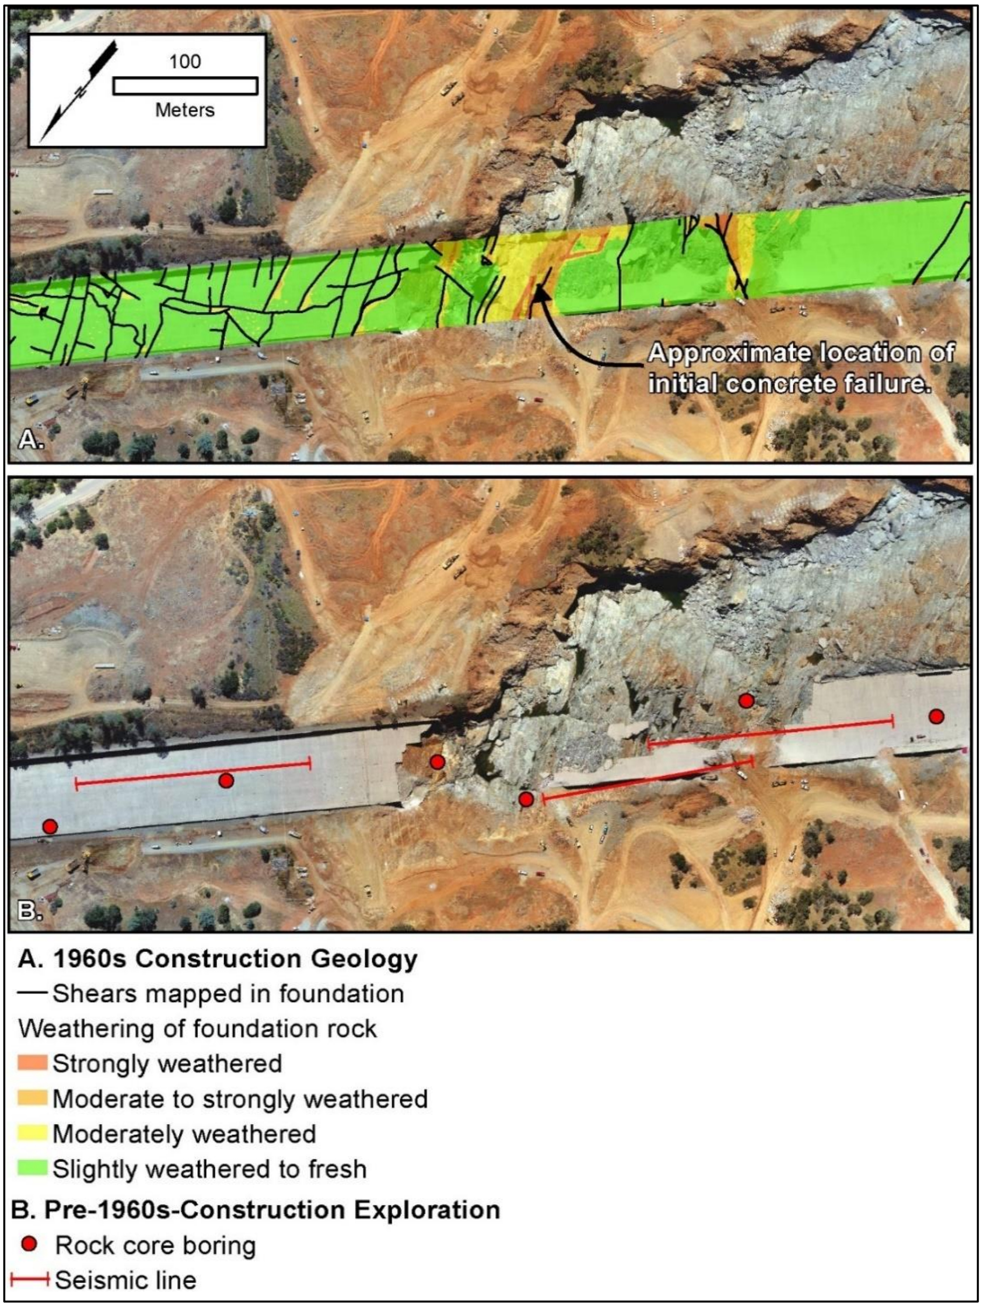

Figure 4
A. Geologic map of FCO Spillway Chute showing initial concrete failure location [6]. B. Aerial photo showing pre-1960s-construction exploration locations [5].

However, on the right side of the chute's scour hole, there was an area of intensely-weathered rock that continued to ravel into the scour hole during the Spring 2017 FCO Spillway releases. These disparate exposures raised questions about the continuity of rock weathering and indicated that the presence of cross-cutting shears could greatly affect the continuity of rock materials. Exploration locations were added to investigate the continuity of similar rock materials.

In the days after the Emergency Spillway flows, between February 10 and 12, 2017, water was observed to be seeping immediately downstream from the Emergency Spillway structure through fractures in the rock with very little head. This led to questions of the efficacy and integrity of the original grout curtain beneath the Emergency Spillway. Exploration locations were added on both sides of the Emergency Spillway to investigate the rock conditions and the hydraulic conductivity of the rock formation.

Figure 5 - Photo of the scour hole and channel forming to the left of the FCO Spillway chute illustrating the geology left behind by erosion and scour. Five drill

rigs are visible in the FCO Spillway chute and one on the right side of the chute).

In erosion gullies created by the flowing water, interpretations based on new reconnaissance-level geologic mapping suggested some larger shears might project back towards the FCO Spillway chute, resulting in unfavorable conditions. These features needed to be explored in detail to assess the overall stability and foundation conditions for the new replacement spillway chute. A series of rock-core borings was added to identify and delineate the continuity of these shears, with inclinometers installed to monitor the stability of the slopes in critical areas.

The examples above are representative of the types of geologic features targeted to investigate the geology of the site. These types of features were explored primarily by drilling borings with further information derived from the downhole televiewer, surficial geologic mapping, seismic lines, and instrumentation.

3.2. EXPLORATION FOR DESIGN OF OROVILLE EMERGENCY RECOVERY

At the onset of the OER design effort, there were many spillway repair alternatives being examined. Not knowing which design alternative would be selected, the exploration plan accommodated each of the repair alternatives and the issues specific to each alternative. The major design components included repairs or replacement of the FCO Spillway chute, fortifying the Emergency Spillway monolith weirs against potential sliding or over-turning, construction of an erosion cutoff wall downstream from the Emergency Spillway, and erosion protection of the ground surface between the erosion cutoff wall and the Emergency Spillway.

The replacement of the FCO Spillway chute included modifications to the original design features that would bring the chute to current design standards. These modifications included longer chute slab anchors, new underdrains below the slabs (not within them), enhanced underdrain filter designs, and so on. To ensure adequate chute slab anchor lengths, unconfined compressive strength testing was performed on core samples from the foundation rock to accurately calculate the required bond length for anchorage into moderately-weathered or better rock, and for anchorage into intensely-weathered or decomposed rock. Geotechnical borings were also added to collect representative samples of the intensely-weathered to decomposed rock that might be in contact with the chute underdrain materials. These materials were then tested to help design the filters for the underdrain system.

The design criteria for the erosion-resistant cutoff wall within the unlined Emergency Spillway foundation required at least 4.5 m (15 ft) of embedment into the slightly-weathered or better rock. Many rock-core borings were added to the exploration plan to determine the geologic conditions for the proposed erosion-resistant cutoff wall. Several surface P-wave geophysical lines were also performed to examine the variability of rock weathering in the upper 15 m (50 ft). The alignment of the erosion-resistant cutoff wall, which later was designed as a secant pile wall, was adjusted during the design to minimize pile depths based on the geologic conditions encountered.

3.3. FCO SPILLWAY CHUTE EXPLORATION

A major component of the geologic and geotechnical explorations took place within the FCO Spillway chute alignment. As the design process progressed, it became apparent that the reconstruction of the chute would likely take at least two years to complete. Between the two construction seasons, during the Winter Flood Season of 2017-2018, the upstream portion of the original chute nearest the headworks structure would need to remain in place [3]. However, for the design team and dam safety regulators to be comfortable with this situation, many explorations were performed within the upper chute to better understand the actual thicknesses and quality of the concrete slabs, foundation rock quality, concrete-foundation interface conditions, and so on.

To address design concerns, the chute slab concrete was cored at 68 exploration points within the upper half of the FCO Spillway chute, upslope from the initial scour hole. Of the 68 locations, 24 were additionally cored into the foundation rock to assess foundation rock conditions. Falling-head permeability tests were completed in 18 locations to test the bond between the slab concrete and the foundation rock. Ground-penetrating radar (GPR) was also used to image the concrete and the underlying foundation rock in the upper chute; the results from the GPR imaging were used to guide some of the physical exploration locations. Eight wireless vibrating-wire piezometers were installed in six locations to determine groundwater pore pressures beneath the chute slab during spilling and non-spilling events.

In addition to explorations to address design concerns, DWR performed forensic studies that aimed to address the following potential physical factors raised by the Independent Forensic Team in their preliminary report [10]: 1) thickness of the chute slab above herringbone underdrains; 2) variations in slab thickness, 3) characteristics of weathered foundation rock and intensely-weathered rock; 4) foundation rock bonding with the concrete slab; 5) effects of extended drought impacts on foundation materials; and 6) groundwater pressures exerted on the chute slab.

Four areas of the undamaged concrete-lined FCO Spillway chute were evaluated using saw-cut trenching to examine the foundation conditions and potential physical factors that might have contributed to the damage of the FCO Spillway chute. Each area of the saw-cut concrete chute was carefully lifted away from the surrounding slab concrete to minimize disturbance. Each location was then photographed in detail prior to performing any investigative work. Once the area was thoroughly documented, the gravel surrounding the perforated underdrain pipes (vitrified clay pipes placed during original construction) was hand-picked from around the pipes. Any non-rock materials mantling the foundation rock, such original excavation debris, were measured, sampled, described, and then cleared off for final geologic mapping of the foundation rock surface.

The findings from the FCO Spillway chute explorations indicated that – where measured – the concrete slab was greater than 18.3 cm (7.2 in) thick above the underdrain pipes; the concrete slab thickness varied from about 38 cm (15 in) to over 2.1 m (7 ft); there were not large extents of intensely-weathered to decomposed rock; there was generally good bonding between the rock and the concrete slab; and groundwater piezometric pressures within the chute's foundation rock were typically below the concrete-foundation interface.

4. EXECUTION OF EXPLORATION PROGRAM

The initial exploration program was outlined by a team of engineers, geologists, and construction specialists between March 6 and 12, 2017. The first drill rigs were mobilized on March 13, 2017, and drilling began on March 14, 2017. The initial exploration program consisted of 60 rock-core borings, 16 seismic lines, 10 inclinometers, and 10 vibrating-wire piezometers. As design efforts progressed and changed, the exploration program was modified to accommodate those design changes. By the end of July 2017, the exploration program had been expanded to 104 rock-core borings (over 2800 m [9180 ft] of rock core), 22 seismic lines, 15 inclinometers, 15 vibrating-wire piezometers, and 11 piezometers (both open standpipe piezometers and observation wells; Fig. 6). In order to successfully execute a large amount of exploration in a short amount of time (about 4 months), an exploration workplan was prepared to establish the project protocols, a wide variety of resources was identified and mobilized, a field QA/QC program was implemented, a team of geologists and geotechnical engineers was stationed in the office to analyze the incoming data, and regular consultations with the design team were held to ensure that design needs were being met.

4.1. EXPLORATION METHODS

Several methods were utilized to explore the subsurface conditions in and around the FCO Spillway chute and the Emergency Spillway, including the following: concrete and rock-core borings, packer and falling head permeability testing, downhole televiewer surveys – optical and acoustic, borehole geophysical suspension logging, grouted-in-place vibrating-wire piezometers (VWPs), open standpipe piezometers, observation wells, inclinometer casings and instrumentation, P-wave surface geophysics, concrete coring, test pits and bulldozer trenches, laboratory testing of rock and soil for index properties and shear strength data, thin-section petrographic analysis, and x-ray diffraction. These methods are generally described below.

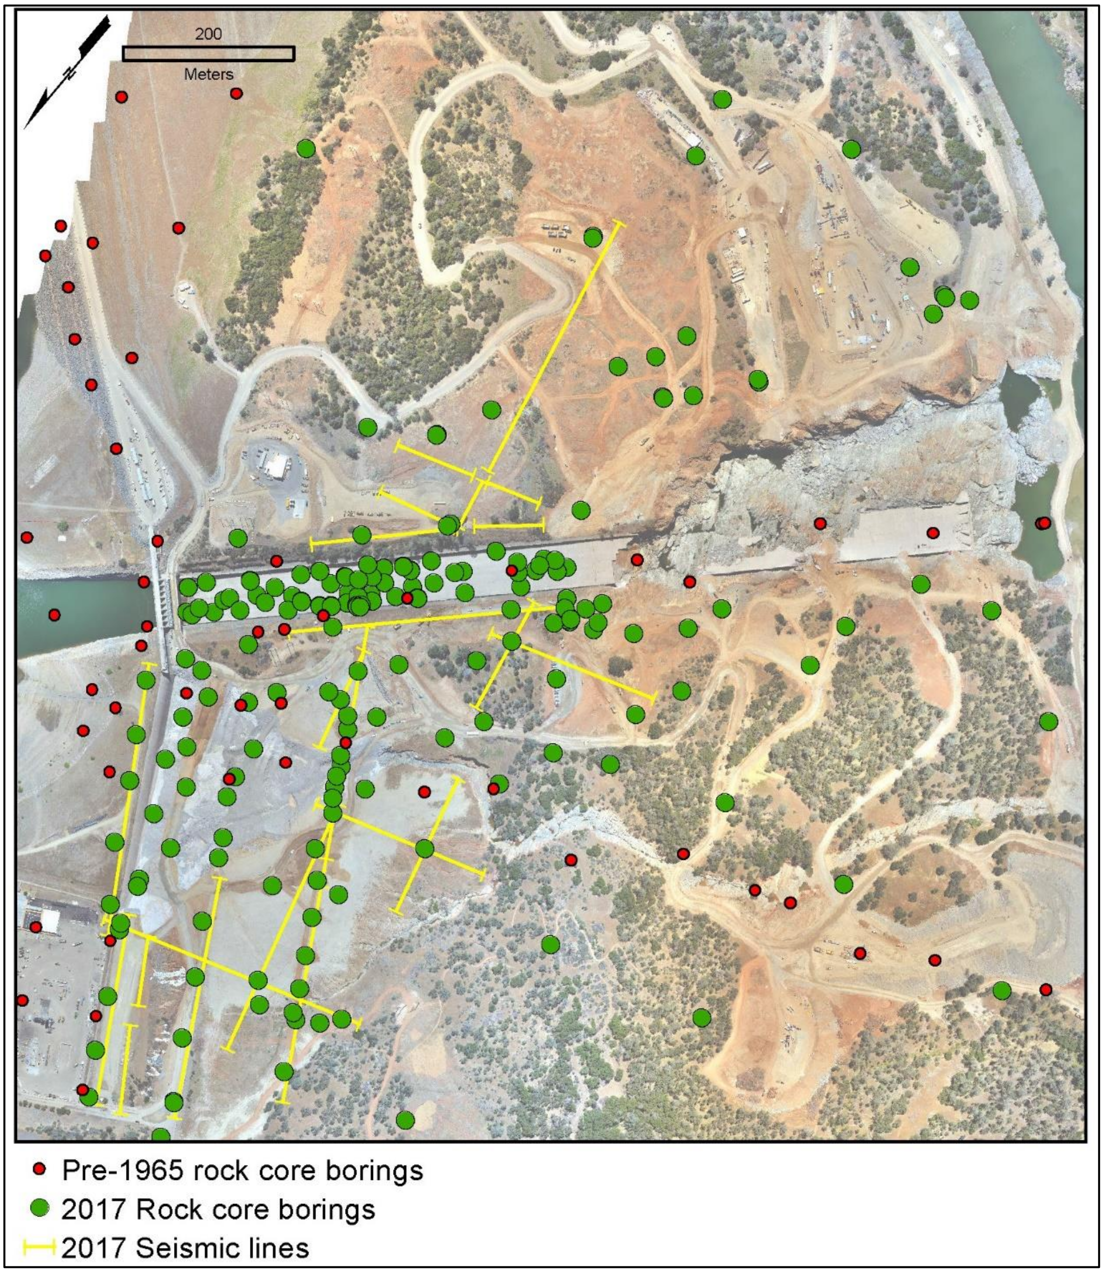

Figure 6 - FCO Spillway Recovery geologic exploration program.

All the rock-core borings were drilled at least 6 m (20 ft) into fresh, un-weathered amphibolite, with drilling depths that ranged up to about 60 m (200 ft). Each boring was logged in accordance with the project procedures, which included the classification of rock lithology, degree of weathering, discontinuities and infilling, Rock Quality Designation (RQD), and descriptions of other relevant geologic features.

The drill rig geologist recorded drilling conditions such as rod drop, water loss and drill chatter, as well as sampling locations, material types, and any occurrences that might have proved informative to characterizing the subsurface conditions. Upon reaching total depth, all drill holes were geophysically logged using either acoustic or optical televiewer, or both, to ensure that the orientation of any discontinuity was documented. Although geophysical logging of nearly every borehole may seem excessive, the decision to geophysically log each boring proved invaluable, considering the time constraints and the need to develop a comprehensive geologic site model to support the range of OER design options being considered. Selected drill holes were additionally logged using suspension P- and S-wave velocity logging techniques to correlate with surficial geophysical results. Upon completion of each drill hole, the borehole was either completed as a VWP, open standpipe piezometer, inclinometer, or it was backfilled with cement-bentonite grout. The ultimate disposition of the borehole completions was developed using a collaborative process with the design team to confirm that the overall purpose of each borehole and the associated design objectives were being accomplished.

Nearly all of the instrumentation (piezometers and inclinometers) was telemetered and viewable on an online dashboard in real time. Six locations within the FCO Spillway chute were completed as grouted VWPs with a data logger and wireless antenna; these data were retrieved manually, rather than through the online dashboard, and the instruments were installed prior to the last controlled spill through the FCO Spillway chute in May 2017.

All drilling work within the FCO Spillway chute began by initially coring through the chute concrete using a 20.3 cm (8 in) diameter thin-walled coring bit. Once the coring reached the concrete-foundation rock interface, select locations were continued using rock-coring methods. Select rock core and hand samples were obtained for shear strength testing and petrographic analysis. Samples of shear gouge and compacted clayey fines from the foundation were analyzed for index properties testing, including mechanical sieve, hydrometer, and Atterberg limits. In addition, select samples were analyzed for clay mineralogy, using x-ray diffraction.

4.2. Resources

Execution of an exploration program of this magnitude is challenging under normal circumstances. In this case, there was very little time for the OER design team to assess the site conditions, review historic construction records, and develop the initial field exploration program. The demand on qualified personnel, including exploration subcontractors and testing laboratories, was unprecedented in magnitude and response. The execution of the initial exploration program, consisting of 60 borings and 16 P-wave surface refraction lines, along with the associated instrumentation, was needed within a very short time-frame to be incorporated into the spillway repair. The exploration program included test locations within the concrete-lined portion of the FCO Spillway chute, which in turn required special coordination with the OER Incident Command personnel and dam safety regulators, and had to be timed to coincide with short-duration spillway outages. Resources required to perform this work included concrete coring units, rock-coring drill rigs, surface and borehole geophysical testing, engineering geologists, field and office management, instrumentation specialists, and construction support (to build access roads, create drill pads, dig mud pits, etc.). Other required support included environmental scientists, archaeologists, and cultural resource specialists to confirm that the proposed drilling sites, surface geophysical lines, and other work items (e.g., temporary roads and/or equipment staging areas) would not impact documented sensitive areas within the project site.

Ultimately, up to 10 drill rigs, with drilling contractors from three private firms and two federal agencies, were utilized to perform the drilling work. Two geophysical firms were selected to perform the P-wave surface refraction lines. Two geophysical firms performed downhole acoustic and optical televiewer surveys, and P-S suspension logging on select boreholes.

For every drill rig, there was at least one engineering geologist to log the rock core. Experienced engineering geologists logging the rock core were resourced from within DWR, two federal agencies, and several consulting firms. The qualifications of the engineering geologists had to be reviewed and approved by Federal dam safety regulators prior to working on the site. In order to maintain consistency with so many engineering geologists, an exploration work plan was prepared in the days leading up to the initiation of the exploration program. The work plan detailed the logging nomenclature and field procedures defined for the project.

At any given time, there were at least two experienced, on-site engineering geologists coordinating the scheduling and movement of drill rigs, clearing sites with environmental and cultural specialists, scheduling the rotating geology staff, interfacing with the OER Incident Command, holding safety meetings, and all the other typical daily routines for an exploration program (but 10 times as big). There were typically 15 to 20 engineering geologists on site daily during the peak of exploration who were logging rock core, geologically mapping rock exposures, and coordinating drill rig and personnel movements. Many engineering geologists and engineers were in the office, performing real-time data analysis for the design efforts.

4.3. Quality Assurance and Quality Control

The drill rig engineering geologists logging the rock core were from several different agencies and consulting firms. To ensure a consistent approach to recording drill hole information, including handling and logging of recovered rock core and performance of borehole testing, a full-time QA/QC Engineering Geologist was assigned to review field logs and recovered rock core throughout the duration of the field exploration program. The QA/QC function included daily monitoring of drilling activities at each drilling location to confirm compliance with the work plan, performing daily review of borehole logs to ensure completeness and accuracy of the logged conditions, and reviewing the final, completed borehole logs.

The borehole logging QA/QC review used a multi-step approach to oversee the process. The initial step consisted of a QA/QC review that was performed in the field by the on-site QA/QC Engineering Geologist to verify that each drill rig engineering geologist was meeting DWR’s borehole logging standards for the project. This review was performed daily at the drill rig, during drilling and sampling. Upon completion of each borehole field log, the QA/QC Engineering Geologist performed an initial field log review to check consistency of logging and completeness of the field log. Then, the borehole log was reviewed and compared to the recovered rock core. If necessary, revisions to the borehole log were made as part of the technical review. The field log was then drafted using Bentley gINT with the QA/QC Engineering Geologist maintaining control over the process until the draft borehole log was accepted as final.

5. CHALLENGES AND LESSONS LEARNED

The geological and geotechnical explorations for the design of OER was a complete success. This success was made possible through the commitment of DWR staff and DWR’s key support personnel sourced from the public and private sectors, along with field services organizations. This integrated team truly rose to meet the challenges. One of the major challenges for the geologic and geotechnical design team was the highly variable geologic conditions, which changed significantly both laterally and vertically within short distances. While there was only one geologic rock mass (i.e., amphibolite) truly present across the site, the cross-cutting shears created a patchwork of rock weathering and fracturing conditions. The overall rock mass strength of the amphibolite was controlled by the degree of weathering and the intensity and orientation of discontinuities (e.g., shears and joints) within the rock. The integration of a detailed surface and borehole geophysics program, coupled with extensive rock-core borings, proved invaluable in making proper assessments of foundation rock quality for this project. The surface refraction methods greatly assisted in developing initial interpretations of rock uniformity (horizontal and vertical) and estimates of rock mass strength through correlations to nearby boreholes.

It was critical to this success that the OER design team assembled very early on to discuss geology and geotechnical needs that might arise during the design process. This allowed a relatively small group of geologists, geotechnical engineers, and construction specialists to develop a comprehensive, but adjustable, exploration program to address design needs. As a result, the geologic and geotechnical exploration program provided high-quality results, while remaining responsive and adaptable to the iterative design process needed to execute the spillway repairs under the very short timeframe.

Active, on-site coordination and QA/QC procedures were critical to the successful implementation of the field exploration program. Although there were daily challenges, the experienced on-site engineering geologists and geotechnical engineers remained flexible and good humored throughout.

The configuration of real-time, accessible instrumentation readings allowed the close monitoring of potential slope instability and changes in groundwater conditions. Placing the instrumentation data in one centralized location that was easily accessible by anyone on the team at any time provided the ability to examine short- and long-term performance trends quickly and remotely. Centralized data storage was essential for time-critical information to be accessible by the design team as needed.

ACKNOWLEDGMENTS

The authors wish to acknowledge many firms and/or entities who assisted with the geologic and geotechnical exploration program: DWR engineering geologists from several divisions, state-wide; Lettis Consultants International, InfraTerra, the United States Bureau of Reclamation, the United States Army Corps of Engineers, Gregg Drilling and Testing, Cascade Drilling, Ruen Drilling, GeoVision Geophysical Services, Gasch Geophysics, NorCal Geophysical (with Terracon), GEI Consultants, Spectrum Petrographics, Cooper Testing Laboratory, Blackburn Consulting, Willamette Geological Service, and Syblon Reid Contractors. Specifically, thank you to Nick Hightower, Bryan Dussell, and Andy Tate, who organized the field teams and were instrumental in successfully executing this enormous exploration program.

SUMMARY

Starting on February 7, 2017, a scour hole formed in the concrete-lined Gated Spillway chute at Oroville Dam. Continued intermittent releases between February and May 2017 led to further damage of the Gated Spillway chute and the creation of a large erosion scour channel to the left of the lower chute. During this time, the unlined Emergency Spillway was used for the first time to release reservoir flows. Significant erosion and scour of the weathered rock at the unlined

Emergency Spillway during just two days of limited overflow release resulted in concerns for the Emergency Spillway structures and the evacuation of communities downstream of the dam.

In early March 2017, the Oroville Emergency Recovery (OER) design team was formed to design and implement repairs in order for the Gated Spillway chute and the Emergency Spillway to be able to safely pass reservoir inflows during the following 2017-2018 Winter Flood Season. Within a week, the OER design team had identified a number of potential repair alternatives and the associated geologic and geotechnical data required to develop the designs. This paper provides a background of the geologic conditions known prior to the incident and the subsequent development and execution of the geologic and geotechnical investigation program to support the OER.

The geologic materials at the Oroville Dam site are structurally complex, with numerous cross-cutting shear zones that make predicting ground conditions difficult. The complex geology coupled with the urgent time-frame in which to develop and implement a field investigation and laboratory testing program and then provide useful high-quality subsurface geologic and geotechnical information to the OER design team presented many challenges. These challenges ranged from resource management, to assessing a wide range of conceptual and then preferred design components, to field investigation QA/QC, to expedited data analysis and interpretations needed to properly support development of the time-critical project design.

By the end of the design phase of geologic exploration in July 2017, the exploration program had grown to over 100 rock-core borings, 22 seismic lines, 26 piezometers, 15 inclinometers, 68 concrete cores, trench explorations, thin section petrographic analysis of over 30 rock samples, x-ray diffraction of 6 clayey samples, and geotechnical testing of many more rock and soil samples.

In order to accomplish the exploration program, consistent documentation was achieved by preparing a workplan and having an experienced full-time engineering geologist serve in a QA/QC role to ensure that the workplan was being followed. Results of the explorations were relayed to the OER design team in real time to be incorporated into the engineering design package. The geological and geotechnical exploration program was successful because of dedicated, coherent design and field teams.

1. INTRODUCTION

Oroville Dam is located on the Feather River in northern California (USA). At 234.7 m (770-ft) tall, this earth embankment is the tallest dam in the United States. With its 4.3 billion m3 (3.5 million acre-feet) of storage, Lake Oroville is the second largest reservoir in California, supplying water to cities as far south as Los Angeles. The Oroville Dam, reservoir (Lake Oroville), and hydropower plant facility is the flagship of the State Water Project (SWP), which is owned and operated by the State of California, Department of Water Resources (DWR).

**OROVILLE BARRAGE RÉPONSE D'URGENCE ET RESTAURATION DE DÉVERSEMENT - ACTIVITÉS D'INGÉNIERIE HYDROLOGIQUE ET HYDRAULIQUE POUR INFORMER LE FONCTIONNEMENT ET LA CONCEPTION*

The 2016-2017 Winter Storms brought record breaking precipitation to the Northern California Sierra mountains including the Feather River watershed. On February 7, 2017, the Oroville Dam's 54.5 m (179-ft) wide Flood Control Outlet (FCO) Spillway chute (Fig. 1) was releasing water to control the Lake Oroville reservoir level in accordance with the prescribed operations plan. During this operation, the FCO spillway suffered a catastrophic failure of the lower chute area eventually resulting in the loss of approximately 427 m (1400 ft) of the lower chute, including the scour of more than 1.2 million m3 (1.6 million yd3 of soil and rock materials. On February 11, 2017, the Emergency Spillway (Fig. 1) was used for the first time since the project was completed in 1968. During this operation, significant erosion and scour caused by the Emergency Spillway overflow led authorities to fear for the safety of the spillway structures, resulting in the activation of the Emergency Action Plan and evacuation of about 188,000 persons from downstream communities.

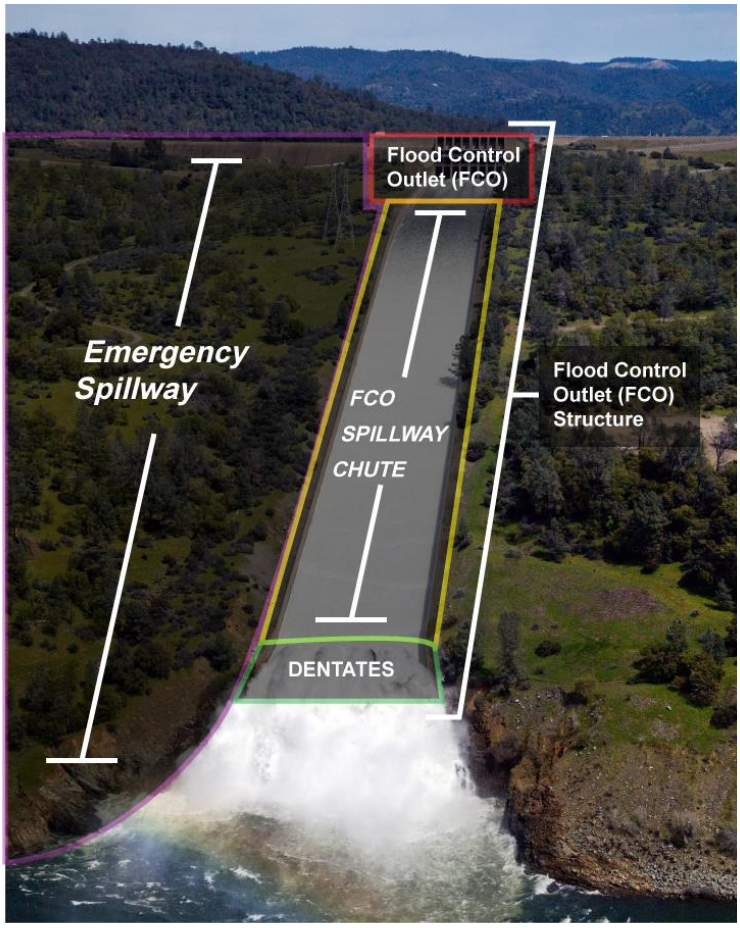

Fig. 1 Flood Control Outlet (FCO) Structure and Emergency Spillway, March 2011

This paper is part of a series developed by the State of California, Department of Water Resources (DWR) to describe the Oroville Dam Spillway Incident Emergency Response and Recovery. This paper focuses on (a) the hydrologic engineering, hydraulic engineering, and reservoir operation analyses completed during the incident and later as part of the recovery; (b) hydrologic, hydraulic, and operation analysis models and methods used for the analyses; (c) strategies for development, review, and coordinated use of the models and methods by a large team of analysts; and (d) problems faced and solutions found as the models were configured, calibrated, and applied to provide information to design staff and influence interim operation decisions required throughout the response and recovery efforts.

2. PROJECT FEATURES AND HISTORICAL PERFORMANCE

The original design of Oroville Dam, including selection of types and capacities of spillways and placement of the Flood Control Outlet (FCO) Spillway chute and Emergency Spillway relative to the embankment, and the details of a tightly-integrated operation policy, were the result of more than thirteen years of hydrologic and hydraulic (H&H) engineering and operation studies.

An initial design and operation policy was proposed in 1953 and refined in 1955 with results from a scaled physical-model study [2]. To accommodate updated operational requirements by the United States Army Corps of Engineers (USACE), the 1955 design was revised in 1958 and again in 1962. A physical modeling study of the revised spillway concept was carried out in 1962 by the United States Bureau of Reclamation (USBR). To address issues identified then, the FCO Spillway chute and the Emergency Spillway were configured as two separate structures [3].

The Oroville Project consists of the main dam, two saddle dams, a flood control outlet structure, an emergency spillway with concrete weir upstream of an unlined hill slope, and a hydropower plant.

The layout of the spillways is shown in Fig. 2, along with the FCO Spillway chute flow and erosion during the failure incident. The 1310.6 m (4300 ft) long FCO Spillway chute includes an unlined approach channel, a flood control outlet structure, a spillway chute, and an energy dissipater. The outlet structure has eight radial gates each 5.36 m (17 ft 7 in) wide separated by six 1.52 m (5 ft) thick piers and one central 2.44 m (8 ft) thick pier. Finally, the geometry of the outlet structure was optimized using results of 1965 physical modeling studies [4]. The FCO Spillway chute is a rectangular concrete-lined channel with a constant width 54.46 m (178 ft - 8 in). Four reinforced-concrete dentate structures at the end of the chute, the design of which is based on these same 1960s studies, dissipate the water energy. The Emergency Spillway includes an ogee section with multiple concrete monoliths of varying heights and a low-sill, broad-crested weir on natural ground. The area downstream of the Emergency Spillway was not cleared of vegetation because the expected infrequent use did not justify the potential adverse economic and aesthetic impact.

Fig. 2 Photograph of Oroville, showing spillways and main dam embankment

The combined spillway capacity was designed to safely pass the probable maximum flood (PMF). During this event, the design FCO Spillway chute maximum release is 8382 m^3/s (296,000 ft^3/s), and the design Emergency Spillway discharge is 10506 m^3/s (371,016 ft^3/s at reservoir pool elevation 279.5 m (917 ft). Integrated design features and operation rules were developed to control a standard project flood (SPF) inflow of 12460 m^3/s (440,000 ft^3/s) without using the Emergency Spillway, and with the FCO Spillway chute release limited to 4248 m^3/s (150,000 ft^3/s). This FCO Spillway chute release target was set to protect downstream urban and agricultural areas from potential flooding.

In the 49 years since construction, the FCO Spillway chute has been used 25 of those years and the remaining 24 years the FCO spillway was not operated. Over operational period, the maximum daily release through the FCO Spillway chute equaled or exceeded 2832 m^3/s (100,000 ft$^{3'}$s) four times. Releases have been at or exceeded 4248 m^3/s (150,000 ft^3/s twice, in February 1986 and January 1997. Fig. 3 shows the FCO Spillway chute, looking downslope, in February 1986. As predicted during design, flow along the chute appears to be aerated through the development of a boundary layer as well as through the piers of the Flood Control Outlet. DWR maintenance records show no significant cavitation damage through the project history [5]. Any damage patterns were random, not clearly related to a particular flow condition in the FCO Spillway chute.

Prior to the event of 2017, the Emergency Spillway had never been used, so no record of historical performance existed for that facility.

Fig. 3 Photograph of FCO Spillway chute during release of 4248 m^3/s (February 21, 1986)

3. HYDRAULIC ENGINEERING, HYDROLOGIC ENGINEERING, AND RESERVOIR OPERATION ANALYSES DURING 2017 INCIDENT

During the 2017 incident, hydrologic and hydraulic engineering and reservoir operation analyses provided information to support decision making by DWR management. Lake Oroville inflow forecasts were made every six hours by DWR staff and the United States National Weather Service (NWS), using conceptual models of watershed hydrology. As snow had accumulated in much of the contributing Feather River Basin watershed, these forecasts included assessments of both runoff from rainfall at lower elevations and snowmelt at higher elevations.

Reservoir behavior and operation with various operation and potential failure scenarios were simulated to predict future pool elevations and timing of potential Emergency Spillway discharge. For this, reservoir conditions were monitored continuously by onsite DWR staff, reported using all available resources, and used as boundary and initial conditions for the models.

Inundation that could result from potential failure of the main dam was predicted and displayed with maps included in the dam's Emergency Action Plan (EAP), which emergency and incident command teams consulted. These inundation maps were augmented with situation-specific maps prepared from near-real-time forecasts as the incident progressed. Both were used to inform local officials regarding the need for evacuation of downstream residents. For inundation mapping, the HEC-RAS [6] and FLO-2D applications [7] were used; maps were created by overlaying computed flood flow depth grids on feature maps with geographic information system (GIS) software. Terrain data and bathymetric data had been collected by DWR in prior years for analysis of downstream floodplain risk and for preparation of the EAP.

Additional hydraulic analyses provided DWR managers with information about potential flow paths along the hill slope downstream of the Emergency Spillway, and with estimates of potential debris and sediment loads in the Feather River downstream. The hill slope was modeled with a 2-D model created with HEC-RAS.

Challenges for analyses during the event in February 2017 included: (1) the need for almost immediate turnaround to provide information critical for decision making; (2) the lack of certainty about near-future inflows to the reservoir due to uncertainty about the weather and watershed response; (3) the lack of certainty about behavior of the never-used Emergency Spillway, with unstable terrain; and (4) the risk of misunderstanding or misinterpreting model results as critical decisions were made. Solutions included: (1) the use of cloud computing, with parallel model runs on multiple servers in the Amazon cloud; (2) analysis with ensemble forecasts, coupled with sensitivity analysis with varying inflow hydrograph properties; (3) constant monitoring and reporting to modelers of observed changes to the spillways so model inputs could be adjusted; and (4) careful communication of results by DWR and consultant subject matter experts.

4. RESERVOIR OPERATION ANALYSES DURING RECOVERY

DWR's Oroville Emergency Recovery (OER) team considered options for restoring the FCO Spillway chute and the Emergency Spillway, and selected the optimal configuration. A consideration in this selection was the way Lake Oroville would be operated to protect public safety prior to, during, and following construction — the reservoir operation plan. Through reservoir operation analysis, alternative schemes were assessed and refined. Once the new spillway configurations were selected, refinement of the operation policy continued (and continues as this paper is written, as full project restoration is not yet complete), with information for decision making provided by reservoir operation analyses.

The reservoir operation analyses were structured to:

- Assess the flood risk of removing the FCO Spillway chute so it could be reconstructed, and identify or confirm decisions about the timing of this removal and reconstruction. Based in part on this assessment, a decision was made to start construction in May 2017.
- Develop an operations plan for the period of construction in 2017 that did not rely on the FCO Spillway chute and that minimized flood risk during construction. This led to drawing the reservoir down to elevation 213.4 m (700 ft) prior to the Winter Flood Season, using the powerhouse outlets.
- Develop flood operations plan for the 2017-2018 Winter Flood Season to safely manage potential flood inflows with the partially reconstructed FCO Spillway chute, limiting releases through that spillway to 2832 m^3/s (100,000 ft^3/s). Because of the RCC invert, the maximum flow from the partially reconstructed FCO chute was limited to 2832 m^3/s.
- Develop flood operations plan that provides a 2018 construction season window with no reliance on the FCO Spillway chute.
- Develop new flood operations plans for the period following the completely restored FCO Spillway chute.

Flood operations for Lake Oroville and Oroville Dam are prescribed by the USACE, so all analyses were completed in collaboration with USACE staff, and all flood operations plans were submitted to the USACE, Federal Energy Regulatory Commission (FERC), and the State of California, Department of Water Resources, Division of Safety of Dams (DSOD) for their collective review and approval. Although flood protection and dam safety are the overriding operation objectives, operation plans also considered: water quality and environmental flow objectives, the need for water to protect endangered species, the rights of water users, and contractual commitments for water delivery by California's SWP.

The USACE HEC-ResSim application [8] and custom applications developed by DWR were used for the analyses of reservoir operations; the majority of the custom applications are spreadsheet-based. The HEC-ResSim applications were configured to simulate operations with various conditions of the reservoir outlets, including FCO Spillway configurations with reduced capacities. The simulations used various boundary conditions: (a) the historical period of record; (b) forecasts of near-term inflow provided by the NWS; and (c) statistically-derived hydrographs with flood volumes of specified exceedance probability, as developed with the hydrologic engineering analyses described below. The simulations used a daily or sub-daily time step, computing time series of pool elevation and reservoir storage, release through all Oroville Dam outlets, and discharge at downstream locations to which releases are routed. This information permitted assessment of the flood risk downstream and the risk to the structural integrity of Oroville Dam.

Challenges in reservoir operation analysis for Oroville Dam included: (1) the need for quick turnaround to set guidelines during construction and provide information critical for decision making about recovery; (2) the need for statistical analysis from which reservoir inflow probability information could be derived; (3) the lack of certainty about seasonal and sub-seasonal inflows to the reservoir due to uncertainty about weather; (4) the risk of misunderstanding or misinterpreting model results as critical decisions were made; and (5) the requirement for concurrence by USACE, FERC, and DSOD with changes in Lake Oroville operations. Solutions included: (1) the use of cloud computing, with parallel model runs on multiple servers in the Amazon cloud, and multiple modelers to configure and execute model runs and synthesize results; (2) parallel statistical analysis of reservoir inflow data by hydrologic engineering experts, as described below; (3) analysis with ensemble forecasts, historical period of record, and statistically-based hydrographs; (4) careful communication to decision makers of results by DWR and consultant experts; and (5) continuous collaboration and coordination with reviewers and regulators through in-person meetings, a series of webinars, and technical memorandums for which review and comments were solicited.

The outcome of the reservoir operation analyses was a series of interim operation plans approved by regulators and implemented by DWR. Operation following those plans has been successful thus far, with the initial phase of construction completed in November 2017.

5. HYDROLOGIC ENGINEERING ANALYSIS DURING RECOVERY

Hydrologic engineering analysis during recovery provided information for sizing the restored FCO Spillway chute and for developing the operation plans described above. The analyses included the following:

- Reassessment of the PMF, a design event that fixes the capacity of the spillways and the operational relationship between release capability and reservoir storage.
- Assessment of hydrologic hazard in terms of statistically likely seasonal inflows to the reservoir. Results of this analysis informed decision makers about the schedule of construction and about operation before, during, and following various phases of the construction.

DWR had scheduled the PMF re-analysis for Oroville Dam prior to the February 2017 incident as a part of normal relicensing activities. The PMF update was to account for: (a) enhanced understanding of atmospheric conditions that lead to the probable maximum precipitation (PMP) — the precipitation event that causes the PMF; (b) improved hydrometeorological monitoring, which yields better information about likely weather and water conditions; (c) improved watershed rainfall-runoff-routing model capabilities, including capabilities to describe watershed properties that influence runoff at greater resolution and with increased accuracy; and (d) changed atmospheric, hydrologic, hydraulic, or operational conditions. Following the 2017 incident, the pace of PMF re-analysis was accelerated. Activities included:

1. Developing a new watershed precipitation-runoff-routing model. In addition to commonly expected features, this model included snow accumulation and melt. The USACE HEC-HMS software application was used for this analysis [9].
2. Calibrating the model with historical events, including events with snow accumulation and melt. Lake Oroville's contributing watershed (the Feather River Basin) permits this, as it is well gauged with stream gauges, rainfall gauges, temperature, wind, and radiation sensors, and snow courses.
3. Selecting final model parameters for analysis of extreme events.
4. Verifying the model using data from precipitation events in addition to those selected for calibration.
5. Updating estimates of the PMP, using guidance from the NWS and DSOD. For this analysis, precipitation boundary conditions were defined by scaling observed storms to have PMP flood volumes.
6. Selecting appropriate initial snowpack and other conditions for application of the PMP storms to the HEC-HMS model.
7. Applying the model to compute PMF inflows.
8. Routing PMF inflows through the reservoir to determine maximum pool elevations and outflows. This was accomplished using the HEC-ResSim software application developed for and used in the reservoir operation analysis described above.

Findings of the PMF study were as follows:

1. The adopted updated PMF inflow hydrograph has a peak flow equal to 21189 m^3/s (743,800 ft^3/s) and a volume of 3.8 billion m^3 (3.1 million acre-feet).
2. Routing the adopted PMF inflow hydrograph with the as-built configuration of the dam and outlets yielded a maximum reservoir pool elevation equal to 280.1 m (919.1 ft) (NGVD29). This maximum reservoir pool does not spill over the dam (crest elevation 281.0 m [922.0 ft]).
3. With the adopted PMF inflow and gate operations, the peak outflow totals 20419 m^3/s (721,100 ft^3/s).
4. Wind wave setup and runup potential is great — up to 2.0 m (6.7 ft). However, the winds required to produce this extreme event are not likely to occur during large winter storms such as the PMF.

Hydrologic engineering analyses also included seasonal analysis of Lake Oroville inflow volume-frequency. Products included the following:

1. Inflow volume-frequency curves for 1-, 3-, 7-, 15-, and 30-day durations for each month.
2. Hydrographs derived from the monthly frequency curves. These were used to develop inflow hydrographs, which were used as boundary conditions for flood routings with the HEC-ResSim model.
3. Results of flood routings with HEC-ResSim for a set of operation scenarios.
4. Monthly Lake Oroville elevation-frequency analysis information for a variety of design and operation alternatives formulated by DWR.

Challenges in the hydrologic engineering analysis for Oroville Dam included: (1) the need for quick turnaround to provide information critical for decision making about recovery; (2) common difficulties calibrating a precipitation-runoff model and determining appropriate initial and boundary conditions for application with extreme events; (3) the risk of misunderstanding or misinterpreting model results as critical decisions were made; and (4) requirement for concurrence by FERC and DSOD with PMF calculations and conclusions about dam safety based on routing the estimated PMF. Solutions included: (1) the use of cloud computing, with parallel model runs on multiple servers in the Amazon cloud, and multiple modelers to configure and execute model runs and synthesize results; (2) the use of the wealth of hydrometeorological and operational data collected and stored by DWR in the California Data Exchange Center, which is accessible at http://cdec.water.ca.gov; (3) careful communication to decision makers of the results by DWR and consultant experts; and (4) continuous collaboration and coordination with reviewers and regulators through in-person meetings, a series of webinars, and technical memorandums for which review and comments were solicited.

6. HYDRAULIC ENGINEERING ANALYSES DURING RECOVERY

Hydraulic engineering analyses were critical to the quick recovery of Oroville Dam's FCO Spillway chute and Emergency Spillway. The analyses completed included the following:

- Simulation of behavior of flow in the FCO Spillway chute to inform decision makers by the DWR design team. This included computation of water surface elevation profiles and hydraulic forces to inform decision makers about chute curvature and alignment, wall heights, and other design properties. It also included assessment of aeration and cross waves in the chute, and evaluation of cavitation potential due to high velocity flow in the chute. Reviews of the original design, maintenance records, and historical performance of the FCO Spillway were also critical to improve the hydraulic performance of the restored spillway chute.

- Simulation of behavior of flow over the Emergency Spillway's monoliths/weir and down the Emergency Spillway hill slope. Information from this analysis informed designs about the type and extent of protection needed downstream, and methods to increase the factor of safety of the concrete monoliths without adversely impacting the outflow capacity.

The complex hydraulics of the project, the immediate data needs of other teams (structure, geotechnical, and geological), compliance with the current codes and design guidelines, concurrence by regulating agencies (FERC and DSOD), and the available time were some of the challenges faced by the hydraulic engineering team.

To meet the project objectives, the team agreed that: (1) initial hydraulic analyses would be done using simplified one-dimensional (1-D) and two-dimensional (2-D) numerical models, with the resulting data passed to other teams; (2) for selected alternatives, the findings from the simplified 1-D and 2-D models would be verified with three-dimensional (3-D) numerical models; and (3) a 1:50 scaled physical model of the FCO Spillway chute would be developed to validate the findings from the numerical models.

Table 2 summarizes the hydraulic engineering analyses completed and the methods used.

Table 2
Hydraulic Models Used in the Restoration of Oroville Dam's Spillways

Feature Analyzed	Model Type	Modeling Objective
FCO Spillway Chute	1-D models	• Determine flow characteristics (flow depth, velocity, drag force, uplift forces, cavitation index, centrifugal forces, boundary layer thickness, and air content) along the spillway chute profile. • Inform design decisions by structural, geotechnical, and geological engineers, and construction managers regarding best design features and methods of construction.

Feature Analyzed	Model Type	Modeling Objective
	3-D (computational fluid dynamics [CFD]) models	• Refine/update the results from 1-D models. • Assess conditions for which 1-D or 2-D models were not appropriate.
	1:50 scale physical model	• Validate results from 1-D and 3-D models. • Study flow phenomenon for which numerical models were highly uncertain or calibration difficult.
Emergency Spillway	2-D models	• Predict depth and velocity of flow on the hill slope downstream of Emergency Spillway to inform design decisions by structural, geotechnical, and geological engineers.
	3-D CFD models	• Refine results from 2-D models. • Assess and refine design of roller-compacted concrete (RCC) buttress for the concrete monoliths, which cannot be modeled well with simpler models. • Simulate discharge from ogee crest for multiple buttress alternatives.

6.1. FCO SPILLWAY CHUTE ANALYSIS

Hydraulic analyses of the FCO Spillway chute: (1) led to refinement of the FCO Spillway chute alignment (profile); (2) provided information about depths and velocities along the chute; and (3) provided information necessary to assess the potential for cavitation along the chute as flows reached capacity.

6.1.1. FCO Spillway Chute Profile Analysis

The initial profile of the FCO Spillway chute closely followed the original natural terrain to minimize the excavation as well as the disturbances of the underlying rock due to blasting. This as-built FCO Spillway chute profile has one vertical curve. Modeling led to refinements in this chute profile, with the recommended chute profile curve lengthened and replaced by two curves. The new profile is hydraulically superior to the original as-built chute profile as it provides a gradual landing of the jet trajectory. In the new chute profile, the elevations of portions of the chute were set 0.6 m (2 ft) above the original elevations, thus reducing the volume of the underlying rock to be removed and reducing construction time.

6.1.2. FCO Spillway Chute Flow Depth and Velocity Analysis

Calculations of the flow depth and velocity along the FCO Spillway chute were done initially with a 1-D model. The calculated velocities and flow depths for selected flows along the FCO Spillway chute are shown in Fig. 4. During the release of 8382 m^3/s (296,000 ft^3/s), the flow depth changed from 7.5 m (24.6 ft) at the end of the outlet structure to about 3.0 m (9.8 ft) near the dentate structures. The corresponding maximum velocity reached about 52 m/s (170 ft/s) near the dentate structures. The flow on the chute remained uniform flow only when the release was lower than 1415 m^3/s (50,000 ft^3/s).

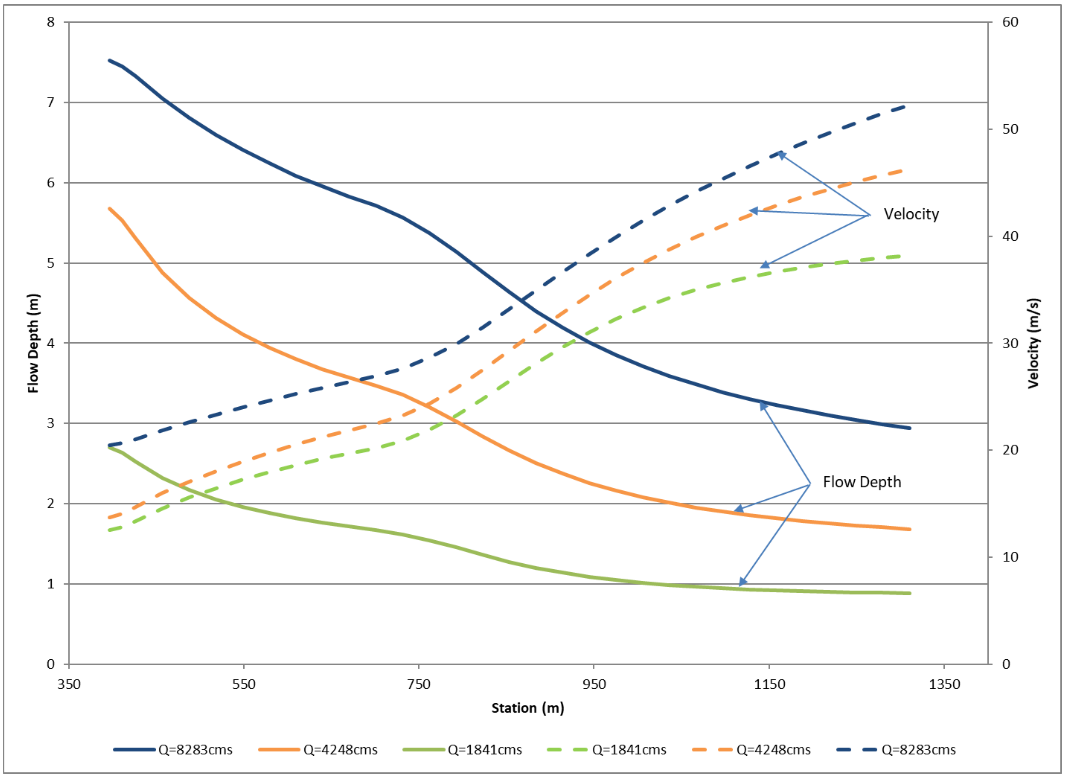

Fig. 4 Variation of flow depth and velocity along Spillway FCO Spillway chute

The 1-D models were used to calculate drag force, uplift due to seepage, centrifugal force at vertical curves, and negative pressures at transverse joints. The resulting chute flow properties were passed to other recovery teams to start their design work. The final wall heights along the chute were determined such that the maximum release of 8382 m^3/s (296,000 ft^3/s) will be fully contained within the chute. The wall height was taken as the non-aerated flow depth plus freeboard. The freeboard was calculated using both USACE [10] and USBR [11] guidelines. These guidelines account for flow depths, pier end wave height, slug flow or roll waves, air entrainment, and minimum freeboard above the mean surface elevation. The proposed final wall heights for the FCO Spillway chute are taller than the original wall heights.

6.1.3. Cavitation Index and Air Concentration Analysis

Cavitation along the FCO Spillway chute was a concern, considering the high velocities created by the largest releases. Hydraulic engineering analyses assessed the potential for cavitation. The potential of cavitation damage is measured by a cavitation index (σ), which is a function of pressure and velocity; no cavitation damage is expected when the index exceeds 0.2. If the cavitation index falls below the recommended value of 0.2, cavitation damage can be prevented if air concentration in the flow is about 10% [12, 13], or by using high-strength materials. The proposed FCO Spillway chute was designed as a self-aerating spillway [3, 14], thus avoiding cavitation even with the highest-velocity flows.

Fig. 5 shows the variation of the cavitation index and entrained air concentration computed with a 1-D model developed by DWR. Near the chute failure location, Station 1021 m (3350 ft), for a release of 1841 m^3/s (65000 ft^3/s), the air concentration is about 25% and the cavitation index is higher than 0.2. This suggests that cavitation was not a significant factor in the failure of the FCO Spillway chute — an assessment that was confirmed by an independent forensic assessment [15]. The entrained air concentration calculation due to self-aeration is very conservative as it neglects the aeration contribution by the outlet structure piers.

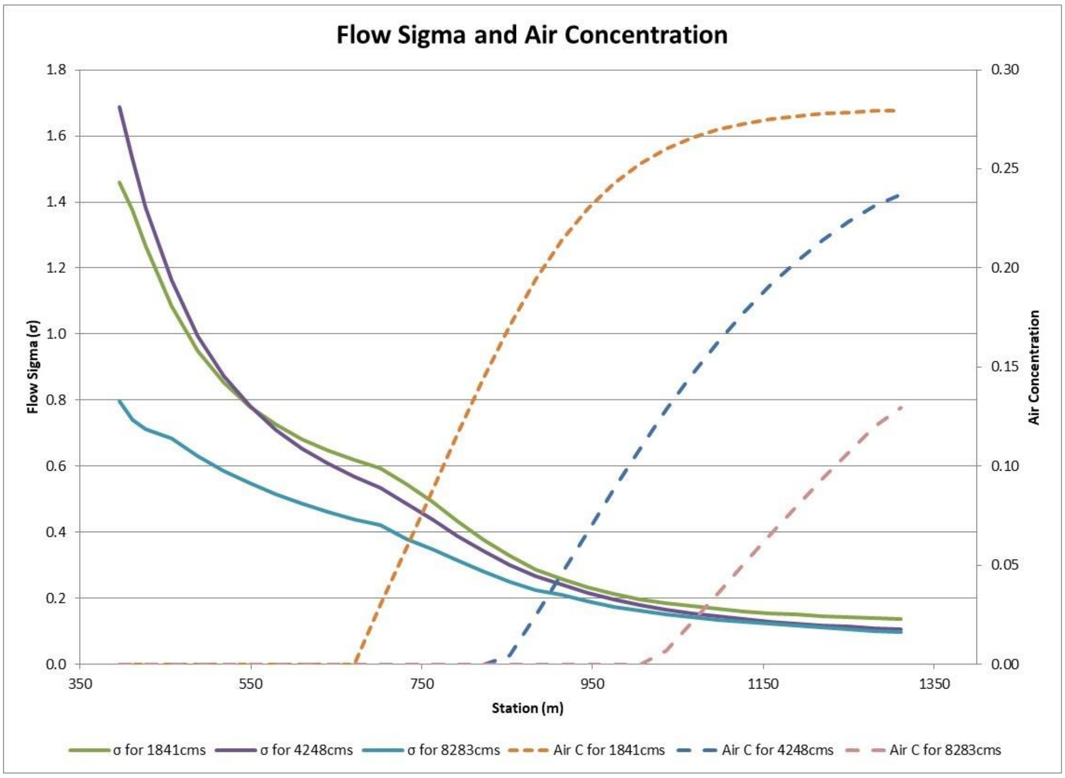

Fig. 5 Variation of cavitation index along the FCO Spillway chute

For a release of 4248 m^3/s (150,000 ft^3/s), the cavitation index falls below 0.2 near Station 975 m (3200 ft), with a minimum value of 0.11 near the dentate structures. However, the air concentration is about 8%, which is about the minimum air concentration recommended to prevent cavitation damage. This is consistent with the historical performance of the FCO Spillway chute. Past maintenance records show that damage to the chute due to cavitation for flows up to 4248 m^3/s (150,000 ft^3/s) was negligible [5]. If the initial aeration entrained by the gate piers is considered, the chute should be able to convey flows up to 8382 m^3/s (296,000 ft^3/s) without cavitation damage.

The need for aerators in the new FCO Spillway chute is still an on-going issue. While model results suggest aerators may reduce potential for chute cavitation, models available are based on certain assumptions not necessarily valid for Oroville Dam. Further, current designs, while efficient for certain flows are less efficient for flows which are larger and/or smaller than the flows. Finally, maintenance of feasible designs is a significant concern. As of December 2017, analysis continues, and no final design decision has been taken regarding aeration.

6.1.4. Model Validation

Measured velocity, flow depth, and air content data along the modified FCO Spillway chute are not yet available to calibrate or verify the models. The model results (velocity and flow depth) from the 1-D model were confirmed by comparing with results computed with FLOW3D, a commercially available 3-D CFD software application.

6.1.5. Analysis with Scale Physical Model

To provide hydraulic engineering information not otherwise available, a 1:50 scale physical model of the FCO Spillway chute, based on Froude number similarity, was built at Utah State University immediately following the spillway chute failure. The model includes the Flood Control Outlet structure, the concrete chute along with energy dissipaters, and part of the Feather River immediately downstream of the terminal end of the chute. This model was used to determine a rating curve of the FCO Spillway structure, to verify flow depth and velocity obtained from numerical models, and to understand flow patterns in the chute in case the spillway construction was not completed in a single construction season.

Initial studies with the physical model were limited to three alternative designs proposed for recovery: a plunge pool alternative, an interim chute, and full restoration of the original concrete chute. Fig. 6 shows the 1:50 scale model of the plunge pool alternative of the FCO Spillway chute; this alternative modified the scour hole created by the spillway failure for use for conveyance and as an energy dissipating device. This alternative was found to be feasible based upon the CFD model runs, but the physical model results showed standing waves on the plunge pool as high as 46 m (150 ft) during a release peak design flow of 8382 m^3/s (296,000 ft^3/s). Therefore, this alternative was discarded.

Fig. 6 Performance of plunge pool alternative of Oroville Dam's FCO Spillway chute

6.2. ANALYSIS OF EMERGENCY SPILLWAY

To inform design decisions about the damaged hill slope downstream of the Emergency Spillway, a 2-D model of the Emergency Spillway, hill slope downstream, and part of the Feather River was developed using HEC-RAS. Terrain data were available from LiDAR obtained with drone flights by DWR following the spillway failure (and periodically thereafter, as construction progressed). The 2-D model was used to calculate water depth, velocity, and bottom shear for various flow conditions. Results were used by OER to assess the potential for future erosion and scour and to inform designers of remediation features downstream of the Emergency Spillway. Those features included a secant pile wall to prevent head cutting, armoring in key locations, and construction of a concrete apron immediately downstream of the weir.

To assess the need for and to inform designers of modifications to the Emergency Spillway weir, a 3-D CFD model of the weir was developed using FLOW3D. Buttressing of the concrete monoliths was proposed to increase the factor of safety against sliding. The 3-D model showed certain configurations that would reduce the efficiency of the weir, thus reducing capacity of the spillway. This, in turn, would adversely affect the ability of the dam to pass the PMF safely. Analysis with the 3-D model led to modifications to the design. The analysis also yielded information about the flow velocity and bottom shear along the planned protection works downstream of the Emergency Spillway.

7. CONCLUSION

Oroville Dam, the FCO structure, the Emergency Spillway, and the operations plan were designed, developed, and constructed following or exceeding the standard of practice 60 years ago. While the Oroville Project had operated successfully for 49 years, failure of the FCO Spillway chute in 2017 created a need for a new design and an associated operations plan for that design as it was to be constructed in phases. To inform the design and operations, a variety of hydrologic engineering, hydraulic engineering, and reservoir operation analyses were completed during the incident and later as part of the recovery. Conceptual and empirical numerical and physical models were used for the analyses. Analysts encountered problems throughout the analysis, but always found solutions as the models were configured, calibrated, and applied to provide information to design staff and influence interim operation decisions required throughout the response and continuing recovery efforts.

SUMMARY

During the Oroville Dam Spillway Incident, hydrologic and hydraulic engineering and reservoir operation analyses provided information to support decision making by DWR management. Reservoir inflow forecasts were made almost continuously by DWR staff and the NWS, using conceptual models of Feather River Basin watershed hydrology. Reservoir behavior and operation with various operation and potential failure scenarios were simulated to predict future pool elevations and timing of potential Emergency Spillway discharge.

Inundation that could result from potential failure was predicted and displayed with maps included in Oroville Dam’s Emergency Action Plan, which emergency and incident command teams consulted. These maps were augmented with situation-specific maps prepared in near real time as the incident progressed. Additional hydraulic analyses provided DWR managers with information about potential flow paths along the hill slope downstream of the Emergency Spillway, and with estimates of debris and sediment loads in the Feather River downstream.

Challenges for analysis during the event in February 2017 included: (1) the need for almost immediate turnaround to provide information critical for decision

making; (2) the lack of certainty about near-future inflows to Lake Oroville due to uncertainty about the weather; (3) the lack of certainty about behavior of the never-used Emergency Spillway, with unstable terrain; and (4) the risk of misunderstanding or misinterpreting model results as critical decisions were made. Solutions included: (1) the use of cloud computing, with parallel model runs on multiple servers in the Amazon cloud; (2) analysis with ensemble forecasts, coupled with sensitivity analysis with varying inflow hydrograph properties; (3) constant monitoring and reporting to modelers of observed changes to the spillways so model inputs could be adjusted; and (4) careful communication of results by DWR and consultant experts.

1. INTRODUCTION

On February 7, 2017, the gated service spillway (also known as the Flood Control Outlet or FCO Spillway) at Oroville Dam was being used to release water to control the Lake Oroville level according to the prescribed operations plan. During this operation, the service spillway's concrete chute slab failed, resulting in the loss of spillway chute slab sections and deep erosion of underlying foundation materials. Subsequently, as the damaged service spillway was operated in an attempt to manage multiple risks, the project's free overflow emergency spillway was overtopped for the first time since the project was completed in 1968. Significant erosion and headcutting occurred downstream of the emergency spillway's crest structure, leading authorities to evacuate about 188,000 people from downstream communities.

After the incident, the United States Federal Energy Regulatory Commission (FERC), one of two regulators for Oroville Dam, required the dam's owner, the California Department of Water Resources (DWR), to retain an Independent Forensic Team (IFT) to investigate the Oroville Dam spillway incident and prepare a report of findings. At the request of DWR, the United States Society on Dams (USSD) and the Association of State Dam Safety Officials (ASDSO) coordinated the assembly of a six-person team, which was approved by FERC. The IFT, composed of the authors of this paper, issued its forensic investigation report on January 5, 2018 [1].

The IFT's work included the review of hundreds of documents covering investigations, design, construction, operations and project reviews, as well as notes taken during the incident. IFT members visited the site, including during forensic investigations made before chute sections were demolished for repairs. The IFT also interviewed more than 75 individuals, conducted two surveys of DWR personnel, and solicited input from the public and DWR employees. Through an iterative process, the IFT applied a mix of fundamental inductive and deductive logic to the assembled information, and provided the resultant evidence, arguments, and findings in its detailed forensic report [1].

The report addressed both the physical factors and the human, organizational, and industry factors that contributed to the Oroville Dam spillway incident. This paper briefly summarizes the IFT's findings and lessons to be learned from this very serious incident. The reader is referred to the full forensic investigation report [1] for more detailed information.

2. PROJECT BACKGROUND

2.1. OROVILLE DAM PROJECT

Oroville Dam is a component of the California State Water Project (SWP), which is the largest state-owned water storage and delivery system in the United States. The Oroville Dam and associated structures were built in the 1960s, with the construction completed in 1968.

The SWP is owned and operated by DWR, which is part of the California Natural Resources Agency and was created in 1956. Oroville Dam is regulated by a separate division within DWR, the Division of Safety of Dams (DSOD), as well as by FERC.

The Oroville Dam facility (see Fig. 1) consists of an embankment dam, a service spillway (also known as the Flood Control Outlet or FCO Spillway), an emergency spillway, the Hyatt Powerplant, and several other appurtenant structures. Oroville Dam is the tallest dam in the United States, at 235 m (770 ft). The design embankment crest is at Elevation 281.0 m (922 ft), and the maximum normal operating pool level is Elevation 274.3 m (900 ft). For reference, the service spillway gate sill is at Elevation 248.0 m ft (813.6), and the crest of the emergency spillway overflow structure is at Elevation 274.6 m (901 ft).

Fig. 1
Overview of Oroville Dam facility prior to the February 2017 incident

2.2. SERVICE SPILLWAY

The service spillway is located on the right abutment of the main dam. It consists of an unlined approach channel, a gated headworks structure, and a concrete-lined chute extending to just above the Feather River channel. The headworks structure has a total of eight top-seal radial gates. The upstream sill elevation of the service spillway headworks is at Elevation 248.0 m (813.6 ft) and the tops of the radial gates (in the closed position) are at approximately Elevation 258.2 m (847 ft). The chute downstream of the headworks structure is about 54.6 m (179 ft) wide and just over 914 m (3,000 ft) long, with a drop of about 152 m (500 ft). The first 305 m (1,000 ft) of the service spillway chute downstream of the headworks slopes at about 5⅔ percent, after which the chute transitions through a vertical curve to a much steeper slope of about 24.5 percent for the last 443.5 m (1,455 ft). Four large, reinforced concrete “dentate” blocks are located at the downstream end of the chute, to disperse the spillway flow and dissipate energy as the flow enters the river.

The service spillway discharge would be 8,382 m^3/s (296,000 ft^3/s) with Lake Oroville at Elevation 279.5 m (917 ft) and all gates fully open [2].

2.3. EMERGENCY SPILLWAY

The emergency spillway is also located on the right abutment, to the right of the service spillway. The emergency spillway consists of two sections: a 284-m (930-ft) long, concrete, gravity, ogee weir on the left side, and a 244-m (800-ft) long broad-crested, concrete weir on the right side. The crests of both sections are at Elevation 274.6 m (901 ft), which is 0.3 m (1 ft) above the maximum normal operating reservoir level, Elevation 274.3 m (900 ft). The maximum height of the emergency spillway crest structure is about 15.2 m (50 ft) in the ogee weir (left) section. Water flowing over the emergency spillway crest structure would then pass over natural terrain down to the Feather River.

The emergency spillway discharge would be 9,910 m^3/s (350,000 ft^3/s) with the reservoir at 279.5 m Elevation (917), which corresponds to a depth of flow over the crest weirs of about 4.88 m (16 ft) [2].

2.4. SPILLWAY OPERATION HISTORY

The service spillway gates are operated to control reservoir levels in accordance with the operation plan for the facility. The gates were first operated in 1969, within a year after the project was completed, with a maximum service spillway discharge of almost 2,320 m/s^2 (82,000 ft^3/s) in that year.

Service spillway operations vary from year to year, depending primarily on snowpack in the Feather River Basin. The operating record includes extended periods of time when spillway gate operation was not required, e.g. 1975 through 1979, 1987 through 1992, and 2007 through 2010. Of the 48 years from 1969 through 2016, there were 23 years when the service spillway did not operate, 11 years during which discharges exceeded 1,420 m^3/s (50,000 ft^3/s), and three years during which discharges exceeded 2,830 m^3/s (100,000 ft^3/s). The record service spillway discharge was 5,530 m^3/s (160,000 ft^3/s), in 1997. From 1998 through 2016, spillway discharges exceeded 312 m^3/s (11,000 ft^3/s) in only three years: about 1,700 m^3/s (60,000 ft^3/s) in 2005, 2,100 m^3/s (74,000 ft^3/s) in 2006, and 878 m^3/sec (31,000 ft^3/s) in 2011.

The emergency spillway was activated for the first time in the project's history during the February 2017 flood event and spillway incident.

2.5. SERVICE SPILLWAY CHUTE DESIGN AND CONSTRUCTION

Understanding the service spillway chute design and construction is critical to understanding the chute slab failure in February 2017.

The nominal service spillway chute slab design thickness was a minimum of 38.1 cm (15 in), although the nominal chute slab thickness as-constructed was significantly greater in many locations. However, as discussed below, the chute slab thickness over the chute's underdrains was much less than 38.1 cm (15 in).

The design included an underdrain system consisting of herringbone drains beneath the chute slab, connected to collector pipes outside of and parallel to the service spillway chute walls. Each herringbone drain was oriented across the spillway with the pipes on either side of the spillway sloping downstream for drainage, from a point beneath the spillway centerline, as shown in Fig. 2. The herringbone drains were spaced at an interval of 7.6 m (25 ft) along the flatter upstream section of the chute and at 6.1 m (20 ft) along the steeper downstream section. When viewed in plan, the pattern of these drains looked like fish bones or herring bones, as shown in Fig. 2, hence the name. Sets of herringbone drains connected to separate collector drain pipes on either side of the chute. The collector drain pipes extended downstream to outfall locations near the tops of the chute walls. To accommodate all of the herringbone drains, there were 12 collector drain pipes on each side of the chute, for a total of 24 collector drain pipes.

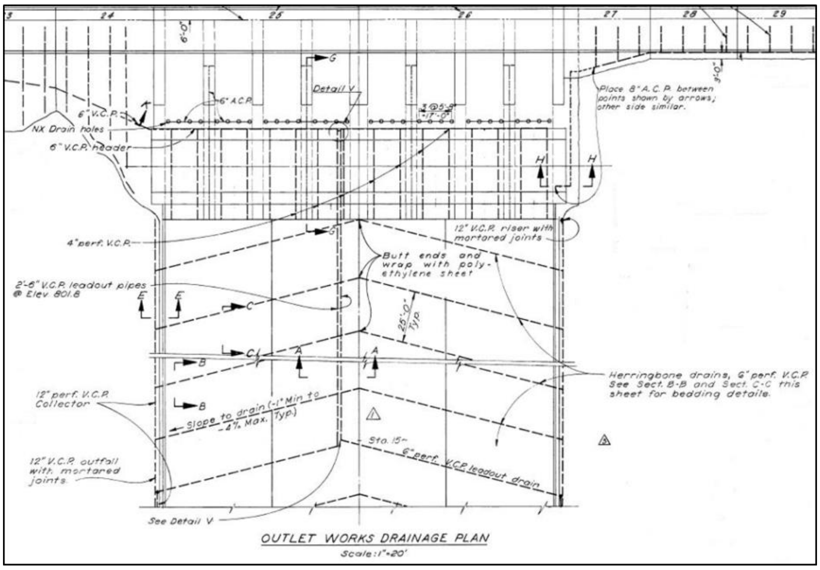

Fig. 2
Plan view of headworks (top) and upper service spillway chute showing herringbone drains and collector pipes

In the original design/bid drawings, the herringbone drains were indicated as 10.2-cm (4-in) diameter perforated vitrified clay pipes (VCPs) surrounded by gravel, and the collector pipes were indicated as 20.3-cm (8-in) and 15.2-cm (6-in) diameter VCPs. However, construction records indicate that the herringbone drain size was increased to 15.2-cm (6-in) diameter and the collector pipe size was increased to 30.5 cm (12-in) diameter, which is consistent with the as-built drawings and the pipe sizes observed during the post-incident forensic investigations.

In both the design and as-built drawings, the herringbone drains are not located entirely beneath the chute slab, but rather they protrude up into the slab section, as shown in Fig. 3, taken from the as-built drawings. This location of the drain pipes substantially reduced the thickness of the slab immediately above the drains. The drawings noted the slab thickness above the drains as a minimum of 17.8 cm (7 in). From available information, it appears that, in most locations, even when the as-constructed slab thickness increased, the drain pipe locations were maintained near the top of the slab.

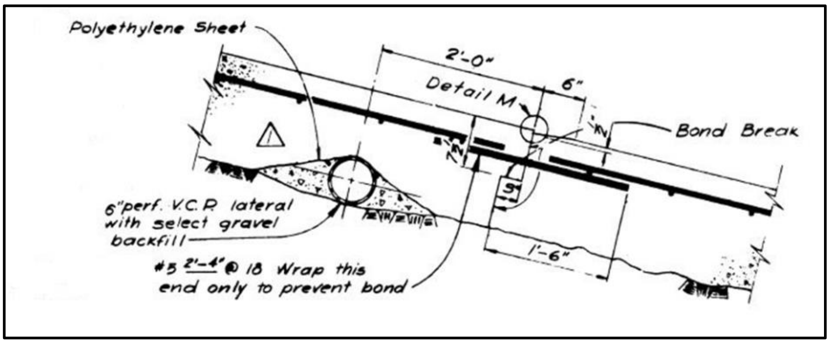

Fig. 3
Herringbone drain VCP pipe protruding into slab section

As designed and constructed, the chute slab included a single layer of reinforcing bars near the top of the slab, as shown in Fig. 4. The reinforcing bars were 15.9 mm (No. 5) bars, spaced at 30.5 cm (12 in) each way.

The chute design also included 35.8 mm (No. 11) anchor bars, spaced at 3 m (10 ft) each way in plan view, to extend 1.5 m (5 ft) minimum into the foundation or 5 ft (1.52 m) minimum into sound rock and to be grouted into the foundation. The anchor bar detail is shown in Fig. 4. From construction records and photographs, it does not appear that anchor lengths were adjusted when “sound rock” was not located at foundation grade, nor when the concrete slab was thicker than 38.1 cm (15 in). Hence, the anchors likely extended a maximum of about 1.5 m (5 ft) into the foundation.

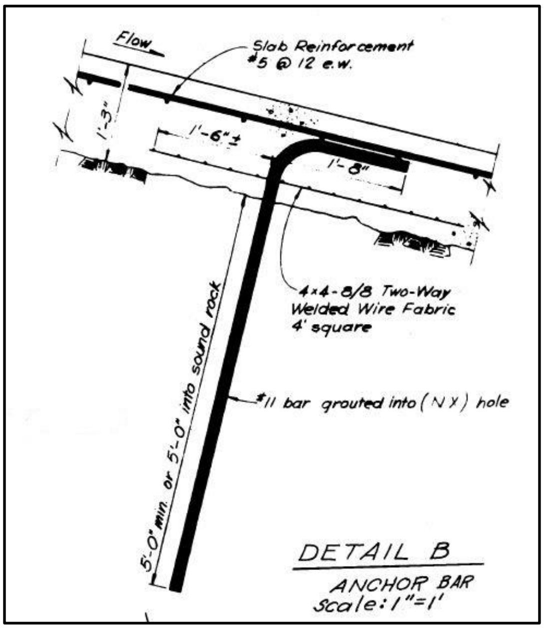

Fig. 4
Typical reinforcing bar and anchor bar configurations

The chute slab included both formed and unformed transverse contraction joints. The as-built drawing details show formed transverse contraction joints including a 19.1-cm (7.5-in) deep key, in which the downstream edge of the upstream slab overlaps the upstream edge of the downstream slab, as shown in Fig. 3.

Construction records and photographs indicate that much of the chute slab was constructed using slip-form methods. Although the as-built drawings show 12.2 m (40 ft) wide by 15.2 m (50 ft) long chute slab panels, it is believed that the slip-forming used to construct the chute concrete allowed the contractor to place more than one 15.2 m (50-ft) long concrete chute slab panel at a time. It is further believed that the contractor created unformed contraction joints by cutting shallow grooves in the freshly placed concrete to initiate a crack at intermediate design joint locations within the slip-form length, rather than stopping the slip-forming operation to construct a formed contraction joint. Formed contraction joints would have been constructed at the ends of the slip-form runs.

The as-built drawings show that all longitudinal contraction joints were to be keyed. The specific key configurations varied for different longitudinal contraction joints.

According to the as-built drawings, all contraction joints were completed with 0.4-cm (1-in) deep by 0.098-cm (0.25-in) wide filler material, placed in a groove formed at the top of the joint, and 15.9 mm (No. 5) dowel bars at 45.7 cm (18-in) spacing were constructed across all of the chute slab formed joints (see Fig. 3). These dowel bars were embedded and bonded for a length of 45.7 cm (18 in) on one side of the joint, and were wrapped to prevent bond for 25.4 cm (10 in) on the other side. The dowels were shown just below the reinforcement mat near the top of the slab.

Although all formed joints were intended to be keyed, formed joints without keys were observed at a few locations during the post-incident forensic investigations.

Based on the design drawings and specifications, as well as an interview, the design intent was for the chute slab to be founded directly on moderately weathered rock or better, which could not be further removed by heavy-duty power excavating equipment. The excavated surface was to be pressure-washed to remove all mud, debris, and loose or unsound rock fragments. However, the foundation requirements were substantially relaxed during construction. In some places, the prepared foundation appeared to have high points of reasonably sound rock surrounded by areas of what appears to be rock weathered to soil-like material, as shown in Fig. 5. In other locations, the prepared foundation appears to have been almost entirely rock that had weathered to soil-like material, as shown in Fig. 6, which was taken in the area of the initial chute slab failure.

Fig. 5
Example of the clean-up effort for the service spillway chute prior to concrete placement.

The chute slab concrete was specified to have a 28-day compressive strength of 21,000 kPa (3,000 lb/in^2), and all concrete cores tested in the post-incident field investigations had compressive strengths higher than the specified strength. Type II cement was used for the concrete, and the coarse aggregate was up to 15.2-cm (6-in) size. While large size coarse aggregate can be beneficial in thicker placements, the 15.2-cm (6-in) maximum size would seem to be too large for a 38.1-cm (15-in) slab thickness with 7.6-cm (3-in) reinforcing bar cover and 17.8-cm (7-in) drain pipe cover. The construction documentation indicates that some of the large aggregate caused breakage of the herringbone drain pipes as the concrete was being placed.

Although it is believed that broken drain pipes were repaired when they were observed during construction, there may be other locations where pipes were damaged during concrete placement but the damaged pipes were not observed and were not repaired.

2.6. SERVICE SPILLWAY CHUTE SLAB REPAIRS

The service spillway chute slab concrete has been repaired numerous times since the original construction. Documented repair efforts occurred in 1977, 1985, 1997, 2009, and 2013. It is possible that there were other undocumented repair efforts.

The observed spillway chute damage that led to the repairs was caused by various different mechanisms including cracking, removal of joint filler, delamination, and spalling. The cracking occurred predominantly over the herringbone drains. These cracks were first documented in a 1969 report [4], which indicated that cracks appeared above herringbone drains during slab concrete curing, within one month after concrete placement. These cracks provided pathways for leakage through the slab at times when there was water flowing down the chute.

Over time, joint filler was removed from joints by the high velocity flows in the spillway. Loss of the joint filler would have resulted in increased leakage through joints when water was flowing down the chute.

Spalling occurred almost entirely in delaminated concrete at joints and cracks and at patches from previous repairs, generally in the concrete above the level of the reinforcing steel and dowels. Delamination led to spalling of the slabs near the joints and cracks. The spalling exposed the reinforcing steel in the chute slabs and the dowel bars at the joints to corrosion, leading to reinforcing bar failure (see Fig. 7) when subjected to tension during the winter contraction cycle. Depending on the magnitude and orientation of the spalls, vertical faces that result in stagnation pressures during spillway discharge could have been created.

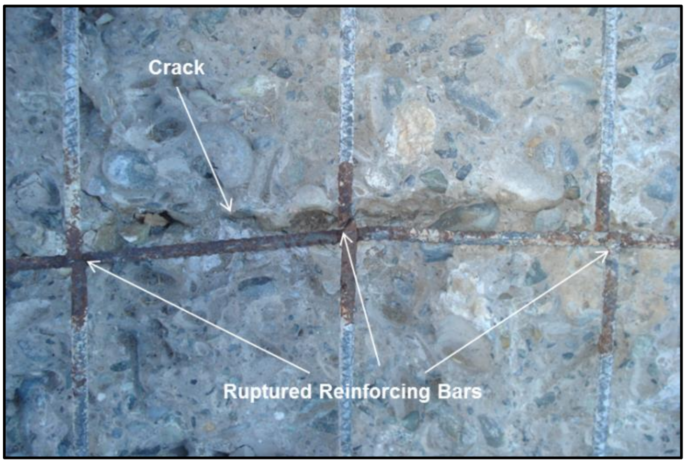

Fig. 7
Corroded and ruptured steel reinforcing bars at a slab crack

The chute repairs were generally shallow, involving removal of damaged concrete and patching of spalls to restore the flow surface. In some cases, the chute repairs also involved replacing the joint filler, reconnecting broken reinforcing bars with couplers, and grouting of cracks. In at least one of the repair efforts, the dowels in some of the formed lateral joints were cut in order to place joint-filler material. Although much of the damage resulted from temperature related stresses, there is no evidence that temperature studies were part of any repair design effort.

Based on reports of repair efforts and interviews with DWR personnel, the IFT understands that spalling both recurred in previously patched areas and occurred in areas that had not exhibited spalling before.

The photograph in Fig. 8 shows a section of the concrete chute slab that was removed during post-incident forensic excavations. Protrusion of the underdrain into the slab section, cracking above the underdrain, repair of the concrete above the reinforcing layer, and recurrence of the cracking are all illustrated in this photograph.

Fig. 8
Section of service spillway chute slab removed
during post-incident forensic investigation

2.7. Service Spillway Chute Underdrain Flows

In its first report, DWR's Independent Board of Consultants (BOC), which was convened after the February 2017 incident to provide review and advice for the spillway recovery and repair program, commented that:

> "The amount of drain water flowing from the pipe discharge openings along the spillway training walls seems extraordinarily large." [3]

The IFT concurred. The amount of water that discharged from the chute drains when there was flow in the service spillway was unprecedented in the IFT's experience.

Significant flows from the service spillway chute drain outfalls were observed at the time of the first discharge through the spillway, in 1969, as described in a DWR report and DSOD notes [4, 5, and 6]. The report states that the high flows from the outfalls were related to spillway discharge and that the "high flows from the spillway drains are mystifying but probably not dangerous as the chute is anchored." The report also states that "inquiry to the designers regarding this aspect of performance would be in order." The IFT was not able to locate any documents indicating that the designer(s) were consulted at that time. From the design documents, the IFT is confident that the intent of the chute underdrain system was to collect seepage from groundwater beneath the slab, and not to collect large amounts of leakage from flows in the spillway chute.

Over the life of the project, reports of flows from the spillway chute underdrain outfalls were sporadic and limited. From an evaluation of the available reports, it can be concluded that, when the spillway was discharging, high chute drain flows consistently occurred, and the data indicate that the drain flows increased with increasing spillway chute flow, though not necessarily proportionally. High drain outfall flows were not limited to times when the spillway gates were open. Rather, significant outfall flows were also observed when the gates were closed and the reservoir level was high enough for water to be against the upstream sides of the service spillway gates. In these circumstances, gate leakage resulted in significant flow in the spillway chute.

The IFT agreed with the initial 1969 conclusion that the high drain flows were principally attributable to discharge leakage through the cracks and joints in the service spillway chute slab. This was dramatically demonstrated during post-incident repair work in 2017, when water was observed flowing on the spillway chute from leakage with the gates closed. To facilitate investigation and repair work, sand bags were placed on the spillway chute to direct the leakage flow toward a narrow area near the left chute wall. When the sand bags were placed, drain outfalls on the right side, which had been flowing significantly, stopped flowing, which indicates that the water collected by the drains was not seepage through the foundation, but rather leakage through the slab.

3. CHRONOLOGY OF THE FEBRUARY 2017 SPILLWAY INCIDENT

In January and February 2017, the service spillway experienced its first significant discharges since 2011.

After some limited service spillway discharges earlier in January, the discharges were ramped up beginning on January 30, in response to an approaching large precipitation event. In the first few days of February, discharges were in the range of about 425 to 708 m^3/s (15,000 to 25,000 ft^3/s). On February 6, 2017, the spillway discharges were increased to between 1,190 and 1,270 m^3/s (42,000 and 45,000 ft^3/s) and were held in that range until the morning of February 7.

At about 10:10 am on February 7, 2017, on-site DWR personnel noticed a substantial disturbance in the service spillway's flow pattern, while discharges were being ramped up from about 1,200 m^3/s (42,500 ft^3/s) to about 1,490 m^3/s (52,500 ft^3/s). On-site DWR personnel contacted DWR headquarters in Sacramento, and an order to close the service spillway gates was issued at about 11:15 am on February 7, 2017. After the gates were fully closed by about 12:25 pm, it was found that a significant section of the service spillway chute slab was missing, and a large erosion hole existed in the foundation in the area where the slab sections were missing, as shown in Fig. 9. This initial erosion hole in the service spillway chute was examined by a climb team on the morning of February 8, 2017.

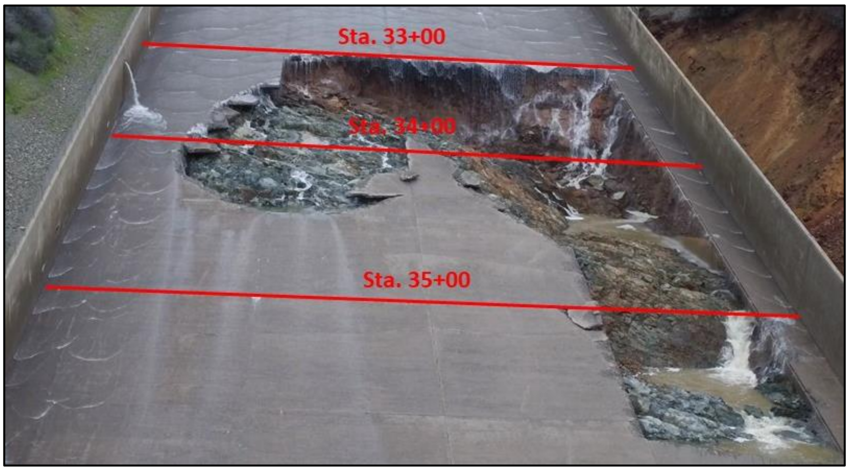

Fig. 9
Service spillway chute damage observed after gates were closed on February 7

DWR knew that it would need to operate the damaged service spillway because of expected inflow to Lake Oroville; hence, it was decided to begin opening the spillway gates to test the service spillway's capabilities in the damaged condition. The gates were reopened at about 4:00 pm on February 8, 2017, and several different discharge levels were trialed through February 10, while the service spillway chute was observed for additional damage. Spillway discharge reached 1,840 m^3/s (65,000 ft^3/s) at 3:00 am on February 10, and was held there for about 17 hours. At about 8:00 pm on February 10, the service spillway discharge was reduced to about 1,560 m^3/sec (55,000 ft^3/s) and maintained at that level through 3:35 pm on February 12.

Meanwhile, inflows to Lake Oroville continued to increase. Sometime between about 7:00 and 8:00 am on February 11, the reservoir level exceeded Elevation 274.6 m (901 ft), and water began flowing over the emergency spillway crest structure for the first time in the facility's history. The reservoir level increased to a maximum level of about Elevation 275.1 m (902.6 ft), about 0.49 m (1.6 ft) above the emergency spillway's crest, at about 3:00 pm on February 12, about 31 hours after the flow over the emergency spillway began. The flow over the emergency spillway at the peak reservoir level was estimated to be about 354 m^3/s (12,500 ft^3/s), less than 4 percent of ultimate capacity.

The emergency spillway discharge channelized as it flowed across the natural terrain downstream of the crest structure and caused extensive erosion, with some of the erosion areas headcutting aggressively back toward the emergency spillway crest structure. According to Incident Command notes [7], at 3:44 pm on February 12, an evacuation order was issued for about 188,000 downstream residents, because of the rapidly advancing erosion areas in the emergency spillway's discharge channel.

DWR increased the discharge through the service spillway, beginning at 3:35 pm on February 12, about nine minutes before the evacuation order was issued, according to the Incident Command notes [7]. Service spillway discharge was increased to about 2,830 m^3/s (100,000 ft^3/s) by about 7:00 pm on February 12 and this discharge level was maintained through 8:00 am on February 16. Discharge over the emergency spillway crest ceased at about 8:00 pm on February 12, about 36 hours after it began and about 5 hours after the flow had peaked.

At about 3:30 pm on February 14, the evacuation order was changed to an evacuation warning, under which residents were allowed to return but were advised to monitor the media and be prepared to evacuate again, if necessary. No further evacuation orders were judged necessary, and the evacuation warning was lifted five weeks after the evacuation order was first issued.

DWR established a target reservoir level at Elevation 259.1 m (850 ft), which is 15.2 m (50 ft) below the normal full-pool level. This target elevation for Lake Oroville was reached on February 20.

The service spillway gates were closed on February 27 to allow for on-site investigations to support remedial actions. After that time, investigations and remedial actions were interrupted occasionally for service spillway releases to manage the reservoir. The service spillway gates were closed for the season on May 19, 2017, so that construction of spillway repairs could begin.

During service spillway operations between February 8 and May 19, 2017, additional spillway chute slab sections were lost and the slab failure and foundation erosion at the service spillway enlarged significantly, as shown in Fig. 10.

Fig. 10
Ultimate damage at the service spillway

4. THE PHYSICS OF WHAT HAPPENED

4.1. SERVICE SPILLWAY

The IFT believes that the service spillway chute failure most likely initiated by the uplift and removal of a section of the chute slab in the vicinity of Sta. 33+50, at about 10:10 am on February 7, 2017. Once the initial section of the chute slab was removed, the underlying moderately to strongly weathered rock and soil-like foundation material beneath the slab at this location (see Fig. 6) was directly exposed to high velocity spillway flow. The high velocity flow rapidly eroded the foundation materials at this location, removed additional chute slab sections in both upstream and downstream directions, and quickly created the large erosion hole that was observed by 12:30 pm on February 7 (see Fig. 9), as flows diminished following spillway gate closure. These findings are based on eyewitness accounts, as well as photographic and videographic records, as explained in detail in the full forensic investigation report [1].

While there are numerous physical factors that contributed to the chute failure, which the IFT studied in detail, the IFT focused on the factors that it believed likely played the most significant roles in the failure of the service spillway chute.

The IFT concluded that the initial uplift and removal of a slab section was most likely caused by water uplift pressure beneath a section of the chute slab, producing an uplift force that exceeded the uplift capacity of that particular section of slab. The uplift force was a product of both the uplift pressure and the area over which it was applied, and the uplift pressure likely involved transmission of stagnation pressure through the slab to the foundation. The resistance to uplift was provided by a combination of the weight of the slab, the weight of the water above the slab, the uplift resistance provided by the foundation anchor system, the structural interaction of slab panels with adjacent slab panels, and any bond between the concrete slab and the foundation. Once the upstream end of the slab section lifted, creating an offset into the flow, the pressure under the slab rapidly increased due to greater stagnation pressures and produced the sudden failure of the slab.

The initial chute slab failure section could have been small. Once even a small section of slab was removed, the high velocity flow would have quickly attacked the underlying erodible foundation material and would have begun to remove additional sections of the chute slab. Additionally, the edges of the remaining downstream slab adjacent to the removed section would have presented a significant offset into the flow, which would generate high stagnation pressures that could jack out all but the most resistant slab sections. Subsequent downstream slab sections were removed until the flow encountered a slab section with enough resistance to counter these high uplift forces.

The excessive flow into the foundation was mainly due to the high velocity spillway flow injecting water into and through slab surface features, such as open joints, unsealed cracks over the herringbone drains, spalled concrete at either a joint or drain location in either a new or previously repaired area, or some combination of these features that produced offsets into the flow. Localized slab deterioration and repairs existed in the area of the initial slab failure prior to February 7, and these localized areas would have been vulnerable to damage during high velocity spillway flow.

Flows into the foundation would generally increase as flow velocities near the chute surface increased. The chute failure occurred very shortly after the spillway gates were opened more to increase discharge down the spillway chute, which led to higher surface flow velocities, and likely higher injection flows which exceeded drainage capacity and resulted in increased uplift pressures.

Over time, there was likely also some shallow underslab erosion of fines from the weathered rock and some loss of underdrain system effectiveness, which contributed to increased slab uplift forces.

In evaluating the physical factors, it is important to consider why the chute failure happened in 2017 at a spillway discharge of about 1,490 m^3/s (52,500 ft^3/s), whereas the service spillway chute had not failed previously during higher discharges, most recently a discharge in excess of 1,420 m^3/s (70,000 ft^3/s) in 2006, and historically discharges as large as about 2,270 m^3/s (160,000 ft^3/s) in 1997. In other words, what changed from 2006 until 2017 such that the chute slab failure happened in 2017, rather than 2006 or earlier?

There are a number of possibilities for changes that could have occurred during that time period. The IFT believes that some combination of the following factors most likely was involved:

- New chute slab damage and/or deterioration of previous slab repairs, which could have created stagnation pressure and increased flow into the foundation in areas that were already vulnerable because of weak foundation conditions
- Expansion of relatively shallow void(s) under the slab, through foundation soil erosion and/or shrinkage of clayey soils, which would have increased uplift force by increasing the area over which uplift pressure was applied
- Corrosion of the steel reinforcing bars or dowels across concrete cracks or joints, which then failed in tension, resulting in reduced uplift capacity
- Reduction in foundation anchor capacity due to corrosion or reduction in bond length due to erosion, which would have reduced uplift capacity

All of these factors, as well as other less prominent factors and factors eliminated from consideration, are discussed in detail in the full forensic investigation report [1].

Cavitation, groundwater flow/pressure, and seismic loading are physical factors that were suggested by others but were judged by the IFT to not have been significant contributory factors.

The IFT completed calculations that indicated that, for the original service chute, cavitation would be expected only downstream of Sta. 31+00, and there only for extended periods of discharge greater than 2,830 m^3/s (100,000 ft^3/s). The historical discharges greater than 2,830 m^3/s (100,000 ft^3/s) were not of sufficient duration to cause significant cavitation damage. This conclusion was supported by observation of chute slab sections remaining in place downstream of Sta. 31+00 after the incident, which did not reveal telltale indicators of incipient cavitation.

The IFT reviewed available information concerning groundwater and geologic conditions in the area of the service spillway. This review led to the conclusion that there was no evidence of large amounts of groundwater flow in the spillway location, and such groundwater flow would not have been expected for the geologic conditions at that location. Therefore, although groundwater flows may have contributed in a very small way to uplift pressures that developed under the chute slabs, it was the IFT's opinion that groundwater was not a significant contributor when compared to water pressure injected through slab joints and cracks when the service spillway was operating.

The IFT completed a review of seismic activity in the vicinity of Oroville Dam over the last 20 years, with a conclusion that no earthquakes stronger than M 4.0 occurred within 160 km (100 mi) of the site in that time period. No ground motions generated by earthquake events strong enough to conceivably cause damage to large civil structures were recorded by instrumentation at the project within the prior 20 years. Principally for these reasons, the IFT concluded that seismic damage was not a likely contributor to failure of the chute slab.

4.2. Emergency Spillway

The development of the damage to the emergency spillway discharge channel was closely observed during the incident. Photographs and videographic footage, along with eyewitness reports, provide documentation of the development of the emergency spillway damage.

During the incident response, in preparation for the possible use of the emergency spillway, trees had been cleared from the natural hillside downstream of the spillway crest structure before flow over the crest structure occurred. As the emergency spillway discharge flowed over the natural ground downstream of the crest structure, erosion began to occur. Erosion of surficial soil deposits began to develop as expected. However, erosion continued into the underlying weathered bedrock to greater depths than expected. By the afternoon of February 12, concentrated areas of erosion were observed to be rapidly progressing upstream (headcutting) toward the emergency spillway crest structure (see Fig. 11), resulting in the issuance of the evacuation order.

Fig. 11
Emergency spillway headcutting on February 12

The principal physical factor contributing to the damage at the emergency spillway was clearly the presence of significant depths of erodible soil and rock in features orientated to allow rapid headcutting toward the crest control structure. Hillside topography and the presence of infrastructure (roads, transmission towers, etc.) may have concentrated flows and increased erosive forces, facilitating headcut formation. Insufficient energy dissipation at the base of the spillway ogee crest structure and the absence of erosion protection downstream of the crest structures may have also contributed to the development of the erosion.

5. WHY THE INCIDENT HAPPENED

The February 2017 Oroville Dam spillway incident was the result of interactions of numerous physical and human factors, beginning with the design of the project and continuing during the nearly half-century until the incident. The incident was generally the result of a long-term systemic failure of DWR, regulatory, and general industry practices to recognize and properly address the deficiencies and warning signs which preceded the incident. There was no one root cause, nor can the incident reasonably be “blamed” mainly on any one individual, group, or organization.

5.1. SERVICE SPILLWAY

The conditions that led to the service spillway chute failure have their roots in the original design and construction of the chute, which, combined with the locally poor geologic conditions at the site, resulted in vulnerabilities in the as-built structure. These vulnerabilities were not recognized in various inspections and evaluations that were completed throughout the history of the structure. In fact, warning signs of the vulnerabilities came to be accepted as “normal,” and then generally were not questioned further. Because the seriousness of the vulnerabilities was never recognized, chute slab repair efforts were neither well-conceived nor effective, and likely contributed to the deterioration of chute conditions over time.

As detailed in the forensic investigation report [1], the spillway chute design was generally at the middle of the range of practice for the 1960s for spillway chutes founded on rock. For a structure of the significance of Oroville Dam, the IFT would expect the design to have reflected the best practices of the time, which it did not. The one aspect in which the design was at the very low end of practice of the time was the significant protrusion of the chute underdrains into the slab section. This feature was uncommon and led to the development of extensive cracking over the drains and resulting leakage through the slab at the cracks.

Communication among geologists, designers, and construction managers during the service spillway’s design and construction apparently was poor. This ultimately resulted in a design which was probably more appropriate for a spillway chute on rock foundations rather than one constructed on more variable foundation conditions, including strongly weathered rock, most notably an extensive area of such material at the location of the initial chute slab failure. These conditions compromised anchor resistance and potentially promoted the formation of shallow voids beneath the slab.

Although the slab cracking and resulting large drain flows were recognized during the first year of project operation, they apparently were judged as non-threatening, and subsequently became accepted as normal. These conditions were reported in many inspections with no further comment. After completion of the project, the detailed geologic information concerning the extent of strongly weathered rock in the right abutment and beneath the service spillway chute was relegated to project records, and the abutment was incorrectly assumed and portrayed as being composed of generally non-erodible rock below a few feet of soil cover.

The seriousness of the weak as-constructed conditions and the lack of repair durability was not recognized during numerous inspections and review processes over the almost 50-year history of the project, including three Potential Failure Mode Analyses (PFMAs) completed between 2004 and 2014. The first two PFMA efforts did not identify any significant potential failure modes (PFMs) related to the service spillway chute. The 2014 PFMA identified the service spillway PFM that initiated in February 2017, but it was judged extremely unlikely and ruled out of further consideration, principally because it was believed that the rock foundation would not headcut enough to fail the headgate structure and result in uncontrolled release of the reservoir.

There is no record of the original design and construction of the service spillway chute having been subsequently reviewed for consistency with more modern design and construction practices or for potential chute failure modes.

Chute slab repairs were neither effective nor durable. Over time, chute flows and temperature variations led to progressive deterioration of the concrete and the corrosion of steel reinforcing bars and anchors, with likely loss of slab strength and anchor capacity.

5.2. EMERGENCY SPILLWAY

Prior to the February 2017 spillway incident, the geology of the right abutment of the dam, including the hillside downstream of the emergency spillway crest structures was fundamentally mischaracterized and misunderstood by DWR, its consultants, DSOD, and FERC. Although geologic data from the time of original design identified the presence of areas of relatively deep strongly weathered rock, over the history of the project DWR's geologists had come to believe that the hillside downstream of the emergency spillway crest structure consisted of shallow soil cover over non-erodible rock, and this was accepted by all others involved, without a critical review of the available information. Hence, the erosion and headcutting that occurred when the free-flow emergency spillway overtopped were not expected.

Once the incident initiated with the failure of the service spillway, DWR attempted to find a "sweet spot" in balancing the risks of operating the service and emergency spillways, with the goal of releasing limited flows down the service spillway to both reduce ongoing service spillway erosion and prevent Hyatt Powerplant flooding, while also not overtopping the emergency spillway weir. These multiple constraints and objectives resulted in very difficult decisions, which were further influenced by a number of changing conditions and differing perceptions and viewpoints. Along the incident management timeline, there were particular points when decisions were made to limit discharge through the service spillway, even though the risks associated with powerplant flooding were clearly diminishing. This ultimately resulted in flow over the emergency spillway weir.

In general, the IFT believes that all decisions during the incident were made with the best of intentions, but in some cases were against the advice of a number of civil engineering and geological personnel. In limiting service spillway discharge to reduce the likelihood of powerplant flooding, the additional dam safety risk associated with the use of the emergency spillway may not have been appropriately considered.

5.3. ORGANIZATIONAL, REGULATORY, AND INDUSTRY FACTORS

The February 2017 Oroville Dam spillway incident can be viewed as a "textbook" case of a major dam incident, in terms of typifying the extent of contribution from human factors, including organizational, regulatory, and industry factors. Through a historical trajectory involving decades of somewhat complex interactions and effects of human and physical factors, numerous warning signs of the spillway chute failure were missed, and many barriers, which were intended to provide "checks and balances," were overcome to eventually produce the spillway chute failure and emergency spillway damage.

The IFT identified a multifaceted array of human factors, additional to those specific to the spillways, which contributed to the incident:

- DWR was significantly overconfident and complacent regarding the integrity of its SWP civil infrastructure. This was not atypical among large dam owners in the United States, and was influenced by a belief that the SWP was designed by the "best of the best" and a lack of prior major incidents at dams owned by DWR. In addition, less attention was generally paid in the United States dam engineering and safety industry to spillways as compared to main dams, which contributed to complacency in managing spillway risks.
- DWR was largely in a mode to react to problems with its civil infrastructure as they arose in the short term, rather than taking preemptive actions to proactively prevent problems. This approach was not atypical among large dam owners in the United States, and was influenced by external and internal pressures to control costs, while focusing on the needs of operations, water delivery, and hydroelectric power production.
- The dam safety culture and program within DWR, although maturing rapidly and on the right path, was still relatively immature at the time of the incident, and was about in the "middle of the pack" as compared to other large dam owners in the United States. DWR had been too reliant on regulators and regulatory processes, including associated periodic inspections and reviews, with the assistance of its numerous consultants. In addition, there was no clear identification of a senior executive within DWR who was responsible for dam safety, and the Chief Dam Safety Engineer, while highly dedicated, was not in a position to best influence either investment or emergency decisions related to dam safety.
- DWR's information management system was not sufficient to efficiently and effectively handle the very large amount of accumulated information associated with its dams, and thereby ensure that the right information was in the right hands at the right times. This factor was particularly impactful when judgments regarding the quality of the rock at the spillways were being made.
- DWR's two regulators, FERC and DSOD, like other dam safety regulators in the United States, faced numerous challenges and limitations with respect to maintaining sufficient qualified technical staff to meet workloads, addressing uncertainties when trying to balance the costs imposed on dam owners versus the risks imposed on the public and the environment, and gaining compliance from dam owners with regulatory requirements and expectations.
- DWR, and to some extent its regulators and consultants, also lacked necessary technical expertise in some areas of dam engineering and safety, with expertise generally tending to be stronger for dams than for appurtenant structures. Influencing factors for DWR included excessive organizational pride, organizational insularity, emphasis on electrical and mechanical aspects as compared to civil engineering and geologic aspects, and cost pressures and bureaucratic constraints related to technical staffing. An influencing factor for the United States dam safety industry was that the available technical literature

was not organized as a set of integrated and regularly-updated national guidelines which could readily be found and navigated by engineers and others involved in dam safety.

- Internal relationships within DWR were strained for decades prior to the incident, especially between DWR's Division of Engineering and its Division of Operations and Maintenance. While this strain was not atypical among large dam owners in the United States, it had a negative impact on DWR's decision-making and deployment of technical expertise related to its dams, both during the half-century prior to the incident, as well as during the incident response.

6. LESSONS TO BE LEARNED

In the opinion of the IFT, the following are some of the general lessons to be learned by the broader dam engineering and safety community:

- In order to ensure the safe management of water retention and conveyance structures, dam owners must develop and maintain mature dam safety management programs which are based on a strong "top-down" dam safety culture. There should be one executive specifically charged with the overall responsibility for dam safety, and this executive should be fully aware of dam safety concerns and prioritizations through direct and regular reporting from a designated dam safety professional, to ensure that "the balance is right" in terms of the organization's priorities.
- More frequent physical inspections, primarily based on visual observation, are not always sufficient to properly identify problems, determine risks, and manage dam safety. Some problems can only be identified through records review and/or subsurface investigations or non-destructive testing.
- Periodic comprehensive reviews of original design and construction records and subsequent performance reports are necessary, especially for large and high-hazard dams and their appurtenances. These reviews should be based on complete records and need to be more in-depth than periodic general reviews, such as the current FERC-mandated five-year reviews.
- Appurtenant structures associated with dams, such as spillways, outlet works, power plants, etc., must be given attention by qualified individuals. This attention should be commensurate with the risks that the facilities pose to the public, the environment, and dam owners, including the risks associated with events which may not result in uncontrolled release of reservoirs, but may still result in reduced control of the reservoir or otherwise be highly consequential.
- Shortcomings of the current Potential Failure Mode Analysis (PFMA) processes in dealing with component failures and complex systems must be recognized and addressed. A critical review of these processes in dam safety practice is warranted, comparing their strengths and weaknesses with risk assessment processes used in other industries worldwide and by other Federal

agencies. Evolution of “best practices” in dam safety should continue by supplementing current practice with new approaches, as appropriate, drawing on other industry and international experience and realistically accounting for inherent human fallibility.

- Compliance with regulatory requirements is not always sufficient to manage risk and meet dam owners’ legal and ethical responsibilities.

SUMMARY

The Oroville Dam spillway incident was caused by a long-term systemic failure of practices of DWR, its regulators, and the United States dam safety industry to recognize and address inherent spillway design and construction weaknesses, poor foundation bedrock quality, and deteriorated service spillway chute conditions. The incident cannot reasonably be “blamed” mainly on any one individual, group, or organization.

During service spillway operation on February 7, 2017, water injection through both cracks and joints in the chute slab, and associated transmission of stagnation pressure under the slab, resulted in uplift forces beneath the slab that exceeded the uplift capacity and structural strength of the slab, at a location along the steep section of the chute. The uplifted slab section exposed the underlying poor quality foundation rock at that location to unexpected severe erosion and extreme uplift pressure, resulting in removal of additional slab sections and more foundation erosion.

Responding to the damage to the service spillway chute necessitated difficult risk tradeoffs while Lake Oroville continued to rise. The resulting decisions, made without a full understanding of relative uncertainties and consequences, allowed the reservoir level to rise above the emergency spillway weir crest for the first time in the project’s history, leading to severe and rapid erosion and headcutting downstream of the weir and, ultimately, resulting in an evacuation order for about 188,000 people.

There are a number of lessons to be learned, for both DWR and the broader dam safety community. The question is whether dam owners, regulators, and other dam safety professionals will recognize that many of these lessons are actually *still to be* learned. Although the practice of dam safety has certainly improved since the 1970s, the fact that this incident happened to the owner of the tallest dam in the United States, overseen by a Federal agency, repeatedly evaluated by reputable outside consultants, in a state with a leading dam safety regulatory program, is a wake-up call for everyone in the dam safety community. Challenging current assumptions on what constitutes “best practice” in this industry is overdue.

1. INTRODUCTION

Single trace of inflow forecast has been commonly used for guiding short-term reservoir operation and provided a better way of managing water resources, compared to traditional rule-based-only operations. However, uncertainty of the inflow information is a major challenge to the operator as the single trace of inflow forecast may deviate far from the reality due to forecast errors. To better represent the uncertainty associated with the inflow forecast, ensemble stream flow prediction [1], also called ESP is gradually used to replace the single trace inflow forecast. The ESP is essentially a collection of multiple inflow forecasts that are resulted from multiple runs of weather models. The advantage of the ESP is that the inflow uncertainty under largely variable weather condition e.g., climate change are accounted through different realizations of inflow. However, the usage of the ESP may lead to a high computational cost for optimization of reservoir operation due to uncertainty modeling.

This study use a functional expansion-based method namely Karhunen-Loeve expansion to model the uncertainty associated with the ESP and demonstrate its high efficiency with a case study.

2. METHODOLOGY

The Karhunen-Loeve (KL) expansion[2] [3] [4]is a representation of a random process as a series expansion involving a complete set of deterministic functions with corresponding random coefficients. Consider a random process of $Q(t)$and let $\overline{Q(t)}$ be its mean and C(s,t)=cov($Q(s)$, $Q(t)$) be its covariance function. The Q(s) and Q(t) are variables at different time step. Then, the KL expansion of $Q(t)$can be represented by the following function:

$$Q(t) = \overline{Q(t)} + \sum_{k=1}^{\infty} \sqrt{\lambda_k} \psi_k(t)\, \xi_k \qquad [1]$$

where $\{\psi_k, \lambda_k\}_{k=1}^{=\infty}$ are the orthogonal eigen-functions and the corresponding eigen-values, obtained as solutions of the equation:

$$\lambda\psi(t) = \int C(s,t)\psi(s)\, ds \qquad [2]$$

Equation (3) is a Fredholm integral equation of the second kind. When applied to a discrete and finite process, this equation takes a much simpler form that can be easily solved. In its discrete form, the covariance matrix C(s,t) is represented as an N×N matrix, where N is the time steps of the random process. Then the above integral form can be rewritten as $\sum_{s,t=1}^{N} C(s,t)\, \Psi(s)$ to suit the discrete case. In Eq. [1],$\{\xi_k\}_{k=1}^{=\infty}$is a sequence of uncorrelated random variables (coefficients) with mean of 0 and variance of 1 and are defined as:

$$\xi_k = \frac{1}{\sqrt{\lambda_k}} \int [\, Q(t) - \overline{Q(t)}] \psi_k(t) dt \qquad [3]$$

The form of the KL expansion in Eq.[1] is often approximated by a finite number of discrete terms (e.g., M), for practical implementation. The truncated KL expansion is then written as:

$$Q(t) \approx \overline{Q(t)} + \sum_{k=1}^{M} \sqrt{\lambda_k} \psi_k(t)\, \xi_k \qquad [4]$$

The number of terms M is determined by the desired accuracy of approximation and strongly depends on the correlation of the random process. The higher the correlation of the random process, the fewer the terms that are required for the approximation[5]. One approach to roughly determine M is to compare the magnitude of the eigen-values (in descending order) with respect to the first eigen-value and consider the terms with the most significant eigen-values. With the truncated KL expansion, the large number of variables in time-domain is reduced to fewer coefficients in the transformed space (i.e., frequency-domain). The KL expansion has found many applications in science and engineering and is recognized as one of the most widely used methods for reducing dimension of random processes[6] [7] [8] [9].

3. CASE STUDY AND RESULTS

The Qinshitan Reservoir is a major hydraulic facility of the Lijiang River basin in the southwest of China. It is located at the upstream of the Gantang River, which is the largest tributary of the Lijiang River. The Qinshitan Reservoir is operated for agricultural irrigation, power generation and domestic water supply for the city of Guilin[10]. The inflow to the Qinshitan Reservoir is a critical parameter for the operation, however, is associated with large forest error, particularly in flood season.

For a period of two weeks during flood season, the ESP of inflow (six different forecasts) to the reservoir varied largely in the magnitude (shown in Fig.1). To represent the uncertainty in the ESP, we treat the ESP for the two weeks as six realizations of the random process of Q(t). By following the steps in the section of Methodology, the eigen-value and eigen-fucntion of the Q(t) are calculated. The first ten eigen-values are illustrated in Fig.2.

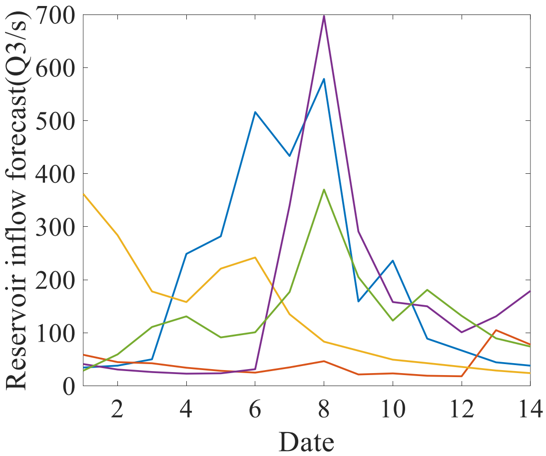

Fig. 1
ESP of Qingshitang Reservoir
de Qingshitang Réservoir

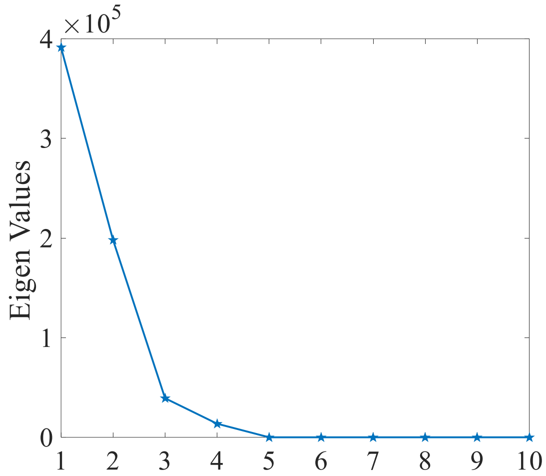

Fig. 2
The First ten Eigen Values of the ESP ESP
Les valeurs de Eigen dix premiers de l'ESP

It is observed from Fig.2 that the first three eigen-value are much larger than the rest, accounting for a large proportion in the sum of eigen-value. According to the KL expansion theory, this result means that significant portion of the random process can be approximately represented by the first three terms (Namely M=3 in this case), and is written in the following:

$$Q(t) = \overline{Q(t)} + \sum_{k=1}^{3} \sqrt{\lambda_k}\varphi_k(t)\,\xi_k \qquad [5]$$

In the Eq.[5], the average of Q(t) can be easily calculated. The eigen-value and eigen-function for the first three terms are calculated and are deterministic parameters in the equation. Therefore, the uncertainty of the ESP is only determined by three uncorrelated random variables (coefficients) with mean of 0 and variance of 1. In other words, we could use only three variables to approximate the uncertainty that are associated with the ESP of the inflow to the Qinshitan Reservoir.

4. DISCUSSIONS

The KL expansion form of the inflow ESP to the Qinshitan Reservoir (Eq.[5]) results in a great reduction for approximating the ESP uncertainty. This is particular useful for optimization the reservoir operation under uncertainty. In the conventional modeling, Monte Carlo method is used for modeling the uncertainty, which lead to a very high computation cost as thousands or even millions of simulations are carried in each time step. As a comparison, the KL expansion form of the inflow ESP has only three variables and is invariant to the time step. A high efficiency in optimization of reservoir operation can be achieved, as shown in [11]. However, it is worth mentioning that the representation of the KL expansion is specific to inflow distribution. Different inflow ensembles i.e., the ESP may result in different KL expansion form in which the parameter of M may vary from case to case.

5. CONCULUSIONS

The ensemble inflow and its associated uncertainty can be modeled by a KL representation with only three terms, meaning three variables. This result in a high efficiency in modeling the propagation and optimal control of the inflow uncertainty in reservoir operation, comparing to Monte Carlo method which normally sampling thousand times in each optimization routine.

ACKNOWLEGEMENT

The authors thank National Natural Science Foundation of Hubei Province (2017CFB613) and open funding of Hunan Provincial Key Laboratory of Key Technology on Hydropower Development(PKLHD201705). The authors would also like to thank Prof. Nathan Gibson and Dr. Veronika Vasylkivska for providing the Matlab code for the Karhunen-Loeve expansion.

ABSTRACT

One obstacle of in imbibition of dam's reservoir in time of Floodwater is the Existence of Suspended sediment in floodwater. On the other hand because the lack of water resources in arid regions, providing of water is dependent on imbibition of dams. Thus existence of Suspended sediment in reservoir's water can malfunction in the imbibition programs. Also Entry of this sediments to hydraulic structures can disorder their Performance.

Using vortex settling basins can be suggested as a solution to control the amount of sediments. One of negative point of this basins is settling some part of sediments and not flashing from bottom outlets. In current paper we recommend to use curvature submerge vanes for solving previous problems. The main propose of using this vanes is to adjust and increase the power of vortex flow and to locate the best place for installing curvature submerge vanes in the basin floor. The tests results illustrate that using this vanes with appropriate arrangement can flush out sediments of basin floor, while keeping basins efficiency. The best efficiency is for arrangements which are far away from orifice. More over while increasing Input flow and decreasing radial section of vanes, improves the efficiency of use curvature submerge vanes.

Keywords: Efficiency, Sediment, Settling basin, Submerge Vane, Vortex Flow.

1 Introduction

Since most rivers pass across loose and erodible areas, they always act as the most important factor of transferring eroded materials from the solid crust of the earth. Disregarding incoming sediments to intakes causes the transfer of sediments into water utilities and their settlement in different parts of the transmission network which will cause many problems. Sediment particles in water at high speeds cause irreparable damages to hydro mechanical parts of the hydroelectric structure such as pumps and turbines. In plants in India, irreparable damage to turbine blades due to sand in water (After two to three thousand hours of operation of turbines) (Ranga Raju *et al*. 1999).

In water transmission, especially in networks where the water is transmitted by gravity, water flow cannot hold sediment particles in the suspended mode because water speed is low and this leads to settlement and accumulation of sediment particles in the channel bed over time. This causes problems such as: A) Accumulation of sediments in the channel and a decrease in the channel free depth and capacity; B) High cost of dredging irrigation canals; C) Erosion of channel walls and aquatic structures; D) Creation of favorable conditions at the floor of canals for growth of plants, and changes in roughness coefficient. These kinds of problems have encouraged many aquatic structure experts to take on appropriate and effective measures from the beginning and avoid the entry of sediments into water transmission and distribution networks as much as possible.

One way is to separate sediments using vortex settling basins. In this type of settlings, vortex flow is used to separate sediment from water flow. This method is a solution for separating solids from liquids at high speeds, unlike classical settling basins in which settling occurs at lower speeds using the gravity force. The vortex created in these basins is generally a Rankine-type vortex consists of a forced vortex in the center of the basin and around the central orifice and a free vortex in the outer section of the central vortex of the basin (Athar *et al*. 2002). In this type of settlings, flow is directed within the basin completely tangentially and exits from the top weir while rotating around the basin. The settling phenomenon and sediment movement towards the washing orifice are occurring by secondary flows. Sediment particles are separated from water with the loss of only a small amount of discharge. Sediment particles entering the basin move along a spiral path towards the basin center (Ziaei 2000). Therefore, in such systems, the extension of the settling path of sediments is several times larger than the basin size.

Among the advantages of this sediment control method compared to other conventional methods like classic settling basin, one can point to reduce water losses, cost-effectiveness, its permanence unlike other settlings, no need for short-term dredging and smaller size (Paul 1991).

Extensive research has been conducted on a vortex settling basin by Vokes and Jenkines (1943), Velioglu (1972), Salakhov (1975), Cecen and Bayazit (1975), Sulivan *et al.* (1978), Curi *et al.* (1979), Mashuri (1981,1986), Svarovski (1981), Ogihara and Sakagouchi (1984), Sanmogantan (1985), Esen (1989), Zhou *et al.* (1989, 1997), Paul *et al.* (1991), Ziaei (2000), Athar *et al*. (2002, 2003) , Keshavarzi and Gheisi (2006) and Niknia *et al.* (2011). By changing the basin size and shape, these researchers tried to increase its efficiency. Ogihara and Sakaguchi (1984) suggested a plan that differed from other plans in the weir outlet flow. In this basin, they used a Bell-mouth weir within the basin for smooth water transmission. Mashauri (1986) proposed a plan in which inlet and outlet flows were separated by a horizontal vane. Paul (1991) proposed a plan in which a Soleus-shaped vane (deflector) was installed at a distance of one-third of the flow depth in the basin inlet channel. Saneie (1999) studied hydraulic parameters of vortex flow within vortex settling basins. Ziaei (2000) proposed a new model of vortex settling basins that is actually a combination of two inlets for clockwise and anti-clockwise flows. Athar *et al.* (2002) proposed two other models for vortex settling basins. Using experimental models and changing the orifice radius, Chyan and Quang (2010) determined the discharge coefficient C_d for the orifice. In their experiments, Niknia, *et al.* (2011) investigated the flow structure under the deflector and compared it with the flow structure without deflector for counterclockwise inlet flow to vortex basins.

One problem of vortex settling basins is the settlement of part of sediments in the basin floor. More studies are necessary to provide a method to remove or reduce these sediments. At Istanbul University of Technology (IUT), researchers such Cecen and Akmandor (1973), Curi *et al.* (1979) and Cecen and Bayazit (1975) found that the existence of a radial gradient in the floor towards the orifice can lead to better performance of the basin and reduced sediments settled on the floor. Salakhov (1975) proposed two percent increase in the gradient of the basin floor. Paul *et al.* (1991) and Ziaei (2000) suggested that the sediments deposited on the floor can be washed by installing two inlets for the flow and changing the flow from clockwise to counterclockwise and vice versa. To increase the residence time on the floor and increase the sediment washing efficiency in the basin floor, Nguyen (2011) used deflector in different arrangements and by combining one, two and three deflectors.

The present study proposes a plan to solve the problem of sediments being deposited in such basins and investigates the efficiency of vortex settling basins. This plan consists of a batch of curved submerge vanes with different arrangements in vortex settling basins. In fact, the aim of installing curvature submerge vanes in the basin floor is to modify the vortex flow shape and strengthen vortex flow to direct sediments towards the flushing orifice. These submerge vanes were first used to deal with the external erosion of rivers. Moreover, the application of these structures has been developed to control sediments in intakes due to their successful results.

2 Experimental Equipment

2.1. *Experimental Model*

Experimental studies in this research were done at a basin with a height of 96 cm and a diameter of cm. The flow direction in this basin was clockwise. This basin had a weir with a length of 168 cm. The diameter of the inlet opening of the flushing orifice of the vortex sediment basin is 59 mm. Sediments exiting from the basin flushing orifice are entered into a rectangular basin with dimensions of 2×1.5 m and a height of 0.5 m by a tube with a diameter of 17 cm for collection and analysis. Due to the turbulence caused by pumping water from the storage tank, it was necessary to reduce the flow turbulent before the flow enters into the vortex settling basin. So, at the beginning of the inlet channel, the flow smoothing basin was established with dimensions of 2.5 × 2.5 m and a depth of 2 m. The basin inlet channel had a length of 4 meters and a width 42.86 cm and a height of 71 cm.

The vortex settling basin floor had a gradient of 0.1 towards the flushing orifice and also a deflector was installed below the weir, and a diaphragm was placed in the opening of the inlet channel. The deflector structure was installed in horizontal, flat and semicircular forms. To avoid leaving sediment particles on arrival at the basin influenced by the jet outflow, it was installed on top of the weir which increased residence time of the flow containing sediment within the basin and also sediments' spinning. The diaphragm was used in the settling basin to: a) improves the shape and conduction of the jet inflow to the basin; b) create vortex flow and increase the centrifugal force for the removal of suspended sediments in the vortex basin; c) increase the basin hydraulic efficiency and improve the core shape of central air (Keshavarzi and Gheisi 2006).

At the downstream of the vortex settling basin, there were two channels; one for transporting passing water on top of the vortex basin weir and another for transporting the water of a rectangular settling basin after deposition of sediments, both of which had a width of 60 cm and a height of 60 cm.

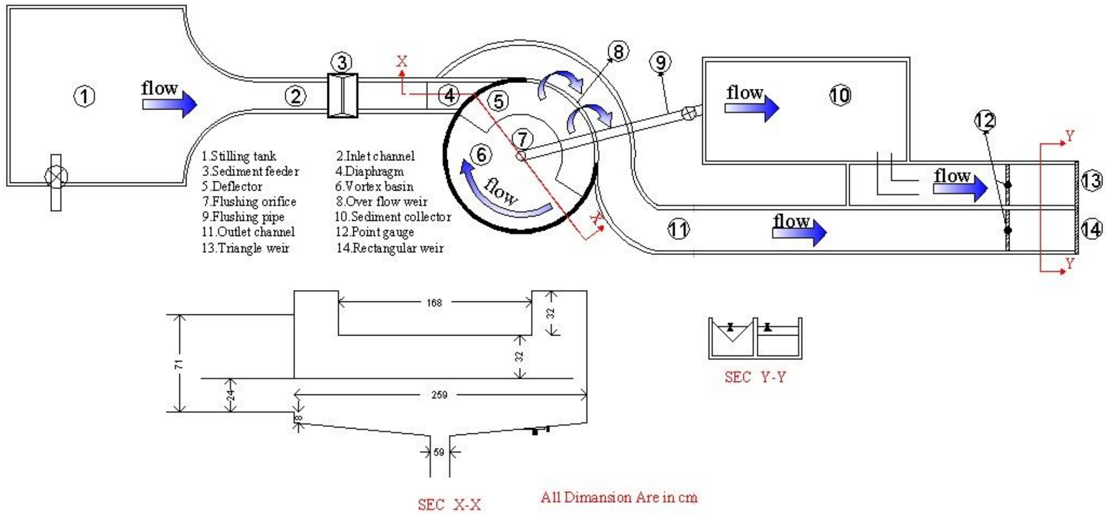

Figure 1 the plan of the experimental model of vortex settling basin

To determine the basin inlet discharge, the discharges of two downstream channels were calculated by measuring their water surface figures using a point Gauge. At the end of these canals, there were two calibrated weirs. The outlet channel weir of the vortex settling basin weir was rectangular and the outlet channel weir of the settling basin was triangular with an angle of 90 degrees.

2.2. *Sediment Injection*

In experimental models, sediments were injected in such a way that there was the necessary matching between the model and the actual sample. Therefore, the material collected from various parts at the end of the experiments must be equal to the amount of the injected upstream. Moreover, the sediment load should be poured in a suitable place so that it has the opportunity to have a uniform distribution in the flow cross section, and also sediments are entered into the basin in a suspended manner. In their studies, researchers used different grains, some of which are shown in Table 1. Different materials were examined to determine the type of settled material and finally, given issues such as sediment supply, grain size, injection, sampling, collection, drying, density and uniform distribution, sand drift was used. Sediments are made of sand drift with a grain size of d_{50}=0.22 mm.

In previous studies, sediment injection was done with different methods. Athar *et al.* (2002) carried out sediment injection by a device composed of a circular-shaped cylinder and sediments lied within it. The device was installed in the floor of the vortex settling basin inlet channel and the sediment injection rate was controlled by a cable. Keshavarzi and Gheisi (2006) performed sediment injection by a device that worked like an hourglass. Niknia *et al.* (2011) mixed sediments with water in a tank and performed sediment injection by obtaining a specific concentration.

The sediment injection device used in this study is seen in Figure 3. For sediment injection, a certain volume of the desired sediment was poured into the injection device tank with a volume 50 liters (funnel-shaped tank) and dry sediment were regularly getting out of the device and poured into the channel by rotating the roller inside it that had three longitudinal grooves. The roller rotation was done by an electric motor that had a controllable revolution. The precision of this control was in revolution per second. This device was placed at a distance of 1.5 m from the upstream channel of the vortex settling basin.

2.3. *Curvature Submerge Vanes*

Submerge vanes are vanes whose effective application in changing flow pattern and bed shear stress in order to control local erosion and change sediment movement pattern has been studied by many researchers. First, Odgaard and Kennedy (1983) and Odgaard and Spoljaric (1986) attempted to design submerge vanes. Then, extensive studies on the application of submerge vanes to avoid bed load entering the intake were done by Barkdoll *et al.* (1999), Nakato and Ogden (1998), Wang *et al.* (1996) and also to control riverine erosion by Odgaard and Wang (1991a, 1991b), Marelius (2001), Voisin and Townsend (2002). According to extensive research on designing these vanes in the mentioned fields, research and theory have been offered on the use of submersibles vanes and also optimal dimensions and arrangements for vortex settling basins.

Vane dimensions were determined based on recommendations by Odgaard and Kennedy (1983) and considering the flow depth (*d*= 8 cm) which is the prolapse of jet flow in the inlet opening of the vortex settling basin. Submerge vanes are galvanized with a rectangular initial shape (Figure 4) and a thickness of 2 mm. Table 2 shows the dimensions of submerge vanes.

Table 2 Dimensions of curvature submerge vanes

Parameter	Height of submerge vane H_v	Length of submerge vane L_v
Recommended by Odgaard and Kennedy (1983)	$0.2 < \frac{H_V}{d} < 0.5$	$3H_V < L_V < 4H_V$
Applied value	$0.5 = \frac{H_V}{d}$	$3H_V = L_V$

The vanes placed on the basin floor are curved. The curvature of any vane is equal to the circular arc laid on its perimeter. Therefore, given the radial distance of vanes from each other, vanes have six different curvatures with radiuses of 27.95, 40.45, 52.95, 65.45, 77.95 and 90.45 cm. Figure 5 shows six different types of vanes with different curvature.

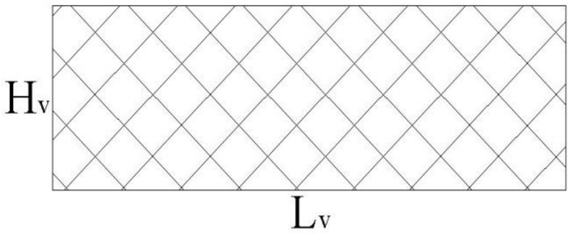

Figure 4 Profile of curvature submerge vanes

Figure 5 Vanes submerge with six types of curvature

To place vanes in the basin floor and achieve the ordered and optimum arrangement, various conditions were considered:

- To evaluate the effect of longitudinal distances of vanes on the vortex basin efficiency, its floor was divided into radial sections with the same angle. The longitudinal distance was examined in three modes with 4, 6 and 8 radial sections with identical angles which were 90, 60 and 45 degrees, respectively. The radial sections are called *S4*, *S6* and *S8*, as shown in Figure 6.

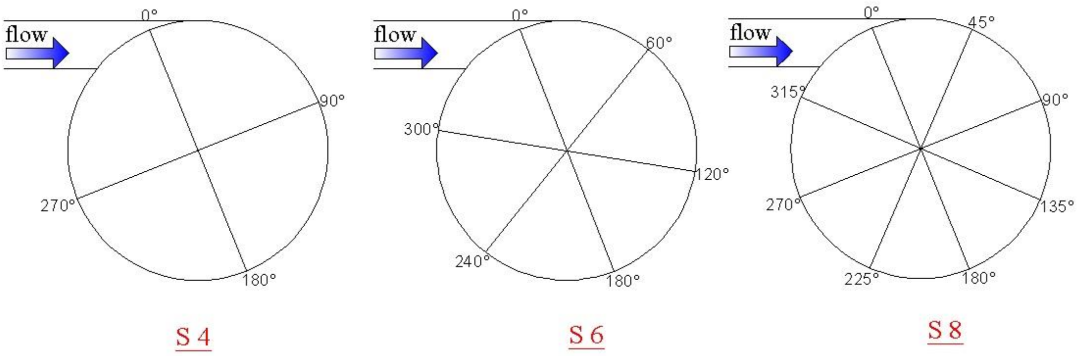

Figure 6 Radial sections of vanes

- To evaluate the radial distance of vanes from the flushing orifice, the basin floor was divided into four equal-interval concentric circles. Figure 7 shows circles with the number of areas intended for them.

- For vanes to affect vortex flow more, another vane was placed between the vanes. The radial distance of vanes from each other considered the constant $\delta_n=3H_v$ (Odgaard and Kennedy 1983).

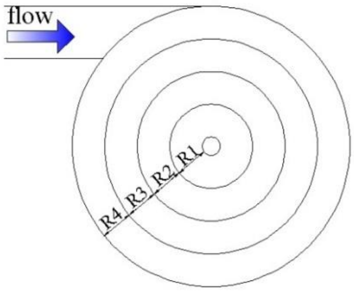

Figure 7 Areas for vane insertion on the basin floor

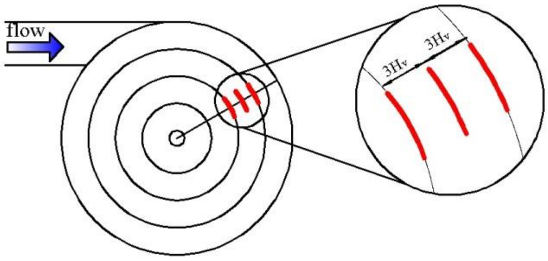

Figure 8 Radial distance of vanes from each other

- Initial tests of sediment injection in the no-vane mode showed that no sediment remains at a distance of the first ¼ of the radius around the orifice (area 1) (Figure 9). However, at a distance of the next ¾ of the vortex basin radius (areas 2, 3 and 4), most sediments are accumulated. So vane insertion was ignored in area 1. Submerge vanes were inserted in six arrangements. Each arrangement was named according to the vane position area. Since the insertion of several submerge vanes besides each other can affect a larger area, they first were placed separately in the desired radial section in a circle with triplet bunches in areas 2, 3 and 4 called *R2*, *R3*, *R4*, respectively. Then, vane insertions in circles were combined (*R2 3*, *R3 4*, *R2 3 4* arrangements) to broaden the area affected by one. The effect of this widening was investigated on the sediment removal efficiency. The used arrangements are shown in Figure 10.

Figure 9 Initial test of sediment injection in the no-vane mode

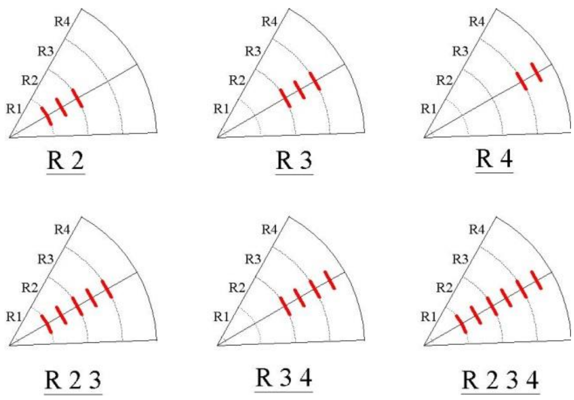

Figure 10 Arrangements of curvature submerge vanes

3 An Experimental Program

In this research, for starting tests, water was entered into the system by pumping. Water flow entered into the vortex settling basin from the inlet channel through the inlet opening under the diaphragm. Once a steady and constant flow was established in the model, the discharge of the water entering the vortex settling basin was measured by two rectangular and triangular weirs at the end of outlet channels. After flow fixation and discharge adjustment, sediment supply began with a constant discharge for a specified duration (20 minutes). When sediments finished, the pumps were turned off (water inflow to the basin was cut off), the flushing orifice exit valve was closed. Then the sediments within the vortex basin and the sediments exited from the orifice and the weir were separately collected, dried and weighed. This procedure was done for discharges of 45 and 37 l/s and six vane arrangements in three radial sections.

4 Results and Discussion

To calculate the vortex settling basin efficiency, Ziaei (2000) used the sampling method. He gathered samples from the weir outlet and the flushing orifice and then calculated the basin efficiency using sample concentrations. Keshavarzi and Gheisi (2006) and Athar (2000) used another method to calculate the vortex settling basin efficiency. They collected and dried sediment exited from the weir and the flushing orifice and then calculated the vortex settling basin efficiency based on the weight of collecting sediments. After examining methods for determining the vortex settling basin efficiency, it was known that the methods of Keshavarzi and Gheisi (2006) and Atahr (2000) are more accurate. Therefore, the present study used that method.

Sediments in this system are divided into three main categories. The first category is sediments which are transferred out of the basin together with some percent of water from the flushing orifice. The second category is the sediments settled in the vortex basin floor and, over time, they cause dysfunction in the settling performance of the structure. Finally, the third category which consists of a small percent of sediments exited through the vortex weir with water flow. To calculate the vortex settling basin efficiency according to the harvested lab data, parameters η_T, η_O and η_B were used. These parameters were defined as follows:

$$\eta_T = \eta_o + \eta_B \tag{1}$$

$$\eta_o = \frac{W_o}{W_T} \tag{2}$$

$$\eta_B = \frac{W_B}{W_T} \tag{3}$$

Which η_T is total settling efficiency, η_O is the settling efficiency of the orifice, η_B is the settling efficiency of the basin floor, W_T is the total weight of the sediments entering the basin, W_O is the weight of sediments entering the flushing orifice, and W_B is the weight of sediments on the basin floor.

Also, to show the sediment washing rate of the floor, parameter *G′* was used:

$$G' = \frac{(\eta_B^{'} - \eta_B)}{\eta_B^{'}} \qquad (4)$$

Which *G′* is sediment washing efficiency of the basin floor, η'_B is settling efficiency of the basin floor without curvature submerge vanes and η_B is settling efficiency of the basin floor with curvature submerge vanes.

First, initial tests were conducted without vanes on the floor with sediment. These tests were done with discharges of 45 and 37 l/s. The two tests were performed as a benchmark for comparing, analyzing, and determining the effectiveness of the modes with and without curvature submerge vanes. In these tests, the total efficiency of the vortex settling basin was obtained 93.66 and 95.76% for discharges of 37 and 45 l/s, respectively. In the presented results, *R0* and *S0* represent tests without curvature submerge vanes. *R0* means without arrangement and *S0* means without radial sections.

(a) (b)

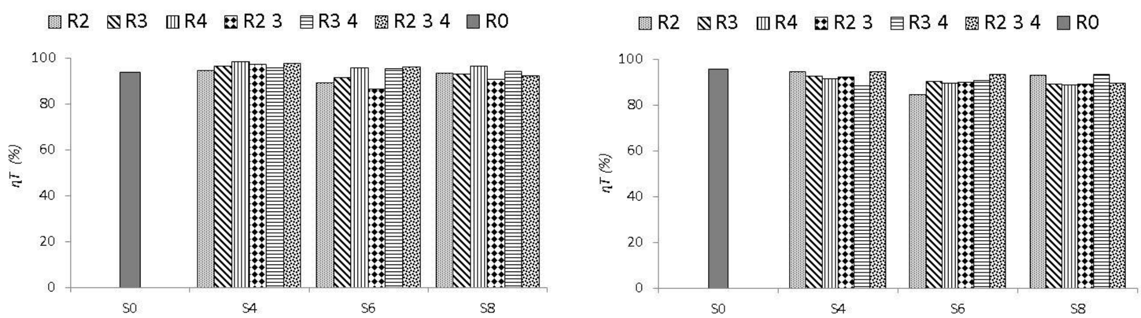

Figure 11 Total efficiency of the vortex settling basin in a) discharge of 37 l/s ,b) discharge of 45 l/s

In Figure 11, according to changes in radial sections of vanes and discharge, it was observed that curvature submerge vanes have a little impact on total efficiency of the vortex settling basin. Overall, for discharge of 37 and 45 l/s, they increased total efficiency of the basin in some arrangements by 0.51-4.68% and decreased it in some arrangements by 0.47-11.45%. The reduction of total efficiency occurred in the discharge of 45 l/s due to the reduction in the efficiency of the basin in the floor. The insertion of submerge vanes in the floor of the vortex settling basin caused significant changes in the share percent of sediments settled in each part of the basin so that these vanes increased the floor efficiency and decreased the orifice efficiency in some arrangements, so these arrangements are not desirable. In some arrangements, the floor efficiency decreased and the orifice efficiency increased. So in these arrangements, the goal which was sediment washing of the basin floor was realized. This change in the share of settling can be attributed to the vortex flow caused by submerge vanes. These vortices flow move sediments settled on the floor and direct them toward the flushing orifice. As shown in Figures 12 and 13, by holding constant the total efficiency, different modes of arrangements could change the orifice efficiency and the floor efficiency. With these changes, for each R mode, when the orifice efficiency increased compared to its corresponding no-vane mode, the floor efficiency decreased compared to its corresponding no-vane mode.

(b)

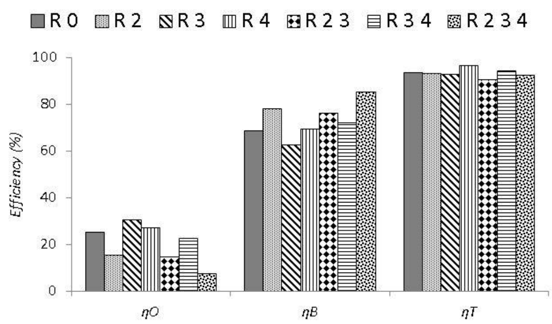
(c)



(c)

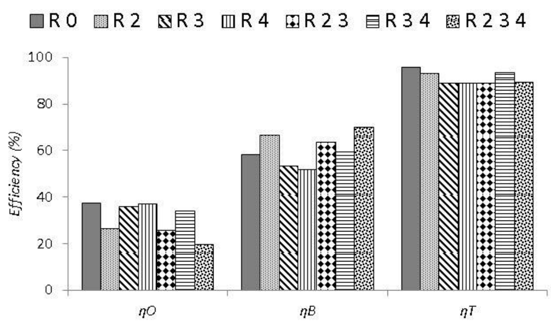


Figure 12 Total, orifice and floor efficiencies in the discharge of 37 l/s (a) *S4* mode, (b) *S6* mode, (c) *S8* mode

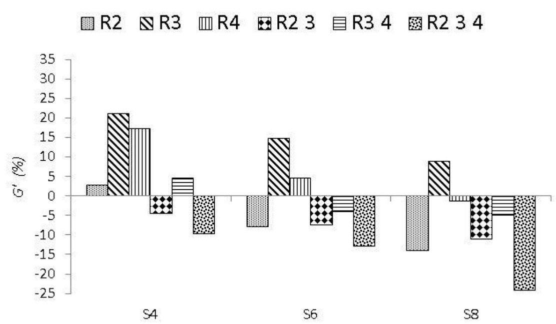
Figure 13 Total, orifice and floor efficiencies in the discharge of 45 l/s (a) *S4* mode, (b) *S6* mode, (c) *S8* mode

Efficiency in each part of the vortex settling basin is the weight ratio of the sediment accumulated in that section. Thus, an increase in the orifice efficiency compared to the no-vane mode is desirable but increase in the floor efficiency is not desirable because it means the accumulation of more sediments in this area and the lack of sediment washing of the floor. Thus, as shown in diagrams, *R3*, *R4* and *R3 4* arrangements have better efficiency because they reduce the share of sediments settled on the vortex settling basin floor and increase the share of sediments exited from the flushing orifice. In these modes, the floor efficiency reduced and the orifice efficiency increased.

According to no-vane tests, the desirability of such arrangements were somewhat predictable so that most sediments settled on the vortex settling basin floor in no-vane modes are in areas *R3* and *R4* (Figure 9). So the insertion of vanes in the two areas will increase sediment washing from the floor.

As shown in Figure 14, among *R3*, *R4* and *R3 4* arrangements, *R3 4* has the lowest efficiency in sediment washing. Curvature submerge vanes in some arrangements decreased sediment washing from the floor. This reduction can be attributed to the impact of vanes in avoiding secondary flows which occur in the vortex settling basin floor towards the orifice.

(a)



(b)

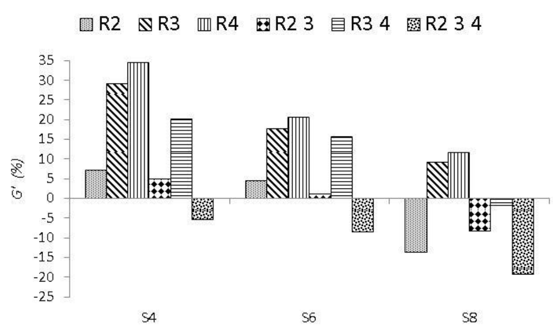


Figure 14: Percent of the floor sediment washing compared to no-van mode (a) discharge of 37 l/s ,(b) discharge of 45 l/s

This study examined the effect of radial sections in curvature submerge vanes. The vanes were inserted in three modes, with radial sections with angles of 90, 60 and 45 called *S4*, *S6* and *S8*, respectively. Figures 12 and 13 show the results of changing the number of radial sections of vanes inserted in the floor on the efficiency of each part of the basin. It is noteworthy that *S0* represents the no-vane mode. According to the results, with an increase in the radial sections of vanes, total efficiency reduced compared to the no-vane test *S0* that among the three modes, minimum orifice efficiency was related to *S8* and maximum orifice efficiency was related to *S4*. The results also show that with an increase in the radial sections of vanes, the orifice efficiency reduced in both discharges and the floor efficiency increased (lower sediment washing from the floor). Among *S4*, *S6* and *S8* modes, *S4* has the best performance. Studying the effect of discharge on the vortex settling basin shows that discharge changes had little impact on the basin total efficiency but changed the share of settling in each part of the vortex settling basin. As seen in Figures 12 and 13, higher discharge (45 l/s) reduced the floor efficiency and increased the orifice efficiency. Lower discharge (37 l/s) reduced sediment washing from the floor.

According to Figure 14, parameter G' was positive in *R3* and *R4* arrangements and both discharges but the reaction of these two arrangements was different in two discharges so that in the discharges of 37 and 45 l/s, *R3* and *R4* showed better reactions, respectively. *R3 4* was somewhat successful in sediment washing from the floor but its value was less than *R3* and *R4* arrangements. As shown in Figure 14, the parameter *G′* was negative at discharges of 37 and 45 l/s for *R4* and *R3 4*. This decline in sediment washing increased with radial sections of vanes (increased radial sections). Reduced sediment washing (*G′*) at the discharge of 37 l/s occurred for all tests. The reason for reduced sediment washing of the floor at the lower discharge is the reduced vortex strength and the reduced speed because these basins have a better efficiency at high speeds. *S0* when discharge is low, sediments are not affected by vortex flows within the basin and begin to settle on the basin floor. However, according to Figures 12 and 13, reduced orifice efficiency and reduced sediment washing on the basin floor also occur at lower discharges in no-vane modes. *S0*, in this type of basin, with an increase in discharge, vortex strength and thus vanes' efficiency in the basin will increase. Finally, the best cases of sediment removal from the floor occurred at the discharge of 45 l/s at the longitudinal distance of *S4*, and *R3*, *R4* and *R3 4* arrangements. The amounts of increase in sediment removal from the floor at the best cases for *R3*, *R4* and *R3 4* arrangements were 29.12%, 34.49% and 20.15%, respectively. Moreover, these arrangements increased the orifice efficiency in the discharge of 45 l/s by 13.66%, 15.73% and 4.26%, respectively.

Finally This study first introduced previous research on vortex sediment basin and then provided a solution for a problem in vortex sediment basins which is the settlement of some percent of sediments on the basin floor and non-exit from the flushing orifice. The solution presented in this paper is to use curvature submerge vanes to increase vortex power and better conductivity of the floor sediments towards the flushing orifice. It was observed that after inserting curvature submerge vanes in the basin floor, with little change in total efficiency, one can change the share of the sediments entering the orifice and the sediments settled on the basin floor compared to the no-vane mode. How these vanes work (sedimentation or settling from the floor) depends on their distance from the orifice. At a low radial distance (areas 1 and 2), they increase sedimentation on the floor by preventing the movement of sediments towards the orifice. But at a large radial distance (areas 3 and 4), they remove sediments from the floor by directing the floor sediments towards the flushing orifice so that increased sedimentation on the floor was observed for *R2* and *R2 3*, and *R2 3 4* arrangements and sediment removal was observed on the floor for *R3* and *R4* and *R3 4* arrangements. Also, tests for inserting curvature submerge vanes in three modes of radial sections showed that the lower number of radial sections, the better the settling on the floor will be done. Among the three modes, *S4* (90-degree radial sections) had higher sediment removal efficiency.

GROWING NEED FOR STORAGE AS AUSTRALIA TRANSITIONS FROM COAL ENERGY TO RENEWABLES

Richard HERWEYNEN
Principal Consultant - Civil, ENTURA

Nick WEST
Senior Hydropower Engineer, ENTURA

AUSTRALIA

1. INTRODUCTION

Climate change is a global problem. On 10 November 2016, Australia ratified the Paris Agreement, committing to achieve a 26 to 28 per cent reduction in greenhouse gas (GHG) emissions below 2005 levels by 2030 [1]. The energy sector accounts for 79 per cent of Australia's emissions and therefore will play a key role in Australia's reduction targets.

As a result, Australia's national electricity market (NEM) is going through a transition as it moves towards low-carbon-emissions generation in response to climate change. This is resulting in new opportunities for existing hydropower generators, leading to potential changes in operating regimes.

2. THE AUSTRALIAN ENERGY MARKET

Australia's electricity system was founded on centralised, carbon-intensive coal-fired generation. Currently, coal-fired generation (both brown and black coal) makes up 78 per cent of electricity generation across Australia's National Electricity Market (NEM). The sector is the single largest contributor to GHG emissions, and contributes approximately a third of Australia's total emissions. As coal-fired power stations reach the end of their lives they will be decommissioned. A total of 45 TWh of coal-fired generation is set to retire in Australia.

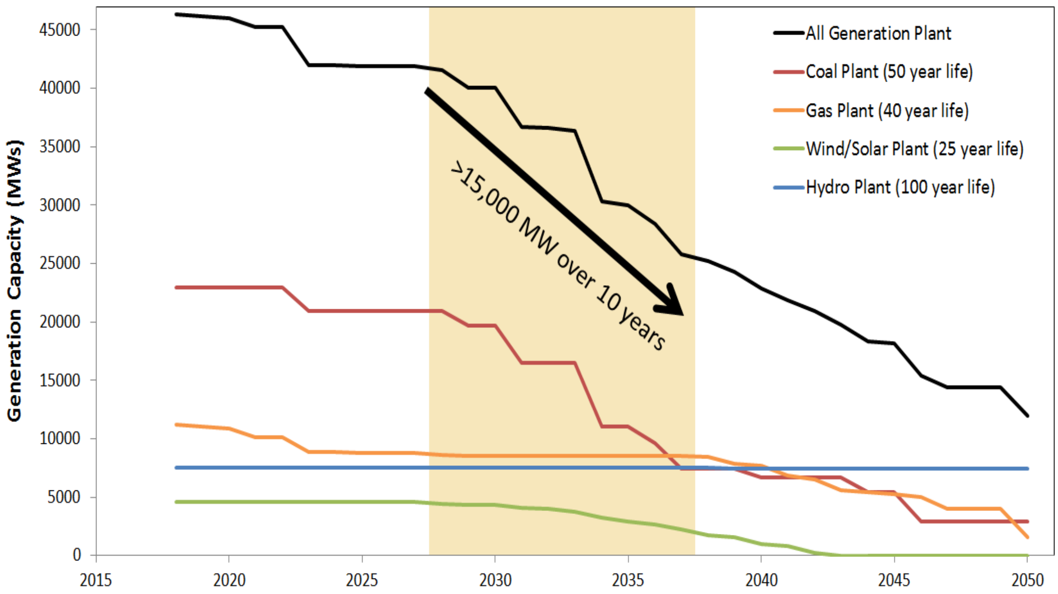

Fig. 1
Expected retirement profile of generation assets in Australia - based on life expectancy [2]

The CSIRO's Low Emissions Technology Roadmap [1] has identified that the most likely pathway for Australia to meet its commitment to reduction in GHG emissions is to replace the coal-fired generation with renewable energy, mainly wind and solar PV. However, these renewables are highly variable and non-dispatchable. Fig 2 shows the NEM generation mix and how it is likely to transition.

As the proportion of variable renewable energy increases, increased storage is required for supply–demand matching to manage the variability in generation and provide the required system flexibility. Hydropower storage plays an expanding role in integrated power systems internationally and can enable increased use of intermittent renewable energy sources such as wind and solar.

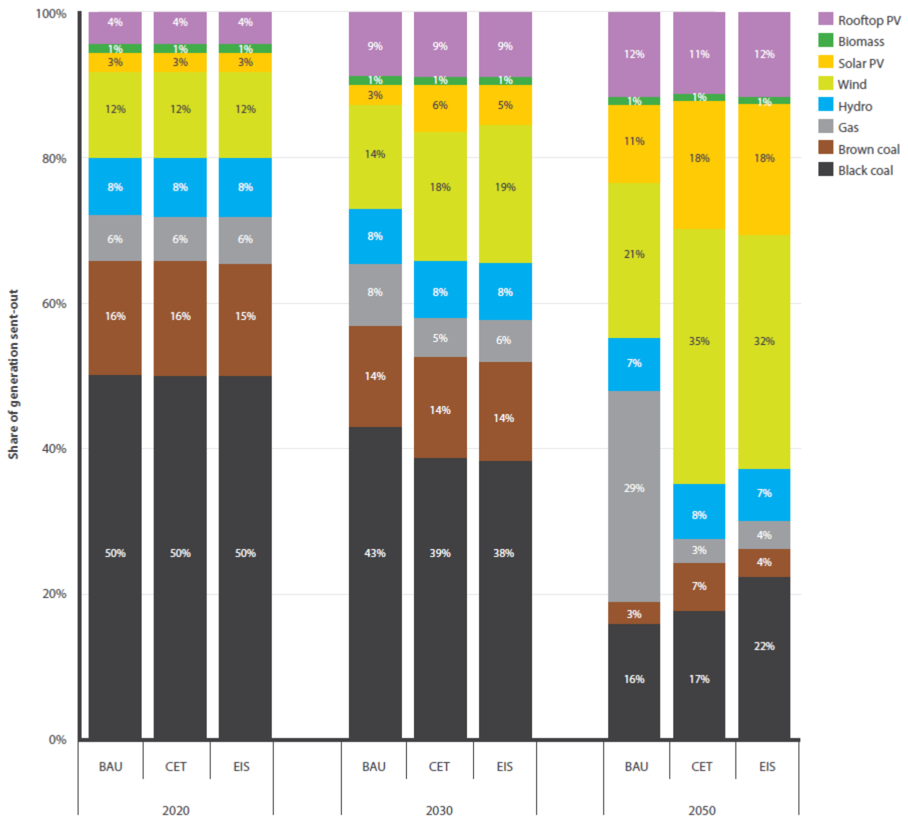

Fig. 2
NEM generation mix, 2020, 2030, 2050 [3]

While moving towards a low carbon future, the challenge is the energy ‘trilemma’ of security, equity (accessibility and affordability) and environmental sustainability. These three factors need to be in balance to ensure a secure power sector that meets the present and future needs of energy consumers while moving towards a lower carbon future.

2.1. The Need for Large-Scale Storage

The rapid growth of renewable energy generation has been driven by two concurrent factors: the falling levelised cost of the energy produced by wind and solar, and the retirement of a number of coal-fired power stations. The recently released Finkel Review [3] notes that by 2035, approximately 68 per cent of the current fleet of Australian coal-generating plants will have reached 50 years of age.

Renewables cannot, on their own, meet the fluctuations in demand that occur throughout the day without some regulation as to when power reaches the grid. Power needs to be dispatchable, which means that energy can be provided upon request. If the sun is not shining or the wind is not blowing, renewable energy cannot be dispatched unless it has been stored in some way. With increasing proportions of renewable generation in the energy mix, the dispatchability of generation to meet demand becomes more important, as shown in Fig 3. Once way of improving the dispatchability of renewables is to add storage in the power system

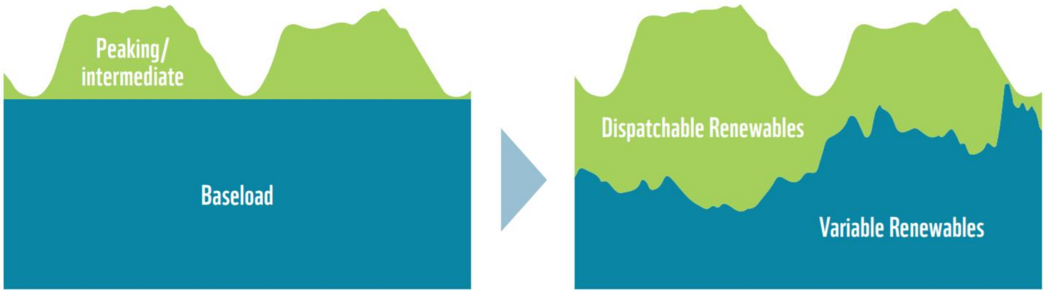

Fig. 3
Comparison of a baseload dominated electricity system (left) and a variable and dispatchable model (right) [4]

There are a number of different types of storage but the two being discussed most widely right now are batteries and pumped storage hydropower. These two technologies are very different and there are some limitations involved in comparing a well-known and established technology, like pumped storage, with one that is new and developing rapidly, like battery technology.

Pumped storage hydropower is based on well-established synchronous generation, providing critical ancillary services to the grid, through the provision of inertia, frequency and voltage support and sufficient fault level support. Battery inverter technologies are still catching up on most of these fronts. The potential for batteries to provide 'synthetic inertia' or fast frequency response is high but they rely on system strength to be able to deliver this support. They offer minimal support with fault levels but can still provide some support to system frequency and voltage regulation.

Recent electricity price spikes and a state-wide blackout in the state of South Australia have highlighted the need for reliable power to balance the potential volatility of some renewable power sources.

2.2. Hydro Storage Projects

With an increased amount of renewable energy within the Australian grid, hydro storage has gained increased attention. Whether this be pumped storage hydropower, like the Kidston pumped storage project in Northern Queensland, or better use of existing hydropower storages, like Tasmania's "Battery of the Nation" concept. Since connecting to Australia's National Energy Market via the Basslink interconnector in 2006, the flexible hydropower system of the island state of Tasmania has already acted as a giant 500 MW battery [5] for Australia, because of the volume of water stored.

A brief summary of some of the current hydro storage projects currently being investigated in Australia is given in the following sections.

3. PUMPED STORAGE PROJECTS IN AUSTRALIA

3.1. Pumped Storage Hydropower

As the proportion of renewable energy in an energy market increases, the need grows for the stability and consistency provided by utility-scale energy storage. For example, South Australia needs system-wide storage of 500 MW for a period of 10 hours to improve the flexibility of wind farm operators, according to the Melbourne Energy Institute [6].

At the smaller scale of energy storage, the buzz about various types of batteries continues – but the only storage option with a proven track record at the utility scale is pumped storage hydropower.

Pumped storage hydropower works by pumping the water stored in a lower reservoir into a more elevated reservoir. The water stored at height can be passed through a turbine on its path back to the lower reservoir, creating electricity as and when needed, and making the best use of the water resource without waste.

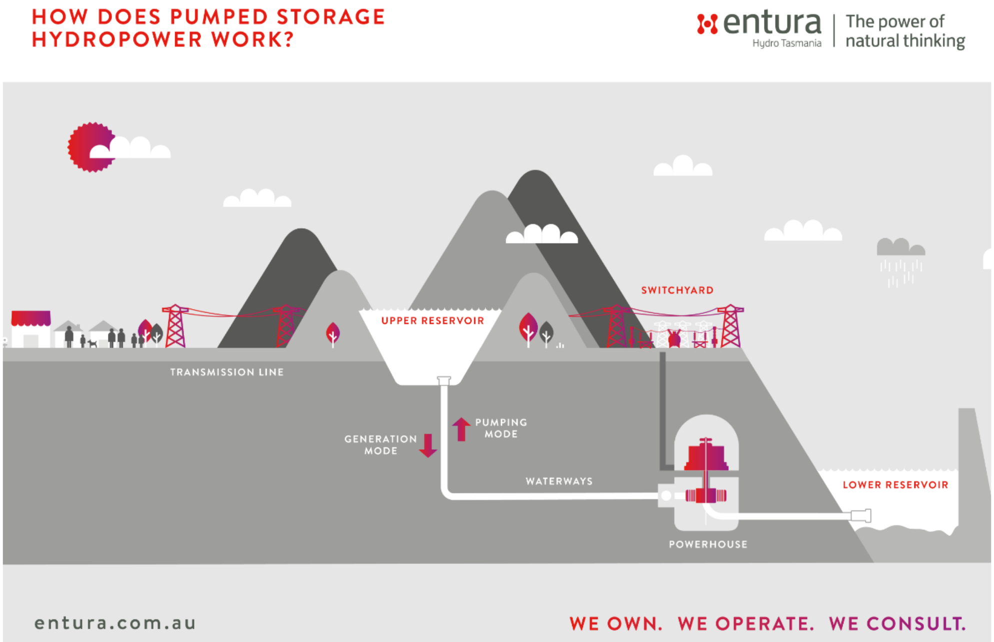

Fig. 3
How pumped storage hydropower works [7]

3.2. EXISTING AUSTRALIAN PUMPED STORAGE

Despite the significant potential and benefits of pumped storage hydro projects, only three projects currently exist in Australia (two in New South Wales and one in Queensland). These projects were built in markets in which thermal sources dominated, where the pumped storage could supplement supply at times of peak demand.

The existing pumped hydro projects in Australia include:

- Tumut 3 Power Station – construction completed in 1963. Installed capacity: 1800 MW (600 MW pumping)
- Shoalhaven Scheme – construction completed in 1977. Installed capacity: 240 MW
- Wivenhoe Power Station – construction completed in 1984. Installed capacity: 500 MW.

3.3. DRIVE TO FIND NEW PUMPED STORAGE PROJECTS

As the proportion of renewable energy in an energy market increases, the need grows for the stability and consistency provided by utility-scale energy storage. A number of high-level studies to identify potential pumped storage hydropower sites have been undertaken using available GIS information. One such study has been undertaken by the Australian National University, which has identified 22 000 potential sites [8], which will need to be further refined. In addition, a number of detailed feasibility studies have recently been completed for two new pumped storage projects in Australia, namely the Kidston Pumped Storage Hydro Project and the Cultana Pumped Hydro Project. A brief summary of these two projects is provided below.

3.4. KIDSTON PUMPED STORAGE HYDRO PROJECT

Genex Power is the developer of the Kidston Energy Hub in the north of the Australian state of Queensland. The site of the proposed development is the disused Kidston Gold Mine near Georgetown. Should the project be developed to its full potential, it will ultimately consist of a 250 MW pumped storage project, collocated with a 270 MW solar PV installation [9]. A 50 MW solar PV project is currently in the final stages of commissioning. A unique aspect of the Kidston Pumped Storage Hydro Project is its use of two existing mine pits as the upper and lower reservoirs.

Given the significant potential water head differential that the pits offer, and the vast quantity of water the pits can hold, the project has been optimised to support 2000 MWh of continuous power generation in a single generation cycle

(250 MW of peaking power generation over an 8-hour period). The power generated will be sold directly into the NEM.

A concrete-lined pressure tunnel will connect the upper reservoir to the underground generation powerhouse. A concrete-lined tailrace tunnel will, in turn, connect the powerhouse to the lower reservoir. A shaft from the surface will connect the underground infrastructure to a surface power control room, which will be connected to a transformer station located on an existing pit bench.

The Kidston Pumped Storage Hydro Project (250 MW) is a closed-loop system, which will involve the transfer of water from the upper reservoir to the lower reservoir. This will ensure minimal environmental impact during operation, on what is an already disturbed former mining site.

3.5. CULTANA PUMPED HYDRO PROJECT

Energy Australia is the developer of a potential seawater pumped storage project on the Eyre Peninsula in South Australia. A lack of freshwater resources in inland South Australia means sites adjacent to the coastline are worthy of consideration for pumped hydro projects. The Cultana site was selected based on the elevation, proximity to the coast, proximity to grid connection and minimal environmental and cultural impacts [10].

There are many precedents for freshwater pumped storage projects globally; however, there is only one international precedent for large-scale seawater pumped storage projects – a 30 MW facility in Okinawa, Japan, which was decommissioned in 2016 [11].

The prefeasibility study for the project considered a capacity envelope of between 100 MW and 250 MW. Below 100 MW it was expected that the fixed costs of large civil construction would be too high to yield a viable project due to lack of economies of scale. Beyond the upper limit of 250 MW there is a risk that the storage capacity would be too large for the South Australian market. The larger the capacity, the lower the expected market revenue per unit of capacity.

Within this range, the proposed 225 MW nameplate capacity of the Cultana Pumped Hydro Project was determined based on the maximum scale that could be achieved while avoiding any significant incremental changes in cost [10].

4. CHANGING USE OF EXISTING HYDRO STORAGES

4.1. EXISTING HYDRO IN AUSTRALIA

The two largest hydro generation companies in Australia are Snowy Hydro and Hydro Tasmania.

Snowy Hydro Limited operates and maintains the Snowy Mountains Scheme in Australia's Southern Alps. Construction started on the scheme on 17 October 1949 and was completed in 1974. On completion, the scheme consisted of seven power stations, 16 major dams, 145 km of interconnected tunnels and 80 km of aqueducts. The company today has 16 power stations, which generate 4500 GWh on average per annum and also has more than 5500 MW of multi-fuel generation capacity across New South Wales, Victoria and South Australia [12].

Hydro Tasmania is Australia's largest generator of renewable energy and largest water manager. Since its inception in 1914, Hydro Tasmania has been a leader in clean energy innovation in Australia - building 54 major dams, 30 hydropower stations with an installed capacity of about 2200 MWh and two major wind farms. Hydro Tasmania produces about 9000 GWh of clean renewable electricity from hydropower every year [13].

4.2. OPPORTUNITY TO OPERATE DIFFERENTLY

The same drivers that are causing the market to explore pumped storage hydropower are also causing existing hydropower energy companies to consider using their existing hydro storage assets differently to meet the growing storage need and/or to modify their assets to meet this new opportunity. This has resulted in two major strategic projects: Snowy 2.0 and the Tasmanian "Battery of the Nation". Both are discussed briefly below.

4.3. SNOWY 2.0

The proposed Snowy 2.0 Pumped Storage Project is currently the subject of a feasibility study. Linking two existing storages, Tantangara (upper) and Talbingo (lower) via 27 km of tunnels and with an installed capacity of 2000 MW, Snowy 2.0 would be one of the largest pumped storage projects in the world and would add about 35% to the installed capacity of the Snowy Mountains Scheme.

One of the most significant aspects of the project is that the volume of the existing storages provides an energy storage capacity of about 350 GWh, or 175 hours of continuous operation at full output – something that is rare amongst pumped storage projects around the world. To put this into context, research by the Australian National University has found that the optimum pumped hydro energy storage contribution is 1525 GW of power capacity with 15-30 hours of energy storage to support a 100% renewable electricity system in Australia [14].

Snowy Hydro, the developers of the Snowy 2.0 project, state that the project will serve the market and consumers by providing dispatchable generation to address supply volatility, as well as fast-start capability and large-scale storage to address intermittency issues.

An investment decision on Snowy 2.0 is expected by the end of 2018. Initial estimates suggest costs in the range of AUD $3.8 billion to AUD $4.5 billion.

Assuming the project meets its financial hurdles, it could begin operation in 2024 [15].

4.4. BATTERY OF THE NATION

The 'Battery of the Nation' [16] project aims to set a blueprint for how Tasmania's renewable resources could be developed over coming decades. With funding support from the Australian Renewable Energy Agency (ARENA), Hydro Tasmania is investigating future development opportunities through which Tasmania could make a greater contribution to the National Electricity Market (NEM).

With further interconnection to mainland Australia, favourable market settings and a sound development plan, Tasmania could produce significantly more renewable energy and realise the full value of Tasmania's hydropower system.

This initiative, if realised, would lock in full energy security for Tasmania, help give Tasmanians access to the lowest possible power prices and deliver reliable, cost-effective clean energy as the 'Battery of the Nation'.

The program of works includes:

- 'future state' National Electricity Market analysis – investigating and developing a pathway of future development opportunities for Tasmania to make a greater contribution to a future National Electricity Market
- the Hydro Tasmania pumped hydro energy storage project – assessing opportunities for pumped hydro in Tasmania, including potential conversion of existing hydro generators and new installations
- power system improvements – investigating projects that will improve and optimise power generation including options for redesigning the Tarraleah Power Scheme to boost efficiency and improve management of environmental flows through the Gordon Power Station.

5. CONCLUSIONS

This paper has demonstrated the growing importance of storage in Australia's NEM as coal-fired generation is replaced by variable renewables. It has also highlighted the importance of hydro storage and how this can be achieved through either pumped storage hydropower or better utilisation of existing hydropower storages. It is highly probable that the transition to renewables will lead to a change in the way existing hydro storages are operated, not only providing energy but also providing grid reliability and flexibility.

CLIMATE EFFECT ASSESSMENT OF THREE GORGES PROJECT

ABSTRACT

The reservoir was formed by runoff dam, sluice, embankment construction, water conservancy project and weirs water impoundment. The reservoir can be used for water supply, irrigation, power generation, flood control, shipping, tourism and improve the environment, but with the global water resources and energy demand increase, sharp increase in the number and size as well as the reservoir, environmental effects and social impact is gradually being recognized.

The China Three Gorges Project has generated extensive concerns both domestically and abroad.

How to evaluate the climate effect of the Three Gorges water conservancy project scientifically、objectively and quantitatively? Scientists are very concerned about the issue, The assessment of the climate effect of the Three Gorges project is of great significance for the normal operation of the Three Gorges Project and the correct understanding of the Three Gorges Project by the society and the public.

In order to answer this question and to objectively evaluate the climatic effects of Three Gorges project, China Three Gorges Corporation organize relevant experts to carry out research on the climate effect of serious and systematic problems of Three Gorges reservoir. The study yielded a range of objective, scientific conclusions on the climate effects of the project that can be use to develop climate services for informing future decision-making.

KEYWORDS

Climate, Reservoir, Three Gorges Project

1. THE PROJECT

The Three Gorges Water Control Project includes a river-blocking dam, a water reservoir, power generators, navigation structures, and more. It is one of the largest water conservancy projects in the world.The Three Gorges Dam controls a drainage area of 1 million square kilometers－55.6 per cent of the total drainage area of the Yangtze River Basin.

Three Gorges Reservoir is able to retain 39.3 billion m^3 of water, with a flood control capacity up to 22.15 billion m^3. The reservoir feeds the Three Gorges Hydropower Station, which has 34 generator units with an installed capacity of 22.5 million kw and an annual generating capacity of 88.2 billion kwh.

When the Dam's water level is raised to the desired capacity of 175 m, the 632 km^2 of land flooded in the Three Gorges Reservoir form a man-made lake 600 km long and 1-2 km wide, with a total area up to 1,084 km^2.In this paper, the Three Gorges Reservoir Area refers to the Yangtze River main stream area from Chongqing city to Yichang city.

2. LOCAL CLIMATE MONITORING SYSTEM IN THE THREE GORGES RESERVOIR AREA

The Three Gorges Reservoir area is complex, and the valley basins are different from each other. There are vertical differences in climate in different regions. In general the valley in the hot summer and warm winter, cool in summer and cool winter mountain, rain, fog wet weight, and has the characteristics of slopes of different climate. The location of the reservoir is unique in the climate, which is one of the non zonal climate types in China, and is also one of the most typical representative of the microclimate in the water body. The climate in the reservoir area is affected by regional weather and climate system changes. At the same time, after the completion of the Three Gorges Dam, the water level will rise and the water area will expand due to impounding. It will cause the change of the thermal properties of the underlying surface and cause the change of the local microclimate in the reservoir area.

In order to fully understand the construction of the Three Gorges Reservoir area before and after the local climate change characteristic, based on the existing business system of meteorological department China, established the "Three Gorges local climate monitoring system", the system includes 1 key local climate monitoring stations、7 reservoir climate information and security monitoring center station、50 real-time monitoring of base stations.The realization of real-time monitoring, data acquisition in online and fast delivery, tracking and monitoring the whole process of the impact of climate change caused by three gorge project and meteorological disasters.

3. OBSERVATION AND ANALYSIS OF THE THREE GORGES RESERVOIR

3.1. CHANGE OF METEOROLOGICAL ELEMENTS

Through the analysis of local climate monitoring system, we found that after the Three Gorges Reservoir construction, the average annual precipitation in the reservoir area decreased, but the difference was obvious every month. The precipitation in June and July decreased compared with that before storage, while in August and September, it increased slightly compared with that before storage. The precipitation days of each station in the reservoir area decreased after the storage, but the number of annual rainstorm days increased, the intensity of precipitation in the reservoir area became larger and the frequency of extreme precipitation increased.

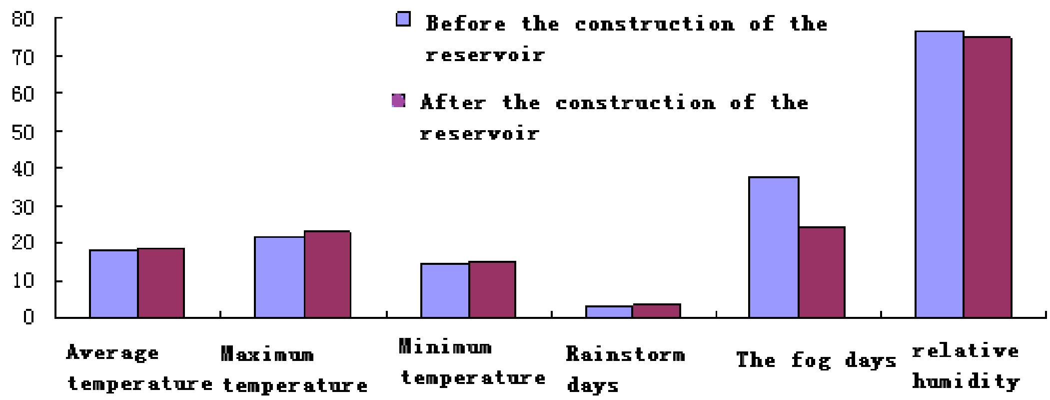

Figure 1: Comparison of annual mean value of meteorological elements

Compared with pre storage, annual mean temperature, maximum temperature and minimum temperature were significantly increased, the average annual temperature of temperature rise in the area between 0.1℃~0.4℃, especially in the seasons of spring and autumn warming significantly, but the change is not obvious in summer temperatures. In addition, after the completion of the reservoir, the annual evaporation amount increased slightly, but the change trend was not significant; the annual relative humidity decreased, the annual fog days decreased, and the change trend was significant.

3.2.

The Three Gorges reservoir has a regulating effect on the local climate after the storage of the Three Gorges reservoir, and the effect of cooling in summer and Warming in winter is obvious

In order to analyze the impact of the Three Gorges Reservoir on the small climate, the near reservoir area and the far reservoir area are divided according to the distance between the main stream of the Yangtze River. The meteorological stations near the reservoir area (Wushan and Badong) are the representative stations near the reservoir area, and the meteorological stations far away from the reservoir area (Wuxi, Xingshan, Enshi and Jianshi) are the representative stations.

The temperature monitoring number in the near and far reservoir areas is selected and compared with the difference between them. Through the analysis we can see that, The annual variation trend of annual average temperature in the near and far reservoir area is consistent, The annual mean temperature difference between the near and far reservoir areas increased after 2003. the difference is 0.8℃, the average annual temperature difference than 1976-2008 (0.5℃) increased by 0.3℃,It shows that the temperature near the reservoir area is slightly increased after water storage.

time interval	content	Winter temperature difference	Summer temperature difference
After storage	Temperature difference(Near and far reservoir area)	0.9□	0.4□
Pre storage		0.5□	0.5□
change		Increase0.4□	reduce0.1□

Table 1: Comparison of temperature difference between the near and far reservoir area

Further analysis showed that the summer warming in the near reservoir area was smaller than that in the far reservoir area after the impoundment, resulting in a decrease of the average temperature difference between the 0.1℃ in summer, indicating that the reservoir had a cooling effect on the waters near the area. In winter, near reservoir area is affected by reservoir, and the increasing range is slightly larger than that in far reservoir area. The average temperature difference between them increases by 0.4℃, indicating that the reservoir has "warming effect" near the water area. As the temperature difference has ruled out the impact of the climate background on the entire reservoir area, we can think that the change of mean temperature difference in near and far reservoir area is caused by local climate effect of reservoir, increasing temperature in winter and cooling in summer.

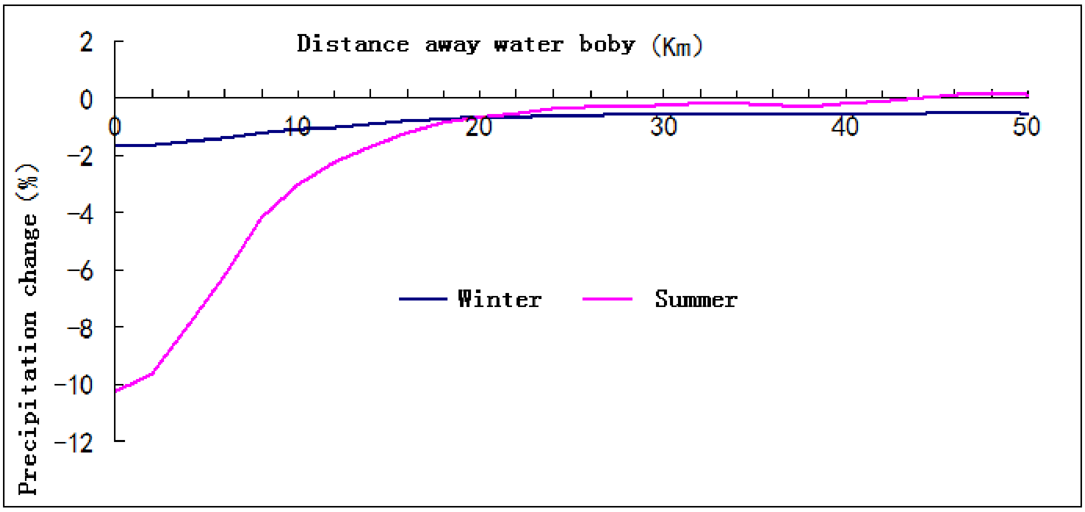
3.3. THE CHANGE OF PRECIPITATION NEAR THE RESERVOIR AREA IS NOT OBVIOUS COMPARED WITH THE FAR RESERVOIR AREA

The comparison method of precipitation ratio in two regions(near and far reservoir area) is used. the effects of the removal of large scale changes and to a relatively stable ratio change, found near reservoir area and far reservoir precipitation ratio change trend is not obvious,The fluctuation of precipitation ratio in the years after storage is in the interdecadal cycle of change,showed that the effect of the impoundment of the Three Gorges Dam on the surrounding of precipitation is not obvious.

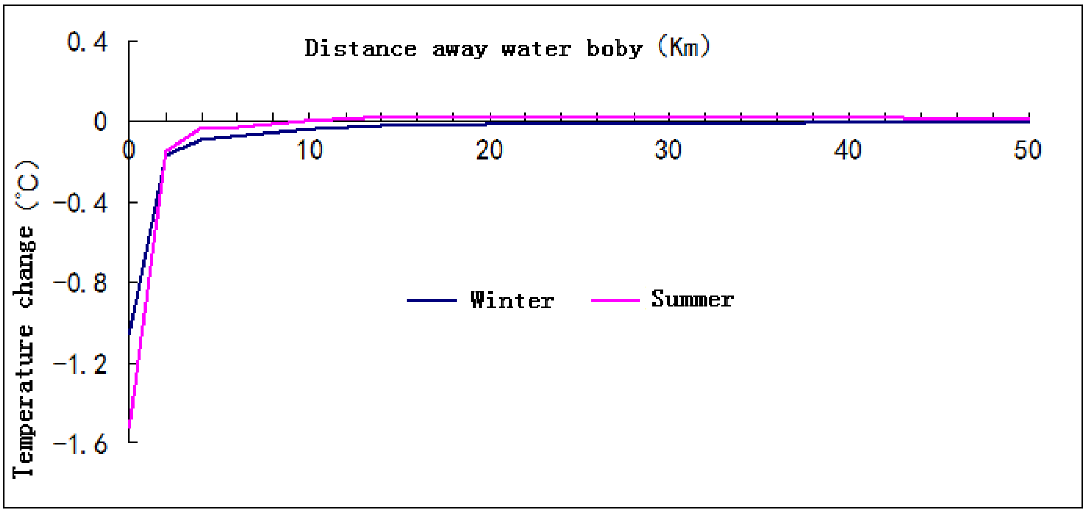
4. NUMERICAL SIMULATION OF THE CLIMATE EFFECT OF THE THREE GORGES RESERVOIR

Regional climate modeling shows that the Reservoir would produce some impact on the neighboring areas climate, But the maximum range of impact is not more than 20km,The Reservoir would noticeably bring down the air temperature above the water surface, by 1℃ in the winter, and 1.5℃ in the summer,with only 0.1° C for the land surface close to the water.

The water body’s evaporative cooling effect would cause the air to sink, and as a result there would be less precipitation. However, the decline in precipitation would be small in winter, a 1 to 2 per cent drop within a 10km radius, and higher in summer, a 10 per cent drop. That 10 per cent would weaken to 3 per cent at a 10km radius and to 1 per cent at a 20 km radius.The numerical model simulation results show that the Three Gorges reservoir, as a typical and very narrow channel reservoir, has a very small impact on the regional climate.



a



b

Figure 2: The scope of the Three Gorges Reservoir's impact on (a) precipitation and (b) temperature in the winter (blue line) and in the summer (red line)

5.

In the last 50 years, the trend of climate change in the Three Gorges area is consistent with the trend of the larger climate change, and the basic climate characteristics of the Three Gorges region have not changed.

In the past 50 years, the Reservoir Area has registered an ascending trend for annual mean temperature, with the largest increase in the last 10 years, though the increase is significantly lower compared with the increase of the Yangtze River Basin. In both the Reservoir Area and the Yangtze River Basin, annual precipitation does vary significantly, but inter-decadal figures do show significant variation. The Reservoir Area saw limited annual rainfall variations from the 1960s to the 1990s, though with significantly reduced rainfall in the last 10 years. Meanwhile, the Yangtze River Basin became abnormally wet in the 1990s, but abnormally dry in other years. In the past 50 years or so, both the Reservoir Area and the Yangtze River Basin witnessed a reduced numbers of rainy days, of annual mean wind speed, and of relative humidity, though the former is on the slower side compared with the latter.

5.1.

Since 1961, the Three Gorges Reservoir area climate warming trend with the global synchronization, the annual average temperature showed an overall warming trend, on average every 10 years increased by 0.08℃, the last 10 years in 1960s compared to an increase of 0.4℃, the annual average temperature change trend and the southwest region of the upper reaches of the Yangtze River, the Yangtze River and the whole consistent reservoir after this trend in 2004 no significant change.

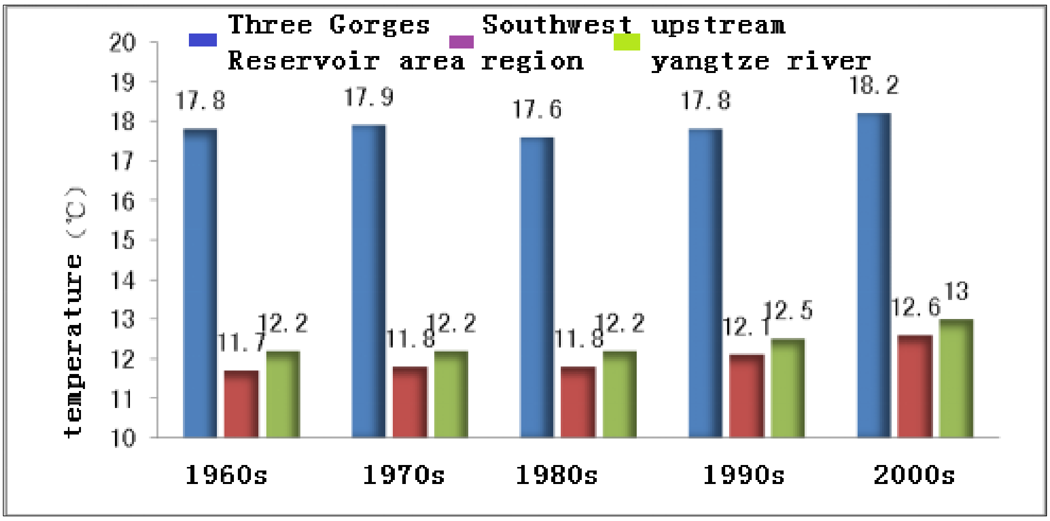


Figure 3: Interdecadal change of average temperature

5.2 Since 1961, the annual precipitation in the Three Gorges Reservoir area has been characterized by annual intergenerational changes. 1970s~1980s is slightly more precipitation. 1960s~1990s precipitation is slightly less; since this century, precipitation has been the least 10 years in the last 50 years. Less rain for nearly 10 years from the beginning of 1999, the annual precipitation increased from more than 1100 mm to more than 1000 mm reduced, reduced by about 10%. The contrast analysis shows that the change of precipitation in the reservoir area before and after the completion of the Three Gorges project is consistent with the trend of the changes in the southwest, the upper reaches of the Yangtze River and the whole Yangtze River Basin.

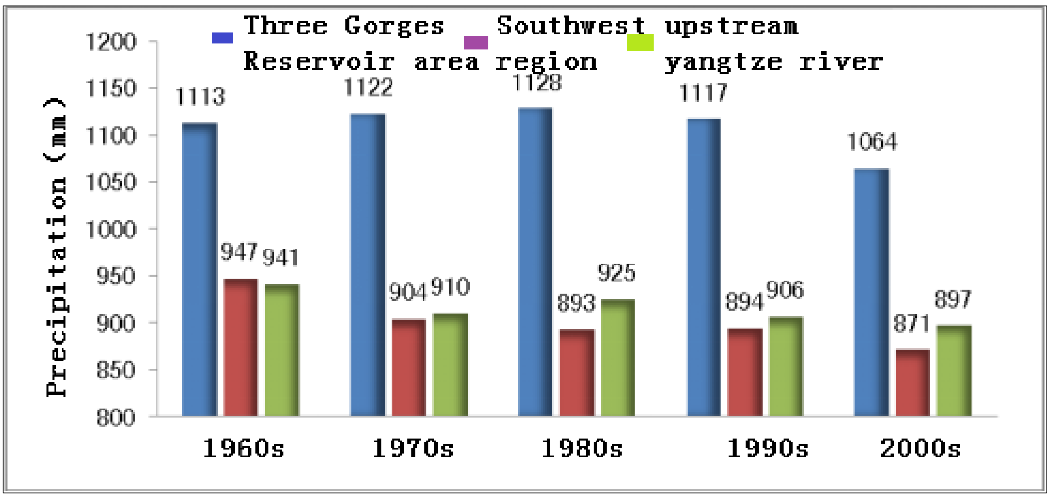

Figure 4: Interdecadal change of average precipitation

6. SUMMARY

After the construction of the Three Gorges reservoir, the average annual precipitation in the reservoir area decreased, but the number of rainstorm days increased, and the precipitation intensity in the reservoir area became larger. Compared with the pre storage, The annual average temperature, the annual average maximum temperature and the minimum temperature increased significantly, and the warming was obvious in spring and autumn. After the completion of the reservoir, the annual evaporation amount increased slightly, but the change trend was not significant, the annual relative humidity decreased, the annual fog days decreased, and the change trend was significant.

Over the past 50 years the average temperature rise, precipitation has interdecadal characteristics. from 1999 the rainy period was less rain, The change of temperature and precipitation is basically the same as that in the southwest and the Yangtze River Basin .After the completion of the Three Gorges reservoir, the temperature in the vicinity of the reservoir area was fine-tuning, warm in winter and cool in summer . After the change of water level, the impoundment only has a slight effect on the climate in some areas, but the influence range is not more than 20 kilometers. There is no obvious change in the climate of the reservoir and surrounding areas.

1. INTRODUCTION

Sutami Dam and Lahor Dam is located on Malang Regency, Province of Jawa Timur, Indonesia. This study needs to be done considering the extreme weather changes in recent years and the issue of global warming in the last decade that impacted the high intensity of rainfall and the change of land use in the upstream which affects the rise of runoff so that the flood discharge in the river becomes larger. Beside that, Sutami Dam and Lahor Dam at the time of planning (1975) is still designed with 1000 year return period of flood, while the dam safety standard set by the Dam Security Commission is currently the flood discharge of Probability Maximum Flood (PMF).

it is necessary to raise awareness of the possibility of a PMF by evaluating the spillway performance of the PMF discharge that exceeds the initial flood discharge. So that the effort of awareness raising that can be done by the dam operator is by maintaining the Control Water Level (CWL) of the reservoir, so that during the PMF discharge, the reservoir can still reduce the flood and the overtopping can be avoided or the frequency can be reduced minimally. It is an effort to manage the dam safety in the Brantas River Basin.

In the normally calculation of the PMF discharge can only represent the annual value. If this value is applied to the reservoir operation to maintain CWL it will cause a big losses. Because the volume of water that can be utilized must be wasted to maintain the CWL. Probability of PMF discharge is different for every month. Therefore it is necessary to do research to get the value of PMF discharge for each month to get different CWL for each month.

2. METODOLOGY

2.1. DESCRIPTION OF STUDY AREA

Topographic conditions in Malang Regency are dominated by highland or mountainous areas. With such topographical conditions, it is possible to build dams as regulators for water regulator and flood control. There are three dams in the upstream of Brantas River Basin: Sengguruh Dam, Sutami Dam and Lahor Dam, which are interrelated systems. Sengguruh Dam serves as a power plant and sediment controller, so that sediment sediments do not go directly into the Sutami Reservoir. The Sutami and Lahor Reservoirs are interconnected with tunnel, which in the planning of the Lahor Reservoir serves to supply the water needs to the Sutami Reservoir for hydroelectric power plant.

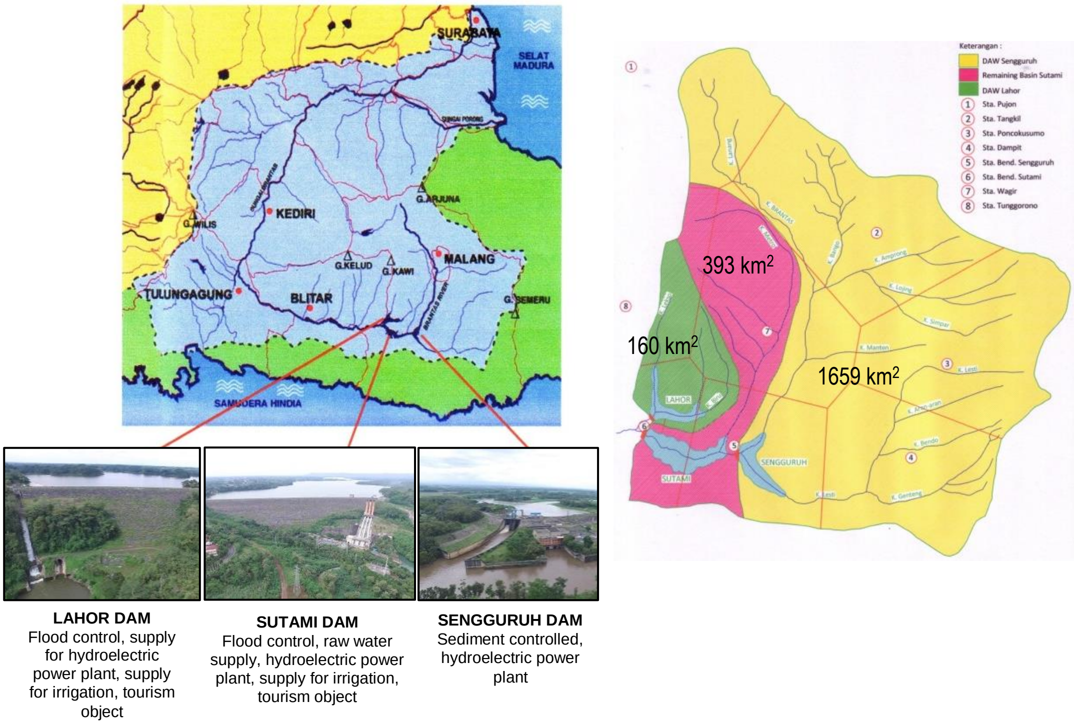

Fig. 1
Dam Location and Chatchment Area Scheme

2.2. STAGES OF ANALYSIS

In the design flood analysis and flood routing analysis there are some related things that affect that is:

- The Sengguruh Dam located on the upstream of the Sutami Dam, resulting in a flood reduction by Sengguruh Reservoir. Beside that the outflow from Hydroelectric Power Plant of Sengguruh also affect the flood discharge into the Sutami Reservoir.
- The connection tunnel between the Lahor Reservoir and Sutami Reservoir affected on flood routing analysis. On the analysis also considered the incoming or outgoing discharge through the tunnel simultaneously by water level difference in both reservoirs. The tunnel gate is located in the Sutami Reservoir, the operation of the tunnel door is rarely done so that the tunnel condition is always open.
- The outflow from hydroelectric Power Plant of Sutami is also taken into flood routing analysis of Sutami - Lahor Dam because the outflow value can reduce the peak flood discharge that occurring.

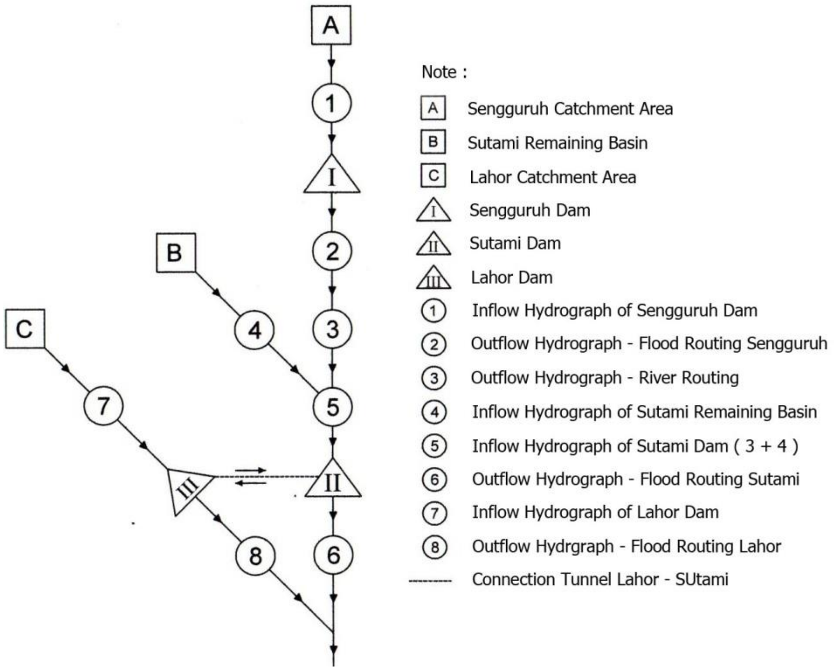

Fig. 2
Chatchment Area System Scheme

Several stages for the completion of this study are hydrological data processing which is principally rainfall design analysis for design flood and flood routing which include; a. Daily maximum rainfall analysis, b. Design rainfall Gumbel type I method, c. Probability Maximum Precipitation (PMP) analysis, d. Frequency distribution match analysis (Chi square & Smirnov Kolmogorov), e. Synthetic unit hydrograph analysis (Nakayasu), f. Design Flood hydrograph analysis, g. Curve reservoir capacity analysis and widespread reservoir (storage area curve), h. Spillway capacity analysis, flood routing analysis (spillway) and river routing analysis, i. CWL determination as a safe guideline to get flood peak reduction in order to avoid the possibility of overtopping, j. recommendations on maximum water level control at each month as a guideline for reservoir operations related to avoid the possibility occurs overtopping.

3. RESULT AND ANALYSIS

3.3. DESIGN RAINFALL

Based on the value of the maximum daily rainfall monthly and yearly at each point of review calculated the value of PMP rain and the design rain on the re-time of 1000 years with the gumbel type I method as a comparison.

The following is the result of PMP calculations and the annual and monthly of design rainfall are presented in Table 1. The calculation of the synthetic unit hydrograph of Nakayasu method is done with the control point of Sengguruh Dam, Remaining Basin Sutami, and Lahor Dam. The result of the unit hydrograph analysis presented in “Fig 3”.

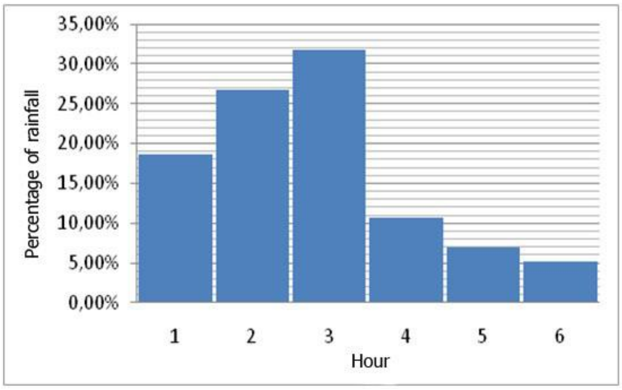

Fig. 4
Hourly Rainfall Distribution Graphic

3.4. FLOOD DESIGN

The following is the peak point of the result from the calculation of flood design of Q1000 th and QPMF (annual and monthly). With the consideration that, the reference of maximum flood is annual maximum, so the maximum monthly flood design needs to be corrected based on the maximum annual flood design with the following results:

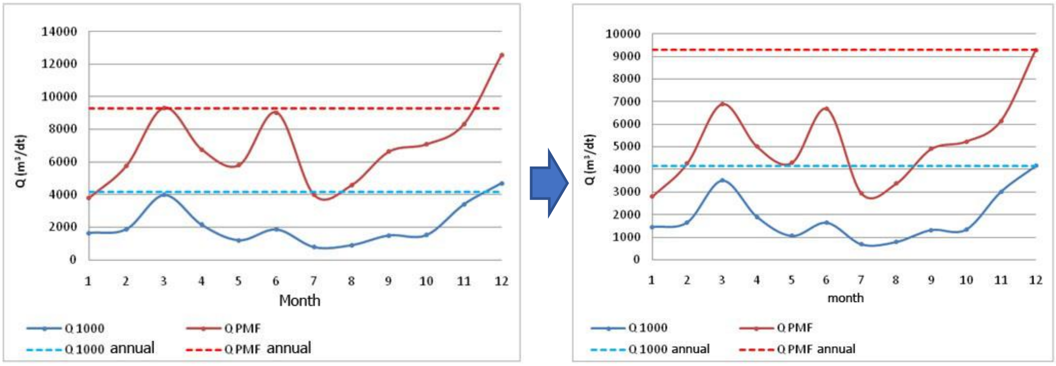

Fig. 5
Maximum Flood Design Annual and Monthly Corrected in Sengguruh Dam

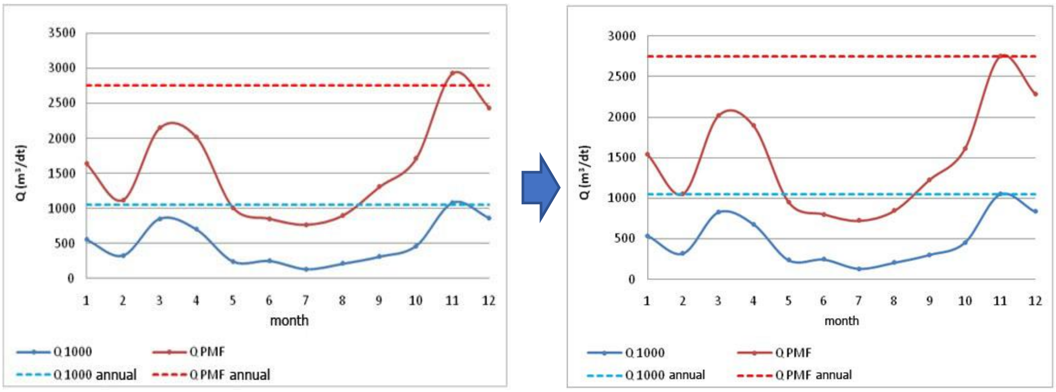

Fig. 6
Max. Flood Design Annual and Monthly Corrected in Remaining Basin Sutami

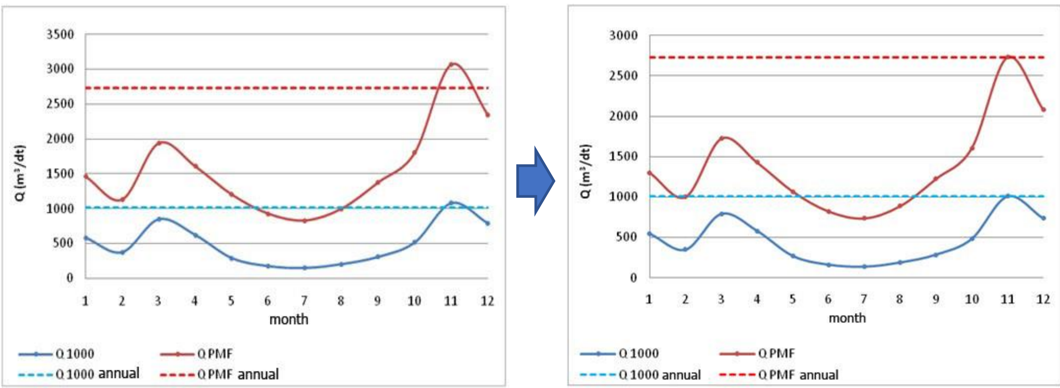

Fig. 7
Maximum Flood Design Annual and Monthly Corrected in Lahor Dam

3.5. FLOOD ROUTING

The result of flood design on Sengguruh Dam then calculated by flood routing in Q1000 th and QPMF to obtain outflow value from Sengguruh Dam (from spillway & turbine). The outflow result from Sengguruh Dam is then used as inflow discharge value for the calculation of river routing (Sengguruh-Sutami). The result value from river routing then combined with flood design from Remaining Basin Sutami to get the inflow value at Sutami Dam. The result of flood design in Lahor Dam then calculated by flood routing to obtain the outflow value at Lahor Dam.

The inflow value of Sutami Dam then calculated by flood routing in Sutami reservoir by considering the in/out discharge from connection tunnel and discharge from hydroelectrical power plant of Sutami. The flood routing also considered the water level on PMF discharge so that the reservoir can still reduce the flood that occurred. Graphical representation of the calculations result can be viewed in “fig 8 and 9”.

In order to obtain safety to manage at Sutami and Lahor Dam on possibility of overtopping caused by PMF discharge in the rainy season, the operation of Sutami and Lahor reservoir need to consider the application of CWL at elevation between +257,00 m to +267.00 m.

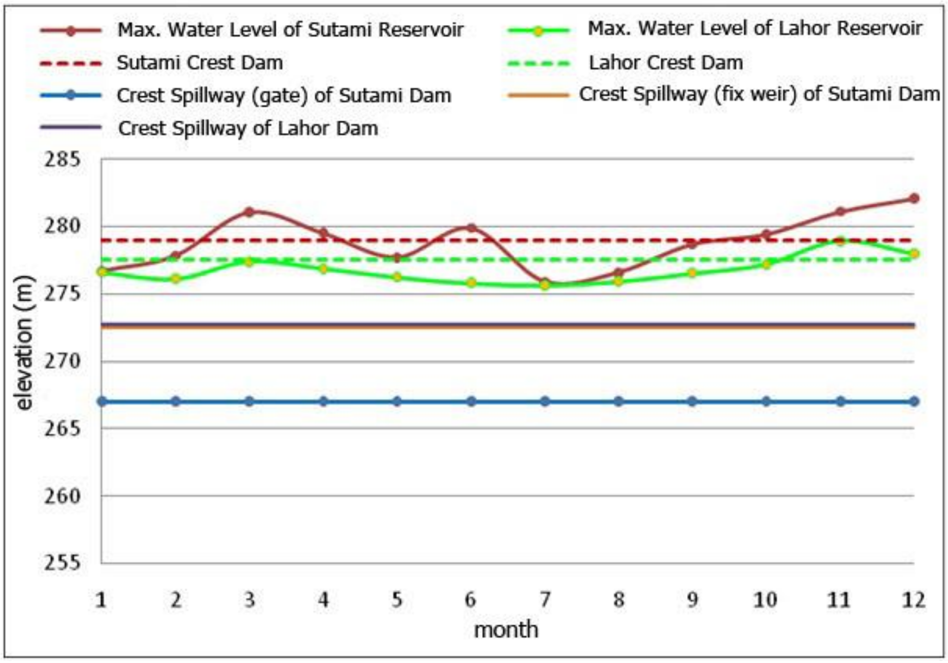

Fig. 8
Water Level Elevation of PMF Discharge

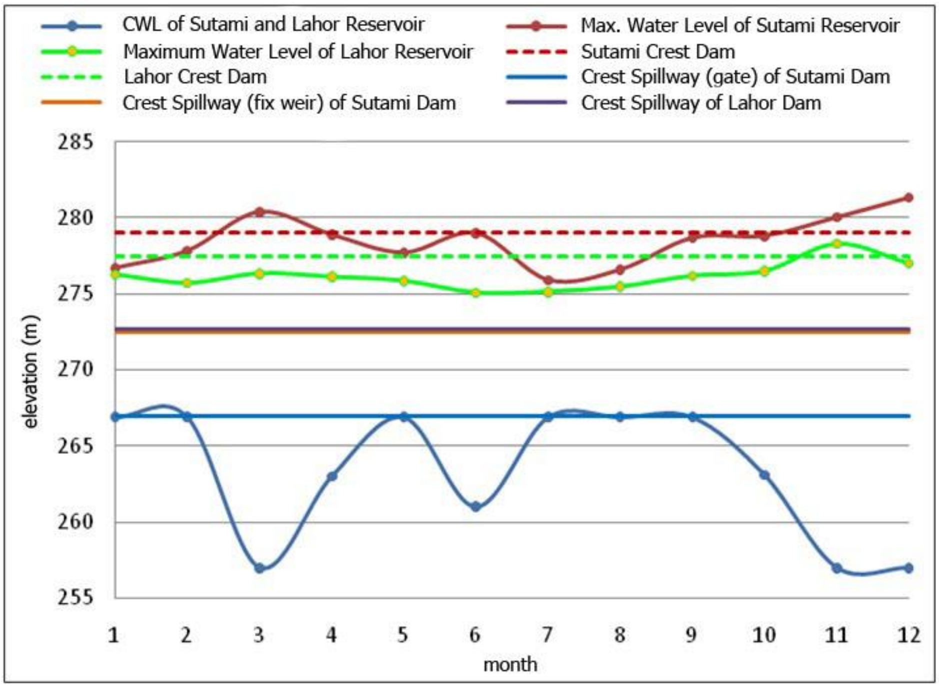

Fig. 9
Water Level Elevation of PMF Discharge with CWL application

3.6. SUMMARY

In hydrology analysis of the annual PMF discharge that potential to occur in the Sutami Dam is very large at 11,629.14 m3/s, where the PMF discharge value is equivalent to 2.31 x $Q_{1000\ years}$ and with the parapet wall as high as 1 m at the top of the dam and CWL management at elevation between + 257.00 m up to +267.00 m still have 3 times potential of overtopping with water level 3.09 m above the top of the dam. The annual PMF flood discharge that potentially occurs in the Lahor Dam is very large at 2,731.00 m3/s, where the discharge value is equivalent to 2.70 x $Q_{1000\ years}$ and with the parapet wall as high as 1 m and with CWL management at elevation between +257.00 m up to +267.00 m is not potentially overtopping. The CWL in the Sutami and Lahor reservoirs is difficult to applied because the dams function is to collect water in the rainy season and utilize it during the dry season so that in order to anticipate the possibility of overtopping, emergency spillway is needed to build at the Sutami Dam.

1. INTRODUCTION

The Yangtze River is the largest river of China, with a total length of 6300km and a total drainage area of 1.8 million km^2. The Three Gorges Reservoir (TGR) is the key backbone project for controlling the Yangtze River and developing and utilizing the water resources of the Yangtze River. Its normal storage level is 175 m, flood control level is 145 m, flood control capacity is 22.15 billion m^3, and utilizable capacity is 16.5 billion m^3, having a huge regulation and storage capacity; the reservoir takes on flood control, power generation, navigation, and other comprehensive utilization tasks. According to the preliminary design diagram, TGR start to impound on October 1 each year and will impound water to 175m by the end of October or November. From January to April of the following year, the water supply dispatch was implemented for the middle and lower reaches to meet the needs of shipping, water supply and ecology. The impoundment of TGR is an important prerequisite for giving full play to its huge water supply benefits.

At present, a large number of reservoirs with large storage capacity and good regulation capacity have been built or will be built in the upper reaches of the Yangtze River. According to the long-term planning, the total regulation capacity of TGR and the upstream controlled reservoirs will approach 100 billion m^3 and the total flood control storage will be 50 billion m^3. As the upstream reservoirs are gradually put into operation, the regulation of runoff by the cascade reservoirs will become more and more obvious. The regulation of water volume during the year can reach 1/4 of the average annual water discharge of Yichang Station. These cascaded reservoirs are concentrated in the annual water storage from August to October, reducing the amount of storage water in the Three Gorges Reservoir and increasing the risk of failure in water storage of TGR.

In recent years, many scholars have carried out a large amount of research on staging design floods, the comprehensive utilization of the TGR during the storage period, water level and node control water level optimization, and analyzed the flood control risks brought by the optimization plan. Based on the long series of runoff data used in the preliminary design, the long runoff data of TGR from September to October was calculated by considering the impact of reservoir water storage in upstream reservoirs at different levels. Without reducing the design flood control standards of the Three Gorges Reservoir, a number of water storage schemes are formulated to calculate the full capacity of the Three Gorges Reservoir and seek for a better water storage scheme.

2. NEW SITUATION OF TGR IMPOUNDMENT

2.1. IMPACTS OF UPSTREAM RESERVOIRS ON WATER STORAGE

As of 2017, there are 28 reservoirs in the upper and middle reaches of the Yangtze River that are jointly dispatched, with a total capacity of 57.5 billion m^3 and a total flood control storage capacity of 41.5 billion m^3. Including TGR, there are 21 reservoirs, with total water demand of 31.87 billion m^3, to be large water storage.

In the joint water storage plan approved by the state flood control department in 2017, the flood control reservoir was taken as "sub-reservoirs and gradually water storage". 7 reservoirs started to impound on August 1 ahead of schedule, and the remaining 13 reservoirs began to impound on September 1, partially overlapping the storage time of TGR, drastically reducing the amount of water infused into TGR. In the long term, four large reservoirs of Wudongde, Baihetan, Lianghekou and Shuangjiangkou will also be added on the basis of 2017, and the pressure of water storage will be further increased.

In the 2017 level year, the total storage of upstream reservoirs in September and October is 9.7 billion m^3, which is equivalent to 43.9% of the maximum storage capacity of TGR. In the prospective level year,assuming that all four newly added reservoirs begin to impound in September, the total water storage capacity of the upstream reservoirs from September to October is 22.2 billion m^3, which is basically the same as that of the Three Gorges Reservoir.Therefore, the impoundment of large-scale upstream reservoirs has a significant impact on runoff in September and October, significantly reducing the inflow into TGR during the impoundment period.The reservoirs have been built and will be built in the upper reaches of the Yangtze River are shown in Figure 1.

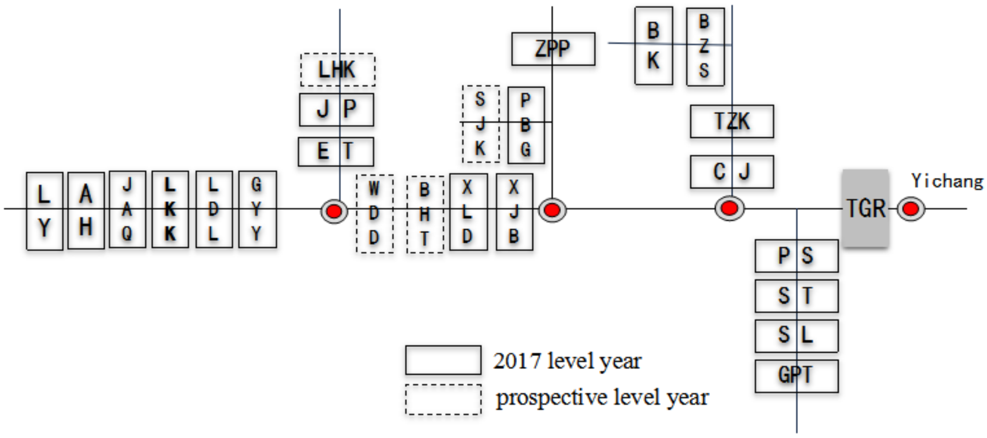

Fig. 1

Large reservoirs in the upper reaches of theYangtze River

August belongs to the main flood season, relatively abundant water.According to the joint scheduling scheme, seven reservoirs from the beginning of August water storage, and water demand is smaller. Assuming that all of them are fully stocked by the end of August, then they will be controlled by the outbound and inbound balances in September and October. Therefore, the impact of these reservoirs on the runoff in September and October is not calculated during the calculation.

2.2. Water demand in downstream areas during the impoundment period

TGR has huge comprehensive benefits such as flood control, power generation, navigation and water resources utilization. With the development of economy and society and the change of the ecological environment, the water demand in the middle and lower reaches of the Yangtze River has changed greatly compared with the initial design, and the water consumption presents an increasing trend.TGR is located at the last stage of the reservoirs with regulatory capacity in the mainstream of the Yangtze River. The impact of upstream reservoirs on the middle and lower reaches is mainly reflected in TGR. Since TGR was put into operation, some new situations and new problems have emerged in the lower reaches. As for the use of water, higher discharge requirements for reservoirs during the storage period have been put forward.

According to the approval requirements of the State flood control department for TGR impoundment program in recent years, the discharge volume of TGR is not less than 10000 m^3/s in September and not less than 8000 m^3/s in October, To meet the demand of shipping, water supply and ecology .

3. ANALYSIS OF THE INFLUENCE OF UPSTREAM RESERVOIRS ON THE RUNOFF OF TGR DURING THE IMPOUNDMENT PERIOD

3.1 HORIZONTAL YEAR DIVISION

In 2017 level year, 13 reservoirs were selected from the reservoir that has been incorporated into the joint operation,including Guanyinyan, Xiluodu, Xiangjiaba, Zipingpu, Pubugou, Goupi Beach, Silin, Shatuo, Pengshui, Bikou, Baozhusi, Tingzikou and Caojie that impound in Septerber or October.

In the long-term horizon year, 4 large-scale reservoirs, including Wudong, Baihetan, Lianghekou and Shuangjiangkou, will be added on the basis of the 2017 level year, for a total of 17 reservoirs.

3.2 RUNOFF CALCULATION

According to the water storage scheme which has been built and proposed in the upper reaches of the Yangtze River, the amount of water storage needed to be allocated in every ten days is calculated.The long series runoff data of 110 years (1881-1990 years) were calculated by 2017 level year and long-term level year respectively, and the runoff data of Three Gorges dam site under the operation conditions of upstream cascade reservoirs were obtained.Based on the calculated data of long series of runoff, the accumulating rate of TGR and the influence on the downstream are analyzed and compared under different schemes.

The average runoff of the 110-year-long series (1881-1990) of the Three Gorges Dam site in September and October was 122.5 billion m^3. The runoff series for the 110-year (1881-1990) Three Gorges Dam site were calculated considering the upstream reservoir construction conditions .In 2017 level year, there are 13 reservoirs operating above TGR, reducing the total runoff of 9.7 billion in September and October. In the prospective level year,there are 17 reservoirs operating above the Three Gorges to reduce the total runoff of 22.2 billion m^3.The simulation results show that 75 years is less than the multi-year average of the preliminary design in the 2017 level year, accounting for 68.2%.,and 90 years in the prospective level year, accounting for 81.8%.

4. CALCULATION OF THE FULL STORAGE RATE OF TGR

4.1 CALCULATION SCHEME AND CONTROL CONDITION

The initial water storage time of TGR is September 1st, 10, 20 and October 1st, athe initial water level starting from the flood control limit 145m.Considering flood risk and scheduling requirements, the maximum water level at the end of September is controlled at 165m.During the water storage period, the needs of the downstream shipping, production and ecology should be taken into account, so as to minimize the impact of reservoir impoundment on the middle and lower reaches of the Yangtze River.The minimum discharge of TGR is 10000m^3/s in September and 8000m^3/s in October, and full storage at the end of October.

Impounding from October 1st, the number of non-full storage years are 25 years in 2017 level year and 26 years in prospective level year , and the rate of full storage is 77.3% and 76.4%, respectively.Impounding from September 20, the number of non-full storage years are 12 years in 2017 level year and 18 years in prospective level year , and the rate of full storage is 89.1% and 83.6% respectively.Impounding from September 10, the number of non-full storage years are 6 years in 2017 level year and 15 years in prospective level year , and the rate of full storage is 94.5% and 86.4% respectively.Impounding from September 1st, the number of non-full storage years are 4 years in 2017 level year and 11 years in prospective level year , and the rate of full storage is 96.4% and 90.0% respectively.

In 2017 level year, TGR began to impound from September 10th and reached 90% of the designed rate. In the future level year, due to the large storage capacity of new reservoirs, it was necessary to store water in advance until September 1st, so that the design storage rate of 90% could be achieved.The influence of different level year on the full storage rate of TGR is shown in table 1.

Table 1

The influence of different level year on the full storage rate of TGR

Date	Year of non-full		Full storage rate	
	2017	prospective	2017	prospective
Oct.1st	25	26	77.3%	76.4%
Sep.20	12	18	89.1%	83.6%
Sep.10	6	15	94.5%	86.4%
Sep.1st	4	11	96.4%	90.0%

Based on the calculation and analysis, it is reasonable for TGR to start impounding on September 10 in accordance with the current joint storage of cascade reservoirs in the 2017 level year. Due to the large storage of new large reservoirs in the prospective level year, without considering raising initial water level of impounding, TGR should be further advanced to September 1 to meet the initial design full storage rate.

4.2 THE INFLUENCE OF RAISING INITIAL WATER LEVEL ON THE FULL STORAGE RATE OF TGR.

Since 2008, TGR started for the first time to carry out 175m experimental water storage,according to the principle of " safety, science, reliable and Gradualism".In view of the runoff reduction in the impoundment period, the simultaneous storage of the upstream reservoir and the increase of the water demand in the lower reaches, the contradiction between the water storage and the discharge is outstanding.After fully demonstrating the flood control safety and sedimentation of pre-impoundment, the impounding mode of the Three Gorges reservoir has been further studied, and a water storage way to undertake the flood control stage and raise the water level has been put forward.TGR have achieved 175m water target for 8 consecutive years from 2010 to 2017 after further optimizing the storage scheme, and the discharge standard increased from about 5500m^3/s to 8000m^3/s during October.

Practice in recent years has also shown that storing flood resources and raising the initial water level TGR, were effective measures to improve the full storage rate. Based on the simulated runoff of Three Gorges dam site after the operation of cascade reservoirs in different levels, the storage rate of TGR under different storage levels was calculated.

In the prospective level year, TGR began to store water in September 10th and when the initial water level reached 152m, the full storage rate could reach over 90%. If the water storage started in early September 1st, the storage level from 148m to 152 had little effect on the full storage rate of TGR.The influence of different initial water level on the full storage rate of TGR is shown in table 2.

Table 2

The influence of different initial water level on the full storage rate of TGR

Date	Initial water level	Year of non-full		Full storage rate	
		2017	prospective	2017	prospective
Sep.10	148	6	13	94.5%	88.2%
	150	6	12	94.5%	89.1%
	152	4	10	96.4%	90.9%
	155	4	7	96.4%	93.6%
Sep.1st	148	4	11	96.4%	90.0%
	150	3	11	97.3%	90.0%
	152	3	10	97.3%	90.9%
	155	2	6	98.2%	94.5%

4.3 THE INFLUENCE OF RAISING INITIAL IMPOUNDING WATER LEVEL ON THE DISCHARGE OF TGR DURING IMPOUNDMENT PERIOD.

According to the present situation of scheduling rules, TGR began to impound from September 10th. compared with the 145m water level, if the initial water level of TGR is raised up to 148m, 150m, 152m and 155m respectively,the average discharge can be increased by 350m^3/s, 590m^3/s, 860m^3/s and 1310m^3/s during the impoundment period.Since 2010, TGR has been reached to the normal water level of 175m for 8 consecutive years of water.Except for the serious water shortage in early September and low water storage level in 2016, the TGR initial storage level of other years were above 152m.The discharge of TGR during the impoundment period was raised, effectively alleviating the contradiction between reservoir water storage and downstream water use.

5. CONCLUSION

After the operation of the upstream large reservoirs, the runoff of Three Gorges Dam from September to October is 9.7billion m^3 and 22.2 billion m^3 less than that of the initial design value respectively, which has a great impact on the impoundment of TGR.In the 2017 level year, that is the status quo year, it is reasonable for TGR to start impounding on September 10 based on the current joint storage of cascade reservoirs in the basin. But the initial water level should be raised to the increase the discharge during the impoundment period.In the prospective level year, due to the large storage capacity of new large reservoirs,the impounding time of TGR will need to be arranged on September 1 in advance,in order to reach the designed full storage rate .

The contradiction between the centralized storage and downstream water supply will be further exacerbated after the operation of the constructed and proposed reservoirs in the upper reaches of the Yangtze River .Therefore, the water storage scheme of TGR needs to be optimized continuously.In general, the impounding time of upstream reservoir is earlier than that of TGR. Therefore in the preparation of the annual impounding scheme of TGR, raising up the reservoir initial water level under the premise of ensuring the safety of flood control according to the real-time progress and inflow forecast.The full storage rate of TGR could be increased and the contradiction between reservoir water storage and water supply in the downstream area will be relieved.

SUMMARY

A large number of reservoirs with large storage capacity have been constructed in Upper reaches of Yangtze River. These reservoirs impound from August to October annually, and store large amounts of water. Thus the Inflow of Three Gorges Reservoir decrease in September and October. In this paper, we analyzed the runoff characteristics of upstream of Yangtze River and the runoff sources of Yichang hydrological station. Then we selected 2017 level year and prospective level year, simulated the runoff of the hydrological station in the upper Yangtze river, and analyzed impact of Upper Yangtze cascade reservoirs operation on Three Gorges Reservoir in impoundment period. The results show that the runoff of tributary and Yichang hydrological station decrease significantly, especially in dry years. Meanwhile, with the increase of the number of upstream reservoirs, the impact increases gradually. We calculated the proportion of the water storage of upper Yangtze cascade reservoirs in impoundment period of Three Gorges Reservoir. The results can be used to optimize the measures of reservoir operation, such as the use of the flood resources at end of flood period and the initial control water level of impoundment.

1. INTRODUCTION

The TGP reservoir is the key project in the Yangtze River basin, with the benefits of flood control, power generation, navigation, water supply etc.. As an important part of the flood control system in the Yangtze River basin and power supply station for power grid security, the TGP reservoir plays an important role in the economic development of the Yangtze River basin and the whole China.

As a critical backbone project for the control of the Yangtze River and harnessing of its water resources, the TGP reservoir is located at Sandouping of Yichang, Hubei Province with a controlled area of 1 10^6 km^2, a normal water level of 175m and an accommodation capacity of 16,500 million m^3. The project has experienced the stages from the preliminary design, the initial operation to the formal operation. It stored water level to 135m in June 2003 and hence entered the period of power generation. In 2008, the TGP reservoir started 175m experimental storage 5 years ahead of schedule, and firstly stored water level to 175m in 2010. Few years later the reservoir entered the formal operation period in 2016.

The climate change definitely cause the change of precipitation in the basin, which indirectly affects the total runoff and its annual distribution in this area. Corresponding to the obvious change of precipitation in the upper reaches of Yangtze River, the inflow of the TGP reservoir has also been affected, which shows that the inflow has a decreasing trend in the total year, while in the annual distribution, it increased in the dry period and decreased in the flood season and the storage period.

To sum up, with the climate change in the upper reaches of Yangtze River, the hydrologic characteristics of inflow series of the TGP reservoir have changed to a certain extent. It’s necessary to make quantitative analysis on the impact of climate change, and deeply research the change regular of precipitation and runoff, and put forward countermeasures from technical aspect and management aspect, to guide the TGP reservoir to give full play to its comprehensive benefits more effectively.

2. THE ORIGINAL DESIGN DISPATCHING RULE OF THE TGP RESERVOIR

The original dispatching rule of the TGP reservoir is designed with the demand in flood control, power generation, shipping, water replenishment etc., based on the historical precipitation characteristics and conditions of water and sediment in the basin. T The design scheduling methods in these periods are as follows:

(1) Dispatching rule in flood season

The reservoir is operated at the flood control limit level of 145m during the flood season. In the premise of ensuring dam safety, the flood control compensation in the TGP reservoir improves the flood resistance standard of Jingjiang dike.

(2) Dispatching rule in storage period

The reservoir stores water in the storage period, during which the minimum discharge is not lower than the corresponding flow for smooth downstream shipping, the water level will gradually increase to normal level till the end of October.

(3) Dispatching rule in falling period

The TGP reservoir gradually drops the water level and carries out water supply, drought resistance, shipping and ecological water replenishment for the downstream in falling period. The outflow in the falling period is not less than the guaranteed power output and the corresponding flow of lowest water level for navigable in the downstream. The water level is gradually dropped to limit water level to make preparation for flood season.

3. CLIMATE CHANGE IN THE UPPER REACHES OF YANGTZE RIVER

The mainly influence of climate change on human life is the change of rainfall and temperature. This paper analyzes the climate change in the upper reaches of Yangtze River according to the change of precipitation and temperature, based on 1963~2017 annual climate data.

(1) Precipitation

The annual average precipitation in the basin has been decreasing since 60s. It was more than average value before 80s and less than average after that, and the drop rate is about 17.4mm/10a. As to the annual distribution, it shows that the rainfall has a decreasing trend in spring, autumn and winter, while the precipitation in summer is increasing due to the strong rainfall.

(2) Days and intensity of rainfall

The average annual precipitation days (rainfall more than 0.1mm as a rainy day) in the upper reaches of Yangtze River ranged from 132 to 171 days, showing a decline trend with a rate of 2.9d/10a(α=0.001). However, it shows that the average daily precipitation intensity is increasing, which increases the probability of flood.

(3) Days and intensity of rainstorm

The average annual rainstorm days (rainfall more than 50mm as a rainstorm day) ranged from 13 to 30 days, showing a slight upward trend. Also, the rainstorm intensity is increasing. The average intensity of rainstorm is greater than the annual value after 80s, and mainly concentrated in the flood season, increasing the probability of rainstorm.

(4) Temperature

The annual average temperature in the Yangtze River basin is on the rise, with an average increase of about 0.14℃ every 10 years. The upward trend in the northwest of basin is more obvious because of its special geological conditions and altitude characters. It is predicted that the overall temperature of the basin is on the rise in the next 50 years under the background of greenhouse gas emissions, and the increase of temperature is about 0.25 ~ 0.41 /10a.

(5) Extreme weather events

The characteristics of extreme precipitation events are demonstrated by spatial distribution and intensity analysis of extreme precipitation events and continuous drought events.

1) Extreme precipitation

The daily maximum precipitation has reached more than 300mm in 2 stations, which are located in the middle of the basin, while the precipitation in most areas is between about 100 mm~300mm. The distribution of the maximum 3-day precipitation was similar to the daily one. Furthermore, the maximum consecutive precipitation time has reached more than 40 days in 5 stations in the southeast area of the basin.

2) Extreme drought

Continuous drought events had occurred more than 10 times in 14 stations in 55 years in the upstream of TGP, and occurred most in Qingshui river(20times)，followed by Zunyi(14 times)，while the events occurred 3~9 times in other areas.

4. THE INFLUENCE OF CLIMATE CHANGE ON THE TGP RESERVOIR

The influence of climate change on the operation of the TGP reservoir is manifested in two aspects: on the one hand, the change of precipitation and temperature which are caused by climate change, leads to the runoff change and the inflow variation. On the other hand, climate change causes extreme weather and special hydrological events, proposing higher requirements in the emergency dispatching. Therefore, it is necessary to analyze the variation characteristics of inflow and sum up the new requirements for the dispatching in extreme events, so as to lay a foundation for the optimization of the reservoir operation rule in the new environment.

4.1. RUNOFF CHANGE IN THE TGP RESERVOIR

Through analyzing the change trend of annual average inflow in the TGP reservoir based on 1963~2017 years' data, it shows that the overall annual runoff has a downward trend. After comparing the runoff in the trend fitting line, it is found that the measured runoff before 80s is more than the average value, and less than average after that (Fig.1).

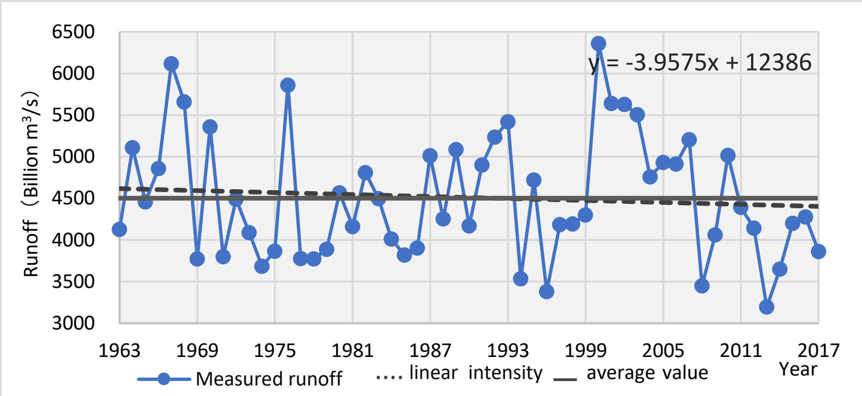

Fig. 1
Annual runoff variation in YiChang Station

The monthly inflow is compared with the time line in 2003, when the TGP reservoir began to store water (Fig.2). According to the figure, it can be seen that the average monthly inflow in the TGP reservoir after 2003 is much less than that before 2003. As to the monthly distribution, it shows that it is slightly more than that before 2003s from January to April in recent years, while the inflow from June to December decreased in varying degrees, and mainly decreased from August to November, when the runoff decreased by 3638 m^3/s and 6747 m^3/s respectively. It is known that the formation of runoff in flood season and storage period is mostly derived from precipitation, except little runoff in storage period are affected by the discharge from reservoir group in upstream, which can be ignored compared with the influence of the precipitation in storage period.

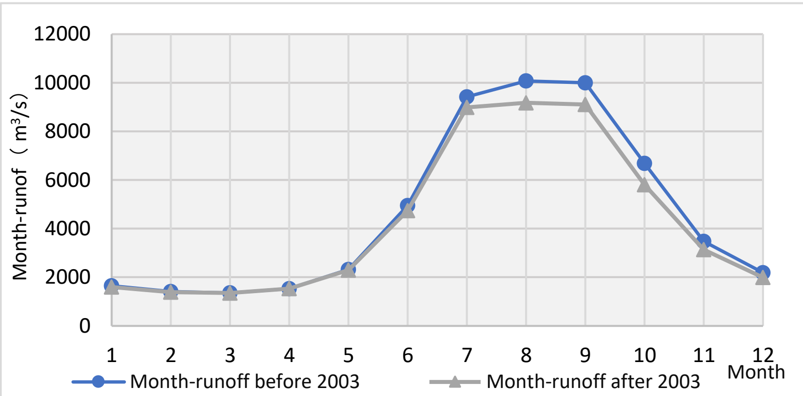

Fig. 2
Monthly runoff before and after 2003 in Yichang station

In the background of runoff decreased, if the TGP reservoir is still operated in the flood limit water level in the flood season， the flood will be almost completely abandoned and unable to be effectively used. From the analysis above, the inflow in the water storage period is obviously decreasing, causing the water for storage is not enough. Therefore, if the reservoir still be operated by the original rule and doesn’t store water until October, it will be difficult to fill up the reservoir and the demand for water supply in the lower reaches in dry period will be hard to be guaranteed.

4.2. INCREASES OF EXTREME DROUGHT AND FLOOD

Through summing up the reservoir inflow in recent years, it shows that the extreme dry event occurred 3 times and the extreme precipitation event occurred 1 time in less than 5 years，

(1)In the late September and early October in 2013, the precipitation in the upper reaches of TGP reservoir reduced 30% and 73% respectively compared with the same period in history. In the flood season in 2015, the runoff in the overall upper reaches of Yangtze River are less than 34% and 38% respectively over the average annual runoff in history. The extreme drought occurs again in 2016, the inflow of the TGP reservoir in the early-September is only 11700 m^3/s, ranking the least in the data series.

(2)The strong flood occurred in non-flood season in 2017. The heavy rainfall from October 2nd to 4th ranked second in the historical strong flood series. Affected by this, the inflow of the TGP reservoir freshened the maximum record in the same period in history.

Under the same prediction accuracy range, the extreme runoff can increase the forecast flow error which is proportional to the size of flood or drought. Frequent extreme drought and flood bring difficulties to forecast work. With the increase of unforeseeable degree in the forecast dispatching, the flood control operation in super flood will be at greater risk, and the difficulty of water storage work will be increased.

4.3. THE DEMAND IN EMERGENCY SCHEDULING IN THE MID-LOWER REACHES OF THE YANGTZE RIVER

Frequent extreme weather events also has different influence in the middle and lower reaches of the Yangtze River, and mainly manifested in the disaster caused by severe convective weather and extreme strong rainfall. Through the analysis of extreme weather events in the middle and lower reaches of the Yangtze River, this paper demonstrates that the extreme weather events bring great challenges to the coordination of flood control and water storage work, and put forward higher requirements for emergency operation.

During the May in 2011, the precipitation in the middle and lower reaches of the Yangtze River decreased 50% compared with the same period of many years, resulting in the worst drought in 60 years. The water level of some lakes dropped even close to the dead water level. The TGP reservoir increased the discharge by 10000m^3/s to ease the drought.

In the flood season in 2015, the tornadoes occurred in the middle and lower reaches of the Yangtze River, resulting in the overturn of "Star of the East". The discharge in the TGP reservoir is gradually reduced by 10000m^3/s in 3 hours, and helped to rescue the capsized ship in time.

In 2016, after the heavy sustained precipitation in the middle and lower reaches of the Yangtze River, the water level in the downstream of Yangtze River are almost all over the warning level. In the same period in 2017, the heavy storm occurred again in the middle and lower reaches of the Yangtze River, the water level in some tributary stations have reached the highest in history. The TGP reservoir intercepted water and reduced flood peak timely and effective control of danger.

The cities in the middle and lower reaches of the Yangtze River bear the backbone power of the national economic development. As the key project in the Yangtze River Basin, the emergency assistance of the TGP reservoir plays a crucial role in the city's normal development and the handling of the events. Due to the wide range of the middle and lower reaches of the Yangtze River and the rapid development of the cities along the basin, there are more and more emergencies and hidden dangers, posing higher requirements in the reservoir' emergency dispatching.

5. RESEARCH ON THE COUNTERMEASURES

In view of the influence of climate change on the dispatching of the TGP reservoir, the countermeasures are put forward from the technical and management aspects. Due to the runoff changed in the new climate environment, it is necessary to research on the optimal dispatching mode technically to match with the new runoff conditions. On the other hand, the frequent occurrence of extreme events raises requirements for the emergency response capacity. It is urgent to establish a complete emergency management system and strengthen the reservoir's emergency management ability.

5.1. OPTIMAL SCHEDULING METHOD BASED ON HYDROLOGICAL FORECAST

The change of climate has an adverse effects on the reservoir inflow, which is mainly manifested in inflow decreased in flood season and storage period. Precise flood forecast is an important prerequisite for reservoir operation. Therefore, this paper optimizes the operation mode of the TGP Reservoir during these periods, to ensure the comprehensive benefits such as flood control, shipping, power generation, water supply and ecological environment protection etc..

(1)Utilization of flood resources in flood season

According to the trend that the runoff decreased in flood season and the improved hydrological forecast technology, the TGP reservoir changes the flood control method, and tries to take full use of flood resources rather than defensing flood singly. Through the proactively management of flood, realizing the flood resource utilization under the risk controllable. It regulates small-mid-flood by using the limited storage capacity, combines with the short-mid-term hydrological forecast, and give full play to the benefits of the water head with level elevation. In addition, according to the runoff forecasting in late flood season, the reservoir balances flood control and water storage with the method that it intercepts the flood in late flood season to pre-storage with predicted abandoned water, and creates favorable conditions for the water storage after the flood season.

Since the mid-July in 2017, it sustained high temperatures and little rain. According to the inflow forecast, the TGP reservoir reduced the discharge by 3000 m3/s and raised the water level by small and medium flood. It orderly takes the benefit of water head to guarantee the demand of big peak shaving in dry summer.

(2)Optimization of water storage in late flood season

Due to the decrease of natural runoff and the increase of water demand in the downstream in storage period, the full storage ratio of the TGP reservoir with design dispatching mode is low, greatly affecting the navigation and ecological water guarantee during the dry water period. The TGP reservoir optimizes the storage process by moving up the storage time, rising the origin storage level and controlling the water level dynamically combined with the hydrological forecast.

Firstly, the trend of water volume in the storage period is judged according to the long-term prediction, and the water storage scheme can be initially proposed. Also, the impounding strategy is constantly rolling and correcting according to the short-term prediction with high accuracy in the later, is concrete is: when the inflow forecast shows low, storing water in advance appropriately and making full use of the water in late flood season. If the forecast shows low continuity in the storage period, raising the water level in stages in this period, and the water level should be raised in different degrees according to the runoff reduction degree in the forecast. That is to say, the reservoir is regulated with separated methods in wet year, dry year and extreme-dry year ,and the water level in control nodes in the storage period are gradually raised on the basis of the design dispatching regulation, to ensure the completion of water storage tasks at different runoff levels.

Based on the optimization strategies above, the TGP reservoir improves the operation mode with storing water in advance properly and raising the water level in stages according to the runoff forecast. The TGP reservoir has successfully stored to 175m for eight years since 2010(Fig.3). Under the implementation of this optimization method, the TGP reservoir combines the flood control and water storage work. Flood resources in late flood season are fully utilized. The water level elevation in September can increase the water storage capacity, effectively ensuring the reservoir's full filled. Also, the reduced demand for water storage in October can greatly alleviate the impact of water storage on the downstream.

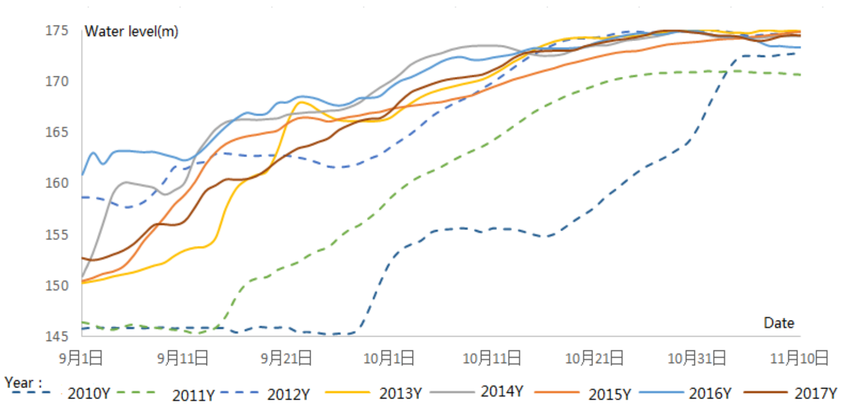

Fig. 3
The storage process of the TGP reservoir from 2010 to 2017

5.2. Emergency dispatch management system

As a backbone project in the Yangtze River basin, the TGP reservoir has made many breakthroughs and contributions for emergency assistance. For instance,it increased power generation to cope with the electricity demand under the ice and snow disaster in 2008.It supplemented freshwater to repulse saline water in dry season in 2014,and rescued the “Star of the East”, who is overthrown by a tornado in 2015. Also, it carried out compensation regulation in flood control for the lower reaches of Yangtze River in 2016 and 2017.With these rich experiences in emergency dispatching, the TGP reservoir has gradually formed a complete emergency response system.

In the emergency dispatching, the TGP reservoir takes the protection of social benefits as the goal, and minimizes the loss with systematic and efficient management method. The main measures are as follow, the reservoir management organization has established a coordination system with flood control department, shipping department, land resources office and other departments, and share the information with each other; Also, enhancing operation situation analysis and premeditated simulation of accident, to prepare the emergent schemes in advance; Thirdly, building the emergency management system: Distributing the responsibility according to the event types, and forms a complete emergency command mechanism; Also, responding to events in a hierarchical manner, clear the workflow with conferences at different levels, to find the solution to deal with emergency events efficiently. In order to further improve the emergency system, it records the event and summarizes the experience after solving the problem.

Through the emergency dispatching for special events, the TGP reservoir improves its ability to deal with emergencies and brings remarkable social benefits. Also, in the cooperation of public activities, its political and public welfare value is highlighted.

6. SUMMARY AND PROSPECT

This paper focuses on the analysis of reduced precipitation, which is caused by climate change. In view of this, it put forward the optimization scheduling method: utilization of flood resources in later flood season and water level elevation in stages in water storage period based on the hydrological forecast, and the modified scheduling strategy are proved effective and applicable by practice. Furthermore, it sums up the TGP Reservoir’s emergency management measures for disaster events caused by extreme weather, and demonstrates the positive significance of the emergency dispatching system.

Meanwhile, with the construction of the reservoirs in upstream and the accumulation of reservoir operation experience, the accuracy of runoff prediction can be improved based on the information sharing in the basin, so as to coordinate the operation and optimize the storage and discharge structure in reservoir groups. But the operation time of the reservoir in upper reaches is relatively short and the operation experience is not very enough. The joint operation of large reservoir groups in climate change environment needs further study and the optimization potential needs further exploring in the future, so as to better cope with the climate change and greatly play the role of overall coordination in the Yangtze River basin.

1. INTRODUCTION

The Harz (10.2 – 11.5 degr. East and 51.5 – 52.0 degr. North) is the main water tower in central Germany. Because of its freshwater endowment, the Harz mountains water resources of have been developed since the 16th century to support the mining industry and since the late 19th century for public water supply. Today, nine multi-purpose dams located in the Harz are providing high quality raw water for public water supply. Based on these reservoirs, water treatment and long-distance water transfer schemes have been developed in the 20th century, comprising a total of 1250 km of mains pipe serving more than 3 million people and numerous industries in the five states of Lower-Saxony, Saxony-Anhalt, Saxony, Thuringia and the City State of Bremen. Neustadt dam – a stone masonry dam (H = 33.4 m; L = 127.0 m) – is the Southernmost and smallest of these nine dams and is fulfilling its water supply function since 1905. At present, all safely available water (1.3 MCM) from the dams reservoir is committed in a raw water supply contract and the buyer – the local water company WVN – has requested

---

* *CHANGEMENT DU REGIME HYDROLOGIQUE EN ALLEMAGNE CENTRALE: MAGNITUDE, CAUSES ET EFFETS SUR L'EXPLOTATION DU RESERVOIR*

the dam owner and operator Thüringer Fernwasserversorgung to increase water withdrawal in the future. On the other hand, with an already fully committed water budget, any long-term or sudden changes in the dam's inflow regime would have a direct impact on safe yield. Safe yield water withdrawal is constricted by the precipitation and runoff regime of the 5.32 km^2 catchment area and the total available storage volume of 1.24 MCM. When updating the long-term operational plan of the dam, the owner/operator carried out an analysis of the water balance using historic records. The following questions were guiding the analysis:

- Did significant changes of meteorological parameters and runoff occur in the last 100 years?
- Were these changes gradual or sudden?
- What are the implications for dam operations and which mitigating measures could be put in place?

2. MATERIALS AND METHODS

The location of the dam site and surrounding area is given in Figure 1. Temperature data were taken from Braunlage and Artern met stations (data source: DWD). Precipitation records were taken from three nearby stations (see Figure 1).

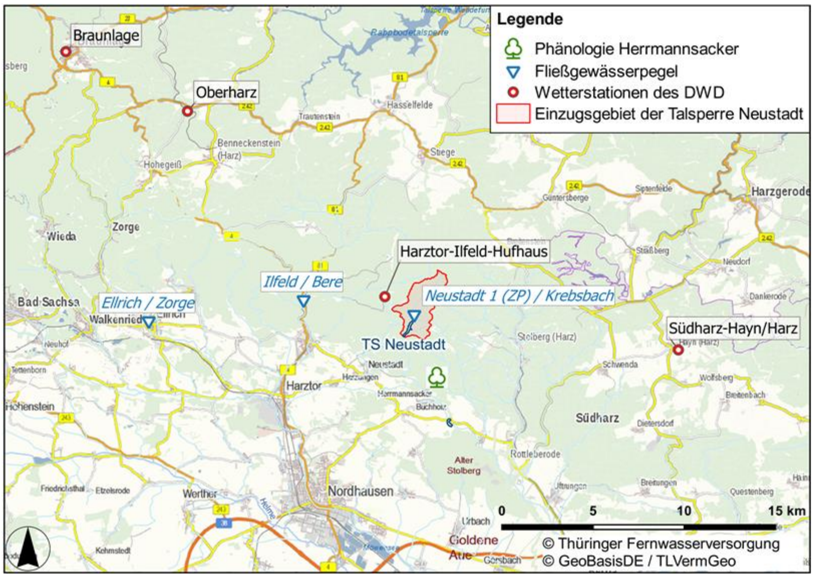

Fig. 1.
Location of Neustadt dam and the location of measurements. Artern met station (not depicted) is located 37 km southeast oft he dam site

A proxy for the onset and duration of the vegetative season, during which active transpiration does occur, was estimated as the temperature sum above the

5°C threshold. This method (GDD) by Ernst and Loeper is widely used in German agriculture. The commencement of the growing season is set at a daily mean temperature sum of GDD=200°K and the annual temperature sum is a proxy for duration and intensity of the growing season. Vegetative development was analysed at Herrmannsacker phenological station, where the day of year (DOY) of the onset of the pine sprouting is being recorded since 1965 (data: DWD).

Flow data is being recorded at the dams inflow gauging station Neustadt 1/Krebsbach (A_E = 2.96 km^2, records 1912 - 2016, 1 gap year). Furthermore, the state-run stream gauging stations at Ilfeld/Bere (A_E = 62.5 km^2, 1952 - 2015) and Ellrich/Zorge (A_E = 42.1 km^2, 1970 - 2015) were also analysed (data: TLUG).
All data series were analysed for long-term trends using the package „Trend", implemented in the R software [1]. Since several studies have indicated that climate and phenological changes might occur suddenly rather than as a long-term gradual trend [2], [3], such a test was also carried out with all long-term data, using the package „Kendall" in R.

3. RESULTS AND DISCUSSION

3.1. AIR TEMPERATURE AND GROWING SEASON

Recorded annual temperature sums above the 5°C-threshold ($\Sigma GDD_{5°C}$) at both Braunlage and Artern meteorological stations showed no clear trend in the first half of the data series, but a steady and significant increase from the late 1980ies onwards (Figure 2). A highly significant breakpoint ($p < 0.0001$) was

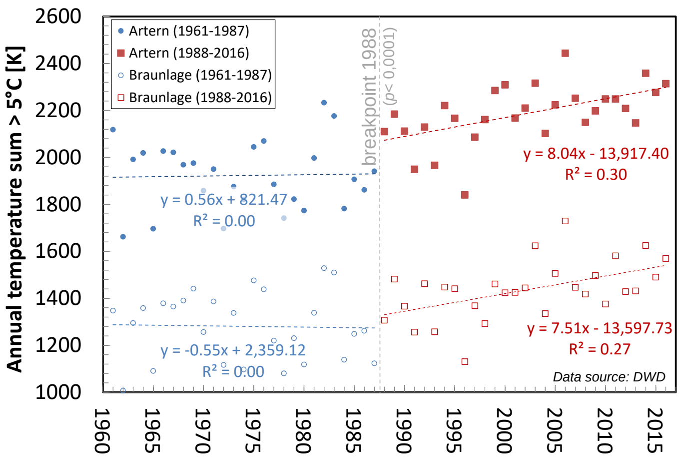

Fig. 2
Annual temperature sum > 5°C at Artern und Braunlage met stations

identified in 1987/88, which is in line with earlier studies in Europe [4]. The day of year (DOY) at which the sum of mean daily temperature had reached the 200°K mark has moved forward by 17 and 12 days at Artern and Braunlage, respectively, when comparing the 1988-2016 with the 1961-1987 sub-periods. At Herrmannsacker, beginning of pine tree sprouting has been advancing at a rate of 6 days per decade, or with a sudden shift of two and a half weeks starting in the late 1980ies (Figure 3). These results can be directly transferred to the catchment area of Neustadt dam, which has a forest cover of 96 %.

3.2. Precipitation

Precipitation is a key determinant of catchment runoff. At Harztor-Ilfeld-Hufhaus gauging station seasonal long-term trends (1916 - 2016) were weak and statistically not significant, showing small increases in the winter (Nov-Apr) and small decreases during the summer (May-Oct), as shown in Figure 4. Monthly trends for the entire record and sub-periods thereof are given in Table 1 for three precipitation gauging stations in the Southern Harz region. Two of the three stations showed significant linear increases in winter precipitation over the 101 year record length. Comparing annual precipitation for the 1961-1987 and 1988-2016 period revealed s small but significant increase during the latter period for two out of the three stations. A comparison of individual months prior to and after the 1987/88 breakpoint revealed significant decreases in April and June at all stations and, while July, September and October and to some extent also January and February stood out with particularly large increases.

3.3. RUNOFF AND RESERVOIR INFLOW

The time series of 105 years streamflow data at Neustadt 1 did show a small but insignificant decrease of seasonal and annual runoff (Table 2), a finding that is in line with observed trends in the Western Harz mountains [5]. At Ilfeld and Ellrich gauging stations, the decreases in summer runoff were significant and at Ellrich, even the decreasing annual runoff trend was statistically significant.

However, the latter stations record started in 1970 rather than the Neustadt 1911 commencement date, hinting that record length might have impacted the results in some way. The observed long-term changes in seasonal and annual runoff at all three gauging cannot be explained by the long-term trends in precipitation, thus indicating that runoff changes were influenced by other processes. Looking at individual months, we find that at the dams inflow stream gauge Neustadt 1, nine out of twelve months registered significant decreases following the 1987/88 breakpoint (Figure 5). While streamflow in individual months decreased by 50 % or more, seasonal summer inflow decrease was a staggering 36 %, a finding well confirmed at the other two nearby gauging stations of Ilfeld and Ellrich as well as findings in the Eastern part of lower Saxony [6]. Average annual reservoir inflow at Neustadt dam had decreased from 2.56 MCM (1912-1987) to 2.15 MCM (1988-2016). During the 1988-2016 sub-period, March had replaced April as the month with the highest mean runoff as compared to preceding sub-period ending in 1987, hinting at an earlier and smaller snowpack-melt, which is well in line with the temperature records presented above. However, the statistically significant decrease in March runoff during the most recent period (1988-2016) at two out the three gauging stations seems to indicate that the run-off shift towards the start of the year is still ongoing (Table 2).

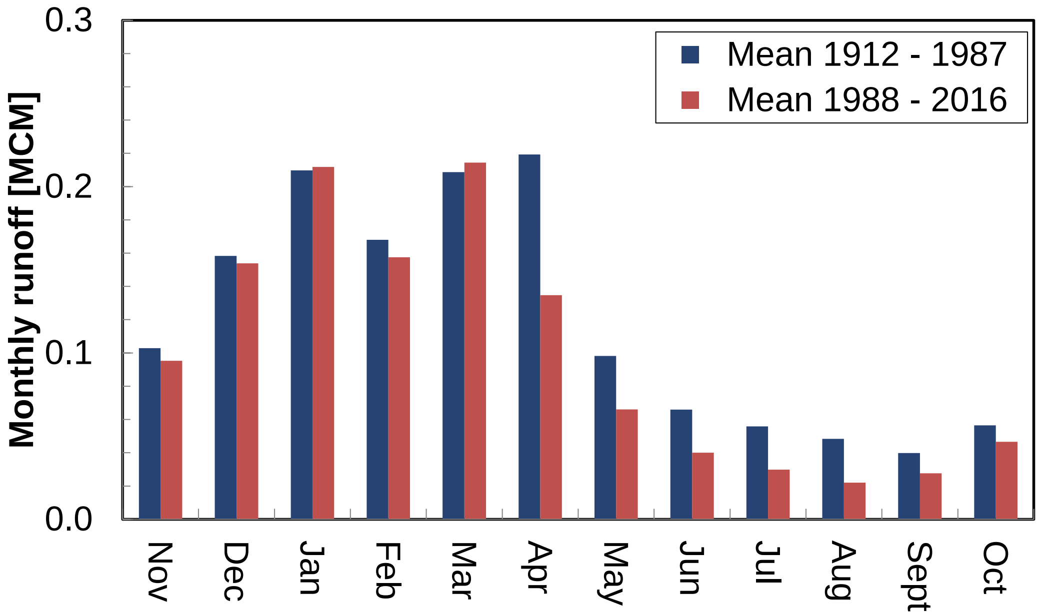

Fig. 5
Changes in mean monthly runoff at Neustadt 1 streamflow gauging station after the 1988 breakpoint

3.4. IMPLICATIONS FOR RESERVOIR MANAGEMENT AND POSSIBLE REMEDIES

With climate projections for the coming decades all pointing towards a strengthening of the trends observed in the last three decades, the dam operators working hypothesis at this point is, that the current changes in runoff regimes are likely to continue into the foreseeable future. This hypothesis must be verified periodically by rigid statistical analyses of measured data. However, there is a residual risk that sudden shifts and breakpoints will only be recognizable in hindsight, when the subsequent time period is long enough, i.e. at least 10 years.

The seasonal partitioning of reservoir inflow flow (winter/summer), as a percentage of mean annual inflow, shifted from a 26/74 ratio during 1912-1987 to a 19/81 ratio after the 1987/88 breakpoint. This increased seasonality and variability has a diminishing effect on safe raw water withdrawals from the reservoir, as has been shown in [7]. Keeping with the current raw water withdrawal RWW_{365} of 3650 m^3 d^{-1} would in turn mean decreasing reliabilities of supply RoS once mean inflow decreases and becomes more variable. Hence it is recommended to always include RoS in raw water delivery contracts, thus making sure that the residual risk of water deficit periods is well understood and agreed upon in advance.

As these trends and shifts will continue to impact flow volumes and variability in the future, societal demands towards infrastructure, i.e. dams, fulfilling an increased buffering function in the hydrological cycle are also likely to increase. Since some of these dam functions and requirements are contrarian to each other, e.g. flood protection and drinking water supply, it can be expected that dam and reservoir management will become more challenging in the coming decades. Water industry experts are therefore required to plan and prepare possible remedies and solutions well in advance.

At Neustadt dam, one remedial measure includes the calibration and operation of a mid-term reservoir management model (MBM), which helps the operator in determining beginning and duration of hydrological surplus periods, based on current and modelled inflow and actual storage content, during which raw water withdrawals can safely be increased beyond RWW_{365} without compromising RoS [7]. In the future, this model could also be expanded by a module accounting for the water volume occasionally stored in the water catchments snowpack during the winter.

Alternatively, one could consider increasing storage capacity from currently 0.48 of mean annual flow to a higher level. Compared to new dam construction, the incremental costs of dam heightening are usually considered smaller. Nevertheless this approach requires careful economic and hydrologic analysis. It must also be pointed out that it does not solve the problem of decreasing inflows per se but merely increases the useable percentage of that flow.

An alternative solution includes increasing mean annual reservoir inflow by means of a 5.6 km long gravity transfer tunnel tapping into neighbouring streams at higher altitude than the reservoirs full supply level. An initial survey has revealed that the catchment area could thus be tripled. A geological, hydrological and economic scoping study for this investment is scheduled for 2018.

4. CONCLUSIONS

This investigation revealed clear signs of a changing meteorology, hydrology and phenology in the Southern region of one of Germany’s most important water towers. The breakpoint identified in 1987/88 and the sudden shifts associated with it are particularly noteworthy. It contradicts the notion that these changes do manifest themselves in a gradual and linear fashion. The evidence suggests an increased duration and intensity of the vegetation season. In the absence of significant aquifers in the catchment area, the considerable decreases in reservoir inflow observed in the last three decades have most likely been caused by increased actual evapotranspiration. Which portion of the increased evapotranspiration has been caused by modified forest management and decreased forest damage due to improved air quality has not been a subject of this study and can thus not be safely determined at this point. Diminishing reservoir inflow certainly has a negative impact on safe yield, especially if all safe withdrawal is already committed in an existing water delivery contract. The two most prominent adaptation strategies pursued by the dam owner/operator include close monitoring and modelling of the reservoirs short- and long-term water balance combined with exploring additional infrastructural investments aimed at increasing the catchment area and thus reservoir inflow.

SUMMARY

The Harz is the main water tower in central Germany and its water resources have been developed since the 16th century to support the mining industry and since the 19th century for public water supply. Today, nine multi-purpose dams in the Harz provide high quality raw water for public water supply. Neustadt dam is the Southernmost and smallest of these nine dams and is fulfilling its water supply function since 1905. At present, all safely available water is committed in a raw water supply contract and the buyer – a local water company – has requested to increase the water withdrawal in the future. On the other hand, with a fully committed water balance, any long-term or sudden changes in the dam's inflow regime would have a direct negative impact on safe water withdrawal. In this paper, long-term records from the dam's inflow gauging station, two nearby stream gauges, two met stations, three rain gauges and a phenological station were analysed for any shifts or changes. The investigation revealed significant changes in in the flow regime. Firstly, starting in the late 1980s, monthly maximum reservoir inflow shifted from April towards the beginning of the year. Secondly, mean summer runoff had decreased by 35 %, and in some months by up to 55 % in the last 30 years. A breakpoint analysis revealed 1987/88 as a statistically highly significant point in time when these changes occurred, this finding was independently confirmed by data from two nearby gauging stations. The observed changes in the flow regime could not be explained by precipitation data at the site, which showed neither any significant trends nor any breakpoints. This implies a change in the partitioning of precipitation into runoff, evapotranspiration and groundwater recharge. Because of the geological characteristics of the catchment area, both groundwater recharge and subsurface runoff are negligible. The working hypothesis is that a shift of runoff volume towards evapotranspiration has occurred after the 1987/88 breakpoint. This hypothesis is supported by the direct link between measured increases in air temperature and potential evapotranspiration. Furthermore, phenological observations and seasonal temperature sums provide clear evidence of an earlier onset and longer duration of the vegetation season at the site. Going forward, it is expected that future trends and sudden shifts of meteorological and hydrological parameters will potentially increase the demand and expectations of society on dams and their buffering role in the hydrological cycle. However, some of these functions and purposes are contrarian to each other, hence dam management will potentially become more challenging. Finally, several remedial adaptation strategies for dam operators with a fully committed water balance are discussed in general and the two approaches towards increasing safe water withdrawal from Neustadt dam are briefly outlined.

STUDY ON RISK ANALYSIS FOR FLOOD PREVENTION AND DAM SAFETY BASED ON STOCHASTIC SIMULATION*

Jie GAO

Senior Engineer of China Renewable Energy Engineering Institute
Master supervisor of China Three Gorges University

CHINA

Abstract: Based on stochastic simulation of inflow flood for cascade reservoirs, the P-III distribution of flood peaks, flood regulation and reservoir operation were taken into account. The probabilities of flood overtopping, stage exceeding several critical levels were calculated based on a great number of stochastic samples. Refer to study on acceptable risk analysis, considering climate change, taking four cascade reservoirs as a case study, the procedure of assessment for risk analysis of flood control and dam safety were proposed.
Key words: flood control; hydrology; safety of dams; Risk analysis; risk analysis for dam safety; flood control and dam safety; overtopping risk analysis

1. INTRODUCTION

Public security is closely related to project safety. Both researchers and engineers focus on the analysis, assessment and criterion of project risk. The

* This work is funded by Power Construction Corporation of China（DJ-ZDZX-2016-02）

acceptable risk level frequently serves for decision-making after balancing the cost against benefits from that risk. ALAPR (As low as reasonably practicable) is a widely used acceptable risk criterion which involves unacceptably high risk, generally acceptable risk and negligible risk [1]. The acceptable risk level lies between unacceptably high risk region and generally acceptable risk region, which determines the feasibility. HSE (The Health and Safety Executive) proposed that risk of existing infrastructure is annual fatality risk of 10^{-4} [2]. Concerned with the acceptable risk of dam safety, USBR (United States Bureau of Reclamation) and ANCOLD (Australian National Committee on Large Dams) suggested 10^{-2} and 10^{-3} fatalities/person/year for each dam failure event respectively, while BC Hydro presented the acceptable life and economic risk associated with each dam failure is of 10^{-3} fatalities/person/year and US$7120/year respectively [3].

Risk depends on probability of failure and loss of hazard. The loss varies with time and place, is closely related to the development of local economy and society, while failure probability can be approached by statistics and simulations. In this article, we focus on dam failure probability. According to analysis on different dam failure modes, flood related problems including flood exceeding control criterion and spillway failure both leading to erosion damage on dams and bank joint, which accounts for one third of overall dam failure events. The dam in United States which were built after 1950s with a height more than 30m is of a failure probability in the range of $1.3\times10^{-3} \sim 3.0\times10^{-3}$. It indicates [4] the dam failure caused by flood related problems is in the range of $0.43\times10^{-3} \sim 1.0\times10^{-3}$. Yang et al[4] considered $10^{-3} \sim 10^{-4}$ on the lower side of criterion for dam safety and flood control. Regardless of flood regulation, Xu [5] provided 10^{-5} as risk probability of spillway for high dam. As the technology of design, construction and management for dams and reservoirs improved, dam failure events reduced. In China, from 1990 to 2011, there were 278 dam failed in the overall approximately 98000 dams [6]. It offered a dam failure probability of 2.84×10^{-4} and deduced that probability of flood related risk is 9.47×10^{-5}.

The probability of flood related problems could be attained by numerical simulation as well as statistics. Xu [7] attributed flood-related risk to large flood and failure of spillway, and applied JC method to risk calculation. The P-III and normal distribution were used to describe the uncertainty of flood inflow and initial stage respectively, while triangle and normal distribution were applied to describe the uncertainty of spillways capacity. Based on stochastic simulation approach, Mei et al [8] took both hydrological and hydraulic uncertainty into account, used seasonal AR(1) models to generate a great number of reservoir inflow. The results revealed that flood-related hydrological uncertainty plays the major role in risk analysis compared with any other factors.

Based on stochastic simulation, we researched in the view of: (1) dam safety itself, (2) flood control capability of dam and, (3) flood control for downstream regions provided by dam. The case study is 4 built cascade reservoirs in the Jinsha River, China. Based on statistical parameters obtained from observed 49-year flood peak series of 3 hydrological stations in the study area, climate change is studied and stochastic simulation is adopted to reflect the uncertainty of flood inflow. The calculation and procedure will contribute to conduct flood related risk analysis for dam safety.

2. METHOD

2.1. STATISTICAL PARAMETERS OF OBSERVATION

According to the drainage characteristic of study area, the representative hydrological stations are selected. Annual maximum discharge in several-year time series are collected and following a P-III frequency distribution curve. The average of annual flood peak (*EX*), coefficient of variation (*Cv*) and skewness (*Cs*) are derived from the fitted P-III frequency curve.

2.2. STOCHASTIC SIMULATION FOR FLOOD PEAKS IN REPRESENTATIVE HYDROLOGICAL STATION

Considering changes in landscape and climate which may lead to nonstationary hydrological regimes, GAMLSS (Generalized Additive Models for Location, Scale, and Shape) model[10] is introduced to provide a flexible modeling framework for flood peaks and to reveal the trend of flood peaks observed in hydrological stations. For a stationary hydrological series, according to the *EX*, *Cv* and *Cs* deduced in 2.1, followed the sampling method of P-III distribution [9], a great number of flood peaks for representative hydrological station are generated.

2.3. RESULTS FOR CASCADE RESERVOIRS

According to hydrological analogy method and typical hydrograph, the inflow flood hydrographs for each reservoir are acquired.

2.4. FLOOD REGULATION

Based on water balance principle and regulation requirements, adopted storage-capacity relation of reservoir and stage-discharge relation of spillway, applied trial and error method, the outflow and maximum stage corresponding to each inflow flood are calculated. Therefore, considering the uncertainty of flood inflow, the probability of different stages for each reservoir can be identified.

3. CASE STUDY

Based on the abundant water power resources and mountainous topography in middle reach of the Jinsha River, China, four concrete gravity dams(A, B, C, D) were built for the development and utilization of hydropower resources. The four dams lie among three hydrological stations: Shigu, Jinjiangjie and Panzhihua, making a series of cascade reservoirs. According to feasibility studies, the four dams are all scale first-grade first-class projects with check standard for flood control equals to 5000-year return period.

3.1. PARAMETERS OF REPRESENTATIVE HYDROLOGICAL STATION

Annual flood peaks recorded in the 3 representative hydrological stations during 1957 and 2005 [11] are gained by P-III distribution curve fitting which deduces the best-fitting EX, Cv and Cs for each hydrological station. Results are shown in Table 1.

Table 1
Parameters of curve fitting

Hydrological station	Parameters			Flood peak in different frequency($m^3 \cdot s^{-1}$)		
	EX	Cv	Cs/Cv	0.01%	0.02%	0.2%
Shigu	5140	0.29	4	14600	13900	11500
Jinjiangjie	6710	0.31	4	20200	19200	15800
Panzhihua	7360	0.31	4	22200	21100	17300

3.2. STOCHASTIC SIMULATIONS FOR REPRESENTATIVE HYDROLOGICAL STATION

3.2.1 Climate change

In consideration of climate change, GAMLSS[12,13] is used to identify the optimum flood distribution[14], reveals whether time series is stationary or not.

Firstly, three probability distribution functions (PDF) are selected, namely:

(1)Gumbel distribution

(2)two parameter LogNormal(LN2)

(3)two parameter Pearson Type II (P2), Gamma distribution

Secondly, time trend is assumed in the first two moments (the mean value and the standard deviation):

(1) trends in the mean value (A)

(2) trends in the standard deviation (B)

Thirdly, three time-trend function are included:

(1) Stationary, not varied with time (S)

(2) linear form of a trend (L)

(3) parabolic form (P)

The Akaike Information Criterion (AIC) is applied to identify the optimum model, which possesses the minimum AIC value.

$$AIC = -2 \ln ML + 2k \quad [1]$$

Where, ML denotes the maximum likelihood, k is the number of fitted parameters.

The results for curve fitting of flood peak at Shigu, Jinjiangjie and Panzhihua hydrological stations are as follows[15]:

Table1 AIC value of Gumbel, Lognormal and Gamma distribution for flood peaks at Sigu, Jinjiangjie and Panzhihua hydrological stations

model	Gumbel	LogNo	Gamma	Gumbel	LogNo	Gamma	Gumbel	LogNo	Gamma
	AIC value of Shigu station			AIC value of Jinjiangjie station			AIC value of Panzhihua station		
ASBS	***930.56***	***917.18***	***917.27***	***910.64***	***896.04***	***895.42***	900.82	883.69	883.73
ALBS	932.51	919.17	919.27	912.64	897.63	897.08	902.81	885.53	885.53
APBS	933.08	918.53	918.92	912.44	898.02	897.15	***900.60***	***881.19***	***881.59***
ASBL	932.21	919.14	919.24	912.04	898.02	897.34	901.65	885.40	885.65
ALBL	934.20	921.11	921.22	913.72	899.54	898.90	903.25	887.36	887.52
APBL	935.08	920.52	920.90	912.83	899.35	898.33	901.15	883.15	883.42
ASBP	934.14	921.02	920.98	913.87	899.26	899.03	903.48	887.35	887.39
ALBP	936.14	923.01	922.98	915.66	901.18	900.81	904.92	889.25	888.99
APBP	936.72	922.15	922.40	914.83	901.07	900.22	902.90	884.44	884.68

The results indicate that the best curve fitting for flood peaks of Shigu, Jinjiangjie and Panzhihua stations are stationary LogNormal, stationary Gamma distribution and nonstationary Lognormal distribution with linear trend of mean value and stationary standard deviation.

The 1st to 3rd reservoirs are located between Shigu and Jinjiangjie. Meanwhile, the 4th reservoir lies between Jinjiangjie and Panzhihua, it is much closer to Jinjiangjie than that to Panzhihua. In the view of watershed scale, the nonstationary impact on flood peak series is not taken into account in this article, and the conventional sampling method for P-III distribution are employed.

3.2.2 Sampling method

(1) Parameters for sampling

$$a_1 = EX \times (1 - \frac{2C_v}{C_s}) \tag{2}$$

$$a_2 = \frac{2}{EX \times C_v \times C_s} \tag{3}$$

$$a_3 = \frac{4}{{C_s}^2} \tag{4}$$

$p = a_3 - n$, where, n is an integer and $0 < p < 1$ [5]

(2) Three uniform random number u_1, u_2, and u_3 in [0,1] are generated.

(3) $a_4 = -\sum_{i=1}^{n} \ln u_i$ [6]

(4) Three uniform random number u_{n+1}, u_{n+2}, and u_{n+3} in [0,1] are generated.

(5) $s_1 = {u_{n+1}}^{\frac{1}{p}}, s_2 = {u_{n+2}}^{\frac{1}{1-p}}$ [7]

(6) if $s_1 + s_2 \leq 1$,

then $t = \frac{s_1}{s_1 + s_2}$, $x = -t \times \ln u_{n+3}$, $z' = x + a_4$, $z = \frac{z'}{a_2} + a_1$ [8]

Thus, z is a random variable following P-III distribution.

Else if, $s_1 + s_2 > 1$, then return to (4).

40000 samples are generated following the program mentioned above and should be undertaken hypothesis testing to confirm the results.

3.3. FLOOD INFLOW FOR EACH RESERVOIR

The 1st, 2nd and 3rd cascade reservoirs were located between the 1st and 2nd hydrological station, while the 4th reservoir lies between the 2nd and 3rd hydrological station (see Fig 1). Flood peaks of the four cascade reservoirs are calculated by hydrological analogy method based on 40000 flood peak samples of the three hydrological stations and drainage area ratios.

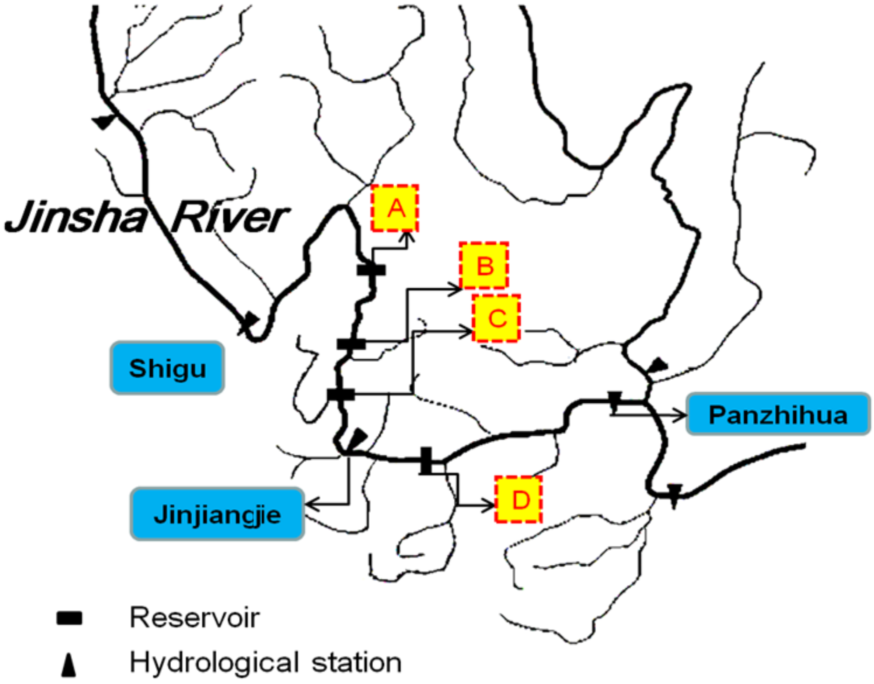

Figure 1 Location of cascade reservoirs and hydrological stations

Among the three hydrological stations, the 2nd hydrological station is the nearest one to all the four reservoirs. From total 49-year observations in 2nd hydrological station, the hydrograph with maximum flood peak and volume is abstracted as typical hydrograph which determine the shape of inflow flood and used to generate 40000 inflow flood processes into each reservoir.

3.4. Flood Regulation and Probability Statistics

Based on the 40000 inflow flood processes into each reservoir, according to relationships of stage versus capacity, stage versus discharge, following specific regulation, from a certain initial stage (such as normal storage level or full supply level or top level of flood control), 40000 maximum stages for every reservoir are calculated after flood regulation. The probabilities of not exceeding initial stage, exceeding stage of check flood level and overtopping are acquired.

4. RESULT AND ANALYSIS

4.1. Results

The probabilities under several scenarios for each reservoir are calculated based on 40000 stochastic simulations. The results are shown in Table 3.

Table 3
Probability under different scenario for cascade reservoirs

Probability \ Reservoir	1st(A)	2nd(B)	3rd(C)	4th(D)
Maximum stage not exceeding the initial stage (top level of flood control or normal storage level)	0.99785	0.99775	0.999175	0.99745
Maximum stage exceeding stage of check criterion for flood control	7.5×10^{-5}	2.0×10^{-4}	5.0×10^{-5}	1.75×10^{-4}
Maximum stage overtopping	2.5×10^{-5}	0	0	5.0×10^{-5}

4.2. ANALYSIS

(1) In the view of dam safety itself, in flood season, dam failure is frequently caused by overtopping. The risk will be unacceptable, if risk probability of overtopping exceeds a certain threshold. According to the statistics of dam failure events between 1950s and 1990s caused by flood related overtopping issues, the threshold or acceptable risk probability will be 1.0×10^{-4} [4]. However, based on the statistics of data after 1990s [6], the critical value decreases to 9.47×10^{-5} that becoming stricter. In the case study, the risk probability of overtopping for 1st to 4th reservoirs are 2.5×10^{-5}, 0, 0, and 5.0×10^{-5} respectively, which are all below the threshold or acceptable risk probability for flood control and satisfy the demands for dam safety.

(2) In the view of flood control capability of dam, when flood of check standard occurs, the spillway works with designed maximum discharge to ensure that stage stops rising and not exceed check flood level. In the case study, the check standard of flood control for all the four reservoirs is with a return period of 5000 years, which means a probability of 2.0×10^{-4}. Based on the statistics of 40000 stochastic simulations, the probabilities of exceeding check flood level for 1st to 4th reservoirs are 7.5×10^{-5}, 2.0×10^{-4}, 5.0×10^{-5}, and 1.75×10^{-4} respectively, which doesn't exceed check standard and satisfy the requirements for flood control capability of dam.

(3) In the view of flood control for downstream regions protected by dam, during flood season, if water level of reservoir maintains lowering than the initial stage, the spillway works to perform flood regulation and reduce outflow comply with the safe and multipurpose requirements of downstream regions. In the case study, the probability not exceeding initial stage is approximately 99.75% for the four reservoirs, which indicates that when flood with a return period less than 400 years occurs, flood regulation works and makes the downstream regions safe and

efficient.

(4)The four reservoirs have similar project scale and flood control standard, and all meet the requirements for flood control. Actually, the procedure will be more applicable for earth and rock-fill dams rather than concrete dams. However, this procedure will contribute to establish a systematical risk assessment method for dam safety.

5. SUMMARY

Based on 40000 stochastic simulations of flood inflow for four reservoirs, the P-III distribution of inflow flood, flood regulation and reservoir operation are taken into account. The probabilities of flood overtopping, stage exceeding several critical levels are calculated based on the 40000 stochastic samples for each cascade. Refer to study on acceptable risk analysis, in the view of dam safety itself, flood control capability of dam and flood control for downstream regions protected by dam, the procedure of assessment for risk analysis of flood control and dam safety are proposed.

1. INTRODUCTION

Asahan River becomes the main source of water flow for Siruar, Sigura gura and Tangga Dam. The Siruar dam serves to regulate the stability of the water coming out of Lake Toba to the Asahan River and to supply water to the power station constantly to the Asahan hydroelectric power plant (Asahan I, Siguragura and Tangga power plant). This type of dam is a mass concrete with a height of 39 meters.

Since the changes of land use in the most Asahan catchment area, erosion and sedimentation became problem for the Siruar Dam especially for the operation of Asahan I hydroelectric power plant. Jasa Tirta I as state own enterprise which has authority to manage water resources in Toba Asahan River Basin (given by Government with Presidential Decree No. 2/2014) conducted comprehensive study to indentify the rate and sources of sedimentation and the countermeasures as well in 2016 - 2017.

2. DATA COLLECTING METHOD

The primary data taken by topographic survey, bathymetry and also sediment sampling along 14.5 km of upstream Asahan and 5 km of its tributaries which are Bolon and Mandosi River, and water sampling for quality test. In order to get deeper analysis, secondary data also collected through government institutions such as statistical agency, planning and development agency, geophysics and meteorology agency, ministry of public works and ministry of forestry.

3. ANALYSIS AND RESULTS

The study identified that the sediment rate per year is 20.25 ton/ha. The grain sediment analysis also showed that 50% of sediment which setlles in river bed is sand. The sources of the sediment were from the lake and from Asahan tributaries which are Bolon and Mandosi river. From the water quality analysis, chlorine has significant parameter for the Asahan water. Asahan River, of which a major part is used by the people around Toba Samosir Regency, is utilized as a place for washing, bathing, industry, and agricultural activity runoff.

THE COUNTERMEASURES OF SEDIMENTATION

Based on the Technical Plans for Rehabilitation of Forest and Land Asahan Barumun Water Catchment Area 2015–2029 by Ministry of Forestry, targets of erosion control in the study area are established to be at least equivalent to the target of erosion control in the Toba Asahan watershed.

Table 1
Proposed Program for Sediment Countermeasure (data processing 2017)

Indicator	Natural Condition	Exsisting Condition	Target of Sediment Control by Ministry of Forestry	Proposed Target of Study	Projection
The erotion hazard level → light and very light	78,3 %	63%	>50%	>70%	72,8%
Sediment rate per year	11,5 ton/ha	20,25 ton/ha	<20 ton/ha	<15 ton/ha	14,7 ton/ha
Gully plugs = 300 units Check dams = 10 units Strip Vegetation = 160 ha Reforestation = 13.074 ha					

Another approach for sediment control management is dredging works. The analysis showed that dredging works have to be done regularly with estimate volume of 21.000 m3 in order to maintain sedimentation.

4. CONCLUSION

The objective of this study is to identify the rate and sources of sedimentation at Upstream Asahan and the countermeasures as well in order to ensure the sustainability of Siruar Dam and Asahan hydroelectric power plant. From the analysis, the rate of sedimentation reached 20.25 ton/ha/year and 50% which settled in river bed was sand. Changes of land use has important role to speed up the sediment rate, therefore conservation of land, reforestation and civil conservation approach such as check dams, gully plugs have to be done. Another technical approach to maintain deposit sediment in the river is dredging works. The study recommends for regular dredging with estimate volume of 21.000 m^3 sediment per year.

1. ABSTRACT

Wlingi Reservoir is one of the reservoirs in the Brantas River Basin management system. Besides as a flood control, this reservoir has an important role as a supplier of 2 x 27 MW of electrical and serves irrigation area of 15,132 Ha. The reservoir was completed in 1979 and has total storage capacity of 24 million m3, however due to severe sedimentation caused by Mt. Kelud eruption and critical catchment condition, by the year of 2016 its capacity decreased to only 2.55 million m3 or 10.63% of the initial capacity.

To extend the economic lifetime of the reservoir, many efforts have been undertaken, including some preventive activities through conservation in the upstream areas as well as some corrective measurements. Some corrective measurements that have been done are sedimentation dredging (through spoil bank disposal and riverine disposal) and sedimentation flushing. Based on technical and financial aspect, sedimentation flushing is considered more efficient than the other measurements. Based on the technical evaluation, sedimentation flushing can remove approx. 300,000 m3 to 1,2 million m3 sediment per year from reservoir, which is higher than the sedimentation dredging that only remove approx. 100,000 to 350,000 m3 per year. Based on the financial evaluation, sedimentation flushing can save the cost of Rp. 35.85 billion compared to dredging with spoil bank disposal, while dredging with riverine disposal to channel below can save about Rp. 14.96 billion compared to the dredging with spoil bank disposal. Another advantage of sedimentation flushing is the supply of

300,000 m3 up to 1.2 million m3 of sediment per year that may tackle the issue of riverbed degradation at the downstream part of the reservoir, which is currently the riverbed degradation is happened approx. 2 to 8 m caused by rapid illegal sand mining. However flushing implementation should consider the availability of water so it cannot be done every year.

Keywords: Wlingi Dam, flushing, dredging, sedimentation.

2. INTRODUCTION

Wlingi Dam was completed in 1977 with a total catchment area of 2,890 km2, located in Blitar, East Java, Indonesia. It has gross reservoir capacity 24.0 million m3 and effective capacity 5.20 million m3. The dam was built as the after bay of Sutami Hydro Electric Power Plant (HEPP) and has benefits:

- Controlling flood discharge from 2,824 - 2,370 m3/sec.
- Providing water for irrigation 17,50 m3/s to Lodagung irrigation area of 15,132 Ha (in Blitar and Tulungagung).
- Generating HEPP with installed capacity 2 x 27 MW, producing energy 164.980 million KWh / year.
- Fisheries and tourism.

Due to its location in the downstream part of Kelud Volcano (one of the most active volcanoes in Java island), cause a huge sediment supply to the reservoir. Combined with land degradation in the upper area of its catchment, sedimentation become the main issue of water resources management in Wlingi dam. To overcome the above issues, some measurements has been conducted such as conservation, dredging, flushing, and preparing sabo dam and check dam in the upstream. Flushing and dredging with riverine disposal that hydraulically pumped the sediment into the downstream of the dam.

The purpose of the study is to know the effectiveness of the management sediment through flushing, dredging with spoil bank disposal, dredging with riverine disposal to channel below. Knowing the effectiveness of this sediment management is expected to increase the lifetime of the reservoir.

3. PROBLEM OF WLINGI DAM AND BRANTAS RIVER MANAGEMENT

SEDIMENTATION

The main problem in managing the reservoir is sedimentation. This problem is a fundamental problem that is almost experienced by all reservoirs in the world. Illegal logging, volcanic activity and land degradation (due to excessive land use exchange) are the main causes of sedimentation.

The Wlingi Reservoir, which was completed in 1979, has a sedimentation rate of 0.81 million m3 per year or 3.34% of reservoir per year, which the Sutami Reservoir, the largest reservoir in the same basin, has a sedimentation rate of 5.07 million m3 per year or 1, 47% of reservoir per year. From the data it appears that the sedimentation rate at Wlingi reservoir is 2.3 times the largest reservoir in the same river basin. The Wlingi Reservoir, built with an initial total storage capacity of approximately 24 million m3, now has only 4.42 million m3 or 18% of its initial storage capacity. This indicates that the sedimentation rate in Wlingi Reservoir is very large. The main cause is the influence of the eruption of Mount Kelud which is still active and is 40 km from Wlingi Reservoir. During the past century, Mount Kelud eruptions occurred in 1901, 1919, 1951, 1966, 1990 and 2014.

Table 1 Wlingi Reservoir Capacity

Years	Gross Storage		Effective Storage		Dead Storage	
	Volume (million m3)	Percen t (%)	Volume (million m3)	Percent (%)	Volume (million m3)	Percent (%)

2011	4.42	18.4	2.00	38.5	2.42	12.9

Note: 1) The volume reservoir between 1977 and 1996 was obtained from "The Brantas River Rehabilitation Project, Supporting Report 1, Evaluation of River Dredging Works for Wlingi and Lodoyo Reservoirs, December 1996" between 2001 and 2004 based on the HV curve prepared by PJT-1. 2) NA = Not Available. (Source: Jasa Tirta I Public Corporation)

Mount Kelud last eruption was happened in February 2014, but the last eruption has no significant impact on the Wlingi Reservoir. But the eruption of Mount Kelud in February 1990 had a very significant impact on the Wlingi Reservoir. Wlingi Reservoir is fully with sediment. Many efforts have be done as corrective measurements to increase reservoir capacity such as dredging and flushing. It can recovered to 4.42 million m3 reservoir capacity or 18.4% of the initial capacity of 24.0 million m3.

Total volcanic eruption in 1990 (estimated by the Volcanic Directorate of the Department of Energy and Mineral Resources) was approx. 125 million m3, which 22.3 million m3 of it deposited at Wlingi Reservoir through the Lekso, Semut, Jari, Putih and Kali Abab rivers.

RIVER BED DEGRADATION

Wlingi Dam is located in Brantas River where upper reach occurs sedimentation, but in the middle and lower reach occurs river bed degradation. This degradation occurs due to illegal sand mining. Regularly controlled by the local government in cooperation with Jasa Tirta I Public Corporation, has not been able to reduce the number of people mining sand along Brantas River. The volume of sand mining conducted by 6,280 workers along Brantas River is 2,695,000 m3 / year with details as shown in the Table 2.

Table 2 Volume of Sand Mining Brantas River in 179 Location

Location (City)	Volume of Sand Mining (m3/year)			Number of Workers (person / day)
	Manual	Pump	Total	
Sidoarjo	42,500	-	42,500	150
Mojokerto	151,500	111,000	262,500	1,060
Jombang	822,600	168,200	990,800	3,220
Nganjuk	267,100	383,000	650,100	720
Kediri	200,800	135,700	336,500	510
Kediri city	47,900	182,800	230,700	220
Tulungagung	-	183,900	181,900	400
Total	1,532,400	1,164,600	2,695,000	6,280

As a result of excessive illegal sand mining leads to degradation of the river bed. The decrease in the riverbed ranges from 2 - 8 m below the initial river bed. Even at a certain point the river decline reaches 11 m in the area of KB 80. The following illustrates the long section of the river bed at Kali Brantas.

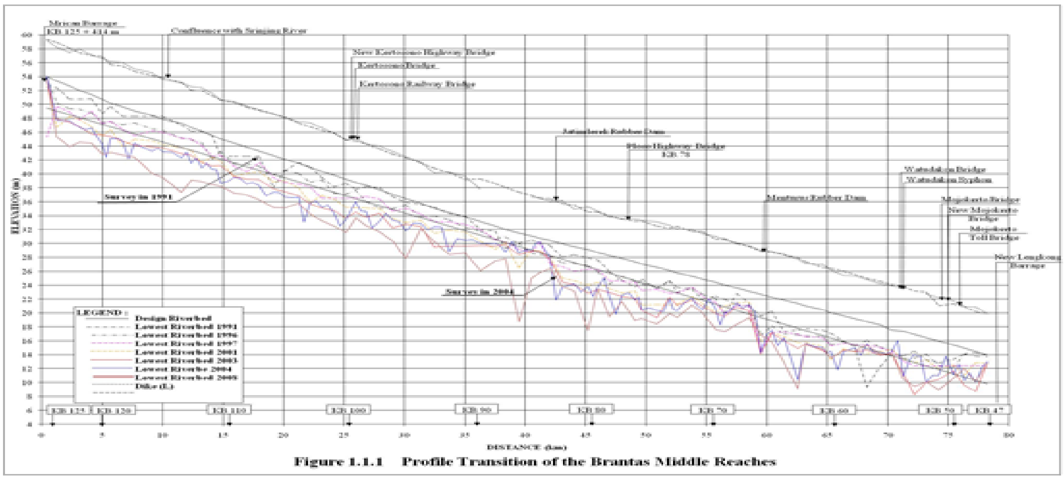

Fig. 1
Long Section of Brantas River

The extreme degradation of riverbed causes the destruction of infrastructure across the river such as the landslide of the embankment, the deformation of the bridge pier, and the decline of the water level which causes the difficulty of water supply for the beneficiaries.

Fig. 2
Damage of Deformation of Bridge Pier and Landslide of Embankment

4. SEDIMENT MANAGEMENT

Flushing Implementation

Rainfall, runoff, and river channel erosion provide a continuous supply of sediment that is hydraulically transported in rivers and streams. All reservoirs formed by dams on natural rivers are subject to some degree of sediment inflow and deposition. Because of the very low velocities in reservoirs, they tend to be very efficient sediment traps. Therefore, it is necessary to transfer sediment from reservoir to the downstream of the river. It is expected that flushing can keep the sediment balance in a river. Flushing carried out at Wlingi Dam during the last 10 years is as in the following table:

Table 3 Flushing at Wlingi Dam

Year	Wlingi Reservoir M3)	Remaks
2008	395,480	
2009	145,514	
2010	561,192	
2011	351,625	
2012	426,481	
2013	269,514	
2014	No flushing	Limited inflow
2015	No flushing	Limited inflow
2016	1,026,500	
2017	787,330	

Source: Jasa Tirta I Public Corporation

Flushing implementation is done by gradually lowering the water level of the reservoir by operating the gate so that water can flow in free flow condition. After a while, the water level is raised again. In order for optimal results, if the discharge is sufficient, this process can be repeated until obtained the planned reservoir profile. Duration for flushing implementation is about 16 - 20 hours with a potential power loss is approx. 969,000 Kwh.

After the completion of flushing, measure of the reservoir profile to calculate the amount of sediment that was flushed and examined the condition of water resources infrastructure in the upstream and downstream of the dam. Technical evaluation conducted to see whether there is damage to water resources infrastructure or not. In the event of damage, calculated how much the damage lost. From the results of several times flushing activities, apparently, no damage to water resources infrastructure.

DREDGING RESERVOIR

In addition to flushing, to increase lifetime of the reservoir is also dredging. Implementation of flushing have to consider inflow while dredging is less concerned inflow. The main obstacle of dredging is limited spoil bank land. Especially recently where high cost of land acquisition of new spoil. If the land acquisition of spoil bank encounters of constraints, then dredging with riverine disposal to channel below is carried out. The dredging of sediments in the Wlingi reservoir over the last 5 years is as shown in the following table.

Table 4 Dredging in Wlingi Dam

Year	Dredging with Spoil Bank Disposal (m3)	Dredging with Riverine Disposal to Channel Below (m3)
2013	150,800	100,031
2014	283,148	110,140
2015	377,384	
2016	100,436	250,475
2017	115,020

5. FINANCIAL ANALYSIS OF SEDIMENT MANAGEMENT

5.1 CALCULATION OF FLUSHING AND DREDGING COST

As a basic for evaluation of financial aspects assumed as follows:

- Flushing costs include flushing operational costs, lost potential revenue costs from water services and the cost of losses of electricity production due to discontinued hydropower operations.
- The amount of sediment due to flushing is calculated based on the average of flushing data for 5 years (2009 to 2013, since 2014 and 2015 have no flushing, whereas 2016 and 2017 volumes of sediments are flushed greatly considering 2 years previously not flushing)
- Loss of hydropower production is assumed based on the operating hour loss multiplied by the installed capacity multiplied by 75% (34,000,000 x 38 x 0.75 = 969,000 kWh)
- Dredging unit price refers to the existing unit price estimate in Wlingi Reservoir, which is Rp 64.100 / m3. Analysis of unit price as attached
- Tariff of water service for hydropower based on tariff which is valid in 2017 at Jasa Tirta I Public Corporation, which is Rp 167 / kWh
- Value of electricity benefit is calculated based on the basic electricity tariff issued by National Electricity Company in 2017 is Rp 1.352 / kWh
- Flushing is assumed not influence to irrigation because the flushing implementation is less than 2 days (38 hours) and not carried out during the dry season.
- During flushing there is no loss due to the temporary interruption of irrigation water supply, domestic and industrial raw water due to the relatively short implementation period.
- Operational cost of flushing based on the existing data in Jasa Tirta Public Corporation is Rp 133.330.000,

Table 5 Flushing Cost Calculation

Discription	Unit	Volume	Unit Price (Rp)	Amount (Rp)
Sediment FLushing = 350,865 m3				
Loss of Water Service Fee	(kWh)	969,000	167.0	161,823,000
Loss of Electricity Service	(kWh)	969,000	1,352	1,310,088,000
Cost of Flushing Implementation	Lump sum	1	133,330,000	133,330,000
Damage of Water Resource Infrastructure				-
Total Cost of Flushing				1,605,241,000

Table 6 Dredging Cost Calculation

Description	Explanation
A. Land Acquisition Cost	
Land acquisition Rp 290,000/m2	
Spoil bank can accommodate sediments 10 m high	
Land Acquisition Cost = 290,000 / 10 = Rp 29,000 / m3	
Spoilbank Embankment Construction	
For the sediments of 1 m3 the volume of spoil bank embankment is = 1/3 = 0.333 m3	
Unit price of embankment is Rp 40,930 / m3	Calculation see attachment 1
Spoil bank embankment construction cost = 0.333 x 40,930 = Rp 13,630 / m3	
Sediment Dredging Costs	
Sediment dredging cost = Rp 64,100 / m3	Calculation see attachment 2
Dredging with Spoil Bank Disposal Costs = A + B + C = Rp 106,730 / m3	
For dredging of 350.865 m3 of sediment cost = 350,865 x106,730 = Rp **37,454,838,750**	
Dredging with Riverine Disposal to Channel Below Costs = **C** = **Rp 64,100 / m3**	
For dredging of 350.865 m3 of sediment cost = 350,865 x 64,100 = **Rp 22,490,446,500**	

From the above table it can be concluded that flushing implementation is more effective than dredging. Flushing can save the cost of Rp. 35.85 billion (Rp 37,454,838,750 – Rp 1,605,241,000) compared to dredging with spoil bank disposal, while dredging with riverine disposal to channel below can save about Rp. 14.96 billion (Rp 37,454,838,750 – Rp 22,490,446,500) compared to the dredging with spoil bank disposal.

5.2 FLUSHING AND DREDGING BALANCE AGAINST RIVER BED DEGRADATION

As described above that in sedimentation upper reach and degradation of river bed are also problem in water resources management. The degradation of river bed along Brantas River is between 2 s / d 8 m. To reduce of river bed degradation some efforts that have been done are:

- Controlling illegal sand mining
- Conducting public awareness on the impact of illegal sand mining
- Implementation of flushing or dredging with riverine disposal to channel below.

Over the past five years, the average sediment that flows to downstream is 350,865 m^3/year. While the amount of sediment that can be supply form dredging with riverine disposal to channel below is 250,475 m^3/year. If the amount of illegal sand mining along the Brantas River in lower reach of Wlingi dam is 2,470,600 m^3/year, and there is no dredging with riverine disposal to channel below, flushing should be done 7 times a year. This is very difficult because the implementation of flushing is depend on the available inflow. Implementation of dredging 2 million m^3/year with riverine disposal to channel below in Wlingi Reservoir requires a huge cost. The possible efforts have be done through sustainable public persuasive and constructive actions through controlling the illegal sand mining.

5. CONCLUSION

1. Implementation of flushing is very effective to reduce sediment in the reservoir which has river bed degradation in lower reach. Financially sedimentation flushing can save the cost of Rp. 35.85 billion compared to dredging with spoil bank disposal, while dredging with riverine disposal to channel below can save about Rp. 14.96 billion compared to the dredging with spoil bank disposal. However flushing implementation can not be implemented every year because it must consider the reservoir inflow.
2. If the inflow is not possible to carry out flushing, dredging with riverine disposal to channel below can be done.
3. Although not significant, the implementation of flushing and dredging with riverine disposal to channel below can reduce the river bed degradation occurring in lower reach. To balance the illegal sand mining in downstream it is necessary to flush 7 times a year and it is difficult to achieve. Other efforts to maintain the river bed are the control of illegal sand mining, and public campaign.

ABSTRACT

Bogel River located in Sutojayan area, Blitar, Province of East Java. It collected into the Brantas River about ±1.5 km from the upstream of Lodoyo Dam. It have several subordo river in the upstream there are Kedungpuring River, Kedungunut River, Pijeran River, Kedungriwuk River, and several other subordo river. Seasonal type, Bogel River often overflow and impact of flood in the surrounding area, especially in Sutojayan area. Its because of the land condition in the catchment area already critical / bald and the silting up of the several suborder river in the upstream. Beside that Bogel River system is also used for irrigation. Jasa Tirta I Public Corporation have developed an early warning system and done the handling activities during flood events, although it's not included in working area of the Jasa Tirta I Public Corporation. Mitigation of Bogel River flood until today just partial and emergency activities. So it is necessary for arrange the comprehensive and integrated study and flood mitigation management, supported by the Government and related stake holder. To get the right solution for mitigation the flood of the Bogel River, need a concept in all aspects and stages, so it can give the real benefits and on target. The method used are direct controlling by (a) operating the Lodoyo weir according to Dam Operational Guidelines, Procedures and Work Instructions of Flood Control, (b) arrange the evaluation for historical flood that ever happened, (c) arrange the concept of the proposed for flood mitigation by making the comprehensive study of flood mitigation, short term action 2016, middle term-long term cction, (d) completing the hydrology observation instruments in Bogel River

System. By these integrated flood mitigation concepts in Bogel River will completing the efforts that have been done by Jasa Tirta I Public Corporation, directly and emergency action by participation from all stakeholders according to the authority. By normalitation of the condition and function of the existing water resources infrastructure, the flood control system can be implemented optimally. Of course, the real efforts can be realized so as to built the preparedness for possible flood and reduce the impact that especially for regions and communities in the district Sutojayan, Blitar. It is also become the responsibility of Jasa Tirta I Public Corporation in water resources integrated management.

Keywords : flood, mitigation management, Lodoyo weir, Bogel River

INTRODUCTION

The existence of Bogel River is expected by communities around the watershed to support the needs of water mainly for irrigation. Bogel River watershed with a total area of 54.4 km2 is a catchment rivers with a total length of 14.4 km. Bogel River system consists of three main tributaries namely Unut River, Gondang River, and Rau River with a meeting point in the Area / District Sutojayan. Most of area in Bogel watershed is relatively gentle slopes and even tend to be flat and partly is hilly area with 60% of deforested conditions. The shape of the watershed is wide/dilated which have a large flood peaks and short flood peak time, so it could potentially have a high flood peak discharge. The rapid of development with community activities around the watershed, the river's capacity is no longer sufficient to be function as drainage channels. Besides that reducing capacity because of sedimentation, especially in the estuary and the effect of water level fluctuations of Brantas River in the upstream Lodoyo Dam is also a cause which must be anticipated. (Department of Public Works.,2005)

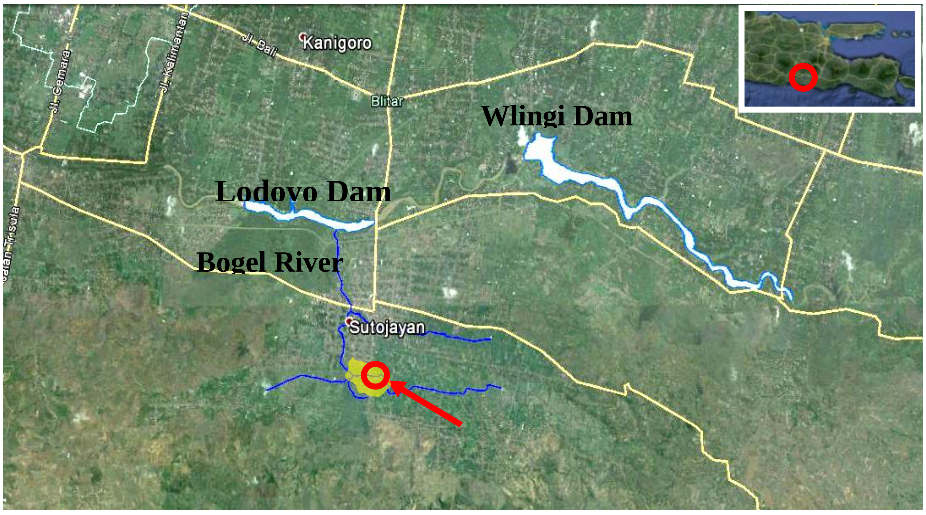

Figure 1. Location map of Bogel River

METHODOLOGY

Discussion in this paper generally consists of two subjects. The first part discusses the flood problem of Bogel River. This is done by studying the secondary data available, the results of previous studies, collecting and analysis of primary data in the field. The second section discusses the planning and solution in order to mitigation and overcome the flood problem of Bogel River. The method used is as follows :

1. Arrange the evaluation for historical flood that ever happened
2. Direct controlling by operating the Lodoyo weir according to Dam Operational Guidelines, Procedures and Work Instructions of Flood Control
3. Arrange the concept of the proposed for flood mitigation that includes :
   a. Make the comprehensive study of flood mitigation
   b. Short Term Action 2016
   c. Middle Term-Long Term Action
4. Completing the hydrology observation instruments in Bogel River System

RESULTS AND DISCUSSION

THE FLOOD PROBLEM OF BOGEL RIVER - SUTOJAYAN

Flood in Sutojayan is a complex problem caused by several factors:

1. Watershed is relatively gentle slopes and even tend to be flat
2. Condition of land in the catchment area is in a critical / deforested so the potential of sedimentation is huge
3. There was silting in most of the tributaries upstream because of erosion and sedimentation
4. Areas that frequent flooding is in the district Sutojayan due to the topography of the area is a basin which is lower than the elevation of the water level of Bogel River
5. The number of irrigation dams in the upstream impede the flow of water during a flood. Moreover, the condition is also full of sediment (sedimented)

Based on the information in the field floods that hit several villages in the district Sutojayan actually a regular puddle on every rainy season. This is because the area in the region is lower than the elevation of the water level of Bogel River, so the drainage can not drain the water into the river.

<u>Historical Events Flood of 2004 that ever happened</u>

1. Chronology Flood of 2004
   a. Rain drops began on December 2, 2004 at 07.00 am with cumulative rainfall in some places very high: 441 mm Tunggorono, Bhirowo 371 mm, 366 mm Wlingi.

b. December 3, 2004 at 06.00 am weir Lodoyo provide standby signal III / red for discharge = 1,016 m3 / sec.
c. The operation of the sluice weir Lodoyo already done on December 2, 2004 beginning at 1:00 am.
d. The rain did not stop so that the discharge tends to increase steadily even on December 3, 2004 at 08:30 pm at the weir Lodoyo out flow discharge reached 2,115 m3 / sec.
e. Areas affected by the inundation is under flood water level of Bogel River, so that when water is abundant and several tributaries berms fail then there is a pool of sufficiently high (the highest inundation reached El. 139,87m, while areas were inundated elevation 137.00 - 139.00 m).
f. Based on the evaluation, the flow capacity of Bogel River in the upstream (15 m3 / s), while in the central part of 20 m3 / s, and upstream tributaries after meeting capacity up to 110 m3 / sec. The estimated calculation of flood discharge reaches + 190 m3 / sec.

(Jasa Tirta I Public Corporation,2005. *Flood Audit Report*)

2. Impact of Fatalities of Flood 2004

There are six (6) people died in the district Sutojayan, Blitar in the event of flooding. (Jasa Tirta I Public Corporation,2005. *Flood Audit Report*)

FIGURE 2. FLOOD 18 JANUARY 2016, WATER LEVEL REACH 30 CM

FIGURE 3. FLOOD 2 FEBRUARY 2016, WATER LEVEL REACH 80 CM

The Evaluation of Flood

1. Flood 2004
   a. The influence of Lodoyo reservoir water level in the estuary of Bogel River at the time of floods is estimated at El. +138.20 (from the analysis of non-uniform flow for discharge of 2,000 m3/s and water level in the Lodoyo weir is +136.00).
   b. With the same discharge conditions when the Lodoyo water level was lowered to El. 134.00, so the water level in the estuary Bogel River is +138.05.
   c. And when the gate fully opened, the discharge of 2,000 m3 / sec, so the Lodoyo water level +131.00 and the water level in the estuary of Bogel River is +138.05.
   d. Based on these conditions indicate that the water level during a flood in Bogel River not influenced by the water level in Lodoyo Weir, but is determined more by the discharge that passing through the river.
2. Flood dated January 18, 2016 and February 2, 2016
   a. By two flood events that occurred on January 18, 2016 and February 2, 2016 seen on Flood Hydrograph that during heavy rainfall, water level Bogel River increase up quickly and additions are quite large. Example: In the event of flooding dated January 18, 2016 an increase of water level from +135.5 m to 138.2 m (2.7 m) within 2 hours.
   b. Effort to reduce the water level of Lodoyo weir already done, but require quite a long time to reduce Bogel River water level. For example on two flood events that take more than 24 hours to reduce the elevation from 1.0-1.5 m.

Table 1. Result of Flood Evaluation 2016

Date	Max. Rainfall (time -mm)	siren sounds (time)	Bogel River Max. Elevation (time-m)	Gate Opened (time) El.min (m)	Gate closed El. Normal (time) Time of Pool (hour)
18/Jan/2016	06.00 pm 142 mm	07.30 pm	09.00 pm +138,25 mm	08.00 pm +131,8 m	10.00 pm (on 19 Jan 2016) 26 hours
2/Feb/2016	O2.00 pm 88 mm	04.00 pm	06.00 pm +137,75 mm	04.00 pm +133,2 m	08.00 pm (on 3 Feb 2016) 24 jam

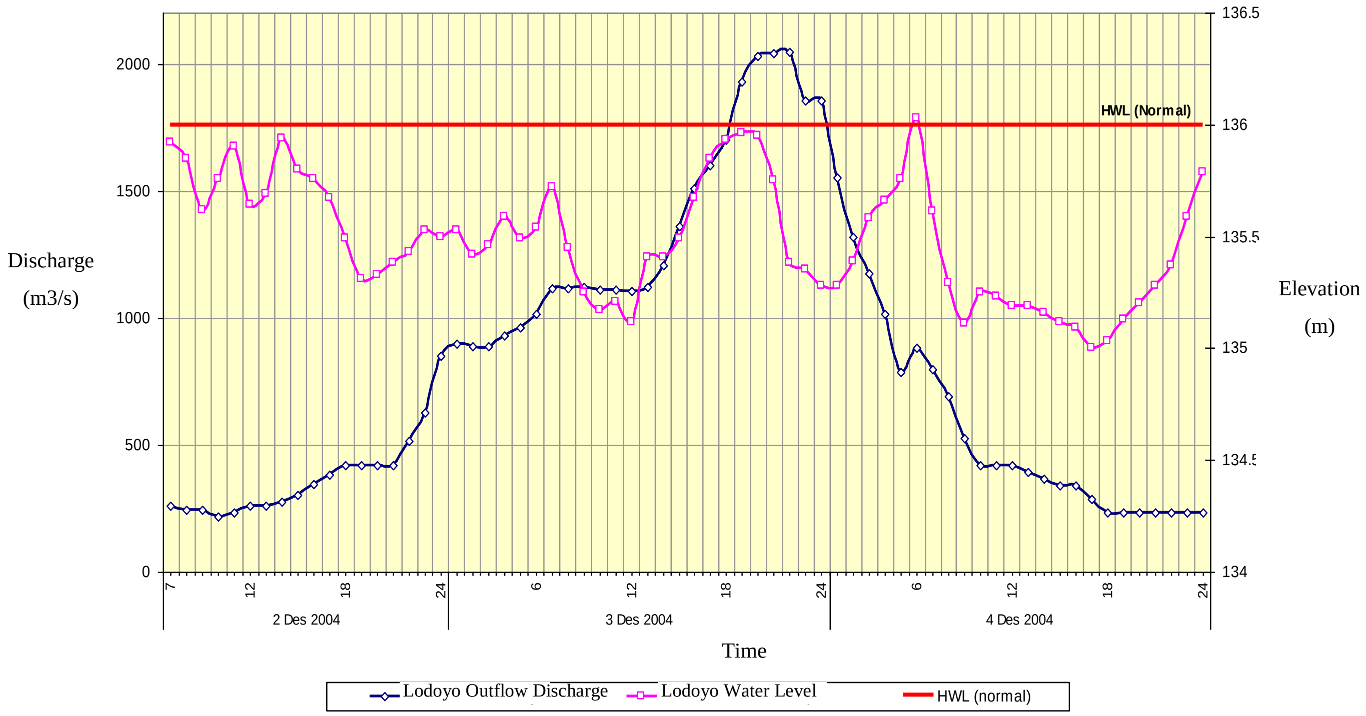

Figure 4. Flood Hydrograph and Water Level of Lodoyo Dam, 2-4 December 2004 (Jasa Tirta I Public Corporation,2005)

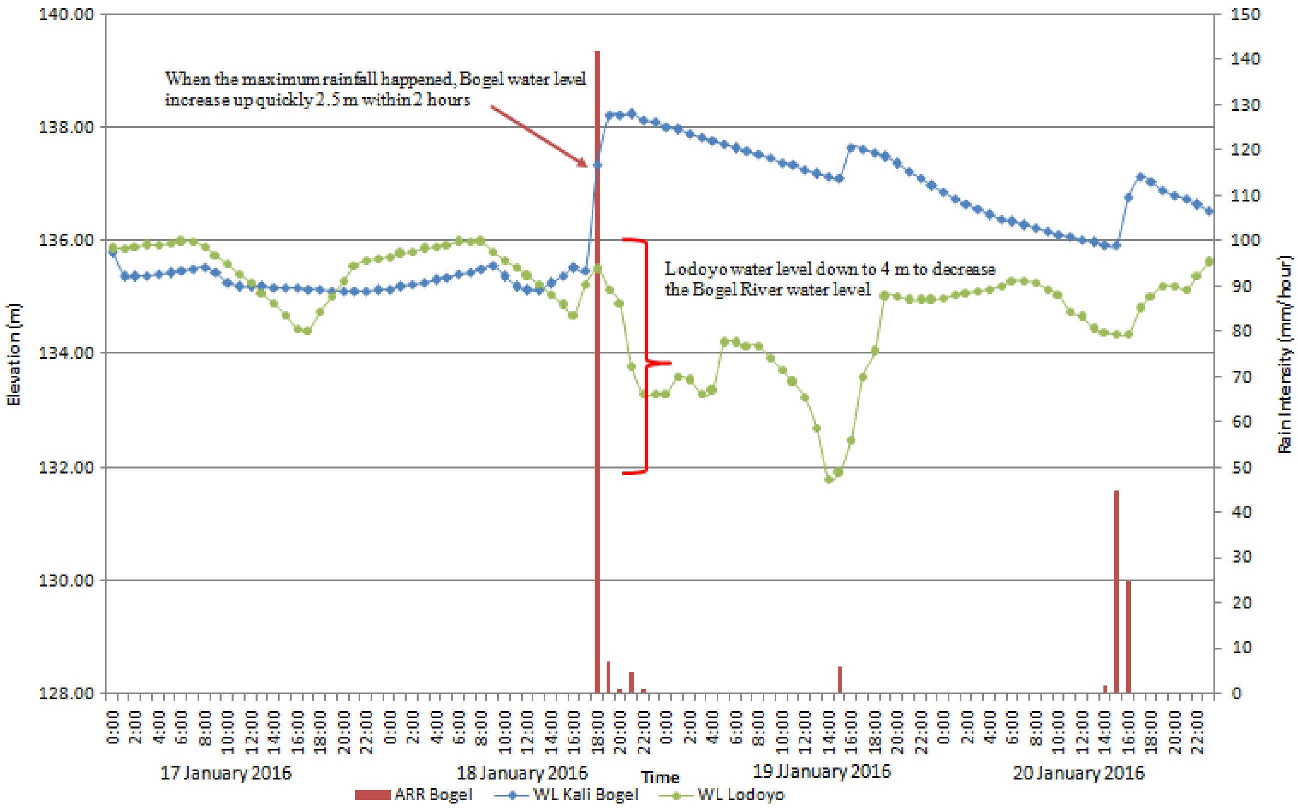

Figure 5. Flood Hydrograph Bogel River, 18 January 2016

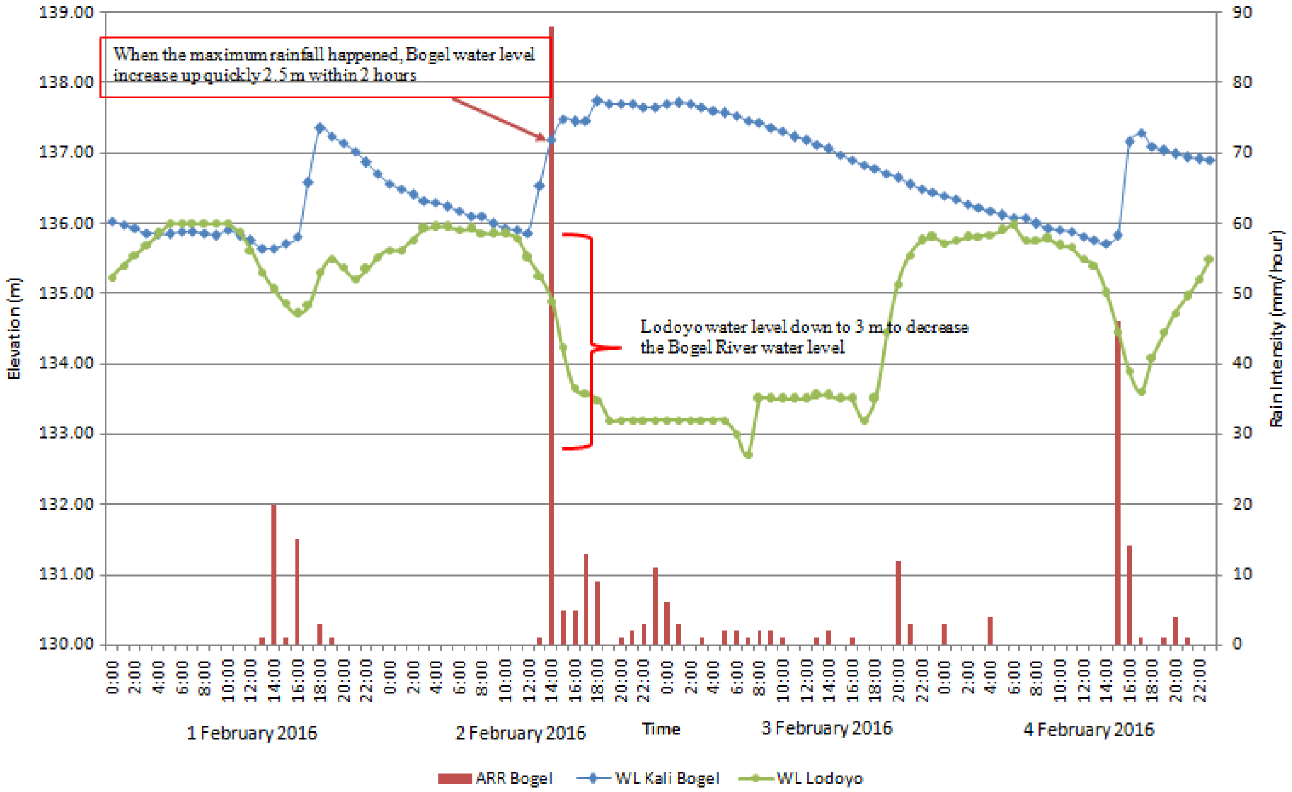

Figure 6. Flood Hydrograph Bogel River, 2 February 2016

The Planning and Solution to Mitigation The Flood Problem of Bogel River

Efforts have been done

1. Jasa Tirta I Public Corporation has doing Bogel River Dredging Works in 2005-2006 by self-managed as follows:
   a. In 2005 : dredging volume 3,828 m3
   b. In 2006, Period 1 : dredging volume 25.000 m3
   c. In 2006, Period 2 : dredging volume 3.925 m3

   The total length of the river was dredged from Kedung Bunder Bridge-Bacem Bridge 3600 m
2. Drain Oulet Construction Unut - Bogel River in 2005
3. Doing the emergency repair in several times

Efforts to be Proposed

1. Preparation of a comprehensive study of Bogel River flood
2. Short Term Action in 2016
   a. Emergency repair of Kedungunut river embankment
   b. Normalization Bogel River start from Gondanglegi Dam until Lodoyo Channel
   c. Periodically doing the normalization in river upstream :
      - Kedungpuring River, Margomulyo as long as ± 2 km
      - Kedungunut River, Bacem as long as ± 2 km
      - Pijeran River, Pandanarum as long as ± 3 km
      - Kedungriwuk River, Bacem as long as ± 2 km
   d. Repair of drainage channels in the township
   e. Overcome the domestic waste Sutojayan which often cause blocking under the bridge.
3. Middle Term-Long Term Action
   a. To evaluate the function and proposed irrigation dam on the upstream dam to be functioned as long storage.
   b. Make ponds / retarding basin for the water parking and the water storage tank for the community, because Bogel River is a perennial river / seasonal which is there are some water during the rainy season and dry during the dry season.
   c. Implement conservation in the upstream of the catchment area to reduce the run-off and erosion.
   d. Make short cut Bogel River to the downstream of Lodoyo weir (must be studied further).
4. Completing the hydrological observations station on the Bogel watershed
   a. Increasing the number of AWLR stations in the Bogel watershed
   b. Increasing the number of ARR stations in the upper of Bogel River, such as in the Mountains Kendeng
   c. Completion of the Early Warning System, which has been pioneered by Jasa Tirta I Public Corporation to be integrated with other agencies

CONCLUSION AND RECOMMENDATION

Conclusion

1. Jasa Tirta I Public Corporation doing the direct controlling by operating the Lodoyo weir according to Dam Operational Guidelines, Procedures and Work Instructions of Flood Control
2. By this integrated flood mitigation concepts in Bogel River will completing the efforts that have been done by Jasa Tirta I Public Corporation, directly and emergency action by participation from all stakeholders according to the authority.
3. By normalitation of the condition and function of the existing water resources infrastructure, the flood control system can be implemented optimally. Of course, the real efforts can be realized so as to built the preparedness for possible flood and reduce the impact that especially for regions and communities in the district Sutojayan, Blitar. It is also become the responsibility of Jasa Tirta I Public Corporation in water resources integrated management.

Recommendation

Need to do a more study on the conservation action in Bogel watershed so that the management could be done more effectively and efficiently.
Socialization needs to be done at each stage of implementation and involve the community participation

ACKNOWLEDGEMENTS

The authors thank to Jasa Tirta I Public Corporation, the River Basin Organization in Brantas, Bengawan Solo, Jratunseluna, Serayu Bogowonto and Toba Asahan River basins in Indonesia for providing data used in this paper.

ABSTRACT

Sengguruh dam located in Brantas River watershed, East Java, Indonesia was completed in 1988. The objectives is for generating hydroelectric power plant with installed capacity 2 x 14,5 mW produce of 91 million kWH per year. Located at uppermost of the series dams in Brantas River Basin and therefore is utmost suffered of sedimentation. Also, it prevents sediment comes to the Sutami which is the biggest reservoir at down stream part. The inflow come from two main rivers, namely Brantas River and Lesti River has a catchment area of 1.659 km^2. The condition currently declining due to the high rate of sedimentation. Based on the echosounding result conducted in 2016, is known that effective capacity has been reduced to 0,6 million m^3, or approximately 24% of the initial conditions of 2,5 million m^3 and electric generation has been reduced to 68,8 x 10^6 kWH. The dredging activity has been done routine every year from year of 2001 with an average dredging volume of 300,000 m^3/year. Total achievement of the volume of dredging result seems large, but it is not adequate. Based on the present evaluation, particularly in the zone at front of hydropower intake (namely zone 1), was in fact already quite critical because the sediment is getting closer. The zone distance is about 100-200 m with the difference elevation from sediment surface reaching 7-12 m above desired reference base elevations. On contrary, the dredging has been done in the upstream area which is quite far away $\pm$ 1,500-2,000 m from zone 1 due to get close of spoilbank location. In order to sort out the problem and to support President Joko Widodo's Government policy in energy security, the dredging method in 2016 was changed. The innovation and development of methods to improve its effectiveness are (a) with the combination of 2 dredging types using available dredgers and additional heavy equipment (amphibious excavators) to take out sediment which located at positions could not be done by dredgers (dry-wet excavation), (b) installation of booster pump and floating pipe as support of the dredgers, (c) modification of dredger ladder, (d) management of spoilbank by re-arrange of hauling and reloading cycles, and accelerate sediment material drying by installing vertical-horizontal drainage. By these methods the dredging of sediment can be implemented more effectively and efficiently to ensure high hydropower production, maintain effective storage capacity and prolong age of reservoir with of course considering environmental aspect around the area.

Keywords : dredging, sedimentation, hydropower productivity, Sengguruh Dam

1. INTRODUCTION

Sustainability of the function and lifetime of reservoirs in the world is increasingly threatened today due to the high rate of sedimentation. The conditions of the upstream area which are deteriorating due to devastated watershed and improper land management and ignoring the good aspects of soil and water conservation, has led to increased soil erosion and the rate of sedimentation in the reservoir, thus diminishing the volume of the storage reservoir. The sedimentation of reservoirs in Indonesia today is one of the issues to be a priority in efforts to handle by the government era of President Joko Widodo towards water, food and energy securities.

Management of reservoir sedimentation have a variety of alternative efforts such as: a) an effort to minimize the rate of sediment entering the reservoir through watershed management (conservation, regulation of land use, etc.), and control of sediment into the reservoir with the technical construction in the river (check dams, gully plug, etc.), b) minimize the deposition of sediments in the reservoir by sluicing sediment and venting turbidity density current, and c) remove sediments from reservoirs through flushing and dredging.

Reservoir dredging work is done in many countries like the USA, France, Austria, Switzerland, South Africa, Japan, China, and others. In China, the reservoir dredging routinely performed in many reservoirs such as in the Guanting Reservoir (Yang et al, 2003). In general, the dredging of reservoirs is an expensive effort in order to maintain and restore the reservoir storage capacity, and only considered if the implementation of other alternative measures are not possible or difficult to implement. Dredging the reservoir is limited to removal of sediment that accumulates in front of the intake or for the recovery of the small storage reservoirs (Basson & Rooseboom, 1999). Morris and Fan (1998) give consideration to dredging the reservoir includes four (4) basic components: 1) the sediment that will be dredged (location dredging), 2) dredging equipment, 3) equipment for deliver the dredging materials (eg. pipe for dredging hydraulically, and 4) dredged material disposal site (riverine disposal into the river below the dam or off-stream disposal/spoil bank).

Sengguruh dam located in Brantas River watershed, East Java, Indonesia was completed in 1988. The location of Sengguruh dam is shown in Figure 1. Sengguruh dam is one of the oldest dams were constructed in accordance with the Brantas River Basin Master Plan for Water Resources Development of the Brantas River Region. The objectives is for generating hydroelectric power plant with installed capacity 2 x 14,5 mW produce of 91 million kWH per year.

Figure 1. Location map of Sengguruh dam

Carte de localisation du barrage de Sengguruh

Located at uppermost of the series dams in Brantas River Basin and therefore is utmost suffered of sedimentation. On the other hands, it prevents sediment comes to the Sutami which is the biggest reservoir and located at down stream part. The inflow come from two main rivers, namely Brantas River and Lesti River has a catchment area of 1.659 km2. Condition and sustainability functions of the reservoir currently declining due to the high rate of sedimentation. Based on the echosounding result conducted in 2016, is known that effective capacity has been reduced to 0,6 million m3, or approximately 24% of the initial conditions of 2,5 million m3 and electric generation has been reduced to 68,8 x 10^6 kWH.

2. METHODOLOGY

Discussion in this paper generally consists of two subjects. The first part discusses the problem of sedimentation in Sengguruh reservoir. The study on sedimentation in Sengguruh reservoir is done by studying the secondary data available, the results of previous studies, collecting and analysis of primary data in the field. The second section discusses the work of sediment dredging in Sengguruh reservoir by explain the current method and development planning to get the best method to doing the dredging operation, there are (a) with the combination of 2 (two) dredging types using available dredgers and additional heavy equipment (amphibious excavators) to take out sediment bank which has become solid and located at positions could not be done by dredgers (dry-wet excavation), (b) installation of booster pump and floating pipe as support of the dredgers, (c) modification of dredger ladder to increase the range of dredger, and (d) management of spoilbank by re-arrange of hauling and reloading cycles, accelerate sediment material drying by installing vertical-horizontal drainage and increase spoilbank capacity. The second discussion includes planning and application method of the dredging work through field studies conducted in Sengguruh reservoir which is conducted at this time.

3. RESULT ANALYSIS AND DISCUSSION

3.1. SEDIMENTATION OF SENGGURUH RESERVOIR

From the results of sediment testing on the soil laboratory in Perum Jasa Tirta 1 there are 6 types of sediment in Sengguruh Reservoir namely loam, silt, silt loam, sand, sandy loam, and loamy sand. Sediment of silt loam type is the most sediment type found in Sengguruh Reservoir

Group	Type	Information
A	[C]	**Clay**
B	[SaC]	**Sandy Clay**
C	[SiC]	**Silty Clay**
D	[SaCL]	**Sandy Clay Loam**
E	[CL]	**Clay Loam**

3.2. DREDGING WORK ON CURRENT CONDITION

Some control efforts have been made actually, both in stream or off stream, one of them is by sediment dredging. This dredging activity has been done routine every year from year of 2001 with an average dredging volume of 300,000 m3 / year using 2 (units) cutter suction dredger. The location of sediment disposal area (spoilbank) spread out around the reservoir, meanwhile available spoilbank is very limited and provides the new one is very costly. the dredging has been done in the upstream area which is quite far away + 1,500-2,000 m from hydropower intake due to get close of spoilbank location, to get low fuel consumption, to maximize available dredgers production capacity which has limited operational range (both depth & discharge),and to reduce length of dredging pipelines. Shortly, this condition is not good for keeping high hydropower productivity which affected much of zone 1 condition.

Figure 5. General Plan Dredging Work on Current Condition
Travaux de dragage du plan général sur l'état actuel

3.3. DEVELOPMENT PLANNING OF DREDGING WORK TO RECOVERY HYDROPOWER PRODUCTIVITY

The dredging method in 2016 was changed in order to make the dredging of sediment can be implemented more effectively and efficiently to ensure high hydropower production, maintain effective storage capacity and prolong age of reservoir. The development planning are (a) with the combination of 2 dredging types using available dredgers and additional heavy equipment (amphibious excavators) to take out sediment which located at positions could not be done by dredgers (dry-wet excavation), (b) installation of booster pump and floating pipe as support of the dredgers, (c) modification of dredger ladder, (d) management of spoilbank by re-arrange of hauling and reloading cycles, and accelerate sediment material drying by installing vertical-horizontal drainage.

A. COMBINATION OF 2 DREDGING TYPES USING AVAILABLE DREDGERS AND ADDITIONAL HEAVY EQUIPMENT (AMPHIBIOUS EXCAVATORS)

Seeing the condition of the sediment surface in Sengguruh Dam is not evenly distributed in the entire pool area of the reservoir. In some areas the sediment elevation conditions to the water elevation are shallow enough with a depth of 0.5-1 m whereas deep conditions are found in areas that are the main river channel with a depth of more than 1m. This condition causes the dredger can not reach the shallow areas due to the limited draft of the ship and the minimum reach of the dredger ladder. Overcoming this need to be combined using amphibious excavators because the tool can operate in a wetland area that is not too deep or called dry-wet excavation.

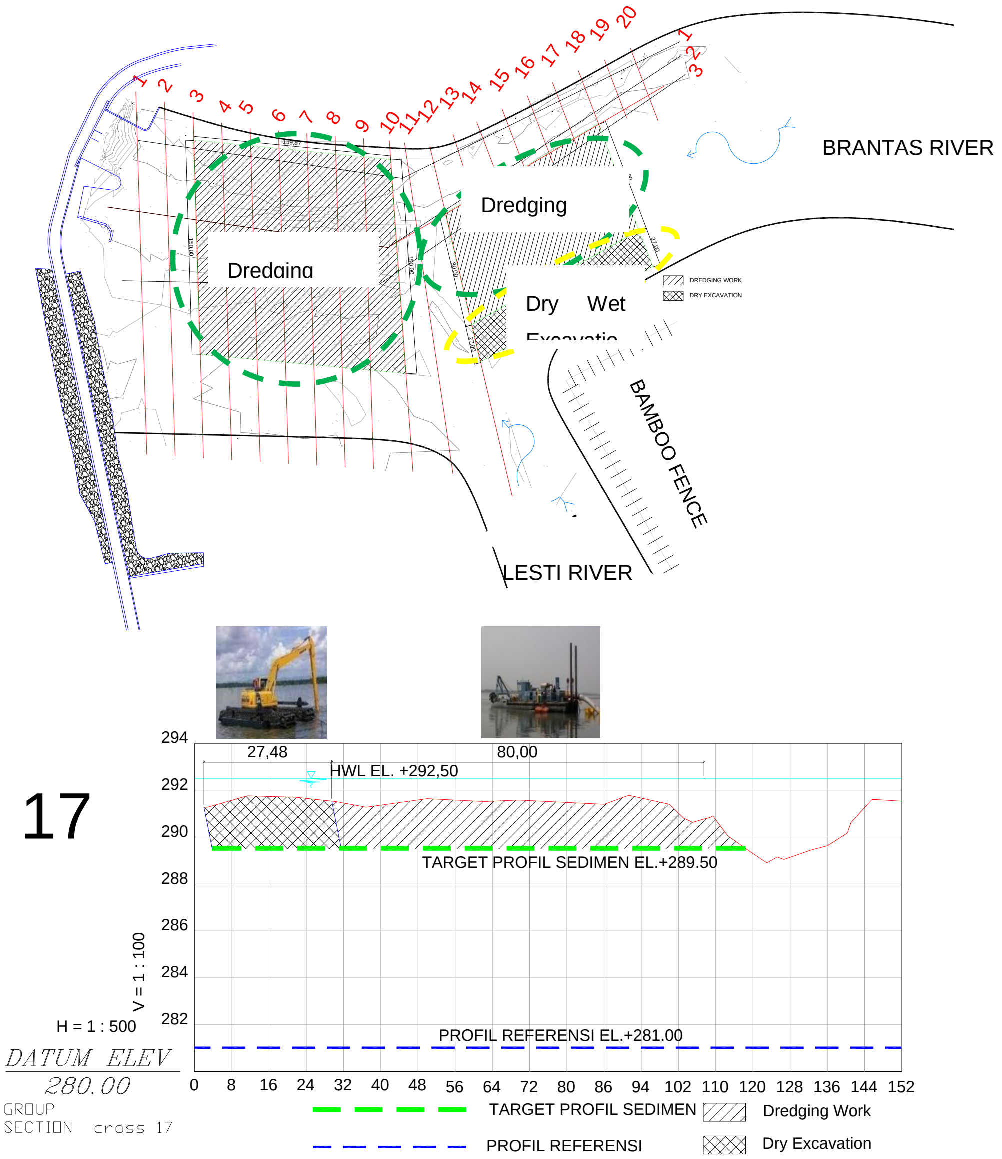

Figure 6. General Plan Dredging Work Combine with Dry Wet Excavation
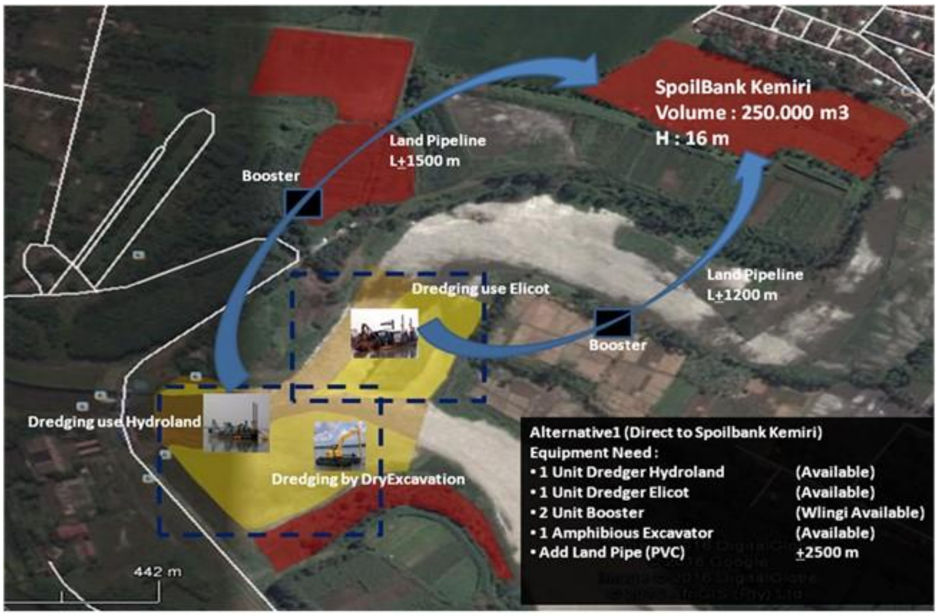
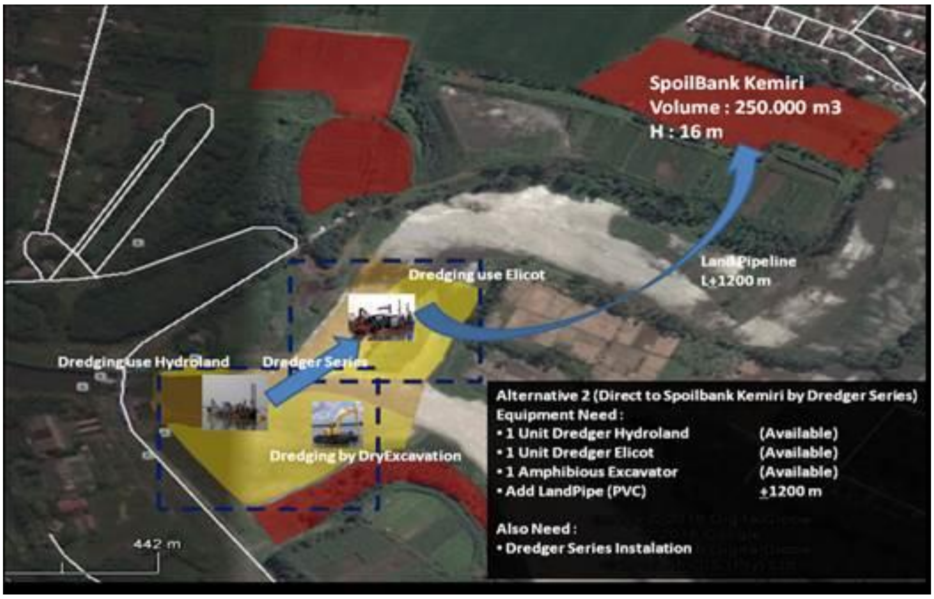
Combinaison du travail de dragage du plan général avec l'excavation humide à sec

B. INSTALLATION OF BOOSTER PUMP AND FLOATING PIPE AS SUPPORT OF THE DREDGERS

This method is used in order to support sediment flow from zone 1 near intake to spoilbank area with distance 1500-2000 m at 18 m height. Specifications of existing dredger with type Hydroland and Ellicot are only able to drain sediment optimally at a distance of $\underline{+}$500 m with a capacity of $\underline{+}$ 70-100 m3 / h, so that additional booster is needed, while the previous pipeline using iron pipe and PVC pipe will be replaced by using HDPE floating pipe to be more efficient because of the cheaper material price than the iron pipe and more flexible by using a combination of rubber pipe.





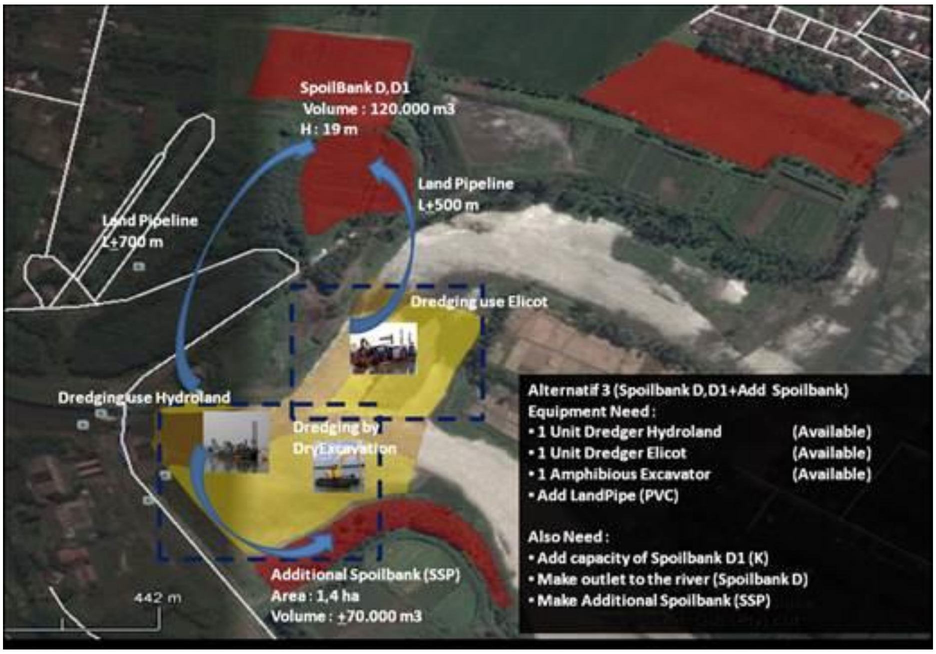


Figure 7. Alternative Scenario of Dredging Work Development Plan in Sengguruh Dam
Scénario alternatif du plan de développement du travail de dragage au barrage de Sengguruh

C. MODIFICATION OF DREDGER LADDER

This is done because the existing dredgers specification is only able to reach the depth of sediment up to $\pm$ 5 m, whereas we know that the thickness of the sediment from the surface to the base has reached more than 12 m so that to improve yield and productivity we make modification efforts by extending ladder dredgers become 10-12 m.

D. MANAGEMENT OF SPOILBANK BY RE-ARRANGE OF HAULING AND RELOADING CYCLES

As we already know that the limited availability of land for spoilbank becomes an obstacle in the effort of managing sediment especially to support sediment dredging efforts, because the guarantee of spoilbank availability as a place for the dump material of the dredged sediments greatly influences the volume or the dredging target.

The current condition of existing spoilbank capacity is able to accommodate sediment up to $\pm$200.000 m3 volume for 1 year period, whereas we have to do annually dredging activities. For that purpose, we made several efforts to maintain the availability of spoilbank by arranging the spoilbank utilization cycle schedule consisting of the hauling schedule (mechanical transfer) and reloading. From the existing spoilbank spoilbank D, D1, and Kemiri we set the maintenance cycle and its use with the aim of all the spoilbank in turn can be used every year.

This arrangement is required because every spoilbank loaded must be dried in advance up to ±2 years to be reload, and to support the spoilbank drying period acceleration we also make efforts to add technology to the spoilbank construction that is complete with horizontal vertical drain so that the water of the sediment material can immediately flow out so that drying can be faster with an estimated time of 1 year faster. In addition we also make efforts on land acquisition in downstream dam to increase the spoilbank area in the area spoilbank Gampingan.

4. CONCLUSION AND RECOMMENDATION

4.1. CONCLUSION

Sedimentation is a problem faced by almost all the reservoirs in the world. High sedimentation rate which would threaten the sustainability of the reservoir function and shorten the useful life of the reservoir. Sengguruh reservoir has lost almost 75% of the effective storage since the dam was completed in 1988. To overcome the problem of sedimentation in Sengguruh reservoir some efforts has been conducted sediment management, consist of conservation in the upstream of Brantas River watershed, construction of sediment controlling infrastructure, and sediment dredging. Non-structural efforts such as empowerment and public education have also been carried out. Dredging work in Sengguruh Dam using the dredger has been conducted since 2001. Starting in 2016 the development of dredging work has been done by (a) combination of 2 dredging types using available dredgers and additional heavy equipment (amphibious excavators) to take out sediment which located at positions could not be done by dredgers (dry-wet excavation), (b) installation of booster pump and floating pipe as support of the dredgers, (c) modification of dredger ladder, (d) management of spoilbank by re-arrange of hauling and reloading cycles, and accelerate sediment material drying by installing vertical-horizontal drainage. This dredging method gives the benefit that the dredging of sediment can be implemented more effectively and efficiently to ensure high hydropower production, maintain effective storage capacity and prolong age of reservoir with of course considering environmental aspect around the area. More importantly, it can be done near the hydropower intake because the sediment is increasingly moving forward to the dam.

4.2. RECOMMENDATION

Need to do a more study on the characteristics and processes of sedimentation in Sengguruh reservoir so that the management of sediment through dredging work could be done more effectively and efficiently. Environmental management need to be studied further to minimize the impact.

5. ACKNOWLEDGEMENTS

The authors thank to Jasa Tirta I Public Corporation, the River Basin Organization in Brantas, Bengawan Solo, Jratunseluna, Serayu Bogowonto and Toba Asahan River basins in Indonesia for providing data used in this paper.

1. INTRODUCTION

As severe global warming climate comes into effect, the occurrence, frequency and intensity of extreme climate events are increasing rapidly since unbalanced precipitation exists in China's Southwest region.In addition,environmental temperature and humidity significantly effect animals and plants, as well as the stability of the geologic structure[1-2].Hydraulic engineering construction plays an important role in water resource allocations,avoiding drought and flood[3-4].However,the reservoirs formed by hydraulic engineering structures may affect air temperature and air humidity by changing different evaporation capacity,which could lead to various changes causing extreme climate or disasters[5-7],such as changes to annual precipitation,annual mean temperature and annual evapotranspiration rate.

Since giant reservoirs could affect local climate over some distance[8-10],many scholars carried out research topics on quantitative and qualitative analysis of reservoir effects.Their research is mainly based on theory analysis,calculation simulation, prediction or site measured data analysis for giant hydropower reservoirs:China Three Gorges reservoir,Ertan reservoir,Danjiangkou reservoir etc.[11-14] The main parameters of annual precipitation and evapotranspiration are different for each location, as the local climate and topography vary.Generally,annual precipitation and annual air temperature increase;annual evapotranspiration rate decreases in summer,but increases in winter in some places.Calculation simulation and experimental research show China Three Gorges reservoir affects air temperature and humidity mainly between 2km upstream and 10km downstream,and nearcirculation could increase air temperature by about 1℃ duringsummer nights, with a 3% humidity difference within10km ofthe Three Gorges reservoir[15-16].

A world-class hydropower station with large reservoir iscurrently being studied by researchers.It has great water storage capacity,and the local climate is quite complex with the influence of Pacific airflow and Indian airflow in southwest China.Because of actual complex situations and operation data limitations,there are no scholars doing related research for reservoir climate changes in southwest China,especially when the giant reservoir is filled.What's more, local climate around the reservoir is quite different pre and post the hydropower station construction, as well as being affected by reservoir water storage,which could be confirmed clearly by observation of vegetation before and after the reservoir water storage(Figure 1).

a.Before water storage　　　b.After water storage

Figure 1. Vegetation before and after the reservoir water storage.

2. PHISICAL MODEL

A representative giant reservoir and its surroundings were extracted from the typical hydropower station model in Southwest China that could clarify the reservoir climate changes clearly and representatively.The dam is a double curvature arch dam within maximum height of 285.5m,and results in 600m normal pool level and 540m dead storage level,which provides 12.8 billion m3 of total reservoir volume and 6.5 billion m3 of regulating storage volume(Figure 2).As the hydropower station operates normally,the reservoir will submerge some county districts of

A(Yongshan County),B (Jinyang) and C County (Leibo) etc., as illustrated in Figure 3.

Water depth in the reservoir rises from B County to A County, when the dam comes into effect to store water,and the water depth next to the dam is deepest.The water surface area and water temperature of the reservoir vary from Spring to Winter for various reservoir water levels.

Figure 2. Giant reservoir of the hydropower station in southwest China

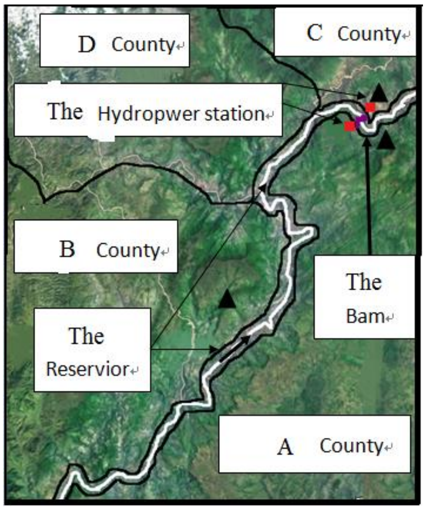

Figure 3. Geographical position of the hydropower station and main reservoir district : ▲stand for measurement points, which could measure air temperature and humidity when reservoir comes into water storage or other conditions

As mentioned in the paper[17],air humidity would be a specific constant value when, air vapor and water surface evaporation are in dynamic equilibrium. In addition,the vapor medium exchange demonstrates that there exists a law of mutual influence between air humidity and both air temperature and reservoir water temperature.Therefore, there would be significant variations in air temperature and air humidity would around the reservoir,since rainfall and water temperature vary seasonally.

In order to study the mechanism of how reservoir water storage change climate,air temperature and humidity measurements in the district of A County and collection of climate data around the reservoir were promoted carefully in the past six years.The research mainly concentrated on topics of climate changes pre (2011-2013) and post (2013-2016) the reservoir construction, comparative study on water storage rate and air temperature,humidity, etc.Quantitative and qualitative analysis results of the giant reservoir could form laws,which are beneficial to hydropower station design,local vegetation and residents,avoiding extreme disasters in the region.

3. THEORY ANALYSIS

Heat and moisture transfer occurs between the air and the reservoir water surface, according to equation (1).When there is a temperature difference at the reservoir water surface,sensible heat,latent heat and moisture would transfer continuously to approach the equilibrium state[18].

$$E = S\left[6.1\exp\left(\frac{L}{273R_v} * \frac{t}{273+t}\right) - \rho_v R_v (273 + T)\right] \quad (1)$$

Where E represents evaporation capacity of reservoir water surface(Kg).It is determined by surface areas S(m2) and moisture difference value between air moisture concentration and saturated concentration,L for latent heat of water evaporation(KJ/Kg),Rv for specific gas constant of water and vapor,t for reservoir surface water temperature(K),T for air temperature(K) and rvfor density of water vapor(Kg/m3).

The air boundary layer transfers sensible heat to the reservoir water surface, when the air temperature of the boundary layer is higher than that of the water surface,and water vapor transfers from the reservoir water surface to the air boundary layer,if its molecular solubility does not reach the saturated solubility of air vapor.Thus,heat and moisture transfer mainly depends on the temperature difference and moisture solubility of the air boundary layer,and the macroscopic computational complexity of the process could be solved by followed equation (2).

$$PE = \frac{0.408\Delta(R_n - G) + \gamma\frac{900}{T_a+273}u_2(e_s - e_a)}{\Delta + \gamma(1+0.34u_2)} \quad (2)$$

Where PE represents possible evaporation amount(mm/d),Rn for surface net radiation[MJ/(m*d)],G for soil heat flux[MJ/(m*d)],Ta for daily mean temperature(K), u2 for wind velocity at 2m height(m/s),es for saturated vapor pressure(kPa),ea for actual vapor pressure (kPa),Δfor curve slope of saturated vapor pressure(kPa/℃),γfor psychrometric constant (kPa/℃).

Taking everything into account,air temperature and moisture are affected by heat and mass transfer between the air boundary layer and the reservoir water surface,especially during the water storage period the contact area.Based on the above theory analysis,research on climate changes firstly collected related annual and monthly climate dataand calculated correlation between climatic elements and time sequences to summarize climate tendency at different times.In order to test the significance of important parameters, the t testing method was taken to verify the average difference of climate elements, pre and post reservoir water storage,and the F testing method was for evaluating the influence of climate change in the above process.

4. THEORY ANALYSIS

Climate changes were analyzed in representative counties around the reservoir. A County was selected for climate trend analysis close to the reservoir, as well as the dam (about 3km from the weather station),B County for the reservoir upstream(about 7km from the weather station). Additionally,A County was also analyzed for the effects of water storage,since it is largely affected by the reservoir.Air temperature, humidity and precipitation were studied comprehensively concerning climate changes, from 1st January 2011 to 31stDecember 2016. To distinguish the trends of climate change, periods of air temperature and air humidity were analysed as follows:1st December to 28th February,1st March to 31stMay,1st June to 31stAugust, 1st September to 30th November, being winter,spring,summer and autumn respectively, and the main flood season was taken as1stMay to 30th September.

4.1. CLIMATE CHANGES IN A COUNTY

As shown in Figure 4, the air temperature of A County displays some differences before and after water storage, especially in the winter and summer seasons. Compared to the air temperature before water storage, the air temperature after water storage has little temperature difference, which is concentrated between8.4 ℃ and25.2 ℃.The maximum temperature difference is 7℃ higher thanthe previous record in winter. What's more, air temperature is essentially the same in the spring and autumn seasons.

Due to the huge specific heat capacity of water,large temperature differences result in summer and winter after water storage.Reservoir water releases heat to the air,causing higher air temperatures than beforeand vice versa in summer.Air temperature keeps consistent in spring and autumn, since there are no large temperature changes and little heat transfer between air and water.Therefore,there exists a more suitable environmental for people to live and plants to grow.

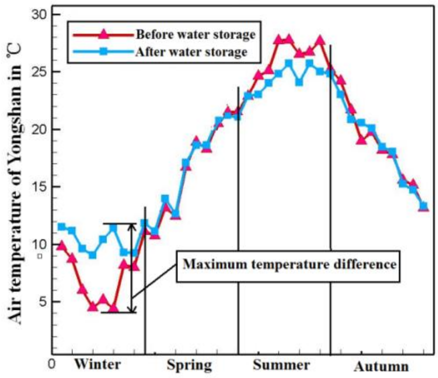

Figure 4. Air temperature comparison of A County pre and post water storage of the reservoir

Figure 5 shows that air humidity in A County rises greatly after water storage. In total, the maximum humidity difference is 25% in spring. Increases in both the evaporation area of the reservoir water surface and the environmental temperature are the main reasons for air humidity increasing. In contrast with other seasons, the air humidity in summer shows little increasebecause of the high humidity and temperatures in this season,when it is difficult to break air vapor balance.

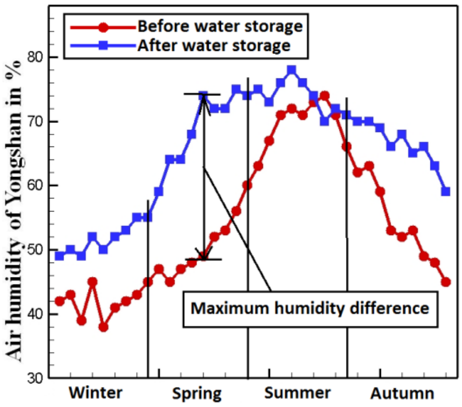

Figure 5. Air humidity comparison of A County pre and post water storage of the reservoir

Precipitation of A County is mainly concentrated between the months of May and September, which have 78% of annual precipitation.As illustrated by the air humidity analysis in Figure 6,air humidity is relatively higher in late spring, summer and early autumn,and could be beneficial in the vapor condensation process.Monthly mean precipitation is above 120mm between June to August,so potential flood disasters should be considered due to extreme weather events.

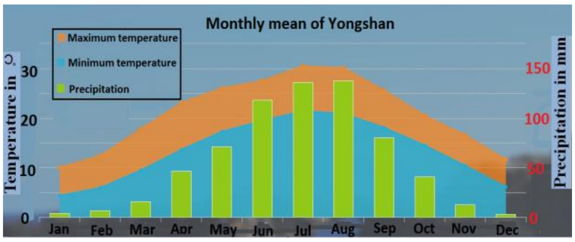

Figure 6. Monthly mean temperature and precipitation of A County after water storage

After water storage in the reservoir,precipitation of A County increases during all seasons, including during the flood season(Figure 7).Annual precipitation increases nearly 70% than the previously.However, precipitation in winter and spring is often scarce for human consumption and agricultural production,so the reservoir could provide a water source for these.

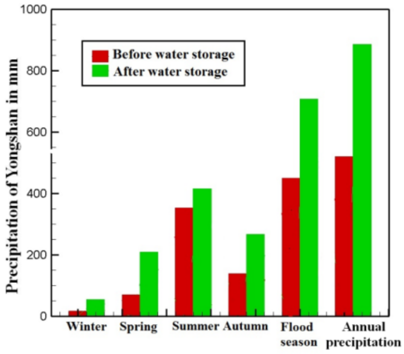

Figure 7. Precipitation comparison of A County pre and post water storage of the reservoir

4.2. Climate changes in B County

As shown in Figure 8,air temperature of B County has the same change trend asA County pre and post the water storage of the reservoir,but within smaller changes.For example, maximum temperature difference of B County is 3.8℃ in summer,and A County is 7℃ in winter.This is because temperature of B County is higher than A County in summer,and the reservoir has less effect on B County air temperature.

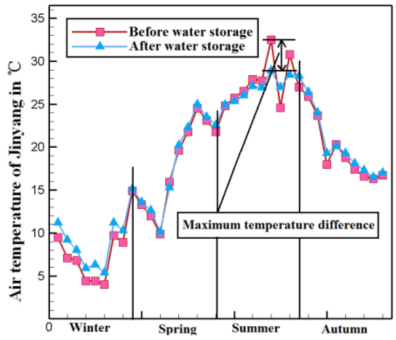

Figure 8. Air temperature comparison of B County pre and post water storage of the reservoir

Figure 9 demonstrates that the air humidity of B County is less affected than for A County. The maximum humidity difference of B County is 18% in springcompared to 25% for A County.Their maximum humidity differences are all in spring, since air temperature in springkeeps median values,with almost the same evaporation.

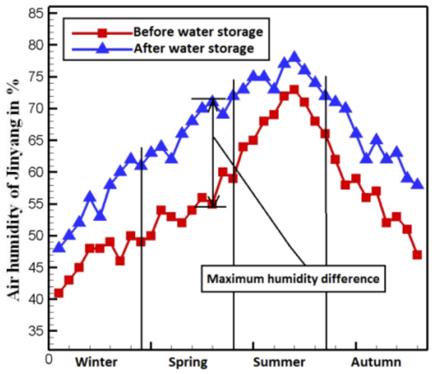

Figure 9. Air humidity comparison of B County pre and post water storage of the reservoir

Precipitation of B County again increases in all seasons, with annual precipitation increases just 31%.Compared to A County,B County has less specific heat capacity of water,lower temperature adjustment and air humidity at a farther distance from the dam.

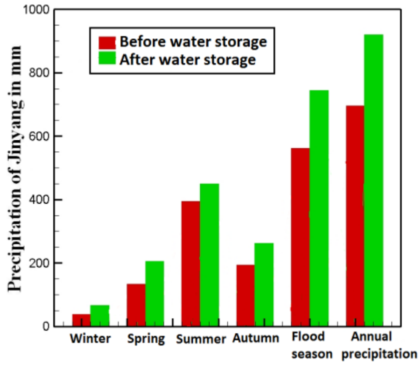

Figure 10. Precipitation comparison of B County pre and post water storage of the reservoir.

SUMMARY

1.Air temperature of A County and B County display some differences pre and post water storage,especially in the winter and summer seasons,with the maximum temperature differencesbeing7℃ and 3.8℃ respectively.After water storage in the reservoir,air temperature is more stable than previously. In addition, air temperature effects depend on the distance from the dam to the data measuring points and are more obvious at closer locations.

2.After water storage in the reservoir,air humidity increases largely in the seasons of winter,spring and autumn, with little rise in summer.Air humidity of A County behave similarly to B County,but the former is more obviously affected than the latter.The maximum air humidity differences are 25% and 18% respectively.

3.Precipitation of A County and B County increase all year round, as well as during the flood season.Annual increases in precipitation are 70% and 31 % respectively,and the main precipitation is concentrated during the flood season,which warns that human beings should expect extreme weather events and potential flood disasters in this period.

4.Water storage in the reservoir could increase the specific heat capacity of the water volume and affect air temperature and humidity by the evaporation-condensation process.Air temperature is quite an important factor regarding air humidity, as the transfer of humidity to precipitation is the reason why annual precipitation is mainly concentrated during the flood season, with the need to prevent flood disasters during this period.

RUNOFF AND SEDIMENT TRANSPORTATION IN UPPER AND MIDDLE REACHES OF JINSHA RIVER

Yan XIA, Zhou YINJUN, Jin ZHONGWU

CHANGJIANG RIVER SCIENTIFIC RESEARCH INSTITUTE, WUHAN

CHINA

EXTENDED ABSTRACT

Jinsha river is the lower stretch of the source region of the Yangtze river, whose runoff mostly delay on the melting of glaciers, and is greatly affected by climate change. Otherwise the hydropower resources is rich in Jinsha basin, and since the Jin Anqiao Hydropower Station has been built in December 2010, several reservoirs have impounded successively. A reservoir group has been formed in middle reach of Jinsha river basin, which plays a huge role in intercepting sediment.

Through statistical analysis of water and sediment data of Zhimenda, Shigu and Panzhihua hydrologic stations in the upper and middle reach of Jinsha river basin, this paper presents the sediment transport characteristics of the reach, including the sediment sources and distribution, the annual variation and annual distribution of sediment load. Then, the method of multiple regression analysis was used to evaluate the sediment trap amount of the reservoir group in the middle stretch.

The calculated results showed that, during year 2001 to 2016, the annual average runoff amount of the Zhimenda station has increased about 24.24% than that of year 1957 to 2000, but the runoff of Shigu and Panzhihua stations haven't changed much. Compared to the annual average sediment discharge of year before 2000, during year 2001 to 2010, the three stations have increased 6.97%, 28.94%,4.75%,respectively; during year 2011 to 2016, the Zhimenda and Shigu station both increased about 11%, however, the Panzhihua Station decreased

about 88.21%. The sediment trap amount of the reservoir group in the middle reach of Jinsha river is about 2.08×108t during year 2011 to 2016.

1. INTRODUCTION

The Lancang - Mekong River, originating from the Tanggula Mountains in Qinghai-Tibet Plateau of China, flows from north to south successively across Qinghai, Tibet and Yunnan in China, and then Myanmar, Thailand, Laos, Cambodia and Vietnam. It empties into the South China Sea to the west of Ho Chi Minh City of Vietnam. The Lancang River has a river length of 2100km, and a drainage area of 17.4×10^4km^2. 23 cascade hydropower plants have been planned with a total installed capacity of about 32 million kWh. At present, six cascade power plants have been built on mainstream of the middle and lower reaches of the Lancang River, which are successively downstream Gongguoqiao, Xiaowan, Manwan, Dachaoshan, Nuozhadu and Jinghong. And now the Lancang River is the only north-to-south cross-country river that has been totally developed in China. Changes in hydrology and the ecological environment of an international river due to the hydropower development are now drawing more and more attention internationally. One major problem is the sedimentation caused by dams, which have influences not only on the reservoir operation， but also on the migration and transformation of the biogenic substance including carbon and phosphorus in the river. For this reason, it is very important to study the sedimentation problem of the Lancang River due to damming, evaluate and predict the problem scientifically and provide a theoretical foundation and data support for studying the reservoir operation and the ecological environment

---

changes in the transboundary river.

The Manwan HPP is the most typical case of reservoir sedimentation problems of the Lancang River. Its construction was started in 1986 and put into operation in 1993. As the first hydropower plant on the main stream of the Lancang River, it has accumulated lots of measured data on sedimentation over the years. The Manwan HPP stands on the middle reach of the Lancang River, the backwater of which reaches the Xiaowan HPP, and it neighbors the Dachaoshan HPP downstream. Its dam is a concrete gravity dam with a crest length of 418m and a maximum dam height of 132m as well as a crest elevation of 1002.0m. Its normal water level is 994m, total capacity of reservoir is 920 million m^3, dead storage capacity is 663 million m^3, and the regulating storage capacity is 257 million m^3. It is a seasonally regulating reservoir. The annual mean sediment runoff is about 40 million tons, the measured maximum sediment charge is 14.3kg/m^3, and the mean sediment charge is 1kg/m^3.

The limiting level during the flood season (June - September) for desilting was set for the Xiaowan HPP before it was put into operation, which was 988m. When the Xiaowan HPP was put into operation, the Manwan HPP's operating water level for desilting during the flood season was deactivated. Within 20 years after the Manwan HPP was put into operation, the reservoir was mainly operated in the method of "storing clear and releasing muddy", where the operating water level was lowered prior to and after the flood season every year and the sediment was flushed through the special holes at the bottom of the right and left banks to effectively clear away the mud at the water intake and reduce the regulating capacity loss. In 2010, after the operation commencement of the Xiaowan HPP, its regulating ability as the leading reservoir began to function. To fully exert the power generation capacity of the hydropower plants, the Manwan HPP has been operating at a high water level all year round since then. The change in the operation mode has led to the change in sedimentation in the reservoir.

2. SURVEY OF SEDIMENTATION IN THE MANWAN RESERVOIR

2.1. UNDERWATER TOPOGRAPHIC SURVEY PLAN FOR THE MANWAN RESERVOIR

According to the current situation and characteristics of the reservoir area of the Manwan HPP, the following underwater topographic survey plan shall be implemented: A multi-beam sounding system shall be used to collect the cloud data of underwater high-density points, which consists of a SONIC 2024 high-performance multi-beam sounding instrument from R2Sonic Company of America, Octans fibre-optical rhumbs from France and a Trimble R7 GNSS receiver from America; GPS-RTK real-time positioning technology shall be used for the underwater data collection with the assistance of Hi Target HD27 single beam echo sounder in the shallow area and the total station and the digital echo sounder shall be used for the data collection where GPS signal is unavailable; For topographic survey on the shore, GPS-RTK shall be the main collecting mode while using the total station as assistance.

Within 2km of the section in front of dam, the survey shall be carried out as per the scale of 1:200 and the reservoir area as per 1:2000.

2.2. CROSS SECTION SURVEY OF RIVERS IN THE RESERVOIR AREA

The latest survey in 2014 covered 72 cross sections of main stream (Fig.1), which were numbered LM09 - LM73, and 8 tributary stream sections of the Gonglang River, numbered LMG01 - LMG04, so the total number were 80 (of which, the A water gauge, B water gauge, lower water gauge and LM73-1 - LM76 for a total of 7 sections were within the warning line of the Xiaowan HPP and were not included in the survey). GPS-RTK real-time dynamic positioning technology shall be used for the layout detection of each end point of the cross section. If the horizontal positioning accuracy is within 3cm and the elevation accuracy is within 3cm, it can be concluded that the end points of the cross section are relatively steady.

(1) Two underwater survey plans shall be prepared for cross section survey: First, use the GPS RTK real-time dynamic positioning technology assisted by the multi-beam sounding system for automatic survey, where the point cloud data of the underwater area scanned by the multi-beam sounding system shall be outputted and the underwater topographic points of the cross section line shall be worked out; Second, use the GPS RTK real-time dynamic positioning technology assisted by the HD27 single beam echo sounder for automatic survey and data collection in addition to collecting plane and 3D data of the measuring points.

A total station or GPS RTK shall be used to record the plane and elevation data of measuring points for the on-shore part of the cross sections.

(2) Before the survey, GPS RTK shall be checked with two or more known points which shall not be put into use before qualification. The measured values are all fixed solutions and information from more than 5 satellites shall be received.

(3) The data collection of measurement points by GPS RTK with the assistant HD27 shall be carried out at the space of 3m. The water depth shall also be collected simultaneously and the navigation procedure shall be activated to follow the cross section reference line.

(4) The allowable control accuracy of the horizontal measuring points shall not be greater than 0.5m away from the cross section lines.

(5) The elevations of the two reference points via the cross section regulation are the same and the calculated distance of the two end points is equal to the accumulated distance of the cross section.

(6) The remark column of the survey results of the cross sections shall indicate the properties of each measuring point (e.g. paddy field, dry land, land type, steep canker, cliff, highway, village, water edge, underwater).

2.3. LONGITUDINAL SECTION SURVEY OF RIVERS IN THE RESERVOIR AREA

Two methods shall be used for the longitudinal section survey of rivers in the reservoir area: First, the polar coordinate method; Second, GPS RTK real-time dynamic positioning method. The GPS RTK real-time dynamic positioning is the major method to be adopted with the polar coordinate method as the supplementary means. All the waterpoints within the reservoir area shall be surveyed in addition to the important feature points on land for data collection at a space of 20m. The main technical requirements for the survey operation are as follows:

(1) Survey Scale: 1:2000.

(2) Survey Coverage: From the Manwan HPP dam site to the warning line of the Xiaowan HPP (from the dam site to LM73), including a main-stream river length of 58km and a branch river length of 3km.

(3) Characteristic positions, such as cross sections, bridges, hydropower plants, tributary inlets, water gauges, and the flow gauging cable way of the hydrometrical station shall be provided with the measuring points and labeled with names. The measuring points shall be densified at the river sections with rapids, drops, river bends and branching based on the principle of controlling the longitudinal change of the river.

(4) The measuring point shall be indicated where it is at a place with a characteristic topography or ground feature. For example, villages, bridges, tributaries (gullies) inlets (left and right banks), rapids, drops, river bends, beaches, and the hydropower plants. Also, the elevations of the characteristic places like the bridge decks and hydropower plants (plant floor, tail water) shall be indicated.

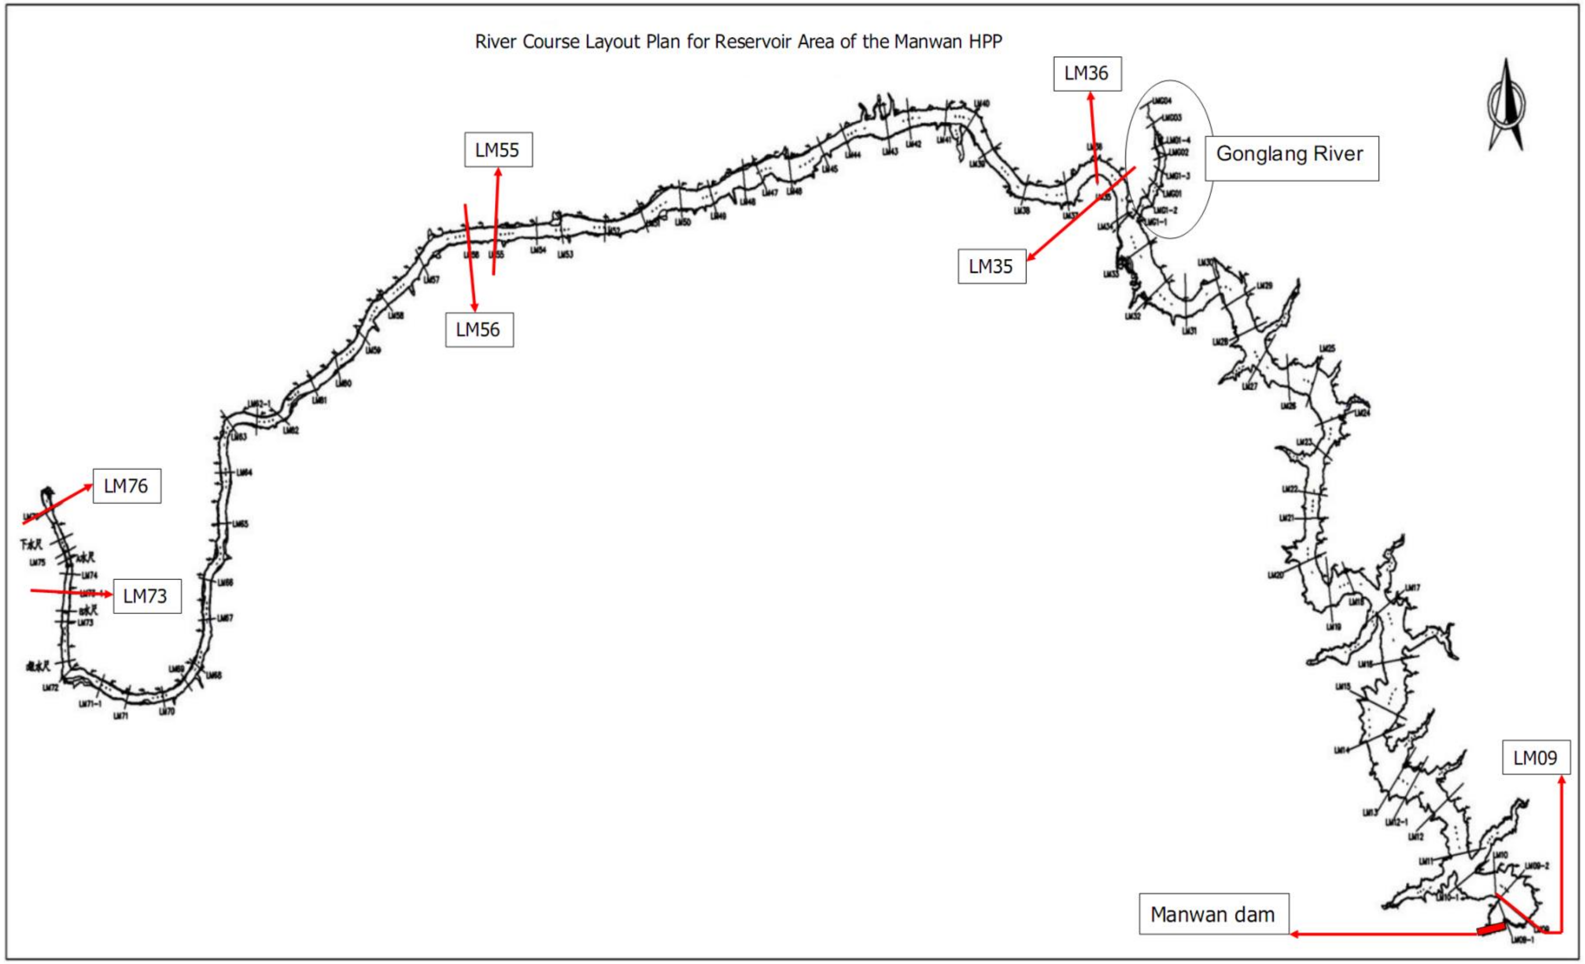

Fig. 1
River Course Layout Plan for Reservoir Area of the Manwan HPP

3. ANALYSIS OF SEDIMENTATION IN THE MANWAN RESERVOIR

3.1. THE SEDIMENTATION FORM OF THE RESERVOIR

The sedimentation analysis shall be based on the section drawings based on the data collected during the surveys in 2005, 2009 and 2014, as shown below:

(1) Fig. 2 is the Main-Stream Talweg Longitudinal Section of the Reservoir, which shows that the sedimentation takes on an obvious delta deposit form, with a front slope gradient of about 2.6‰ and a top slope gradient of about 0.20‰. The sedimentation surface of the delta has been raised year by year and pushed forward to the dam. The head of the delta is about 16.9km from the dam, and the top elevation of the delta is about 983.34m, trending basically the same as in 2009. The reservoir has not reached the balance between scouring and silting.

(2) The Xiaowan HPP was impounded in 2009, thus, based on the relevant data, the yearly average sediment volume to be retained of the Xiaowan Reservoir is 48 million tons (about 32million m^3) above the dam site, which greatly relieved the sediment problem of the Manwan HPP. In terms of the lateral distribution of sedimentation of the reservoir, compared with the results in 2009, the sedimentation volume for the whole reservoir is relatively small, the sedimentation volume in the section in front of dam (dam - LM35 section) is more than the back section, with the average sedimentation height of 1.2m and the highest sedimentation height of 6.1m; The sedimentation volume in the section in the middle of the reservoir (LM36 - LM55) is relatively small with the average sedimentation height of 0.5m; The section at the end of the reservoir (LM56 - LM73) generally shows the scouring, which mainly occurred on both sides of the reservoir; For the section conditions, the section in front of the dam (LM09 - LM35) basically shows the horizontal sedimentation, and the section in the middle of the reservoir mainly shows the balance between scouring and silting, the sedimentation volume in the section at the end of reservoir is quite small, and the section near the Xiaowan dam site shows the scouring on both sides.

(3) There are few tributaries in the Manwan Reservoir area, and there is only one bigger tributary – the Gonglang River in the reservoir area. The distance from the mouth of the tributary to the Manwan dam site is about 21km. The upstream area basically shows the scouring, while the scouring volume is quite small. And, as per the scouring sedimentation volume, the Gonglang River has basically reached the balance between the scouring and silting.

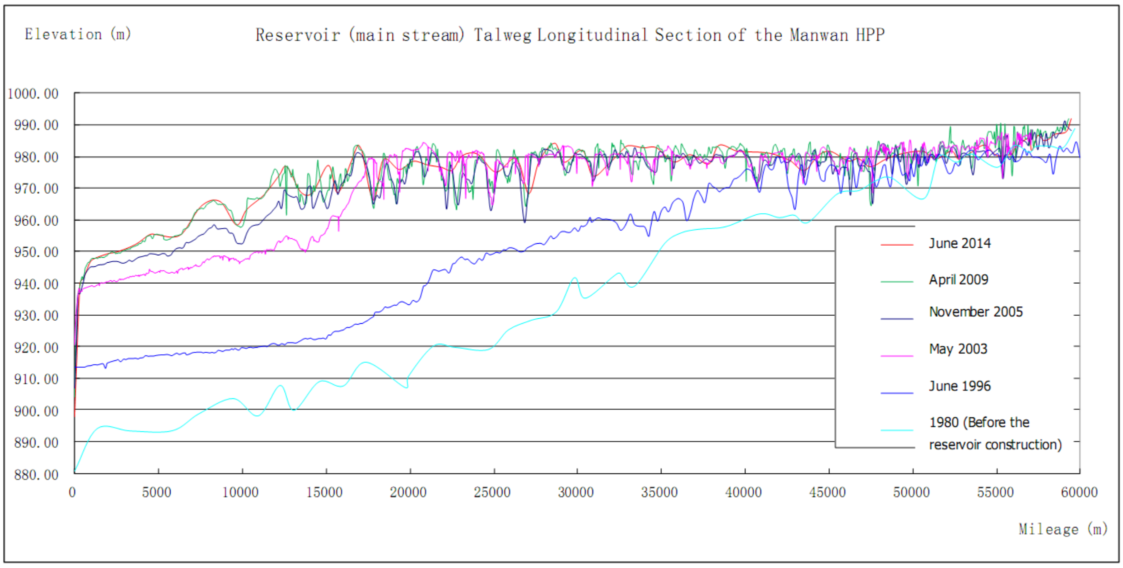

Fig. 2
Talweg Longitudinal Section

3.2. Analysis of the Sediment-Caused Storage Capacity Loss

Now, the storage results calculated and measured by the topographic map before the reservoir construction, in 1996, 2005, 2009 and 2014 have been collected, as well as the results of the cross section survey of the reservoir before the reservoir construction, in 1996, 2000, 2003, 2005, 2009 and 2014, and the method of section is applied to calculate the storages over the years. In order to eliminate the errors caused by the two calculation methods, the storage capacities calculated by the method of section in 2000 and 2003 shall be corrected, and the calculated characteristic capacity and sediment-caused storage capacity loss are shown in Fig.3 and Table 1.

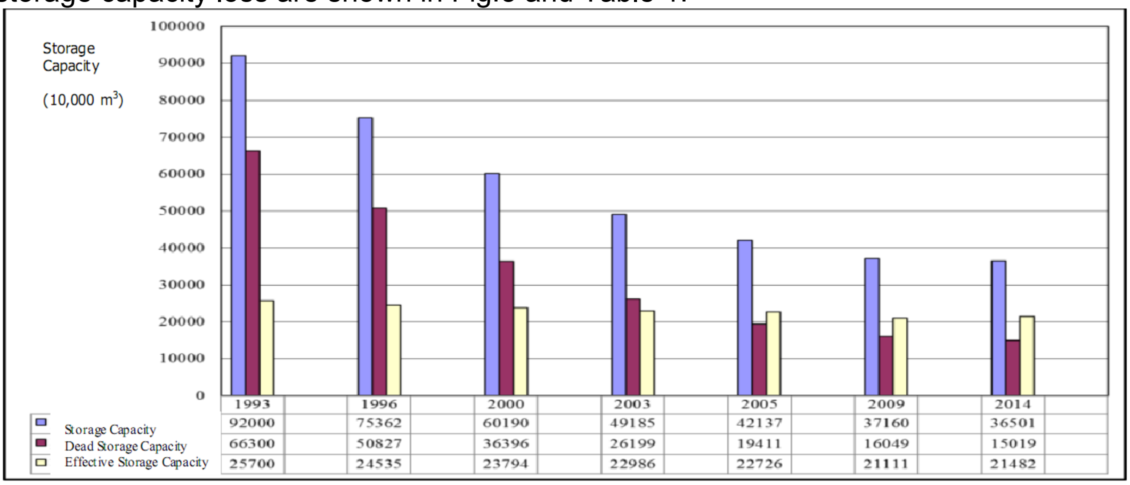

Fig. 3
Characteristic Storage Change in the Manwan Reservoir

Table 1
Characteristic storage of the Manwan reservoir and the sediment-caused storage capacity loss

Project	Before the Reservoir Construction	Impounding after April 1993						
	1993	1996	2000	2003		2005	2009	2014
Storage Below NWL (10,000 m^3)	92000	75362	60190	49185		42137	37160	36501
Sediment-Caused Storage Capacity Loss Below NWL (10,000 m^3) - between the Two Measurements		16638	15172	11005	7048	4977	659	
Rate of Sediment-Caused Storage Capacity Loss below NWL (%)		18.08	34.58	46.54		54.20	59.61	60.33
Dead Storage Capacity (10,000 m^3)	66300	50827	36396	26199		19411	16049	15019
Sediment-Caused Dead Storage Capacity Loss (10,000 m^3) - between the Two Measurements		15473	14431	10197	6788	3362	1030	
Rate of Sediment-Caused Dead Storage Capacity Loss (%)		23.34	45.1	60.48		70.72	75.79	77.35
Effective Storage	25700	24535	23794	22986		22726	21111	21482

Capacity (10,000 m^3)								
Sediment-Caused Effective Storage Capacity Loss (10,000 m^3) - between the Two Measurements		1165	742	807	260	1615	-371	
Sediment-Caused Effective Storage Capacity Loss (%)		1.53	7.42	10.56	11.57	17.86	16.41	

According to Fig.3, the variation tendency for storage capacity of the Manwan Reservoir is: the storage capacity below NWL, dead storage capacity and effective storage capacity is reduced year by year, the loss ranges for the storage capacity below NWL and dead storage capacity are quite large and basically synchronized, and the loss range for the effective storage is relatively small. Since the Xiaowan HPP was put into operation in 2009, the sedimentation in the Manwan Reservoir area is significantly mitigated.

According to Table 1, since the power plant is put into operation until 2014, the total sedimentation volume below the normal water level - 994m is 554.99 million m^3, the residual storage capacity below NWL of the reservoir is 365.01 million m^3 and the loss rate for the storage capacity below NWL is about 60.33%; the sedimentation volume below the dead water level - 982m is 512.81 million m^3, the residual dead storage capacity is 150.19 million m^3, and the loss rate for the dead storage capacity is 77.35%; and the sedimentation volume for the effective storage capacity is 42.18 million m^3, the residual effective storage capacity is 214.82 million m^3, and the loss rate for the effective storage capacity is about 16.41%.

See Table 2 for the comparison of the measured reservoir sedimentation volume over the years and the predicted sedimentation volume in the initially-set stage.

Table 2
Characteristic storage capacity of the Manwan reservoir and sediment-caused storage capacity loss

	Sedimentation Volume in 5 Years 1998	Sedimentation Volume in 10 Years 2003	Sedimentation Volume in 15 Years 2008	Sedimentation Volume in 20 Years 2013
Predicated Data	1.54	2.99	4.38	5.64
Measured Data	2.43	4.29	5.48	5.55
Difference	0.89	1.30	1.10	-0.09

From the view of the total sedimentation volume, the actual sedimentation of the Manwan Reservoir in the first 15 years of operation is more serious than the result of the original design forecast. This is mainly due to the deviation in the forecast which is based upon the historical hydrological and sediment data and the specified operation and dispatching modes. From the view of the actual sediment volume, affected by human activities, the sediment volume shows a significant increase trend. From 1994 to 2008, the average annual sand volume is 60.49 million tons, but the calculated design value in the preliminary design is only 44 million tons, with an increase of about 50%; Acccording to the operating water level of the Manwan HPP recorded from 1994 to 2009, the average operating water level of the Manwan HPP since its operation during the flood season from June to September is 987.44m, which is 2.44 m higher than the results of the preliminary design.

4. SEDIMENTATION CALCULATION

The sedimentation of the main stream of the reservoir is calculated by the constant flow unbalanced sediment transport method through the program SUSBED_2 provided by Wuhan University of Hydraulic and Electrical Engineering. The WUHEE Zhang Ruijin Formula is adopted as the sediment carrying capacity formula of suspended load.

4.1. Calibration of Sedimentation Parameters

Before the sedimentation calculation of each scheme, the calibration of sedimentation parameters is carried out firstly. The calculation is carried out based on the terrain data measured in 1996 with year 2000 as the end. The calculation results and the data measured in 2000 will be compared.

The inflow water level adopted for the sedimentation calculation is the average monthly water level recorded at Jiajiu Station from 1996 to 2000. The average monthly operating water level of the Manwan Reservoir from 1996 to 2000 is adopted as the water level in front of the dam. See Figure 4 for the comparisons between the calculated and the measured sedimentation longitudinal sections in 2000; See Table 3 for the Comparison Between the Calculated and the Measured Sedimentation Volumes.

Table 3
Comparison of the parameter-calibrated sedimentation results

Time	Measured Sedimentation Volume (10,000 m^3)	Calculated Sedimentation Volume (10,000 m^3)
1996 - 2000	13402	13270

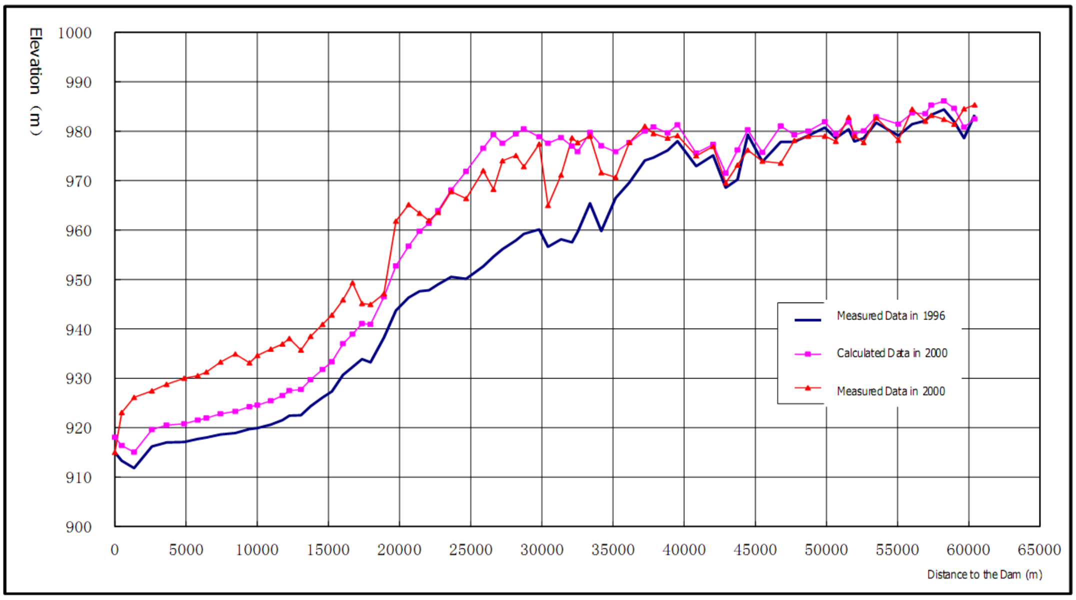

Fig. 4
Comparison of Sedimentation Longitudinal Section of the Reservoir in 2000 (Model Calibration)

According to the calculation of the sedimentation longitudinal section, the sedimentation thalweg point of the section in front of the dam is slightly lower, while that of the section at the tail of the reservoir is slightly higher. From the total sedimentation volume point of view, the measured and the calculated results are almost consistent. On the whole, the calculation can basically reflect the actual sedimentation, but the calculated sedimentation of the tail section is slightly higher than the actual situation. When analyzing the impact on the Xiaowan HPP, it will be safer.

The results of the parameter calibration are as follows: 1) WUHEE Zhang Ruijin formula: m is taken as 1.0; for k value, it is taken as 0.3 for the middle section of reservoir, and 0.2 for the rest sections; 2) Comprehensive Coefficient of Recovery Saturation: It is taken as 1.0 at the scouring condition, and as 0.75 and 0.5 respectively for the two groups of finest suspended sand, and 0.25 for the rest groups.

4.2. CALCULATION FOR THE SEDIMENTATION VERIFICATION

The above-mentioned calibrated parameters are applied to calculate the sedimentation till the time before the flood season in 2003 on the basis of the measured terrain data in 2000. The inflow water level adopted for the sedimentation calculation is the average monthly water level recorded at Jiajiu Station from 2000 to 2002. The average monthly operating water level of the Manwan Reservoir from 2000 to 2002 is adopted as the water level in front of dam. Refer to Table 3 for the sedimentation grain classification and parameter calibration.

See Fig. 5 for comparison between the sedimentation calculation and the calculated longitudinal section in 2003; and see Table 4 for comparison between the calculated sedimentation volume and the measured sedimentation volume.

Table 4
Verification results of the sedimentation volume

Time	Measured Sedimentation Volume (10,000 m^3)	Calculated Sedimentation Volume (10,000 m^3)
2000-2003	11234	11710

According to the verification results, the sedimentation longitudinal section is still slightly lower at the section in front of the dam and slightly higher at the section at the tail of reservoir, and the sedimentation volume is still well consistent with the measured data, which verifies that the calibrated parameters for the calculation is appropriate, and can be used for sedimentation forecast calculation of the reservoir.

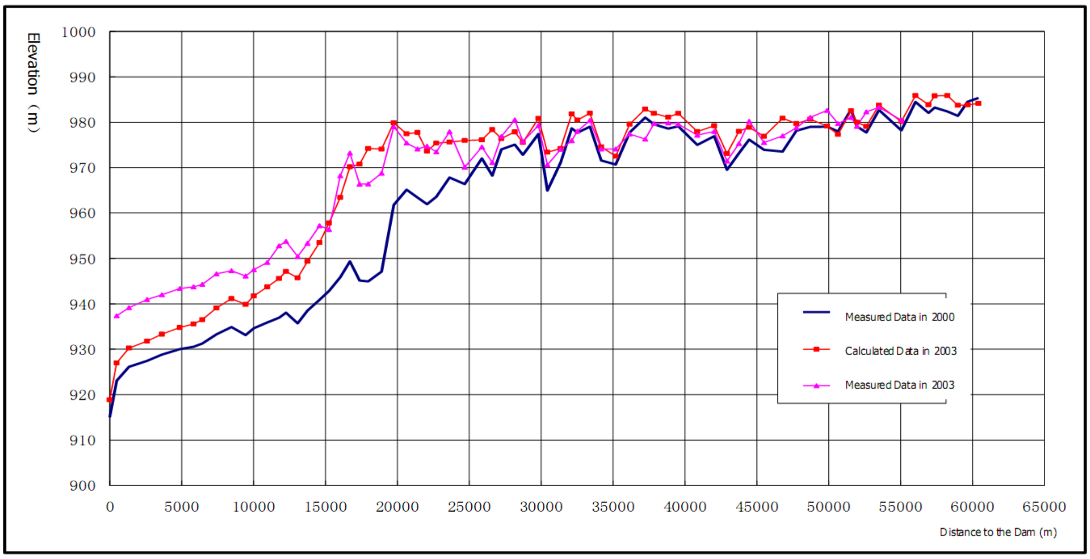

Fig. 5

Comparison of Sedimentation Longitudinal Sections of the Manwan Reservoir in 2003 (model verification)

4.3. Sedimentation Forecast

4.3.1 Calculation Data and Parameters for Sedimentation

(1) Longitudinal and Cross Sections of the Reservoir Area

The longitudinal and transverse profiles of the reservoir area were surveyed by the Surveying and Mapping Branch of the Kunming Engineering Corporation Limited of Power China from April to May 2014, and the layout of the profiles for scouring and silting calculation of the reservoir is shown in Figure 6, with 71 profiles in total. The section spacing is between 75m--- 1,321m, which can satisfy the calculation requirements. Compared with the measured data in 2009, there are 8 sections less in the end area of the reservoir; and combined the comparison of the calculated results in 2009 and 2014, the scouring and silting in river of the end area of the reservoir changed a little; hence the measured results in 2009 shall be applied for the 8 sections.

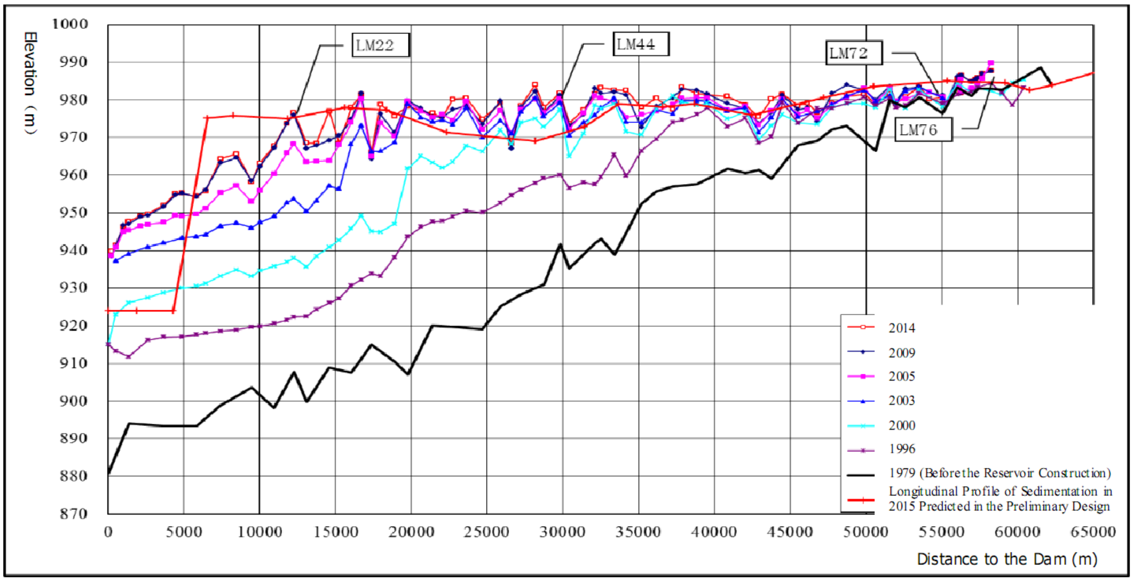

Fig. 6
Longitudinal Section of Sedimentation over the Years for Main Stream of the Manwan Reservoir

(2) The Inflow Flow and Sediment

Considering the impounding and power generation of the Xiaowan HPP since 2009, the Xiaowan HPP has a large sediment ratio, with over year regulating ability; According to the calculation, the sediment retaining ratio of the Xiaowan HPP is up to 95%, and all the outflow sediments are fine wash-load sediments, which is quite hard to be deposited in the Manwan Reservoir area, therefore the inflow sediment volume in the sedimentation calculation is calculated only by applying the sediment volume between the area from the Xiaowan to Manwan areas; Affected by the regulation and storage of the Xiaowan HPP, the inflow water is not natural flow, and the inflow discharge shall be applied with the yearly and monthly inflow discharge of the Manwan dam site after regulation and storage.

(3) Water Level in Front of the Dam

Monthly average water level over the years after runoff regulation

(4) Calculated Parameters

Applied Calibration Results

4.3.2 Calculated Results

See Fig. 7 for the longitudinal section of sedimentation, and see Table 5 for reservoir capacity loss.

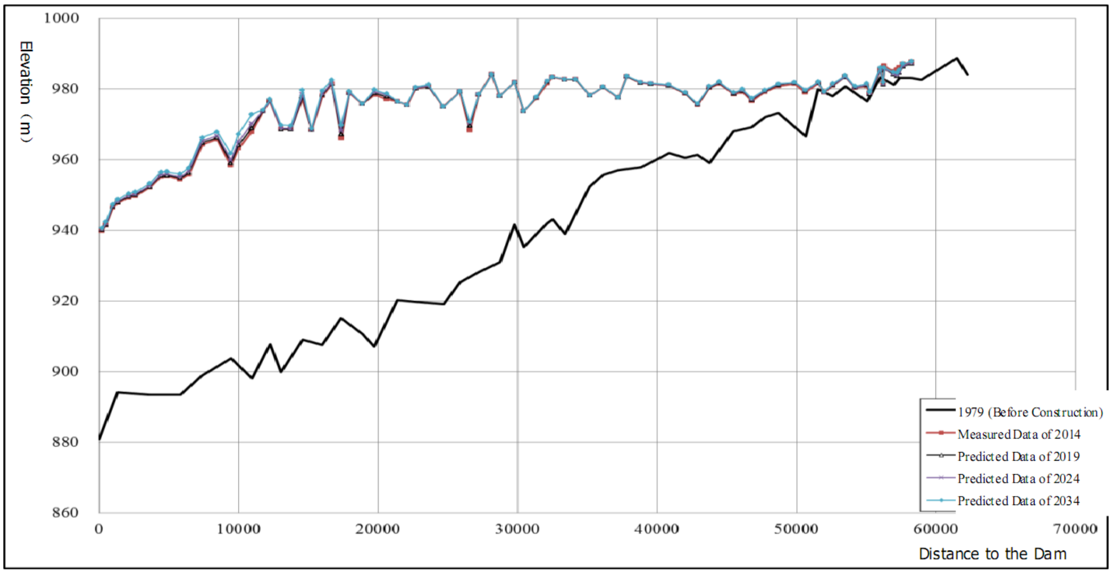

Fig. 7

Longitudinal Section of Sedimentation over the Years for the Manwan Reservoir

According to the calculated results: Affected by the sediment retaining of the Xiaowan HPP, the inflow sediment volume in the Manwan HPP decreased a lot, and it is predicted that the sedimentation volume below the normal water level will be 18.6 million m^3 after 20 years, of which the sediment-caused storage loss rate is 6.17% compared with 2014; The sedimentation volume within the dead storage capacity is 11.32 million m^3, of which the sediment-caused storage capacity loss rate is 9.63% compared with 2014; and the sedimentation volume of effective storage capacity is 7.29 million m^3, of which the sediment-caused storage capacity loss rate is 3.97% compared with 2014.

The results of the longitudinal section of the annual sedimentation over the years are shown in Fig.7. Compared with the measured results of the longitudinal section in 2014, the scouring and silting in the Manwan reservoir area changed little, where most sedimentation happened in the section in front of the dam, the scouring and silting in the section in the middle of the dam changed little, while a certain scouring happened in the section at the tail of reservoir due to the clear water discharging of the Xiaowan HPP.

Table 5
Forecast of the Reservoir Storage Capacity Loss for the Reservoir Sedimentation over the Years

	Project	Results		
Designed Storage Capacity of the Reservoir	Normal Water Level (m)	994		
	Storage below NWL (10,000 m^3)	92000		
	Water Level (m)	982		
	Dead Storage Capacity (10,000 m^3)	66300		
	Adjusted Effective Storage Capacity (10,000 m^3)	25700		
Calculation of the Measured Section in 2014	Normal Water Level (m)	994		
	Storage below NWL (10,000 m^3)	30124		
	Dead Water Level (982m) (m)	982		
	Dead Storage Capacity (10,000 m^3)	11756		
	Effective Storage Capacity (10,000 m^3)	18369		
Sedimentation Forecast	Sedimentation Period (Yrs)	5	10	20
	Residual Storage Capacity below NWL (10,000 m^3)	29655	29185	28264
	Residual Dead Storage Capacity (982m) (10,000 m^3)	11483	11203	10624
	Residual Effective Storage Capacity (10,000 m^3)	18172	17982	17640

Note: The calculated storage capacity of the surveyed sections in 2014 is the main stream storage capacity calculated by the section method, which does not include the storage capacities of tributaries. It satisfies the requirements for storage capacity loss forecast, and has a certain difference with the storage volume calculated by the contour method in 2014.

5. CONCLUSIONS AND SUGGESTIONS

Most sections of the Manwan HPP are covered by the luxuriant vegetation, and the main sources of sediments mainly are: ① The sediment in the upstream flows into the Manwan Reservoir; there are large populations and farmlands around the Gonglang River, thus the water and soil loss is quite serious; ③ Some gullies in the reservoir area are covered by little vegetation, therefore the sediment flows into the main stream through the tributaries and the rainwater.

Sediment of the whole reservoir is mainly deposited below the dead storage capacity. The Xiaowan HPP was impounded in 2009, which greatly relieved the sediment problem of the Manwan HPP. The storage below NWL, dead storage capacity and effective storage capacity have little change compared with the previous data. The total loss rate of the effective storage capacity below the normal water level - of 994m is 15.21%, and the total loss rate of the storage capacity below the dead water level - elevation: 982m is 77.47%.

Suggestions:

(1) After completion of the Xiaowan Reservoir, the data of the inflow and outflow sediment have been changed fundamentally, the sediment observation and analysis shall be conducted to know the rules for the sediment transport in the Manwan Reservoir, forecast the sediment problem in the reservoir and instruct the operation of the plant.

(2) Regularly (normally 2---3 years) measure the cross section of sedimentation in the main stream and tributaries and the topographic map in the Manwan Reservoir.

(3) Pay attention to the soil and water conservation. Continuously insist on the operation mode of the reservoir - “Storing Clear Water and Releasing Muddy.”

ACKNOWLEDGEMENTS

1. INTRODUCTION

Sand bar is a geomorphologic pattern which is often observed in estuaries and reservoirs. For estuaries, Sand bar alleviates water depth and blocks water and sediment transportation. It is also a threat for navigation (Li, 1997). For reservoirs, San bar blocks river mouth of tributaries, reduces storage volume of reservoirs (Li et al., 1985; Wang and Hu, 2003). Therefore, the research on the evolution of sand bar is valuable for engineering. Separately, the evolution of sand bar in estuaries is influenced by the flow conditions upstream and oceanic dynamic conditions downstream (Hu and Zhang, 2006). And the evolution of sand bar in reservoirs is caused by two ways : the first way usually occurs in a small or median reservoir, the slope in the main channel is mild while in the tributaries is steep. In flood season, the water with sediment and gravel will flow from the source of the tributaries to the main channel and deposit in the river mouth of the tributaries(Qi, 1996); the second way usually occurs in a large reservoir, the slope in the main channel is steep while in the tributaries is mild. In flood season, the water with sediment and gravel will flow form the main channel to the tributaries and deposit in the river mouth of the tributaries (Wang et al., 2011). Because the evolution of sand bar is influenced by many different factors, it is a focus for scientists and engineers. Limited by the complexity of the problem and traditional techniques, former research on sand bar mainly fixed on the influence of a single factor (Shen et al., 1983; Li and Ji, 1988; Yang et al., 2001). With the development of new analysis techniques, now the research turns to be quantitative (Wu et al., 2002) and modelling (Zhang et al., 2003). Accordingly, this paper established a response formula between the height's increment of the sand bar in the tributaries in the Xiaolangdi Reservoir area and a number of influencing factors. Using sensitive analysis, the key factor for the evolution of the sand bar is also found to support the engineering constructions for dealing with sand bar in the reservoir area.

2. STUDY REGION

In this chapter, six main tributaries in the Xiaolangdi area were selected firstly (see figure 1): Dayu River, Zhenshui River, Shijing River, Dongyang River, Xiyang River and Yunxi River.

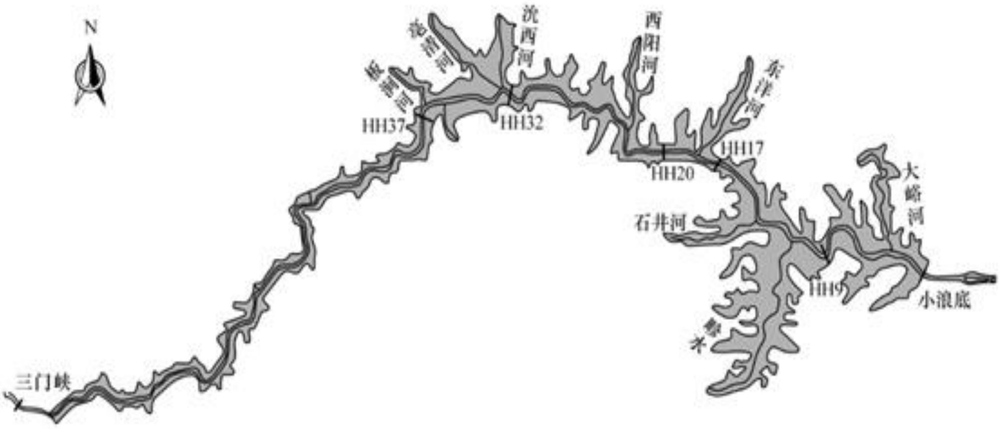

Figure 1. Sketch of Xiaolangdi Reservoir Area

The basic information of six tributaries can be seen in table 1 as follows:

Table 1. Original parameters of tributaries in Xiaolangdi Reservoir Area

name	location		distance from the dam /km	storage volume $/10^8$ m^3	river length /km	river basin area $/km^2$	channel gradient $/^{0}/_{000}$	backwater length under the 230m (water level before the dam) conditions/km	backwater length under the 230m (water level before the dam) conditions /km
Dayu River	Left bank	HH3-HH4	3.9	5.80	55	258	100	9.3	12.3
Dongyang River		HH18-HH19	31.3	3.11	60	571	92	7.9	11.7
Xiyang River		HH23-HH24	41.3	2.35	53	404	106	5.5	9.4
Yunxi River		HH32-HH33	57.6	4.07	72	576	120	4.8	7.2
Zhenshui River	Right bank	HH11-HH12	18	17.67	53.7	431	56	14.5	21.3
Shijiang River		HH13-HH14	22.7	4.80	22	140	120	6.8	10.3

The data series began from 2001 spring and end to 2014 spring. A further analysis on the data showed that Dayu River was too close to the dam of the Xiaolangdi reservoir, the cross-section of that was influenced by the fluctuation of water level before the dam. As a result, the gradient of the main channel of Dayu River changed quickly and sometimes turned negative. Additionally, the phenomenon of sand bar is not significant in the river mouth of Dayu River. As to fix on the evolution of sand bar, we deleted the data series of Dayu Rvier, focus on the other five tributaries.

3. STUDY INDEXES

Using dimensionless parameters, this paper set a multiple regressive formula between the height increment of sand bar and different influencing factors. The form of the formula is as follows:

$$\hat{Y} = K\hat{X}_1^{\alpha_1}\hat{X}_2^{\alpha_2} \dots \hat{X}_n^{\alpha_n} \quad [1]$$

In which $\hat{Y}$ is a dimensionless dependent variable, $\hat{X}_1, \hat{X}_2, \dots, \hat{X}_n$ are dimensionless independent variables, K, α_1, α_2,…, α_n are undetermined coefficients.

The research aim is the evolution of sand bar, so the annual height increment of sand bar Δh (m) and annual depositing volume ΔV (m^3) are chosen as dependent variables, the dimensionless forms are:

$$\hat{Y}_1 = \frac{\Delta h}{D_{50}}, \hat{Y}_2 = \frac{\Delta V}{D_{50}^3} \quad [2]$$

[3]

In which D_{50} (m) is the median grain size of bed material load in the river mouth of the tributaries, which is measured every year before flood season.

As the former research, the evolution of sand bar is related to water and sediment conditions, local terrain factors and flow regimes. So the selected independent variables should include all these aspects (See Table 2 and Table 3):

Table 2. Selection I of independent variables for the evolution of sand bars - water and sediment processes

	Water and sediment conditions				
factors	Water level condition $\hat{X}_1$	Flow Condition I $\hat{X}_2$	Flow Condition II $\hat{X}_2^*$	Sediment condition I $\hat{X}_3$	Sediment condition II $\hat{X}_3^*$
Direct Indexes	Averaged water level in flood season H（m）	Averaged inflow of the reservoir in flood season Q（m^3/s）	Averaged outflow of the reservoir in flood season Q*（m^3/s）	Averaged sediment flowing into the reservoir in flood season S(kg/m^3)	Averaged sediment flowing out of the reservoir in flood season S*(kg/m^3)
Dimensionless indexes	$\frac{H}{D_{50}}$	$\frac{Q}{\sqrt{gD_{50}^5}}$	$\frac{Q^*}{\sqrt{gD_{50}^5}}$	$\frac{S}{\gamma/g}$	$\frac{S^*}{\gamma/g}$

Table 3. Selection II of independent variables for the evolution of sand bars -local terrain and flow regimes

	Local terrain conditions			*Local flow regimes*	
Factors	Terrain conditions in the tributaries $\hat{X}_4$		Terrain conditions in the main channel $\hat{X}_5$	Location of the front of the Delta $\hat{X}_6$	
Direct indexes	Width of the river mouth of the tributaries B_h(km)	Maximum width of the tributaries B_m(km)	Gradient J_z(1)	Distance from the river mouth to the dam L_0(km)	Distance from the front of the delta to the dam L(km)
Dimension-less indexes	$\frac{B_h}{B_m}$		J_z	$\frac{L}{L_0}$	

4. MULTIPLE REGRESSIVE FORMULA

According to the analysis above, using forward and stepwise regressive methods, we got a full regression model (considering all independent variables) and a selecting regression model (Selecting most important independent variables) separately as follows:

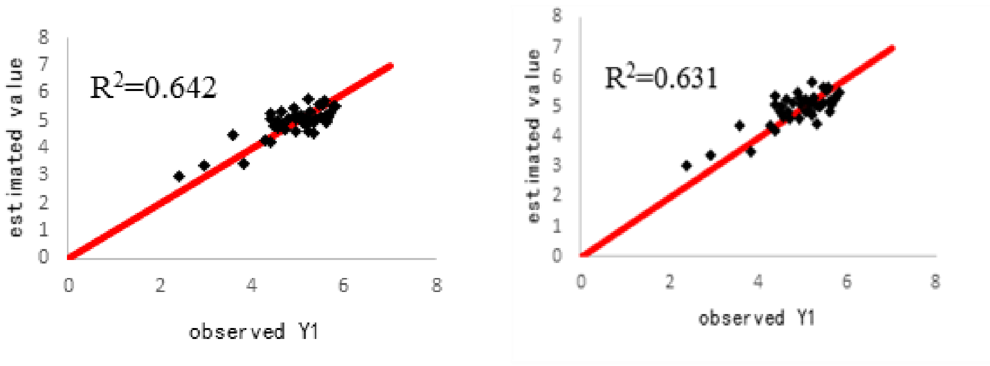
$$\hat{Y}_1 = 0.265\hat{X}_2^{*0.417}\hat{X}_3^{0.415}\hat{X}_3^{*-0.070}\hat{X}_4^{-0.031}\hat{X}_5^{-0.030}\hat{X}_6^{0.951} \quad (R^2=0.642) \qquad [4]$$

$$\hat{Y}_1 = 0.0736\hat{X}_1^{0.415}\hat{X}_6^{1.151} \quad (R^2=0.631) \qquad [5]$$

$$\hat{Y}_2 = 185.353\hat{X}_2^{*1.373}\hat{X}_3^{-0.430}\hat{X}_3^{*0.248}\hat{X}_4^{0.317}\hat{X}_5^{0.320}\hat{X}_6^{0.719} \quad (R^2=0.827) \qquad [6]$$

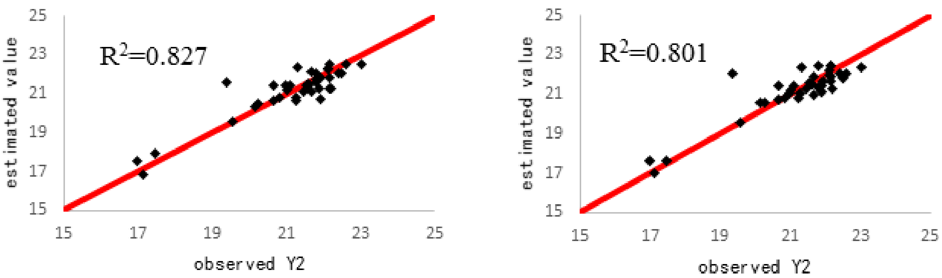
$$\hat{Y}_2 = 3.540\hat{X}_2^{*1.428} \quad (R^2=0.801) \qquad [7]$$

Figure 2 and figure 3 gave the results of the regression models.



(a) full regression model (b) selecting regression model

Figure 2. Multiple regressive result of height increment of sand bars in the tributaries in Xiaolangdi Reservoir Area



(a) full regression model (b) selecting regression model

Figure 3. Multiple regressive result of annul sedimentation quantity in the tributaries in Xiaolangdi Reservoir Area

Given from fig 2 and fig3, the regressive results agree well with the observed data. The effects of the formula can be accepted. Furthermore, a detailed analysis based on physical meanings should be done:

(1) The full regression model and selecting regression model of Y_1: the main influencing factors on Y_1 are outflow discharge (the exponent number is 0.417), sediment concentration flowing into the reservoir (the exponent number is 0.415), sediment concentration flowing out of the reservoir (the exponent number is -0.070), local terrain factor in the tributaries (the exponent number is -0.031), local terrain factor in the main channel (the exponent number is 0.030) and the location of the front of the delta (the exponent number is 0.951). Considering the importance of those factors, the location of the front of the delta, outflow discharge and sediment concentration flowing into the reservoir take the first three places and agree well with the physical meanings. Additionally, although the exponent number of the local terrain factor in the tributaries is small enough, the correlation coefficient of that is significant. So the local terrain factor should also be chosen. Then the final form of the regressive model for Y_1 is shown as follows:

$$\hat{Y}_1 = 0.534\hat{X}_2^{*0.4}\hat{X}_3^{0.4}\hat{X}_4^{-0.1}\hat{X}_6 \text{ } (R^2=0.638) \qquad [8]$$

The exponent number and independent variables are all simplified and the results are shown in fig 4.

(2) The full regression model and selecting regression model of Y_2: the main influencing factors on Y_2 are outflow discharge (the exponent number is 1.373), sediment concentration flowing into the reservoir (the exponent number is -0.430), sediment concentration flowing out of the reservoir (the exponent number is 0.248), local terrain factor in the tributaries (the exponent number is 0.317), local terrain factor in the main channel (the exponent number is 0.320) and the location of the front of the delta (the exponent number is 0.719). Considering the importance of those factors, outflow discharge, the location of the front of the delta, and sediment concentration flowing into the reservoir take the first three places. Based on the physical meanings, these three factors should all have positive correlations with the depositing volume in the tributaries, while the sediment concentration flowing into the reservoir showed an opposite relation in this model. The physical interpretation is: the sediment flowing into the reservoir area is not equal or positive related to the depositing volume in the reservoir area, because there is a drastic process of the sediment exchange between the channel bed and water flow. Even though clear water flows into the reservoir area, it also may cause a sediment transporting process and a deposition in the river mouth of the tributaries. As a result, the sediment concentration flowing into the reservoir is deleted from the model. Similarly, we can get the final form of the regressive model for Y_2 :

$$\hat{Y}_2 = 85.57\hat{X}_2^{*1.4}\hat{X}_4^{0.3}\hat{X}_5^{0.3}\hat{X}_6^{0.7} \text{ } (R^2=0.820) \qquad [9]$$

The exponent number and independent variables are also simplified and the results are shown in fig 5.

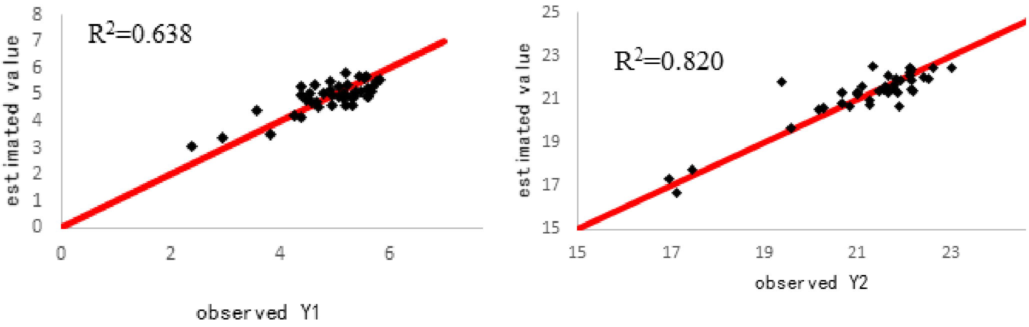


Figure 4. Predictions of final formula of height increment of sand bars (left);
Figure 5. Prediction of final formula of sedimentation quantity (right)

Take the physical expressions of all the variables into equation [8] and [9], we can get the final formula as follows:

$$\Delta \mathrm{h} = 0.534\left(\frac{Q^*}{\sqrt{gD_{50}^5}}\right)^{0.4}\left(\frac{S}{\rho}\right)^{0.4}\left(\frac{B_h}{B_m}\right)^{-0.1}\frac{L}{L_0} \quad (R^2=0.638) \qquad [10]$$

$$\Delta \mathrm{V} = 85.57\left(\frac{Q^*}{\sqrt{g}}\right)^{1.4} D_{50}^{-0.5}\left(\frac{B_h}{B_m}\right)^{0.3} J_z^{0.3}\left(\frac{L}{L_0}\right)^{0.7} \quad (R^2=0.820) \qquad [11]$$

5. SENSITIVE ANALYSIS

The aim of sensitive analysis are: (1) searching the sensitive factor and using the factor to control the dependent variable; (2) confirming the limitation of the dependent variable.

In this chapter, the annual height increment of sand bar in tributaries and depositing volume in tributaries are two dependent variables. Using the data in Zhenshui River in 2012, we did sensitive analysis in table 4 and table 5:

Table 4. Sensitive analysis of height increment of sand bars in the tributaries (unit: m)

Influencing factors	-20%	-10%	-5%	+5%	+10%	+20%
Outflow discharge	-0.107	-0.052	-0.026	0.025	0.049	0.095
Sediment concentration	-0.107	-0.052	-0.026	0.025	0.049	0.095
Relative width in the river mouth	0.028	0.013	0.006	-0.006	-0.012	-0.023
Distance from the front of delta	-0.252	-0.126	-0.063	0.063	0.126	0.252
Distance from the river mouth	0.315	0.140	0.066	-0.060	-0.114	-0.210

(Note: the mathematic meaning of the sensitive analysis table is: the change for one single factor causes the change of the dependent variable. For example, if the outflow discharge decreases by 20%, then the height of the sand bar will decrease 0.107m).

Table 5. Sensitive analysis of annual sedimentation quantity in the tributaries (unit: $\times 10^6 m^3$)

Influencing factors	-20%	-10%	-5%	+5%	+10%	+20%
Outflow discharge	-3.334	-1.704	-0.861	0.878	1.774	3.613
Grain size of bed material load	1.467	0.672	0.323	-0.299	-0.578	-1.083
Relative width in the river mouth	-0.805	-0.387	-0.190	0.183	0.360	0.699
Distance from the front of delta	-1.797	-0.883	-0.438	0.432	0.857	1.692
Distance from the river mouth	2.101	0.951	0.454	-0.417	-0.802	-1.489
Gradient in the main channel	-0.805	-0.387	-0.190	0.183	0.360	0.699

Given from Table 4 and Table 5, some conclusions can be obtained:

(1) For the height increment of sand bars in the tributaries, the sensitive order is: Distance from the river mouth to the dam> Distance from the front of delta to the dam> Outflow discharge= Sediment concentration> Relative width in the river mouth;

(2) For the annual sedimentation quantity in the tributaries, the sensitive order is: Outflow discharge> Distance from the front of delta to the dam>Grain size of bed material load> Gradient in the main channel= Relative width in the river mouth.

6. CONCLUSIONS

Using dimensionless multiple regressive analysis and sensitive analysis, some conclusions can be get:

(1) The evolution of sand bar in the river mouth of those tributaries in Xiaolangdi reservoir area, is related to the water and sediment conditions, local terrain factors in the tributaries and main channel, location of the front of the delta in the reservoir area and others. Among them, the location of the front of the delta is the most sensitive factor;

(2) For engineers, the aim is to limit the evolution of sand bar and utilize the depositing capacity in those tributaries in the reservoir area. According to this paper, these actions are effective: increasing the sediment concentration flowing into the reservoir in flood season, decreasing the grain size of bed material load, increasing the gradient of the main channel, increasing the relative width of the river mouth of those tributaries. Specifically, increasing the relative width of the river mouth is recommended, which can not only limit the evolution of sand bar, but also increase the depositing volume in the tributaries.

SUMMARY

Using multiple regression analysis and dimensionless parameters, this paper established a response formula between the height's increment of the sand bar in the tributaries in the Xiaolangdi Reservoir area and a number of influencing factors: water and sediment conditions, terrain factors in the main channel and tributaries and local flow regimes and so on. And also a similar formula between the sedimentation quantity in the tributaries and the influencing factors was obtained. The results show that: the water and sediment conditions, terrain factors, local flow regimes, grain size of bed material were all influencing factors for the evolution of the sand bar. Throughout sensitive analysis, the key factors for the evolution of the sand bar is the flow discharge and local flow regimes. These conclusions will be helpful for the engineering projects to control and limit the evolution of the sand bar in the tributaries in the Xiaolangdi Reservoir area.

ABSTRACT

Ringlet reservoir is a multipurpose reservoir that is part of Cameron Highlands – Batang Padang Hydroelectric Scheme. The reservoir has the original design storage of 6.7 million m^3, of which 2 million m^3 is dead storage and 4.7 million m^3 is live storage. The catchment is a famous tourist area with active highland agricultural activities. Changes in land use have been significant since 1960's, showing an increase in agricultural area and reduction of forest cover.

A number of studies were conducted in the past to examine the effects of land use changes on the operation of the hydroelectric scheme. Based on survey and sediment monitoring records, the sedimentation rate has increased by 6 times from original design of 25,000 m^3/year (in 1960's) to an average of 139,712 m3/year in 2010, causing a significant reduction of total storage capacity of Ringlet Reservoir from 6.7 million m^3 in 1965 to 3.1 million m^3 in 2008. Bertam Intake, which is the main power intake is often choked by the sediment built up within the area.

To continue the hydropower operation, various mitigation strategies have been implement such as development of an Integrated Lake Basin Management Plan for Cameron Highlands' catchment to control sediment production at source. At the same time, sediment in Ringlet Reservoir is continuously removed via dredging. The dredged material is dried temporarily at the designated decantation area and disposed at the selected areas. Dredging is not a sustainable solution, mainly due to larger sediment loads entering the reservoir as compared to capacity of removal. Land availability for disposal area is becoming limited in the future and subsequently increase the total cost of removal. Another strategy considered is construction of two (2) check dams and settling basins at the main inlet rivers into Ringlet Reservoir, namely Habu and Ringlet check dams. Mechanical excavation at the check dams is cheaper than deploying dredger to remove sediment from inside the reservoir.

In conclusion, managing hydropower operation in rapidly changing land use especially in agricultural area is challenging. Rate of reservoir sedimentation in this area can easily exceed the original design, causing the reservoir operators to carefully plan ahead to manage the potential problems. TNB as the responsible manager, has done extensive works to manage and mitigate the sedimentation problem faced at Ringlet Reservoir. Other options such as controlling the reservoir operating regime and operation of the low level outlet can also be considered. There are still other ways to improve the current sediment management practice and they require extra effort to ensure the sustainability of the operation.

1. INTRODUCTION

Conventionally, the sediment production and the flowing down situation from the upstream of the river are estimated by aerial photointerpretation or topographic survey etc. The design sediment volume in a dam is usually estimated according to sedimentation results of neighboring dams that have similar watershed condition. And the sediment transport in river channel is not properly measured during the flood event.

In recent years, the observation technology of sediment discharge in the river has greatly improved, so that the bedload can be directly observed by a hydrophone, and the suspended load by a turbidimeter. Additionally, the sediment volume variations in a mountain stream can be estimated from temporal change of riverbed height by satellite SAR (Synthetic Aperture Radar) analysis.

In this paper, using the model of Omukawa River, a branch of Kamanashigawa, Fujikawa River system, we combine the data of sediment discharge obtained by various observation techniques and try to improve the observation methods for estimating the volume of sediment from the watershed, that will be useful for the sediment management in dam.

2. OUTLINE OF STUDY SITE

2.1. OUTLINE OF STUDY SITE

The study site in Omukawa River is located at the top of the Kofu alluvial fan, left branch of the Kamanashigawa, Fujikawa River system, a rapid river with an average gradient 1/58 and an extension of 16.4 km. The study area corresponds to about 8.3 km of its downstream section (Fig. 1). The upstream area consists of low to middle mountains composed of granite and volcaniclastic materials. Within this river section, about 50 Sabo dams and groundsels exist in the channel.

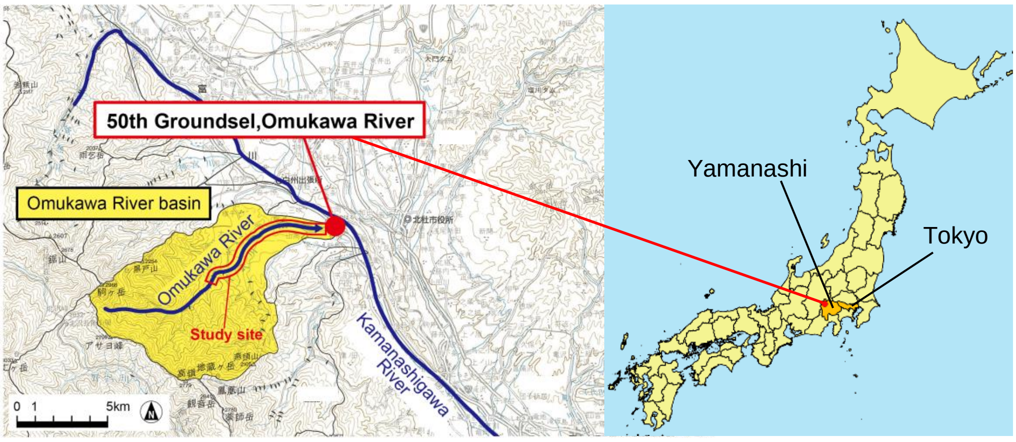

Fig. 1
Sediment discharge observation site map

2.2. IMPLEMENTATION OF SEDIMENT DISCHARGE OBSERVATION

In order to observe the volume of sediment discharge from the mountain stream, sediment discharge measurement is continuously carried out from 2011 by several equipment, such as hydrophone, turbidimeter, water level gauge, suspended load sampler, and a buried sediment trap pit, etc., on the 50th groundsel in Omukawa River. The layout of observation site and a sample of obtained data is shown in Fig. 2 and Fig. 3 respectively. The annual volume of sediment discharge calculated from the observed data is shown in Fig. 4.

The observed results of the hydrophone and sediment trap pit showed that the detectable grain diameter lower limit by hydrophone is about 2 mm, and the volume of sediment measured by the hydrophone is about 2% to 50% of the actual flowing down sediment volume that deposited in trap pit [1], and the ratio depends on the flood conditions such as the season, water depth and so on (Table 1, Fig. 5).

2.3. ESTIMATION OF SEDIMENT TRANSPORT BY SAR IMAGE ANALYSIS

2.3.1. SAR image data and analysis period

In the SAR image analysis, a SAR sensor mounted on an artificial satellite sends microwave obliquely to the ground surface and receives backscatter. The image data are obtained by receiving backward scattering from the ground surface. By interference analysis of two observed SAR images next to each other, the ground displacement that occurred during the observation period can be calculated. Using SAR image interference analysis, it is possible to observe ground surface displacemet without being influenced by weather and day or night [2].

Here, we use the following 9 SAR images acquired from the ALOS-2 satellite passing over Japan. Interference SAR image (inSAR) analysis of 8 periods (① ~ ⑧) with pairs next to each other were carried out to obtain river bed fluctuations of about 8 km river section on the upstream of 50th groundsel in Omukawa River (Table 2).

Table 2

		⑧	2017/03/03	2017/06/09

2.3.2. Analysis method

In SAR image analysis, the width of river channel more than 5 times the minimum image resolution (3m) is needed, so that we choose the middle to downstream river section of Omukawa River as a study site, where sediment discharge observation has been carried out at the downstream end since 2011.

In calculating the volume of sediment transport in the river way, the channel was divided into 58 blocks, in order to remove the range of river crossing constructions (e.g., bridges, groundsels etc.) where there is no displacement during floods. Furthermore, each block was subdivided into meshes of 5m squares. The procedure of interference analysis of SAR image was shown in Fig. 6 and Fig. 7.

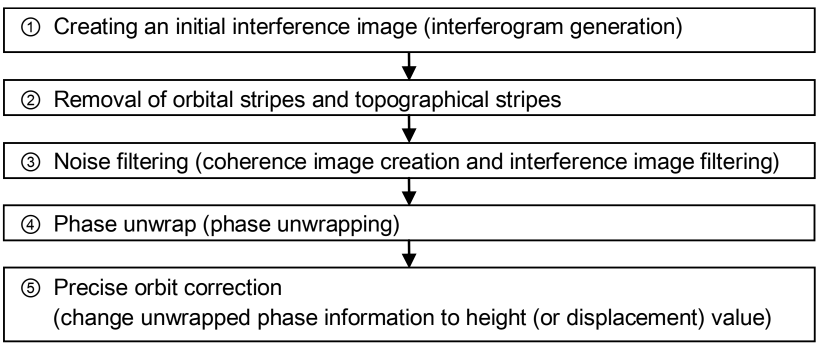

Fig. 6
Procedure of SAR image interference analysis

Fig. 7
Image of channel block division and SAR interference analysis

2.3.3. Results of SAR image analysis

Interference analysis on adjacent SAR images by the method shown in Fig. 6 and Fig. 7, the changes in ground height of each mesh occured between two SAR images is directly obtained. And by each mesh area (si) x average height (Δhi), the volume change (Δvi = si × Δhi) of each mesh is calculated. Then, cumulating the results from each mesh the total volume of sediment transport for each block or the whole section can be calculated.

The vertical sectional view of the riverbed height variation (block average) calculated by the above method is shown in Fig. 8. While, the volume of sediment transport for every analysis period (① to ⑧) is shown in Table 3 and Fig. 9, and the temporal change of sediment volume within the study river section is shown in Fig. 10.

Table 3
Sediment transport volume by inSAR image analysis

No.	Analysis period		Period (Day)	Sediment change volume by inSAR analysis Vs (m^3)
	from	to		
①	2014/09/19	2014/11/28	70	9743.98
②	2014/11/28	2015/04/03	126	-5361.75
③	2015/04/03	2015/06/26	84	1840.07
④	2015/06/26	2016/03/18	266	-21229.55
⑤	2016/03/18	2016/06/24	98	9752.34
⑥	2016/06/24	2016/11/25	154	1599.06
⑦	2016/11/25	2017/03/03	98	-648.32
⑧	2017/03/03	2017/06/09	98	9596.02

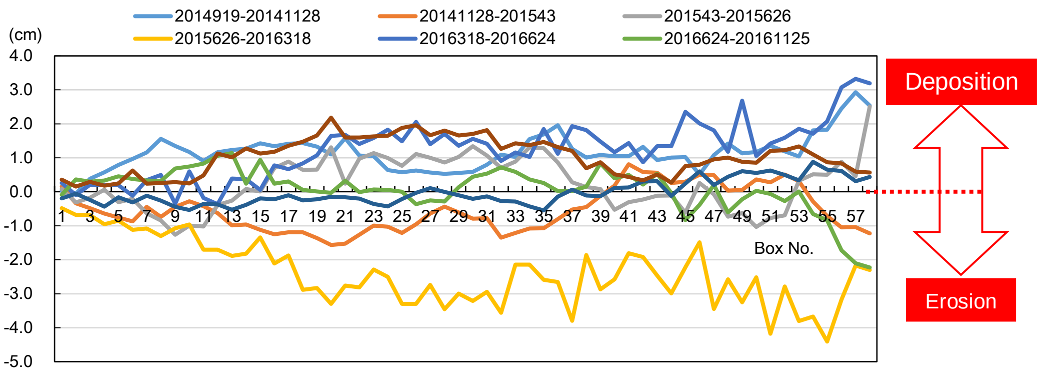

Fig. 8
River bed height variation on longitudinal section during each analysis period

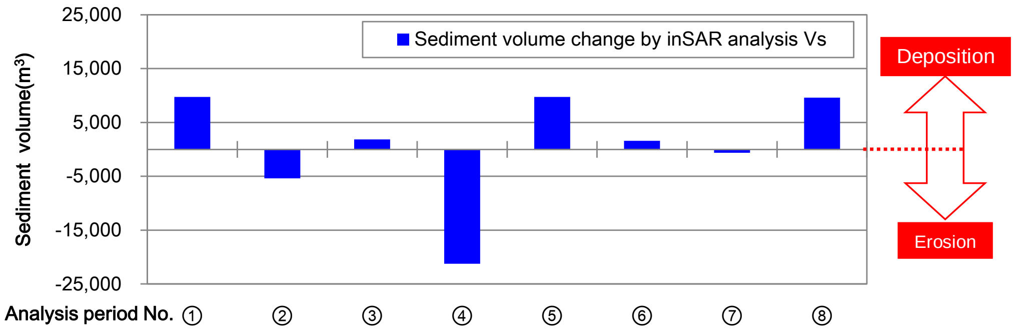

Fig. 9
Sediment transport volume during each analysis period

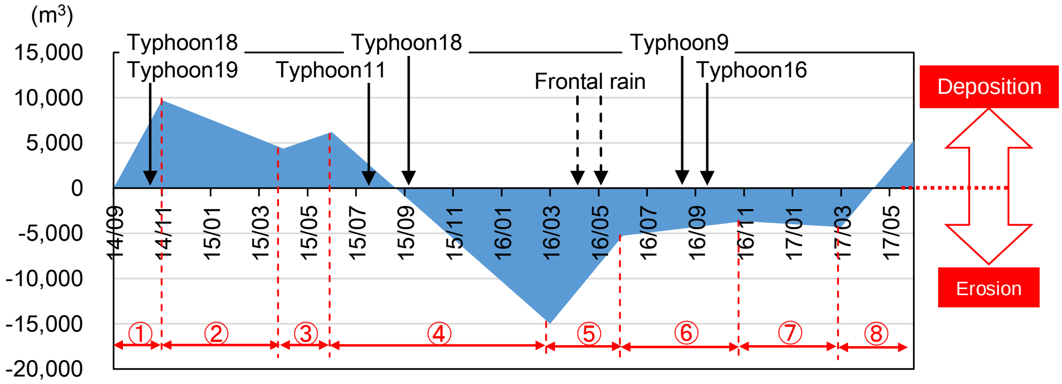

Fig. 10
Sediment temporal change in river channel

From above results, the riverbed rise (deposition) or decrease (erosion) was observed according to the observation target periods. Basically, during the period when large floods (typhoon) occurred, a riverbed rise (deposition) appeared and if there is no flood in a long term, a tendency of river bed decrease (erosion) is recognized due to the sediment gradually flowing out.

3. RESULTS

3.1. RESULT COMPARISON AND ITS CONSIDERATION

A comparison of transport sediment volume (bedload and suspended load) observed by equipment (hydrophone, turbidimeter, water level gauge etc.) installed at the downstream end in Omukawa River and that calculated from SAR image interference analysis in the same period is shown in Table 4 and Fig. 11.

※ Sediment change in volume revised by void ratio of river bed material (0.40)

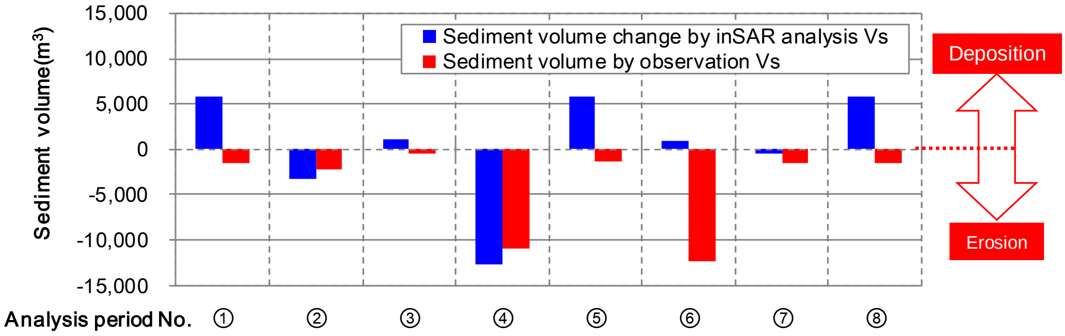

Fig. 11
Comparison between results by inSAR image analysis and observation

During flood period, i.e. ①, ③, ⑤, ⑧, sediment balance within the river section showed positive (deposition). It is presumed that there was abundantly sediment supply from the upstream.

In other hand, during the non-flood period, i.e. ② and ⑦, the balance of sediment within the river section shows negative because the volume of outflow is larger than the inflow. Meanwhile, the period ④ that spans both the flood and non-flood periods, is influenced both by the in-flow during the flood and the outflow in the non-flood season. As the result, the sediment balance showed negative in this case.

Relationship between the sediment volume change in the river section by inSAR analysis and the sediment discharge observed at downstream end by the equipment is shown in Fig. 12. Although the data showed some dispersion, an approximate linear correlation was recognized.

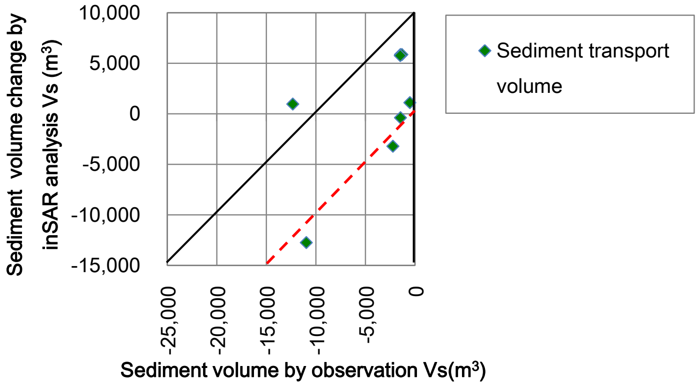

Fig. 12
Relationship between results by SAR image analysis and sediment observation

4. CONCLUSION

In this study, even though it was difficult to precisely analyze and verify the results, because there was limited SAR image data taken in accordance with the flood event (immediately before/after), but the followings can be concluded from the above examination:

1) Combinating observation with trap pit can verify the accuracy of sediment observation with hydrophone as well as measure spatio-temporal sediment transport during flood event. By interference analysis of adjacent SAR images, it is possible to capture the change of micro topography in the riverbed.

2) This method can be fully utilized to measure and analyze geomorphologic changes in mountain streams where periodical survey is difficult.

3) In this study, clear correlation between sediment volume obtained by SAR analysis and observed one by hydrophone, turbidimeter, etc. was not be

confirmed due to the limitation of the verifiable data. Moreover, since a hydrophone (length = 2.0 m) is installed at one side near the sidebank of about 72m wide river, it maybe have some difficulties to represent the sediment transport volume calculated by the hydrophone for the entire width of the river.

4) Measurement of topography deformation by interference SAR image analysis is a new technology that rapidly progressed in recent years. In order to obtain accurate data and make precisely analysis, further study and improvement on observation equipment and analysis technique are needed in the future.

ACKNOWLEDGEMENTS

We sincerely thank the staffs in the Fujikawa SABO office, Kanto Rigional Development Bureau, the Ministry of Land, Infrastructure, Transport and Tourism (MLIT), Japan, for their kindly supports in this work.

SUMMARY

Taking the middle to downstream section of Omukawa River (extension L = 8.3 km, gradient 1/58) as a study site, A comparison between sediment transport obtained by SAR image interference analysis and sediment discharge observed by hydrophone etc. during 2014-2016 period.

The result shows that, although there was data variation, an approximate linear correlation was recognized.

The reason of the difference between two data is assumed that sediment discharge is measured only at the downstream end with a length L= 2.0 m, with respect to the river width of 72 m, which is not adequate for representing the entire river cross section.

1. INTRODUCTION

Integrated management of sediment and flows downstream of dams is still relatively rare. In France, we have developed a "morphogenic water release concept" which aims at optimally design the necessary flows/duration of these releases on the basis of "expected results" clearly defined by the stakeholder. The most common "expected results" range from simple surface cleaning of coarse alluvial substrates (low flow/duration releases) to active lateral erosion of meanders (high flow/duration releases) and removal of alluvial vegetation from the medium bed. One of these objectives may concern reducing sand accumulation in downstream reaches that occurs, as a result of reduced bed-mobilizing flows and high sediment load from tributaries.

This is the case of the Selves River (164 km² watershed in the Massif Central - France) downstream of the Maury dam (Fig.1), which creates a reservoir with a 35 million m^3 storage capacity. Flow diversion has had a major influence on both average flows and floods. Dam spillovers are infrequent: a single event has occurred since the impoundment of the dam in 1947. The bypassed reach downstream of the dam (approximately 11 km long) is located in a narrow valley with numerous tributaries, which transport large quantities of sand during thunderstorms. Because of flow reduction downstream of the Maury dam, most of this sand accumulates in the riverbed of the bypassed section. This sand accumulation has been noted for several years by both stakeholders and the local hydroelectric company, Electricity of France (EDF). Therefore, it has been decided jointly to implement targeted water releases (i.e., flushing flows) to remove the excess of sand in order to improve fish habitat (refuges and reproduction zones).

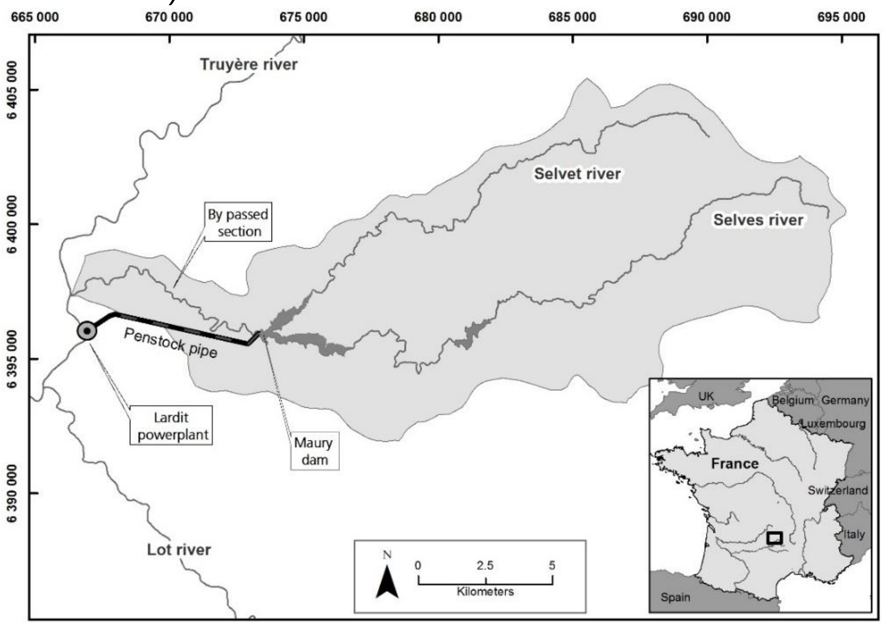

Fig. 1
The Selves River in France and the bypassed reach downstream of the Maury dam.

2. DESIGN OF THE WATER RELEASES

The objective of these experimental releases was to determine the most effective flow rate to remove fine sediments and sand from the river bed. Several flows are tested in order to determine the most efficient flow to entrain sand particles while avoiding the movement of coarser sediments essential to the functioning of the aquatic fauna. These tests will allow us to determine the flow magnitude and duration required for the overall rehabilitation of the bed, and then the frequency, magnitude and duration of the releases to be carried out routinely.

Three water releases of 10, 15 and 20 m^3/s were tested, each lasting 4 hours. To meet environmental and safety constraints, the hydrographs were characterized by a progressive ascent to 10 m^3/s to limit effects on fish, then a plateau of 1h at the same flow corresponding to an alert wave necessary for the safety of third parties. The target flow rates were then maintained for 4 hours. The transit time of these releases was estimated to be about 2.5 hours. However, we retained a duration of 4 hours to ensure the success of the operation. The releases were conducted on September 6, 13 and 20, 2016.

Fig. 2
Hydrographs of the clear-water releases conducted in 2016.

3. MONITORING PROGRAMME

To evaluate the effectiveness of the water releases, an ambitious monitoring programme has been implemented, targeting every major component of the aquatic ecosystem. Two monitoring objectives are targeted : (1) to directly evaluate the effectiveness of the releases (with respect to reduced channel bed clogging) and (2) to evaluate the overall effectiveness of flow restoration measures on biota over a period of at least 3-6 years. This article corresponds to the first phase of the study.

To monitor the efficiency of releases and to avoid environmental degradation, continuous measurements of conductivity, temperature and dissolved oxygen were conducted during the release. Water depth, Suspended Sediment Concentration (SSC) and turbidity were monitored during the releases at two stations. The first station is located immediately downstream of the dam in order to verify the hydrograph and the upstream TSS concentrations. The second station, located in the downstream part of the bypassed reach, serves to verify the diffusion of the hydrograph and of the silt in the bypassed reach.

116 transects spaced at 100-m intervals were surveyed between the Maury dam and the confluence with the Truyère River downstream during the summer preceding the three releases (t0) and in the autumn (t3) to quantify changes before and after the experiments. Within each transect (defined by its bankfull width), water depth, grain size distribution and the fine sediment thickness (silts and sand) were measured.

More detailed transects were also surveyed at 5 stations before the first release (t0), after the first (t1), the second (t2) and the third release (t3). The average station length was 250 m and each of them was composed of about 30 transects. These stations were supposed to be more clogged than the average observed on the river. The parameters measured at these cross-sections are the same as those of the previous protocol. At each of these stations, painted plots and scour chains were installed to determine the size of the sediments mobilized during the various releases.

At Station 4, coloured sand particles were also injected before the first release and before the third release. This method has been already implemented to track the movement of sands in coastal environments (Ingle, 1966) but few studies have used it in rivers (Grosprêtre, 2011). 400 kg of coloured particles (grain size 2-4mm) were placed on a river cross-section (Fig. 3) before each of two releases. Several sediment samples, of approximately 5 kg, were collected after each of the three releases over several hundred meters until the coloured particles disappeared in the samples. The number of sand particles present in each sample was assessed by image analysis. The sand used in each injection had a different color to improve the two releases comparison.

Fig. 3

Photograph of the injection of fluorescent sand tracers on a transect of the Selves River.

4. INITIAL RESULTS

4.1. WATER RELEASES DESIGN

The flow wave of each release was well propagated downstream. The discharge at Maury dam was equal to the flow generated at the downstream reach. On the other hand, the gradual ascent carried out to prevent aquatic fauna impact and ensure the safety alert was not observable at the downstream station. The flow rate quickly rose to the maximum nominal flow rate designed during the tests.

The duration of the hydrograph was sufficient to export the suspended sediment. The SSC was divided by 4, 3 and 2 after the three releases after only 2.5 hours of release, whereas the release has a plateau of 4 hours at maximum flow. During each release, the SSC rates became similar after 1h20 of maximum flow (Fig. 4).

4.2. SUSPENDED SEDIMENT TRANSPORT

The SSC reached 2.1 g/l, 1.6 g/l to 1 gl/l respectively for releases of 10,15 and 20 m^3/s (Fig.4), which is substantial given the morphological context of the valley. The SSC observed immediately downstream the dam were less than 0.1 g/l during the three releases carried out.

These results illustrate the effectiveness of the releases on the suspended sediments, which primarily come from the wetted channel, starting at only 10 m^3/s, as the particle size analysis show silt was infrequent along the cross-sections.

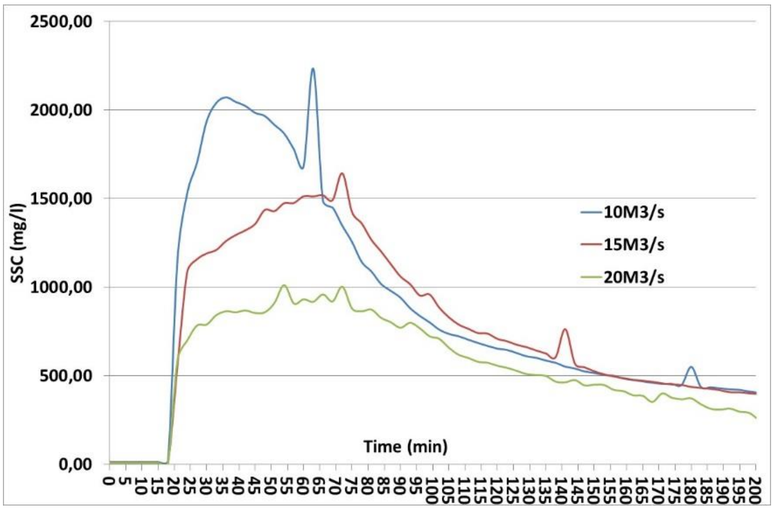

Fig. 4
SSC observed at the downstream station during each water release.

The SSC decreased with each successive release, despite the increased nominal flow rate (10, 15, 20 m^3/s). This decline in SSC production has been observed in other studies and is the result of the progressive scouring of fine sediment from the riverbed.

These initial results confirm that regular releases at relatively low flow rates (10 m^3/s) and lasting 5 hours could prevent clogging by silts and clays in the Selves River.

4.3. EFFECT ON BEDLOAD TRANSPORT

Fluorescent sand tracers were collected after each release. Their proportion in the sediment samples and the transport distance from the injection point were recorded. The results show a progressive change in mean position, distance travelled by a given fraction of the tracers and maximum distance travelled as a function of flow. The median, average and maximum transport distances have more than doubled between 10 and 15 m^3/s, which is not the case between 15 and 20 m^3/s. These findings clearly show that release efficiency increases with flow and that there is a relationship between the flow and the distance travelled by the tracers.

The 10 m^3/s release mobilized only a few gravels. The second release at 15 m^3/s mobilized the same grain size classes with a slightly larger amount of particules entrained. However, these latter were mobilized over short distances. During the last release, fewer plots were set up, but the results show a more damaging transport of coarse particles.

4.4. EFFECT ON HABITAT

The linear survey made it possible to characterize the initial state (t0) of sand and silt deposits along the Selves and to identify the tributaries contributing the most in fine sediments. It was then possible to measure the evolution between the initial state and the state after the three successive releases. The results are spatially heterogeneous. Both declines and increases in which both variables were observed over the entire length of the bypassed section. In particular, heavily clogged areas near the tributaries have tended to become unclogged and water depth has increased.

Changes in the fine sediment thickness are closely linked to the different geomorphic units. Fine sediment accumulation was non-existent in lotic reaches and in areas where pre-release clogging was already negligible. The most significant changes occurred in glides for which the median values and distribution were considerably reduced and concentrated.

Surveys carried out over the length of the bypassed reach showed that fine sediment thickness has been nearly divided by 3 on average. The proportion of sands and fine gravel remained essentially the same as the 3 releases were not long enough to allow for significant sediment exports outside the bypassed reach. Fresh sand deposits were observed on the channel banks after the releases, similarly to what it has been shown on the Colorado River [3]. Deposits were also been observed near the wetted channel and in some areas, vegetation has been covered with fines.

Reducing the stock of fine sediments in the river has had a positive impact on water levels and therefore on the habitats available for aquatic fauna.

5. CONCLUSION

The step-by-step design of water releases implemented in the Selves, even if it required considerable human and financial resources, has proven to be a worthwhile strategy. The flow rates were selected in an adequate range and through this process, the optimum flow rate for future operations was identified. We now know that a flow slightly less than or equal to 10 m3/s allows for a significant mobilization of the TSS and that a flow of 15 m3/s allows a much more significant mobilization of the sand fraction. In addition, even if the risk of mobilizing coarser sediments remains relatively low, the cost/benefit of using higher flows does not appear to be worth it. The morphological evolutions observed indicate that in rivers with a high sand load, even modest flows can achieve morphological changes in the active channel.

From an environmental point of view, the various objectives were achieved. There was substantial evacuation of sand and silt in the bypassed section that even exceeded our expectations, thereby improving the quality of available spawning areas. Furthermore, at the upstream station, new habitats are available for aquatic fauna in relation to the increase in water level.

SUMMARY

Integrated management of sediment and flows downstream of dams is still relatively rare, including in France. Flow experiments are often necessary to determine appropriate management actions and to verify that environmental objectives (often various) are being met. One of these objectives may concern reducing sand accumulations in downstream reaches that occur as a result of reduced bed-mobilizing flows and high sediment load from tributaries.

This is the case of the Selves River (164 km² watershed in the Massif Central - France) downstream of the Maury dam, which creates a reservoir with a 35 million m^3 storage capacity. Flow diversion has a major influence on both average flows and floods. Dam spillovers are infrequent : a single event has occurred since the impoundment of the dam in 1947. The bypassed section downstream of the dam is approximately 11 km long. This section is located in a narrow valley with numerous tributaries, which load large quantities of sand during thunderstorms. Because of flow reduction downstream of the Maury dam, most of this sand accumulates in the riverbed of the bypassed section. This sand accumulation has been documented by both stakeholders and the local hydroelectric company, Electricity of France (EDF), for several years. It has therefore been decided jointly to implement targeted water releases to remove the excess sand in order to improve fish habitat (refuges and reproduction zones).

The first empirical calculations estimated that the displacement rate of the sand would be about 10 m^3/s. Implementing a water release at a discharge below this value would risk using water with no significant effect on riverbed morphology. Therefore, 3 operational water release tests (10, 15 and 20 m^3/s) were carried out in September 2016 to define the discharge necessary to transport a maximum of sands without mobilizing the coarser elements (gravels and pebbles) necessary to aquatic organisms. The release duration was limited to 5h for each test to minimize environmental impacts and potential problems associated with dam operations.

Suspended sediment monitoring carried out during the releases show a recovery of the stock of fine sediments (clays - silts) present in the bypassed section. At one of the stations, fluorescent particles (2-4 mm) were added prior to releases to observe the distance traveled by the particles as a function of the released discharge. In addition, biological monitoring is underway to elucidate the long-term ecological effects of the releases. The latter two approaches will only be partially discussed here.

The results indicate that the flow rates were selected in the appropriate range for the stated objectives. Furthermore, it was possible to determine the optimum discharge for future releases: a flow rate equal to 10 m^3/s allows a significant mobilization of suspended sediments and a flow rate of 15 m^3/s allows for substantial mobilization of the sandy elements. Above 15 m^3/s, although the risk of mobilizing coarse elements remains relatively low, the cost-benefit ratio of this discharge level does not appear to be advantageous. From an environmental perspective, the different objectives were achieved.

La mise en œuvre d'une gestion environnementale des débits en aval des barrages fait l'objet de plus en plus d'études scientifiques. Ces actions sont encore peu développées en France et des expérimentations sont nécessaires pour les mettre en œuvre car les objectifs sont multiples, tout comme les contextes dans lesquels ils sont conduits et les dimensionnements qui sont appropriés. L'un des problèmes concerne notamment l'ensablement des sections à l'aval de réservoirs lorsque celui-ci influence significativement les débits critiques alors que la charge provient des affluents.

C'est le cas de la Selves (164 km², affluent de la Truyère, dans le Massif Central) à l'aval de la retenue de Maury (volume de l'ordre de 35 millions de m^3). L'ouvrage, dont les eaux dérivées sont turbinées à la centrale de Lardit, a une influence majeure sur l'hydrologie moyenne et de crue du cours d'eau. Les déversements sont peu fréquents, une seule occurrence depuis la mise en eau du barrage en 1947. Le constat d'ensablement a été partagé entre les gestionnaires du territoire et EDF depuis plusieurs années. Il a donc été décidé conjointement la mise en œuvre de lâchers de dessablage en aval du barrage de Maury en vue d'améliorer les habitats de refuge et de reproduction pour la population piscicole. Le Tronçon Court-Circuité (TCC) de la Selves en aval du barrage mesure environ 11 km de long. Très encaissé, il reçoit de très nombreux affluents de faibles longueurs et très pentus, qui réagissent principalement aux phénomènes orageux au cours desquels ils transportent d'importantes quantités de sables. Du fait de la réduction des débits en aval de l'ouvrage de Maury, la plus grande partie de ces sables s'accumule dans le lit de la Selves.

Les premiers calculs empiriques ont estimé que le débit de mise en mouvement du sable sur la rivière était d'environ une dizaine de m^3/s. En dessous de cette valeur, le risque est d'utiliser de l'eau sans effet notable sur la morphologie. 3 tests opérationnels (10, 15 et 20 m^3/s pendant 5h – période courte permettant de préserver les milieux et de limiter les problèmes d'exploitation des ouvrages) ont été réalisés en septembre 2016 pour définir le débit permettant de transporter un maximum de sables sans pour autant mobiliser les éléments plus grossiers (graviers, galets) favorables aux organismes aquatiques. Un suivi physico-chimique de la qualité des eaux a été réalisé pendant toute la durée des lâchers montrant une reprise du stock de sédiments fins (argiles – limons) présents dans le TCC. Sur l'une des stations, des granules (2-4 mm) fluorescentes ont été injectées afin d'observer les distances parcourues par les particules en fonction des débits lâchés. En complément, des mesures biologiques sont mise en œuvre pour suivre les effets sur le milieu à plus long terme.

Les résultats soulignent que les débits ont été choisis dans la bonne gamme et permettent même de déterminer le débit optimum pour les futures opérations : un débit légèrement inférieur ou égal à 10 m^3/s permet une mobilisation significative des MES et un débit de 15 m^3/s permet une mobilisation bien plus significative des éléments sableux. Au-delà de 15 m^3/s, même si les risques de mobilisation d'éléments grossiers restent relativement faibles, le coût/bénéfice de cette gamme de débits n'apparait pas intéressant. D'un point de vue environnemental, les différents objectifs sont atteints.

1. INTRODUCTION

The aim of the project is to develop adaptation strategies for dams and reservoirs that take into account shifting precipitation regimes and their resulting discharge and water quality conditions.

For several years, changes in the precipitation regime have been observed in Germany. Rainfall in February to April shifted more into the summer. Although total annual rainfall remained nearly the same, the resulting discharge was less due to higher losses in the summer months. As a consequence, reservoir operators experience difficulties in reaching full supply level in spring in order to fulfill existing and competing uses and requirements over the course of each year. This also impacts on local communities and water suppliers.

The emphasis of this study lies on the early recognition of droughts and corresponding reservoir management. The identification of possible counter measures if a drought situation becomes more likely is part of the project. The approach will be transferred into a concept for the adaptation of operation rules taking into account competing uses and target conflicts.

The approach uses hydro-meteorological indices to identify the need for counter actions at an early stage. Based on this, necessary individual and site-specific solutions can be worked out for each reservoir. It is envisaged to integrate the course of action identified during the research project into a guideline for Germany. German water authorities and a wide range of reservoir operators from Germany are involved in the research project.

The project ends in spring 2019.

2. DATABASE

Observation data on precipitation, run-off and climate data such as temperature, evaporation or sunshine duration was provided for the project from the participating reservoir operators. The data was collected from monitoring stations located in the study area for the period from 1970 to 2016 with a temporal resolution of one day.

Forecast data on precipitation was obtained from the National Oceanic and Atmospheric Administration (NOAA) [1]. Since May 2011, NOAA issues long-term forecasts of monthly values. This is a relatively short period, so that the data still lack extreme values or extreme events respectively.

NOAA data is given in a grid format with a resolution of approximately 0.94 degrees. In the context of bias correction, it had to be determined with which ground stations (see Fig. 1) and observed values the NOAA data can best be correlated in order to be able to recognize and correct any bias.

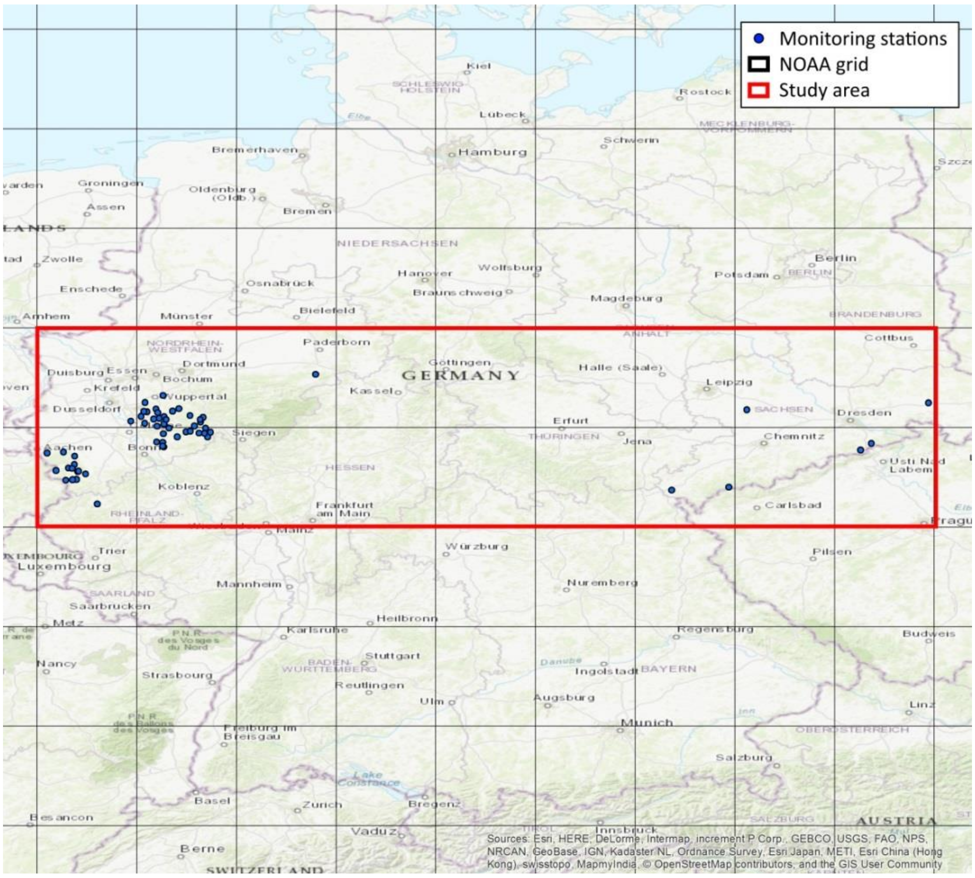

Fig. 1
Relation between study area, monitoring stations and NOAA raster data

3. METHODS

3.1. NOAA FORECAST DATA / BIAS CORRECTION

Bias correction was performed using two different methods: quantile mapping and formation of monthly factors.

The monthly factors were calculated for each calendar month. First, average values for each month were calculated for each observation station and forecast grid over the entire time period for which observed and forecasted datasets are available. This was the time period from 2011 to 2016. Then, the correction factor was calculated for each month by computing the ratio between the observed and the forecasted values. The correction factors are specific to each combination of observation station and forecast grid. Bias corrected forecasts could then be obtained by multiplying each value of the forecasted time series with the appropriate monthly correction factor.

Bias correction using quantile mapping (qmap) was performed according to the method developed by Gudmundsson et. al. [3]. This method entails an empirical adjustment of the distribution of the forecasted values to fit the distribution of the observed values.

The results of using both bias correction methods individually and of using quantile mapping followed by a correction using monthly factor were evaluated using goodness of fit indicators such as the Pearson coefficient, Nash-Sutcliffe efficiency coefficient, bias error, mean absolute error and mean square deviation.

3.2. INDICES

Hydro-meteorological indices play a crucial role in the project. Indices have to be interpreted from the viewpoint of reservoir operation. As indices have differing inertia and apply to different periods, they can be used for predictive operation.

The appropriateness of these indices, the way they should be interpreted and their usefulness regarding early detection of hydrological stress, is tested by conducting hindcast experiments. Indices providing the best skill in hindcast experiments are selected for conducting forecasts. As long as the forecast quality is adequate, this will lead to an enhancement of the current early detection methods.

For a start, the Standardized Precipitation Index (SPI) was used. The SPI is recommended by the World Meteorological Organization for meteorological drought monitoring [2]. The SPI can be calculated for different aggregation periods, e.g. only one month or even up to 60 months.

In order to address uncertainty contained in the forecasts, the SPI is calculated for time periods that extend both into the past as well as into the future, thus consisting of different amounts of observed and forecasted values. The performance of indices calculated with different observed and forecasted aggregation periods was compared with results that used only observed values for computing SPIs. In doing so, it is possible to determine how reliable the SPI computed using forecast data is for different forecast lengths.

In a next step, the Standardized Precipitation Evaporation Index (SPEI) and the Water Supply Index will be tested in terms of their suitability.

4. RESULTS

4.3. BIAS CORRECTION OF FORECAST DATA

Examples for a monitoring station in eastern Germany are shown. The accuracy of the bias-corrected forecast time series was evaluated by means of the above-mentioned goodness of fit measures (see Table 1). Mean absolute error as well as mean square deviation were significantly improved, the Pearson coefficient only slightly. Looking at the bias error, the perfect value of one is nearly achieved.

Table 1
Error values before / after correction, example eastern Germany

Goodness of fit measure	before correction	factor corrected	qmap corrected	qmap + factor corrected
Pearson coefficient	0.51	0.62	0.54	0.55
Bias error	0.77	1.00	1.01	1.02
Nash Sutcliffe eff. coefficient	0.05	0.39	0.001	0.19
Mean absolute error	29.04	21.87	26.57	24.69
Mean square deviation	37.34	28.78	33.46	31.70

In addition, a qualitative statement can be made using a line graph (see Fig. 2), which maps the graphs for the forecast values before and after bias correction and the observed values. A direct comparison of the original NOAA monthly mean values with the values of the stations showed that amplitudes were not sufficiently reflected. After the bias correction, however, the range of observed values was enhanced and an improved representation of inner-annual patterns was achieved.

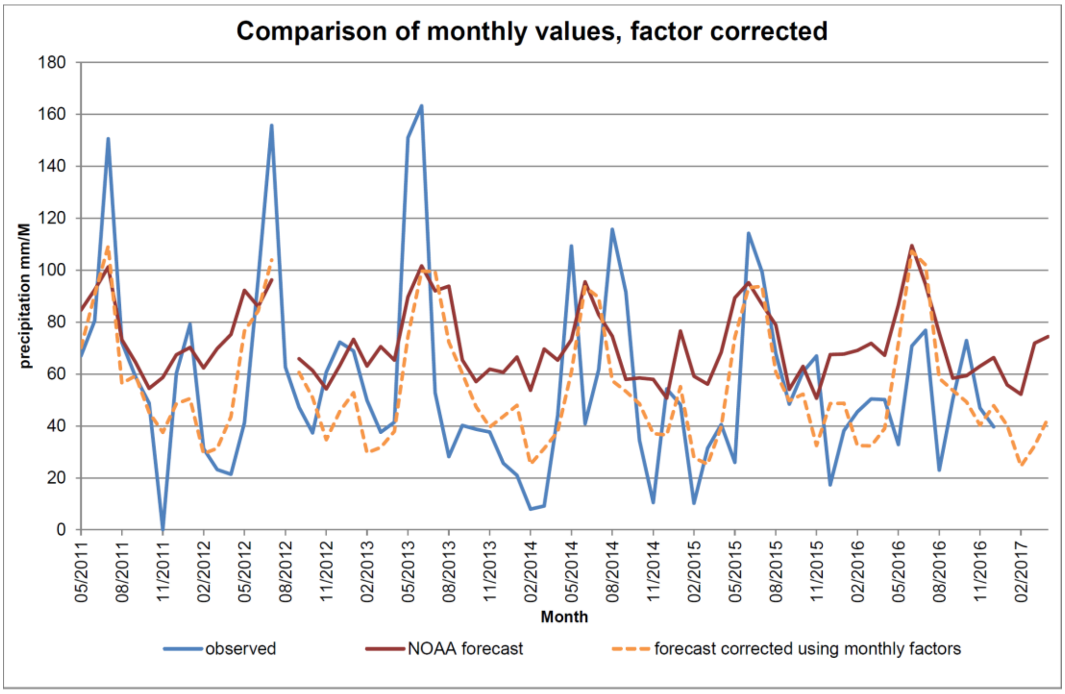

Fig. 2
Comparison of NOAA forecast data before / after factor correction, example eastern Germany

It was found that the quantile mapping method does not produce results that are usable for this study. The reason is that quantile mapping does not take the temporal sequence of values into account, but only adjusts the distribution of values. If, as is the case here, the input time series already contain large differences regarding the temporal sequence of values, quantile mapping can even amplify these differences and produce time series whose goodness of fit parameters are in some cases worse than those of the original time series (see Table 1 and Fig. 3).

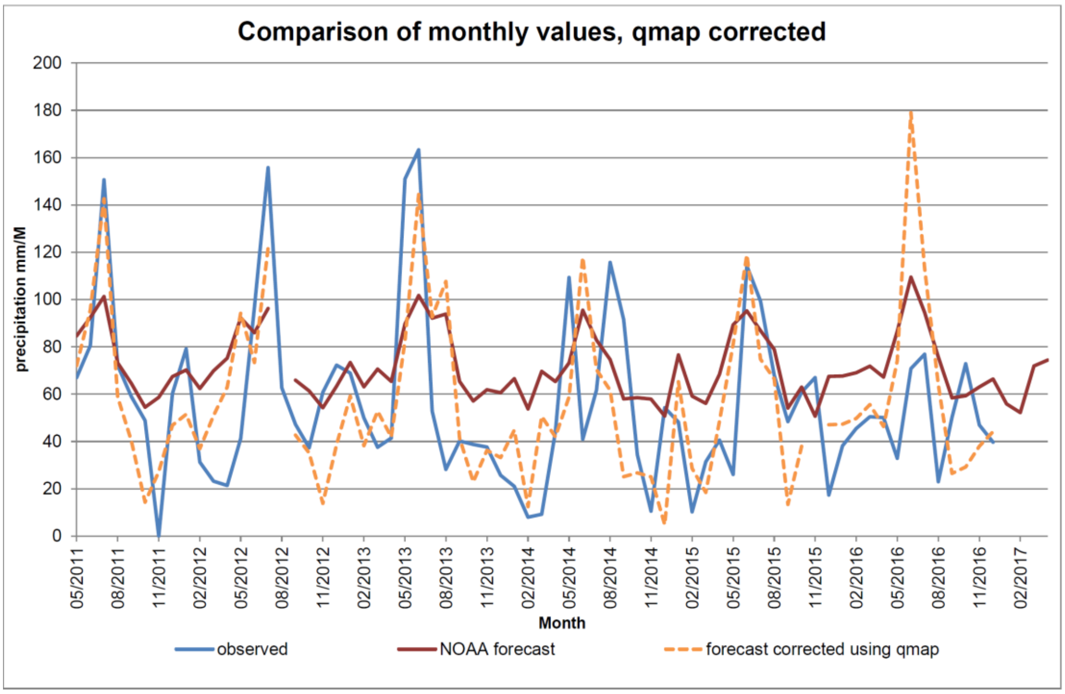

Fig. 3

Comparison of NOAA forecast data before / after qmap correction, example eastern Germany

Performing the bias correction using monthly factors consistently produced better goodness of fit parameters (see Table 1).

Tests using quantile mapping and monthly factors in sequence also produced worse results than using monthly factors alone (see Fig. 4).

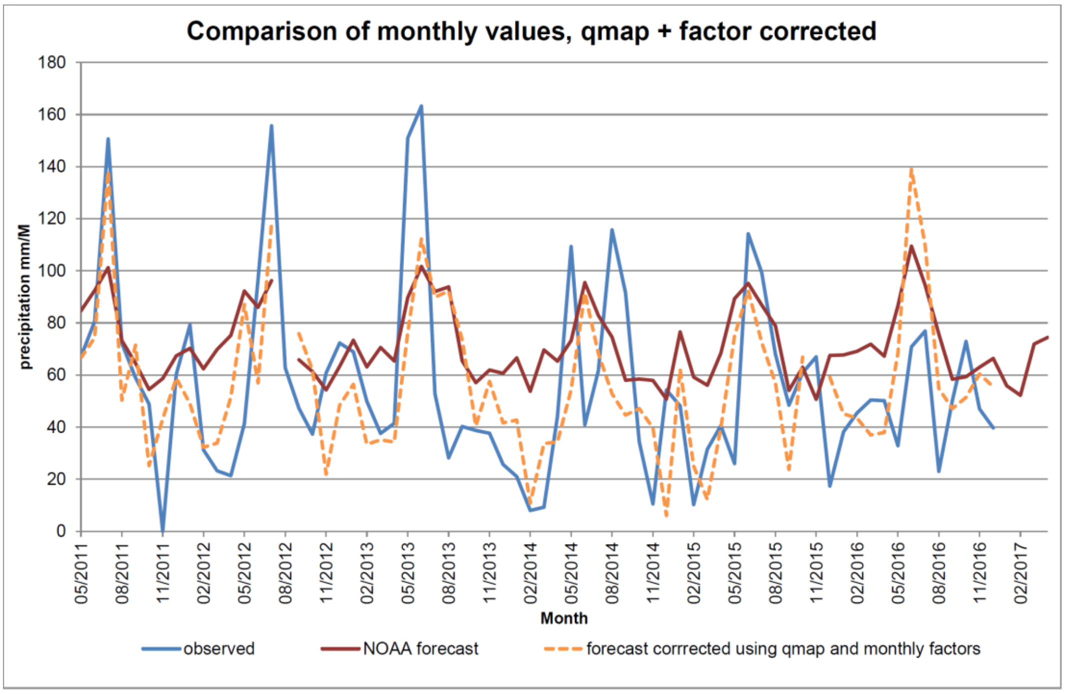

Fig. 4
Comparison of NOAA forecast data before / after qmap and factor correction, example eastern Germany

4.4. INDICES: SPI

Based on observed and bias-corrected forecast data, the SPI was calculated for different aggregation periods. The SPI calculated using only observed data ("certain knowledge") was compared with the SPI obtained by considering different fractions of observed records and NOAA forecasts.

Fig. 5 shows results for a 12-month aggregation period for two ground stations in eastern Germany. The SPI calculated using NOAA forecasts reveals a good fit in comparison to the SPI based on measured data and more significantly exhibits the same tendency for upcoming dry periods.

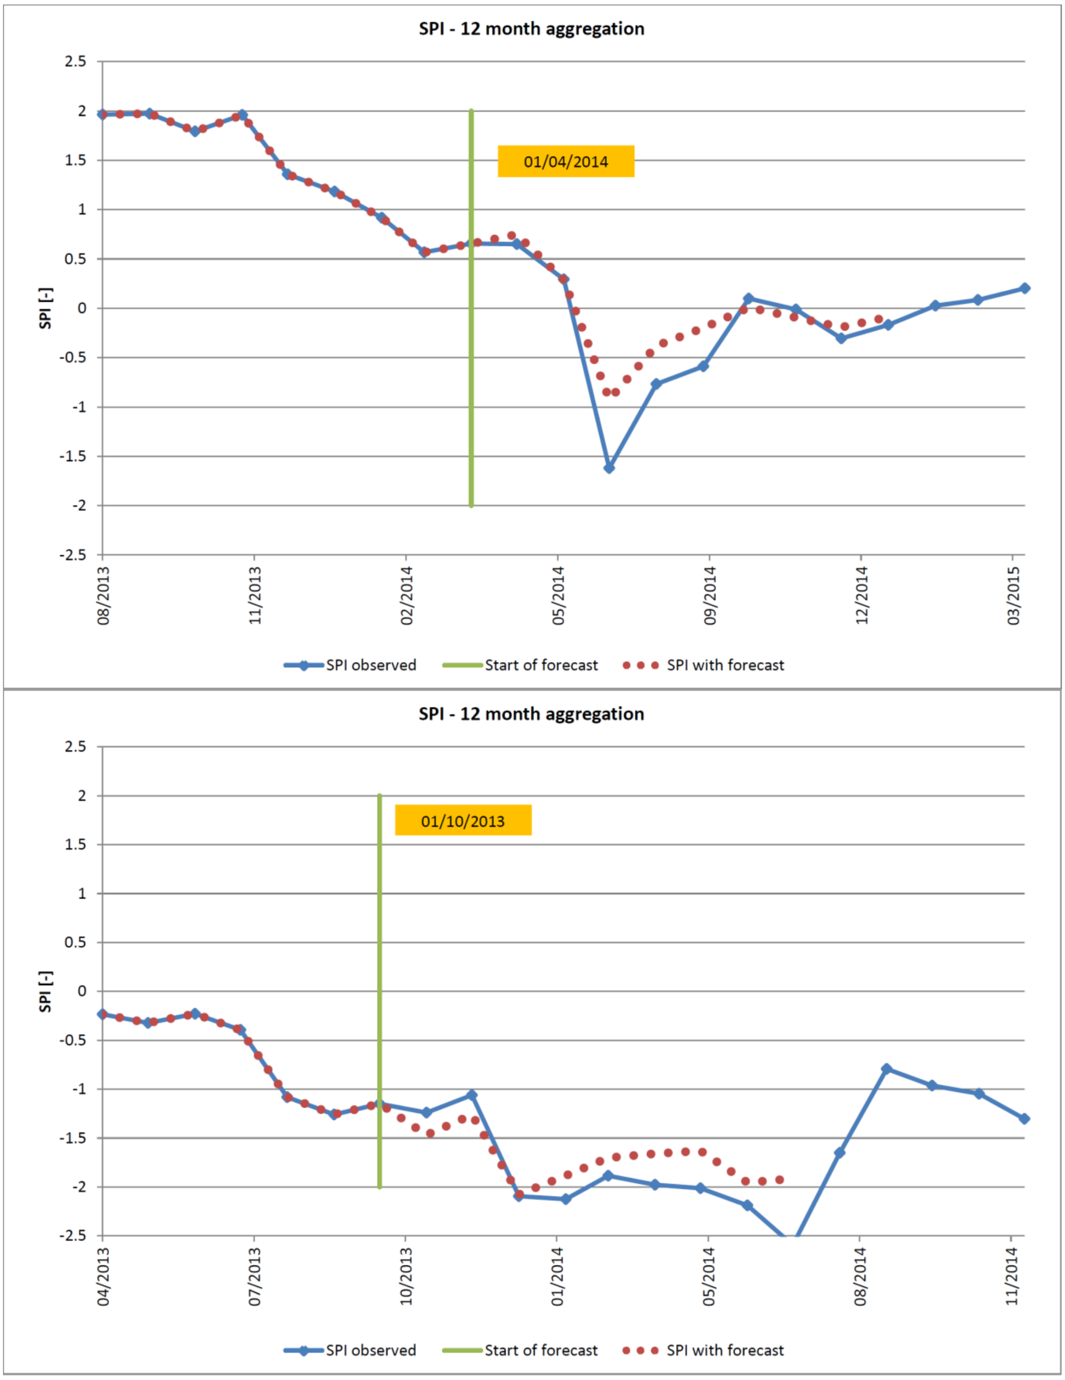

Fig. 5
SPI calculated with observed / NOAA forecast data, examples from different sites in Germany

5. ADJUSTMENT OF OPERATION

Once the SPI (or indices in general) is calculated based on past and forecasted values, it can be used to adjust operation of reservoirs. Adjustment cannot be established in a general way but requires site-specific rules. However, what can be generalized is the way in which the results of indices are introduced. First, site-specific operation rules best suited for intervention must be identified. Second, threshold values for indices must be identified for when intervention should be triggered. Third, the aggregation period is highly dependent on the local situation and needs to be determined for each individual case.

Reservoirs in West-Germany with catchment areas ranging from 250 to 600 km², operated with pool-based rules, could be improved by using a 9 to 12 month aggregation period and a threshold value of -1.5 (SPI + Evaporation based indices). When the index dropped below -1.5, release rules associated with the next lower pool were applied to counter an expected decrease of inflow. This meant a reduction of downstream releases or a different release pattern related to inflow and depending on the time of year and current storage volume. Not surprisingly, not all critical periods could be identified by applying this approach. However, two thirds of critical low flow conditions with corresponding low water levels in the reservoirs could be tackled in a timely way. The approach was used without forecasts prior to 2011 and as of 2011 with forecasts to make full use of the observation period with more than 100 years.

In central Germany, a reservoir with a catchment area of less than 50 km² revealed a different pattern. Only aggregation periods longer than 18 months with a threshold value of -1.0 showed good results. Shorter aggregation periods or lower threshold values were either not consistent enough or started too late to result in counter measures that took effect. In this case, the target operation rules for intervention was water supply provision. Similar to a hedging rule, water provision was subjected to a quota of a rather small percentage as soon as the index dropped below -1.0 to prevent larger reductions later on. In doing so, the reservoir could be mostly kept above a water level that becomes critical from the viewpoint of water quality.

The initial assumption that the size of a catchment area is a reasonable parameter for estimating aggregation periods could not be confirmed. The interplay between climate, the catchment area’s geology as an indicator for inertia and the reservoir itself seems more complex. As a result, each reservoir or reservoir system must be individually scrutinized to find the best set of aggregation periods and threshold values.

ACKNOWLEDGEMENTS

The project is funded by the Federal Ministry for the Environment, Nature Conservation, Building and Nuclear Safety (BMUB).

SUMMARY

The aim of the project is to develop adaptation strategies for dams and reservoirs that take into account shifting precipitation regimes and their resulting discharge and water quality conditions.

The emphasis of this study lies on the early recognition of droughts and corresponding reservoir management. The approach will be transferred into a concept for the adaptation of operation rules taking into account competing uses and target conflicts.

The approach uses hydro-meteorological indices to identify the need for counter actions at an early stage. Long-term precipitation forecasts from NOAA are bias-corrected for individual ground stations in Germany, for which observed precipitation data is available. The forecasted precipitation values are then used to calculate indices (e.g. Standardized Precipitation Index (SPI)).

Conclusions are that the SPI calculated using forecasted data adequately represents the SPI calculated from observed data. In particular, upcoming dry periods can be detected using the forecasts.

Using the forecasted SPI to adjust reservoir operation rules based on a certain trigger threshold for the SPI in one case lead to reduced critical low flow conditions. In another case, using operation rules adjusted to respond to a certain SPI threshold resulted in fewer occurrences of reservoir water levels below a critical level. These case studies also showed that the SPI aggregation period and the SPI threshold value for triggering adjustments to the operating rules have to be determined individually for each site.

Further steps in the study will involve testing different indices and establishing generalized approaches for integrating index forecasts into reservoir operation.

[2]*Environment Research Center and Department of Environmental Health Engineering, School of Health,* ISFAHAN UNIVERSITY OF MEDICAL SCIENCES, ISFAHAN, IRAN

1. INTRODUCTION

The storage water in Zayandehrood dam reservoir is supplies drinking water demand of around 5 million peoples and also for agricultural and industrial consumption. The reservoir nominal capacity is 1.5 B m^3 and nowadays deceased to less than 200 M m^3 due to drought period. The present study aimed to explain the water quality of the reservoir with water quality index (WQI), national sanitation foundation water quality index (NSFWQI) and Carlson's trophic state index (CTSI).

2. MATERIALS AND METHODS

Five points were sampled within dam reservoir form 2016 to 2017. At each point, for bacterial, nutrient, heavy metal, and pesticide analysis, the surface (< 1 m depth) samples were collected and transferred to the laboratory. The other parameters including chlorophyll *a* and physicochemical parameter were measured on site by using CTD (Sea & san Technology: CTD 75M). The WQI, NSFWQI and CTSI were calculated.

3. RESULTS AND DISCUSSION

The pH and EC was relatively stable among and within the stations. Seasonally, high levels of turbidity were observed mainly during the cold weather.

The higher values of COD (sampling point No. 02) indicate water pollution, which is related to wastewater effluents discharged from recreational town. The CTD profiles at sampling point No. 05 for a chlorophyll *a*, temperature, DO, EC and pH were presented in Fig. 2. For other sampling point, the CTD profile was provided but data are not shown.

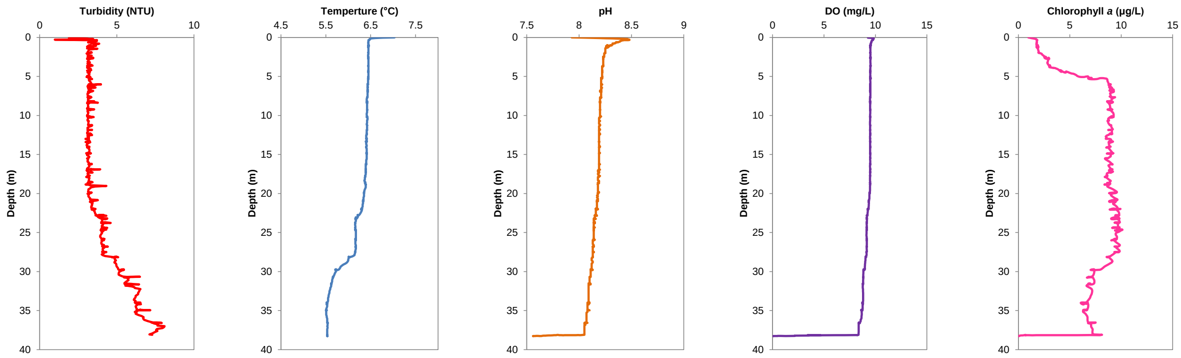

Fig. 1. CTD profiles at sampling point No. 05 (Winter 2016)

As seen in Fig. 2, the increasing of water depth led to decreasing of temperature, DO and pH values. But, the other parameters including turbidity and chlorophyll a showed the different pattern and increased. As seen in Fig. 2, at sampling point No. 05 (deepest point), the thermocline was typically at a depth of 25 to 30 m. The separation of the epilimnion from the hypolimnion is fundamental to lake processes because the stratification typically isolates the hypolimnion from sunlight and atmospheric oxygen. Thus, stratification typically separates the nutrient depleted, slightly less saline and algal enriched epilimnion from the oxygen depleted, nutrient enriched and slightly more saline hypolimnion.

Since, the analytical cost involved could be a limiting factor for reservoir quality assessments in developing countries, certain quality indices were used in this study. Fig. 3 shows comparison of WQI evaluations and trophic level for Zayandehrood dam reservoir.

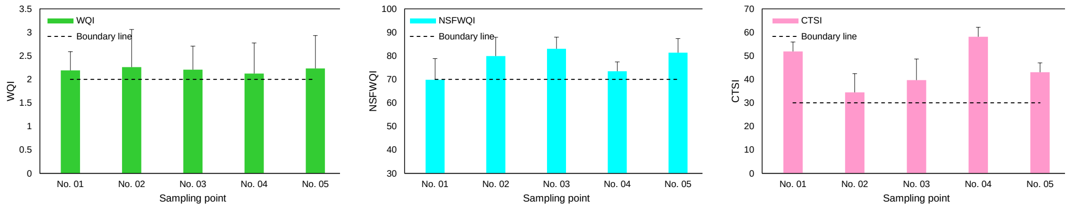

Fig. 2. Variations of WQI, NSFWQI and CTSI (2016-2017)

The values of WQI (WQI and NSGWQI) are in good agreement. The results indicated that WQI 2-3, NSFWQI from 70-90, while CTSI 35-60 for overall studied period.

4. CONCLUSION

Through WQI, NSFWQI and CTSI, it can also be concluded that physicochemical and biological and also trophic characteristic of Zayandehrood dam reservoir water shows sign of well physicochemical and biological characteristic, but mesotrophic (moderately productive) and eutrophic (highly productive) state.

ON THE ESTIMATION OF SEDIMENTATION LEVE IN IMHA DAM RESERVOIR, KOREA

Hongjun JOO, Duckhwan KIM, Jaewon KWAK, Hungsoo KIM

Department of Civil Engineering, INHA UNIVERSITY

KOREA

This study examined how to determine the optimal sediment level in dam reservoir for efficient plan and operation of dam. Currently, Korea is applying a horizontally accumulated method for sediment level estimation for the safety design of dam and so the method estimated relatively higher level than others. However, the sediment level of dam reservoir should be accurately estimated because it is an important factor in assessing life cycle of a dam. The sediment level in dam reservoir can be determined by SED-2D model linked with RMA-2, horizontally accumulated method, area increment method, and empirical area reduction method. The estimated sediment level from each method was compared with the observed sediment level measured in 2007 in Imha dam reservoir, Korea and then the optimal method was determined. Also, the future sediment level was predicted by each method for the future trend analysis of sediment level. As the results, the most accurate sediment level was estimated by the empirical area reduction method and the future trend of sediment level variation followed the past trend. Therefore, we have found that the empirical area reduction method is a proper one for more accurate estimation of sediment level and it can be validated by the results from a numerical model of SED-2D linked with RMA-2 model.

Table 1 Comparison of the method for sediment level estimation by case

Method for sediment level estimation	Sediment level (El.m)				Remark
	2007	Present (2017)	After 50 years (2067)	After 100 years (2117)	
Observed	110.00	Unobserved	Unobserved	Unobserved	Upstream of dam
RMA-2 & SED-2D model	110.58	111.21	112.43	114.22	
horizontally accumulated method	113.70	114.78	118.53	126.48	
empirical area reduction method	110.25	110.79	111.93	113.50	
area increment method	111.95	112.38	114.35	117.58

1. INTRODUCTION

The areas that rapidly increase the electricity demand in Indonesia are South Sulawesi and Central Sulawesi. these regions have potential electric power with Central Sulawesi electrification ratio reached 48.3%. Based on the potential, will be built hydro electric power Poso-1 dam located in the Saojo village, North Pamona, Poso, Central Sulawesi.

This hydropower in addition to serve the needs of the area around the project (Central Sulawesi), are also expected to support the electricity needs throughout Sulawesi, particularly the mining industry spread across South and Southeast Sulawesi.

2. ELECTRICAL SYSTEM IN CENTRAL SULAWESI

Up to the third quarter of 2014, the electrical system of Central Sulawesi Province is supplied by power plant generator centers, diesel and hydropower with total installed capacity is 314 MW with the composition of the plant is still dominated by diesel-fueled HSD amounted to 224.1 MW, or 71 % of total generating capacity, followed by hydropower for 63 MW or 20% of the total generating capacity of 27 MW and a power plant or 9% of total generating capacity. With the completion of construction of 150 kv transmission network Poso-Palu will maximize the evacuation of power from Poso hydropower electricity system, Central Sulawesi.

2.1. Electricity Projection Needs in Central Sulawesi

With the implementation of Special Economic Zones (SEZ) in the Palu city, in the future economy of Central Sulawesi will certainly increase. Almost all sectors of the economy will grow up. In order SEZ can running well, the electricity supply needs to be strengthened in order to support the Government's program. Based on electricity sales data within 5 (five) years and taking into account regional economic growth trends including the regional industry, population growth and increased electrification ratio on future, the projected demand for electricity from 2015 to 2024 can be seen in the following table:

Table 1.
Electricity Projection needs in Central Sulawesi 2015 – 2014

Year	Economic growth (%)	Sale (GWh)	Production (GWh)	Peak load (MW)	Customer
2015	10,90	957	1.081	208	518.509
2016	11,44	1.050	1.229	218	533.401
2017	12,15	1.188	1.382	246	572.185
2018	12,51	1.345	1.613	268	612.940
2019	12,69	1.520	1.805	302	653.976
2020	12,33	1.711	2.016	340	696.067
2021	12,33	1.904	2.229	378	728.451
2022	12,33	2.104	2.454	416	754.118
2023	12,33	2.308	2.677	454	772.538
2024	12,33	2.526	2.918	494	787.202
Growth (%)	12,13	11,4	11,7	10,1	4,8

2.2. Electric Power Development Plan in Central Sulawesi

The generation facilities construction plan in the Central Sulawesi Province regard to potential of local primary energy (hydropower) include the distribution pattern of population. Large hydropower potential of Poso watershed can be developed into a large-scale hydropower up to 575 MW. To meet the electricity needs until 2024, an additional generating capacity was planned about 457 MW with the following details:

Table 2. Development Plant in Central Sulawesi

No	Project	Capacity (MW)	COD
1	Ampana	2x3	2016

Construction of Hydroelectric Power Plant (HEPP) Poso-1 with 4x30 MW capacity will utilize water resources derived from Poso River, with headwaters in the form of Lake Poso.

3. HEPP POSO –1

3.1. Location

Hydroelectric Power Plant Poso-1 (4 x 30 MW Nett) is located in Poso River, administratively located in the District of North Pamona, Poso regency, Central Sulawesi Province. Geographically, the study area is located at position 120 ° 39'07.6 "- 120 ° 39 '35.8" east longitude and 01 ° 39' 49.5 "- 01 ° 40 '23.1" South Latitude.

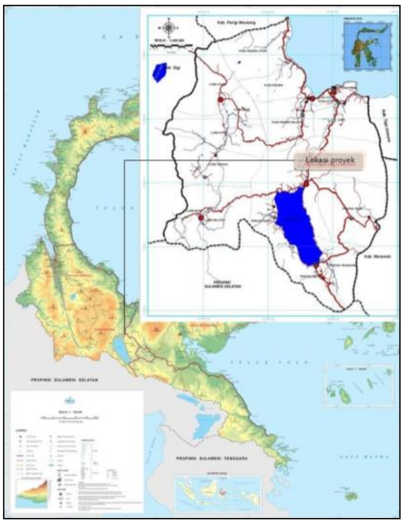

Figure 1.
Map of HEPP Poso-I, Indonesia

3.2. Purposes of HEPP Poso-I

Poso-1 Dam construction is part of Poso-1 hydroelectric project that serve as a regulating dam through Poso River from Poso Lake in Central Sulawesi Province. The purpose of the construction of Dams Poso-1 (regulating dam) is:

- Regulating water for electric power.
- Water supply in dry season.

3.3. Technical data

- Reservoir

Normal water level	:	+511,7 m
Reservoir volume	:	1,97 million m^3
Reservoir area	:	148 ha
Maximum water level	:	+512,7 m

- Dam

Type	:	Gravity dam
Heigh from deepest foundation	:	23,5 m
Dam volume	:	62.547 m^3

3.4. Reservoir Operation Rule

a) Poso Lake Water Level

Poso lake water level elevation Data varies from 509.3 m to 512.6 m. Higher elevation is assumed to be very high (flood / flood) and low (dry). To set up the lake, the water will be collected when the water level below the elevation of 511.70 m. When the water level above the elevation of 511.70 m it will be spill out through the gates of the natural capacity of the lake outlet, the highest elevation lakes will follow natural behavior. Because of this, the water level in the lake will not be lower than the existing high data so won't cause environmental impacts. While Minimum Operation Level (MOL) on the dam is setted at elevation of 507 m.

Determining the rule of operation based on the operation of the flow diagram is shown in Figure 5.

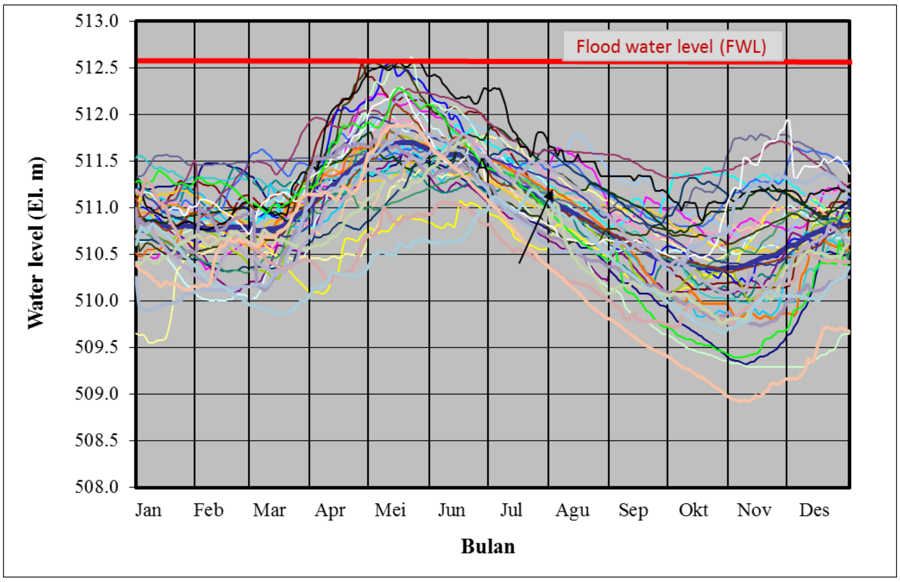

Figure 4. Water level rule chart of Poso Lake

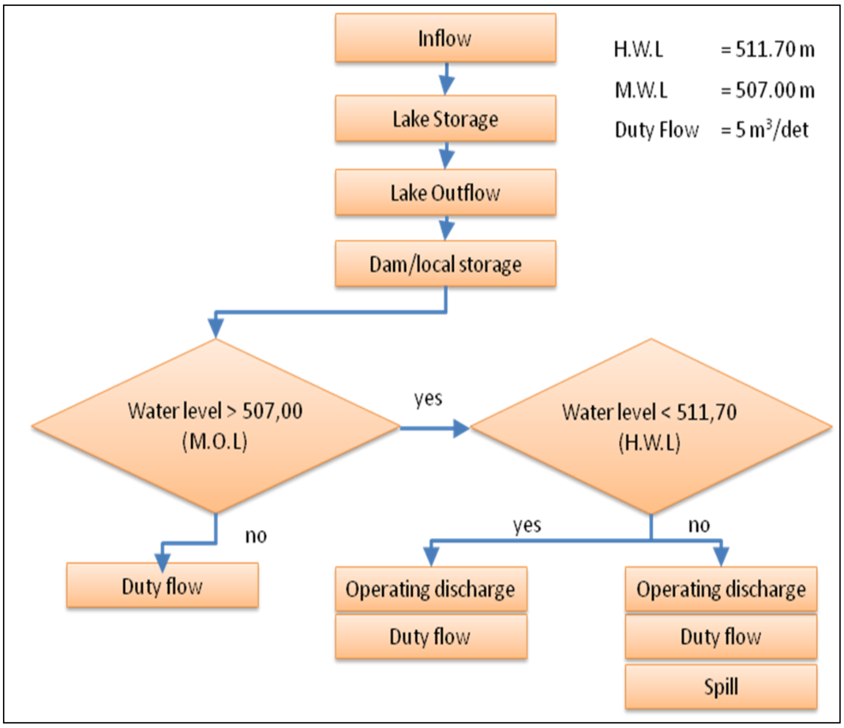

Figure 5. Operation rule chart

Operation rule bounderies without dredging:

- H.W.L = El.+ 511.70 m
- MWL = El.+ 510 m
- Poso lake operation rule using installed capacity of 160 m3 / s

In these conditions the technique things that happen are:

- When lake water level is high, the outflow is controlled by regulating gates.
- When lake water level is low, the outflow is adapted to the cross section of the lake.
- regulating gates will be functioned as a regulator discharge output after passing the peak of the rainy season, so the water reservoir can be utilized as an energy generator with a longer duration.
- The condition of lake water level before the peak of rainy season should be restored as a natural condition for giving the sufficient storage when large discharge into the lake and prevent the overflow above the secure elevation as social impact.

b) Scheme of Operation

Selection of the operating rule is done by making some alternative operating scheme. Alternative schemes operating pattern plan that is chosen is the scheme 2 of the various alternatives available in Table 3, Figures 6 and 7.

Table 3.
Comparison of Daily Averages for Operations Plan

Deskripsi	Skema-1	Skema-	Skema-	Skema-4	Skema-5
Plant discharge capacity (m^3/sec)	160	160	160	160	160
Daily rated discharge (m^3/sec)	160	93	103	108	113
Minimum operating discharge (m^3/sec)	40	40	40	110	113
Duty flow (m^3/sec)	5	5	5	5	5
F.W.L (m) untuk Q_{100}	512.84	512. 84	512. 84	512. 84	512. 84
H.W.L (m)	511.7	511.7	511.7	512.02	512.27
M.O.L (m)	507	507	507	507	507
Generated Energy (GWH/year)	425.0	403.9	410.2	408.7	413.1
Primary energy (GWH/year)	136.5	317.3	341.4	364.1	376.5
Secondary energy (GWH/year)					
Capacity Factor					

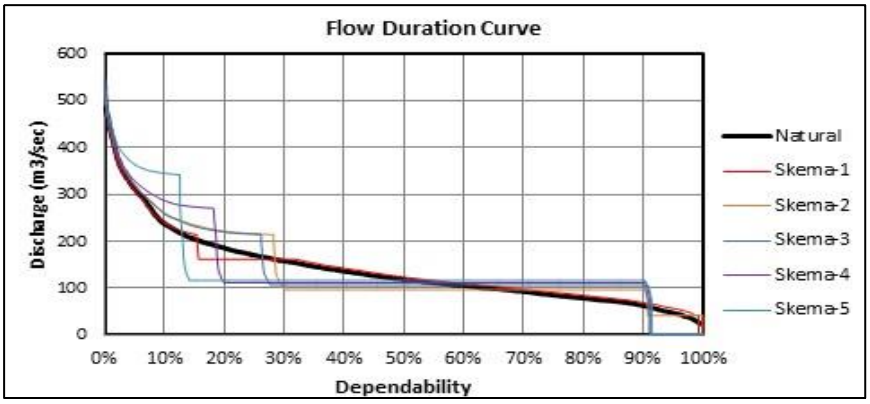

Figure 6.
Dependeble Flow

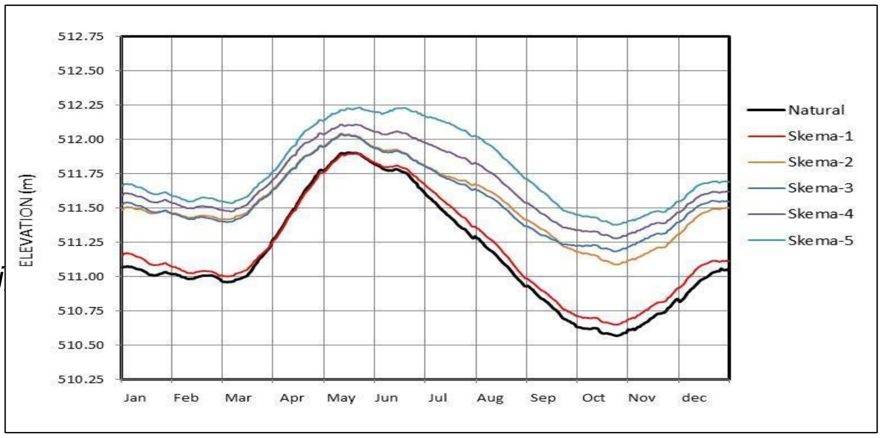

Figure 7.
Water level storage chart for each operation rule alternative

Scheme 2 has advantage that it fits the electricity absorption rules by the State Electricity Company and at dry season is still able to provide electricity at peak hours. Additionally, secure against potential flood in puddles, as well as the primary energy is fulfilled. While the drawbacks in the form of operating at low elevation reservoirs is limited. This scheme has the flexibility to be converted into one scheme in wet years and became scheme 3 when targeted to generate a larger primary energy.

From the simulation shows that:

- High water level during the rainy season can be arranged with a longer duration to be able to meet the flow of water in the dry season.
- Lowest lake water level and lake lowest discharge setted up from October into November.
- With longer dependable discharge duration will be able to increase energy.
- The elevation of annual highest Lake water level average is at 512.01 m and lowest at 510.24 m.

4. CONCLUSION

Based on the results of hydropower potential investigation and analysis in Central Sulawesi shows that:

- The potential for hydropower development in Sulawesi stored is still very large.
- Poso hydropower development can improve the welfare of people especially in the Centre Sulawesi.

5. ACKNOWLEDGEMENT

The authors would like to thank to Dam Safety Unit, Directorate General of Water Resources, Ministry of Public Works and Housing and also Poso-1 HEPP company for the authorization to publish the main result of the present study.

1. BACKGROUND

The construction of dams and reservoirs is experiencing a worldwide renaissance. There are international standards for the construction, the design and the safety of dams. However, similar standards for the subsequent operation of reservoirs do not exist. In contrast to construction, design and safety, the importance of decade-long reservoir operation and its impacts on environmental, economic and social issues is strongly undervalued.

Neglect, inadequate monitoring and data management, a lack of strategies for dealing with competing uses and insufficiently trained personnel lead to enormous problems that translate to failure to meet water usage goals, an inefficient use of resources and considerable environmental impacts. This applies in particular to developing parts of the world such as Africa and South-East Asia.

In contrast, reservoir operation e.g. in Germany is very sophisticated, involving detailed release strategies, risk management, coordinated operating rules for reservoir systems, the use of real-time models to support operation and even the use of scenario simulations to account for climate change and other uncertainties.

2. CURRENT SITUATION

In technologically highly advanced countries such as e.g. Germany it is considered state of the art to model the long-term operation of reservoirs using simulation models, to adjust operation rules to changing boundary conditions on the medium term by looking at scenarios and to react proactively to current events in the short-term.

The practical aspect of reservoir operation is supported by the use of simulation software in which current environmental conditions such as water levels, discharge, precipitation and temperature are recorded and visualized. The necessary operational settings are made based on these observations and the operating rules. In the case of multipurpose reservoirs (e.g. hydropower, flood protection, water supply), the use of simulation tools makes it possible to develop operating rules that are optimized towards catering to all purposes as much as possible and at the same time contain solutions and approaches for dealing with conflict situations. Simulation tools also allow for risk management, coordinated operation and emergency plans to be incorporated into the operating rules.

In other regions such as Africa and South-East Asia, operating reservoirs based on complex operating rules and with the support of simulation tools is the exception. In most cases, operating rules either do not exist or are very simplified [1], [2], [6], [7], [8], [9]. In Ethiopia and Sudan, long and medium term operation is carried out using Excel worksheets [1]. Thus, the complexity of the local conditions, of cause-effect relationships and of target conflicts is hardly considered, if at all. Often, minimum releases for securing downstream ecosystems are not considered as an independent purpose of a reservoir [1], [10], [11], [12]. In Thailand, all reservoirs of the Royal Irrigation Department are operated using a so-called standard rule curve. This rule curve is derived in a simplified manner from precipitation data and reservoir size and provides the desired water level over the course of the year. Usually, this rule curve is not verified for site-specific suitability [2], [3], [8]. In Myanmar, there are currently no guidelines for the operation of reservoirs. Each reservoir operator decides for themselves for example how much residual flow is granted to the downstream water course [4]. In Swaziland, there are reservoirs that do not have rules, monitoring nor qualified personnel [5]. In general, there is a lack of awareness among reservoir operators about the problems that lacking know-how can cause for reservoir operation.

In summary, the following problems can be identified:

- Insufficient data

- Lack of experience with the assessment and evaluation reservoir operation (sustainable vs. not sustainable)
- Lack of tools for assessing the effects of different operating rules
- Lack of strategies for solving conflicts when dealing with conflicting purposes
- Lack of suitable software for simulating reservoir operation both in the planning stages as well as for operational use
- Lack of adequately qualified personnel

This project aims to increase awareness of these problems among reservoir operators and to provide a tool that is suitable for transferring the knowledge necessary to tackle them.

3. PROJECT DESCRIPTION

In this paper, we present an innovative piece of software called the Reservoir Operation Simulator (ROPES), whose purpose is to support classic knowledge transfer (training) regarding reservoir operation.

The simulator is a tool for raising awareness and transferring existing knowledge regarding efficient, sustainable and environmentally friendly reservoir operation to regions where this is lacking and can thus aid in strengthening resource efficiency, reducing environmental strains and improving sustainability.

ROPES can be used to train local reservoir operators regarding reservoir operation while considering different climatological and hydrological conditions and competing uses and goals. Training exercises can cover the following topics:

- Strategies for serving conflicting uses and how to apply them to actual operation
- Impacts of reservoir operation with a focus on the natural environment
- Importance of monitoring and data management
- Integrated reservoir management consisting of catchment, upstream auxiliary dams, water transfers, reservoir water body, dam, operating facilities, power station, water courses
- Risk assessment, emergency planning, reporting
- Comparison of the effects of different operating strategies by simulating and evaluating different scenarios
- Necessity of regularly reevaluating and adjusting operating rules

4. ROPES

Similar to a flight simulator, ROPES mimics the actual control interface for reservoir operation and exposes the trainee to different conditions, in which he must make decisions regarding the operation of the reservoir.

Reservoir operators usually operate the reservoir using a supervisory control and data acquisition (SCADA) system that exposes the variables and controls necessary for supervision and operation of the system in a schematic interface (examples are shown in Fig. 1, Fig. 2, Fig. 3 and Fig. 4).

Fig. 1

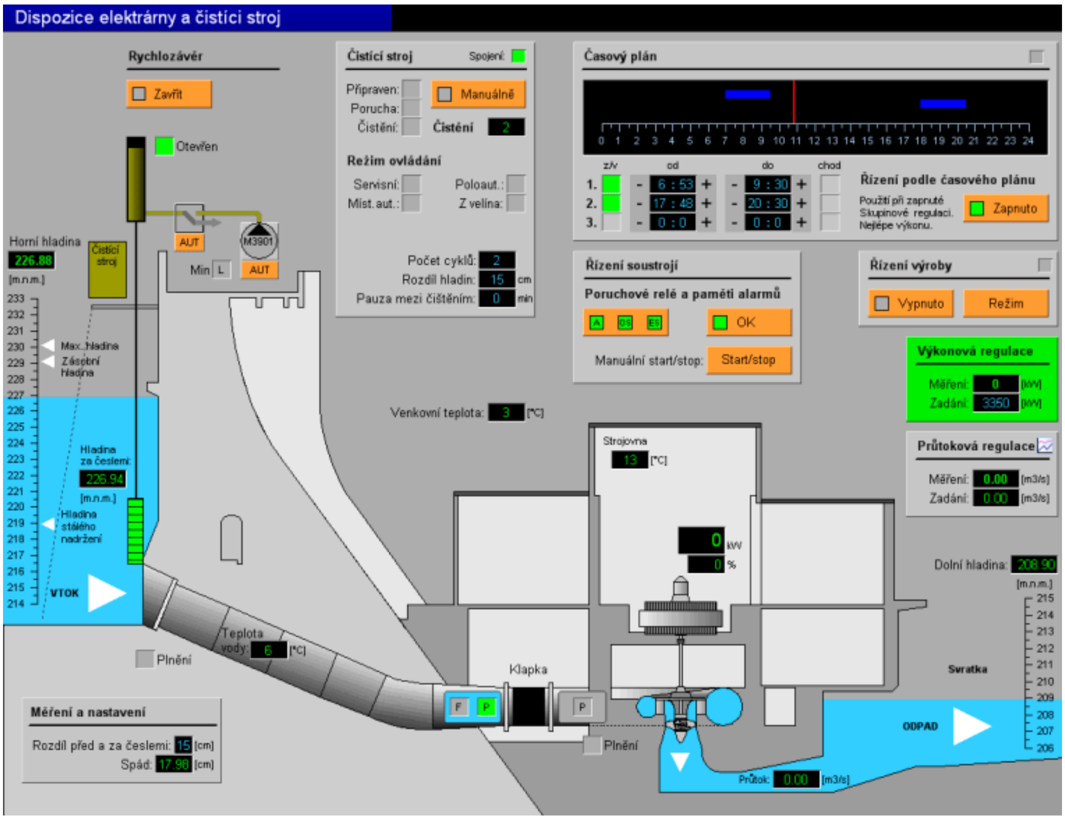

Fig. 2

SCADA interface in a small hydropower plant in Kníničky (source: promotic.eu)

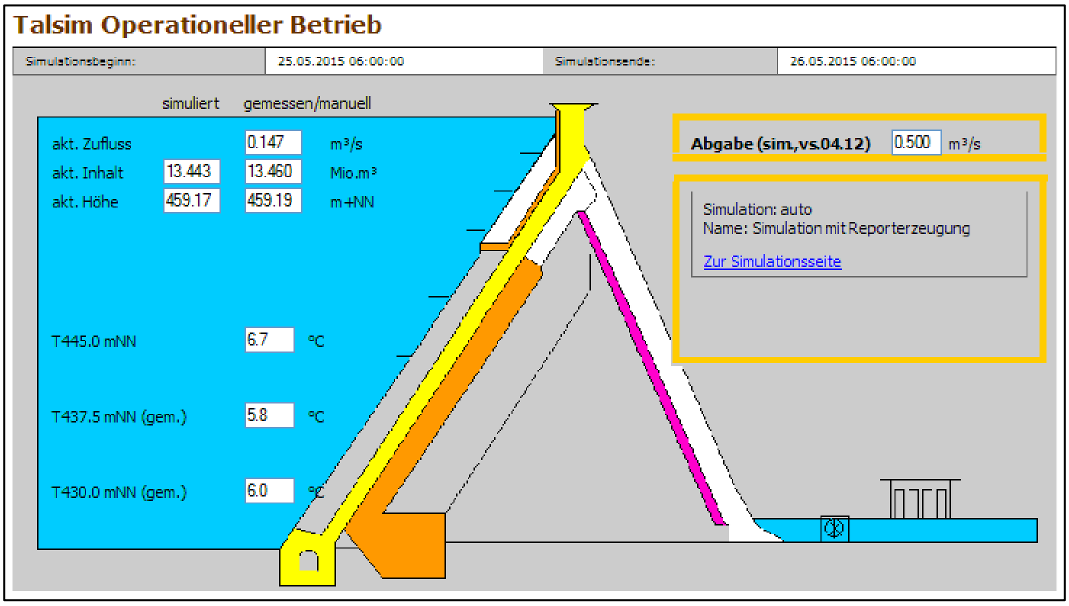

Fig. 3

Interface for the operation of a reservoir in Germany with real-time simulation results

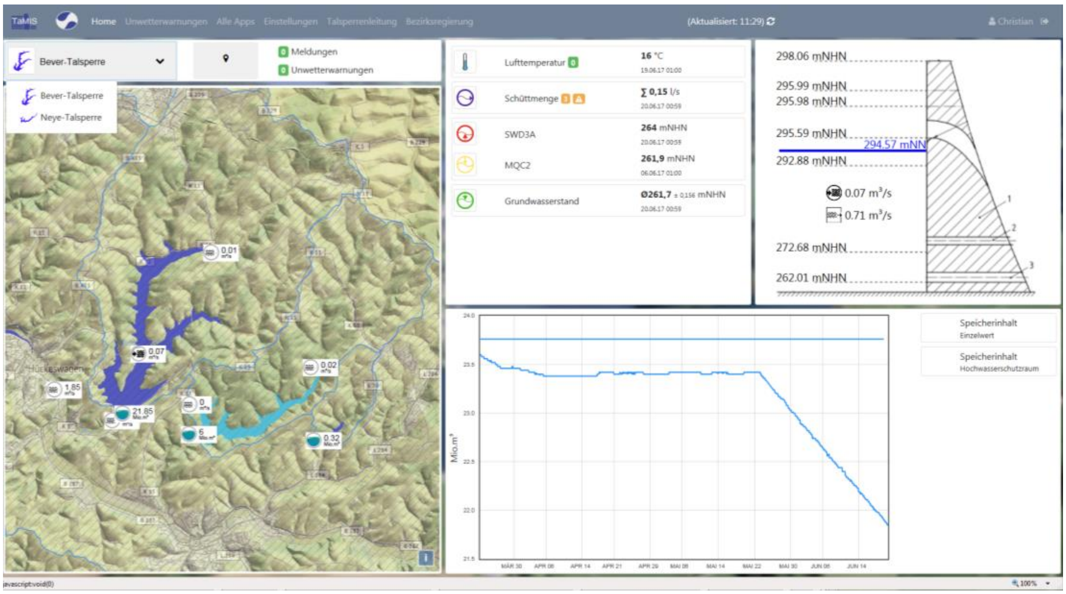

Fig. 4

Web interface of a reservoir monitoring system in Germany (source: fluggs.wupperverband.de)

The ROPES interface is highly customizable and designed to be able to mimic the control interface that the operator uses for actual operation. This also means that the interface visible to the trainee only exposes those variables and controls that he would be able to access during actual operation. So, depending on the system being simulated, the interface may only display a few simple variables such as reservoir water level and the status of the gates. Or, when simulating more complex systems equipped with more monitoring equipment, the displayed variables may also include measurements from across the catchment, as well as other information such as current demand values or even forecasts.

A second interface, only visible to the trainer or supervisor, acts as an administrative interface and allows the trainer to access all variables of the simulated system. With this information, the trainer is able to intervene in the trainee's decision-making while the simulation is still ongoing, if necessary. Ordinarily, however, the second interface is only used to review the trainee's decisions and their effects on the system in the review phase after the simulation has been completed.

4.1. SIMULATION ENGINE

ROPES uses the software Talsim-NG as the backend for running the simulations. Talsim-NG was developed by SYDRO and has been proven and tested as a simulation tool for reservoir operation, rainfall-runoff calculation and flood routing both in planning stages and in real-time operation for more than 15 years.

Talsim-NG has a proven track-record for being able to accurately simulate a wide range of different reservoirs and can consider all important aspects of reservoir operation simulation, including e.g. hydraulic constraints of turbines or other release openings. It also has the ability to accurately compute evaporation and precipitation onto the reservoir surface and incorporates a sophisticated algorithm for calculating the reservoir's water balance, even when multiple variable inflows and outflows are involved. Additionally, the rainfall-runoff and flood routing modules make it possible to simulate not only the reservoir itself, but also catchments and water courses.

Thus, the simulation engine is capable of simulating any existing, planned or fictional reservoir or even entire reservoir systems, including the catchments and water courses upstream and downstream of the reservoirs. It can utilize archived or real-time monitoring data from ground stations or remote sensing as input and can also integrate forecasts into the simulation.

Using Talsim-NG, it is possible to simulate the entire range of possible operating conditions, including exceptional events such as extreme rainfall or failure of control components.

ROPES distinguishes between the internal time step used for the actual simulation by Talsim-NG and the external, or operating time step which is the interval in which results and current conditions are displayed to the trainee and in which the trainee can make inputs.

The internal time step depends on the system being simulated and on the temporal resolution of the input variables.

The operating time step is adjusted to reflect the normal operating interval of the system being simulated. For example, if a reservoir operator usually makes operating decisions once a day, the operating time step is also set to one day. After each operating time step, the simulation is paused in order to await the decisions made by the trainee. The simulator then takes the trainee's decisions as input and calculates the effects of the decisions within the entire system during the next operating time step. Then, the interface is updated to reflect the new system state, and the simulation is paused again to await the trainee's decisions for the next operating time step.

When a simulation scenario includes situations in which the operator receives false or no readings from a malfunctioning instrument, the values displayed in the interface may deviate from the actual values used in the simulation or may be missing entirely from the interface. Similarly, the inputs made by the trainee can be configured to cause unexpected effects in order to simulate malfunctioning controls, e.g. a gate that will not open or close properly.

All decisions made by the trainee as well as all of the system variables, whether visible to the trainee or not, are recorded over the entire course of the simulation and output to result files so that it is possible to review the trainee's decisions and the effects that they had on the system after the simulation has ended.

4.2. SCENARIOS

The scenarios that are simulated using ROPES are designed and predetermined by the trainer. The trainee, on the other hand, does not know what exactly is going to happen during the simulation.

Scenarios can be adjusted to the trainee's level of knowledge and can become more complex or difficult over the course of the training exercise.

There is practically no limit to the kinds of scenarios that can be simulated. For example, scenarios can include different climatological and hydrological conditions and competing uses and goals.

Besides "normal" conditions, scenarios can also include exceptional occurrences such as large flood events, drought periods, the failure of monitoring equipment or malfunctioning controls.

Scenarios can utilize archived or real-time monitoring data from ground stations or remote sensing as forcing data and can also integrate forecasts into the simulation. As the simulation engine also contains a rainfall-runoff module, forcing data for the inflow to the reservoir can consist either of precipitation or of flow time series, or of a combination of both.

4.3. EVALUATION

An important part of the training exercise is the evaluation phase. Using the records from the simulation, all decisions made by the trainee and the effects that they had on the system are reviewed after the simulation has ended. The review process is accompanied by an experienced reservoir operator/expert. Aspects to be reviewed can include the following:

- Were all water supply and/or other demands met?
- Were all constraints on reservoir operation (e.g. maximum discharge, reservoir water levels) adhered to?
- Did the operator deviate from the existing operating rules? If so, could this have been avoided?
- Did the operator make the correct decisions while dealing with emergency situations?

If applicable, a scenario can be simulated again in order to assess the effect of different operating decisions.

5. ROADMAP

Institutions such as the Nile Basin Initiative, the Eastern Nile Technical Regional Office, the Mekong River Commission, the Ethiopian Institute of Water Resources of the Addis Ababa University and the Walailak and Kesetsart

Universities in Thailand have already expressed their interest in conducting a pilot study and aiding in the dissemination of the project's ideas.

Interested parties are invited to contact us at ropes@sydro.de to explore possibilities for cooperation.

SUMMARY

The use of a reservoir operation simulator for the training of reservoir operators is an innovative, target-oriented and motivational approach towards highlighting the importance of the management and operation of reservoirs.

In this paper, we present the concept of the Reservoir Operation Simulator (ROPES), which uses Talsim-NG as the simulation engine on the backend and a highly customizable SCADA-like interface on the frontend, as a software tool for conducting training exercises for reservoir operators.

UNSTEADY STATE APPROACH FOR ESTIMATION OF SEDIMENT TRANSPORT INTO RESERVOIR

Balkrishna Shankar. CHAVAN

Scientist-D, Central Water and Power Research Station, Pune.
India

1. INTRODUCTION.

Mathematical modeling is based on computation techniques, it has become very popular in the past few decades, mainly due to the increasing availability of more powerful and affordable computing platforms. Much progress has been made, particularly in the fields of sediment transport, water quality, and multidimensional fluid flow and turbulence. Many computer models are now available in the market. Some of the models are in public domain and can be obtained free of charge. Graphical user interfaces, automatic grid generators, geographic information systems, and improved data collection techniques (such as LiDAR, Light Distancing and Ranging) promise to further expedite the use of numerical models as a popular tool for solving river engineering problems.

A. Camenen and Larson (2007)

$$\Phi = 12\,\theta^{3/2}\,e^{(-4.5(\theta_{cr}/\theta))} \tag{1}$$

where

$$\Phi = \frac{q_b}{\sqrt{[g(s-1)d^3]}}$$

$$\theta = \frac{\tau_0}{\rho g(s-1)d}$$

$$\tau_0 = \rho C_D \bar{U}^2 \tag{2}$$

$$C_D = \left[\frac{k}{1+\ln\left(\frac{z_0}{h}\right)}\right]^2$$

k= Von Karman's constant =0.4

k_s= 2.5d_{50}

z_0= k_s/30

Where:

θ	= Shield's parameter
θ_{cr}	= Critical Shield's parameter
Φ	= Dimensionless transport number
q_b	= Volumetric bed-load transport rate per unit width
g	= acceleration due to gravity
ρ	= density of water
s	= ratio of densities of sediment and water
d	= grain diameter
C_D	= total drag coefficient
τ_0	= Bed shear stress
$\bar{U}$	= Depth averaged velocity

B. Engelund and Hansen formula- (1972)- Estimates total sediment load

$$S_t = \frac{0.05UC\tau_c^2\{1+0.5\left(\xi\frac{U_b}{U}\right)^2\}^2}{\rho^2 g^{\frac{5}{2}}\Delta\rho_s^2 d_{50}} \tag{3}$$

where

C	=	Chezy's coefficient
ξ	=	a coefficient
τ_c	=	Bed shear stress due to current, N/m^2
U_b	=	Amplitude of orbital velocity at the bed
d_{50}	=	Grain diameter

C. Ackers and White's (1973) Method – It is based on flume and field data, estimates total sediment load

$$\left(\frac{u_*}{U}\right)^{C_1}\frac{\gamma_f C_T D}{\gamma_s d} = C_2\left[\frac{F_1}{C_3} - 1\right]^{C_4} \tag{4}$$

where

$$F_1 = \left[\frac{u_*^{c_1}}{\sqrt{\frac{\Delta\gamma_s d}{\rho_f}}}\right]\left[\frac{U}{\sqrt{32\log\left(\frac{10D}{d}\right)}}\right]^{1-c_1}$$

$$d_* = \frac{d}{\left[\frac{\rho_f \nu^2}{\Delta\gamma_s}\right]^{\frac{1}{3}}}$$

a. For 1.0<d_*<60

$$C_1 = 1.0 - 0.56\log d_*$$

$$logC_2 = 2.86\log d_* - (\log d_*)^2 - 3.53$$

$$C_3 = \left[\left(\frac{0.23}{d_*^{\frac{1}{2}}}\right) + 0.14\right]$$

$$C_4 = \left[\left(\frac{9.66}{d_*}\right) + 1.34\right]$$

b. For d_*>60

$$C_1 = 0.0, C_2 = 0.025, C_3 = 0.17\ and\ C_4 = 1.50$$

D. **Meyer-Peter and Muller(1948**) An empirical relation based on a large number of experiments with uniform sediment 3–29 mm, in flumes 20–200 cm bedload transport equation applicable to gravel-bed rivers of coastal British Columbia is the Meyer-Peter & Muller (M-P&M) equation

$$\Phi = 8(\theta - \theta_{cr})^{3/2} \tag{5}$$

E. **Nielsen(2000)-**

$$\Phi = 12\,\theta^{1/2}\,(\theta - \theta_{cr}) \tag{6}$$

F. **The Bijker Equation:**

Bijker derived the total transport in to two parts, the bed load and suspended load transport. The bed load transport is calculated using the Kalinke-Frinjlink formula in which combined action of wave and current is accounted by a modification of the bed shear stress.

$$S_b = \frac{BDU\sqrt{g}}{C} e^{\left[\frac{-0.27\Delta\gamma_S d}{\gamma\tau_C\left\{1+0.5\left(\frac{\xi U_b}{U}\right)^2\right\}}\right]} \tag{7}$$

G. **Bagnold-Bailard Equation:** Bagnold (1960, 1966) developed an approach to bed load transport prediction that is based on stream power per unit channel width

Average velocity (U) can be given by

$$U = u_c + u_t \tag{8}$$

where u_c = fluid velocity due to current effect (m/s)

u_t = Orbital fluid velocity above the bed at time t (m/s)

assume u_c = U, then bed load transport S_b is related to IUI^2U

$$S_b(t) = \frac{\tau_0}{\left[1-\frac{\rho_f}{\rho_s}\right]}\left\{\frac{e_b}{tan\alpha} + e_s(1-e_b)\frac{\bar{u}}{\omega_0}\right\} \tag{9}$$

the suspended load transport Ss is related to IUI^3U and computed from

$$S_s(t) = \frac{\tau_0 U}{\left[1-\frac{\rho_f}{\rho_s}\right]}\left\{\frac{e_s}{tan\alpha} + e_s(1-e_s)\frac{\bar{u}}{\omega_0}\right\} \tag{10}$$

The Bijiker model predicts too small concentration magnitudes and too large fluid velocities in the near bed zone. These results in current related sediment transport rates that are 4 times for small transports (<0.001Kg/ms) and 4 times large transports.The evaluation of sediment transport based on above methods except Bijker and Bagnold is given in table2.

Table:1. Prediction of Sediment by Investigators

S No.	Investigators	Predicted Sediment ton

Present Studies:

(A)Proposed Equations for Steady State Flow:

Present studies describe prediction of sediment inflow based on the published data. The catchment area of the basin is 6271 square kilometer. Width of the river at gauging station is 71.4 m. Empirical equation in mathematical form is proposed based on the data sample of 1312 observations collected over span of 20 years.

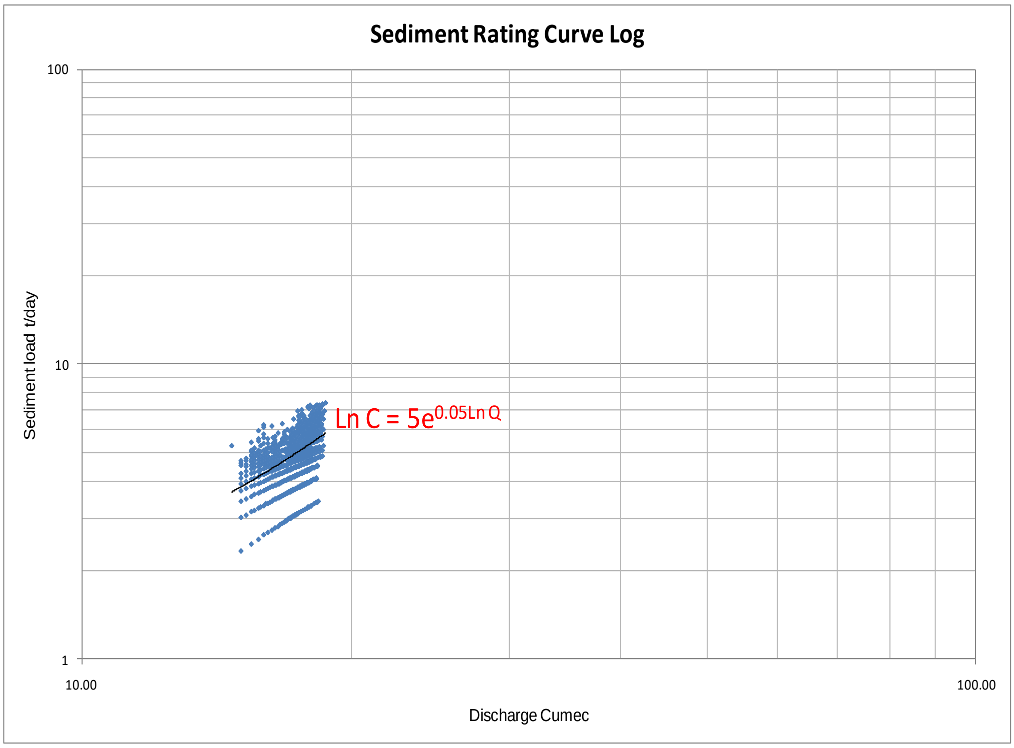

Fig. 1: Variation of Sediment Concentration and discharge (Log plot)

The Correlation coefficient R^2 for the equation (10) is 0.958457, which is shown in Fig. 2.

$$Ln\ (C) = 5e^{0.05(LnQ)} \tag{11}$$

Considering the data following power equation is proposed :

$$C = 700Q^{-0..9} \tag{12}$$

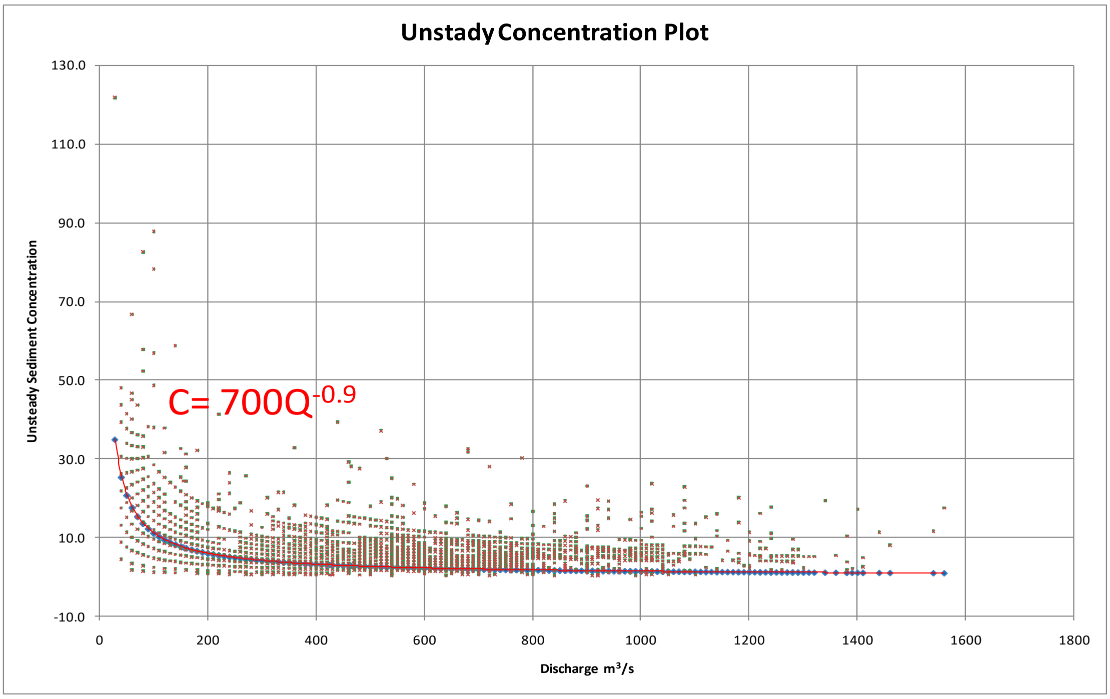

Fig. 2: Variation of Sediment Concentration rate and Discharge

It is hyperbolic curve, underestimates the sediment concentration. Therefore the data was re-analyzed and the proposed quadratic equation is:

$$C = 0.0005Q^2 - 0.2Q + 125 \tag{13}$$

The proposed equation (13) is of second order. It envelops 94 % of the sediment data at one hundred percent band width, it is also seen that 63% of the sediment data at fifty percent band width, which is shown in Fig. 3.

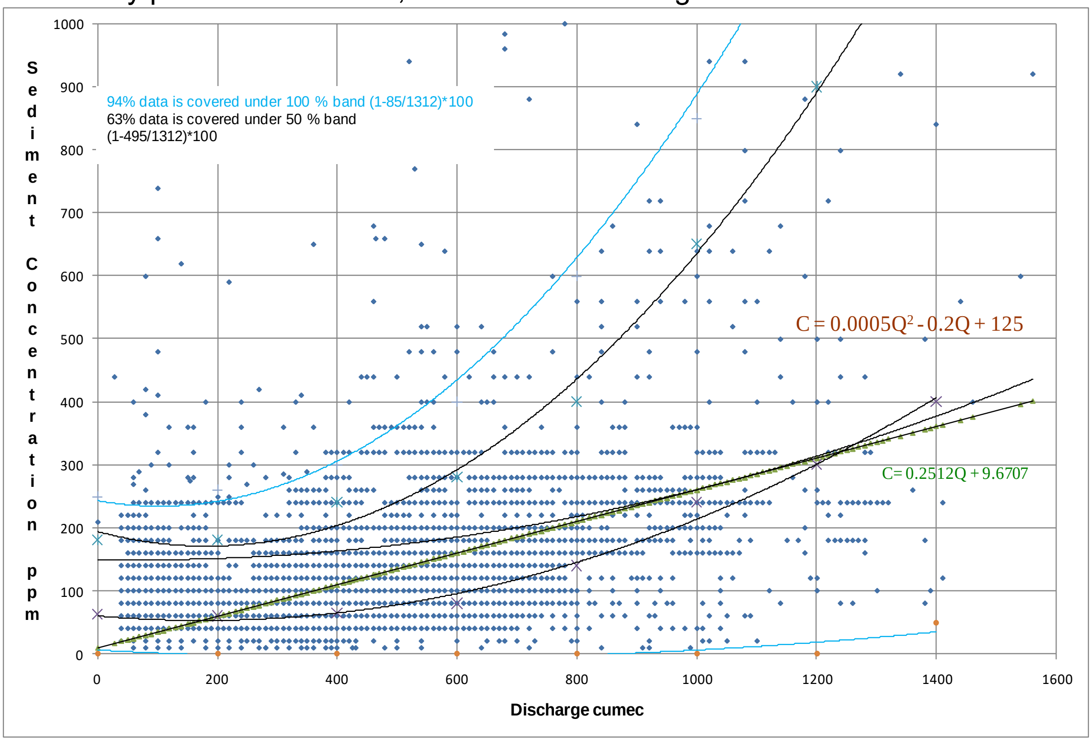

Fig. 3: Variation of Sediment Concentration and Discharge

The proposed equation (13) is of second order. It envelops 94 % of the sediment data at one hundred percent band width, it is also seen that 63% of the sediment data at fifty percent band width, which is shown in Fig. 3. Steady state flow equations which are compared with the observed data are tabulated in table2 given below:

Table:2. Prediction of Sediment for Steady State Flow Equations

S No.	Method/law	Predicted Sediment ton
Present Studies		
Steady State Flow Equations		
1.	Log-log plot $5e^{0.05 \ln Q}$ Method	316959.32
2.	Quadratic $0.0005Q^2 - 0.2Q + 125$ Method	297696.70
3.	Power $700Q^{-0.9}$	127052.40
	Observed	119607.29

(B) Unsteady State Flow Equation:

As in the de St. Venant equations, x represents a boundary attached downstream coordinate. The equation of sediment continuity was first delineated by the Austrian researcher Exner at the beginning of the 20th century, First a one dimensional case is considered Sediment mass balance is expressed in volume form (by dividing the mass balance by ρs) below;

$$\left(1-\lambda_p\right)\frac{\partial \eta}{\partial t} = -\frac{\partial q_{bs}}{\partial x} - \frac{\partial q_{bm}}{\partial n} + \nu_s(\bar{c}_b - E_s) \tag{14}$$

In the above equation (14) λp denotes the porosity of the bed deposit q_{bm} and q_{bs}. c_b denotes the volume concentration of suspended sediment, averaged over turbulence, just above the bed. E_s is sediment entrainment into suspension. Bed-load is seen to act as a flux term and suspended sediment as a source/sink term. The bed elevation of a control volume increases if more bed-load is entering than exiting, resulting in net deposition of bed-load. Noting that vs denotes the volume flux of suspended sediment settling on to the bed and vs E denotes the volume flux of entrainment of bed sediment into suspension, bed elevation increases due to the net deposition of suspended sediment. If $\bar{c}_b > E_s$. When the length scales of interest are large compared to the relaxation distance (U/vs) H associated with the settling of suspended sediment, (12) can be rigorously reduced to a simpler form,

$$\left(1-\lambda_p\right)B\frac{\partial \eta}{\partial t} = -\frac{\partial q_t}{\partial x} \tag{15}$$

For the homogeneous unsteady flow neglecting viscous diffusion and including buoyancy effect the rate of change of sediment concentration (ed. Garcia 2007) is:

$$\frac{\partial \bar{C}}{\partial t} = \frac{\partial}{\partial z}\left[\frac{\upsilon_t}{\sigma_t}\frac{\partial \bar{C}}{\partial z}\right] + \frac{\partial (w_s \bar{C})}{\partial z} \tag{16}$$

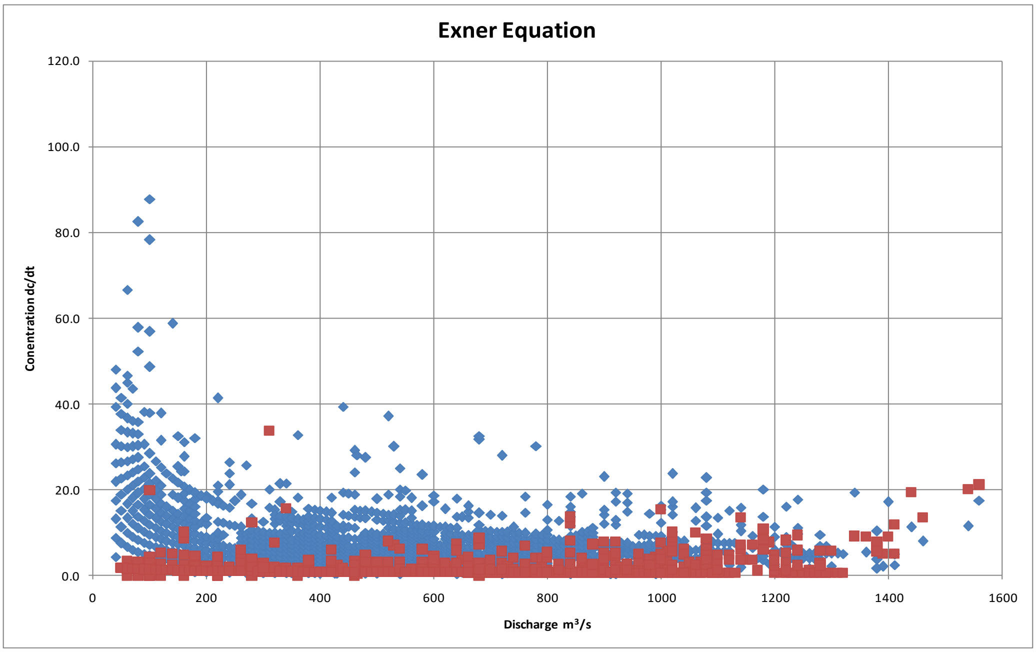

Fig. 4: Variation of Sediment Concentration rate and Discharge,(Exner)

$$\frac{\partial C}{\partial t} = 700\left(\frac{\partial Q}{\partial x}\frac{dx}{dt}\right)^{-0.9} \tag{17}$$

Since the Exner Equation, Garcia ed.(2007) under estimates sedimentation by 6.19% than observed therefore following best fit equation is proposed.

$$\frac{\partial c}{\partial t} = -5 + 1.35\left\{\left(\frac{\partial Q}{\partial x}\frac{dx}{dt}\right)^{0.96} + \left(\frac{\partial Q}{\partial x}\frac{dx}{dt}\right)^{-0.5} - \left(\frac{\partial Q}{\partial x}\frac{dx}{dt}\right)^{-0.25}\right\} \tag{18}$$

This equation precisely predict sedimentation well within 1.7% bandwidth.

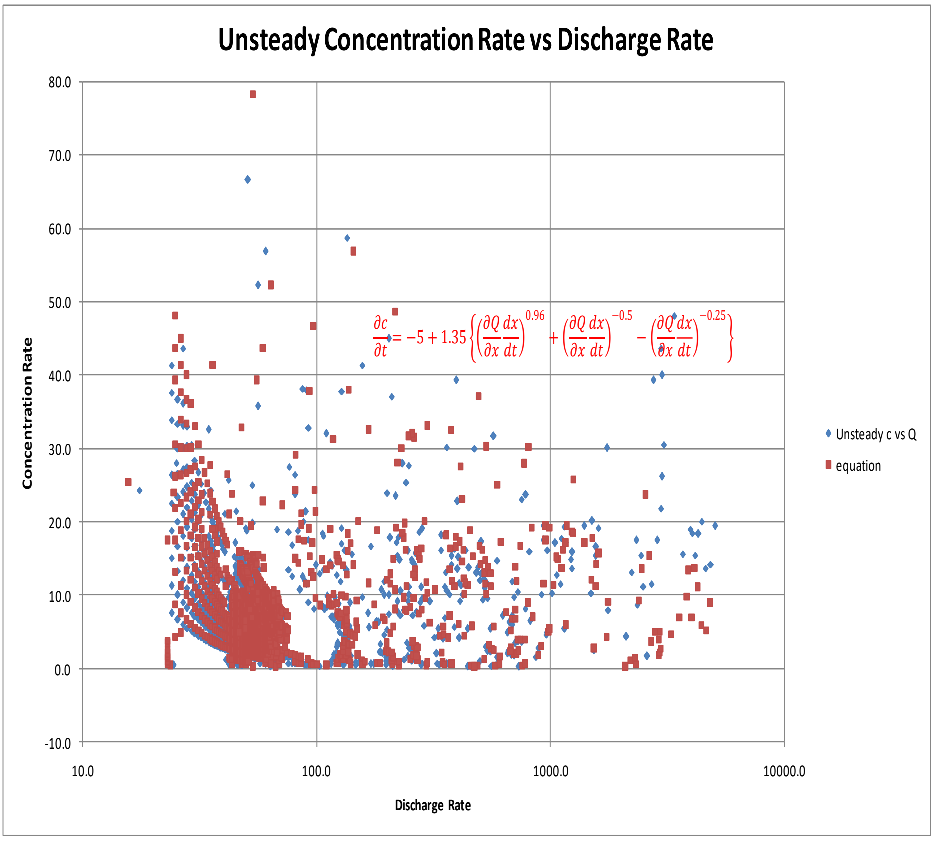

Fig. 5: Unsteady State Observed and Predicted sedimentation

A graph was plotted for the accuracy of predicted with observed and it was found that total data 1312 covered best within ±5% precisely. The calibration is shown in figure number 6.

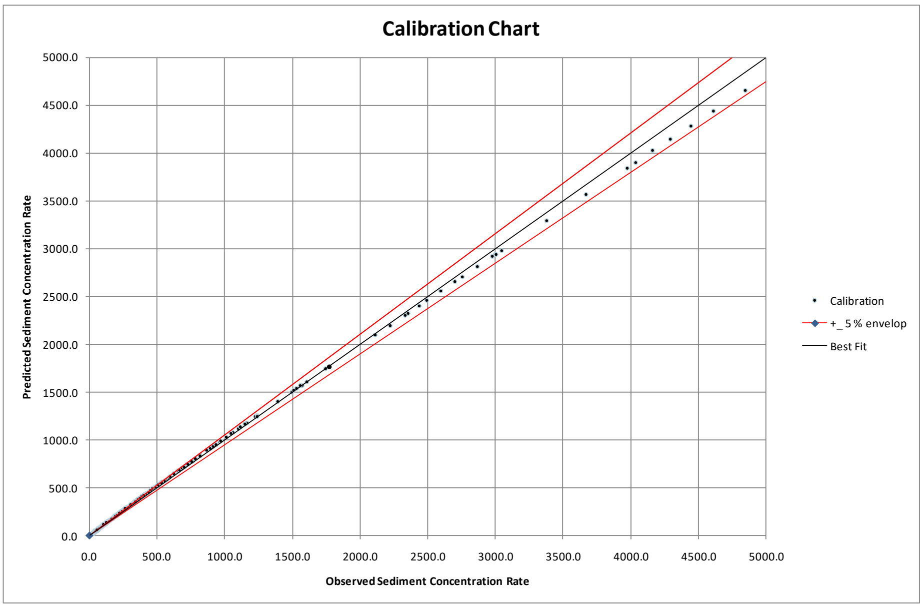

Fig.6: Variation of observed and Predicted data by Equation 18

The computations made for unsteady flow condition, comparison of quantum and the proposed equation are given in table:3.

	Observed	119607.29

Actual sediment deposited in the reservoir and the prediction of sediment by different investigators is tabulated in table 4. This table also includes predicted sediment by empirical equations for steady as well as unsteady flow condition through S. No. 6-10.

Conclusions

From this study to predict the sediment, it can be concluded that:

- Table 1 shows wide variation in results by various methods to predict the sediment in steady state condition flow. Methods/laws are applicable for a region of studies.
- The quadratic equation (13) it is observed that 63% of the sediment data is enveloped at fifty percent band width.
- Equation (13) envelops 94 % of the sediment data at one hundred percent band width,
- Empirical equation (18) shows the prediction for smaller discharges are well within 3%, whereas for the higher discharges it envelops 95% data. The predicted sedimentation is close to the observed quantity.
- Unsteady flow Exner, total sediment estimates lower by 6.19% than observed.
- The equation number 18, has standard error of 3.4%, predicts sediment higher by 6.22% than observed.
- The proposed equation number 18 predicts sedimentation well within 1.7% bandwidth.

SUMMARY

Quantitative estimate of sediment transport in alluvial channels is one of the most important task in river engineering for project planning, design, construction, operation and maintenance of hydraulic structures such as river (bridges and training dikes), reservoirs (dams and barrages.), lakes and coastal (jetties, berths, breakwaters, dikes, wave absorbers, revetment, seawalls and bulkheads). Even today, numerical models of sediment transport processes are confronted with some difficulties, often of conceptual nature. One of these difficulties is the simulation of unsteady non-uniform sediment transport. This paper describes sediment transport theory in brief, empirical equations proposed by different investigators such as Camenen and Larson, Engelund and Hansen, Ackers and White's, Meyer-Peter and Muller, Nielsen, Bagnold, Bijker, method. Macroscopic concept based on single sediment size has been used for computations. Present research paper is compilation of work carried out by various investigators for steady state and unsteady state flow condition. Published data of Sediment Transport collected over 20 years in Punatsangchhu river basin by Division of Water Resources Engineering, Bhutan is used for analysis. Performance of empirical equations for Bhutan/Indian sub continent is evaluated and presented in a tabular form. New mathematical equations in a log, power and binomial form for steady state flow are compared with various methods as mentioned above. Results obtained by unsteady state equation proposed by author match with observed quantum of sediment. This

equation precisely predicts sedimentation well within 1.7% bandwidth. The variation between predicted by proposed equation and observed sedimentation was accurate initially up to concentration of 2500 mg/l and beyond it within ±5%.

1. INTRODUCTION

Sedimentation has been the most challenging problem faced by any dams in the world. This condition is worsened by climate change effects. The climate change shifted the rainy season in Java Island to heavier rainfall in a shorter period of time, which forced the upstream farming area produce extra sedimentation to the dams downstream.

The study uses case of two large dams in Serayu-Bogowonto River Basin Territory: Wadaslintang and Sempor. Both are located in mid-stream of the rivers and faced with the different scale of sedimentation problems. For both dams, the sedimentation is worsened due to the rapid changing upstream land use of the catchment (1,2) combined with the impact of climate change (3), which add the probability for landslide and flash floods falling into the reservoirs.

However, the current dams operation managers' work only on the focus of water availability data. They lack the tool to analyze whether the way they manage these dams has a balance point. This paper seeks to find and compare what is considered as 'the balance of water conservation-sedimentation-energy' for both locations using the Nexus approach for water governance (4). The locations are selected based on the existence of data for the bio-ecological review (5). The result of the review is compared with the periodical data of the dam's operation throughout the last 20 years and the regulation on Indonesian dam management [6].

Fig. 1
Dams in comparison: Wadaslintang (left) and Sempor (right)

2. NEXUS CONCEPTS AND METHODS

3.1. NEXUS CONCEPTS

From the literature review in finding the balance of sedimentation, water conservation, and energy: the Nexus approach came as the highlight. This review is then followed up by a historical review of the approach. The Nexus approach 1st was launched at the 2011 Bonn Conference (6), which addresses the theme of "The Water, Energy, and Food Security (WEF) Nexus – Solutions for the Green Economy." However, the need for 'nexus' has been identified in 2008 at the World Economic Forum annual meeting (7). This approach has been developed since then through serious attempts to make it a simplified tool.

A literature review done by Bassel and Mohtar (2015) identified four main tools used commonly in to address the WEF nexus: WEAP (SEI, 2014), LEAP (SEI, 2013), MuSIASEM (FAO, 2013), and CLEWS (KTH, 2013). Out of which, this paper uses the simplified models of CLEWS and WEAP-LEAP to define the balance of dam management. This paper uses the following data as input: technical data of the reservoir: water for conservation (volume), water balance (discharge versus outcome), and sedimentation (upstream land use, sedimentation rate), while the outputs are categorized as:

(1) water: drinking water need
(2) energy: energy production, water for energy generation need
(3) food: irrigated land, food production, irrigation water need

3.2. METHODS

The methods in defining the balance of the input and output for the tool will be presented by percentage. If the water percentage for the input lower than the output, it shows that the water storage capacity of the dam should be on function, in order for the dam management to be declared as an effective balance for the WEF nexus. The lower the percentage shows the yield of water using the reservoir storage is high, for example, the number 10% means the yield of 1m3/sec can be for the usage of 10m3/sec. This shows an effective number, but also questions whether the water input is not too low. If the output is lower than input, this means the capacity of the dam is mostly only for storage, which does not represent an effective balance WEF nexus or multi-purpose dam function. For example, for the number 60%, this means 60m3/sec as input is stored, while the output is only 1m3/sec. This condition can mean the reservoir is in filling mode, so the WEF nexus balance is not effective.

Another percentage is used to show the comparison of the sedimentation and volume percentage. Those with higher number show less effective upstream catchment management. For example, the number 50% shows that the volume of the reservoir is no longer in balance, as the age of the dam is half way of its lifetime. The lower the number, the better the condition of the dam.

A better balance is shown when the WEF percentage is between 15-25% (showing effective use of water storage function with water usage) and a better balance for sediment percentage is under 10% (also based on the age of the dam). In the meantime, the dams are hypothesized as in a balance, but we will see what the tool will show.

The data collection methods being used are site visits, secondary data comparison of ‘water-energy-food’ models and document analysis of published materials. These models are used to seek the balance of sedimentation-water conservation and energy output. A slight adjustment is made to fit the existence of data and the need for the objective of this paper.

As a showcase of the Nexus approach, the multi-purpose reservoirs are included (8) in this paper: Sempor and Wadaslintang Dams. Both dams were built in the 1980’s, but data availability constraints in presenting the whole range of time. Thus, the data is using the last ten years data only.

3. RESULTS

The results are found using the data from these dams to test the implementation of the Nexus approach in multipurpose reservoirs. They are based on data collected from different sources and put into the adapted nexus tool specified for the approach in this paper.

3.1. DAM MANAGEMENT

The main research partner for this paper is the dams’ operation manager: BBWS Serayu Opak. Site visits were done to the dams’ location and their catchment areas to confirm the maps and printed data. The daily operator for both dams is under the BBWS Serayu Opak. However, partnerships of management are done with different aspects of the dam. It is divided based on the tasks of the institutions and proves the existence of public-private partnership and division of roles in the partnership (table 1).

Table 1
Dam Management

Management	
Dam Operation	BBWS Serayu Opak (National Government-Ministry of Public Works and Housing)
Energy Operation	Indonesian Power (Private Company)
Water Supply Operation	PDAM (Local Government Owned Company)
Irrigation Operation	Balai PSDA Probolo (Local Government)
Catchment Management	BPDAS Serayu Opak Progo (National Government-Ministry of Forestry and Environment)

3.2. DAM CONDITION

As a summary, table 2 shows the comparison of the dams' data for the dam catchment and sedimentation condition.

Table 2
Data for catchment and sedimentation for Sempor and Wadaslintang

Data	**Sempor**	**Wadaslintang**
Maps of Catchment	Green Belt (9) 	Slope catchment (10) Catchment Area	43 km2 (9)	196 km2 (11)
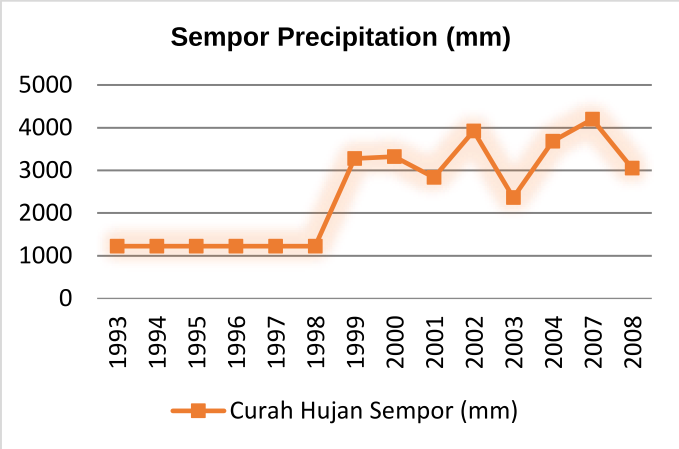
Land use of catchment	42% for agriculture (9)	21% for agriculture, forest, etc.
Sedimentation rate	419,914 m3/year (2011) (1)	711,247 m3/year (2008) (12)
Catchment slope	25 – 50^{o}(1)	5-55^{o} (10)

Aside from the change of land use in the upstream catchment, the climate change impacts also cause the change of average precipitation for both dams. These precipitations increase the potential of sedimentation to the dam since the catchment of the dam is not fully forested, and many parts are used as agricultural lands for seasonal cropping pattern (vegetables). The data (figure 2) is showing increased intensities confirming the research on climate change impact to Indonesian island laying below the equator (3): where a higher intensity of rain happens.



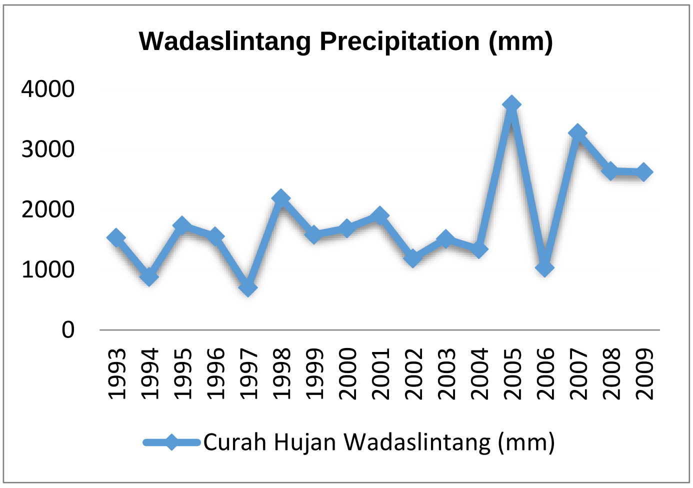


Fig. 2
Precipitation for Sempor and Wadaslintang (1993-2009)

3.3. NEXUS TOOL IMPLEMENTATION AND ANALYSIS

The Nexus tool is used to aggregate and simplify the technical data (see table 3). But, before the data is used, all of them are reduced into average numbers for the last ten years, except for the sedimentation data availability for Sempor, which was last calculated in 1994. The data came from different sources: reports and previous studies. In applying the tool, an adaptation version is made based on the availability of data and the data needed for the models (WEAP-LEAP and CLEWS).

Table 3
Nexus tool implementation in multi-purpose dams

Input		
	Sempor	Wadaslintang
Average discharge (origin)	Average 2.8 m^3/sec (Rivers: Sampang, Kedungwringin) (1,9)	Average 9.1 m^3/sec (Rivers: Cingcingguling, Lukulo, Jali, Bogowonto, Bedegolan (11)
Volume for conservation needs (effective volume)	46,500,000 m3 (9)	408,000,000 m3 (11)

Sedimentation	12,04 million m3 (1994) (1)	27.227 millions m3 (2008) (12)
Output		
Water:		
Drinking water need	50 l/sec (9)	600 l/sec (2019 SPAM Keburejo) (13)
Food:		
Food production	3 Ton/ha rice (9)	3 Ton/ha (11)
Irrigated field	17,800 ha (9)	33,279 ha (11)
Irrigation need	11.00 m^3/sec (9)	27 m^3/sec (10)
Energy:		
Energy production	6,000,000 KWH (9)	92,000,000 KWH (11)
Energy need	3m^3/sec (9)	24 m^3/sec (11)
Total water need	14.05 m3/sec	51.6 m3/sec
Percentage of input vs. output for water	20%	18%
Sedimentation percentage vs. volume effective	26%	7%
WEF vs. sedimentation	77%	264%

The table shows that at the moment both dams are in a balance for effective WEF nexus need and functioning effectively as the percentage is between 10-25%. Meanwhile, for sedimentation, Sempor data is so outdated (1994), which needs to be updated to the current condition, which should be higher than this. However, even so, using this data, the calculation shows the sedimentation in Sempor is much worse than in Wadaslintang. The comparison for WEF and sedimentation also shows that the percentage for Wadaslintang is about three times better, which corresponds to a better balance for Wadaslintang dam management.

Although the data for the dam managers are similar, the condition of Sempor is worse than Wadaslintang. This condition is caused by different the land use of dams' catchment. This paper shows that lack of coordination for catchment management can happen even though both dams are managed by the same institutions, and this may contribute to the sedimentation problem.

This issue can be addressed by introducing and advancing awareness of the water management interrelations to other resources in the river basin level using the Nexus approach. It also recommends the policymakers to make use of the tool for easy visualizations to see these interrelations.

4. CONCLUSION AND RECOMMENDATION

In this paper, the nexus tool is used to give a simple overview of what the approach is about and to showcase that it can be used as a fast assessment towards dam management condition. The results also show that the WEF percentage correlates with the dam effective level of storage and water usage, while the sedimentation percentage correlates with the effective volume of the reservoir. Both percentages are needed to see the whether the balance condition of the dams is met. The case study of Wadaslintang in this paper is proven to be by far in more balance towards the WEF and sedimentation condition than the Sempor.

However, this tool is an over-simplified version of the available tools for the WEF nexus and may need a more precise method to formulate an even comprehensive approach. By means of using a longer time series data and data range rather than using the average data for the input and output may result in better precisions. Also by using an automated source of data will improve the exactness of the results.

5. ACKNOWLEDGEMENT

The authors would like to express their gratitude to BBWS Serayu Opak and INACOLD for their continuous support in the writing process and also the chance to present this paper at ICOLD 2018.

1. INTRODUCTION

In this study, hydrological safety vulnerability assessment on dam facilities were estimated using dams' hydrological safety evaluation result and in-depth inspection assessment result and considering climate change scenario. Hydrological safety assessment of the existing dams was performed by calculating the PMP/PMF using the climate change scenario. Using the results, Multi-Criteria Decision Making was used for vulnerability ranking decision on dams, and assessment scores and weights of hydrological safety evaluation considering climate change were applied as payoff matrix and weight coefficient. In this study, it was evaluated vulnerability ranking that hydrological safety evaluation of existing dam considering climate change.

.

2. ANALYSIS METHOD

Dam Hydrological safety vulnerability for climate change ranking is calculated using hydrological safety 3 step assessment results and Climate impact factor for future climate results.

Using the results of the existing 4 dams and 3 type method of Multi-Criteria Decision Making (MCDM). Location of 4 target dams was shown in Fig. 1. Three dams belong to the Han river, and one dam belongs to the nakdong river and the 3 target dam type was concrete dams and 1 dam type were fill dam.

2.1. HYDROLOGICAL SAFETY ASSESSMENT

Hydrological dam safety has been currently evaluated depending on freeboard allowance, overflow and downstream hazard without any consideration of types, material and structural conditions. Hydrological safety assessment is made in three steps (MOLTL, 2011), The first step for safety evaluation is to check overflow possibility and freeboard allowance under the consideration of structural type and physical condition obtained from dam inspection results. Fill dam and CFRD(Concrete Faced Rock fill Dam) was applied to a more stable basis than concrete dam because of dam body safety difference when overflow.

If the first step is not satisfied, structural safety evaluation for overflow condition should be carried out as a second step. The evaluation of downstream hazard including human and economical factors is the final step. The final step is assessed to downstream risk with reference to the EAP on the assumption that PMF occurs.

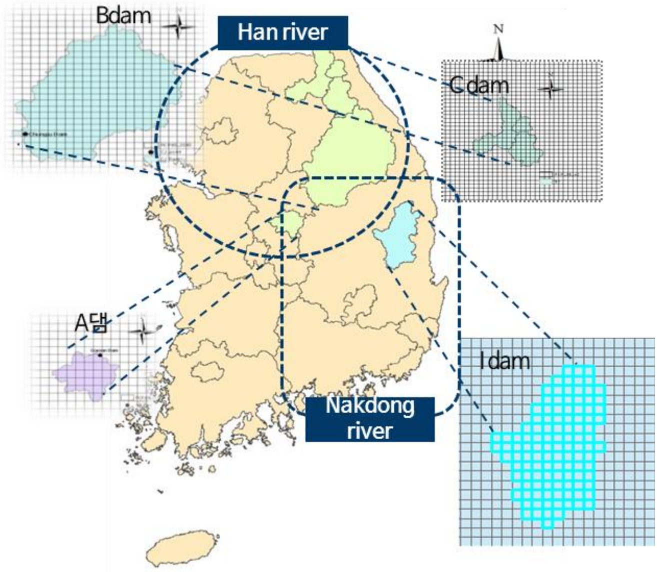

Figure 1 Target dams location

The current hydrologic safety assessment is based on the analysis of the ability to discharge into weir. In this study, To analyze the impacts on climate change, climate change scenarios PMP(RCP 4.5 2040s) were used to assess hydrological safety. And it intends to further assess the factors that may cause a burden on the operation of the target dams in the future.

The factors are criteria 4~6. In order to estimate the long-term variability of climate factors using the data of climate change scenarios, We used the minimum temperature that can affect monthly maximum rainfall, annual rainfall intensity and dam condition.

Table 1. Hydrological safety evaluation 3 step

Evaluation step	Evaluation contents	Evaluation standard
1st	Evaluation for freeboard allowance and overflow	Whether or not to secure dam freeboard
2nd	Evaluation of structural safety for overflow(PMF)	Dam structural stability during overtopping for the PMF
3rd	Evaluation for downstream hazard(PMF)	Assessment downstream for PMF

Table 2 Long term climate effect factor

Evaluation step	Evaluation contents
1st	Rate of Monthly maximum rainfall
2nd	Ratio of rainfall intensity to rainfall
3rd	Minimum temperature

2.2. MULTI-CRITERIA DECISION MAKING(MCDM)

Multiple-criteria decision-making is a sub-discipline of operations research that explicitly considers multiple criteria in decision-making environments (Triantaphyllou, 2000). Pareto optimal solution is a concept in multi-criteria optimization that allows for the optimization of multiple criteria. MCDM is the process of finding such a Pareto optimal solution (Alternative) on a variety of criteria (Criteria) and shown in Fig. 2(Kim, 2013).

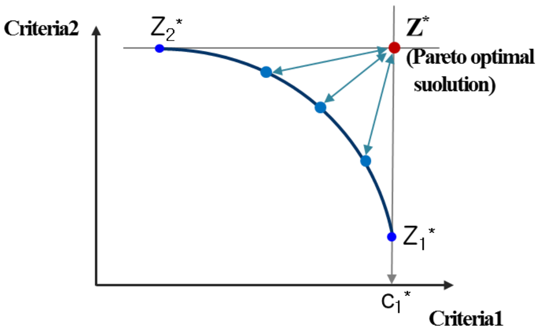

Figure 2 Pareto Optical solution of MCDM

In this study, MCDM was used for vulnerability ranking decision on dams, and assessment scores of each step of the hydrological safety evaluation results which was applied as payoff. It can be available for calculating dams' vulnerability ranking considered dams' hydrological safety.

Compromise Programming(CP), PROME-THEE, VIKOR and TOPSIS, generally used as MCDM technique, were applied to determine the hydrological vulnerability ranking of dams According to each technique, the dam ranking was calculated. In conclusion, the most vulnerable dam and the most safety dam was selected.

3. ANALYSIS RESULTS

In this study, It was ranked using various techniques of MCDM that hydrological safety assessment vulnerability ranking. Criteria of MCDM payoff matrix was shown in Table 3.

Table 3 MCDM criteria

Evaluation contents	Criteria	Evaluation Criteria
Assessment of freeboard for dam type and condition assessment	Criteria1	Lower the vulnerable
Assessment of dam Structural stability during overtopping for the PMF	Criteria2	Lower the vulnerable
Assessment of dam downstream risk	Criteria3	Lower the vulnerable
Rate of Monthly maximum rainfall	Criteria4	Higher the vulnerable
Ratio of rainfall intensity to rainfall	Criteria5	Higher the vulnerable
Minimum temperature	Criteria6	Lower the vulnerable

The target dams were ranked by 6 criteria. The score range of 3 criteria(1~3) is between 1 and 5. And the vulnerability has been evaluated as vulnerable if indicating a lower score for 4 criteria(1~3, 6). If dam has high hydrological safety vulnerability, that ranking is low value (ex: 1 ranking). Table 4 was shown by MCDM payoff matrix. The payoff matrix score in 6 criteria was used as hydrological safety assessment value of recently performed the in-depth inspection and climate change scenario(IPCC AR5).

Table 4 MCDM Payoff Matrix(RCP4.5 2040s)

	Payoff Matrix					
	Criteria1	Criteria2	Criteria3	Criteria4	Criteria5	Criteria6
weight	33	30	19	8	7	3
Dam A	E(1)	B(4)	E(1)	20.8	13.4	-17.3
Dam B	E(1)	A(5)	E(1)	22.9	14.7	-19.1
Dam C	A(5)	A(5)	A(5)	28.5	19.2	-19.8
Dam I	E(1)	E(1)	A(5)	4.1	7.4	-14.9

MCDM result values and ranking were shown in Table 5. MCDM result values were calculated according to various methods. The dams' hydrological safety vulnerability ranking was calculated by using the average value of the ranking to each result values.

Table 5 MCDM values and vulnerability Ranking hydrological safety

	CP	VIKOR	TOSIS	Ranking
Dam A	0.6542	0.8493	0.6342	2
Dam B	0.5737	0.8041	0.5654	3
Dam C	0.0321	0	0.1835	4
Dam I	0.9225	1	0.7957	1

The Vulnerability ranking of hydrological safety in existing dams was shown in Fig. 3. Dam I estimates the highest priority for all techniques, it showed the most vulnerable on hydrological safety. Dam I is considered to be the hydrological assessment most vulnerable.

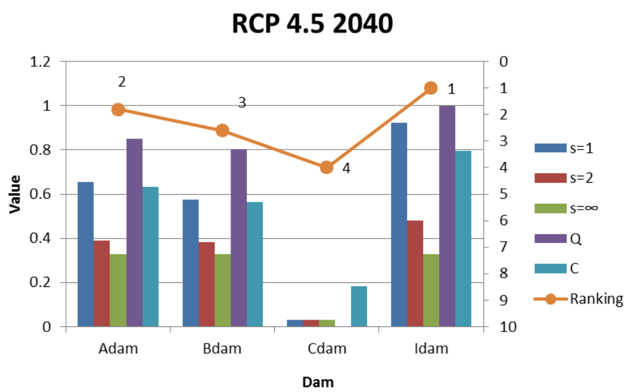

Figure 3 Vulnerability Ranking of hydrological in existing dams

4. CONCLUSION

In this study, Vulnerability Ranking of hydrological safety was ranked using MCDM method in climate change scenario. MCDM technique is difficult the choice of one way due to the differences in the advantages and disadvantages of each method (Min and Song, 2003), However using the results of the various MCDM methods, it is considered to be able to take advantage of prioritization on Vulnerability Ranking for dam hydrological safety. In this study, dam I was calculated as the most vulnerable Dam I. When future peak flooding occurs, it is considered the most vulnerable due to the overflow of dam I. In comparison with other dams, It is considered necessary to take additional actions in the future to secure the remaining capacity of the dam.

EXPERIMENTAL STUDY ON BED EROSION DOWNSTREAM FROM A DAM*

Zhijing LI, Jun WANG

CHANGJIANG RIVER SCIENTIFIC RESEARCH INSTITUTE

CHINA

ABSTRACT

The nature of flow, sediment transport and bed erosion were studied in a laboratory flume using mixed-size sediment under clear water conditions. During each experiment, water depth, bed and water surface elevation, bedload transport and bed state were continuously monitored. Steady inflows were established with an unit discharge of about 0.01 m(2) s(-1) to 0.03 m(2) s(-1). Well sorted gravel and sand were employed to compose four kinds of sediment beds with different gravel/sand contents, i.e., uniform 100% gravel bed, uniform 100% sand bed, and two graded sediment beds respectively with 53% gravel and 47% sand as well as 22% gravel and 78% sand. For different sediment beds, the experiments were conducted under the same discharges, thereby allowing for the role of sediment composition in dictating the bed erosion to be identified. The measured bed elevation for all the twenty runs show that significant degradation is spotted, yet the scour is mainly confined to the upstream part. For a specific sediment sample, the degradation enhanced with the increase of the inlet flow discharge. Under a specific unit-width flow discharge, the degradation for the four sediment samples generally follows the rule that the scour process increases with the increase of sand content in the sediment bed. However, it also exhibits an interesting phenomenon that the maximum scour depth with pure sand is not the largest, instead the case with 78% sand content features the deepest scour. In line with this observation, the scour with pure sand extended considerably farther

**titre de l'articlecomplet*

downstream along the channel than other beds. In fact, bed forms like small dunes were present in cases with pure sand, which were not discerned in other sediment beds. This has important implications for the evaluation of the scour hole evolution, echoing that the sediment bed composition has significant and complicated effects on the scour dimensions below sills, as identified in previous studies.

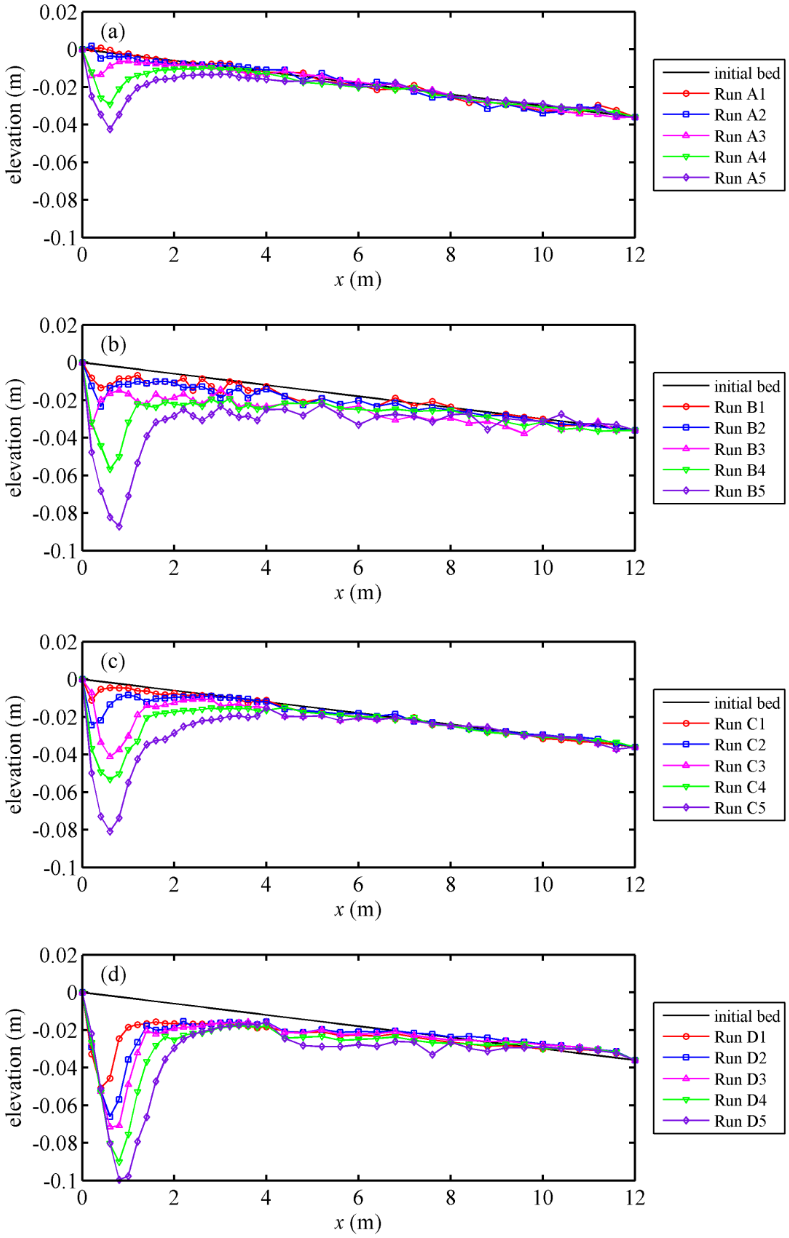

Fig. 1. Cross section averaged final bed elevation in relation to different inflow discharges for (a) uniform 100% gravel bed, (b) uniform 100% sand bed, (c) 53% gravel and 47% sand bed, and (d) 22% gravel and 78% sand bed.

STUDY ON MECHANISM OF RESERVOIR INDUCED SEISMICITY AND COUNTERPLOTS FOR RESERVOIR OPERATION UNDER EXTREME WEATHER

Xinxiang ZENG, Tinggai CHANG, Xiao HU, Lei YANG

Earthquake Engineering Research Center, CHINA INSTITUTE OF WATER RESOURCES AND HYDROPOWER RESEARCH

CHINA

1. INTRODUCTION

The odds of extreme weather events increased significantly recently against the backdrop of global climate change, in which China is one of the most affected countries especially for typhoon and rainstorm. The water level will change rapidly if the typhoon or rainstorm occurred in the reservoir region, which is seemed to increase the occurrence probability of Reservoir-Induced Seismic (RIS). The RIS means typically minor earthquake sequence resulting from reservoir impoundment or variation of water level. The damage of RIS may probably be much bigger than that of natural earthquake because its focal depth is very shallow. Therefore, it is necessary to study the mechanism of extreme weather induced RIS events, as well as provide some corresponding countermeasures for reservoir operation management.

Shanxi reservoir is located in the upper stream of Feiyun river (Zhejiang Province, China) with capacity of $18.24\times10^8 m^3$, and the height of the concrete face rockfill dam is 156.8m. Shanxi reservoir region will be affected by typhoon from June to September every year. The impoundment of the reservoir started from May 12th, 2000. And a M_L3.5 seismic events in reservoir region has been recorded in July 28th, 2002[1]. From that time on, the induced seismic activity has been an issue for the Shanxi reservoir.

2. SEISMIC ACTIVITY

There are total of 8 seismic stations within a 30km radius of Shanxi reservoir. And this earthquake observation network is putting into operation since 2010[2]. In this study, a seismic catalogue contains 5908 records are used to study the seismic activity of Shanxi reservoir region (27° 60' ～27° 80' N, 119° 80' ～120° 10 ' E), which is recorded from July 2002 to July 2016.

2.1. SEISMIC FREQUENCY

Shanxi reservoir is located at weak seismic region where there is no earthquake recorded before the construction of reservoir. As showed in Table.1 and Fig.1, the frequency of seismic activities in Shanxi reservoir region increases significantly after the impoundment. The seismic activities in this area could be recognized as 4 clusters: ① from July to September 2002, the maximum earthquake is M_L3.9; ② from February to October 2006, the maximum earthquake is M_L4.6; ③ from March to November 2010, the maximum earthquake is M_L2.1; ④ from August 2014 to May 2015, the maximum earthquake is M_L4.4. Therefore, we could get a conclusion that the frequency of seismic activity in Shanxi reservoir will increase prominently in every 4 years.

Furthermore, we also found that the seismic events are always accompany with water level decrease, and the latency is relatively obvious. This phenomenon could be observed easily in Fig.2. We suppose the possible mechanism of the seismic activity is that the infiltration of water into the causative fault will increase accompany with water level rising. Thereupon, the original balance of the fault plane was broken under the effect of water erode, and the fault plane will be soften and sliming. In case the water level decreases dramatically, the accumulated energy will release immediately and then cause earthquake.

Daily variations of seismic frequency (bottom bar) in 2014
Blue curve: water level

2.2. SEISMIC MAGNITUDE

Fig. 3 shows that the relationship between water level and seismic magnitude. Combining Table.1, Fig.1 and Fig.3, we recognize that the seismic cluster ② and ④ are much bigger that the other two clusters not only in magnitude but also in frequency. And the seismic activities are mainly weak or micro earthquakes. Actually, more than 99% of the seismic events are smaller than M_L4.0. In addition, the biggest seismic event is M_L4.6 (Feb 9th, 2006), which is right after the water level decreasing dramatically from the first reach of 145+m.

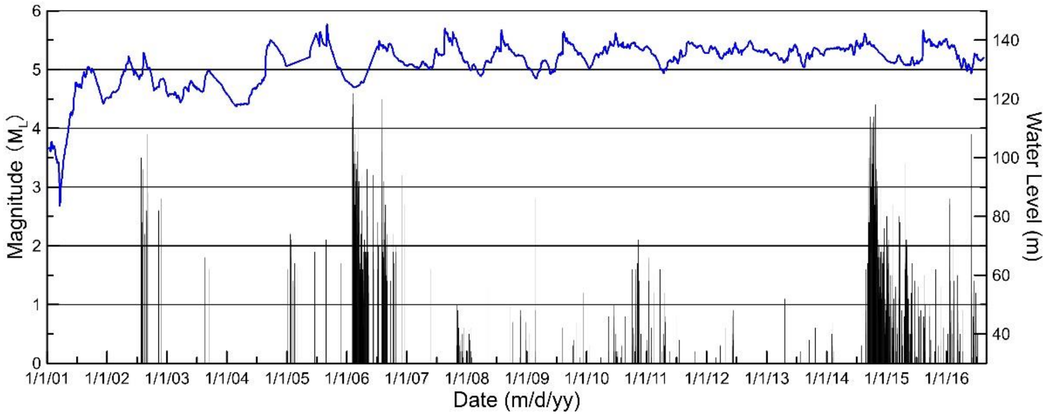

Fig. 3
Time variations of magnitude (bottom vertical line)
Blue curve: water level

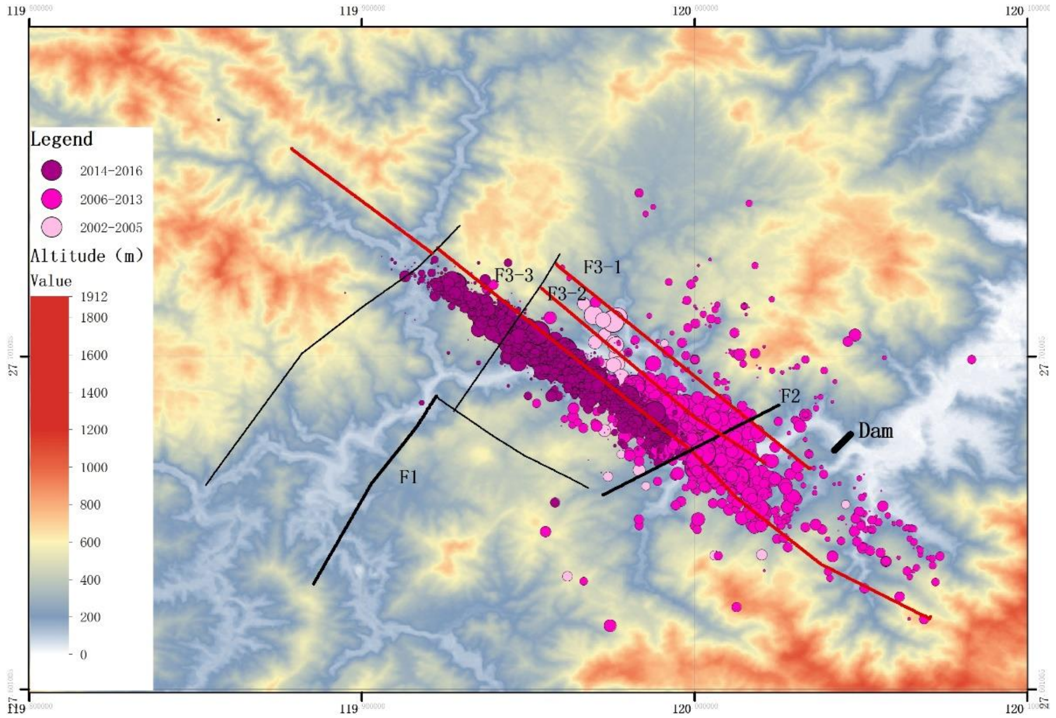

Fig. 4
Spatial distribution of epicenter in Shanxi reservoir region after impoundement
The size of the circle is proportional to the magnitude; F1, Jiangkou-Huixi fault; F2, Yanshang-Chengken fault; F3, Shuangxi-Jiaoyangxi fault.

2.3. Spatial Distribution

There are 14 faults developed in research area[1], in which F1 (Jiangkou-Huixi fault), F2 (*Yanshang-Chengken fault*) and F3 (*Shuangxi-Jiaoyangxi fault*) are considered to be the main-controlled-fault[3]. The fault F3 have 3 branch faults (F3-

1, F3-2 and F3-3) with approximately the same trike of N310° W. As is shown in Fig. 4, the seismic events after the impoundment are mainly distributed in the area near fault F2 and F3. The strike of 2014-2016 comes much more concentrated and closer to that of fault F3 than the 2002~2005 and 2006~2013. In fact, according to the field survey, the permeability of fault F3 is much bigger than that of fault F1 and F2. Furthermore, the permeability order within the 3 branch faults of F3 is F3-3 > F3-2 > F3-1. And the northwest trending faults such as F2 and F3 are parallel tension-shear fault with steep dip[4]. All the geological conditions mentioned above are beneficial to the infiltration of the increasing reservoir water.

3. DOUBLE-DIFFERENCE LOCATION ALGORITHM

3.1. METHODOLOGY

The source parameters such as hypocenter location and focal depth are key points in the study of earthquake mechanism. The ordinary location methods for these source parameters is very complicate and require accurate earth models. Due to our limited knowledge of structures in the earth, it is scarcely possible to get precise location of single earthquake at a time. The main points of the double-difference location algorithm is reformulate the problem to solve for changes in the distance between pairs of seismic events. By forming differences in this manner, we could steer clear of the travel time errors due to the uncomprehending Earth structure and obtain high resolution results of hypocenter location as well as focal depth[5].

3.2. RESULTS

In this study, the double-difference location algorithm is used to conduct data processing of 2014 seismic cluster. The processed results are shown in Fig.5, which indicate the spatial distribution of 2014 seismic clusters are much more concentrated along the strike of branch fault F3-3 compared with that shown in Fig.4. Therefore, we consider the branch fault F3-3 is the causative fault of 2014 seismic cluster. Actually, almost all of the seismic events in 2014 are occurred after the typhoon season. We consider the most possibly reason is that there are some hydraulic connections between the raised water and the branch fault F3-3. The water will erode the fault plane, and reduce the effective stress. In case the water level dropped or changed rapidly, the related fault will loss stability and cause earthquake. This point of view is corroborate with the assumption mentioned in Section2.1. Consider the statistical results of seismic activities and the operating experience, we suggest that the changing rate of water level should be controlled in a relative low level (no more than 2m/day).

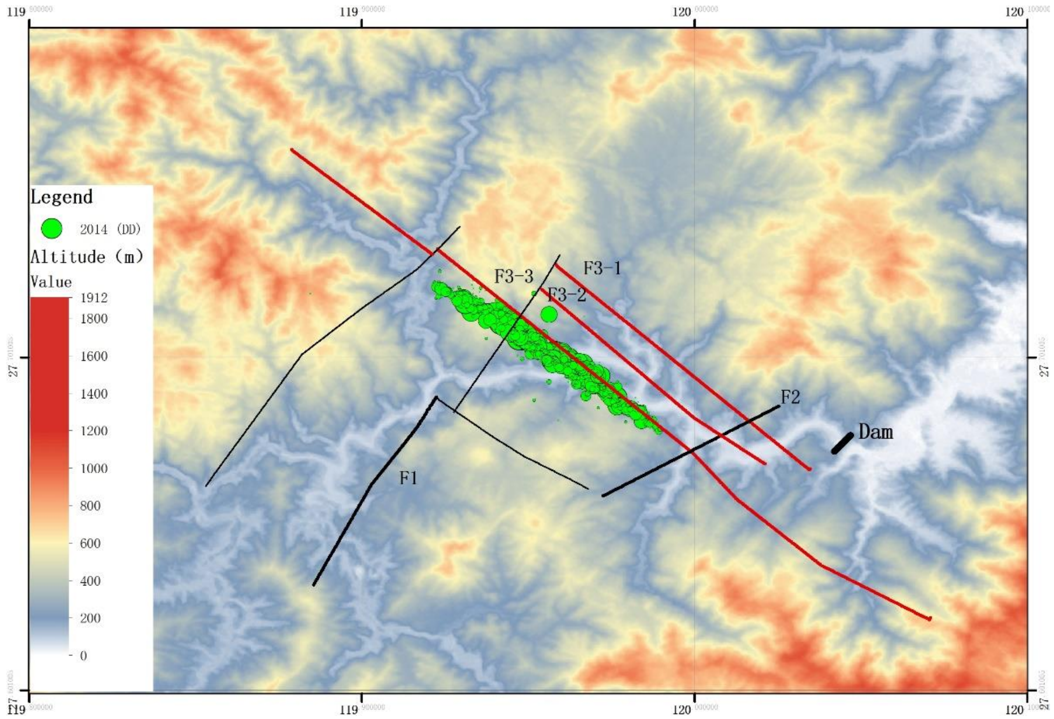

Fig. 5

The results of double-difference location algorithm for 2014 seismic cluster

4. CONCLUSION

Consider the features of seismic activities and geological conditions in Shanxi reservoir, conclusions could be summarized as follows.

1. The seismic frequency of Shanxi reservoir region increases significantly after the impoundment, and the seismic activities shown a periodic change in every 4 years.
2. More than 99% of the seismic events are weak or micro earthquakes, and the maximum magnitude is M_L4.6.
3. The seismic events after the impoundment are mainly distributed in the area near fault F2 and F3.
4. The results of double-difference location algorithm suggest that the branch fault F3-3 is the causative fault of 2014 seismic cluster.
5. The preferably infiltration conditions of fault F3 (steep dip and higher permeability) is the control factor of the seismic activity in Shanxi reservoir.

At last, we suggest that the changing rate of water level in dam operation should be controlled in a relative low level, especially for the water level decreasing rate must be limited to no more than 2m/day.

5. ACKNOWLEDGEMENTS

This study is supported by administration bureau of Shanxi hydro-junction as well as Research Fund of State Key Laboratory of Simulation and Regulation of Water Cycle in River Basin, IWHR (Grant No. 2016TS09). And we also would like to express our gratitude to research fellow Zhong Yuyun in earthquake administration of Zhejiang province for providing us the earthquake catalogue and related data.

1. INTRODUCTION

Citarum River with a length of ± 270 km has an upstream area that is mostly located in Bandung regency and partly in Garut regency. Citarum River flows from the south then moves towards the West which then turns to the North with the largest estuary in Muara Bendera - Java Sea. The Citarum River area which is the working area of Jasa Tirta II Public Corporation consists not only of the Citarum River basin, but is a unified hydrological system that combines the Citarum River and its surrounding rivers, the result of water resources development based on the thought of Blommestein (1949).

On the Citarum River there are three stair-shaped reservoirs (cascade) with a classification of large dams, namely Saguling, Cirata, and Jatiluhur. These three reservoirs are managed by different institutions, namely Saguling by Saguling Power Generating Unit (UBP) under PT Indonesia Power, Cirata by UBP Cirata under PT PJB where PT Indonesia Power and PT PJB is a subsidiary of PT PLN (Persero) while Jatiluhur is in the management of Public Company (Perum) Jasa Tirta II (PJT-II) under the management control of State Minister of State-Owned Enterprises with related technical department is Ministry of Public Works.

The water resources in the Citarum river is the main source of raw water supply other than the surrounding rivers that are integrated in the Jatiluhur infrastructure system for various purposes, including the need for raw water for drinking water of DKI Jakarta and the district / municipal water supply companies, raw water for industry, irrigation area of 240,000 ha, flood control, hydroelectricity and others. The Citarum cascade reservoir has an installed generation capacity of ± 2000 MW with an annual production of ± 3.7 TWh (3.7 x 109 kWh).

Climate change is already a fact. The doubling of CO2 emissions (ppm) compared with the Industrial Revolution in the 19th century is defined as a half degree of world temperature rise. This will lead to an increase in half the degree of global warming for decades to come, due to the inertia of the climate system (Javornik, 2008). The growing awareness of the environment is transformed in the form of global pressure on the use of renewable and environmentally friendly energy sources. Hydropower as one of the environmentally friendly energy sources has an important role in facing the world policy in climate change. On the contrary, hydropower has a dependence on water availability conditions both spatial and time in optimizing its generation, which in this case refers to the operation of the reservoir.

2. CONFIGURATION AND POTENTIAL WATER RESOURCES

The Citarum cascade reservoir operation cannot be separated from the Citarum River Basin system as a whole because the Citarum River has become a hydrological entity through the development of natural resources based on the Blommestein thought that unites the natural resource potential of the Ciujung River (Banten Province) to Kali Rambut (Pemali) (van Blommestein, 1949). This rationale is realized in the development of Citarum River through Jatiluhur Multipurpose Project with the construction of Jatiluhur dam and dam along with irrigation infrastructure so that the Citarum River with the surrounding rivers, from Ciliwung River to Cilalanang River into one hydrological unit as “Fig.1”.

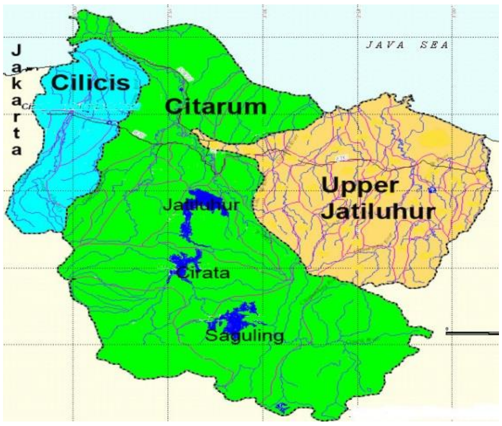

Fig.1
The Citarum River Basin with the surrounding rivers and part of the Ciliwung-Cisadane River Region becomes a hydrological unit.

Extensive infrastructure development with the objective of meeting the water requirement for irrigation of 240,000 ha in the northern plains of West Java as the fulfillment of national food, raw water supply especially for DKI Jakarta in addition to the Regency / Municipal PDAM and industry, electricity generation, fishery, and etc. The development of natural resources in the Citarum River is done by optimizing the availability of water from the surrounding rivers, namely Ciliwung, Bekasi, Cikarang, Ciasem, Cigadung, Cipunegara, and Cilalanang as “Fig.2 “. Citarum cascade reservoir consisting of Saguling, Cirata, and Ir. H.

Djuanda became the main source of supply to meet various water needs downstream of Ir. H. Djuanda dam.

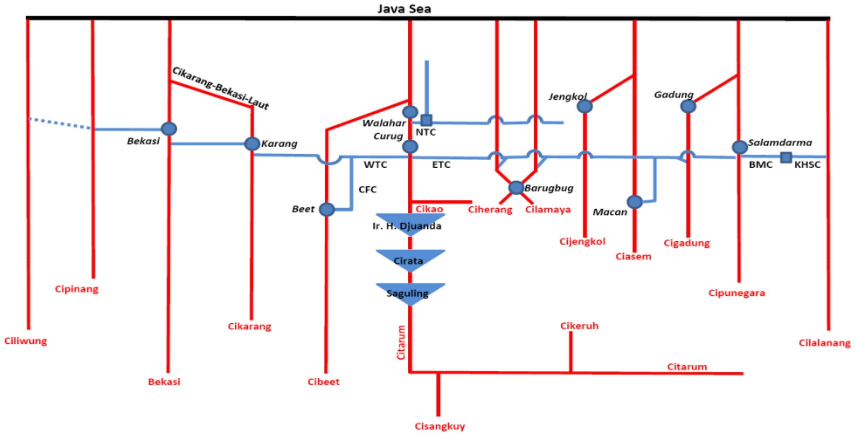

Fig. 2.
Schematic development of water resources in the Citarum River Basin through optimization of water sources from rivers around the Citarum River

The potential of natural resources in WS Citarum can be distinguished into: [1] natural resource potential of Citarum River which is managed through Citarum cascade reservoir operation and, [2] optimization of local water sources through the operation of weirs. With the existence of the three reservoirs in the Citarum River, almost all the potential of natural resources in the Citarum River of 6.0 x 109 m3 can be used to meet various downstream needs as a by product of electricity generation, because the main priority of Citarum cascade reservoir operation is for the fulfillment the need for water downstream of the Jatiluhur dam. With no reservoirs for local water sources, the potential of natural resources of 6.95 x 109 m3 can only be used for 1.65 x 109 m3. The biggest beneficiary is for irrigation by 87% of the total manageable water as “Fig.3”.

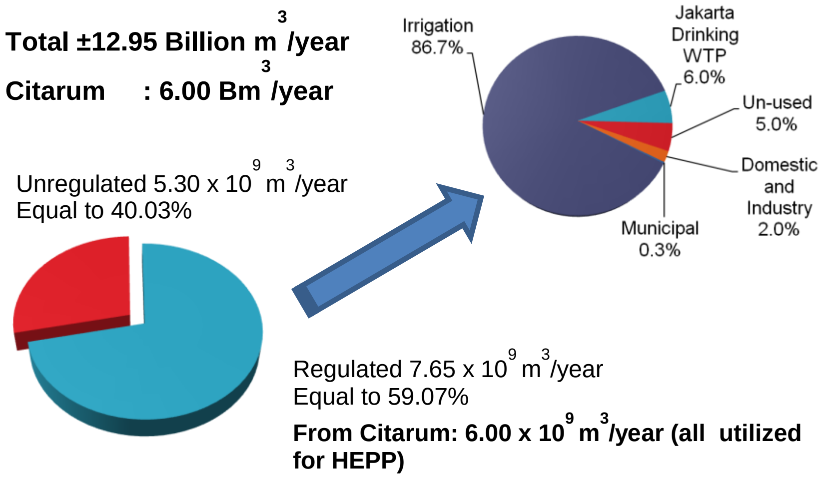

Fig. 3
Configuration of potential and utilization of water resources in Citarum River Basin

3. THE CITARUM RIVER HYDROLOGICAL REGIME.

Indonesia in the tropics in general the main characteristics of the tropical climate is the uniformity of temperature, solar radiation, humidity, wind speed. While the main climate parameter that varies in time and space is rainfall. Factors that control rainfall are (van der Weert, 1994): equatorial double rainy seasons, transfers (monsoons), and local influences. Presents regional variations of rainfall in Indonesia. It is generally seen that seasonal variations are highly visible in Java, Nusa Tenggara, East Timor, and South and Southeast Sulawesi.

Annual runoff depends on rainfall and evapotranspiration. In general, the evapotranspiration in the catchment area is relatively small compared to the existing rainfall, so it is not surprising that the annual rainfall is closely related to runoff (van der Weert, 1994). The runoff component is divided into base flow, interflow and surface runoff. Determination of surface flows for irrigated agricultural areas, mixed gardens, settlements, and plantations is a correlation between soil types, slope and slope length as well as flow management practices.

Citarum River is one of the rivers that have long discharge data. In 1922, the discharge post was installed in Palumbon which was in the upper reaches of Jatiluhur reservoir with an area of 4133 km2 of DAS. In January 1944, during the period of independence war, observation data were interrupted and resumed from May 1962 to August 1987 when the station was dismantled because of the flooding of the Cirata dam construction.

Based on the recording of all long-term data in the Citarum River basin using Isohyet method, the mean annual rainfall is estimated to be 2610 mm. From the comparison of precipitation in the pre-independence period (Sep-22 to Aug-29) with after independence (Sep-79 to Aug-86) the annual rainfall is almost 2454 mm / year and 2470 mm / year but the annual flow is increased by 10% from 1137 mm / year to 1261 mm / year (van der Weert, 1994).

In addition, from the observation data of debit at the Palumbon station fluctuations of flow debits between the period before independence (1923-1943) and after independence (1963-1984) were higher. Based on the Citarum cascade reservoir operation data, there is a decrease in annual flow and also higher fluctuations as “Fig.4”. Changes from this hydrological regime could be attributed to land use change. Unfortunately, there are no statistics on land use data prior to the independence war that can be used as a comparison. Changes in the hydrological regime include the tendency of seasonal leap, longer dry season, shorter rain time with greater intensity as an indication of climate change as “Fig.5”.

Under such conditions, at the operational level of the Citarum cascade reservoir the question arises, "How to treat the reservoir reservoir and Citarum cascade reservoir operation to anticipate the trends?"

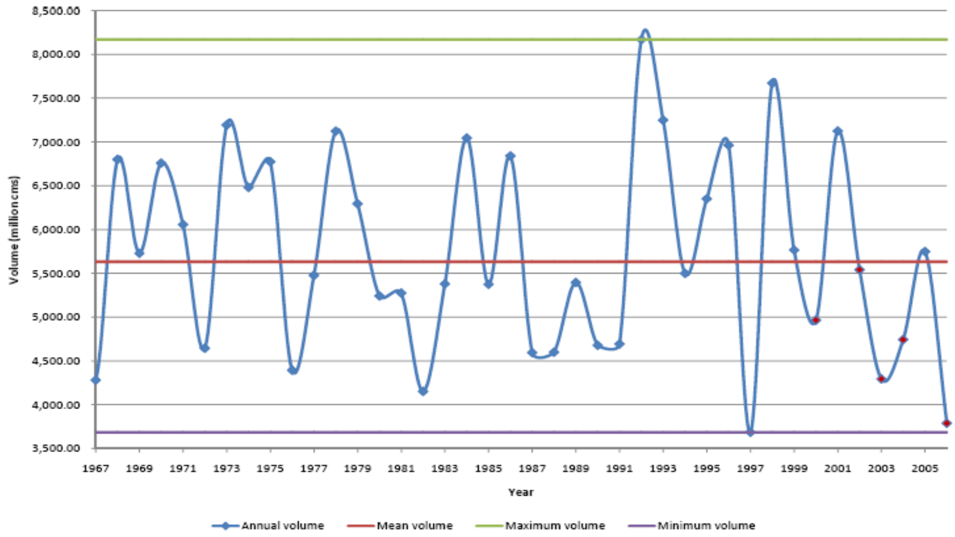

Fig. 4
The annual volume of Citarum during the year 1967-2006.

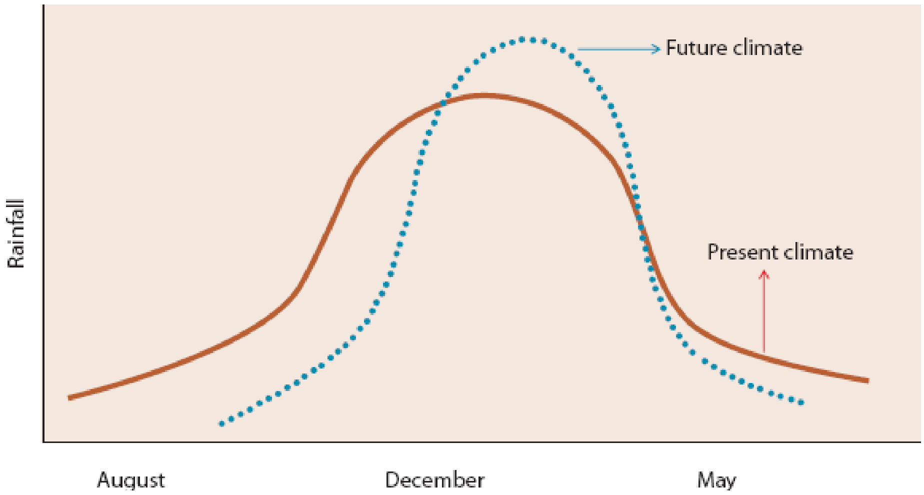

Fig. 5
Trend of rainfall pattern in Java and Bali (source: UNDP Indonesia, 2007)

4. ADAPTATION OF OPERATION PATTERN OF CITARUM CASCADE RESERVOIR

4.1 Operation of Citarum Cascade Reservoir.

The Citarum cascade reservoir has a net capacity of 2.0 x 109 m3, where the net catch is determined from the elevation of the spillway and the minimum elevation of the reservoir (at the Jatiluhur reservoir minimum hydro operation). With annual flow of Citarum in Jatiluhur at ± 5.75 x 109 m3 equivalent to 49% of net capacity, it indicates that this Citarum cascade reservoir is not designed to provide reserve reserves under long drought conditions. The technical data on the Citarum cascade reservoir is presented in as "Table 1".

Table. 1
Technical Data of Citarum Cascade Reservoir

Name of Dam	Saguling	Cirata	Ir. H. Djuanda
Operational	1985	1988	1967
Specific Reservoirs Data			
Full supply level	643 m	220 m	107 m
Dead storage level	623 m	205 m	56 m*)

The annual operation of this Citarum cascade is made by estimating the water requirement, the statistical data of inflows to the three reservoirs with the total energy generated by the system optimized with priority based on the fulfillment of water requirements downstream of the Ir. H. Djuanda Dam. Water needs downstream of the Ir. H. Djuanda reservoir is primarily for the fulfillment of raw water supply of daily necessities (raw water of DKI Jakarta and districts / cities), irrigation, industry and others.

The water requirement downstream of the Ir. H. Djuanda reservoir is mainly for irrigation covering almost 87% of the total water requirement. Therefore, to determine the water requirement required the classification of irrigation water supply for Jatiluhur Irrigation Area of 240,000 ha by considering data of water availability from local sources, channel capacity and plan and condition of existing cropping pattern. The data is traced from the furthest irrigation area to the water requirement at Bendung Curug as the main building for the various needs downstream of the Ir. H. Djuanda dam by considering also the water loss in the channel and the safety factor.

Water needs downstream of the Jatiluhur dam became one of the inputs in establishing the Citarum cascade reservoir operation. Some of the principles (limits) in determining the operation of the Citarum cascade reservoir are as follows:

- Runoff is avoided.
- Water level elevation at the end of the year is equal to or more than the water level at the beginning of the year.
- The principle of equal-sharing operation, ie the proportion of clean reserves for each reservoir against the total system is constant, ie 18.8% for Saguling, 24.4% for Cirata and 56.8% for Ir. H. Djuanda.

The inflow data for the three reservoirs was statistically determined using data from 1988, the year from which the Citarum cascade reservoir system began to operate fully. From the input data, optimization is done so that the maximum power production with the water requirement is fulfilled with the optimization process done by the Solver program.

In operating the model, the reservoir operation model is conducted sequentially and needs to be continually updated and re-operated to obtain the most accurate forecast data on real conditions and how operational decisions are established for each component of the operation of the reservoir. With many interested parties in the operation of this Citarum cascade reservoir, the Citarum cascade operation is always evaluated and updated monthly through a coordination meeting mechanism within the coordinating team for the operation dam cascade of the Saguling, Cirata and Ir H. Djuanda (TKPBSCJ).

4.2 Economic Value of Water on Citarum Cascade Reservoir Operation.

Climate change is one of the risk factors in the sustainability of the reservoir operation so it should be managed as well as possible through the deepening of climate change and its impact on reservoir operation and management of natural resources as a whole. Climate change, which can lead to changes to the hydrological regime in this case decreasing annual flow may result in a decrease in the production of hydropower generation.

It has also been realized that the day the economic value of water is increasing, and water is not only seen as a social good as it is mentioned in the principle of integrated natural resources management (GWP TAC, 2000). The management of natural resources (= Citarum cascade reservoir operation) is very unique considering the history of Jatiluhur reservoir management is based on the idealism to apply self-reliance in the management of natural resources as a whole, where the utilization of natural resources (water, water and water resources) can be used to fulfill the operational and maintenance of natural resources infrastructure although very limited.

More specifically, the equivalence of the amount of water for power generation for each hydropower unit is affected by the installed capacity and the falling height, P = f (Q, H) with Q = f (H). So for PLTA Saguling, Cirata, and Jatiluhur have their own characteristics of the economic value of water in the generation of electricity. Given the impacts of climate change that require the adaptation of reservoir operations to mitigate the impact, which has little impact on the economic value of hydropower generation, this should also be considered in the Citarum cascade reservoir operation as part of integrated natural resource management.

4.3 Alternative Adaptation and Optimization of Citarum Caskade Reservoir Operation.

The water reservoir in the reservoir contributes about 30% of the world's water availability. If the irregularities caused by climate change that affect the hydrological regime continue to increase, then access to water is decreasing which causes the higher levels of water shortage in the world (Berga, 2008). Adaptation to climate change in the form of initiatives and treatments aimed at reducing human and natural vulnerability in the face of the effects of climate change.

There are several potential handling that can be done, ie in the form of pure technology (eg infrastructure, storage, sea water defense, etc.), behavioral management (water conservation, productivity and water efficiency, changes in food and tourism patterns), management Integrated natural resources, alternative farming practices) to policy (eg, regulatory planning). In the SDA sector, this adaptation strategy can include adding water catchments to rainwater harvesting, conservation, water reuse, irrigation water efficiency to desalinization. Adaptive capacity is the ability of a system to adapt to climate change (including climate variability and hydrological regime change) to reduce potential damage, to take advantage of existing opportunities or to anticipate the consequences. In reservoirs with large capacity, changes in water availability are relatively smaller compared to systems with no small containers or containers. Therefore, reservoir operations on large systems are becoming stronger to changes in water availability, more resistant to the effects of climate change, and shelter acts as a buffer against climate change.

With the down-scaling, in the case of the Citarum cascade reservoir system where the largest reservoir is in the Jatiluhur reservoir, with a proportion of 56.8% of overall capacity, the capacity of the Citarum cascade reservoir adaptation is in

Jatiluhur reservoir. So in the Citarum cascade reservoir operation, Jatiluhur reservoir acts as a buffer against two reservoirs above it. This is contradictory to the principle of operation of reservoirs equal-sharing requiring a balance of clean containment proportions for each constant fixed reservoir and avoiding changes in water level in each reservoir to change drastically from month to month.

Changes in the operating principle of Citarum cascade reservoir will have implications for the economic potential value generated from electricity generation. Therefore, in accordance with the idealism in the management of natural resources in the Citarum River Region unit to achieve independence, the economic value of water must be accommodated in the Citarum cascade reservoir operation. At the present stage, the adaptation of Citarum's cascade reservoir operation to reduce the impact of climate change is done by optimizing the capacity of the container to hold water in the wet season as much as possible in the dry season but by providing space for flood control.

In addition to water availability adaptation, adaptation of water needs through on-demand irrigation management and improved rainwater catchment conditions to improve retention capacity as well as efforts to hold water forever in the area upstream activities such as increasing capacity through the construction of water catchments to rainwater harvesting and water reuse.

CONCLUSION

Climate change is a world problem and one way to reduce the impact of climate change is by using renewable energy sources, such as hydropower. On the contrary, with the influence of climate change, especially on hydrological regimes that are closely linked in reservoir operations, the operation of the reservoir needs to be strengthened by considering these conditions in its operations to reduce its impact. Climate change must be understood as one of the business risks that can result in the decline in electricity production. This should also be considered in terms of operation and management of reservoirs.

The hydrological regime in the Citarum River is changing, as indicated by the higher flow rate fluctuation and the higher coefficient of run-off and the indication of seasonal leap, the longer the dry season, the shorter rain time with the greater intensity requires that adaptation of Citarum cascade reservoir operation to mitigate the impacts of climate change, by optimizing the capacity of containers to hold water in the wet season as much as possible for the needs in the dry season but by providing space for flood control.

The greatest capacity of Ir. H. Djuanda dam reservoirs is the value of adaptation capacity in the Citarum cascade reservoir operation so that in the Citarum cascade reservoir operation, Ir. H. Djuanda reservoir acts as a buffer against two reservoirs above it. Adaptation of water demand through on-demand irrigation management and improved rainwater catchment conditions to increase retention capacity as well as efforts to hold water forever in upstream areas such as increasing capacity through the construction of water catchments up to rainwater harvesting and water reuse.

1. INTRODUCTION

Prediction of sediment distribution in reservoirs is an important issue for dam designers to determine the reservoir active storage capacity, outlet sill elevation, dam stability, recreational facilities, and backwater conditions. A lot of methods such as physical, mathematical and experimental models are provided in this field. One of the most important experimental methods to study sediment distribution in the reservoir is area reduction method. Several mathematical models for predicting reservoir sedimentation have been developed based on the equations of motion and continuity for water and sediment. Some of these models have additional specific features such as the GSTARS which is developed Molinas and Yang (1986). In this research, GSTARS3 sediment transport model and areareduction method was used to simulate sedimentation processes in Germi Chay dam reservoir. Germi chai dam is a multi-purpose earth-fill dam with central clay core which has been constructed on Ghermi chai river in the northwest of Iran. Sediment distribution in various reservoir levels is computed and Area-Volume-Height curves for period of 80 years through previously mentioned methods are computed, drawn and compared.

2. DISCUSSION AND CONCLUSION

GSTARS3 sediment transport model was used in this study to predict sediment load from the watershed discharged to reservoir. In order to study the problem and calibrate the models, the results are compared with the experimental method of reducing the level. The results of the experimental method of Area Reduction can be reliable, especially at high reservoir levels. The comparison graphs of Volume-Elevation and Area-Elevation before and after simulation (after a 80-year sedimentation period) are shown in Fig.1 to 2.

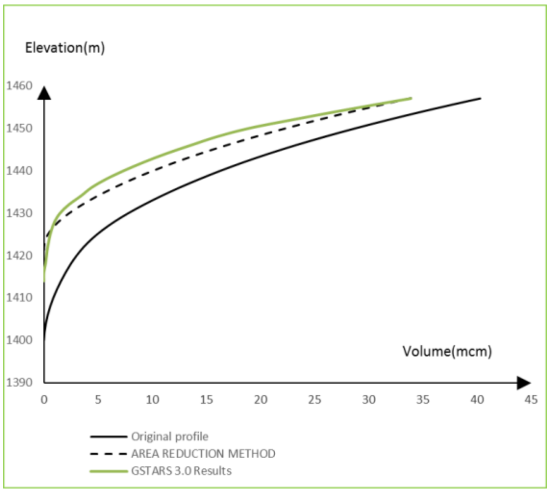

Fig. 1
Volume-Elevation graphs before and after simulation (after a 80-year sedimentation) period

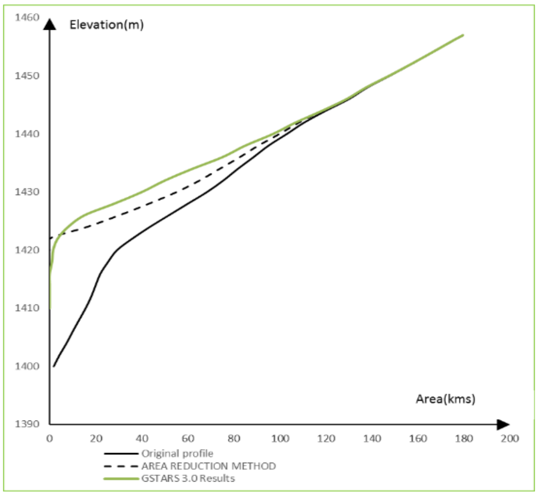

Fig. 2
Area-Elevation graphs before and after simulation (after a 80-year sedimentation) period

According to the research, the Area Reduction Method to estimate the sedimentation in the reservoir of Garmi Chay dam is a priority. Considering that this method can not predict the exact model of sedimentation in the reservoir of the dam such as longitudinal profile, bottom line of reservoir and sedimentation in different sections of the dam reservoir, this is done using the GSTARS3.0 Model.

Comparison of the results of the software in the single-dimensional model and the experimental method of Area Reduction in the low levels of the dam reservoir indicates that the GSTARS 3.0 model is inaccurate near the dam body and transfers a significant amount of sediment input to the outside of the study area.

1. INTRODUCTION

River restoration can involve various methods, from the management of a riverbed for ecosystem recovery to the positive improvement of river channels and

---

* *titre de l'article complet*

flood plains. The river restoration methods of which the discharge is controlled by a dam upstream include flexible dam operation for flood control including artificial flooding (Kondolf and Wilcock, 1996), a dam removal that has lost its functions and improvement of sediment transport through sediment supply to the dam downstream (Gaeuman, 2014). River restoration improves the river morphology, or reproduces flood plains to connect the river with the protected lower channel habitats or to increase the flood frequency of the flood plains, increasing the diversity of the habitats (Gaeuman, 2014). For a river where the sediment is trapped by a dam, sediment supply to the river upstream is the most common restoration project (Bunte, 2004). Reduction of the sediment inflow in the river by a dam construction upstream may change the geomorphic features of the river or disturb the ecosystem habitats in the dam downstream, affecting the aquatic ecosystem. Decrease of the sediment supply to a dam downstream lowers the bed elevation, changes the sediment size in the bed, separates gravel from fine sediment to form an armored layer and spreads the layer to the downstream. Sediment can be supplied to a river through various methods, and the specific implementation method is determined by following the major objectives of the sediment supply. Bunte (2004) proposed the sediment supply method of placing pebble piles in a river during a dry season before a flood event, in which the sediment supplied to a river may be immediately swept by a flood to the river downstream. Recently, various methods have been employed in South Korea to improve the river environment in dams downstream. In particular, methods of sediment supply have been prepared to improve the river environment by supplying sediment to dams downstream. In this study, a numerical simulation was conducted to investigate the efficiency of the plans as a preliminary study. The effect of sediment supply was evaluated in the Naeseongcheon Stream under discharge conditions that were dependent on the dam operation.

2. NUMERICAL MODEL

This study used a physical-based morphodynamic model, Nays2DH, developed by Shimizu(Iwasaki et al., 2015). This model solves the two-dimensional depth-averaged flow equations and calculates sediment transport and sediment sorting, and geomorphic changes considering bank erosion and vegetation. This model has been applied in various rivers.

A numerical model is applied to simulate flow field. The governing equations, *i.e.,* the continuity and momentum equations, for water flow are transformed from the Cartesian coordinate system into boundary fitted coordinate system.

Continuity equation:

$$\frac{\partial}{\partial t}\left(\frac{h}{J}\right)+\frac{\partial}{\partial \xi}\left(\frac{hu^{\xi}}{J}\right)+\frac{\partial}{\partial \eta}\left(\frac{hu^{\eta}}{J}\right)=0 \tag{1}$$

Momentum equations in the ξ and η directions:

$$\frac{\partial u^{\xi}}{\partial t}+u^{\xi}\frac{\partial u^{\xi}}{\partial \xi}+u^{\eta}\frac{\partial u^{\xi}}{\partial \eta}+\alpha_1 u^{\xi}u^{\xi}+\alpha_2 u^{\xi}u^{\eta}+\alpha_3 u^{\eta}u^{\eta}$$
$$=-g\left[\left(\xi_x^2+\xi_y^2\right)\frac{\partial H}{\partial \xi}\left(\xi_x\eta_x+\xi_y\eta_y\right)\frac{\partial H}{\partial \eta}\right]-\frac{C_f u^{\xi}}{hJ}\sqrt{\left(\eta_y u^{\xi}-\xi_y u^{n}\right)^2+\left(-\eta_x u^{\xi}-\xi_x u^{\eta}\right)^2} \quad (2)$$
$$+\frac{\partial}{\partial \xi}\left(\nu_t \xi_r^2\frac{\partial u^{\xi}}{\partial \xi}\right)+\frac{\partial}{\partial \eta}\left(\nu_t \eta_r^2\frac{\partial u^{\xi}}{\partial \eta}\right)-\frac{F^{\xi}}{\rho h}$$

$$\frac{\partial u^{\eta}}{\partial t}+u^{\xi}\frac{\partial u^{\eta}}{\partial \xi}+u^{\eta}\frac{\partial u^{\eta}}{\partial \eta}+\alpha_4 u^{\xi}u^{\xi}+\alpha_5 u^{\xi}u^{\eta}+\alpha_6 u^{\eta}u^{\eta}$$
$$=-g\left[\left(\eta_x^2+\eta_y^2\right)\frac{\partial H}{\partial \eta}\left(\xi_x\eta_x+\xi_y\eta_y\right)\frac{\partial H}{\partial \xi}\right]-\frac{C_f u^{\eta}}{hJ}\sqrt{\left(\eta_y u^{\xi}-\xi_y u^{\eta}\right)^2+\left(-\eta_x u^{\xi}-\xi_x u^{\eta}\right)^2} \quad (3)$$
$$+\frac{\partial}{\partial \xi}\left(\nu_t \xi_r^2\frac{\partial u^{\eta}}{\partial \xi}\right)+\frac{\partial}{\partial \eta}\left(\nu_t \eta_r^2\frac{\partial u^{\eta}}{\partial \eta}\right)-\frac{F^{\eta}}{\rho h}$$

In these equations, ξ and η = the spatial coordinate components in the boundary fitted curvilinear coordinate system; t = the time coordinate in the coordinate system; J = Jacobian of the coordinate transformation given as $J=\tau_t\xi_x\eta_y+\xi_t\eta_x\tau_y+\eta_t\tau_x\xi_y-\left(\eta_t\xi_x\tau_y+\xi_t\tau_x\eta_y+\tau_t\xi_y\eta_x\right)$; u^{ξ} and u^{η} = contravariant components of the depth-averaged flow velocity in the ξ and η directions, respectively, defined as $u^{\xi}=\xi_x u+\xi_y v$ and $u^{\eta}=\eta_x u+\eta_y v$; u and v = the depth averaged velocity components in x and y directions, respectively. The coefficients α_1~α_6 are given in Jang and Shimizu (2005).

The morphodynamic module of Nays2DH includes sediment transport, bank erosion, and bed elevation changes. The two-dimensional sediment continuity equation in boundary-fitted coordinate system is as follows:

$$\frac{\partial}{\partial t}\left(\frac{z_b}{J}\right)+\frac{1}{1-\lambda}\left[\frac{\partial}{\partial \xi}\left(\frac{q_b^{\xi}}{J}\right)+\frac{\partial}{\partial \eta}\left(\frac{q_b^{\eta}}{J}\right)\right]=0 \quad (4)$$

where z_b = bed elevation; λ = porosity of the bed material; q_b^{ξ} and q_b^{η} = contravariant components of the bedload transport rate per unit width in the ξ and η directions, respectively.

The sediment transport rate in the stream line is calculated using the formula of Ashida and Michiue (1972). As a numerical scheme, the cubic interpolated psuedoparticle (CIP) method is used. The numerical method solves boundary problems while introducing little numerical diffusion, and algorithm implementation is more straightforward than for other high-order upwind. In the non-advection phase, the continuity equation and the non-advection terms in the momentum equations are solved for depth as a Poisson equation. The viscous terms are approximated using the central difference method. Readers are referred to Jang and Shimizu (2005) for more details.

3. APPLICABLITY OF NUMERICAL MODEL

The numerical model was validated by using the experimental result provided by Cui *et al.* (2003) who conducted experiments to investigate how the sediment supplied to a channel as discontinuous pulses were moved to the downstream of the channel. The channel was 45 m long, 0.5 m wide, and 0.7 m deep. The slope was 0.0108, the discharge was 0.009 m^3/s, the water depth was 0.0325 m, and the velocity was 0.55 m/s. The sediment pulse, 7.5 cm long and 3.5 cm high, was placed at 8 m away from the inlet of the channel where the sediment was supplied toward the downstream of the channel. The median size of the sediment (D_{50}) was 2.0 mm with the geometric mean of 1.83 mm (Run-2).

Fig. 1 shows the change of the sediment discharge over time. After four minutes of the simulation, a large amount of the sediment was discharged from the sediment pulse. As time passed, the sediment discharge from the pulse decreased. The sediment spread to the downstream of the channel. Alternate bars were developed and migrated to the downstream of the channel. The bars were dissipated at one hour and six minutes. This complies with the experimental results.

Fig. 2 shows the comparison of longitudinal bed changes between numerical and experimental results. At four minutes, the bed elevation at the sediment pulse decreased dramatically, and the sediment was transported to the downstream of the channel (Fig. 2(b)). At 18 minutes, the bed elevation at the sediment pulse decreased and the sediment was gradually diffused to the downstream (Fig. 2(c)). After more time passed, the bed reached an equilibrium state (Figs. 2(d)). The transport and diffusion of the sediment pulse found in the experiment was well simulated numerically.

(d) Time=1:06

Fig. 2 Comparison of longitudinal bed changes between numerical and experimental results: times are written as (hour:min).

4. ANALYSIS OF RIVER CHANGES BY SEDIMENT SUPPLY IN NAESONGCHEON RIVER DOWNSTREAM OF YOUNGJU DAM

4.1 NUMERICAL CONDITION

To supply sediment effectively for improving the river environments at a dam downstream, the spatial range and location, the sediment supply method, and the quantity and size of the supplied sediment should be determined. Locations of sediment supply are determined as a riffle with a sufficient flow where the tractive force may be easily secured, or as a curved region in which a secondary flow is generated to increase the effect of the sediment supply and improve the river environment.

The numerical model was applied to the Yeongju Dam downstream. The Yeongju Dam is located at the Naeseongcheon River upstream, which is the first tributary of the Nakdong River (Fig. 3). The curved regions, No. 1 and No. 2, were chosen as the sediment supply locations (Fig. 3). Secondary flow at meandering channel is generated in the immediate downstream of Yeongju Dam, No. 1. No. 2

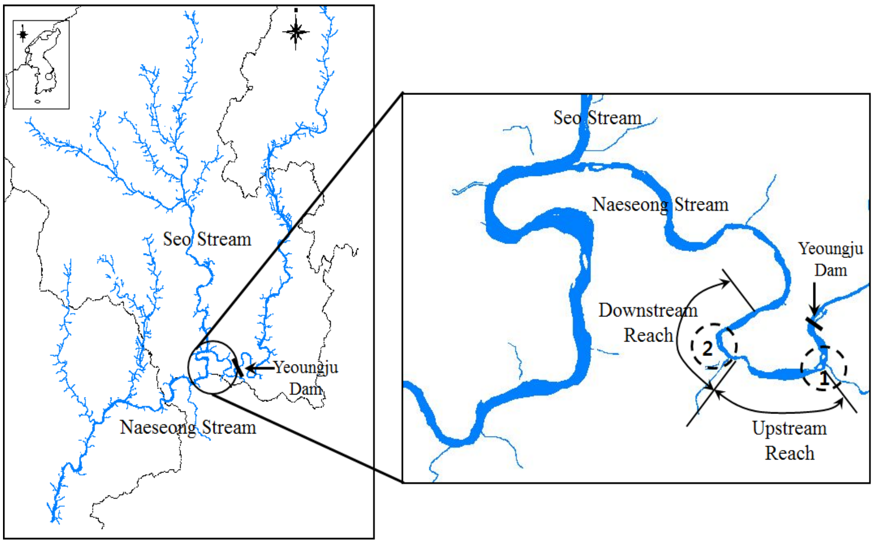

Fig. 3 Location map of study area

is about 1 km downstream from the Yeongju Dam (Fig. 3). At No. 1, the bed slope was 0.0026 and the channel width was 86.5 m. At No. 2, the bed slope was 0.0012 and the width was 112.3 m.

The channel is significantly changed at a bankfull discharge where the water overflows the lower channel and starts to fill the flood plain. Therefore, for the sediment supply to the dam downstream, a bankfull discharge of 9.00 m^3/s, calculated using HEC-RAS, was applied to the study reach. In addition, the effect of sediment supply was analyzed at the discharge of 15.13 m^3/s, considering the discharge from the dam.

4.2 COMPUTATIONAL CONDITIONS

A two-dimensional numerical model, Nays2DH, was employed to simulate the effect of the sediment supply to the dam downstream. Table 1 shows the hydraulic conditions for the numerical simulation. The length of the river was 10 km, and the bed slope was 0.001. The mean diameter of the sediment was 4.61 mm. The Manning's n value was set to 0.031. The time step for the numerical calculation was 0.01 seconds. Considering the geographic effects of the relatively steep slope and the serpentine flow, the grid size was set to 0.2 m in the flow direction and 0.1 m in the transverse direction. To investigate the channel changes,

Table 1 Parameters for numerical simulation

Case	Discharge (m^3/s)	Sediment inflow condition	Remarks
Run-1	9.00	Trap efficiency : 98.7%	Bankfull discharge
Run-2	15.13	Trap efficiency : 98.7%	Water supply

the amount of sediment supply was determined by considering the trapped sediment by the dam.

4.3 NUMERICAL RESULTS

Fig. 4 shows the planimetric changes of the bed for Run-2. In the immediate downstream of the dam, the flow focused on the left bank where the bed elevation decreased. The area corresponded to No. 1 where the sediment placed in the dam downstream. The sediment transported to the river downstream. However, as the flow was dispersed in the straight reach, the bed elevation increased. The bed elevation decreased at No. 2. While the bed elevation decreased in the outer part of the curved region downstream, the elevation increased in the inner part of the meandering reach.

Fig. 5 shows the cross-sectional changes at 400 m and 600 m downstream for Run-2. At 400 m downstream, the bed elevation decreased over time. About 10 hours later, the bed elevation decreased at the center of the river and in the right bank (Fig. 5(a)). The bed decreased initially at the center of the channel, and then the bed scoured in the right bank also as the flow focused on the outer part of the curved region (Fig. 5). The sediment was deposited at the center of the river at 600 m.

Fig. 6 and 7 show the comparison results of the bed changes between Run-1 and Run-2. At No. 1 and No. 2, the bed elevation changed over time, and the change was greater in Run-2 than in Run-1. In other words, the change in the bed elevation was greater at a higher discharge. The numerical results showed that the

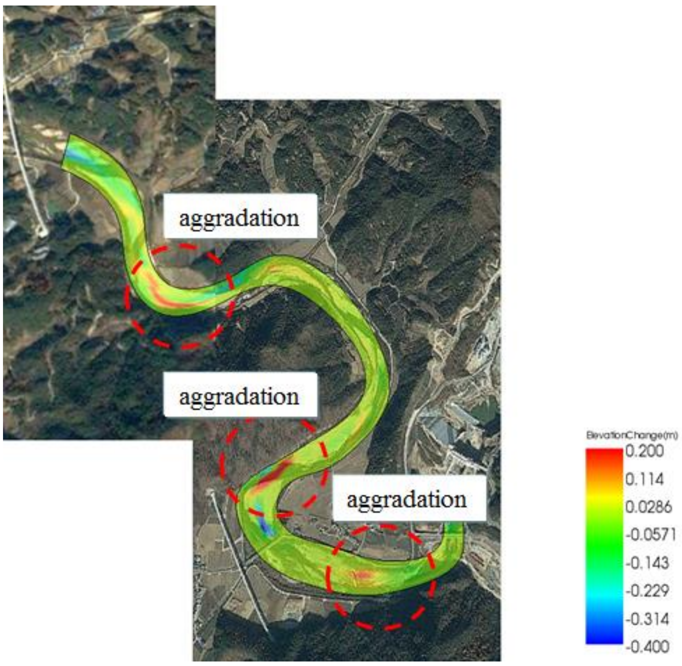

Fig. 4 Planimatric changes for Run-2

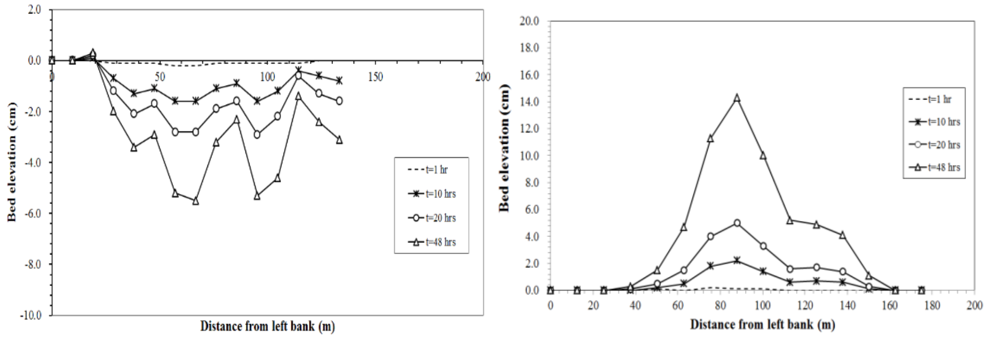
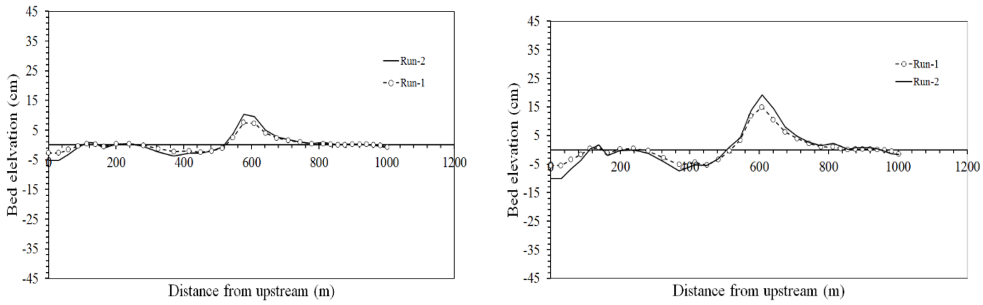


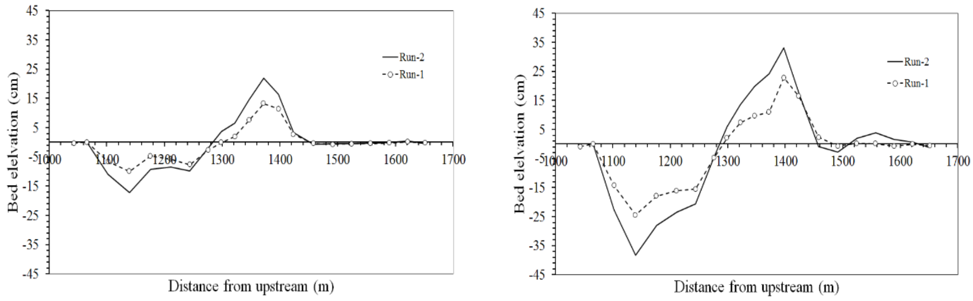
(a) At 400m from inlet (b) At 600m from inlet

Fig. 5 Cross sectional changes for Run-2



(a) T=20 hrs (b) T=48hrs

Fig. 6 Bed elevation changes with time for each run in the immediate downstream of the dam



(a) T=20 hrs (b) T=48hrs

Fig. 7 Bed elevation changes with time for each run at the downstream reach

increasing the discharge from the dam developed the geomorphic diversity of the channel to enhance the effect of the sediment supply on the river in the dam downstream.

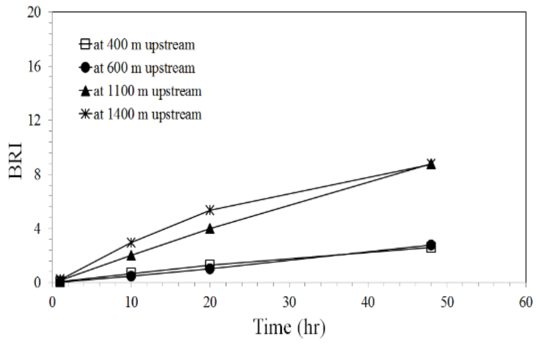
Bed Relief Index (BRI) was calculated in order to quantitatively understand the cross-sectional change of the bed. BRI represents the standard deviation at the mean bed elevation. BRI was calculated based on the bed elevation data at the individual cross-sections, using the following equation (Hoey and Sutherland, 1991):

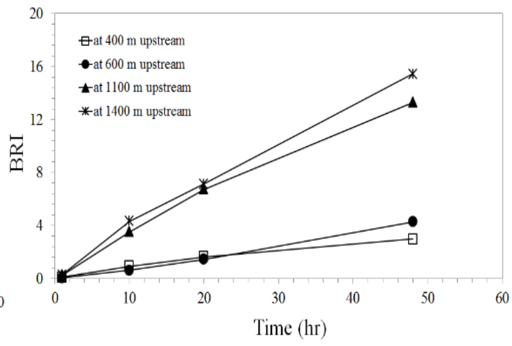
$$BRI = \frac{\left(\sum_{i=1}^{n-1} \left[\left(z_i^2 + z_{i+1}^2 \right) / 2 \right]^{0.50} \left[x_{i+1} - x_i \right] \right)}{\left(x_n - x_1 \right)} \tag{14}$$

where x denotes the transverse distance from the left bank to the i position, and z is the difference between the bed elevation at the i position (z_i) and the mean bed elevation. Fig. 8 shows the change of BRI for each run. BRI increased in both Runs-1 and 2 with time. BRI was great in the areas where the bed scoured and the sediment deposited, indicating that the change in the bed elevation was significant and dynamic. BRI was greater in Run-2 where discharge was 15.13 m^3/s than in Run-1 where discharge was 9.00 m^3/s. In addition, BRI was greater at the 1,100 m and 1,400 m downstream at No. 2 than at the 400 m and 600 m at No. 1. This showed that a higher discharge enhanced the dynamics of the bed with the sediment supply upstream, and that the river was more dynamic at the 1,400 m downstream at No. 2 than in the immediate downstream of the dam, being affected more by the sediment supply.

5. CONCLUSIONS

In this study, a numerical simulation has been conducted to investigate the efficiency of the plans as a preliminary study. The effect of sediment supply was evaluated in the Naeseongcheon Stream under discharge conditions that were dependent on the dam operation. The sediment supply location candidates determined as a riffle or as a curved region where the secondary flow is formed to effectively perform sediment supply. The bed elevation in the immediate downstream of the dam decreased over time. In addition, as time passed, the sediment pulse scoured and moved to the downstream of the channel, and then deposited at positions where the flow velocity decreased. BRI, representing the dynamics of the bed, increased with time, and was found to be greater in the channel downstream than upstream. In addition, as discharge increased, BRI increased because the higher discharge





(a) Run-1 (b) Run-2

Fig. 8 Bed relief Index (BRI) for each run

had a greater effect on the bed, increasing the dynamics of the river channel.

This study showed that a higher discharge enhanced the dynamics of the bed with the sediment supply upstream, and that the river was more dynamic at the downstream of the channel than in the immediate downstream of the dam, being affected more by the sediment supply. This study has some limitations to a review of the efficiency of the sediment supply method through a numerical simulation. A study on the actual implementation of the sediment supply method should be conducted in future research.

1. INTRODUCTION

Reservoirs in mountainous regions are built for many generations to come. Climate change will definitely be a factor of decisive order. In consequence assessing performance and risk of a hydropower plant, it becomes necessary to quantify the impact of climate change. A methodology is proposed which allows the mathematical formulation of changes of performance over time.

2. QUANTIFICATION OF PAST CHANGES AND PREDICITIONS

The archives of LANDSAT, IKONOS, Sentinel and RapidEye images cover a period of 40 years. In case that sufficient satellite images are available, changes within that period can be identified. The following phenomena have been studied:

- Retreat of glaciers and related changes in the creeks
- Indicators for the change in permafrost expressed in debris flow starting at higher elevations
- Changes in shape and volume of natural lakes and ponds
- Changes in vegetation, particularly the lower and upper tree lines
- Changes in vegetation density and character

- Traces of events that happened in the observation period including forming relevant statistics
- Changes in the riverbed and its contributories

The fact that quality and resolution of images has changed over time has to be compensated. Software for change detection is readily available. Nevertheless, plausibility checks are always recommended. Rock falls and all kinds of sliding events receive priority in operational risk assessment.

3. CLIMATE CHANGE, INFLUENCE ON FLOOD AND RAINFALL

Flood risk and, generally speaking, disasters due to natural disasters is constantly increasing. Vulnerability itself tends to change over many areas, due to a range of climatic and non-climatic impacts whose relative importance is site-specific.

Climate-driven changes in future nature-caused disaster frequency are complex, because they depend on the generating mechanism. In many places, for instance, flood risk is likely to grow, due to a combination of anthropogenic and climatic factors. Recent modelling studies show that plausible climate change scenarios project future increases of both amplitude and frequency of natural-disaster events. It is very likely that there will be an almost ubiquitous increase in precipitation intensity in the warming world. Decreasing flood magnitudes, for instance, can be expected in many areas where floods are generated by spring snowmelt. However, global warming may not necessarily reduce snowmelt flooding everywhere.

Several ongoing land-use changes, such as urbanization, deforestation, and reduction of natural storage (floodplains, wetlands), can be regarded as adverse from the viewpoint of safety from nature-caused disasters. Furthermore, human encroachment into unsafe areas has increased the potential for damage. Societies become more exposed, developing disaster-prone areas (maladaptation).

In such a global change, mitigation of the risk disasters calls for a change from reactive to an anticipatory stance.

The warning point is that climate change will perhaps not change the real nature of natural disasters, but their intensity and frequency, thus increasing the risk itself (IPPC,2017).

As a matter of reference, we include the following picture which shows the shows an extreme heavy rainfall event that took place on Aug 15th, 2015 in the area of Eastern Tibet.

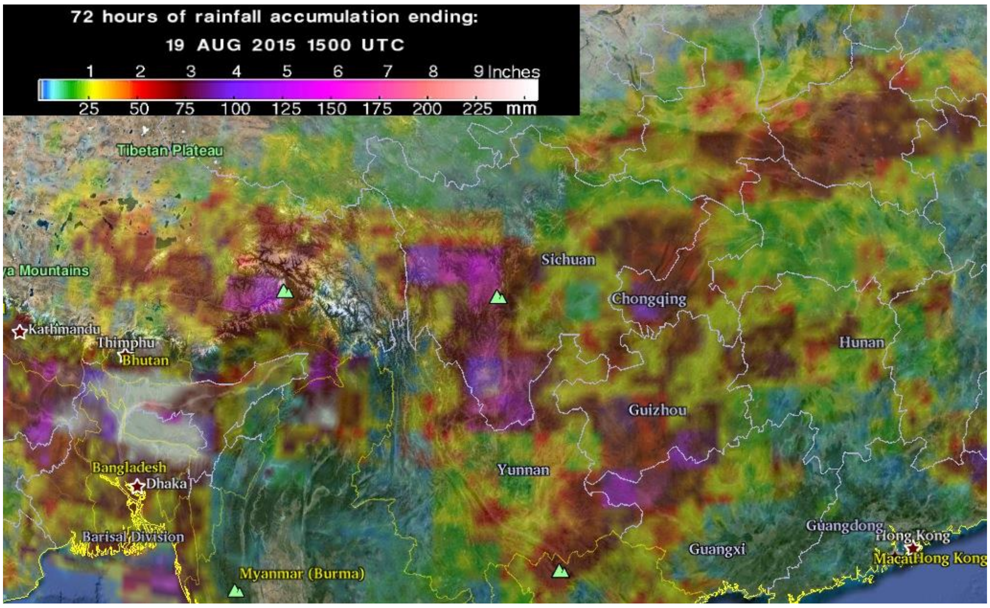

Fig. 1: 72 hours rain event: Extreme heavy rainfall event that took place on Aug 15th, 2015 in the area of Eastern Tibet

4. METHODOLOGY AND APPROACH

The interaction among earth-surface erosion, slope failure, tectonic uplift and the climate is a key issue to understand the processes of mass movements in the study area. The local stress condition is an important factor that may relate to uplift, erosion, deposition, and groundwater fluctuation (Xu, 2014 a and b).

The vertical motion and mechanism in Tibet is very complex: Several geodynamic processes control the complicated uplift pattern in the Tibetan Plateau, including the plate-tectonic movements, glacier isostatic adjustments and the mass loss related to the climate change conditions. The Tibetan Plateau located in central Asia is subject to the northward push from the Indian subcontinent and the collision with Eurasian plate, which results in East-West expulsion and uplift. The uplift rates of most part of the Tibetan Plateau range from 1 mm/yr to 2 mm/yr (Zhang & Jin, 2013). This general uplift also caused local fragmentation into blocks (kilometres or maximally, a few tens of kilometres) of local extent that have subsided and/or uplifted relative to one another. Alluvial deposition of the subsiding blocks contrasts with erosion and formation of gorges in the uplifted blocks. The question arises about the effects of tectonics in a relatively complex setting as drivers for the morphological development and the sedimentary architecture. The study region provides a framework of both regional tectonic uplift overprinted by tectonic movements of more local extent and changing over time.

Climate change will have an influence on precipitations (duration, intensity, frequency, distribution). The following Fig.4 provides an overview of the precipitation distribution during the last decades.

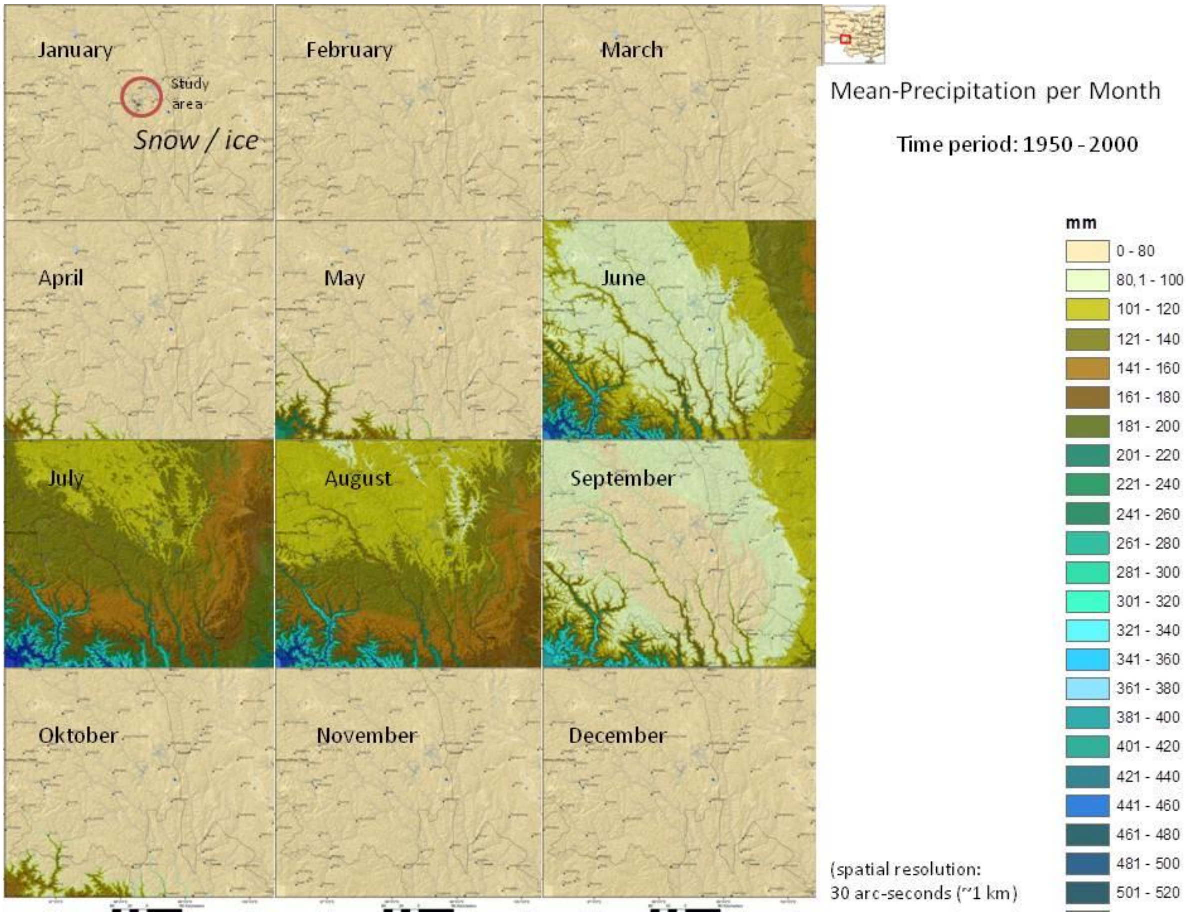

Fig.2: Monthly precipitations during 1950 – 2000 according to WorldClim – Global Climate Data (http://www.worldclim.org/download)

Many features in the high mountain environment such as glaciers, permafrost, vegetation or soil are very climate-sensitive and could experience large changes in the future. As a consequence, the potential starting zones for natural hazards, the dynamics of processes, and the areas potentially affected by natural hazards are likely to change as well. Therefore, the high mountains can be seen as a complex system in which various features react to the rising temperatures in different time scales and intensities. The rock glaciers are expected to thaw over the coming years and decades, posing a new threat of landslides in the avalanche starting zone. However, climatic change may be the most direct cause of terrace formation because hydrological dynamic parameters that dominate riverbed sediment aggradation and transportation (e.g., flux and flow velocity) are directly related to climatic conditions (Wang et al.,2008). Another important factor is the wind situation when considering luv and lee-effects of exposed slopes (sun and rain exposition). Therefore, the wind pattern and wind properties have to be monitored.

The monitoring of the seasonal development and changes of the vegetation forms an essential part in the scope of this research study. Although the impact of vegetation on slope stability in mountainous regions are understood and documented, it is difficult to predict how vegetation will impact mass movement processes, such as landslides and mudflows. Vegetation helps to stabilize slope materials by improving the resistance of slopes to both, surficial erosion and mass wasting. Vegetation survival environments are correlated with slope failure-formational environments. Thus, assessments of the spatial distribution of damaged vegetation and its recovery conditions are important for determining susceptible terrain and surface materials to mass movement processes.

The assemblage of trees and other vegetation growing above hillslopes plays an important role in intercepting slope materials and protecting them from the actions of sunshine, wind and rain. Vegetation, including the plant litter (leaves), helps stabilize the slope materials (1) by extensively altering the soil hydrology by reducing water loss and transpiration, intercepting raindrops and dissipating erosive energy and (2) by altering the mechanical and hydrological properties of the soil by affecting the developing root systems. Thus, vegetation improves resistance on slopes to surficial erosion and mass wasting, whereas the removal of slope vegetation tends to accelerate or increase slope failure. Gravity, flowing water, and temperature changes are the main (geomorphic) forces behind mass movement processes. The primary force that acts on mass movement is gravity. However, the substrate, environmental terrain and several additional factors can induce mass movement processes. Among these causative factors, vegetation affects the accumulation of slope material. The thickness of the material strongly affects the relative slope stability by supporting vegetation with stronger roots and influencing the effect of the subsurface on the overland flow. Hence, interactions between vegetation and materials affect mass movement processes (Zhang et al.,2015).

Vegetation requires water, sunshine, nutrients and specific air temperatures. All of these factors are controlled primarily by the local topographical environment and material properties. Elevation influences the air temperature, slope gradient affects the groundwater conditions, slope aspect controls the sunlight duration, and materials provide the nutrients. The topographical conditions influence mass movement processes, such as rockslides, creep and landslides, by affecting the force balance of the surface materials and providing potential energy.

The vegetation in the study area is mainly characterized by a grass, bush and low tree vegetation (Fig.3), whereby the vegetation is concentrated on the river terraces and in those flatter upper parts of the hills smoothened by glacial erosion. In the lower parts of the valleys debris flow, gully erosion, rockfall and landslides are leading to the decrease of vegetation occurrence and density.

Fig.3: Vegetation in the study area

5. DIGITAL IMAGE PROCESSING

Different satellite data and image processing tools were tested in order to find out whether the satellite data can contribute to the detection of causal factors influencing the susceptibility to slope failure and to seasonal landscape monitoring. For a better overview of seasonal influences multi-temporal analysis of different satellite data has to be carried out, in combination with evaluations of long-term precipitation data, river water and groundwater table measurements in the field and further climate data (precipitation, temperature, wind). Precipitation data and groundwater table data are an important input when dealing with the seasonal influences on mass movements. The different satellite data and the workflow are presented in Fig.4. For the present study mainly Landsat- and RapidEye- images were used. The use of multi-temporal satellite remote sensing data opens up the opportunity for the development of efficient methods for systematic spatiotemporal mapping of landslides over large areas.

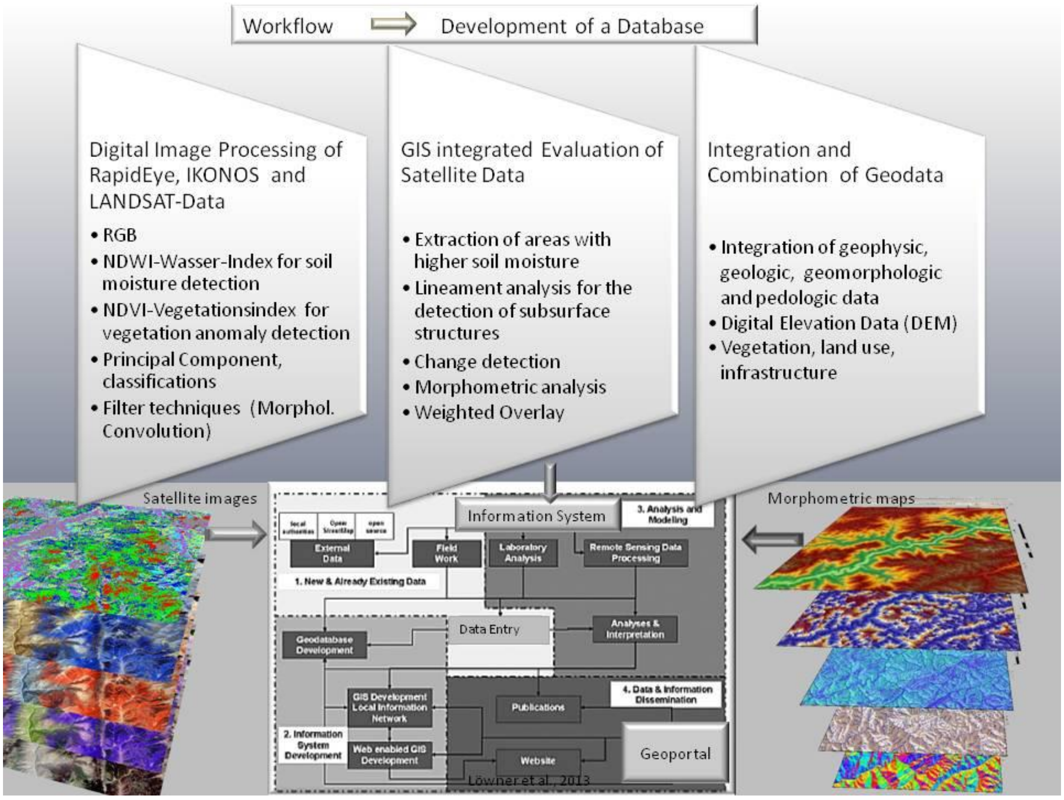

Fig. 4: Data and Workflow

The evaluation of Landsat time series is of special interest. By analysing the landscape development over 40 years environmental changes and future trends become visible. The research is focussed on the detection of the snow cover size and distribution and monitoring of trends (Figs.5 and 6). Unfortunately, many scenes are covered by clouds. This is the reason, why seasonal change detections are not possible for every year. Although cloud covers are a limiting factor for the evaluation of Landsat data, enough data are available to detect seasonal variations and long-term changes. Snow covered areas are classified based on the Landsat-images and then the areas with snow and ice-covers are calculated.

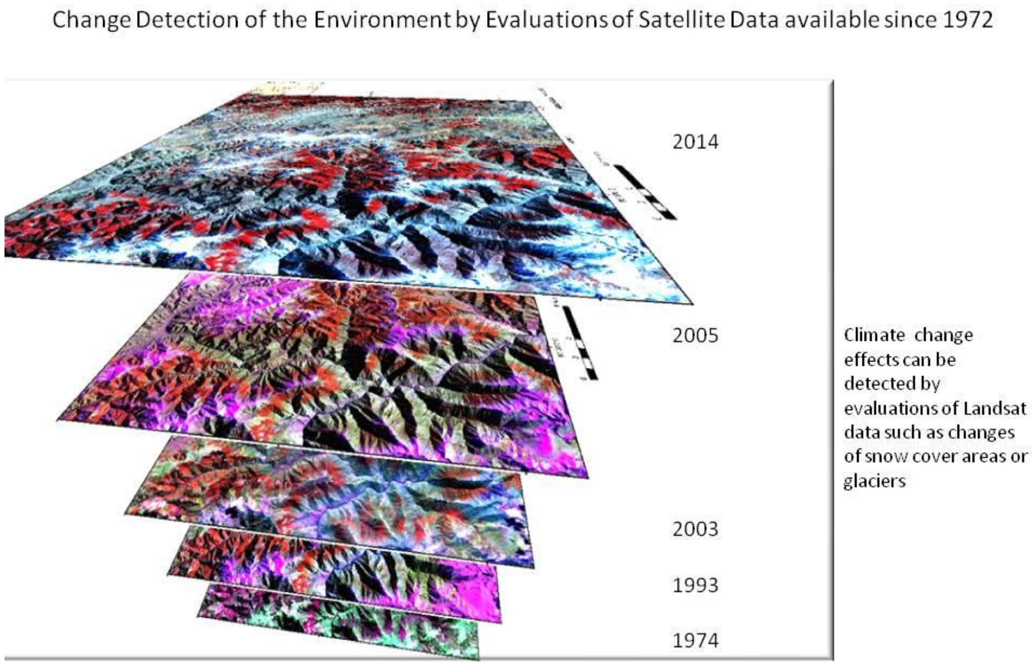

Fig.5 : Evaluation of time series of Landsat-images since 1974

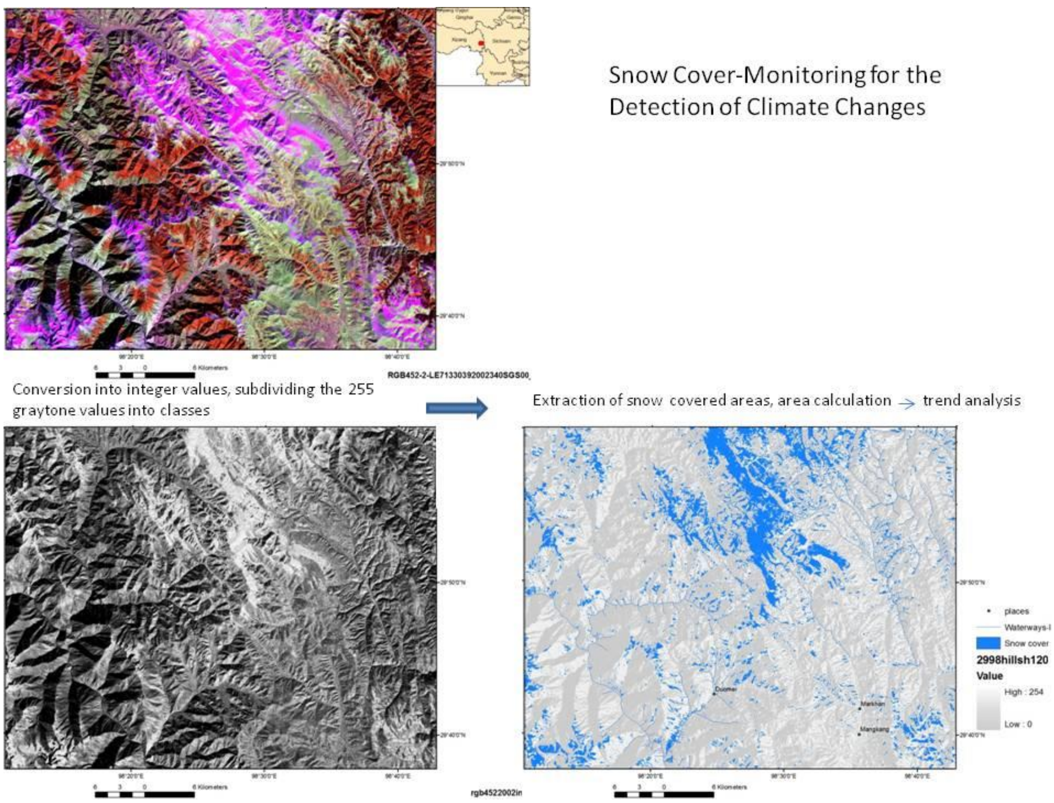

Fig.6: Snow cover detection

6. RISK ASSESSMENT

The methodology implied is oriented at available standards like ISO 31000 on the risk assessment framework and the latest development on risk-based operation in Europe. These approaches follow straightforward strategies consisting of:

- Identification of risks
- Modelling of each individual risk
- Identification of parameters and indicators driving the process
- Monitoring of parameters and indicators
- Periodic determination of changes in parameters and indicators with subsequent adjustment of risk

The entire procedure is organized in loops where the frequency of assessment depends on the magnitude of changes expected.

ABSTRACT

The Wonogiri Dam should continue to contribute to stabilization of people's livelihood as well as improvement of social welfare at least in coming 100 years. This goal will be achieved only in the way to secure and maintain the expected function of the Wonogiri reservoir in terms of flood control, irrigation water, domestic and industrial water supply and hydropower generation.

The Wonogiri reservoir will be separated by closure dike into two reservoirs, namely a Sediment Storage Reservoir with New Gates and a large main Wonogiri Reservoir, and operated independently.

In construction of new dike with saturated soils with soft clay, low bearing capacity and excessive settlement, the ground improvement technique using

deep cement soil mixing is one of the most suitable methods to overcome this problem. The sole purpose of deep cement soil mixing is to improve shear strength of soil by in situ mixing the soil with cement grout.

Keywords: Wonogiri Dam, reservoir, ground improvement, deep cement soil mixing

[1] Model Tes Hidraulik Bangunan Pelimpah Bendungan Cipanundan, Jawa Barat, Indonesia

1. BACKGROUND

The Wonogiri Multipurpose Dam was constructed at Upper Solo River basin in 1978-1981. Since impoundment of Wonogiri reservoir on December 29, 1980, the reservoir has been rapidly filled with sediments. The quantity of sedimentation reached 65% of the dead storage on 2013 that mostly from Keduang River as Bengawan Solo's tributary. To mitigate sediment problem in the Wonogiri reservoir, the Master Plan and the Feasibility Study on countermeasures for sedimentation in the Wonogiri Multipurpose dam reservoir were carried out from 2004 to 2007 by JICA for detail design and supporting report by Nippon Koei Co, Ltd and Yachiyo Engineering Co., Ltd until 2010.

1.1. The Location

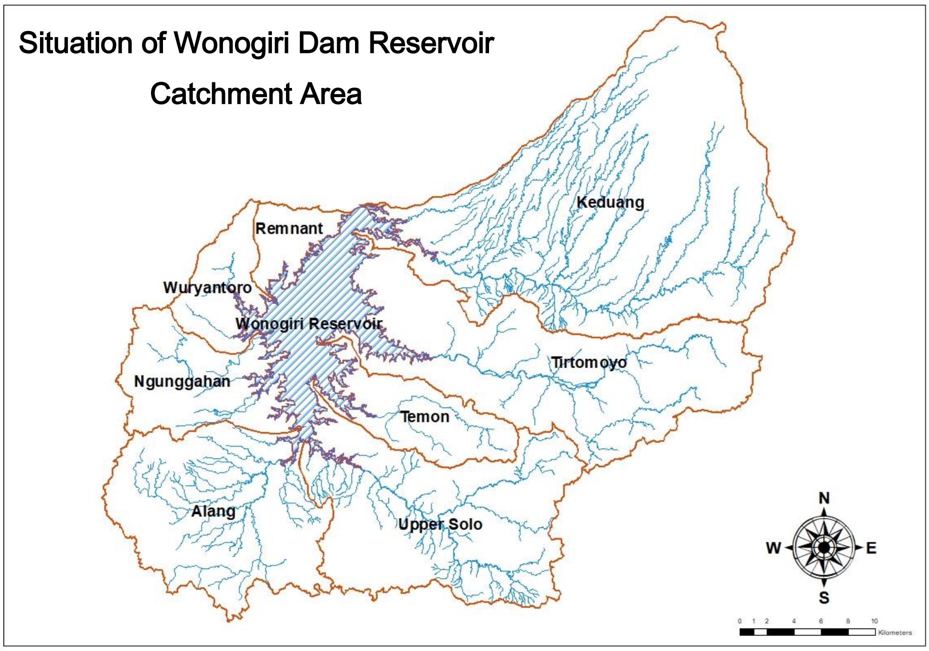
The Project is located in Wonogiri Regency of Central Java Province in the central region of Java Island approximate 600 km east of the Indonesian Capital city Jakarta.

Figure 1.
Indonesian Map, Source: Nippon Koei Report

Figure 2.
Map showing relative location of Wonogiri Reservoir in Indonesia.
Source: Nippon Koei Report

1.2. The Problem

The Wonogiri reservoir is fed by 8 main streams of which Keduang is the largest contributing 35 percent of the inflow and sediment.



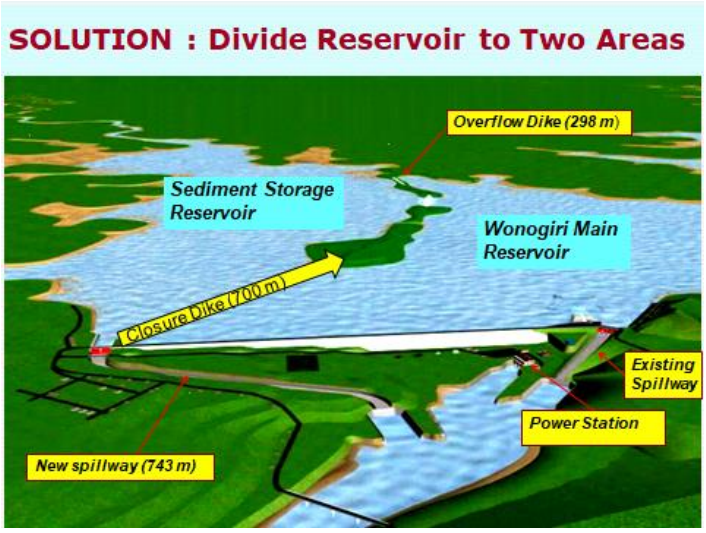
The sedimentation problem is made worse by the fact that the mouth of Keduang River enters the Wonogiri reservior is less than 0.5 km from the intake for power plant / irrigation releases. This results in heavy siltation in front of the the intake which needs nearly continuous dredging to keep the reservior operational, especially in the dry seasons.

Figure 3.
Heavy Siltation requires continues dredging, Source: Nippon Koei staff photo

1.3. The Solution

In order to reduce the amount of siltation that will need to be dredge from in front of the intake, a proposed solution is to divide the reservoir into two parts; a Sediment Reservoir to capture and manage sediment from the Keduang River and a Clear Water Reservoir leading to the intake. The division of the reservoir into two parts is to be accomplished with construction of series of closure dikes between partially submerging islands within the reservoir. A total of three closure dike and an overflow dike (broadcrested overflow spillway) are to be constructed as shown below.

In addition, a new spillway gates shall be constructed at the east bank of Wonogiri Dam closed to the confluence of Keduang River. Sediment trapped in the sediment reservoir will be flushed down through the new spillway gates into the upper solo river during the rainy (flood) seasons.



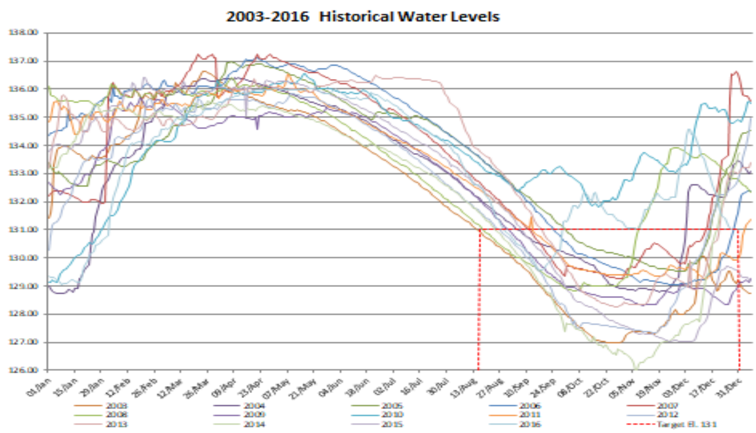
1.4. The Challenges

There are many challenges to be faced in the implementation of projects but right-of-way or resettlement was not an issue here; all of the work will be done within the existing reservoir. That however, leads to the first challenge. The work is to be done inside the reservoir where the water levels fluctuate during the year from the wet to dry seasons. The construction window when it is safe to work within the reservoir is a very limited window.

The second challenge is that the main closure dike is to be constructed on very soft sedimentation deposits that have accumulated over the years to a depth over 20m.

First Challenge – Construction Window

The first challenge, related to the water level, is when can construction start and how long construction can continue until. As seen in the historic fluctuation of water levels below, the timing of drawdown of the reservoir varies over several months.



Fortunately, with close coordination with the Bengawan Solo Water Council representing the various user groups in the basin, the start of a construction window can be controlled by monitoring releases from the reservoir. For the 2017 Construction season the drawdown of the reservoir was very successfully timed to the lower the water levels below Elevation 131.0 to within the exact day (15-Aug-2017) that had been negotiated.

However, the timing of the end of the construction season is not so easily solved as it is dependent on the onset of early rains which induce flash flooding and rapid rising reservoir levels. No amount of “coordination” can control the onset of early rains; therefore, a physical solution is necessary. The two options were considered; using cofferdam against rising waters or raising the base platform for the construction.

Second Challenge – Very Soft Foundation

The second challenge of construction is the soft sediments, which cannot directly support placement of closure dike. The improvement of the soft soils in order to support the weight of the embankment is to be solved with the use of Deep Mixing Soil Improvement (DMSI).

2. DMSI (DEEP MIXING SOIL IMPROVEMENT) – GENERAL

Deep Mixing Soil Improvement (DMSI) is a physical method to form soil-cement columns in soils in order to increase the bearing capacity and / or reduce settlement of soft ground.

Unlike a bored pile where a boring machine excavates a hole, removing the soil which is replaced with reinforcing bar and concrete to form a solid concrete pile, Deep Mixing involves a machine which augurs or drills a mixing blade down a hole and then mixes cement with the soil in-situ, (in place) to form a soil cement columns.

The figure below shows the basic sequence in three steps. In Step 1 - Twin augurs drilling down through the soil until reaching the hard bottom. Then in Step 2- the augurs are rotated back up and at the same time cement slurry is injected from the blades and mixed into the soil. When in Step 3 the augurs are extracted, the remaining column is a mixture of soil and cement. This equipment then moved to the next location and the process repeats.

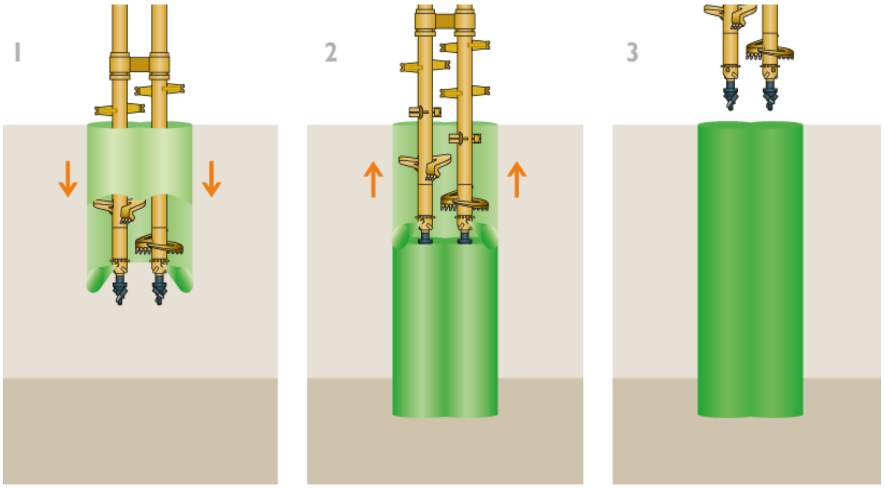


Figure 4.
The Wet DSM method, Source: http://www.kellerholding.com

Figure 5.
Wet Soil Deep Soil Mixing Machine, Source: https://www.liebherr.com

There are several types of Deep Mixing processes / machines I.e. dry mix vs wet mix, (dry cement injected with air vs cement slurry), single screw vs multi screw, and rotary blade mixing vs jet grouting (soil column for a rotary blade mixing has the same diameter with the blade, whereas, jetting makes a column wider than the diameter of blade). For Wonogiri, a twin-screw rotary blade, wet mix machine, will be used, which is similar to the one shown before.

In addition to the deep soil mixing machine, there is need for support from a slurry batch plant complete with cement silos, water storage tanks, batch mixing systems, storage tanks, and slurry pumps with flowmeters and associated control / monitoring systems.

2.1. DMSI Application at Wonogiri Reservoir Rehabilitation

The Wonogiri reservoir has an annual problem of sedimentation with main river (Keduang) mouth discharging within 0.5 km of the main power /irrigation release intake. Nearly continuous dredging has been required to maintain the operation.

The solution is to divide the reservoir into two; - a sediment reservoir to trap Keduang River sediments and a clear water reservoir leading to the intake. The division of the reservoir will be accomplished with three closure dikes and one overflow dike acting as an overflow spillway. Two of the closure dikes, will be the conventional embankments which is constructed on relatively hard ground, but the main dike, Closure Dike A, is a 700 m long dike, which will be constructed on soft reservoir deposits, up to 20 m thickness or more. This soft deposit of soil is built up of Keduang River sediments over the years can NOT support the weight of conventional embankment without improving the soil strength. Therefore, deep mixing soil improvement, DMSI, is used.

Typical Section of Closure Dike A – Embankment Construction on DMSI Columns

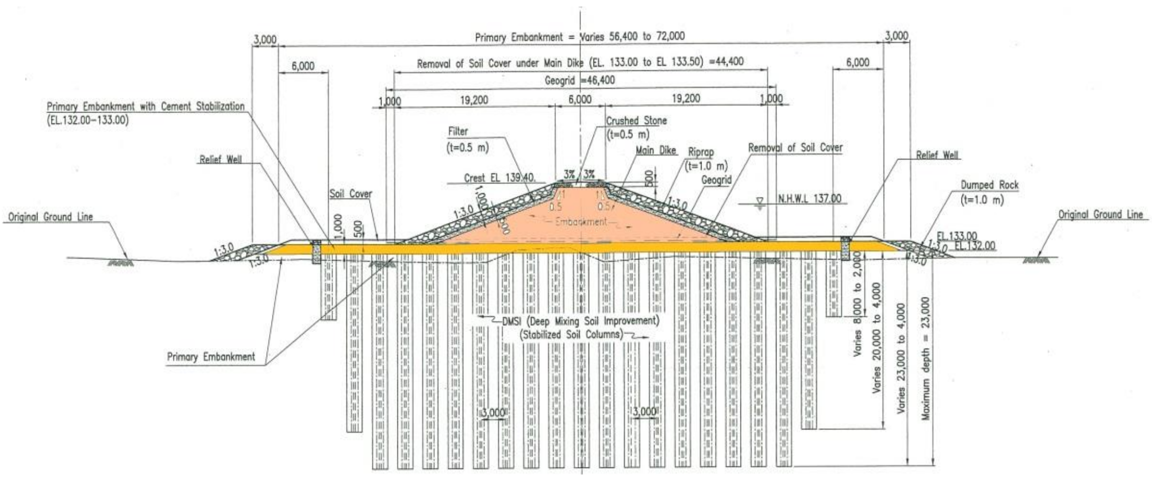

Figure 6.
Typical Section of Closure Dike A – from Bidding Documents of ICB Civil Works – Construction of Closure Dike and Overflow Dike (Package No. 2-1)

2.2. Stage-1. Installation Working Platform, First Construction Season (15-Aug to Dec 2017)

The DMSI equipment including the deep mixing machine and the supporting slurry plant with associated facilities, are heavy and not easily or quickly moved. This becomes a very real problem when the project is being implemented within a reservoir subjected to flash flooding. Therefore, in order to execute the work a working platform is needed that can be made relatively free from flooding. However, it is not just a question of making the platform at a high level, because the platform is being constructed on unimproved soils. The weight of the platform and equipment must be supported by the unimproved soils before the deep mixing soil improvement can be executed to make the suitable foundation for the closure dike. There is a delicate balance between making the platform high enough for safety against flash floods and low enough such that the total weight of the platform and equipment can be supported by the unimproved soils.

In the case of the Wonogiri reservoir that delicate balance resulted in a platform consisting of two parts. First, primary embankment (varying thickness but approximately 1 m) is placed up to Elevation 132. Second, the primary embankment is overtopped with a constant 1 m thick layer of soil cement up to Elevation 133. The DMSI columns will to be drilled thought the soil cement. This layer of soil cement not only formed a firm platform but also acts to tie the columns together to limit their horizontal displacements at the tops of the columns.

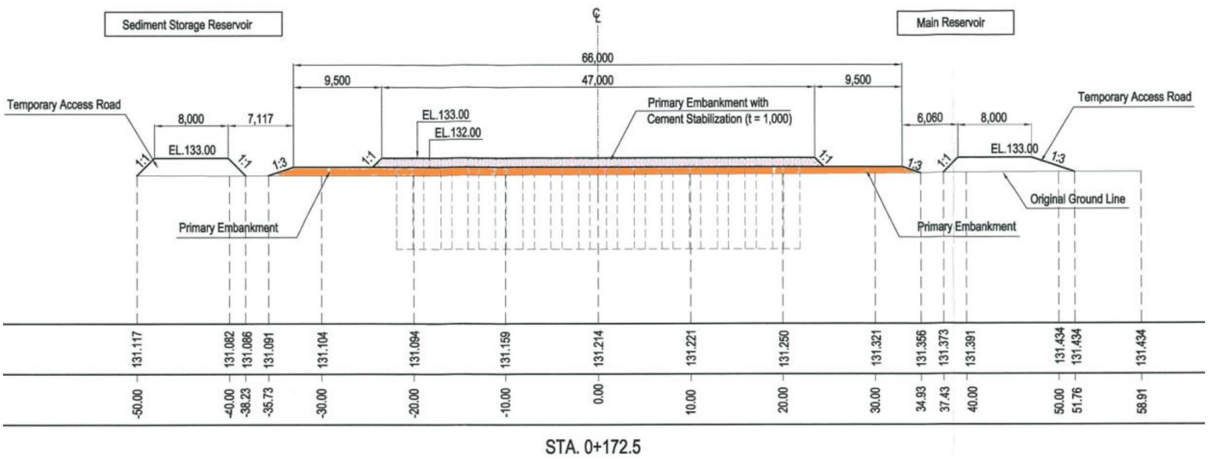

Figure 7.
Typical Section of Primary Embankment and Soil Cement

The average existing ground elevation of the soft reservoir deposits was around Elevation 131 and the construction window was assumed to start when reservoir levels fell below that level. Therefore, the first year construction was to consist of the following steps:

Step 1: After the reservoir level drops the soft deposits were left to dry sufficiently enough to support equipment. Fortunately the construction window corresponds to the normal dry season with strong warm dry winds occur across the reservoir to aid in the drying. While waiting for the drying, clearing and grubbing of the soils was manually executed. When the soils had dried sufficiently to support the load of swamp-track bulldozers the area was then stripped. Since the reservoir deposits were not entirely even, the area was treated by zones corresponding to vary general levels. For the main Closure Dike the area was divided into 7 zones as shown below:

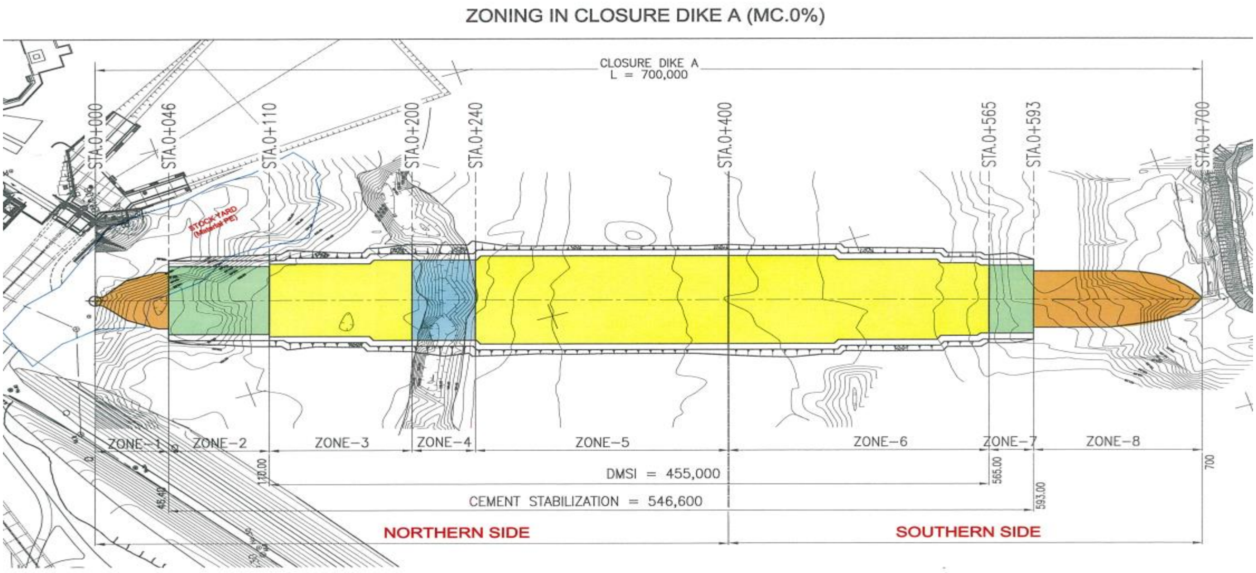

Figure 8.
Seven Zones for Placement of Primary Embankment, Source: Hazma-Ando-Wika JO

Figure 9.
Final inspection of grubbing after stripping and initial compaction

Step 2: After stripping the top of the existing soft reservoir deposit and when the area has dried sufficiently to support trucks and vibratory rollers, the primary embankment was placed and compacted layer by layer up to Elevation 132. (4 layers each 25 cm. each).

Figure 10.
Primary Embankment Placement, Source : Hazama Ando-Wika JO Drone Photo

Figure 11.
Primary Embankment Spreading. Source: Nippon Koei Staff Photo

Step 3: Once the primary embankment was completed the soil cement was placed and compacted layer by layer up to Elevation 132. While the warm-dry winds have been very beneficial during the drying of the exposed reservoir soils to support construction equipment, the same winds become a problem during the mixing and placing of soil cement. Control of the moisture content of the soil before mixing and preparing the placement area was a crucial step in achieving the desired soil cement.

Figure 12.
Soil Cement Mixing Yard. Source : Hazama Ando-Wika JO Drone photo

Figure 13.
Stabilizer Machine mixing soil cement. Source: Nippon Koei Staff Photo

Figure 14.
Soil Cement Placement on Primary Embankment. Source :Hazama Ando-Wika JO Drone

Step 4: Finally after the soil cement is completed the top layer is covered with soil and the project waits till next year before the DMSI can commence. The soil cover used to prevent the Hexavalent Chromium leaching from cement into the water.

2.3. Stage 2. Deep Mixing Soil Improvement,– Second Construction Season (2018)

After the water level decreased in the second construction season, the start the DMSI works will commence. There are planned for approximately 4,300 columns up to 24 m depth. Each column is a column pair made from twin 1-m screws with 20cm overlap. The column pairs will be placed in sections, with 21 column pairs with 2.2 m Centerlines for section width of 45.8 m. Each section along the axis of dike will be placed at 2.2 m intervals.

As mentioned earlier, the DMSI equipment and support facilities are heavy and not quickly moved. Coupled with the very short construction season of less than 5 month the logistics of completing all the work within a single season is a challenge. Originally, it was planned to use six complete DMSI teams (mixing machines with their cement slurry supply plants) but the Contractor has proposed to utilize 3 DMSI groups working double shifts.

After DMSI works have been completed the tops of the DMSI Columns will be covered with soil again to prevent the Hexavalent Chromium leaching from cement into the water. The Project site will then have to wait until the following year to complete the closure Dike.

2.4. Stage 3. Main Embankment – Third and Final Construction Season

At the beginning of the final construction season, the soil cover over the DMSI columns will be removed, the tops of the DMSI columns will be trimmed smoothly of their excess material and a geotextile GeoGrid will be placed on top of the columns. After which, conventional soil embankment will be built layer by layer until the crest is reached. The embankment will be finished with riprap slope protections and top driving surface for maintenance access.

3. NEW SPILLWAY GATES

Construction of New Spillway Gates (2 fixed rollergates; width = 7.50 m; height = 5.60 m) will serve several function as the following:

1. Sediment materials trapped in the sediment reservoir will be flushed down through the new spillway gates into the upper solo river.
2. New spillway gates will provide additional spillway capacity, which will increase safety against emergency situations (probable maximum floods).
3. This will also provide an opportunity to increase operationalwater level (NHWL) by 1 meter (from +136 to +137), which will generate 76 millions m^3 additional reservoir storage.

4. CONCLUSION

1. Sedimentation become a serious problem to dam reservoir in Indonesia, it will decrease reservoir capacity and also the dam function.
2. Prevent the sedimentation rate is a difficult step due to rapid land development on upper side of the catchment area.
3. It needed a new innovation to restore the capacity of dam reservoir during operation, use proper method such as development of closure dike with DMSI.
4. Operational of the new spillway gates will provide an opportunity to increase normal high water level (NHWL) by 1 m, which will generate 76 millions m^3 additional reservoir storage.

5. ACKNOWLEDGEMENT

The authors would like to thank to Bengawan Solo River Basin Authority, Dam Center and Dam Safety Unit, Directorate General of Water

Resources, Ministry of Public Works and Housing for the authorization to publish the main result of the present study. The authors would also like to express the gratitude to Bengawan Solo River Basin Authority as the institution who built the closure dike for having made this fruitful collaboration possible.

1. INTRODUCTION

Many studies so far have provided evidences in support of climatic changes during the past decades as such variations affected the water balance and caused fluctuations in stream flows at both regional and local (catchment) scales. In Iran many studies support the fact that the climate has experienced variations during recent decades (Dinpashoh et al. 2011; Golian et al. 2015; Marofi et al. 2012; Masih et al. 2011) mostly toward more hot and dry conditions. Also, in recent years anthropogenic global warming and its consequences especially in the arid and semi-arid regions of the world received particular attention as many scholars documented occurrence and dominancy of drought, temperature rise and increase in the atmospheric water demand accompanied by reduction of precipitation and runoff (Guo and Shen 2015; Lalika et al. 2015). Also, assessments by IPCC (Intergovernmental Panel on Climate Change) provides means for policymakers to plan for future to adapt to climate change and mitigate its impacts.

Anticipated climatic changes can alter the hydrological behavior such as the amount of discharge or timing of the hydrological regime (Adam et al., 2009; Boyer et al., 2010; Gan et al., 2015). Such alterations can cause socio-economic and environmental consequences. Several studies world-wide predicted that the combination of temperature increase and precipitation change during the present century will result in significant change in runoff (Steele-Dunne et al., 2008; Vezzoli et al., 2015). Also many climate change impact studies have been carried out to investigate the hydrological response to climate change (Pervez and Henebry, 2015; Boyer et al., 2010). For instance it is widely documented that the modeled winter time discharge increase followed by the spring time discharge decrease, which is due to temperature increase; that is the cause to melt snow sooner and remain less snow pack (Arnell and Gosling 2013; Adam et al. 2009 and Boyer et al. 2010). A global scale study on river flow and water temperature changes through forcing by A2 and B1 emission scenarios suggested increase in the seasonality of river flow, i.e. increase in high flows and decrease in low flows for about one-third of the Earth (Van Vliet et al. 2013).

One of the vulnerable industries against climate change is hydropower generation, which completely relies on the amount of precipitation and the stream flow as well as the timing of the flow (Abrishamchi et al., 2012). Based on the IPCC report the potential of hydropower generation is projected to reduce by up to 6%, as a result of climate change (IPCC, 2008). Therefore, it is essential to adapt the water resources management with the future climatic changes (Xu and Singh, 2004). In Iran the climate and hydropower generation changes have been studied by Jahandideh et al. (2015) and Jamali et al. (2013) those focused on Karun and Karkheh river basins, respectively; and they reported reduction of the potential of hydropower generation in both studied basins.

Considering that the freshwater availability is vital in semi-arid and arid basins, it is essential to establish the magnitude of changes in surface water at basin scale. This study is focused on the semi-arid Dez River basin in Iran. Stream flow from this basin is used for hydropower generation, industrial production, irrigation, and domestic water supply. As Dez Basin is not completely developed yet, it is crucial to assess variations of discharge in this basin, under climate change condition and its impact on hydropower generation. Therefore, this research investigates the changes in hydropower generation in two major hydropower plants in the Dez basin. This assessment provides useful information to modify water resources management strategies with regards to the climate change impact on surface water resources in the Dez Basin.

2. MATERIALS AND METHODS

2.1. STUDY AREA

The Dez Basin is located in the Southwest of Iran (31°35′51″ – 34°7′46″ N and 48°9′15″ – 50°18′37″ E) and is the upstream catchment of the great Karun catchment. The basin is comprised of four sub-basins namely Tireh, Marbereh, Sazar and Bakhtiari. The latter is where the Bakhtiari dam is being constructed that its major purpose is to generate electricity. The catchment is located within a mountainous region which provides appropriate head needed for hydro-electric generation. Dez dam is located in the downstream of Bakhtiari and receives two rivers of Sazar and Bakhtiari those join at Tange Panj station which is located just before the lake of Dez Dam. The storage of this reservoir provides water for domestic, agricultural and industrial sectors and also is used to generate electricity.

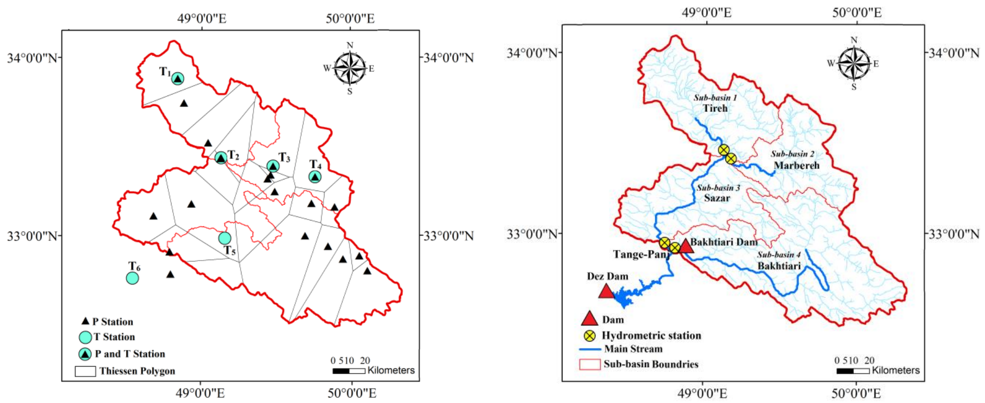

Fig. 1

Study area of the Dez Basin and location of rain gauges, hydrometric and temperature gauging stations

2.2. DATA

Long-term daily temperature (T) and precipitation (P) time-series obtained from I.R. of Iran Meteorological Organization (IRIMO) and Iran Water Resources Management Company (IWRM Co.). To calculate the average T and P in each sub-basin arithmetic mean and Thiessen polygon method applied, respectively.

2.3. GCM-SCENARIO

In order to project the future hydrological condition, two different GCMs were selected (ECHAM5-OM and HadCM3). Description of the applied GCMs is presented in table 1. Also three different SRES emission scenarios (Special Report on Emission Scenarios) of A1B, A2 and B1 were considered to project the future T and P for 2011-2030 (2020's), 2046-2065 (2050's) and 2081-2100 (2080's) time horizons.

Table 1
Description of the Global Climate Models and IPCC-AR4 SRES emission scenarios

Research Centre	GCM	GCM Acronym	Resolution	SRES Scenarios
Max-Planck Institute for Meteorology (Germany)	ECHAM5-OM	ECHAM5	1.9×1.9°	A1B, A2, B1
UK Meteorological Office (UK)	HadCM3	HadCM3	2.5×3.75°	A1B, A2, B1

To downscale T and P under A1B, B1 and A2 SERS scenarios during 2020's, 2050's and 2080's in the study area, the stochastic weather generator of LARS-WG were applied; that generates time-series based on the probability distribution of base period data and correlations between observations. The detailed description of LARS-WG can be found in Semenov (2007).

2.4. HYDROLOGICAL MODELING AND MODEL CALIBRATION AND VALIDATION

The HBV-light, semi-distributed hydrological model is used to simulate the runoff in the Dez basin. This model simulates runoff with temperature, precipitation and evaporation inputs and contains snow routine, soil moisture routine, response function and routing routine. The detailed description of the HBV model structure and routines could be found on Seibert and Vis (2012). Prior to the application of the model it is necessary to calibrate its parameters. This is done through try and error procedure as recommended by Bergstrom (1992).

There are several statistics to identify the efficiency of a model. In this research we examined the goodness of fit with Nash-Sutcliff measure (R_{eff}), coefficient of determination (R^2) and mean annual difference (M_{diff}).

$$R_{eff} = 1 - \frac{\sum (Q_{Sim}(t) - Q_{Obs}(t))^2}{\sum (Q_{Obs}(t) - \overline{Q}_{Obs})^2} \tag{1}$$

$$R^2 = \frac{(\sum (Q_{Obs} - \overline{Q_{Obs}})(Q_{Sim} - \overline{Q_{Sim}}))^2}{\sum (Q_{Obs} - \overline{Q_{Obs}})^2 \sum (Q_{Sim} - \overline{Q_{Sim}})^2} \tag{2}$$

$$M_{diff} = \frac{\sum (Q_{Obs} - Q_{Sim})}{n} 365 \tag{3}$$

2.5. MODELING TWO RESERVOIRS SYSTEM IN VENSIM

To calculate the hydropower generation, two reservoirs system of Bakhtiari and Dez dam were developed in Vensim by entering the equations of mass balance and power generation, considering the restrictions of operation of the reservoirs and power plants.

$$\mathrm{S}_{t+1} = S_t + Q_t - RE_t - RD_t - SPL_t - EVAP_t + ADD_t \tag{4}$$

Where,

S_{t+1}: The reservoir volume at the end of t period (beginning of the t+1 period); S_t: The reservoir volume at the beginning of t period; Q_t: Inflow to the reservoir during t period; RE_t: The outflow from the reservoir to generate energy during t period; RD_t: The outflow from the reservoir to meet downstream demand during t period; SPL_t: The spill from the reservoir during t period; $EVAP_t$: Evaporation from the reservoir during t period; ADD_t: The volume of added flow from upstream reservoir during t period.

The power generation is associated to the installed capacity, efficiency, plant factor as well as the inflow and hydraulic head. Equation below shows the power generation which was used to calculate the energy generation.

$$\mathrm{P}_t = (\gamma Q_t H_t e_t)1000 \tag{5}$$

Where,

P_t: Power generated during t period; γ: Water specific weight; Q_t: the inflow to the turbine during t period; H_t: Net hydraulic head on turbine during t period; e_t :The power plant efficiency.

3. RESULTS AND DISCUSSION

3.1. PROJECTED CHANGES IN TEMPERATURE AND PRECIPITATION

Based on the results, three studied scenarios perform in a similar way during the first time horizon and two GCMs and applied scenarios suggest small temperature changes during 2020's. However, temperature increases up to 1.2 and 1.1 °C is projected. While, based on all considered scenarios a significant rise in the average temperature is projected for 2050's and 2080's time horizons; as the average temperature in 2080's is higher than the average of temperature during 2050's. Generally, the B1 scenario suggests slighter temperature increase during 2050's and 2080's; while, scenarios A2 and A1B revealed a higher rise in temperature during these time horizons. HadCM3 revealed higher temperature increase during 2050's, based on scenarios A1B, A2 and B1, respectively. But during 2080's the highest rates of temperature for all the scenarios is suggested by ECHAM5.

Assessing the magnitude of temperature variations from the base period, suggests that the maximum temperature increase is associated to 2080's time horizon under the A2 scenario that shows an average increase of temperature between 3.6 to 4.4 °C in the study area.

In a similar way, average of the projected precipitation for future time horizons based on two GCMs outputs and scenarios A1B, A2 and B1, show that most of the scenarios suggest increasing precipitation amounts compared to the base period. Also projections mostly suggest precipitation decrease in the first time horizon (2020's) for Marbereh.

Studying the percentage of variation of precipitation from the average precipitation amount in base period shows that, the greatest precipitation changes occur in 2080's; that is mostly toward an increase in the amount of precipitation in the study area. Also, based on the projections, the highest precipitation increase is projected for the 2080's tme horizon and especially for scenario A2.

3.2. HYDROLOGICAL SIMULATION UNDER CLIMATE CHANGE SCENARIOS

To simulate runoff, First, the HBV model calibration and validation carried out using 12 and 5 years of observed discharge data, respectively. The values of Nash-Suttclif statistics of 0.69, 0.60, 0.61 and 0.6 and R^2s of 0.71, 0.61, 0.63 and 0.61 obtained for Tireh, Marbereh, Sazar and Bakhtiari, respectively. After ensuring the efficiency of model, it was applied to simulate discharge under climate change condition with projected T and P time-series as inputs.

The overall changes of the annual flow corresponded to all GCMs and scenarios show that the amount of annual discharge is mostly decreasing in the future; as the reductions are most significant for 2080's time horizon. In Tireh, the greatest reduction of annual flow (19%) is attributed to ECHAM5-B1-2050 and 2080. Similar to Tireh, the reduction of annual flow in Marbereh is more significant in 2080's as it reaches to 26% (ECHAM5-A2-2080). Generally, the amount of annual flow mostly decreases in Sazar. However, some contrasting results obtained, indicating annual flow increase up to 13% (HadCM3-A2-2080). The greatest reductions of annual flow (up to 17% by HadCM3-B1), is corresponded to 2020's time horizon. Also, the greatest reduction of annual flow in Bakhtiari is up to 27% by ECHAM5-B1 in 2080's.

3.3. VARIATION OF THE INFLOW TO DEZ AND BAKHTIARI RESERVOIRS AND HYDROPOWER GENERATION UNDER CLIMATE CHANGE

The amount of annual inflows to the Bakhtiari and Dez reservoirs and percentage of their changes in the future time horizons under climate change condition, compared to the base period and are presented in table 4. Long-term average of the discharges at the outlet of Bakhtiari and Sazar are 5106.88 and 2938.21 Mm3, respectively. Considering that the Bakhtiari Dam is located at the end point of Bakhtiari basin and Dez is located at the downstream of Tange Panj, the inflow to the Bakhtiari reservoir equals to the Bakhtiari basin’s discharge and the inflow to the Dez reservoir is the total discharges from upstream basins, that equals to 8045.1 Mm3. Based on the results, variation of the inflow to the Bakhtiari reservoir under climate change, simulated to vary between -1.7% (HadCM3-B1-2050) and -20.8% (ECHAM5-B1-2080). Also the inflow to the Dez reservoir for future time horizons is simulated to decrease by up to 14.3% (ECHAM5-B1-2080) and increase by up to 3.6% (HadCM3-B1-2080).

The potential of hydropower generation for base period and future time horizons is calculated by modeling the two reservoirs systems, using the inflows obtained from previous step (table 4). Based on the results the potential of hydropower generation simulated to decrese between -24.1% (ECHAM5-A1B-2080) and -0.9% (HadCM3-B1-2050) that is in agreement with the reduction of discharges to the Bakhtiari reservoir. On the contrary, the potential of hydropower generation of Dez dam is simulated to slightly increase by up to 2.6% (HadCM3-A1B-2080); while its inflow is projected to decrease for future time horizons.

As mentioned above, in case of Dez reservoir, there are some inconsistencies between the changes caused by climate change in discharge and hydropower generation. While, the results for Bakhtiari reservoir are more compatible. The difference between the responses of two reservoirs in terms of their potential of hydropower generation could be attributed to different operational rules due to different purposes, as well as the size of the reservoirs and installed capacity of their hydropower plants. To study the reasons to that, time-series of inflow, outflow, spill and the water level in the reservoir for base period were assessed.

About different water utilities, it should be noted that the Dez dam is a multi-purpose dam which provides water for different purposes, in specific time periods, to meet demands. Therefore, the releases from its reservoir are planned and only the part of release or spill, that is not greater that the penstock capacity or turbine capacity, contribute to the power generation. Also, the small capacity of its reservoir (2.7 Bm^3) compared to the discharge from draining catchment (8 Bm^3) causes considerable spills. Having considered that the whole capacity of its hydropower plant is relatively small compared to its inflow and releases, therefore a significant proportion of the releases or spills does not contribute to the power generation. While, the Bakhtiari reservoir with the capacity of 5.16 Bm^3 and average inflow of 5.11 Bm^3 can control most of the inflows with negligible spills. Also, large capacity of its hydropower plant does not pose any limit for energy production. Therefore, in case of Bakhtiari, there is a direct relationship between the changes of the rates of inflow and energy generation. Based on the simulations for future time horizons, fewer amounts of inflows and peak flows to the Dez reservoir leads to less losses through spill, which means more water could be saved in the reservoir and used to generate electricity. Considering the reasons explained above, future changes in the potential of hydropower generation, under climate change conditions, are not consonant with the changes in the inflow to the Dez reservoir. Also slight increase in the potential of hydropower generation could be attributed to the changing of the regime of discharges with smaller peaks, leading to fewer spills and remaining more water to produce electricity.

4. SUMMARY

Assessment of the impact of climate change on climate and discharge in Dez basin is studied based on the downscaled outputs from two GCMs and three SRES scenarios for three time horizons. The study revealed that the basin experiences a significant temperature rise in mid and late 21st century (up to 4 °C). These changes are accompanied by variations in precipitation that is mostly toward a slight increase in the amount of precipitation. Totally, projections of all the scenarios and GCMs indicate a warmer future and slight to moderate increase in precipitation amount. However, obtained results for precipitation are more anomalous, showing both increase and decrease in the amount of precipitation.

To simulate the future discharge at the outlet of each sub-basin under climate change condition, calibrated HBV hydrologic model was enforced with projected temperature and precipitation time-series. Results mostly suggest reduction of annual discharge in the study area. Most significant reduction of annual flow, compared to the base period, reaches up to 33% in two sub-basins located in the upstream of the basin, namely Tireh and Marbereh; while the greatest reductions of the annual flow of Sazar and Bakhtiari sub-basins reach up to 12 and 15%, respectively.

In this study the future climate and hydrological conditions were investigated to assess the climate change impact on the potential of hydropower generation in Dez basin. Based on the results, climate change has the potential to significantly alter the potential of hydropower generation in the basin. Results showed reduction of inflow and electricity generation in Bakhtiari reservoir. While, for Dez reservoir, reduction of the inflow accompanied by a slight increase in the generated electricity. This contrasting result that obtained for Dez reservoir were assessed and has been attributed to the small size of the reservoir (2.7 Bm^3) compared to the basin's discharge (8 Bm^3), capacity of hydropower plant, different purposes

and releases of the Dez dam and the flow regime changes in the future which causes less spills due to the lower peaks of floods.

In conclusion, the results showed the reduction of electricity generation at Bakhtiari's power plant, therefore its design seems to be carry-over for future climatic conditions; while based on the findings there is room for further development of Dez power plant.

1. INTRODUCTION

Fossil resource depletion and climate change have raised the interest of renewable energy around the world. Among them, the development of hydropower is considered to be an effective way to prepare for electricity shortages.

In the case of Pakistan, the government has already set up the "Policy for Power Generation Projects" (2002) to encourage private participation in the electricity market, in which 16 hydroelectric projects have been proposed as long-term plans. Among them, the Patrind Hydro Power Project has been developed by SHPL and is owned by K-water(Main sponsor).

In general, the development and operation of hydropower generation facilities are greatly influenced by hydrological and topographical conditions. In particular, sedimentation in the upstream of a dam causes reservoir volume reductions and generator abrasions. Therefore, a proper management technique for sedimentation is needed for hydropower plant projects.

The area where the Patrind project is located is highly influenced by sedimentation due to the Himalayas. Therefore, it was necessary to apply a sedimentation management method considering topographic and geological conditions and trap efficiency.

2. PROJECT OUTLINE AND SEDEMENT MANAGEMENT GOALS

2.1. PROJECT OUTLINE

The Patrind project is located in the city of Muzaffarabad and is about 120km northeast of Islamabad, which is capital of Pakistan. As it is a run-of-river type hydropower plant, water is taken from the Kunhar River and then generated by the plant located on the Zehlum River through a headrace tunnel. The specifications of the plant are as follows.

Table 1.
Specifications of the Patrind Hydropower Project

Weir				Intake	Energy Generation		
Catchment Area	Type	Height	Length	Design Discharge	Turbine Type	Installed Capacity	Annual Generation Energy
2,400 ㎢	CGD	43.5m	167.6m	153.7 ㎥/s	Vertical Francis	150MW	641.3GWh

Fig 1.
Bird's-eye View of Patrind Hydropower Project

2.2. SEDIMENT INFLOW STATUS

The project site is directly affected by sedimentation erosion from the Himalayas. In order to check the amount of sediments flowing into weir, we analyzed the discharge and suspended sediment observation data of the Garhi Habibullah station, which is managed by WAPDA(Water and Power Development Authority, Pakistan) and located about 12.3kms upstream of the project site, from 1960 to 2002. The sediment rating curve was made as follows through regression analysis using the observed discharge and suspended sediment amount.

$Q_{SS} = 0.043\ Q^{2.86}$

Q_{SS} : Suspended sediment load(ton/day), Q : Water flow(m^3/s)

In addition, the results of sieve analysis by discharge conducted by WAPDA allowed for the prediction of the suspended sediment composition flowing into weir.

In the high flow period, the composition ratio of sand was about twice that of the low flow rate due to the high velocity.

Table 2.
Inflow Suspended Sediment Composition

Suspended sediment composition (%)	Clay	Silt	Sand
High flow season(May ~ Aug)	32	52	16
Low flow season(Sep ~ Apr)	21	46	33

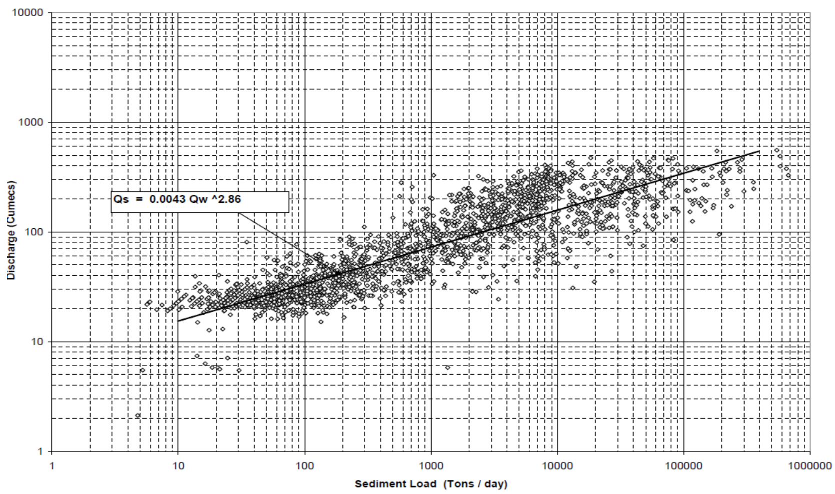

Fig 2.
Suspended Sediment Rating Curve

It was difficult to predict the exact inflow bedload amount due to the lack of observation data. So the bedload was assumed to be about 10% of the suspended sediment. The total amount of sediment flowing into weir was calculated by summing up the bedload and suspended sediment. The amount of sediment was estimated to be 4.4Mt considering the discharge condition during the year.

2.3. SEDIMENT MANAGEMENT GOALS

When the sediments flow in the weir, they have a strong influence on the operation, maintenance, and economics of the hydropower project. Therefore, we set a sediment management goal of preventing 0.2mm or higher of sediments from flowing into the intake.

3. SAND TRAP DESIGN

3.1. DESIGN CHANGE HISTORY OF SAND TRAP

The initial sand trap design was presented in the Feasibility Study prepared in 2007. In that study, the layout included a weir just downstream of the bend of the Kunhar River, with a Power intake in front of the weir on the left side and three underground sandtrap chambers to accomplish goal of sediment management along the headrace tunnel axis.

Table 3.
Specifications of the Sand Trap (Feasibility Study, 2007)

Type	Design Discharge	Chamber		Flushing Tunnel	
		Section	Length	Section	Length
Underground sand trap	153m^3/s (51×3chamber)	15×17m	180m	3.5×3.5m	407m

In the basic design, however, the location of the weir axis was moved 150m upstream from the proposed location in the Feasibility Study, and a surface sand trap was designed as an alternative instead of an underground type sand trap in the Feasibility Study. This is because the geological properties of the original sand trap site don′t have sufficient supporting force for the foundation of the structure. According to a drilling investigation, a clay silt layer is distributed up to 6.0m from the surface. RQD is mostly 0%, even if the values of 10~24.0% are shown, partially.

Table 4.
Specifications of the Sand Trap (Basic Design, 2010)

Type	Design Discharge	Chamber		Flushing Tunnel	
		Section	Length	Type	Section
Open Type	153 ㎥/s (76.5 ㎥×2 chamber)	23×26.7m	140m	Box Culvert	1.8×2.5m

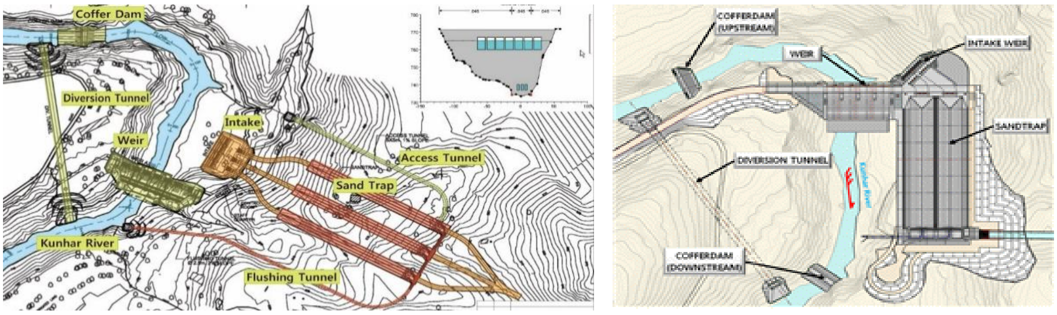

Fig 3.
Project Layout of the Feasibility Study(left) and Basic Design(right)

A numerical analysis(HR Wallingford, 2012) was conducted to review the appropriateness of the modified project layout. For modeling the deposition, a water level of 765m asl, Normal High Water Level, was prescribed at the weir.

Different scenarios were considered for the estimation of annual amount of deposition simulated with the 1D model RESSASS. The results show that the reservoir is likely to be filled in about five years. The average annual amount of sediment deposits is around 2 MT(annual sediment inflow is about 4.2MT) per year.

Several scenarios were considered for the distribution of the sediments near the weir with a 2D modelling system TELEMAC-SYSIPHE-HR. The results show that in front of the intake, deposition occurs in all cases up to the elevation of about 760m asl. The invert of the intakes is at 750m asl. During high flows, the model results show a sand bar forming between the intakes and the weir gates, reaching almost the water level surface. These problems led to the consideration of new sediment management methods.

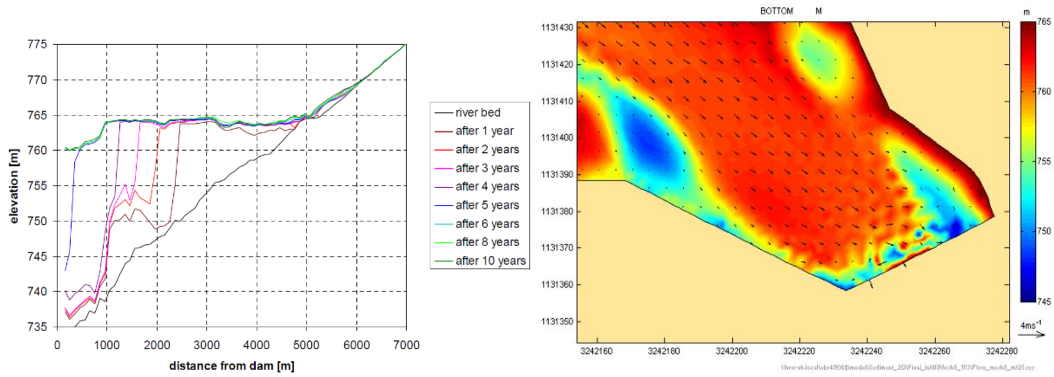

Fig 4.

Bed Evolution During Deposition(left) and Deposition after 48days(Q=153m^3/s)(right)

3.2. OHDS Technique

Generally, management activities to address reservoir sedimentation may be classified into four broad categories (Morris, 2015). Among them, the Patrind Hydropower Project adopted “Route Sediments” and “Remove and Redistribute Sediment Deposits” to handle inflow sediments. We called adopted method “OHDS technique”. This technique was developed by Alam(2014) considering that the flows exceeding the capacity of the intake(153m3/s) would be diverted through a by-pass tunnel. The area of the reservoir and modified pool(hereafter called MP), between the cofferdam and the weir was conceived as acting as a natural sand trap. As this area has a larger volume that the designed sand traps and considering low velocities than in the sand traps, its efficiency should be higher than that of the artificial sand traps.

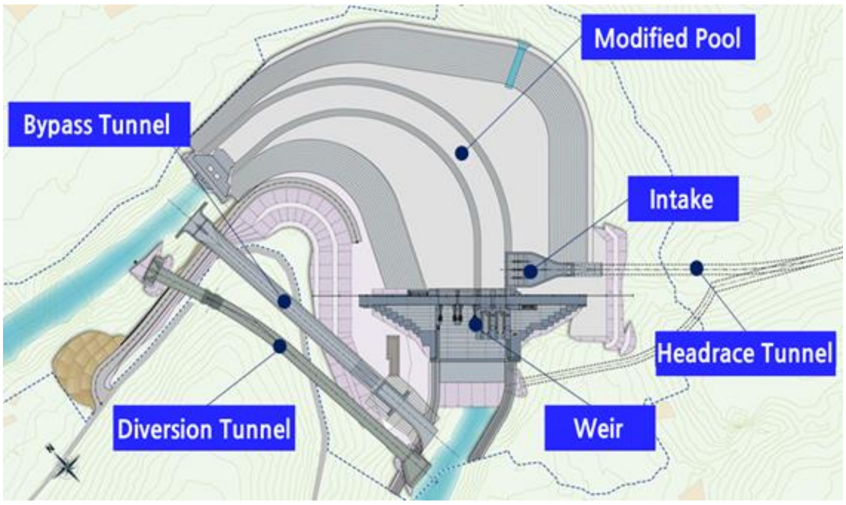

Fig 5.
Layout of the Weir Site(Detail design, 2015)

3.3. NUMERICAL ANALYSIS

3.3.1. Input data and boundary conditions

A numerical analysis was carried out to verify sedimentation management performance of the OHDS technique(HR Wallingford, 2014). The long series of water discharges, from 1960 to 2007 has been used in this analysis as input data. The sediment rating curve described in the Feasibility Study was used to define the amount of suspended material. As well, a bypass tunnel and MP were considered. The diameter, length and discharge capacity of the bypass tunnel were 8.5m, 229m, 804m3/s respectively.

The water discharge is split according to the following rule: when discharge is less than 200 ㎥/s, the bypass tunnel is closed and all water and sediment passes over the coffer dam. When discharge is more than 200 ㎥/s, the bypass tunnel is opened and the discharge in excess of 153 ㎥/s, the design discharge rate, flows through the bypass tunnel.

3.3.2. Analysis results

First, we analyzed the effects of reducing sedimentation using the bypass tunnel. The results show that any coarse material, gravel fractions > 2.9 ㎜, will bypass through the tunnel. 47% of the sand material transported by the flow (as average), with diameters from 0.1 to 0.92 ㎜, will be conveyed towards the MP. The results show that the amount of sand that flows over the cofferdam towards the MP has been fairly constant for all the years (around 0.56Mt)

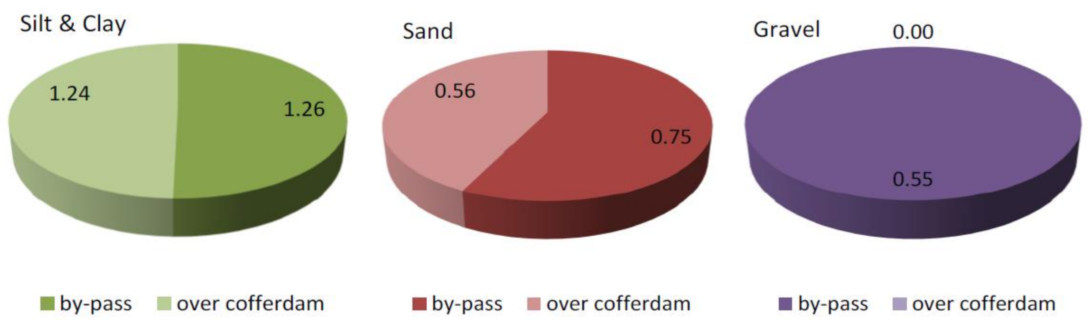

Fig 6.
Average Annual Amount of Sediments(in Mt)

Second, an assessment of the trapping efficiency was presented. MP must meet the velocity standard, 0.2m/s, to function as a sand trap. So a 2D numerical analysis (using TELEMAC) was conducted at a rate of 153 ㎥/s, the design discharge, and 200 ㎥/s, the bypass tunnel open condition. The results show that for discharge of 153 ㎥/s, the flow velocities in the MP do not exceed this limit except locally at the intake. For the discharge of 200 ㎥/s, there are some areas with velocities greater than 0.2m/s. In most of the MP, however, velocity is still below 0.2m/s. Therefore, the MP can act as a natural sand trap.

3.4. PHYSICAL MODEL INVESTIGATION

3.4.1. Introduction and Basic data

Physical model investigation was conducted to verify the performance of sediment management using the OHDS technique. It is conducted by the Laboratory of Hydraulics, Hydrology and Glaciology(VAW) of the Swiss Federal Institute of Technology Zurich(ETH Zurich). The experiments were separated into hydraulic tests with a fixed bed and sedimentological tests with a movable bed and sediment supply.

The inflow water flow discharge and suspended sediment data collected from 1960 to 2012 were used. The sediment rating curve described in the Feasibility Study was used to define the amount of suspended material. As well, the bed load was assumed to be 15% of the suspended load based on a conservative review.

3.4.2. Physical model construction

In order to choose an appropriate model scale, Froude similarity was applied. This was because for free surface flow, scaling with the Froude law is the most commonly used model that represents the best the general hydraulic phenomena.

Table 5

Scaling Factors Applied to Physical Model Construction

Parameter	Length(m)	Time(s)	Velocity(m/s)	Discharge(㎥/s)
Scale factors	1 : 45	1 : 6.71 ($1{:}45^{1/2}$)	1 : 6.71 ($1{:}45^{1/2}$)	1 : 13,584 ($1{:}45^{5/2}$)

The suspended sediments are too fine at the model scale of 45 to be reproduced correctly in the model as the scaled down grain diameter would be affected by cohesion. Therefore, the fine sediments are represented by artificial sediment, distorted in density and size having appropriate critical shear velocity according to the Shields curve and appropriate fall velocity. In general, Ground walnut shells are a common material for suspension modeling as they are cohesion-less, easy to mix, produce a homogeneous distribution and have a specific weight smaller than sand (Kantoush 2008, Jenzer 2011). So for the suspended load tests, ground walnut shells were used. The condition of the physical model applied is as follows.

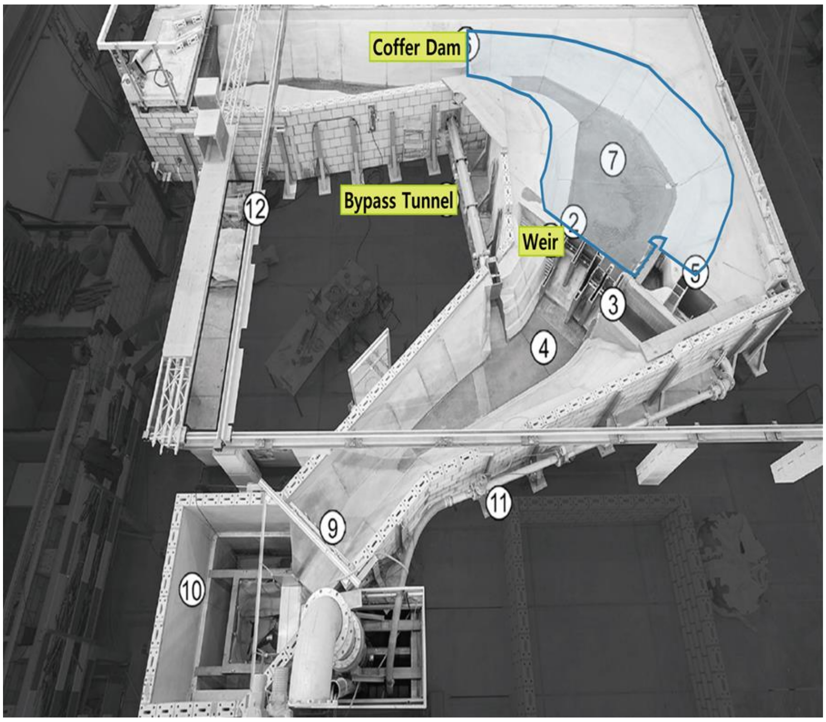

Fig 7.
Bird's-eye View of the Physical Model

3.4.3. Investigation Result

First of all, the flow condition, the water level and the flow velocities in the MP are described for the variant load case. During normal power operation(hereafter called NPO), design discharge Q=156 ㎥/s, the water surface is smooth and no waves were observed in the MP. During a high flow condition, discharge starting power shutdown Q=800 ㎥/s, the flow pattern shows oscillations due to the forming of a vortex in front of the bypass tunnel inlet. The water level in the modified pool is kept at operation reservoir level(765m a.s.l) for NPO and high flow condition. Flow velocities are measured with an Acoustic-Doppler-Velocimetry probe(ADV). During NPO, flow velocities only exceed 0.2m/s in the region of the cofferdam and close to the power intake. In a large region of the MP the vertical velocity fluctuations are smaller than the settling velocity of 2.5 ㎝/s for grains with d=0.2 ㎜ in still water. Therefore, larger grains are expected to settle in the MP during power operation.

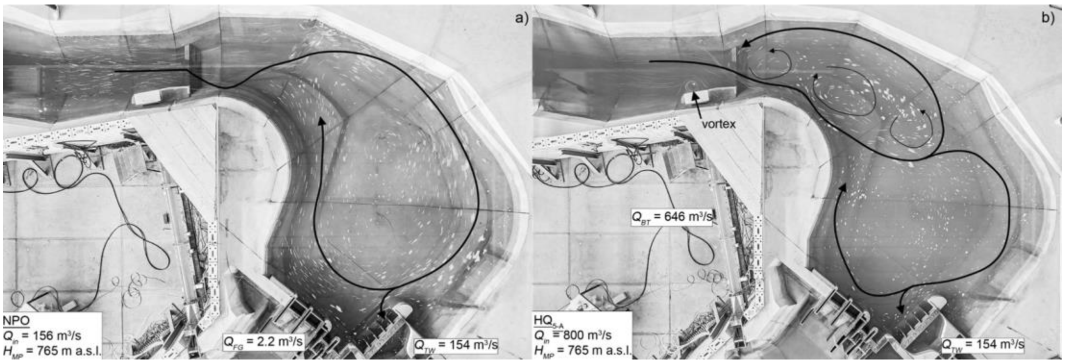

Fig 8.
Top View on the Modified Pool for Q=156 ㎥/s(left) and 800 ㎥/s(right)

Second, a transfer experiment of suspended sediments was conducted for HQ5-A load case, maximum discharge was 748.6m3/s, to identify deposition properties of fine sediment. The following table (Table 8) gives an overview of the deposited and sluiced sediment volumes measured in the model. These results show that all inflow sediment targeted diameters (above 0.2 ㎜) are deposited through the bypass tunnel and modified pool.

Table 6.
Sediment Balance

Parameter (HQ_{5-A})		Bed load		Suspended load	
		Quantity (㎥)	Ratio (%)	Quantity (㎥)	Ratio (%)
Previous depositions		40,000		150,000	
Inflow	added to the inflow	2,750	100	68,000	100
Deposit	Upper coffer dam	2,750	100	49,220	72
	modified pool	-		11,200	16.5
	Sluiced through the bypass tunnel	500		7,580	10.9
	Power intake			400	0.6

Finally, we conducted a reservoir flushing test to find the optimum condition to remove deposited sediments. The performance of the two flushing tests (Q =

150 ㎥/s and 200 ㎥/s) were very similar, though the flushed out sediment volume was about 10% higher for Q = 200 ㎥/s. This means that 85% of the total MP water storage capacity of 687,000 ㎥ were restored. After the flushing, the deposits in front of the power intake were cleared down to the original bed.

Table 7.
Volume Balance of Flushed Deposits in the MP for Load Case

Load case	MP volume (m^3)	Initial deposit volume (m^3)	Erosion		Residue	
			Volume (m^3)	Percentage of eroded volume	Residual deposits (m^3)	Residual MP volume
Q 150m^3/s, 1day flushing	687,000	200,000 (100%)	88,000	44%	112,000	84%
Q 200m^3/s, 1day flushing			96,500	48%	103,500	85%

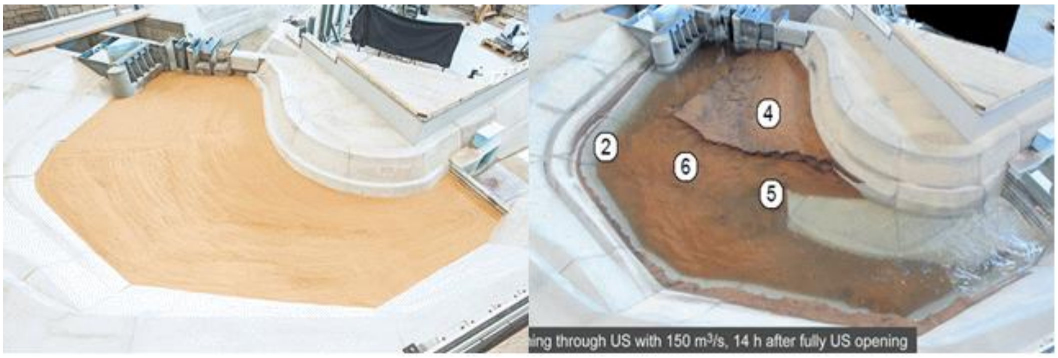

Fig 9.
The Initial Condition(left) and Hydraulic Flushing of Built up deposits with 150 ㎥/s after 14 Hours of Flushing Through the Fully Opened Underway Spillway Gate

4. CONCLUSION

The area where the Patrind project is located is highly influenced by sedimentation due to eroded soil in the Himalayan Mountains. In order to manage sedimentation effectively, topographic and geological investigations, as well as several numerical analyses and physical model investigations were conducted.

Through this process, the project adopted the OHDS technique, bypass tunnel and natural sand trap(MP), to prevent sediment inflow into the intake. In addition to applying OHDS, stability against sedimentation was further enhanced through turbine coating.

The Patrind Hydropower Plant has been in operation since November, 2017 and hydrological monitoring and flushing effect analyses are scheduled to be conducted at the end of the dry season, March 2018, to confirm OHDS appropriateness.

ABSTRACT

The Ciliwung River Basin population density is roughly about 5100 people per km square. In the last ten years this number has increased rapidly. Ciliwung river basin is located in 2 provinces, West Java Province (Bogor Regency, Bogor City, and Depok City) in the upstream and middle reach and Capital City Jakarta Province (South Jakarta, East Jakarta, Center Jakarta, West Jakarta, and North Jakarta) in the downstream area. The dry dam is one of the alternatives for flood control in the urban area, when the resettlement to be main issues in the urban area.

Keywords: Dry Dam, Flood Control, Small Resettlement

1. BACKGROUND

Jakarta as the Special Capital Region of Indonesia has an area of approximately 661.52 km². Jakarta have a big issues to manage the river, with ‘too much water’, ‘too little water’ and ‘too dirty water. Too much water, because every year it were hit by the worst flooding. Too little water, because we have varied rainfall distributions from the wettest (> 4,000 mm/year) to the most drought (< 800 mm/year) and very difficult to fulfill a demand of water supply because the population in the Greater Jakarta is rapidly increase, but the quantity and continuity of water supply is very limited. Too dirty water, because many people (mostly the low incomes) live on the river banks even on the middle of the river, the worst thing from the people who live along the river rely on its use for daily necessities including cooking, cleaning and washing, the river is increasingly being used as a place to dispose of trash and inorganic waste materials.

The problem of Jakarta during the rainy season is flooding in several places in the Ciliwung river basin. Based on the masterplan of flood control in Jakarta, planned to be built Ciawi Dam and Sukamahi Dam which will be useful as flood control, this dam is located in the upper Ciliwung river.

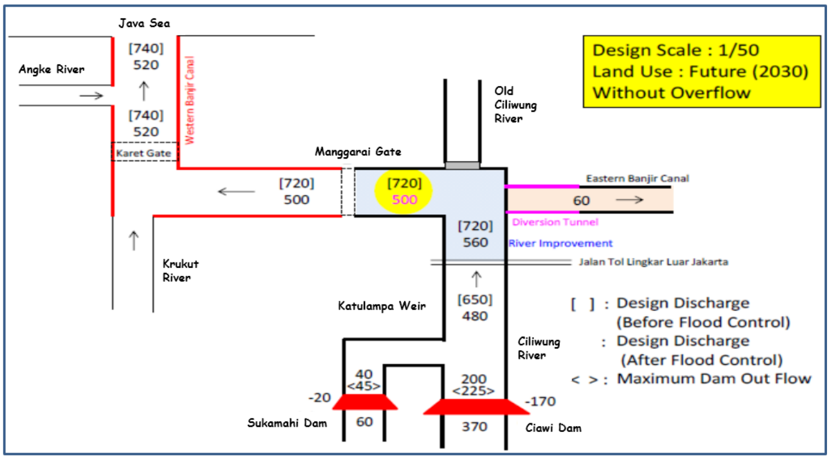

Fig. 1
The Masterplan Of Flood Control In Ciliwung River

Ciawi Dam designed as dry dam, it equipped tunnel without a gate to control the flood. The Dam type is random zone with height 55 meters from bottom fondation, and total volume 6,45 million m3. Sukamahi Dam will be build in Sukabirus river and planned to be build using straight core in the middle, with random zone on shoulder. Sukamahi Dam height 50 meters measured from bottom of the deepest foundation excavation, top Dam elevation + 601 meters with 9 meters width and 198 meters length. Ciawi Dam and Sukamahi Dam are constructed to support flood control system of Jakarta.

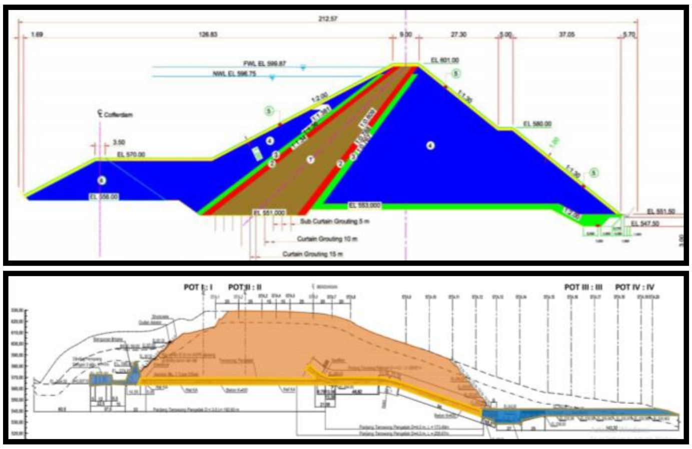

Fig. 2
Typical Detail Design of Sukamahi Dam

Advantages of this type of dam (Dry Dam) are not only the lack of sedimentation in the reservoir, the water quality of the river either upstream or downstream of the natural dam and the supply of the upstream part of the river. Besides, the maintenance of river ecosystem is not disturbed as migration of fish can still go downstream and going home based on previous habit including material condition in all river area.

The main advantage in flood control with dry dam is effective for flood control in the urban area, because with small storage and small resettlement it can delay the peak of flood maximally. The dry dam has a low operating cost and easy to operate because there is no water elevation setting so it can work without door operation. With the above reasons, an engineering operation is performed, which at the beginning of the rainy season, the water level of the reservoir is set to a low elevation so that at the beginning of the flood, the flood discharge flows freely through the tunnel.

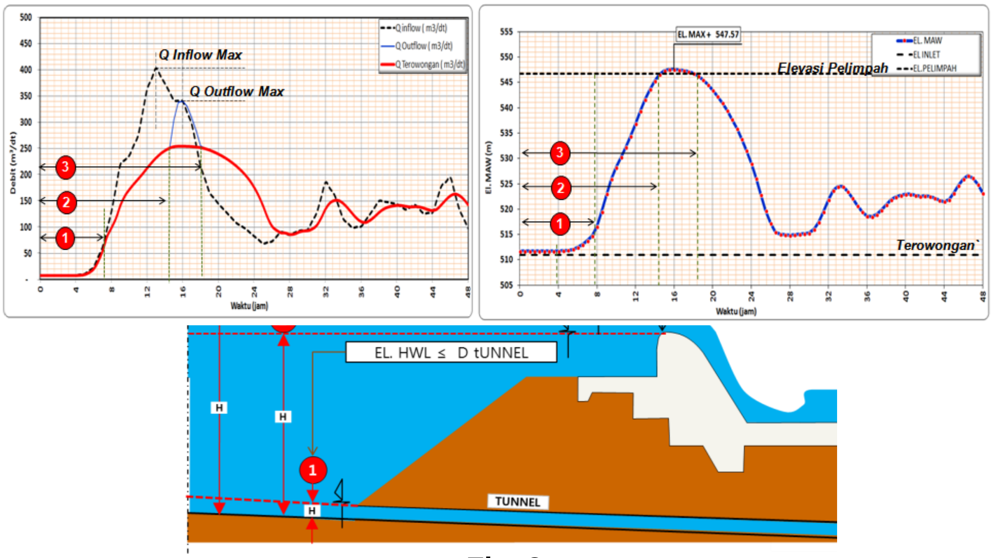

Fig. 3
The Concept of Dry Dam

River Flow Conditions:

a. Condition 1 :
   For low flow with discharge is smaller than tunnel capacity, water level in the beginning of tunnel is lower than or as same as the height of tunnel. Water flows with free flow condition inside the tunnel.
b. Condition 2
   The flood discharge exceeds the tunnel capacity, water will flow up but the level is still lower than spillway crest elevation. Water flows through the tunnel with pressured condition.
c. Condition 3
   The flood discharge exceeds the tunnel capacity, water will flow up and exceeds the spillway crest elevation. Water will flow through the tunnel with pressured condition and overflow through spillway crest.

Considering the need for flood reduction, the concept of control on Ciawi Dam and Sukamahi Dam is as follows:

a. Changing the flow pattern of streams that under existing conditions flow through the natural river channel with the average width of the river bottom 13-15 meters, into a controlled flow by making the dam with the flow of water through the tunnel.
b. As a result of the system, the outflow capacity through the tunnel will be smaller than the natural river, so the water flowing downstream is also smaller.
c. Dam function in the above conditions is to hold the elevation of the rising water surface due to outflow outflow through the tunnel is smaller than inflow discharge.
d. Dam is equipped with spillway, so if the flood discharge happened big enough, the water level of the reservoir rises and the water flows through the spillway. The discharge going downstream of the dam is the total discharge that flows through the tunnel and through the spillway.

2. EXISTING CONDITION OF CILIWUNG RIVER

Water level on Katulampa Weir in the up stream of Ciliwung River currently use as flood reference for the down stream. The limits which are used as the standard of flood early warning are:

Table 1
Katulampa Weir as Flood Alert

Flood Alert	Water Level H (cm)	Discharge Q (m3/s)
Normal	< 80	< 90
Level III	80 - 150	90 - 276
Level II	150 - 200	276 - 442
Level I	> 200	> 442

Based on hourly data from Katulampa AWLR and Cibogo AWLR in period of 2004 – 2013, the history of flood in Ciawi Dam and Sukamahi Dam are:

Table 2
Flood Event in Ciawi Dam and Sukamahi Dam

No	History of Floods	Discharge (m3/s)	
		Ciawi	Sukamahi
1	18-Jan-04	73.19	13.12
2	18-Jan-05	119.34	21.39
3	23-Jan-06	100.63	18.03
4	03-Feb-07	360.91	64.68
5	12-Mar-08	125.96	22.57
6	13-Jan-09	117.72	21.1
7	12-Feb-10	218.19	39.1
8	17-Nov-11	78.31	14.03
9	13-Dec-12	103.63	18.57
10	04-Mar-13	253.34	45.4

From the AWLR discharge data, besides the flood event is known, the flood frequency along the year can be studied in Ciawi Dam and Sukamahi Dam. If the discharge in the Katulampa Weir are known, so by using the catchment ratio, the discharge in Ciawi and Sukamahi Dam could be predicted.

Table 3
Flood Frequency in One Year at Ciawi Dam

Discharge	jan	Feb	Mar	Apr	May	Jun	Jul	Ags	Sep	Oct	Nov	Dec
(m3/s)	The Frequency of Occurrence (time)											
Q > 53,17	75	120	36	16	12	0	5	6	7	8	16	16

From the data above, it can be known that the wet season pattern s arts from November to April and dry season is May to October.

3. ANALYSIS OF FLOOD CONTROL IN CIAWI AND SUKAMAHI DAM

As stated previously, Ciawi Dam and Sukamahi Dam are planed as flood control measures. To optimize the flood reduction, the reservoir water level should be in low condition, where the water flows freely through tunnel.

Flood routing calculation result for flood return period 2 yr, 5 yr, 10 yr, 20 yr, 25 yr, 50 yr, 100 yr and Q_{PMF} at Ciawi Dam and Sukamahi Dam in fully opened tunnel condition as presented in the next figure.

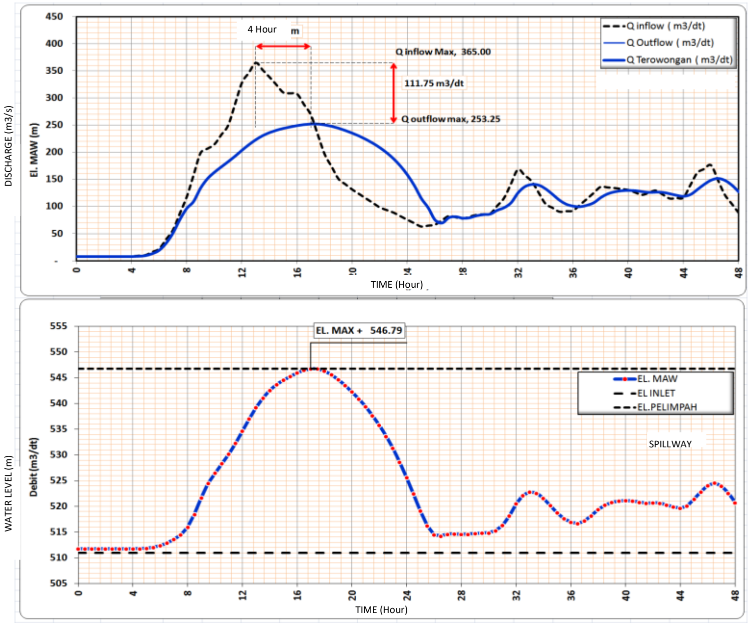

Fig. 6

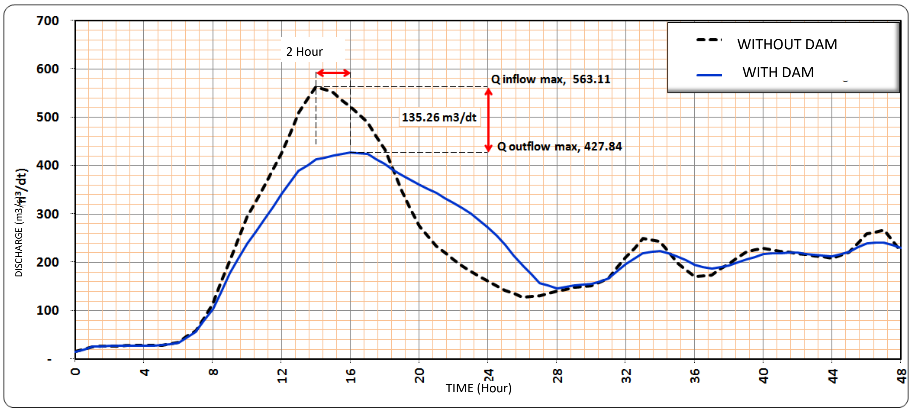

Fig. 8
Change of Discharge in Return Period of 50 year, at Katulampa Weir, due to Ciawi Dam and Sukamahi Dam

From the flood discharge routing for return period of 50 year, with the construction of Ciawi Dam and Sukamahi Dam, the flood discharge in the down stream of Ciliwung River is 577,05 m^3/s. If it's deducted by the discharge to East Flood Canal 60,0 m^3/s, therefore the discharge at Manggarai gate would be 517,05 m^3/s.

The current status of these dam is progressing with site preparation, land acquisition, etc, with schedule of construction commencing in the month of, November, 2017 and plan of completion in 2019.

4. CONCLUSION

This paper can explain the advantages of Dry Dam with single purpose for flood control. Major conclusions are as follows:

a. The dry dam is one of the alternatives for flood control in the urban area, when the resettlement to be main issues in the urban area.

b. The dry dam effective for flood control by cutting and defer the peak of flood by:
   - existing landscapes and ecosystems have not changed;
   - river morphology and river regime (natural flow) are unchanged;
   - easy to operate;
   - No risk in flood control functions.
c. The dry dam has a low operating cost because there is no water elevation setting so it can work without door operation.
d. Ciawi Dam and Sukamahi Dam can delay the flood discharge coming from the river ciliwung to jakarta, so the flood impact in the National Capital of Indonesia can be avoided.

5. ACKNOWLEDGMENTS

This paper was supported by Ciliwung Cisadane River Basin Organization. The author express deep gratitude for the supports.

1. INTRODUCTION

Many dams have been recently constructed in Iran with different purposes, from storing water for agriculture and industrial usages, to household uses for hundreds of years in Persian culture historically. Hydroelectric dams, additionally, act as an alternative to non-renewable energy resources that constitute the majority of the world's energy [1]. Despite enormous benefits of dams, they may have drastic damaging effects on the environment and on the populations that live near dams and thus, have become the subject of great scrutiny, with organizations concerned with environmental health such as Iranian Environmental Organization [2]. In a worldwide perspective, Out of the 38,000 large-scale dams, registered by the International Commission on Large Dams (ICOLD), an international organization that sets the standards for dams, 50 percent of dams are used for irrigation, 18 percent for hydropower, 12 percent for water supply and 10 percent for flood control and the rest for other functions [3]. As such, external effects such as environmental issues are of a huge consideration for any nation.

Water pollution refers to the contamination of a water source by some foreign substance that makes the water unsafe to drink or for use for agriculture and/or industry. This substance could be just about anything, and there are many factors causing water pollution. If the water source is changed in any way by the presence of that substance, then that water should be considered polluted [4].

While hydropower does not cause water or air pollution, it does have an environmental impact: Hydroelectric power plants may harm fish populations, change water temperature and flow (disturbing plants and animals) and force the relocation of people and animals who live near the dam site. Some fish, like salmon, may be prevented from swimming upstream to spawn. Technologies like fish ladders help salmon go up over dams and enter upstream spawning areas, but the presence of hydroelectric dams changes their migration patterns and hurts fish populations. Hydropower plants can also cause low dissolved oxygen levels in the water, which is harmful to river habitats. Reservoirs may also lead to the creation of methane, a harmful greenhouse gas [5].

In this research an environmentally friendly approach for dam construction and maintenance projects in Iran is proposed. The methodology takes into account diverse ranges of environmental issues and categorize them. Afterwards, proper remediation actions are developed to address each category. A brief review of related literature is stated in the next section, followed by Section 3 that presents the methodology development. Finally, Section 4 summarize some concluding remarks.

2. LITERATURE REVIEW

Dams are used for a wide range of purposes including providing drinking water, agricultural water, industrial uses, flood control, and energy generation. The later one began in 1895 when the first dam and hydropower plant was built on the Niagara Falls successfully. The basic of hydropower does not have much changes in 120 years and since then, many efforts have been made to have a fresh look at hydropower to try to make it more environmentally friendly. That’s because, while hydro dams provides 85 percent of the world’s renewable electricity, it comes with a cost. Along with more commonly known issues such as habitat disruption, recent studies suggest reservoirs created by hydroelectric dams are a significant source of greenhouse gas emissions. That's why many environmentalists argue that other sustainable energy sources have evolved as better alternatives. For example, wind and solar have become cheaper in many countries and they are less risky in climate terms. They can be deployed more quickly, and they have smaller environmental and social footprints [6]. On the other hand, there are many experts believing that hydroelectric dams bring several benefits for societies such as job creation and flood control though it is of course necessary to mitigate their adverse impacts. For example, the US Department of Environment (DOE) develops new environmental metrics to assess the environmental performance of new hydropower. The peer-reviewed process starts with defining what sustainability means for hydropower, then setting performance measures for different environmental effects, such as fish migration, energy efficiency and greenhouse gas emissions [7].

As a case study, a team from the University of the Philippines Diliman (UPD) has designed a system for the Gaia dam in Philippines that can control or prevent flooding from torrential rains on farms, along rivers and in coastal areas by minimizing and re-routing the flow of water through storm runoff pathways. Its main structural frame consists of gabion cages: wire mesh baskets filled with sturdy columns of recycled concrete cylinders or rocks, which provide stability against the hydrostatic forces pushing through the dam [8]. Like a miniature hydroelectric power plant, the Gaia dam could divert water into the powerhouse where turbines are installed, yet do so less expensively than the concrete dams that are usually used for this purpose. In addition, the dam is designed to release proprietary proteins and enzymes when water passes through its specialized core. Its proteins are designed to help crops absorb soil nutrients and minerals, while its enzymes would gradually dissolve the exoskeletons of insects and other pests that attack the crops, thereby acting as natural fertilizers and pesticides. Thus the Gaia dam has the potential to help in the production of organic crops.

The dams themselves often flood large expanses of forest (creating methane emissions). Also, dams require networks of roads for dam and power grid construction. These roads frequently open a Pandora's Box of environmental problems, including illegal deforestation, mining, poaching, and land speculation. For instance, the 12 dams planned for the Tapajos River in the Brazilian Amazon are projected to increase deforestation by nearly one million hectares, by 2030 [9]. The modern dam explosion and its indirect impacts via road construction into remote frontiers are arguably its worst consequences of all.

2.1. Fixing Existing Problems

Many dams in Iran and worldwide have been constructed in the past when environmental and social impacts were not that much of concern. Recently, endless efforts are being made to retrofit the hydropower projects in the operation phase [11]. Restoring fish passage is a major focus. Many large dams were built without fish ladders and remain an absolute barrier to fish migration. Climate change makes this an even greater concern, because migratory species like salmon and steelhead need access to cold-water spawning habitat above dams as temperatures warm. Adding fish ladders however, exceeds the original construction cost of some large dams. Compromises include trap-and-haul programs, in which fish are collected and transported by tanker truck around dams, and motorized lifts in various configurations.

Dealing with greenhouse gas emissions is another current environmental challenge. Reservoirs may emit substantial amounts of methane, a powerful greenhouse gas, when vegetation and algae decay with changing water levels. Solutions may include controlling erosion in upstream watersheds and managing water elevation more carefully, especially during warm seasons [12].

Reservoirs also trap pollutants left behind by past industrial practices, which flow downstream and concentrate behind dams. These chemicals can accumulate in fish, making them dangerous for people and wildlife, and also, pose a health hazard in drinking water. Removing pollutants trapped in a reservoir presents a huge logistical challenge.

3. METHODOLOGY DEVELOPMENT

This research strives to present an innovative approach called "Green Dam Reservoir" or GDR that helps minimize environmental effects and maximize dam and reservoir green operation in both construction and operation phases. In order to achieve this goal, a framework shown in Figure 1 is proposed. The common polluting sources in a dam reservoir in various aspects are determined using the dam clinic, a concept developed in [13].

Dam clinic, inspired by human clinic, is an innovative approach for dealing with challenges of O&M issues in dams and hydropower plants that are delivered for operation but suffer from some illnesses such as cracks, leakage, low quality, and so on. Although they can generate revenue, these products create great safety concerns and therefore, need to be treated comprehensively. The proposed conceptual model is shown in Figure 2 and Figure 3. More information about the dam clinic can be found in [13]

Once the polluting sources are identified, they will be categorized and each group analyzed. In the implementation phase of the GDR, a specific remediation action is proposed for each group of polluting source (e.g. chemical source, wastewater source, external source). Combination of remediation actions will result in an integrated remediation approach in which upon approval of the dam owner, can be applied in the construction as well as the operation phases of dam projects.

Dam Clinic Framework [13]

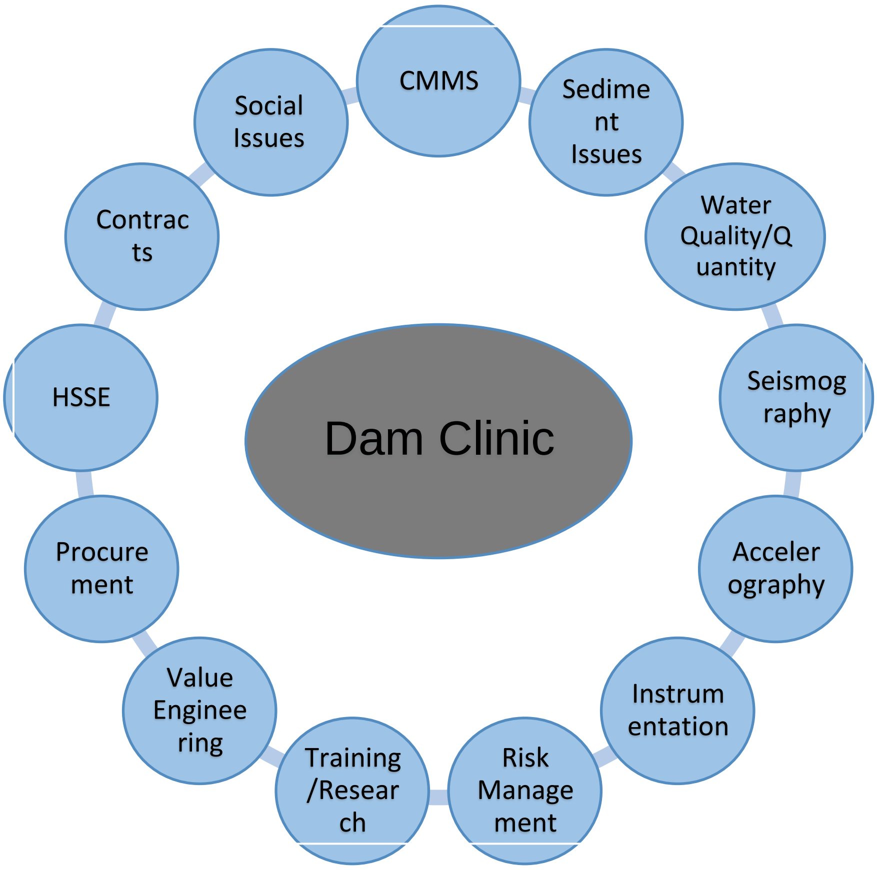

Fig. 3
Various Aspects of Dam Clinic [13]

3.1. Environmental Impact of Large Dams

According to the guidelines of the International Committee on Large Dams (ICOLD), the damaging environmental effects of dams can be categorized as follows.

1. Physical and Chemical Effects: Creation barrier motion, sedimentation in reservoirs, severe erosion along the river, valve blockage, fog formation and raising the relative humidity, climate changes, ground shaking, increased surface evaporation, rising ground water, changing lands to salinity .

2. Biological Effects: reduce nutrient concentrations downstream of dams, Plankton growth, plant growth, extinction of some species, getting limited fish spawning areas, thermal stratification, production of new species, decline in fish populations, serious changes in water quality, increased opacity of water, Release of toxic substances (pesticides, toxic metals, etc.), increasing the concentration of pollutants in the intake water in periods of water shortage, deterioration of vegetation, Greenhouse gas emissions

3. Health Effects: source of many infectious diseases (such as malaria and blood diseases), creating a favourable environment for oviposition.

4. Economical and Social Effects: increasing urban population, immigration, creation of false jobs, destruction of roads and power transmission lines, lack of access to some of Points of the range, loss of agricultural lands, unemployment, destruction of historical and archaeological sites, destruction of some places with specific topographic.

5. Impacts of Dams on Noise Pollution: increasing volume in the construction phase, disturbing the peace, leaving the nest wildlife, increased risk of loss of animals

6. Effect of Dams on Ecosystems of Aquatic Organisms: increasing of BOD in water (at first), formation of anaerobic degradation environment, formation of dark and funky environment, the exceeding of phytoplankton, growing of macro-flora in the water, increasing plant, increasing evaporation and transpiration, making a barrier to stop fish from passing.

3.2. Identify Sources of Pollution

There are many polluting sources that threat surrounding environment of dam projects. In some cases, the pollution may be extended to the river in the downstream of dam, and in some rare cases, the quality of underground water sources may get affected. There are many types of water pollution because water comes from many sources. Here are a few types of water pollution:

1. Nutrients Pollution

Some wastewater, fertilizers and sewage contain high levels of nutrients. If they end up in water bodies, they encourage algae and weed growth in the water. This will make the water undrinkable, and even clog filters. Too much algae will also use up all the oxygen in the water, and other water organisms in the water will die out of oxygen starvation.

2. Surface water pollution

Surface water includes natural water found on the earth's surface, like rivers, lakes, lagoons and oceans. Hazardous substances coming into contact with this surface water, dissolving or mixing physically with the water can be called surface water pollution.

3. Oxygen Depleting

Water bodies have micro-organisms. These include aerobic and anaerobic organisms. When too much biodegradable matter (things that easily decay) end up in water, it encourages more microorganism growth, and they use up more oxygen in the water. If oxygen is depleted, aerobic organisms die, and anaerobic organisms grow more to produce harmful toxins such as ammonia and sulfides.

4. Ground water pollution

When humans apply pesticides and chemicals to soils, they are washed deep into the ground by rainwater. This gets to underground water, causing pollution underground.

This means when we dig wells and bore holes to get water from underground, it needs to be checked for ground water pollution.

5. Microbiological

In many communities in the world, people drink untreated water (straight from a river or stream). Sometimes there is natural pollution caused by microorganisms like viruses, bacteria and protozoa. This natural pollution can cause fishes and other water life to die. They can also cause serious illness to humans who drink from such waters.

6. Suspended Matter

Some pollutants (substances, particles and chemicals) do not easily dissolve in water. This kind of material is called particulate matter. Some suspended pollutants later settle under the water body. This can harm and even kill aquatic organisms that live at the bottom of water bodies.

7. Chemical Water Pollution

Many industries and farmers work with chemicals that end up in water. This is common with Point-source Pollution. These include chemicals that are used to control weeds, insects and pests. Metals and solvents from industries can pollute water bodies. These are poisonous to many forms of aquatic life and may slow their development, make them infertile and kill them.

8. Oil Spillage

Oil spills usually have only a localized effect on wildlife but can spread for miles. The oil can cause the death to many fish and get stuck to the feathers of seabirds causing them to lose their ability to fly. There are some dam reservoirs that cross oil pipelines and in if the pipeline is broken for any reasons, huge environmental pollution of reservoir water will take place.

3.3. Propose Remediation Action

In the previous section, sources of pollution caused by construction and operation of dams are identified and categorized. In this section, a specific remediation action related to each source is proposed, as shown in Table 1. The proposed action should be taken in a right timing by a right team in a right place and should not have the consequences that cause other types of pollution. For example, for dealing with the suspended or particulate matters in the water reservoir, a remediation action may take place to resolve the suspended matter. Such action should not produce the nutrient pollution (First row in Table 1) that needs extra effort to manage. Based on this consideration, there needs an integrated remediation action, as displayed at the end of Figure 1, to make sure that the overall remediation process is effective.

Table 1
Sources of pollution and corresponding remediation action

Sources of Pollution	Effects	Remediation Action
Nutrients, e.g., wastewater, fertilizers and sewage	Develop algae and weed in the water, lack of oxygen in water	1) Prevent Pouring wastes in reservoir, 2) Artificial water turbulence in reservoir, 3) Educate neighbors
Surface water	Polluted water caused by hazardous substances	1) Careful monitoring & controlling, 2) removing hazardous materials along rain waterway to reservoir.
Oxygen Depleting	Growth of more micro-organism and die of more aerobic organisms to produce harmful toxins	More water turbulence in reservoir to enter more air in the water.
Ground water	Pollution of the soil by pesticides and chemicals and then, pollution of underground water	Prevent penetration of pesticides and chemicals into soil by isolating the reservoir
Microbiological	Natural pollution caused by micro-organisms like viruses, bacteria, and protozoa	Prevent direct access for drink of neighboring communities and animals in upstream river
Suspended Matter	They cannot dissolve in water and when settled down in reservoir, kill aquatic organisms that live at the bottom	Design and install gates in the reservoir boundaries to capture substances, particles, and undissolved chemicals
Chemical Water	Wastes produced by farmers and industries pour to the river and causing infertility and killing of many forms of aquatics.	Strict management of point-sources of pollutants (e.g., factories) in the upstream river
Oil Spillage	Widespread life damages to aquatics and dam equipment exposed to water	Displacing the oil pipelines from along the reservoir to another safe place before the reservoir impoundment.

4. CONCLUSIONS

An innovative methodology was developed in this research in order to address environmental threats made by dam construction and maintenance. The methodology is an easy-to-use and logically consistent procedure that can be conveniently applied for under construction and under operation dams and hydropower plants. The owners benefit from using the proposed approach by saving enormous amounts of time and costs for the construction and operation/maintenance activities. There is a great hope that by applying the GDR approach, not only the near-by communities have better life quality but also, reservoirs operate in safer mode both in physical and technical aspects. This research significantly contributes to the provision of more sustainable operation and maintenance of under operation dams. A new era of dam industry in Iran is recently demanding more focus on the environmental issues. This research is a right attempt in a right direction and in a right timing to address these issues and ultimately, make sure these remarkable national and vital investments have lower damaging effects as well as longer life span for current and next generations.

1. INTRODUCTION

Dams are often referred to as monolithic hydraulic structures. Made of adequately impermeable materials, dams arebuilt to create a storage compartment known as reservoir at the upstream to store water for various purposes. These hydraulic structures supply raw water to water treatment plants. In Malaysia, dams contribute to irrigation and flood control mechanisms, on top of its predominant role in generating/ producing hydroelectric energy power source for local consumption.

Despite the aforementioned benefits, dams can also impose risks to the public. In line with current global awareness of water security, the aspect of dam safety has drawn increasing attention from the public as it constitutes the element of a country's national security. The consequences of dam failure may involve substantial downstream injury and property damage as well as catastrophic and long-lasting environmental effects [1]. In Malaysia, Tenaga Nasional Berhad

(TNB) is the owner of most of the larger dams in Malaysia. In fulfilling its corporate responsibility, and also as a responsible dam owner and operator, TNB has embarked a comprehensive research program to study the dam break analysis and assess its impact downstream in terms of social, economic and environmental for all its operating dams since the year 2003.

The dam break simulation results were translated into Emergency Response Plan and quantification of impacts downstream indicating the procedures to be taken in the case of such unfortunate event and the foreseeable loss of all aspects in monetary term. In view of this, TNB has decided to expand the implementation of Emergency Response Plan (ERP) by developing Dam Safety Emergency Response Plan (DSERP) for various TNB power stations to suit both local agencies and TNB station personnel. The DSERP developed to suit the Malaysian Government's management of national disasters, outlined in the Directive No. 20, Policy and Mechanism on National Disaster Management and Relief (In 1997 by National Security Council). The Directive covers all aspects of the management of natural disasters in Malaysia including preparedness, mitigation, response, recovery and rehabilitation.

Potential risks associated with the failure or disruption of these assets could result in significant destruction including loss of life (LOL), massive property damage, and severe long-term consequences [2]. The drill and tabletop exercises prepared the dam personnel in the early detection of the emergency conditions which could endanger the integrity of the dams, provide prescribed procedures for mitigating the emergency condition and timely notification to relevant emergency management agencies. The tabletop exercise helped to ensure timely warning and evacuation of the population at risk by the local agencies. With the SJSIP DSERP manual in place, it will help prevent or minimize the negative impact to the lives and property under the dam failure condition, thus putting corporate image of TNB to greater height.

The implementation of SJSIP DSERP manual through drill and tabletop exercise has successfully highlighted the importance emergency preparedness among dam personnel and also local agencies in minimizing the impact to the society and environment due to dam failure.

1. INTRODUCTION

The latest 2014-2015 drought in Korea caused water scarcity of multipurpose dams that supply living and industrial water and led to difficulty with water management. This drought was so severe that it was recorded as an unprecedented event. Drought affects more people than other natural disasters and results in an enormous social, economic and environmental cost ([1]). Sheffield et al. ([2]) expected that frequency and severity of drought would increase due to global climate change. A regional drought is not limited to regional damages, but affecting food and economic matters over wide areas ([3]).

Wilhite and Glantz ([4]) classified drought into meteorological drought, agricultural drought, hydrological drought, and socioeconomic drought. Therefore, Drought indices are estimated using rainfall, evapotranspiration, runoff, soil moisture, and water supply ability in accordance with study objective. Numerous drought indices had been developed to express droughts which result in various social effects. Typical drought indices are Standardized Precipitation Index (SPI, [5]), Palmer Drought Severity Index (PDSI, [6]), Surface Water Supply Index (SWSI, [7]), Standardized Precipitation Evapotranspiration Index (SPEI, [8]). However, most drought indices are calculated by the lack of amount over the normal phenomenon or the occurrence probability, which has a problem that does not reflect the water supply systems. Modern water use mainly depends on reservoir's water supply system. Therefore, to respond drought in a timely manner and mitigate drought damages, the drought index that considers the dam operation is needed instead of evaluating the shortage of the average or the probability of occurrence.

This study developed Dam Inflow Drought Index (DIDI) considering the criteria for reduction in water supply related to dam operation during a drought. DIDI needs threshold of the cumulative difference between the critical inflow and the observed inflow. In this study, optimal threshold calculated by Receiver Operating Characteristics (ROC) analysis. ROC analysis is commonly used in verification of weather forecast ([9]), but it is also used in verification of drought indices compared with actual drought cases ([10], [11], [12]). The DIDI could be used as the drought monitoring tool that can effectively detect drought of dam basin. Droughts, unlike floods, are characterized by slow progress. Appropriate drought index reflecting the characteristic of water supply system such as the DIDI would contribute to coping with drought and mitigating drought damages.

2. METHOD

Multipurpose dams in Korea have criteria for reduction in water supply during the drought. When using this criterion, we can calculate critical inflow for keeping the criteria by "Eq. [1]."

$$I_{C,i} = AC_i - AC_{i-1} + S_{P,i} \quad [1]$$

where I_C is the critical inflow, AC is the storage of the water supply adjustment criteria, S_P is the amount of the planned water supply, and i is the month.

The difference between the observed inflow and the critical inflow for each month can be calculated by "Eq. [2]," and cumulative the anomalies are calculated by "Eq. [3]." Then the DIDI is calculated by "Eq. [4]."

$$DI_i = I_{O,i} - I_{C,i} \quad [2]$$

$$CDI_i = CDI_{i-1} + DI_i \quad [3]$$

$$CDI_i = CDI/\sigma(CDI) \quad [4]$$

where, DI is the difference in inflows, I_O is the observed inflow, CDI is the cumulative difference in inflows, and $\sigma(\,)$ is standard deviation.

However, when calculating CDI in “Eq. [3],” the upper limit on CDI has to be considered because a considerable amount of inflows that cannot store at the reservoir are not associated with the future water use. In order to determine a threshold, this study calculated “Eq. [3] and [4]” repeatedly with changing the threshold and then conducted Receiver Operating Characteristics (ROC) analysis.

ROC analysis is commonly used in verification of weather forecast, but it is also used in verification of drought indices compared with actual drought cases. This study set ROC model as “Table 1” ROC analysis is separated observed value and prediction value. In this study, the observed value is defined as ‘Water supply’ and the prediction value is defined as ‘DIDI’ in “Table 1” If an actual event occurs and an event predicted in the forecast result, it is expressed as ‘Hit (H).’ Whereas, if an actual event occurs and an event did not predict in the forecast result, it is expressed as ‘Missing (M).’ If an actual event does not occur and an event predicted in the forecast result, it is expressed as ‘False (F).’ On the other hands, if an actual event does not occur and an event did not predict in the forecast result, it is expressed as ‘Negative hit (N).’

Table 1
ROC classification model

		Water supply	
		Reduction	Normal
DIDI	Drought	Hit (H)	False (F)
	Normal	Missing (M)	Negative Hit (N)

The ‘Water supply’ in “Table 1” means that water supply is reduced or normal when dam operation is simulated using the water supply adjustment criteria and historical inflow data. ‘Drought’ in “Table 1” means that DIDI is less than zero and ‘Normal’ of DIDI means that DIDI is equal to or greater than zero. H, F, M, and N with various thresholds can be calculated using ROC classification model in “Table 1.” Then ‘Hit rate (HR)’ and ‘False Alarm Rate (FAR)’ can be estimated by “Eq. [5] and [6].”

$$HR = H/(H + M) \tag{5}$$

$$FAR = F/(F + N) \tag{6}$$

Finally, ROC score has to be calculated to evaluate results of ROC analysis quantitatively. ROC score, which indicates how well the drought index can reproduce actual water shortage, is calculated as the area shown in “Fig. 1.”

The procedure for calculating the DIDI described above is shown in “Fig. 2,” and the optimal DIDI is the DIDI to which the threshold value having the maximum ROC score is applied.

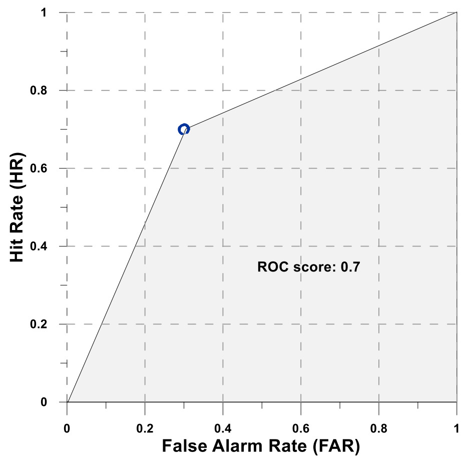

Fig. 1
Description of ROC score

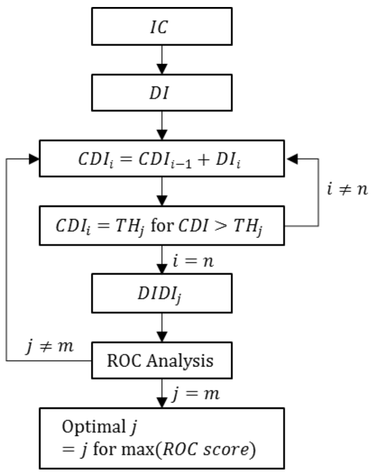

Fig. 2
Procedure for Calculaing DIDI

3. RESULTS AND DISCUSSION

3.1. APPLICATION OF DIDI

This study focused on Chungju Dam in Han River basin. The Chungju Dam, built in the Southern Han River basin which crosses the center of Korean, is the biggest concrete gravity dam in Korea

K-water developed Water Supply Adjustment Criteria (WSAC) to cope with a shortage of water resources in the dam. Drought response strategies of WSAC is divided into four stages, level1 to level4, according to the degree of water shortage. The critical inflow can be calculated by “Eq. [1],” and “Fig. 3” shows critical inflows of Chungju Dam for each month.

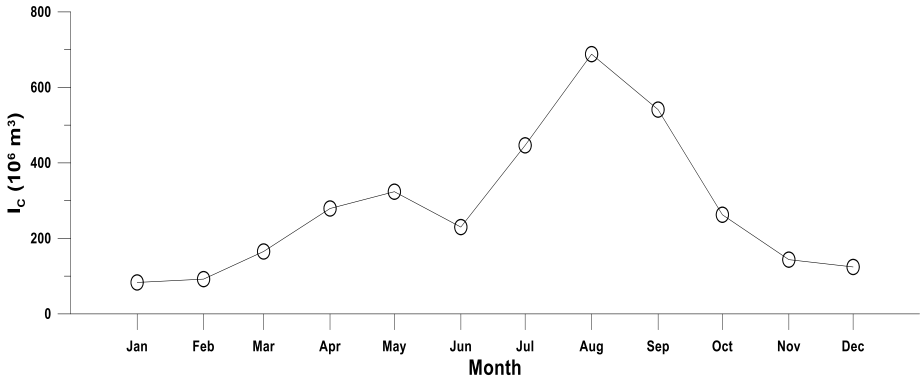

Fig. 3
Critical Inflows of Chungju Dam

“Fig. 4” shows observed monthly inflow of Chungju Dam, and the difference between the observed inflow and the critical inflow can be calculated by “Eq. [2].” “Fig. 5” shows the difference during entire periods. The CDI can be calculated by adding up the DI of “Fig. 5” in a cumulative manner. However, if the upper limit of the CDI is not set, DI continuously increases. Therefore, a threshold for CDI is needed to estimate optimal DIDI.

To determine the threshold of CDI, this study performed ROC analysis. Dam operation simulation was implemented from 1987 to 2015 using observed monthly inflow data and volumes of WSAC’s level1. “ A threshold value for maximum ROC score was determined as optimal threshold value, which was 630 × 10^6 m^3.

“Fig. 6” shows the cumulative difference between the observed inflow and the critical inflow when adapting the optimal threshold. “Fig. 7” shows DIDI and the point at which water supply is reduced. This Figure indicates that DIDI adequately expresses the water reduction timing of Chungju Dam.

3.2. COMPARISON WITH TYPICAL DROUGHT INDICES

This chapter compared DIDI with typical drought indices such as SWSI and SPI. SWSI and SPI are widely used as drought indices. SWSI is calculated by monthly precipitation, snowpack, streamflow, and reservoir storage. Fig. 8 shows DIDI compared with SWSI. SWSI defines -1 or less as drought. The SWSI indicates drought at the time of reduction in water supply adequately, but it can be seen that the drought by SWSI is very common even in the normal water supply condition.

SPI most widely used drought index and it was agreed that using SPI as universal drought index to cope with climate risks at 'The Inter-Regional Workshop on Indices and Early Warning Systems for Drought' held at the University of Nebraska-Lincoln. SPI can calculate simply and easily collect data due to using rainfall only. SPI is calculated by standardizing value of cumulative distribution function (CDF) of Gamma distribution that is estimated using sums of rainfall for a preset period (3 months, 6 months, 12 months, etc.).

"Fig. 9" shows DIDI and SPI of 3, 6, 9, and 12 months. When visually confirmed, DIDI seems to reflect the point of the water supply reductions better. As shown in "Fig. 9," one can see that 6-months and 12-months SPIs that indicate long-term drought are better able to monitor drought than 3-month and 6-month SPIs that show short- and mid-term. In order to evaluate the drought monitoring ability of SWSI and SPI, ROC analysis was also conducted for these. "Table 2" indicates ROC scores of DIDI, SWSI, SPI(3), SPI(6), SPI(9), and SPI(12). ROC score of DIDI was 0.93 which was 0.22 greater than it of SWSI and 0.33, 0.22, 0.16, and 0.17 greater than it of SPI(3), SPI(6), SPI(9), and SPI(12), respectively.

By applying the dam operation and threshold, DIDI was able to express the drought of dam inflow adequately, which indicates that the DIDI is useful for monitoring and responding the drought, and its application would help to mitigate drought damages.

ROC Score	0.93	0.72	0.60	0.71	0.77	0.76

4. CONCLUSIONS

This study developed and evaluated Dam Inflow Drought Index (DIDI) for Chungju Dam in Korea. The DIDI is calculated considering the dam operation. Critical inflows for each month are calculated using the criteria for water supply adjustment. The DIDI can be estimated by dividing the cumulated difference between the observed inflow and critical inflow (CDI) by its standard deviation. Considering the limit of dam storage, the upper limit of CDI has to be determined, and the threshold was estimated by RCO analysis. ROC analysis is implemented using results of the dam operation simulation and DIDI for various thresholds. Optimal threshold of Chungju Dam was calculated as 630 $\times 10^6$ m^3, DIDI applying the threshold expressed the drought at the time of reduction in water supply adequately. And the DIDI also showed much better performance in monitoring dam droughts than SWSI and short- and long-term SPI (3-, 6-, 9-, and 12-months SPI). The DIDI is useful for monitoring and responding the drought of dam inflow, and its application could help to mitigate drought damages.

SUMMARY

This study developed Dam Inflow Drought Index (DIDI) for Chungju Dam in Korea and evaluated the usability of the DIDI by comparing with Surface Water Supply Index (SWSI) and Standardized Precipitation Index (SPI). DIDI is calculated by the cumulative difference between the critical inflow and the observed inflow. The critical inflow means the essential inflow keeping the water supply criteria of the dam. Considering the limit of dam capacity, the upper limit of the cumulative difference has to be determined, and the threshold is estimated by performing Receiver Operating Characteristics (ROC) analysis. The Optimal threshold is determined by a value that represents maximum ROC score. The maximum ROC score of the DIDI was 0.93, and the threshold at this point was 630 $\times 106\ m^3$. The maximum ROC score of the DIDI was 0.21 higher than it of SWSI and 0.33, 0.22, 0.16, and 0.17 greater than it of SPI(3), SPI(6), SPI(9), and SPI(12), respectively. DIDI showed much better performance in monitoring dam droughts than SWSI and short-term and long-term SPI. The DIDI is useful for monitoring the dam inflow drought, and its application could help mitigate drought damages.

1. INTRODUCTION

Throughout history, there have been a series of catastrophic events in the Cordillera Blanca generated by mudflows coming from glacier reservoirs (see also [1] and [2]). One of the main causes of these events are the detachment of glacial masses that impact at the lagoons located at the base of the glacier, generating waves that produce overflows and in some cases a break of the dam body or the moraine. This omnipresent hazard in the Cordillera Blanca together with the increasing mean temperature due to climate change effects (see [3]), which are most visible in the tropical glacier regions, lead to the necessity to know the risks and the possible effects when operating reservoirs in this area of Peru. Recent research ([4], [5], [6] and [7]) shows an overall glacier loss of 46% between 1930 and 2016 with an increasing melting rate for the glaciers in the Cordillera Blanca based on climate change effects. In the present paper, the potential risk of ice blocks falling into a reservoir in the Andean region causing an impact wave, overtopping of the dam and provoking a dam break with significant damages downstream is analyzed. Eighteen glacier blocks with danger of detachment due to the melting and retreat of the glacier because of climate effects were identified based on a glaciological hazards analysis. Furthermore, adapted operation of the reservoir, which is located directly downstream of the Huantsán glacier, is presented.

2. INVESTIGATION ENVIRONMENT AND BASIC DATA

The lagoon with a volume of 29 Mio m^3 and a maximum depth of 90 m is located at the base of the snowcapped Huantsán glacier on the western slopes of the Cordillera Blanca at an altitude of 4,290 meters. The basin includes the Pariac creek and belongs to the province of Huaraz of the Ancash department (see Fig. 1). The ovoid-shaped reservoir corresponds to a very deep depression of glacier origin. The volume of the former glacier lake was augmented by the construction of an earth dam (H_{Dam} = 23 m) above the former moraine allowing a controlled operation of the lagoon. The 5.5 m wide crest of the dam is located at 4294.5 m.a.s.l. and covered with a concrete slab. The dam has a spillway with a fixed concrete overflow crest at 4290.88 m.a.s.l. and a width of 3.0 m.

Lagoon and Huantsán glacier (left; view from down- to upstream) and dam & spillway (right)
Lagon et glacier de Huantsán (à gauche - vue de l'amont vers l'aval) et barrage et évacuateur de crue (à droite)

The bottom outlet is located at 4271.00 m.a.s.l. and consists of a pipe running from the intake at the reservoir to the control house at the bottom of the dam. The rocky buttresses surrounding the reservoir correspond to the Chicama Formation (Js-ch), which consists of shales and fine sandstones, forming rather steep slopes, greater than 45 °.

Fig. 2
Identified glacier blocks and their pathways to the lagoon and corresponding volumes (representative blocks for further investigation marked red)
Blocs glaciaires identifiés, leurs voies vers la lagune et les volumes correspondants (blocs représentatifs pour une enquête plus approfondie marqués en rouge)

At the base of the valley propagation of quaternary deposits of morainic origin and some colluvial deposits of little thickness are found. The catchment area is 17.78 km^2 of which 11.26 km^2 (63% of the total surface) are snow /ice covered. The average annual precipitation (snow and rain) in the basin is 1070.5 mm/year – high flow season is between December and March.

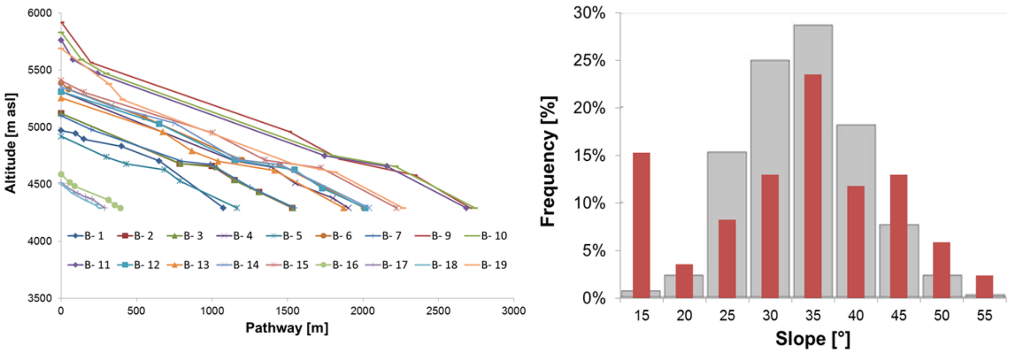

Fig. 3
Sliding paths of the different identified glacier blocks (left) and their slope distribution compared with findings from [9] (grey bars) (right)
Les chemins de glissement des différents blocs glaciaires identifiés (à gauche) et leur distribution de pente par rapport aux résultats de [8] (barres grises) (à droite)

The average annual mean flow rate is 0.87 m^3/s with a mean annual yield of 18.0 x 10^6 m^3. In general, the climate in the area of the lagoon is very cold with a very dry atmosphere, but with alternating temperatures during day and night. From June to September the average temperature at the lagoon (4’290 m asl) is below 4°C and the average annual minimum temperature is 0.07°C. July is usually the coldest month, reaching a monthly average temperature of 3.7°C, with average maximum and minimum monthly means of 11° C and -2.3°C respectively. For the Huantsán glacier, a reduction of the ice masses of 6.4 % was estimated between 1988 and 2008 ([7] and [8]). Due to this reduction of the glacier, the location and corresponding volume of 18 different ice blocks were identified on site (see Fig. 2), which represent a potential risk of detachment. Based on satellite data (ALOS and Sentinel 2b) the mean slopes and topographical conditions were analyzed for these blocks. The determined mean slope for the 18 blocks is 31 ° - maximum slopes reach 65 ° (see Fig. 3). This is also in accordance with the findings from [9], where different glaciers of the Cordillera Blanca were studied with respect of air temperature and slopes. According to the findings from [10], the identified glacier blocks represent a potential threat based on the mean annual temperature, their volumes and the identified slopes (see Fig. 4). Based on these results, the risk of a detachment is eminent and thus consequences of an ice block detachment were analyzed.

3. SIMULATION OF THE IMPACTING ICE BLOCKS

3.1. PRESELECTION OF THE SIMULATED ICE BLOCKS

As it can be seen from Fig. 2, some of the identified 18 blocks have similar characteristics in terms of their elevation and fall trajectory. A preliminary analysis based on the methodology described in Chapter 3 of [12] identified the blocks generating the most unfavorable effects. This methodology also was applied to the event occurred in 2010, where a large block of ice and rocks of 450 000 m^3

(see [13]) fell from the Hualcan glacier into the reservoir 513. The generated wave height over the natural dam of this event was estimated between 5 and 6 m causing downstream inundations and small damages (see [13] and [14]). According to [13], this event occurred when the reservoir had a free board of 20.0 m. According to the model, the 18 selected blocks generate wave heights above the dam crest between 0 and 45 m. The simulated detachment of an entire group of ice blocks resulted in similar wave heights as for individual blocks. Although block B-16 does not to generate a overtopping, this block also was considered in the detailed simulation due to its proximity to the reservoir. Based on this pre-assessment, 6 most important individual blocks were investigated in more detail (Fig. 5 – blocks marked red).

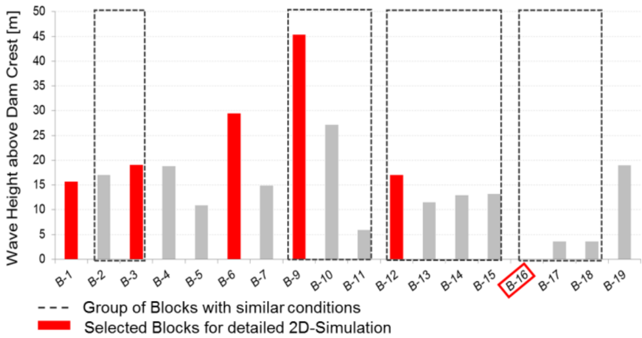

Fig. 5

3.2. Applied Model & Detailed Simulation procedure

For the detailed investigation, a 2D numerical simulation was applied with different scenarios to maintain the operation of the reservoir and at the same time to mitigate the risk of downstream damages due to a glacier block impact and resulting GLOF. The complete process chain of the impact events based on the crated DEM (satellite-, bathymetric- and drone topography) was simulated with a 2-dimensional hydrodynamic model (HYDRO_AS-2D (Hydrotec, Germany)), which is based on the shallow-water equations (depth-averaged) for free surface flow using the Finite-Volume-Discretization. For each selected ice block, (see Fig. 5) the simulation was carried out following a 3-step approach:

(Step 1) Pre-simulations to model the sliding phase,

(Step 2) Main simulation to model the impact phase, the wave propagation in the reservoir and the wave run-up at the dam, and

(Step 3) Iterative simulations to estimate the required reduction of the reservoir water level to prevent overtopping including a variation of the block volumes

Sliding path, impact velocity and impact direction were determined in the pre-simulation (Step 1). To be on the conservative side, the main simulation

(Step 2) starts with a fluid body right before its impact, which has exactly the shape of the ice block as predefined by the glaciologist (in the pre-simulation the sliding fluid body disintegrates somewhat which decreases the impact momentum). The comparison of the results from Step 1 to outcomes from [12] showed minor differences from -9.0 to +5.0% (mean -0.9 %) for the mean impact velocity. Nevertheless, velocities from the pre-simulation (Step 1) are spatially distributed with lower magnitudes at the edges of the impacting fluid body, which decreases the impact momentum. The resulting overtopping wave heights would be in average 22% and the overflow discharges 33% lower. Therefore and to assure a conservative approach, the initial velocity magnitude of the impacting fluid bodies was set constant for the entire fluid body in the main simulations based on the theoretical approach according to Körner [12]. As indicated in Step 3, additional to the 6 base cases, 17 simulations with different ice block volumes maintaining their locations and different reservoir levels were executed to cover the most important conditions and detect the minimal water levels in the reservoir which would prevent overtopping.

3.3. SIMULATION RESULTS

The simulation results show that in five of the six base cases (-a marked red) overtopping occurs when the operational water level is at the actual altitude of 4290.88 m a.s.l.

Reservoir Volume	29	7	29	17	29	29	25	29	27	29	5	29	13	29	28	29	29	7	29	17	29	29	24	[Mio. m^3]

Overtopping heights between 1 and 19 m were obtained based on impact heights between 300 and 1’600 m and volumes between 18’000 and 526’500 m^3. Only in one case (B16-a) no overtopping occurred due to the low volume and impact height. To prevent overtopping at the dam, the water level in the lagoon has to be reduced between 2 and 40 m. Correspondingly, the actual water volume of the lagoon (29 Mio.m^3) is reduced down to 5 Mio.m^3, which represents a reduction of 82 % and would mean to abandon the operation of the lagoon for any means. Block B-6 a has even such a high impact momentum, that prevention of overtopping through a water level reduction it is not possible at all. For the said scenario only an “optimal” lowest water level could be identified which lead to minimal overtopping, which still is 1’126 m³/s. The required reduction would be 50 m. Any further lowering of the reservoir water level again lead to higher overtopping discharges, as the remaining mass of water in the reservoir is not able to damp the impacting momentum (see Table 1). Overtopping heights with the tool from [12] versus the 2D simulation were in general 1 to 45 m (8 to 98 %) higher (see Table 2). By reducing the impact velocity in the range from 8 to 92 % same results as for the 2D simulation can be obtained. Overtopping volumes from the 2D simulation are in general 2 to 6 times higher. Although the impact of the spillway cannot be represented in the pre-assessment tool from [12], it can be said, that mayor impact heights result in increased differences between the tool and the 2D simulation.

4. DISCUSSION OF THE RESULTS

As shown in Fig. 6 (left), overtopping wave heights become more important when the ice block starts to have a significant volume compared to the reservoir volume – threshold for overtopping of the ice block volume is in the order of 50’000 m³ for the investigated situation. Reducing the water level also means to reduce the damping effect of the water mass of the reservoir. As indicated in Fig 7, a reduction of about 40 to 50 meters results to be ineffective regarding the prevention of overtopping. This is also the case, if the volume of the ice block reaches 6 – 10 % of the remaining reservoir volume (Fig. 6 (right)). Of course, not only the block volume and sliding velocity but also the impact location and direction (directly towards the dam or mainly towards a lateral bank) have great influence on the resulting overtopping heights. To figure out these influences in a first step, the relation of impact momentum (i.e. block mass times sliding velocity) and the required reduction of water level to prevent overtopping were analyzed (Fig. 7).

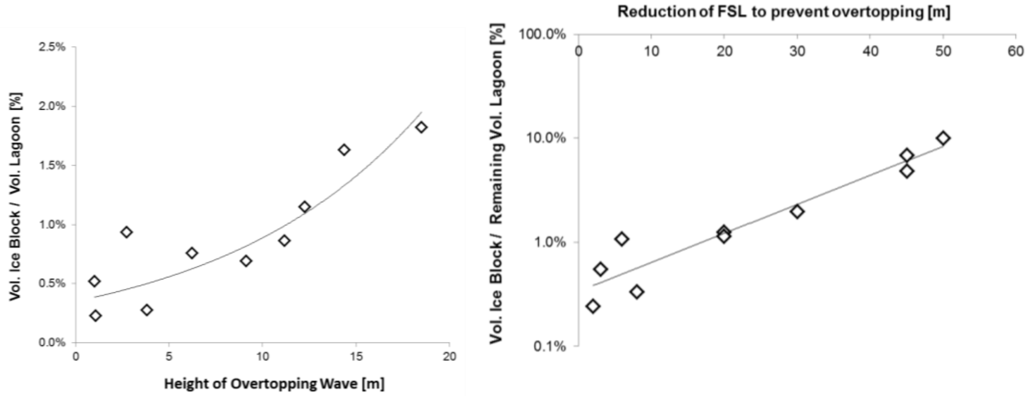

Fig. 6

Relation of ice block to reservoir volume in function of overtopping height (left) and relation of ice block to remaining reservoir volume in function of required reduction of the FSL (right)

Relation entre le bloc de glace et le volume du réservoir en fonction de la hauteur de déversement (à gauche) et la relation entre le bloc de glace et le volume restant du réservoir en fonction de la réduction nécessaire de la FSL (à droite)

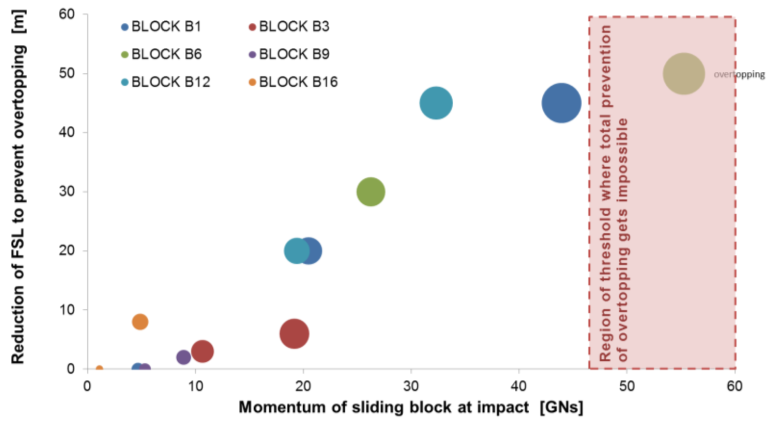

Fig. 7

Analyses of impact momentum and required reduction of reservoir water level to prevent overtopping

Analyses de la dynamique d'impact et de la réduction requise du niveau d'eau du réservoir pour éviter le déversement

From that analysis, it gets clear that some blocks have over-proportional impact in relation to their impact momentum. For instance, blocks B9 (violet dots) and B3 (red dots) do require significantly less reduction for preventing overtopping than other blocks with comparable impact momentum because their impact direction is less critical. Each block is represented by 2 dots (one for each estimated volume). For block B-1 additionally a third dot is drawn to indicate the maximum block volume which does not lead to overtopping. The size of the points is proportional to the volume of the blocks (maximum is B6-v1 with 526,500 m^3 (upper green dot)). Furthermore, prevention of overtopping is impossible for blocks with an impact momentum higher than 45-55 GNs by reducing the reservoir water level. This is at least true for blocks with an impact direction rather straight towards the dam.

SUMMARY

Global warming based on climate change lead to a considerable increase of glacier melting in the sub-tropical region. Most notable the glaciers in the Cordillera Blanca of Peru showed significant reduction of the glacier masses up to 95 % (see [8]). This retreat generates the risk of GLOF due to big ice blocks, which are isolated and fall into the lagoons located at the toe of the glaciers. In the given case 18 ice blocks of the Huantsán glacier with a potential risk of falling into the downstream lagoon were investigated prior identification by the means of site inspections and satellite images. Based on [10] it was shown, that the identified blocks represent a risk of detachment due to the very steep slopes and the high impact heights (up to 1800 m) as well as the mean annual temperature in the area. Based on a pre-assessment applying the excel tool from [12] six ice blocks with the most import potential risk regarding a GLOF event were selected for a detailed 2D simulation. Impact heights between 300 and 1’600 m cause an overtopping of the existing dam with wave heights between 1 and 19 m. For many cases, only a quite drastic reduction of the operational water level, which also would mean to abandon the reservoir, could prevent an overtopping. The technically feasible reduction of the FSL turns out to be approximately 18 m as higher reductions would reach levels below the intake. Even with the initial conditions of the lagoon (without dam), there would be a risk of overflow (wave heights approx. 8 m), as it would be necessary to reduce the level of Lagoon by 35.0 m, far below the level of the former moraine. As there are many other lagoons in the Cordillera Blanca with similar conditions, the risk of a GLOF event in the sub-tropical glaciers becomes more evident taking into consideration the effect of climate change, which already can be observed in the Andean Glaciers in the last decades. To insure the future operation of these reservoirs permanent observation of the glacier by the means of images (satellite and direct photography) might be realized. This also would improve the situation of the still poor database, which nowadays exist in the Andean region with respect of GLOF risk assessment.

ACKNOWLEDGEMENTS

This publication could only be realized with the kind support of the owner ORAZUL PERU who has provided the investigation data. The authors specially want to thanks the team of Richard Rosas (Superintendente de Proceso Hidroeléctrico), which enriched the outcomes based on their experience and the fruitful discusses.

STUDY ON SOIL EROSION OF MAHAWELI RIVER UPPER BASIN UNDER CLIMATE CHANGE USING SWAT MODEL(*)

D. M. T. S. DISSANAYAKE

Chief Engineer, *IRRIGATION DEPARTMENT*

SRI LANKA

1. INTRODUCTION

Reservoir sedimentation is a world-wide issue. The Mahaweli River Upper Basin (MRUB) in Sri Lanka consists of four major hydro reservoirs namely Kothmale, Victoria, Randenigala and Rantambe in a cascade system (Fig. 1). The total storage capacity of these reservoirs are 1,756.3 million m3 ,while total power generation potential is 582 MW equalling to 14.8% of installed total capacity of the country by 2014 [1]. The basin area above Victoria reservoir is considered for this soil erosion study. Selected basin area is of 1,865.52 km^2 where 39.9% of it consists of slopes above 30%. Therefore, the potential for soil erosion is high which can be aggravated by high intensity rainfalls probably due to climate change. Eventually, this would cause sedimentation of reservoirs in the basin. Although, sedimentation cannot be completely avoided rate of sedimentation is very important as it is proportional to the decrease of active storage capacity of a reservoir. When hydropower reservoirs are concerned sedimentation will eventually lead to loss of energy production potential and for Sri Lanka this would be detrimental as the country heavily depends on hydropower.

In addition, the reduction in reservoir capacity may create water scarcity for other users when the demand is high. Further, the loss in capacity of these

---

(*) *Étude sur l'érosion de la rivière Mahaweli bassin supérieur en vertu de changements climatiques à l'aide du modèle SWAT* reservoirs increases the probability of floods as Mahaweli river basin downstream areas are prone to flooding during rainy seasons.

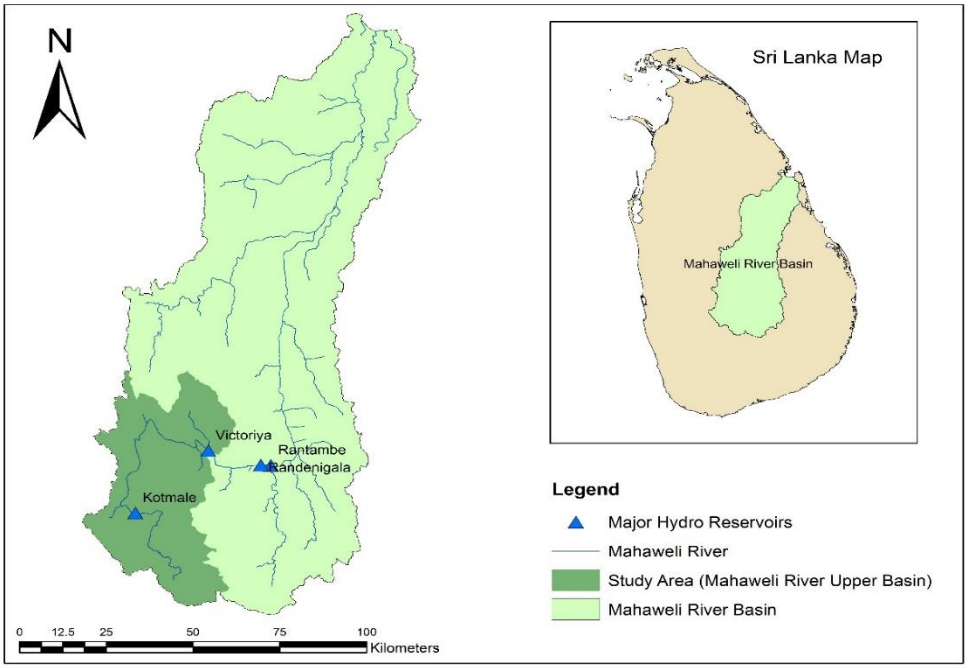

Fig. 1
Mahaweli river basin with major hydro reservoirs

In order to mitigate reservoir sedimentation it is necessary to identify erosion prone areas. Accordingly proper mitigation options has to be planned and executed in order to retard soil erosion. However, reservoir sedimentation analysis need a new approach today due to the influence of climate change. With the climate change it is widely accepted that rainfall intensities are gone up. Intensity of rainfall is a governing factor in soil erosion. Hence, it is important to see the impact of climate change as well, on reservoir sedimentation.

2. LITERATURE REVIEW

2.1 SOIL EROSION PROCESS

The Modified Universal Soil Loss Equation (MUSLE) is widely used around the world to estimate soil erosion [Eq.1]. The SWAT model, which was used for this study and described under methodology, also uses the same equation to calculate erosion outputs (Sed) of a basin area [2].

$$Sed = 11.8 \times (Q_{surf} \times q_{peak} \times area_{hru})^{0.56} \times K_{USLE} \times C_{USLE} \times P_{USLE} \times LS_{USLE} \times CFRG \quad [1]$$

Where; Q_{surf} - Surface runoff volume (mm/ha)
q_{peak} - Peak runoff rate (m^3/s)
$area_{hru}$ - Area of hydrologic response unit (ha); defined under methodology
K_{USLE} - USLE soil erodibility factor
C_{USLE} - USLE cover and management factor
P_{USLE} - USLE support practice factor
LS_{USLE} - USLE topographic factor
$CFRG$ - Coarse fragment factor

As per the MUSLE all other factors except Q_{suf} and q_{peak} are unique characteristics of a basin area. As the same land use and soil map were used throughout the modelling period (1960-2016) of this study, as described under methodology, only Q_{surf} and q_{peak} were the varying parameters. Hence, any increase or decrease in erosion rates during the period considered for the analysis can be attributed to the variability of rainfall.

2.2 TREND ANALYSIS FOR A TIME SERIES

One objective of this study was to check whether climate change has any impact on MRUB soil erosion rate. For finding that time series output of total annual sediment has to be checked for presence of any trend.

The Spearman's rank correlation method is a useful tool for trend analysis of a time series [3]. The Spearman's rank correlation coefficient R_{SP} is defined as follows [Eq. 2].

$$R_{SP} = 1 - \frac{6 \times \sum_{i=1}^{n} D_i^2}{n(n^2-1)} \quad [2]$$

Where n is the total muber of data and D is difference, and i is chronological order number.

$$t_t = R_{sp}[\frac{n-2}{1-R_{sp}^2}] \quad [3]$$

Where t_t, has Student's t-distribution with $v = n - 2$ degrees of freedom. At a significance level of 5 per cent (two-tailed) and the time series has no trend if;

$$t\{v, 2.5\%\} < t_t < t\{v, 97.5\%\} \quad [4]$$

Accordingly this methodology was applied to check whether sediment yield output time series had got any trend.

3. METHODOLOGY

3.1 MODEL DESCRIPTION

Soil Water Assessment Tool (SWAT) was used as the modelling software for this study. SWAT is a continuous hydrological simulation tool jointly developed by USDA Agricultural Research Service (USDA-ARS) and Texas A&M AgriLife Research. It is GIS-based and simulations can be done at daily time intervals. In addition to hydrological modelling SWAT is capable of calculating the sediment yield of a river basin as well. Accordingly, a SWAT model was developed for the study at a daily time-step for the period 1960 to 2016. Although all the reservoirs in MRUB have been commissioned around 1985, a longer period was taken into account to check any impact form climate change on sediment yield of the basin.

The primary inputs to the model were the basin Digital Elevation Model (DEM), digital land use map, digital soil map, daily rainfall and temperature data of meteorological stations within the study area. A Subtle Radar Terrain Model (SRTM) downloaded from United States Geological Survey was used as the digital elevation model. The resolution of the model was adjusted to 60m. The elevation of the area varied from 423 m to 2070 m MSL. The land use data were obtained from Land Use Planning Policy Department and digital soil data from Agriculture Department. Daily rainfall data and temperature data were obtained from Meteorological Department.

As no previous land use data maps were available the latest map was used for the total modelling period. In fact, there had not been any significant land use changes in the area and it was a valid reason for using the same map for the whole modelling period. The description of major land use categories are given with the percentages available in the study area (Table 1). It is interesting to note that nearly 20% of the area consists of forests which would least contribute to overall sediment yield.

Daily rainfall data of 11 rain gauge stations located within the area were used. For daily minimum and maximum temperature data four climatic stations, within and around the basin were used. Unavailable climatic data; solar radiation, wind speed and relative humidity were generated by the model itself using a weather generator provided with SWAT [4].

Table 1
Land use categories in the study area

SWAT code	Descriptive Term	% of Catchment Area
URLD	Low density urban	30.14
AGRR	Tea	26.84
FRSE	Forest	19.91
SHRB	Scrub	6.76
RICE	Paddy	6.19

3.2 MODEL SIMULATION

Model development was done using the QGIS QSWAT interface and associated SWAT Editor tool. The model generated the river network based on the DEM where the threshold value selected was 25 km^2. According to this river network the model delineated 52 sub basins within the study area.

The DEM was categorized into four slope bands as 0-10%, 10-20% and 20-30% and above 30%. During the simulation model created similar sub units with similar hydrological response known as Hydrological Response Units (HRUs). HRUs are areas within the sub basins where slope, land use and soil types are similar. An area threshold of 10% was applied to land use types in order to avoid minor land use types in sub basins to simplify HRU creation. The model was run for the period 1960-2016 in a monthly time step.

4. RESULTS AND DISCUSSION

The model calculated daily sediment yield in the basin area from the beginning of 1960 to the end of 2016. As the rainfall is varying throughout the year the annual series of sediment yields is more appropriate for a trend analysis. The annual totals were plotted for analysis excluding the first and last year of the modeling period to avoid modeling errors due to mass balance (Fig. 2).

It can be observed that highest sediment yield in the basin has been 1,022,717.31 Ton as reported in 2013. The average yield of area for the total period (1961-2015) has been 48.55 Ton/km2/year. However, all the sediments formed due to erosion will not reach the reservoirs as part of it deposits within the catchment itself. On the other hand all the reservoirs have been commissioned around 1985 and soil erosion taken place prior to that time has not contributed to reservoir sedimentation.

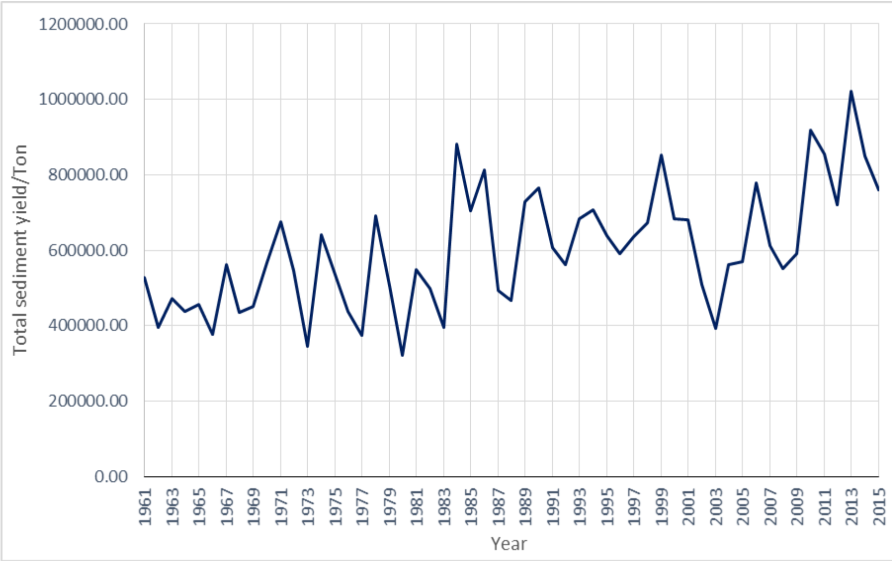

Fig. 2
Annual total sediment yield of study area

If there is an impact of climate change on annual sediment yield during the period 1961-2015 there should be a trend in the time series data. To check whether there is a trend Spearman's Rank-Correlation Method was applied [2]. The results are summarized in Table 2.

Table 2
Parameters for trend analysis calculation

Parameter	Value
Spearman's rank correlation coefficient; (Rsp)	0.60
For Student's t distribution; (t_t)	5.48
Degree of freedom; $v\ (= n - 2)$	53
For significance level of 5% ; Upper level value from t distribution Lower level value from t distribution	2.01 -2.01

If there is no trend in the time series data the value of student's distribution, t_t should be such that; -2.01 < t_t < 2.01. As this condition is not satisfied where the calculated value of t_t equals to 5.48 (Table 2) it can be concluded that annual total sediment yield from 1961 to 2015 has a strong increasing trend. Accordingly, sediment yield of the MRUB is influenced by climate change as rainfall and temperature are the only variables during modeling period (1961-2015).

When sub basins are considered soil erosion has a spatial variation (Fig. 3). For finding exact reasons for this variation requires physical inspection of the catchment in a detailed manner. Therefore, making conclusion on erosion rates of different areas within the study area is beyond the scope of this study.

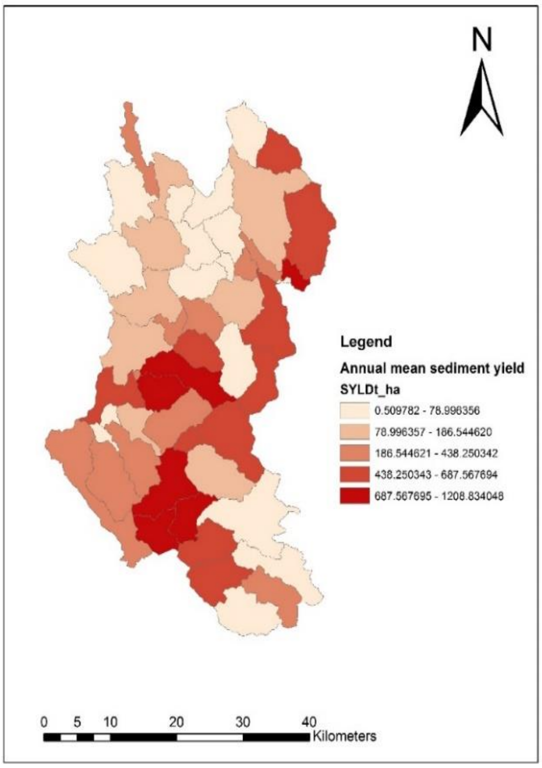

Fig. 3
Annual mean sediment yields of sub basins

5. CONCLUSION & RECOMMEDATIONS

The annual sediment yield rate in the MRUB has an increasing trend during the period from 1961 to 2015. Therefore, it can be concluded that sediment yield rate in MRUB is increasing with climate change posing a risk of rapid reservoir sedimentation. Soil erosion was higher in some of the sub basins within the study area. It is worth finding reasons for this higher erosion rate which is beyond the scope of this study.

Suitable soil conservation methods in agricultural lands and afforestation of bare lands are to be envisaged as measures for erosion mitigation. Further, the future developments within the area, which may take place to cater demands of increasing population, have to be well planned to minimize soil erosion.

ACKNOWLEGEMENTS

Most of the data used for this study were obtained from World Bank funded Climate Resilience Improvement Project (CRIP) under the Ministry of Irrigation and Water Resources Management. Therefore, the author would like to convey his sincere gratitude to Eng. (Mrs) P.A.A.P.K. Pannala, Deputy Project Director of component I of CRIP for giving the permission to use the data.

SUMMARY

The Mahaweli River Upper Basin (MRUB) in Sri Lanka consists of four major hydro reservoirs namely, Kothmale, Victoria, Randenigala and Rantambe situated in a cascade system. The total storage capacity and power generation capacity of these reservoirs are 1,756.3 million m3 and 582 MW respectively. The catchment above Victoria reservoir was the area selected for this study (1,865.52 km2). As 39.9% of this area consists of slopes above 30% aforementioned reservoirs are facing the risk of sedimentation due to catchment soil erosion. Eeventual loss of energy production potential when the storage capacities are reduced would be detrimental as the country heavily depends on hydropower. In addition, the reduction in reservoir capacity may create water scarcity for other users when the demand is high. Further, the loss in capacity of these reservoirs increases the probability of floods as Mahaweli river basin downstream areas are prone to flooding during rainy seasons.

Soil Water Assessment Tool (SWAT) developed by USDA Agricultural Research Service was used as the modelling software for this study. It is GIS-based and a model was developed for the study area at a daily time-step for the period 1960 to 2016. Main inputs to the model were digital elevation model, land-use map, soil map, rainfall and temperature. Unavailable climatic data; solar radiation, wind speed and relative humidity were generated by the model itself.

Although all the reservoirs in the MRUB have been commissioned around 1985 the model analysis was done for a longer period to check any impact from climate change on sediment yield of the area.

It could be observed that highest sediment yield in the MRUB had been 1,022,717.31 Ton as reported in 2013. The average yield for the total period was 48.55 Ton/km2/year. The annual sediment yield rate in the MRUB has an increasing trend. Therefore, it can be concluded that sediment yield rate is increasing with climate change posing a risk of rapid sedimentation of reservoirs. At sub basin level sediment yield indicates a considerable spatial variation.

It is recommended that suitable soil conservation methods in agricultural lands and afforestation of bare lands are to be envisaged as measures for erosion mitigation. Further, the future developments within the area, which may take place to cater demands of increasing population, have to be well planned to minimize soil erosion.

RÉSUMÉ

Le bassin supérieur de la rivière Mahaweli (MRUB) au Sri Lanka se compose de quatre grands réservoirs hydroélectriques, à savoir, de Kothmale, Victoria, Rantambe et Randenigala. Ils sont situés dans un système en cascade. La capacité totale de stockage et la capacité de production d'électricité de ces réservoirs sont 1,756.3 millions de m3 et 582 MW, respectivement. Le bassin versant du réservoir au-dessus de Victoria a été la région sélectionnée pour cette étude (1,865.52 km2). Cependant, 39.9% de cette superficie est constituée de pistes au-dessus de 30%. Par conséquent, ces réservoirs sont confrontées au risque de sédimentation due à l'érosion des sols. Sri Lanka dépend considérablement sur l'hydroélectricité. Diminution de l'énergie hydroélectrique potentiel lorsque les capacités de stockage sont réduits serait préjudiciable. En outre, la réduction de la capacité du réservoir peut créer de la rareté de l'eau pour d'autres utilisateurs lorsque la demande est forte. En aval du bassin de Mahaweli zones sont sujettes aux inondations pendant la saison des pluies. Par conséquent, la diminution du stockage des réservoirs augmente la probabilité d'inondations.

L'outil d'évaluation de l'eau du sol (SWAT) développé par USDA Agricultural Research Service a été utilisé comme le logiciel de modélisation pour cette étude. Elle est basée sur le GIS et un modèle a été élaboré pour la zone d'étude à un pas de temps quotidien pour la période 1960 à 2016. Principaux intrants au modèle ont été modèle d'élévation numérique, modèle d'utilisation des terres, une carte du sol, les précipitations et la température. Les données climatiques comme le rayonnement solaire, la vitesse du vent et de l'humidité relative ont été générées par le modèle lui-même comme non disponible. Bien que tous les réservoirs dans les MRUB ont été construites autour de 1985, d'analyse a été effectuée pour une période plus longue pour vérifier l'impact du changement climatique sur la production de sédiments de la région.

Il peut être observé que la valeur la plus élevée de production de sédiments ont été 1,022 717.31 tonnes tel que rapporté en 2013. Le rendement moyen pour la période totale était 48.55 tonnes/km2/an. Le taux annuel de sédiments dans l'MRUB a une tendance à la hausse. Par conséquent, on peut conclure que le taux de production de sédiments augmente avec le changement climatique. Par conséquent, il y a un risque de la sédimentation rapide des réservoirs. Dans la production de sédiments sous-bassins montre une variation spatiale considerable.

Il est recommandé que des méthodes de conservation du sol dans les terres agricoles devrait être appliquée pour la réduction de l'érosion. D'autres terres nues doivent être plantées d'arbres. De plus, l'évolution future au sein de la région, qui peut avoir lieu pour répondre aux exigences de l'augmentation de la population, doivent être bien prévues pour minimiser l'érosion du sol.

1. RATIONALE

Reduction of sediment flow generated by dam construction leads to erosion on downstream riverbed and on coastal areas; the lack of coarse sediment (sand, gravel) generated channel riverbed deepening and relevant effects on bridge foundation structures, and on other infrastructure affected by water bodies, meanwhile the lack of fine sediment (silt, clay, nutrients) can have serious effects on balance of downstream ecosystems, reducing water turbidity and affecting water temperature.

Loss of reservoir capacity caused by sedimentation can greatly impact reservoir management because it generates a reduction of water availability for several uses (energy generation, irrigation, drinking water). Most recent studies estimated global gross storage capacity at 6,000 km^3 and annual reservoir sedimentation rates at 31 km^3. According to this growing trend, global reservoir storage capacity will be reduced by 50% on 2100.

Both accumulation of sediments in dams and the lack of these in downstream areas have negative effects on the performance and conditions of the infrastructures, on the coastline stability, already endangered by sea level rise (greenhouse effect), therefore actual handling of these sediments is of paramount importance for long term management of artificial reservoirs.

Several possible solutions can be taken into consideration:

- sediment by-passing into the downstream area;
- drawdown routing involves discharging high flows through the dam during periods of high inflows to allow sediment to be transported through the reservoir minimizing sedimentation;
- drawdown flushing, opposite to sluicing, focuses on scouring and re-suspending deposited sediment and transporting it downstream. It involves the complete emptying of the reservoir through low-level gates;
- turbidity current venting can be done when inflowing water with high sediment concentrations forms a higher density current that flows along the bottom of the reservoir without mixing with the lower density clear waters;
- dredging with specialized equipment to remove the sediments from the dam.

In the last years, sedimentation in artificial reservoirs became more and more important, especially in reservoirs where their catchment basin is affected by important surface erosion rates due to poor vegetation coverage (degradation of the vegetation by human action), or to the presence of heavy rains in very short periods (flash floods).

Climate change has increased the frequency of flash floods, therefore sedimentation in artificial reservoirs is one of the most important challenges of Public/Private Authorities responsible for artificial reservoir management. Sedimentation is really important because there are situations, all around the world, where original reservoir capacity has been dramatically reduced by 30/50%, generating important losses in terms of electricity production, reduction of water for irrigation and human use.

This paper deals with the positive experience happened in an artificial reservoir located in the eastern part of the Italian Alps (Ambiesta reservoir) managed by A2A, that is one of the most important energy supplier in Italy. Few years ago, A2A launched a tender to select a Contractor able to propose a cost-effective technology to remove about 23,000 m^3 of sediments settled near the water intake structure located on the right flank of the valley close to the dam, affecting dam bottom outlet, and water intake for hydroelectric purposes.

The tender has been awarded to THETIS COSTRUZIONI & DRAGFLOW which designed, supplied, installed, tested and managed a dredging system which allowed to complete the activity required by A2A fulfilling contractual time and very stringent environmental constraints established by River Tagliamento Authority. In the following pages the reader will find in detail reference data used to dredging system design, characteristics of the dredging system itself, on site activity and monitoring plan during dredging, and finally the conclusions.

2. REFERENCE DATA & CLIENT REQUIREMENTS

2.1. Environmental data

Ambiesta stream is located in the hydrographic basin of Tagliamento river, 3.5 km far from their confluence, in the eastern part of the Italian Alps (Friuli Venezia Giulia region). Ambiesta dam is a symmetric double curved arch dam, with the following characteristics (Fig. 1):

- Dam height: 58.63 m
- Free board: 2.50 m

Fig. 1
Ambiesta reservoir
Ambiesta reservoir

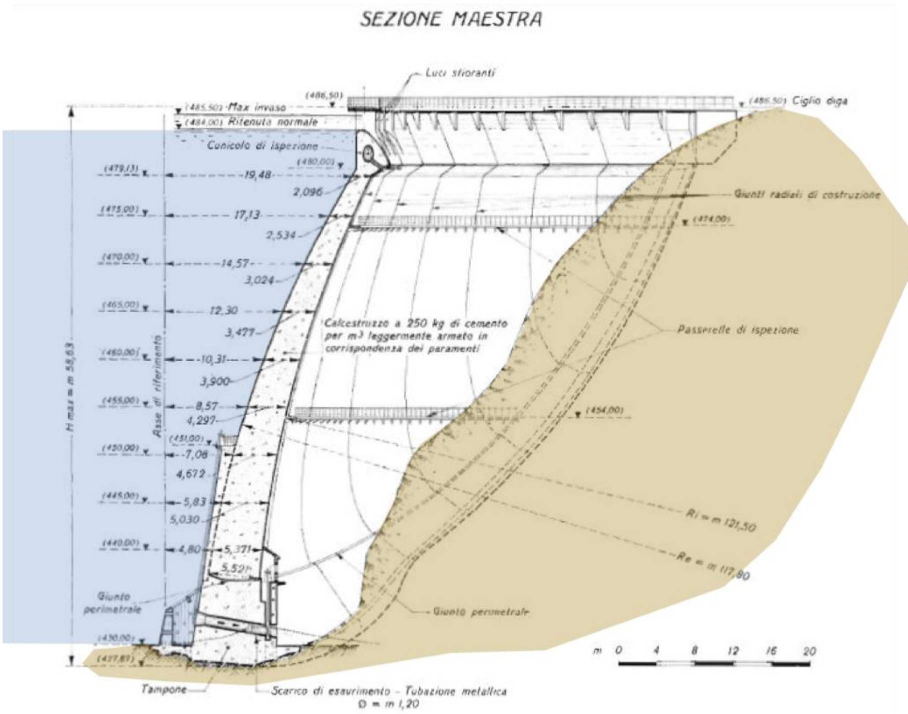

Fig. 2
Ambiesta dam: typical section
Ambiesta barrage: section typique

- Normal operating water level: 484 m a.m.s.l.
- Maximum water level: 485.50 m a.m.s.l.
- Dam volume: 28,734 m^3 of concrete
- Crest length: 144.64 m
- Dam thickness (at the top): 1.80 m
- Dam thickness (at the toe): 5.52 m

Ambiesta dam (Fig. 2) has been equipped with following ancillary structures:

- Surface outlet on the left side, equipped with gates, with flood discharge of 72 m^3/s;
- Surface spillway on the dam body with flood discharge of 120 m^3/s;
- Bottom outlet with discharge capacity of 48 m^3/s;
- Water intake structure on the right flank of the reservoir, which feeds two different tunnels with a diameter respectively of 4.40 m and 5.15 m, that feed Somplago hydroelectric plant.

The dam has been built in the period 1955 – 57 on behalf of SADE (Società Adriatica di elettricità) and transferred to ENEL (Ente Nazionale per l'Energia Elettrica) on March 1963.

In the following picture we can appreciate the dam shape during construction.

Fig. 3
Ambiesta dam (during construction)
Ambiesta barrage (pendant la construction)

2.1.1. Area to be dredged

A2A, the Public Company, responsible for management of Ambiesta reservoir, during the last years has monitored the sedimentation in the reservoir and more in detail sedimentation rate close to the dam structure, through a comparison of several topographic campaigns, to understand the evolution sedimentation phenomenon, and its impact to ancillary structures of the dam (dam bottom outlet and water intake), in terms of efficiency and safety.

On basis of this monitoring, A2A noticed that the quantity of sediments, coming from the rain activity on the surfaces of the catchment basin, reached an alert level especially nearby bottom outlet intake, and water intake structure as well. Through the comparison of topographic surveys developed along several years, A2A identified the area where the sediments have to be removed, and the total amount of them.

Total area to be dredged (Fig. 4) has a surface of 4,500 m^2 and is located at a water depth variable between 20 and 36 m, according to the water oscillation in the reservoir. Globally 28,000 m^3 have to be removed to assure a correct efficiency of the ancillary structures, and the right safety factor. The thickness of the sediment layer to be removed was variable between 6 and 10 m.

In the following picture we can appreciate the area to be dredged (green area), which affects dam bottom outlet, located on the left side of the dam (axis indicated with red dotted line), water intake on the right side, through which the water is driven to turbine of Somplago power plant (axis indicated with red dotted line), and the ancient cofferdam, concrete made, built at the beginning of the construction activity, to divert stream water to the dam bottom outlet, to kept dry the area where dam foundations have been built.

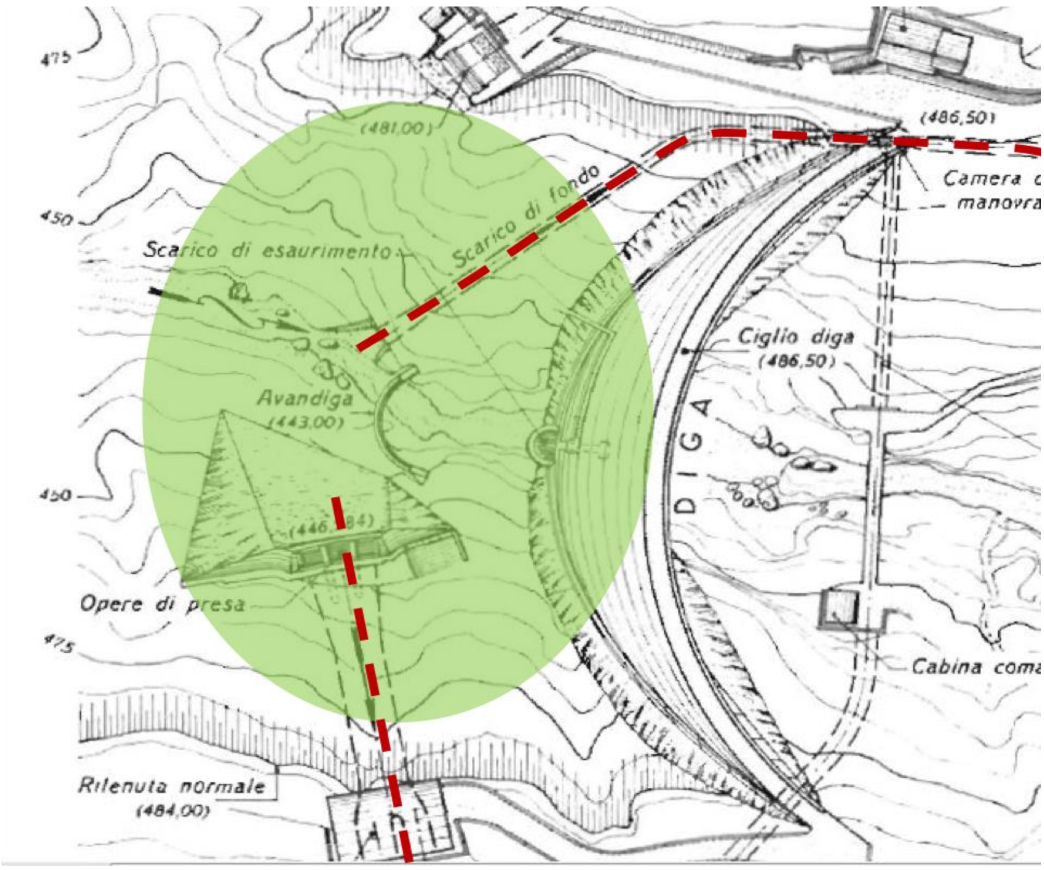

Fig. 4
Area to be dredged
Surface à draguer

As you can imagine, dredging activity has been developed in a quite complicated area from a morphological point of view because of the presence of artificial structures, forcing the submersible pump operator to carefully proceed between existing structures. In Fig. 5 we can appreciate, through an historical photo taken during construction time, the original morphology of the area, with quite big concrete structures (intake screen of the water intake channel) and very steep flanks of the valley.

To correctly design dredging system and determine dredging efficiency of the submersible pump, A2A supplied to the tenderers detailed information on the sediments to be dredged, collected through a field campaign developed all along the reservoir (Fig. 6).

The information used for the project has been related to the sample taken close to the dam. According to the grain size distribution analysis, the sediment to be dredged showed a granular fraction equal to 5%, meanwhile the cohesive fraction reaches 95% (74% silt and 21% clay).

2.2. Client requirements

On basis of the management plan of dam operation, and on the environmental constraints, A2A requested to fulfil following design criteria:

- maximum water level variation to be considered inside the reservoir is 9 m, with a water level variation between 475 and 484 m a.m.s.l.; maximum gradient of water level variation can reach 1 m/hour;
- maximum concentration of sediment in the slurry discharged downstream the dam cannot overcome 9 g/l for environmental reasons;
- possible presence of wood debris and large stones on the sediment layer to be dredged has to be considered;
- during dredging activity, the water intake feeding Somplago power plant is in operation discharging 66 m^3/s (three Francis turbines), therefore turbidity generated by the dredging pump has to kept at the minimum;
- during dredging activity, maximum allowed noise level at a distance from dredging pump of 300/400 m cannot overcome 45/50 dB;
- dredging activity of 28,000 m^3, including mob - demob activities has to be developed and completed in 100 natural days.

3. PROPOSED SOLUTION

On basis of Client's requirements, and taking into consideration dam location and characteristics, and usual dredging solutions already experimented for similar projects, DRAGFLOW, together with the Contractor THETIS COSTRUZIONI decided to propose following technical solution:

- Submersible pump located on a pontoon fully equipped, able to cover all the area to be dredged (4,500 m^2);
- Floating pipeline conveying the slurry from the pontoon to the surface outlet located on the left side of the dam, and from this structure downstream the dam;
- To respect environmental constraints (9 g/l), slurry has been mixed with water discharged by the surface outlet of the dam, managing the gates accordingly;
- To check the respect of maximum concentration of sediment in the slurry, three check points have been organized (on the pumping pipeline on the pontoon, just after the confluence of slurry and Ambiesta stream at the toe of the dam itself, and finally at the final confluence between Ambiesta steam and Tagliamento river, 2 km downstream Ambiesta dam;
- Service boat to allow the staff involved in the activity to reach the pontoon and to leave it at the end of the working shift.

3.1. Dredging system

Taking into account the characteristics of the sediment to be dredged, and the total dredging time allowed by the Client A2A, average slurry discharge has been fixed at 500 m^3/hour, and it has been mixed with 4 m^3/s clear water, taken form the reservoir, and discharged by the surface outlet of the dam located on the left side of the dam, to meet Client's requirements (9 g/l).

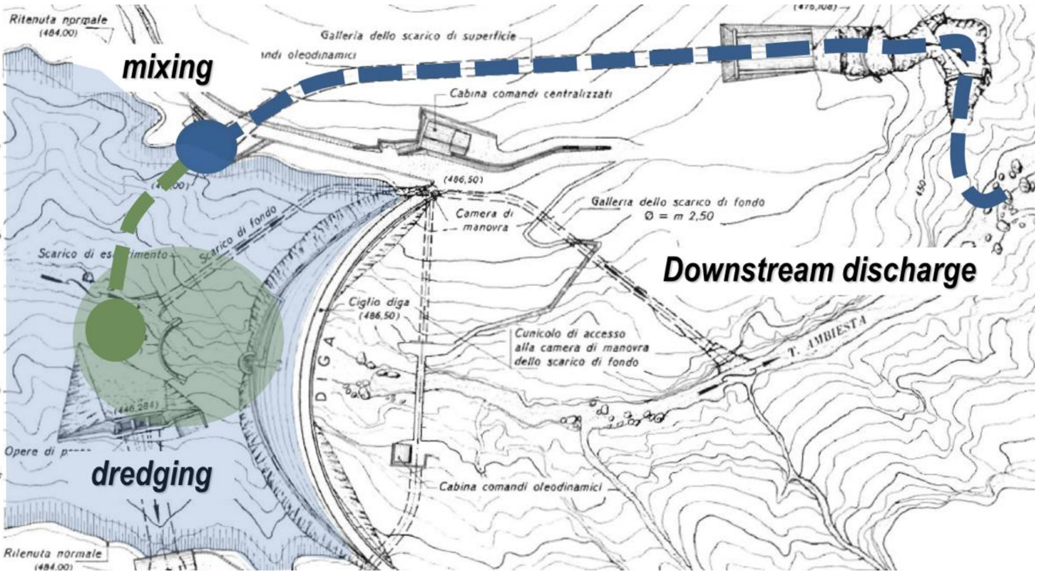

Fig. 7
Slurry mixing to fulfil environmental requirements
Mélange du “slurry” pour se conformer aux critères environnementaux

In Fig. 7 you can appreciate the location of the dredging area, and the mixing point where slurry produced by dredging activity has been mixed with fresh water coming from the reservoir to fulfil Client’s environmental requirements. The pump selected for this project has been DRAGFLOW pump HY85/160B; it’s a hydraulic pump with following characteristics (Fig. 8).

Fig. 8
Submersible pump
Pompe submersible

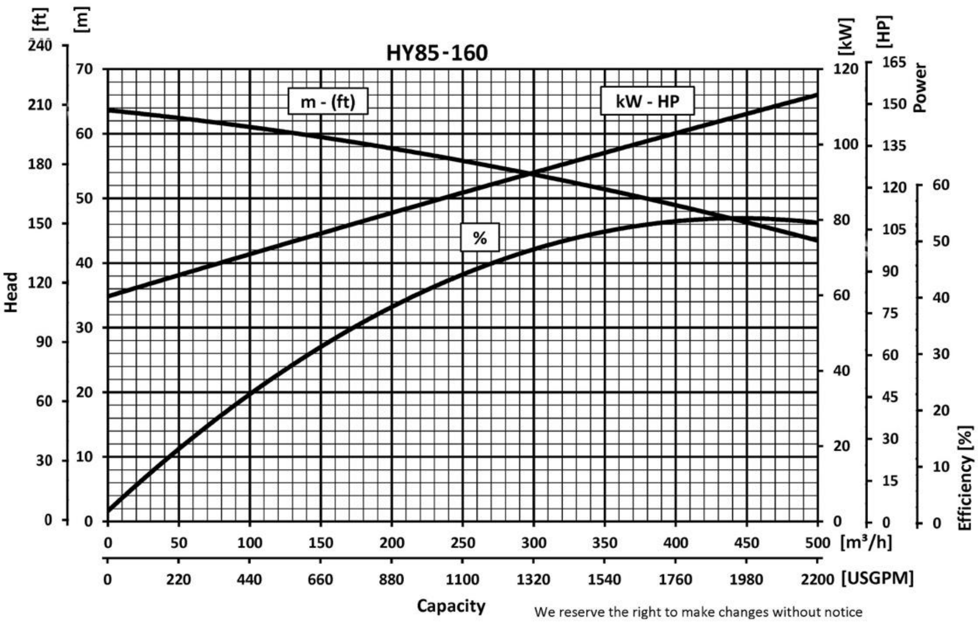

Fig. 9
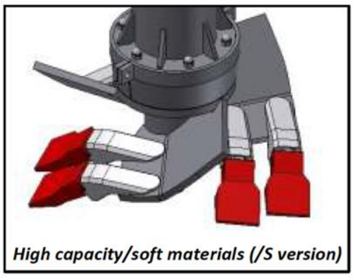
Submersible pump – working diagram
Pompe submersible – schéma de travail

Since most of the percentage of the sediment to be dredged is cohesive, to assure the correct productivity requested by total project time allowed by A2A, the pump has been coupled to two cutter heads, specifically designed for cohesive materials (Fig. 10).



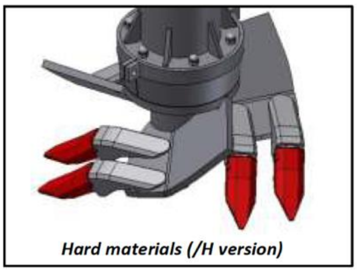


Fig. 10
Cutter heads
Têtes de coupe

In addition to that, according to the request of the Client to minimize the turbidity generated by dredging activity, a special anti-turbidity tool (Fig. 11) has been installed on the submersible pump. This tool allowed to minimize the dispersion of fine sediment around dredging area, avoiding the movement of fine sediment to right side water intake, and the ingestion of fine sediment by turbines installed at Somplago power plant.

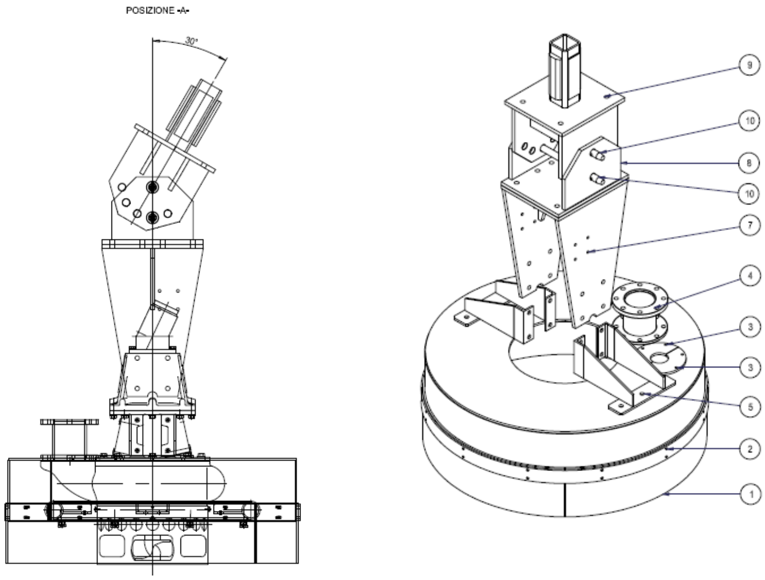

Fig. 11
Turbidity reduction tool
Outil de réduction de la turbidité

Submersible pump is managed through a pontoon specifically equipped (Fig. 12 and Fig. 13). DRAGFLOW's pontoons follow a modular design that has been tested over the years in several projects all around the world. The submersible pumps adopted for this project allowed to use very compact pontoon, achieving at the same time quite large working depths requested by A2A.

Fig. 12
Pontoon
Ponton

Fig. 13
Pontoon and main operation cabin
Ponton et cabine principale de travail

All DRAGFLOW's pontoons are designed for an easy transportation either by container or by trucks. The pontoons are built with internal reinforcement structures and divided in different compartments. The pontoons follow a catamaran design with a steel tripod and hoist as main movement system for the submersible dredging pump. The pontoon is complete with handrails and skids under the floaters with an integrated high capacity fuel tank.

The pontoon is equipped with 4 mooring winches driven by individual electric motors, each one with cable length of up to several meters. The entire dredging equipment is easily controlled and operated from the central cabin were the operator manages all necessary controls to drive each component of the dredging system with indicators of working depths, current absorption and bathymetric survey system.

3.2. Parameters monitored during dredging activities

During dredging activity, several parameters have been monitored, for both reasons: to be sure that Client's requirements are always fulfilled, especially which ones related to the environment, and to check dredging productivity which has a direct impact on the total duration of the project established by the Client's to 100 natural days.

To do that, the Contractor has to know, during dredging activity, where the submersible pump actually is (x,y,z coordinates), which is the actual water depth where the pump is dredging, in relation with water level in the reservoir, and what is the concentration of sediment in the "slurry".

Summarising, following devices have been installed and continuously monitored:

- GPS installed on board (Fig. 14) of the pontoon to know in every moment real time position of the submersible pump (x,y,z coordinates);
- Sediment concentration device installed on board of the pontoon (on the pumping pipeline) able to continuously record sediment concentration of the "slurry".

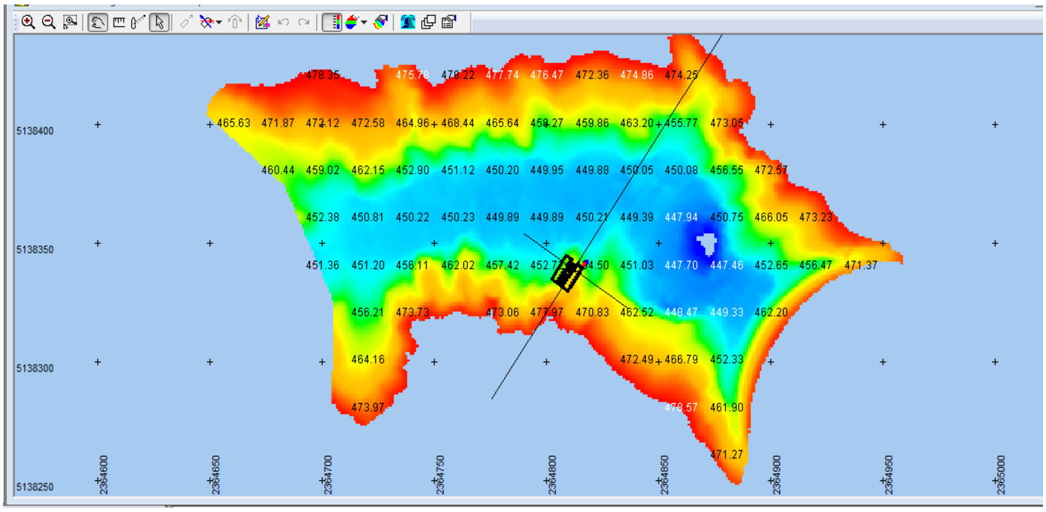

Fig. 14
Dredging pump positioning
Positionnement de la pompe de dragage

GPS coupled with topographic maps of the area to be dredged (Fig. 14) allowed to check every now and then if the dredging thickness required by the Client has been respected.

According to Client's requirement, sediment percentage in the slurry has been continuously checked in three different positions: on board of the pontoon, at the toe of the dam, and at the confluence between Ambiesta stream and Tagliamento river. To correctly understand the location of the dredging activity, the submersible pump productivity, and the new water depths after dredging, the bathymetric survey, done using a multi-beam device (Fig. 15) just before dredging starting, has been compared to a second survey, developed just after dredging activity (Fig. 16).

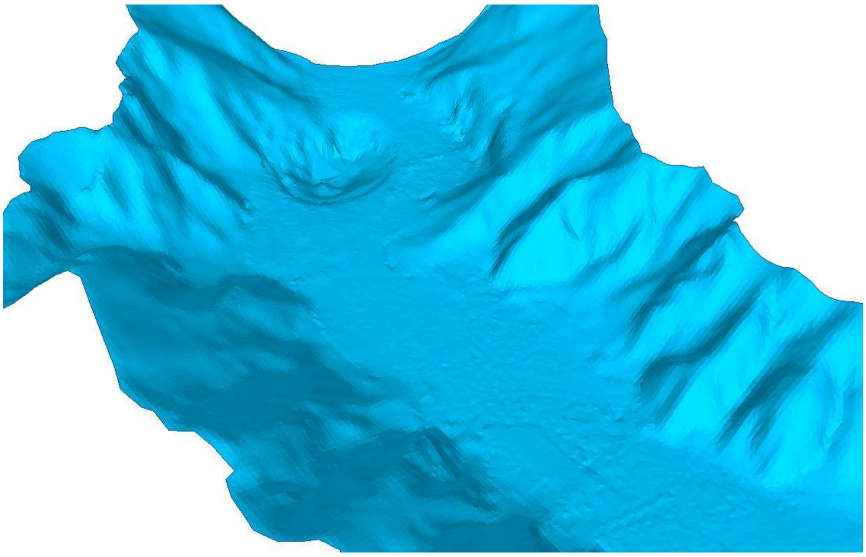

Fig. 15
Multi-beam topographic survey
Relèvement topographique avec le multi-beam

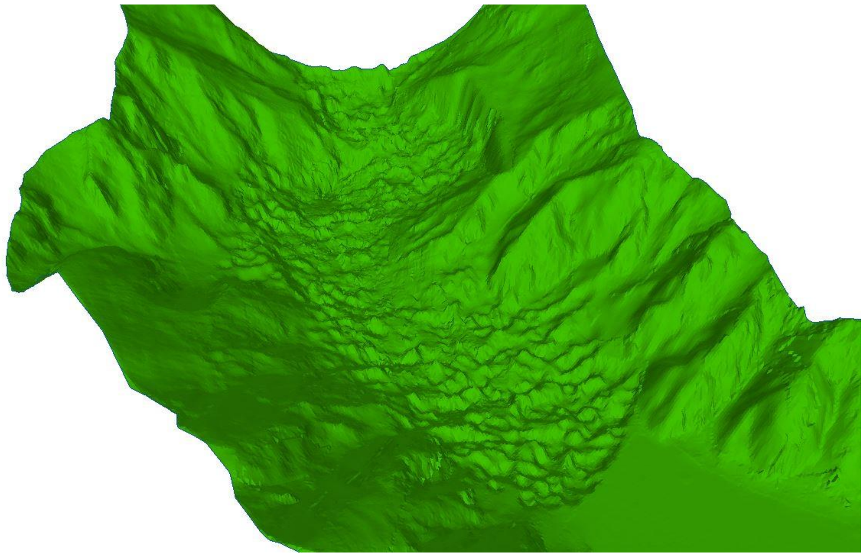

Fig. 16
Multi-beam topographic survey after dredging
Relèvement topographique avec le multi-beam depuis le dragage

From the comparison between two multi – beam surveys, developed just before and just after dredging activity, Client's Project Manager has been able to check total quantity of the materials actually dredged from the reservoir and the relevant time needed to dredge.

In Fig. 17 we can have a clear picture of the monitoring of the concentration of the sediments in the slurry pumped from the reservoir downstream the dam, till to the confluence between Ambiesta stream and Tagliamento river.

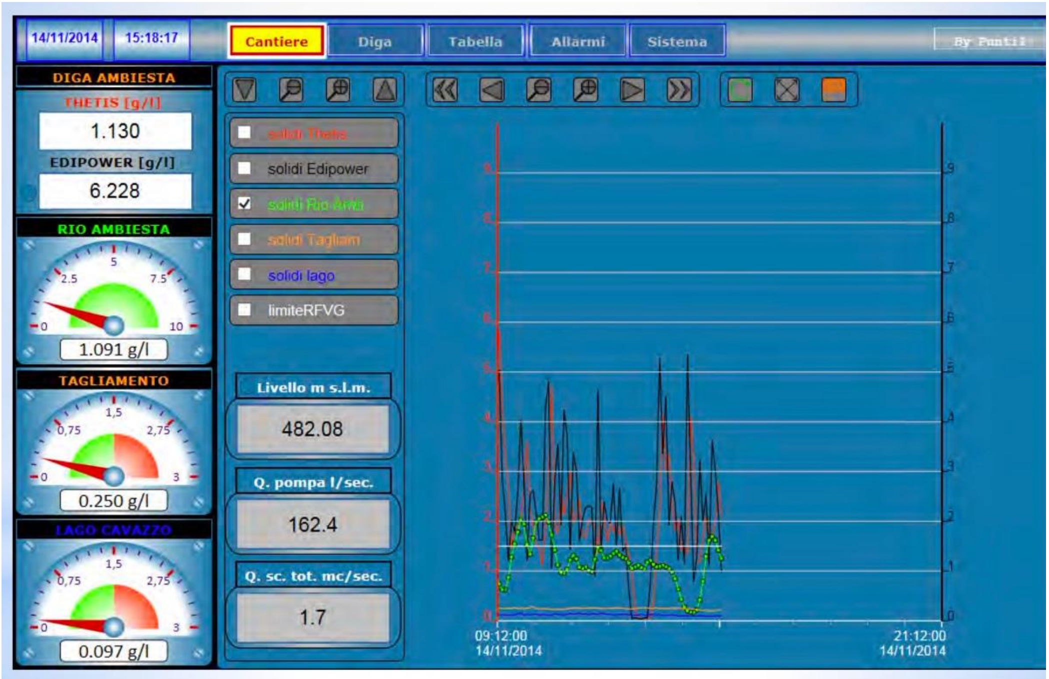

Fig. 17
Slurry concentration monitoring system
Système de monitoring de la concentration du slurry

According to Client's requirements, concentration of the sediments in the slurry has been continuously monitored, giving to the Client and to the Contractor itself, every day, maximum/minimum and average concentration values, through which a simple calculation gave a confirmation of the sediments removed from the bottom of the reservoir calculated using different topographic surveys.

3.3. Productivity rates

Taking into consideration dredging technology, time needed for regular maintenance of the equipment, out of service of some part of the equipment, not constant characteristics of the sediment to be dredged, variable water depth, variable thickness of sediments to be dredged, the dredging productivity, evaluated on daily basis has been the following:

- minimum productivity: 200 m^3/day

- average productivity: 400 m³/day
- maximum productivity: 800 m³/day

Dredging activity has been developed along three shifts, therefore 24 hours per day, using the noise reduction tool to avoid any impact on the nearby village.

In the following picture we can appreciate the dredged profile (blue line) compared to the original bed of the reservoir (green line).

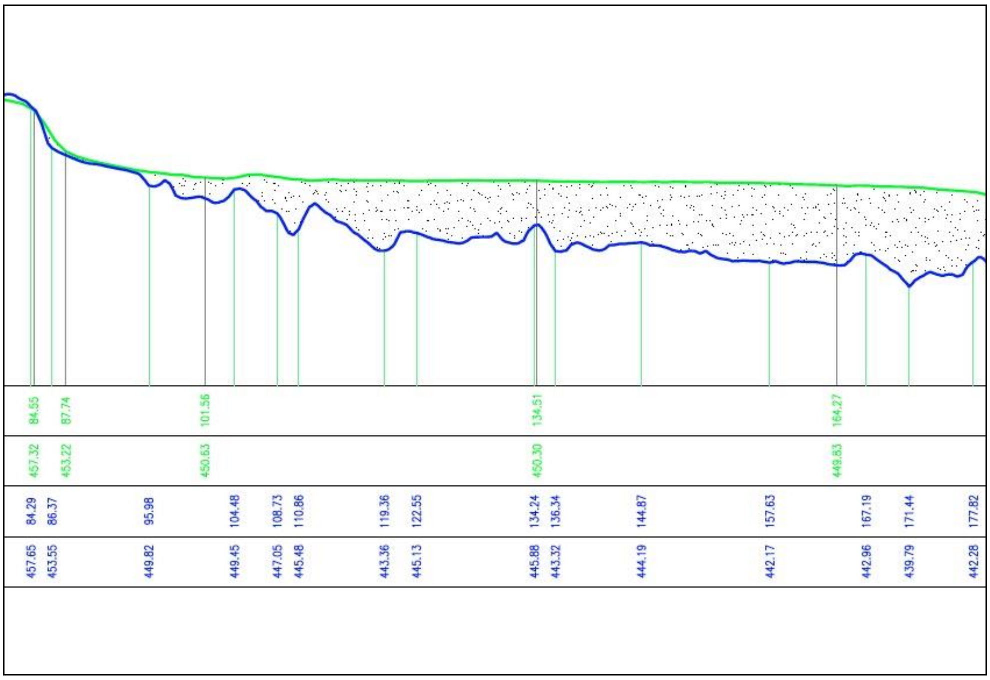

Fig. 18
Dredged profile versus original bed profile
Surface de dragage par rapport au fond original du reservoir

4. CONCLUSIONS

Dredging activity has been concluded fulfilling the total time allowed by the Client, taking into consideration supply and installation of the equipment, preparation of the jobsite area, assembling and testing of the dredging system, maintenance of equipment, and finally the disassembly of the equipment, and the restoration of the jobsite area to the original situation.

Selection of the dredging system demonstrated its validity to fulfil Client's requirements, and maintenance activity was really reduced, demonstrating that DRAGFLOW pumps are really a good and cost-effective solution for slurry dredging. For security reasons a stock pump has been located at the job site just in case, because the respect of the total time (100 days) was mandatory, but this pump has been never used.

In addition, the high efficiency reached by the dredging system, and the capacity to work 24 hours per day along three shifts, allowed the Contractor to get the bonus made available by the Client.

The system used for the topographic surveys (multi – beam) made at the beginning, in an intermediate time, and at the end of the job, has proven high reliability and a good level of precision. The Client really appreciated the job done by THETIS COSTRUZIONI and DRAGFLOW, their availability to discuss together the best solutions to be proposed to overcome usual small problems that sometimes happen during dredging activity, and their proactive attitude.

SUMMARY

This paper deals with the technology proposed and used to remove sediments settled nearby Ambiesta dam, located in the eastern part of Alps, Friuli Venezia Giulia region, Italy. In the Document many aspects have been detailed starting from design data needed to correctly design a dredging system, Client's requirements, characteristics of dredging system detailing all the components, and finally achieved results. Dredging activity has been developed fulfilling total time established by the Client, and the Contractor got the bonus offered by the Client if the job had been completed on time.

Ce rapport concerne la technologie proposée et utilisée pour enlever les sédiments installés à proximité du barrage d'Ambiesta, situé dans la partie orientale des Alpes, région Friuli Venezia Giulia, Italie. Dans le document de nombreux aspects ont été détaillés à partir des données de conception nécessaires pour concevoir correctement un système de dragage, les exigences du Client, les caractéristiques du système de dragage détaillant tous les composants, et enfin les résultats obtenus. L'activité de dragage a été

développée en respectant le temps total établi par le Client, et le Constructeur a obtenu le bonus offert par le client si le travail avait été achevé à temps.

1. INTRODUCTION

The principle of climate change, as a problem, despite of its various angles being discovered worldwide is still discussed by researchers, engineers and managers of related sectors. The importance of climate change issue becomes greatly apparent when this discussion develops issues related to water resource management and flow classification into various sectors of drinking, industry, agriculture and the environment (Cacho et al., 2008). In all of the basins that on its main river, a reservoir dam was constructed, and human factors can thus influence on different parts, the prospect of changing the flow in the basin is a principle. Undoubtedly, the management of two drought and flood issues is one of the priorities of water industry managers, whose short-term and long-term forecasts for making any decision, with respect to the high political, economic and social feedback, are indispensable. Hence, study of climate change and determining its effect on increasing or decreasing the severity of the two phenomena mentioned, as well as basin, along with the explanation of the effect of human factors on the mentioned issues is important. Simultaneously, exploitation of almost all dams constructed on the basin has been increasing (Jalili et al., 2012; Shokoohi and Morovati, 2015). There reported, of course, other analysis that demonstrate the contribution of human factors on the abnormal situation created for the lake through the construction of reservoir dams is effective and approximately 25 to 40 percent of the principal reasons (Hassanzadeh, 2011).

Since many of the data in the actual situation are skidding and do not have normal distribution, therefore, in order to achieve more appropriate result, it is preferred that nonparametric tests, such as Man-Kendal test, which is one of the most widely used and nonparametric methods, be applied to analyze the time-series process (Fujihara, 2016; Modarres, 2009). In studies by Shokoohi et al. (2014), in order to investigate the occurrence of climate change at the 2nd level of the country, it was concluded that in contrast to the decrease of surface currents, the temperature throughout the country has been increasing. In surveys conducted by Nikghoojaghand Yarmohamadi (2008), to investigate the occurrence of climate change in the Sub-basin of Ziyarat River from Gharehosu basin in Golestan Province, was found that the Mean temperature increased. Shokoohi and Daneshkar arasteh (2008)in surveys conducted to investigate the occurrence of climate change throughout the country, concluded that precipitation in some parts of the country was declining, in some sections stable, and in some others, had an increasing trend, but temperatures throughout the country had an increase of 99%. In the studies of climate change in Mazandaran Province by Jahanbakhsh et al. (2010), based on the Mean annual variation in the 20-year time period (last two decades), showed that there is no significant difference in precipitation levels. Mohamadi (2010), also, analyzed the annual precipitation in Iran using data collected from 1437 synoptic, climatic and rainbow stations during the 40 years of 1964-2003. Results showed that in the time series of the station's Mean and precipitation, there observed no significant increase or decrease trend at 95% and 99% confidence levels .Farokhnia and Morid (2012) studied the trend of precipitation changes using four nonparametric tests of trend analysis in some of the stations in the basin of Urmia Lake and concluded that precipitation in this basin was largely lack of any trend. Khaliili et al. (2013) to declare the relationship between the monthly data trend and flow of SharChay River in western Uremia Lake, concluded that the decreasing trend of the flow in this river could be due to the increase of the climate variable and the dependence of the river discharge on the melting snow. Ababaei et al. (2014) investigated the Taleghan dam under the scenarios of climate change during 2040-2069. In this research, in order to demonstrate the ability of information combination methods with individual simulation methods, finally concluded that the Mean daily flow rate of the dam will decrease and the temperature of the basin will increase. The present study pointed out the uncertainty of many studies and significant contradictions resulting from the use of various models.

2. GENERAL LAYOUT

2.1 Materials and methods

In order to achieve the objectives of the study, the following processes were carried out. The status of the annual water balance of the inflow was analyzed to identify the process. Due to the lack of trend on this scale, the study was conducted on a monthly scale. Afterwards, the total monthly precipitation was investigated to find out the cause of changes in monthly input flow. Considering the lack of trend in the amount of monthly precipitation, attention was paid to the factor of precipitation pattern variation in the region. The best factor that could be taken into account in this snowy area is the monthly temperature and its effects on the precipitation pattern. In other words, the change was in precipitation as snow and thus in the monthly discharge and also in the long-term river discharge pattern of Taleghan river. For this purpose, long-term changes in snow coverage in line with long-term changes of the most influencing and crucial climate parameter, namely temperature, were analyzed. In this regard, Mann-Kendal non-parametric method and non-parametric CUSUM free distribution method was used to determine the beginning time of changes in the precipitation pattern of the region and also the thermal climate of the basin, respectively. To study the statistical accuracy of the analyzes, statistics such as Mean absolute error percentage, Mean absolute deviations and Mean square deviations were applied. Data on precipitation, temperature and inflow of the dam were collected from terrestrial stations and for snow data, satellite images of Terra satellite was used as follows.

2.2 STUDY AREA:

The Taleghan Basin, which is one of the important sub-basins of the Sefid Rud waterfall, is located within the study area of Taleghan Alamut. This basin is located on the southern slopes of the Alborz mountains and in the northwestern part of Iran, 120 kilometers from Tehran. In geographical position, the basin is restricted from the north to the Alamut basin, from the south to Zayaran and Samghabad, from the east to the part of the Karaj basin and from the west to Shahroud Basin.

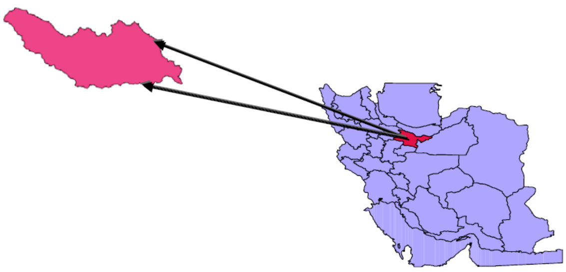

Figure 1: Location of Taleghan Basin

2.3 DATA

In order to study the morphological parameters of hydroxylation, two evaporation stations in the upstream (Joestan station) and downstream of the basin (Zidasht station) and Galinak hydrometric station near the Taleghan dam were used as Table 1 and Fig. 2.

Table 1: Hydrometric meteorological stations of the Taleghan Basin

Name	Digit	latitude	longitude
Zidasht	1931	36-09-29	50-41-46
Joestan	1984	36-11-19	50-53-43
Galinak	1770	36-10-00	50-44-00

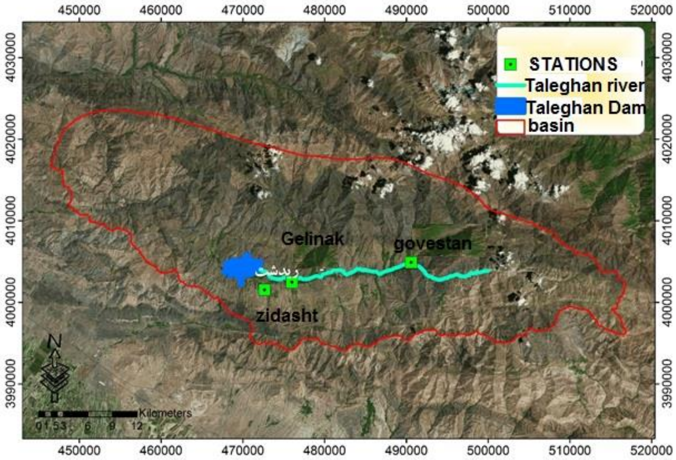

Figure 2: Location of the studied stations and reservoir dam of Taleghan

The time series related to the annual precipitation of the two selected rain-monitoring stations for 1966-2013 was shown in Fig. 3. Also, the summary of their important statistics are given in Table 2. As seen, according to accessible 47-year-old statistics, the annual precipitation of the Zidasht station, which is almost overlooking the Taleghan dam, is about 70 mm less than the Joestan station, at an altitude of about 50 meters. In other statistics, there is a great deal of similarity between the two stations.

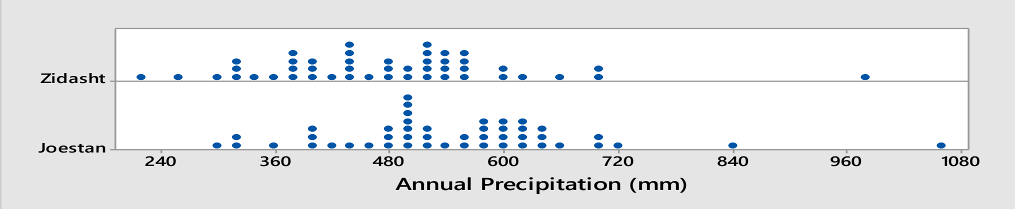

Figure 3: Time series of annual precipitation of Zidasht and Joestan stations related to water during 1966-1967 to 2012-2013

2.4 MANN-KENDAL TEST

The non-parametric Mann-Kendal test, which was presented by Mann in 1945 and then completed by Kendal in 1975, is based on the data rate in a time series. The test is applied to investigate the randomness of the data (the absence of a trend) versus the trend in the hydrological and meteorological time series (Fujihara, 2016; Partal and Kahya, 2005). The advantage of this test is the use of the data rate in the time series ignoring the value of the variables. Therefore, to the mentioned reason, it can also be used for data with skidding. Meanwhile, it is not required to data with special distribution form (Zhang et al., 2000).

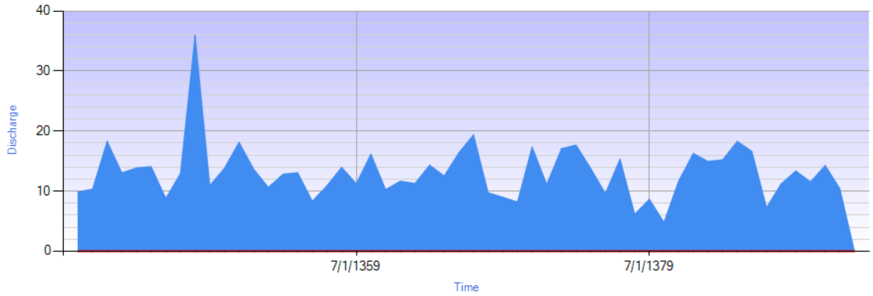

Figure 4: Annual discharge time of the Galinak station (m3 / sec) for the water years from 1961-1962 to 2012-2013

2.4 Remote Sensing:

The estimation of snow-covered surfaces, especially in mountainous areas, involves sufficient information and statistics. Today, the use of remote sensing and satellite images in determining the level of snow cover and the same parameters has had a significant improvement. In order to specify the snow cover level, firstly, eight days snow cover achieved by satellite data from 2000 to 2015 were received from NSIDC site in HDF format. And then the Mean snow level was extracted for each month in the GIS environ. The specifications of these data are shown in Table 4.

Table 4: Specifications and spatial accuracy of satellite data

Data date	Product type	Time accuracy (Day)	Spatial accuracy (meter)	Sensor	Satellite
2000-2014 (January, February, March)	10A2	8 Days	500	MADIS	Terra

3. RESULTS

3.1 RESULTS OF METEOROLOGICAL AND HYDROLOGIC VARIABLES TREND TEST

Fig. 5 a shows the annual temperature variation of the Zidasht station in the middle part of the basin. As shown, the annual temperature rise is significant at a 99% probability level and represents an increase of about 4.56 ° C over 1966 to 2012. This means that the studied basin experienced a Mean temperature increase of 12.2 ° C per year. It is interesting to note that the above studies were carried out for the Joestan station in the basin, but practically, as shown in Fig. 5b, due to the steady slope, there is no particular trend at annual temperatures. Indeed, the upper section of the basin shows a constant annual heat scale, and climate change in terms of the thermal system is not probable in this part of the basin.

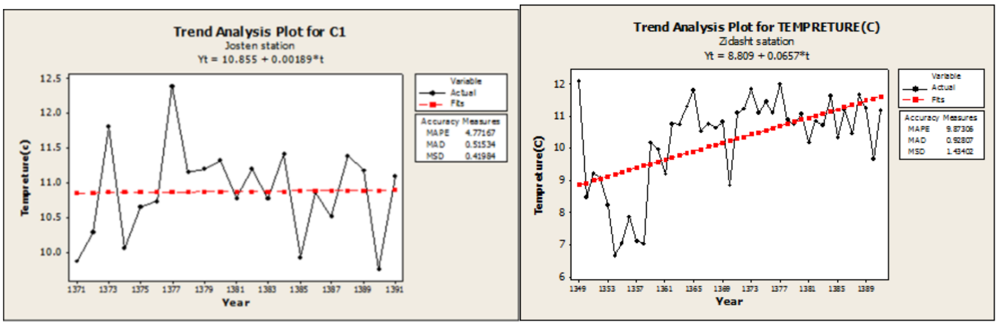

Figure 5: The annual temperature trend in A) Zidasht station, B) Joestan station

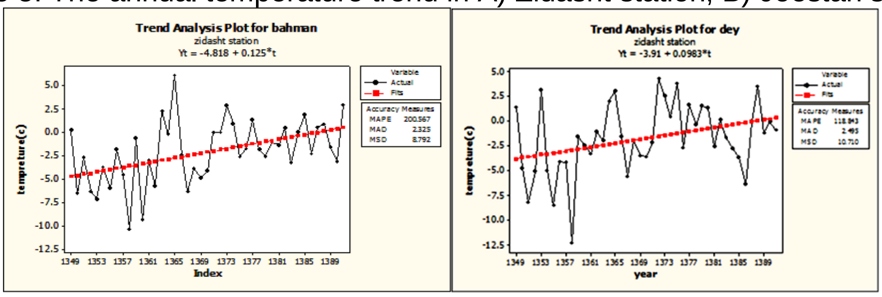

Figure 6: Temperature trend of the Ziadsht station in A) January B) February

Tables 6 and 7 demonstrate the results of trend analysis of precipitation, temperature and runoff variables in monthly and seasonal scales in selected stations.

4. CONCLUSION

Climate change (temperature and precipitation) affects different parts of the ecosystem of a region such as water resources, plant and animal species, the environment, agriculture and community health. Climate change (global warming), by shifting precipitation from cold seasons to warm seasons and vice versa, or changing the pattern of seasonal precipitation from snow to rain, obligate all water resource management components to be reviewed. Changing the precipitation pattern, discussed in this study also reduces the snow storm and the displacement of the rivers' regeneration regime. In this way, river basic discharge and dams' adjustment capacity are lowered and the supply and demand balance of the water system is impaired. On the other hand, changes in the precipitation pattern will increase the uncertainty in supplying the plant's water requirements with effective precipitation in the cultivation season. The first effect of these uncertainties is to increase the reliability coefficients used in supplying the water needs of the agricultural sector and thus increasing the need for water extraction. Investigating Taleghan Basin data during 1959-2012, indicates that significant changes have occurred in some of the hydrological parameters of the area. The most important results from the calculations are:

The issue of the effect of temperature change and precipitation pattern on water resources of Taleghan basin is definite.

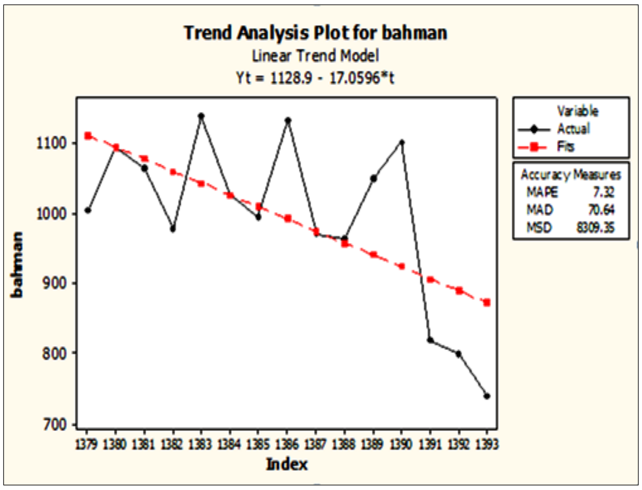

Figure 9: Time series and trend line for snow cover level in Taleghan basin in February

No trend in precipitation series is observed on the annual and monthly scale of precipitation. This confirms other previous researches before referred to in the introduction. Meanwhile, the increasing trend of temperature in the Taleghan basin is in line with the results of the research in other regions of Iran.

Due to the lack of trend in runoff, the annual scale is not a suitable scale for study of hydrological changes in rivers with a snow-rainy regime.

In discharge time series, an incremental trend is observed during the months of March and April (around 7%), and a decreasing trend in May and June (about 10%). This means that the spring runoff has declined sharply, and instead of winter runoff, increased over these periods. This factor stems from the increase in winter temperature, which is due to the decrease in snowfall during recent years, indicating a change in precipitation pattern in the basin and precipitation change from snow to rain.

As changes in the region are actually changes in precipitation pattern from snow to rain, which leads to changing the time of overflowing and dehydration periods as well as floods of Shahroud River, management of Taleghan reservoir dam needs to be reviewed.

The occurrence of changes in the thermal regime in recent year in the study area, and also lack of changes in the flow paths to the dam, reduces or rejects the probability of human intervention in the basin.

6. SUMMARY

The effect of climate change on precipitation, evaporation, and transpiration, surface runoff and extreme hydrological events on the local and regional scale, especially in arid and semi-arid regions of the country, is still a controversial subject. In the present research, the effect of climate change on annual and monthly discharge of Taleghan basin was investigated at the entrance to Taleghan reservoir. To this aim, firstly, the existence of the trend and occurrence of mutation in the meteorological-hydrologic variables was studied on climate change studies using statistical tests. The results of the trend test, while no trends were observed in precipitation, showed an increase in temperature (at a probability level of 99%) and water (at a probability level of 95%) during the winter, especially in the months of February and March. Also, the results of the mutation test showed that the temperature in 1963 was positive at a probability level of 99%. The mountainous state of the basin discusses the theory of increase in the temperature in the winter, snow melting, early runoff, and in other words, early melting of the snow from the spring to winter season. Then, using the remote sensing technique and selecting the Terra satellite, the snow coverage of Taleghan basin during 2000-2014 throughout the winter was investigated. The results indicated a decrease in snow covering level at the probability level of 99% in February. Hence, the effect of climate change on water resources of Taleghan basin, considering all factors such as a significant positive trend in temperature, reducing snow covering, decreasing spring flow and increase of winter flow to the dam were confirmed, although the volume and depth of annual runoff were stabilized. Consequently, it can be argued that climate change in this basin is a change in the precipitation pattern, i.e the change in the type of snowflake to rain as well as seasonal displacement. These studies have shown that according to the existing trend in the amount of annual discharge to the dam reservoir, the effect of human factors on changing the pattern and runoff rate of the basin has not been affected.

Keywords: Climate change, cold climate, flow, Taleghan dam

1. INTRODUCTION

The Moragolla Hydro PowerPlant (HPP) project involves the implementation of a Run-of-River Hydropower scheme on the upper reach of Mahaweli River in Sri Lanka. It will be the latest and presumably the last entry in the upper Mahaweli Complex, which is a cascade of five reservoirs serving for hydropower generation and supply of irrigation water.

The reservoir of the Moragolla HPP will be used for daily hydropower peaking and therefore the time path of the active storage can affect significantly the long-term economic performance of the scheme. Furthermore, the dam owner and operator does not wish the accumulation of sediments in the reservoir, especially since it believes that consolidated sediments would produce H_2S, a detriment to the drinking water quality of the reservoir water.

Numerical simulation indicated that if no sediment management measures are implemented, the reservoir storage will be depleted within approximately 50 years, i.e. the reservoir is non-sustainable. Several sediment management approaches have been developed for handling sedimentation [1], [2]. A preliminary assessment presented below indicated that almost all sediment management techniques can potentially convert the non-sustainable Moragolla reservoir into a sustainable infrastructure for the future generations. The conclusion is however rather generic, since the identification of the best suitable management strategy depends on several other boundary conditions and project development priorities.

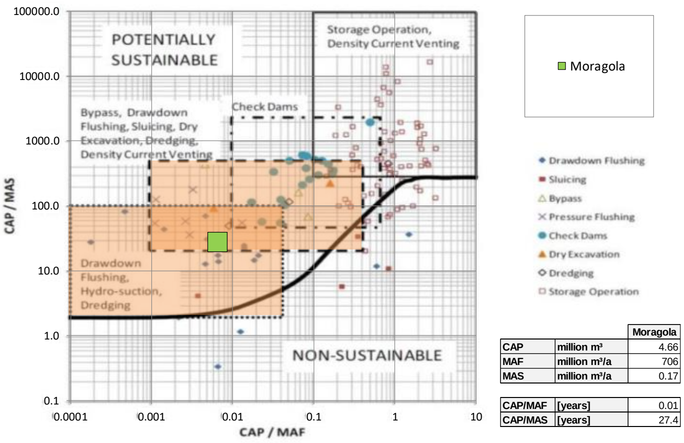

Fig. 1
Preliminary assessment of sediment management options for Moragolla reservoir (Source of underlying nomograph: [3])

For example, an important constraint is imposed by the fact that in the mid to upper reaches of Mahaweli River lives a fish called Labeo Fisheri which has been put on the IUCN Red List of Threatened Species. Therefore, any risk in terms of too high sediment concentrations that would endanger the habitat of the above-mentioned fish species are rendered as not acceptable.

The objective of the paper is the presentation of the rapid screening for the available state-of-the-art sediment management techniques with purpose of the selection and specification of the optimum solution considering the necessary tailoring onto the project specific boundary conditions.

2. THE MORAGOLLA HPP PROJECT

The envisaged Moragolla Hydropower project will be located in the central Highlands of Sri Lanka, approximately 22 km south of the city of Kandy and 130 km north-east of the capital city of Colombo. The installed capacity of the HPP will be 30.2 MW for the rated head of 69 m and design discharge of 50 m³/s. The expected mean annual energy generation is 100 GWh/a. The project comprises a reservoir inundated by a gravity dam equipped with spillway, bottom outlet and fish ladder, a lateral intake, a low-pressure headrace tunnel, a surge shaft, a steel lined penstock tunnel and a surface powerhouse accommodating two Francis units. The general layout is shown in Fig. 2.

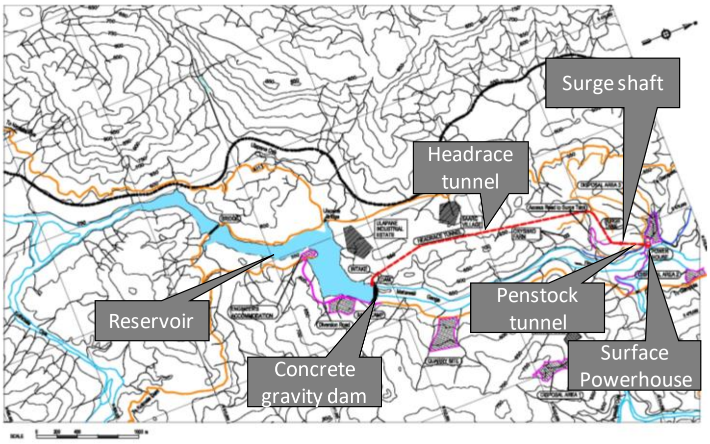

Fig. 2
Project location and general layout

The reservoir will be slightly longer than 3 km with gross storage capacity of 4.66 million m³ at the normal operation water level of 548 masl and active storage of 2.68 million m³. The minimum operating water level will be at 542 masl. The dam will have maximum height of 37 m and length of 236 m. The overflow spillway will be equipped with five radial gates with the ogee crest level at 534 masl. A sand sluice followed by a steel lined conduit embodied in the gravity dam will be installed next to the lateral intake with purpose the removal of sediment deposits. A bottom outlet is also incorporated in the dam body for dam safety reasons. Finally, a micro-hydro power plant will be installed at the dam toe for the exploitation of the hydropower potential of the ecological flow.

The catchment area draining at the Moragolla dam site is 809 km². Upstream of the envisaged Moragolla reservoir is located the Kotmale dam, which inundated the year 1984 a reservoir with gross storage capacity of 177 million m³. The latter regulates the runoff from 562 km², i.e. approximately 70% of the catchment area. It has been calculated that the trap efficiency of Kotmale reservoir is approximately 99.5%. Hence, the regulated part of the catchment will not contribute to the sediment inflow at the envisaged Moragolla reservoir. The unregulated part, i.e. the catchment area excluding Kotmale dam catchment area is 247 km².

The hydrologic analysis concluded that the mean annual flow at the Moragolla dam site will be 22.4 m³/s. The mean annual sediment inflow has been estimated to be 145,000 m³/a. This assessment was based on the specific sediment yield at Kotmale reservoir as calculated from the measured deposits, the trap efficiency and the size of the regulated catchment area. The bulk of sediment transport occurs in the time period June to November with maximum mean monthly sediment load close to 23,000 m^3/month. The sediment inflow at the Moragolla dam site will consist predominantly of silt material, with an important sand content, which will increase with rising river flow. By small discharges i.e.: close to 10 m^3/s as observed during the dry season, the sand content will be close to 10-15%. As the discharge increases the sand content can reach up to 30% of the total sediment inflow.

3. RESERVOIR SEDIMENTATION AND COUNTERMEASURES

3.1. METHODOLOGY

The time path of the reservoir storage development has been initially assessed for the no-action scenario with purpose of the determination of the reservoir service lifetime if no sedimentation management measures are implemented. The assessment was performed with one-dimensional simulation with the widely used numerical model HEC-RAS v. 5.03.

The results of the numerical model served in addition for the calibration of the REServoir Conservation - 2 (RESCON- 2) model that was used subsequently for the screening and evaluation of the state-of-the-art sediment management techniques. The RESCON approach was developed and published in 2003 by the World Bank [4] with the purpose to provide a tool that will allow the identification of the technically viable and economically optimal approach for sustainable management of water storage reservoirs. The RESCON approach was recently upgraded by Fichtner for the World Bank Group and the beta version of the RESCON-2 software is now freely available to download at the internet portal of the International Hydropower Association (IHA)[*]. The improvements incorporated in RESCON-2 can be categorized as follows (5):

- Improved procedure for calculation of the reservoir storage development, allowing allocation of sediment deposits between active and inactive storage as well as partitioning between bedload and suspended load
- Extension of palette of assessed sediment management techniques
- Incorporation of intergenerational equity issues in performed economic appraisal through the concept of declining discount rate
- Climate change analysis allowing the assessment of sediment management as adaptation strategy for increasing the resilience of the infrastructure
- Graphical User Interface (GUI) enhancing the user-friendliness during model setup and result reading

It is pointed out that RESCON-2 serves for a rapid screening and it is not intended to replace detailed studies. The RESCON-2 program is based on

[*] available at https://www.hydropower.org/sediment-management/

empirical methods and therefore sound engineering judgment is required for interpretation of the results. In terms of the Moragolla sedimentation study, the following sediment management techniques were analysed and evaluated.

- No Action (i.e. No sediment management),
- Reduction of sediment inflow by implementing a sediment trap upstream of the reservoir headwaters,
- Deposit removal techniques, including flushing, dredging and trucking and HydroSuction Removal System (HSRS),
- Sediment routing techniques, including sluicing, sediment by-pass and density current venting.

3.2. RESERVOIR LIFETIME FOR THE NO-ACTION SCENARIO

The result of the numerical simulation of sedimentation for the available daily flow time series with duration of 43 years is plotted in Fig. 3 with black points. The black straight lines represent the time-path of the gross and active storage as calculated by RESCON-2. It was concluded that the service lifetime of the reservoir will be approximately 55 years, corresponding to a mean annual storage loss rate of approximately 2%.

The overall good agreement between the results of HEC-RAS and RESCON-2 with regards the gross storage development supports further the application of RESCON-2 for preliminary screening purposes of the available sediment management techniques. Unfortunately, HEC-RAS does not provide the possibility to plot the temporal development of the storage at different pool elevations. This prevented a comparison between the HEC-RAS and RESCON-2 results regarding the allocation of deposits between active and inactive storage respectively. Nonetheless, RESCON-2 indicated that the sedimentation of the active storage pool will commence immediately after the reservoir impoundment due to deltaic deposits at the headwater of the reservoir.

3.3. EVALUATION OF SEDIMENT MANAGEMENT OPTIONS

The assessment of the technical feasibility of the available sediment management techniques and the corresponding temporal development of the reservoir storage has been performed with application of RESCON-2. The specifications of the evaluated sediment management techniques are given in the table below.

The techniques of sediment by-pass and trucking were excluded because they were considered as not economically viable due to very high implementation or annual operation costs. In the case of sediment by-pass, the calculated costs for construction of an approximately 3 km long diversion tunnel were prohibitive for the implementation of this technique. In the case of trucking, the necessary outages for reservoir emptying and removal of deposits by earthmoving equipment would cause high energy generation loss and accordingly revenue losses that rendered this method also not economically viable. Following table presents analyzed and evaluated management options that could be technically and economically feasible.

Table 1
Specifications of evaluated sediment management techniques

Method	Specifications	
Flushing	water level drawdown	25 m (Pool elevation @ 523 masl)
	Flushing discharge	40 m^3/s
	Duration	12 hours after water level drawdown
	Frequency	1 flushing event per year
Dredging	Sediment concentration	30%
	deposits removed per dredging event	115000 m^3/ event
	Frequency	Continuous dredging operation
HSRS	Available head	33 m
	Pipeline length & diameter	3000 m & 1 m (one pipe)
Sluicing	water level drawdown	6 m Pool elevation @ 542 masl
	Duration of sluicing	6 months
	Frequency	Annually
Sediment Inflow Reduction	Reduction of sediment inflow	30% of MAS (exclusion of sand and coarse silt)
	Maintenance	Annual sand mining of

RESCON-2 indicated that a hydrosuction removal system as specified in the table above would have a deposit removal capacity of approximately 90,000 m^3/a with a continuous slurry discharge release of 2.5 m^3/s. The associated water losses would be therefore considerable and would reduce the reservoir firm water yield. Furthermore, the necessary pipeline length of 3 km is marginally at the feasible applicability limits. Therefore, this technique can’t be applied the first years of reservoir operation, it is however a method that could be implemented later in the future. When the trap efficiency drop will reduce the annual deposits, a smaller HSR system will be able to maintain the storage in a sustainable manner.

Following the technical feasibility criterion for density current venting that was developed by Morris and Fan (1998), RESCON-2 indicated that the appearance of density currents is plausible. The initial geometry of the reservoir will have as result however the dissipation of the density currents before they arrive at the low-level bottom outlet. Therefore, the venting, i.e. the release of density currents downstream of the reservoir will not be possible, at least the first years of reservoir operation. The progressive propagation of the deltaic deposits downstream will have as result a steepening of the reservoir invert. Therefore, density current venting might be a feasible option in the future. RESCON-2 indicated that a reduction of the sedimentation by approximately 10% might be possible through density current venting in the future.

RESCON-2 indicated that a standard hydraulic dredger with capacity of 115000 m^3/a, which is within the technically feasible limits of dredging in reservoirs, is the only technique that can sustain the active storage at the pre-impoundment levels. The time path of reservoir gross and active storage is plotted in Fig. 3 with the orange line. Dredging however is associated with high operation costs as well as environmental considerations about the disposal of the dredged.

RESCON-2 calculated for flushing a Sediment Balance Ratio (SBR) of 3.1, i.e. the sediment removal capacity of the specified flushing event will be approximately 3 times higher than the expected annual sediment deposits. This indicates that flushing is a technically feasible solution for Moragolla reservoir. The Long-term Capacity Ratio (LTCR) will be 0.64, i.e. 64% of the reservoir gross storage can be preserved sustainably. Its efficiency however drops to 50% with regards to active storage. The time path of reservoir gross and active storage is plotted in Fig. 3 with green lines. Environmental considerations associated with the expected high sediment concentrations downstream of the reservoir that would endanger the fish habitat of Mahaweli River together with the high energy generation losses due to the necessary full water level drawdown had as result that this technique was evaluated as not acceptable.

The unregulated part of the catchment area draining into Moragolla reservoir is mostly forested or covered by tea gardens which are one of the major economic activities in the project region. It was considered therefore, that measures such as reforestation or change of the agricultural practices with purpose the reduction of the surface erosion are not technically feasible. The effect of dispersed check dams in the catchment area on the sediment inflow was not part of this study and has to be investigated more in detail.

The evaluation of the river morphological features indicated that the reach of Mahaweli River extending approximately 2 km upstream of the reservoir headwaters is characterized by pronounced river meandering and sandy river bed. Limited sand mining is already performed by the local communities at this location. Numerical simulations with the one-dimensional model HEC-RAS indicated that the construction of a relatively short check dam with height of approximately 2.5 m would have as result an intensification of the retention of the sand particles in this river reach. A sediment trap at this location can retain annually approximately 60,000 m^3 of sediment, corresponding to 40 % of the expected total mean annual sediment inflow into Moragolla reservoir. This can be translated as full retention of the material transported as bedload and retention of the coarsest 20% of the material transported in suspension. The necessary requirement for the above described sediment trap performance is the regular and continuous restoration of its trap efficiency by means of sand mining. The impact of this sediment inflow reduction is that approximately 10% of the gross storage and 50% of the pre-impoundment active storage is preserved sustainably. Except from the sediment inflow reduction an important aspect is that the sediment entering now the reservoir is finer since the coarsest part will be retained in the sediment trap. This has as result a drop of the trap efficiency of Moragolla reservoir which protects a large part of the active storage.

The construction of the check dam will raise the water level in the river reach extending upstream of this structure by ≈2.5 m. Drainage pipes through the check dam will keep the reservoir upstream of the check dam lower during the dry season. The extent of the further inundation upstream of the check dam is expected to be approximately 2 km. If the width of the inundated area need to be confined, two lateral dikes along the river main channel shall be constructed. The necessary sand mining activity will cause an increase of the traffic in the local road network. On the other hand, this activity will reduce the transport distances for supplying sand, and may boost the local economy.

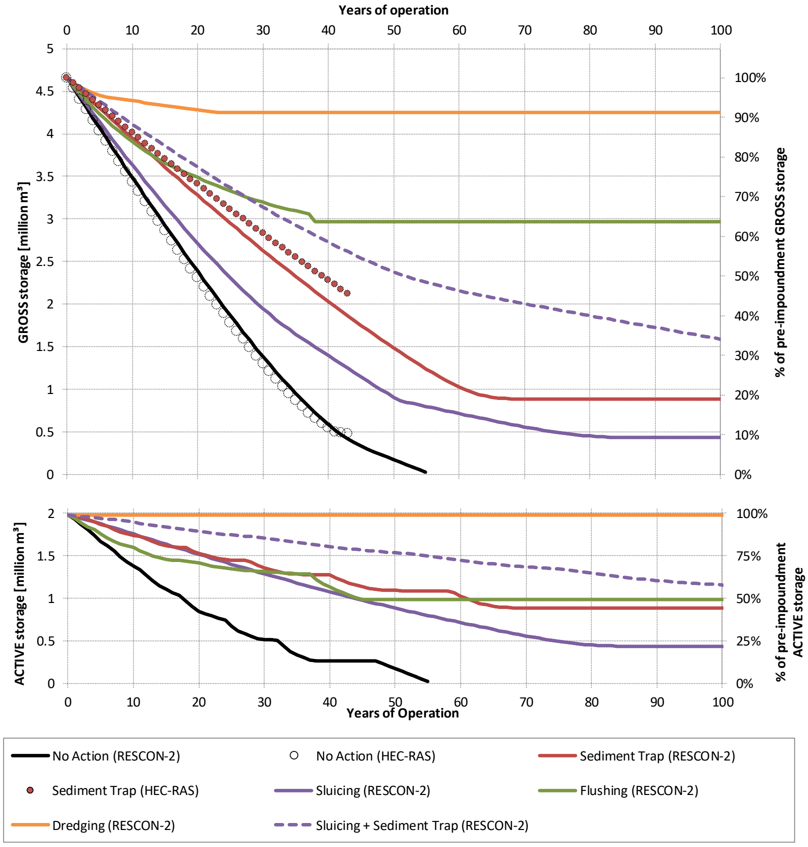

Fig. 3

Storage development for the no-action scenario and the technically feasible sediment management techniques

Sluicing over the spillway crest is technically feasible in Moragolla reservoir as long as a water level drawdown takes place when sediment laden flows enter the reservoir. The prediction of reservoir storage development with RESCON-2 indicated that the first ten years of reservoir operation sluicing will not change substantially the time path of reservoir gross storage because the sediment will be routed into the inactive storage and not out of the reservoir, since it will not be possible to overcome the barrier of the Moragolla dam. Sluicing however, will have as result an alteration of the spatial pattern of deposition in the reservoir which will be characterized by lower sedimentation rate in the active storage and higher sedimentation rate of the inactive storage compared to the no-action scenario. On the long-term sluicing will be able to sustain only 10% of the gross storage. The impact however on the active storage will be substantially larger, and 25% of the initial active storage will be preserved sustainably. Sluicing however will not trigger the adverse environmental impacts that would follow flushing since the sediment routing will be synchronized with the ambient intra-annual variability of the sediment transport regime of the Mahaweli River. The performance of sluicing is substantially improved if it is combined with the sediment trap upstream of the reservoir. The combination of reduced and finer sediment inflow together with the water level drawdown during the high flow season intesifies the sediment routing out of the reservoir. This has as result a long-term capacity ratio for the active storage of 60%. The time path of the gross and active storage for this combination is plotted in Fig. 3 with dashed line. The detailed specification of the optimum sluicing operational rules will require a detailed assessment of the water, energy generation and revenue losses something that is out of the philosophy and the capabilities of RESCON-2.

Based on the aforementioned results of the technical feasibility assessment, it was concluded that the only two techniques that can be implemented without important environmental disadvantages, are the reduction of sediment inflow through the construction of a sediment trap upstream of the reservoir headwaters and sluicing. Even more, it is concluded that the combination of the two methods will further improve the efficiency of sluicing and will reduce thus the associated energy generation losses providing sufficient space for further optimization.

SUMMARY

The Moragolla Hydro PowerPlant (HPP) project involves the implementation of a daily peaking Run-of-River Hydropower scheme in Sri Lanka. Numerical simulations indicated that the service lifetime of the reservoir will be approximately 50 years if no sediment management is applied, i.e. it will be non-sustainable. Furthermore, the active storage loss will affect the long-term economic performance of the facility. The recently developed software RESCON-2 was used for a rapid screening of the state-of-the-art sediment management techniques. The purpose was the selection and specification of the optimum sediment management solution considering the necessary tailoring onto the project specific boundary conditions that can convert the non-sustainable Moragolla reservoir into a sustainable infrastructure for the future generations.

The economic viability assessment indicated that the costs or the water losses associated with the techniques of hydrosuction removal, sediment by-pass and trucking are prohibitive for their implementation. The technical feasibility assessment indicated that the technique density current venting at the moment is not applicable but it might provide an attractive option for the future. The comparative evaluation of the remaining methods, i.e. flushing, dredging, sluicing

and reduction of sediment inflow though construction of a sediment trap upstream of the reservoir is presented in the table below.

Table 2
Evaluation of technically feasible sediment management techniques

Method	Long-term capacity	Water and energy losses	Env. Impacts	CAPEX	O&M
Flushing	++	-	- - -	0	-
Dredging	+++	-	- - -	- - -	- - -
Sluicing	+	-	+++	0	-
Sed.trap	++	+++	-	-	+++

The results indicate that dredging is the only method that can sustain the active storage at the pre-impoundment level. It is followed by flushing and the sediment trap that can preserve 50% of the pre-impoundment storage and finally by sluicing that will have as result a long-term active storage capacity ratio of 25%. Dredging and flushing however are excluded because they will increase the sediment concentrations downstream, endangering thus the fish habitat of Mahaweli River. Finally, the combined implementation of sediment trap and sluicing is the optimum solution because it has the best performance below dredging without the adverse environmental impacts. Sluicing can be implemented within a time horizon of 10 -15 years after the impoundment of Moragolla reservoir, while the sediment trap preferably should be in place by the time of the reservoir inundation. Having in mind the above indicated possibilities of the RESCON-2 model for a rapid assessment of different sediment management strategies as well as good agreement of its results with a widely used one-dimensional numerical model we could recommend it for further use in similar applications.

1. INTRODUCTION

Korea Energy (KOEN) is a leading state owned generation company of Republic of Korea which owns and maintains 13.1% (10,329MW) of total generation capacity of Korea.

To comply with KOEN “Vision 2025” regarding adding of green and clean energy to the grid, KOEN acquired Mira Power Limited on mutual benefit basis where Pakistan was facing acute shortage of energy.

Mira Power Limited, a subsidiary of Korea Energy (KOEN) is a special purpose company, setup to design, construct, own, operate and maintain 102 MW Gulpur hydro power plant as shown in Fig. 1 under Government of Pakistan’s Policy for Power Generation Projects 2002 as adopted in Azad Jammu & Kashmir, Pakistan. The Project “Gulpur Hydropower” is administratively located in Kotli district, Azad Jammu & Kashmir, Pakistan at latitude 33°27’48.99" and longitude 73°51’48.99", about five Km south of Kotli Town on the Poonch River, a tributary of Jhelum River. The site is about 167 Km from Islamabad and 285 Km from Lahore as shown in Fig. 2.

Fig. 1
Gulpur Hydropower Project Design

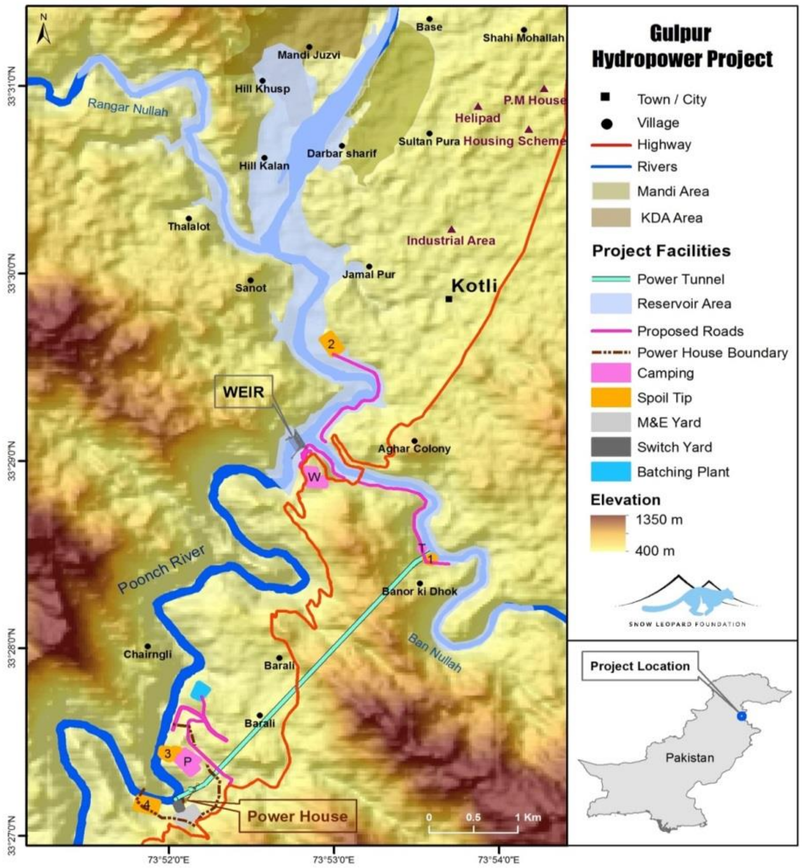

Fig. 2
Gulpur Hydropower Project Location

The Project is being financed by International Finance Corporation (IFC), Asian Development Bank (ADB), Korea Exim Bank (K-Exim), CDC Bank of UK and Multilateral Development Bank of Netherland (FMO). The Project achieved Financial Closing in October 2015 and set to achieve commercial operations by August 2019 with 70% construction already completed. The Project is being constructed by renowned consortium of Korean construction companies i.e. Daelim Industrial and Lotte E&C and many international consultants/technical advisors are collaborating at different levels including Mott McDonalds as technical advisor of Lenders, MWH as Owners Engineer and Multi Consultant (UK) as independent engineer.

Back in 2013 when KOEN decided to invest in Pakistan, the country had a serious power crisis. Everyday millions were being affected by electricity shortage up to six hours in urban areas and twelve hours in rural locations which leads to slowing of productivity and hampering economic growth. KOEN believed at that time that in a country, rich in water resources hydropower can have a significant role in meeting future energy needs.

While acquiring the project KOEN was already very keen to focus on environmental challenges in maintaining the rich ecology and diverse environment specifically in view of already environmental sensitive location where other than rest of the needful almost 128 households were to be resettled/ relocated.

The Project is also in compliance with International Finance Corporation (IFC)'s Performance Standards and Asian Development Bank Safeguard Policy Statements. To meet such requirements and to face the prospective challenges from civil society, NGOs, Government and local communities, KOEN facilitated Mira Power to adopt a comprehensive approach of sustainable development.

2. STEPS TOWARDS SUSTAINABLE DEVELOPMENT

To achieve sustainable development plan Mira Power has adopted flawless strategy and devised following best possible plans:

- Biodiversity Action Plan
- Land Acquisition and Resettlement Plan
- Livelihood Restoration and CSR Plan
- Stakeholders Engagement Plan
- Sustainable Mining Plan
- Security Management Plan
- Construction E&S Management Plan
- Health and Safety Plan

The environment portion discussed in already accepted feasibility study was based on Environment Protection Act (EPA) Azad Jammu & Kashmir (AJK) where the biggest challenge was resettlement/ relocation of 128 households, for which Mira Power management was vigorously thinking to change the project design so that to minimize the relocations.

In the meanwhile, after acquisition of the project it was pointed out that the full length of Poonch River has already been declared as National Park by local environmental authorities, which through legislation restricted various forms of species exploration to ensure that the habitat remains pristine and congenial for the indigenous species.

The nomination of this National Park was promoted and/or endorsed by a number of reputable environmental NGOs, including but not limited to International Union for Conservation of Nature (IUCN), WWF, Himalayan Wildlife Foundation, and Snow Leopard Foundation, as they argued that the Poonch river is essential for the global survival of Kashmir Catfish, and presents a unique natural abundance of the Mahaseer fish, an endangered species whose population has been consistently declining all over Himalayan rivers.

The Strategic Environmental Assessment (SEA) of rivers classifies the Pooch River into the most critical category. A total of 37 fish species are associated with the Poonch River. Of these six fish species are listed in International Union for Conservation of Nature (IUCN) Red List with their status as:

1. **Kashmir Catfish** – Critically Endangered,
2. **Golden Mahseer** – Endangered,
3. Pabdah Catfish – Near Threatened,
4. Butter Catfish – Near Threatened,
5. Common Carp – Vulnerable,
6. Twin-banded Loach – Vulnerable

Golden Mahaseer *Tor Putitora*

Kashmir Cat fish *Glyptothorax kashmirensis*

Fig. 3
Photographs of Golden Mahaseer and Kashmir Catfish

3. KEY ENVIRONMENTAL CHALLENGES FACED BY THE PROJECT

- It was challenging to relocate 128 household in terms of their resettlement and prospective litigation
- Mira Power became aware of National Park notification after submission of initial environmental due diligence and original Environmental Social Impact Assessment (ESIA) to Environmental Protection Agency (EPA) and lenders for approval. Upon knowing of the notification regarding National Park further activity on the project was put on hold due to the new situation emerged with the appearance of critically endangered and endangered fish species within a legally notified area. The situation was pretty much alarming for Mira Power and was requiring immediate strategic interventions with reference to following mandatory requirements:

1) As per AJK Wildlife legislation 'Betterment of the Park' was mandatory to get approved actions and activities normally prohibited in a National Park

2) ADB and IFC in view of declaration of National Park and presence of Endangered Mahaseer and Critically Endangered Kashmir Catfish demanded 'net environmental gain' in biodiversity in Critical Habitant.

4. STRATEGY & IMPLEMENTATION

To cope with the challenging problems Mira Power carried out following key studies/assessments to achieve sustainable development of the project:

- Review of project design
- A critical Habitat assessment study of the entire river in order to establish the actual status of biodiversity and ecological integrity of the river
- A cumulative impact assessment of all projects planned on the river establish that if there is any room for considering the proposed project
- An integrated ecological flow assessment of Gulpur Hydropower project assessing the upstream and downstream response of the project to establish any potential for achieving a net environmental gain and room for betterment of the park
- A Biodiversity Action Plan demonstrating a net environmental gain and a net improvement in the national park

In addition to challenge of relocation of 128 households Mira Power anticipated that the likelihood of achieving a net environmental gain with the original design having 6 kilometers of low flow/dry section with peaking scenarios will be difficult to achieve. Therefore the location design and layout of project design as shown in Fig. 4 was optimized compared with design of feasibility report whereby the dam was located just downstream of confluence of Bann Nullah and Poonch River and a 3.1 KM tunnel located 1 KM upstream in Bann Nullah from its confluence with Poonch River. The Normal Operating Level (NOL) of the project was changed to be at an elevation of 532 meters from the sea level which was modified from 540 meters in the original plan to reduce environmental and social impacts.

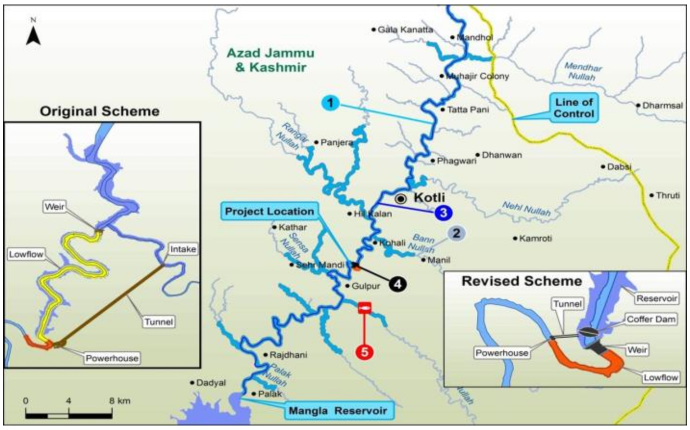

Fig. 4
Change of Project Design

The scheme was changed in order to get following environmental and social benefits:

- Under Feasibility Design, approximately 6.1 km of the River would have experienced the low flows due to operation of the Project while in the revised design only 0.7 km of the River will be affected by these low flows. From an ecological standpoint, the negative impact on the ecological resources of the Poonch River will be much less for the changed design compared with feasibility design.

- During the breeding season, Golden Mahaseer migrates into the tributaries (nullahs) of the Poonch River for spawning including the Bann Nullah and Rangar Nullah as shown in Fig. 5. The construction of a dam, as envisaged in Feasibility Study, at the confluence of Poonch River and the Ban Nullah would disrupt this breeding migration and negatively impact the population of the Golden Mahaseer. Under the new design, the Project facilities will be located about 6 km downstream of Feasibility Study location. The breeding grounds of Golden Mahaseer particularly in the Ban Nullah will not be directly affected by project operations under new scheme.

- The total submerged area (including the present river) will be approximately 320 hectares for design envisaged in Feasibility Report while 292 hectares for the optimized design, therefore, comparatively less terrestrial habitat will be submerged and consequently there will be a lower negative impact on the terrestrial ecology.

- The Resettlement under optimized design is minor in comparison to that for Feasibility Report design.

- For Feasibility Stage design, a new road approximately 1.5 km long was planned to be built from the existing blacktop road to the inlet of the power tunnel in relatively undisturbed pine and scrub forest. For this, vegetation would have to be cleared, and trees cut. For optimized design, a shorter road of 650m length is required.

- The option for peaking mode operations as envisaged in Feasibility Report was discarded to avoid stress on the river ecology downstream of the power house and, therefore, a non-peaking operation of the powerhouse was adopted for the Project in the new design.

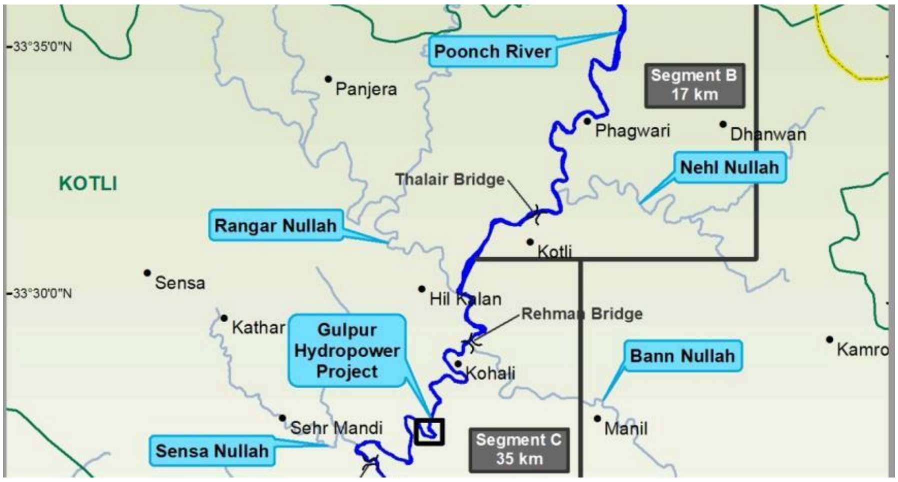

Fig. 5
Tributaries of Poonch River

Based upon changed design the relocation decreased from 128 to almost zero whereas on the basis of above studies/assessments EPA and wildlife departments appreciated Mira Power in terms of efforts towards protection of fish species in National Park specifically Endangered Mahaseer and Critically Endangered Kashmir Catfish and gave approval for:

- Preparation and implementation of Biodiversity Action Plan (BAP) for achieving protection targets of Enhanced Protection Scenario at basin level protection

- Concept of ‘net gain’ in biodiversity in National Park

The above decisions of the regulators were duly endorsed by the lenders who also advised Mira Power to update the original ESIA and resubmit to EPA and Lenders for public disclosure and approvals from investment committees and Board of directors.

To meet the approvals of regulators and the lenders Mira Power carried out following additional studies/assessments:

- Ecological Flow Assessment- based on revised design option
- Detailed Socioeconomic Surveys
- ESIA Update and Integration
- Climate Change Risk Assessment

All revised reports were resubmitted to Environment Protection Agency (EPA), AJK Fisheries and Wildlife Department (FWD) and lenders for their respective disclosure requirements and approvals. In this process Mira Power successfully managed unprecedented support from the major international NGOs including World Wildlife Fund (WWF), Himalayan Wildlife Foundation (HWF) and International Union for Conservation of Nature (IUCN), regulators including EPA and FWD and other civil society and academic institutions.

To discuss above efforts and potential outcome, a number of video conferences were managed where lenders’ experts, Mira Power and various other stakeholders/NGOs participated. Resultantly, subject to following further studies a conditional approval was granted by all lenders based on majority votes:

- Feasibility Assessment for Achieving Net Gain
- Biodiversity Monitoring and Evaluation Plan
- Proposed Ecological Flow Management Plan
- Mahaseer Hatchery Design and Restocking Program
- Proposed Road Map for National Park Management Park (NPMP)

Finally the BAP and ESIA were further updated upon completion of above studies and was requiring an Environmental and Social Management System (ESMS) to implement all the approved plans. The Biodiversity Action Plan (BAP) was developed for the Poonch basin by the project in consultation with all stakeholders. The same is implemented through landmark agreement on a novel concept of public-private-partnership for conservation. An implementing agency, a renowned conservation NGO has been engaged with Government’s Fisheries & Wildlife Department to implement the BAP.

A comprehensive BAP has been developed, outlining Pro2 scenario commitments to achieve net positive gain in the ecological values that triggered Critical Habitat classification, namely (a) Kashmir Catfish, (b) Mahaseer fish and

(c) Poonch River Mahaseer National Park conservation objectives. These actions will include, among others:

1) Implementing an effective watch and ward system supported by institutional arrangements to reduce illegal and indiscriminate hunting and killing of wildlife (both aquatic and terrestrial) including several bans on non-selective fishing, fishing in tributary breeding grounds, fishing during the breeding season, and sediment mining in ecologically sensitive areas
2) Prohibiting removal of vegetation that is important for supporting biodiversity
3) Increasing park staff, patrols and mining inspectors
4) Limiting areas designated for sediment mining
5) Banning of livestock grazing and wood collection in sensitive areas
6) Conducting environmental awareness workshops for local communities. The Sponsors will finance supplemental park staff, equipment, facilities, and logistics to close the existing capacity gaps – including the construction of two park management offices and support to the local Fish and Wildlife Department (FWD) on the construction of a hatchery for Mahaseer on the Poonch river. This hatchery is a key component of the actions needed to increase numbers of the Mahaseer in the downstream portion of the Poonch river after the dam is in place as they will be cut off from their breeding grounds upstream. Therefore, success of this hatchery is critical to the success of the BAP actions and will be planned and monitored carefully. In addition, project sponsors will provide technical support to the local FWD by engaging experts in park management and river ecology. Institutional arrangements proposed in the BAP consists of putting in place a protection system for Poonch River Mahaseer National Park partly financed by the project and implemented by an independent organization
7) Active support from the local FWD by making available existing staff for protection and assistance in coordination with other government line departments such as police and district administration
8) Commitment by the local FWD to provide legal authority to the staff of the independent organization for exercising powers under wildlife legislation
9) Oversight and monitoring by the Wildlife Management Board of the local FWD
10) Monitoring by an independent third party on a long term basis. These actions, along with development of a strong Poonch River Mahaseer National Park management plan, are expected to lead to net gain on the indicator fish species populations and strengthen and support conservation objectives of the park

The Environmental and Social Management System of Gulpur Hydropower project has been designed in compliance with the requirements of project lenders including IFC and ADB. The requirements of applicable performance standards of IFC and safeguard policy statement, 2009 of ADB are the key documents that govern the overall framework. Additionally the other documents of IFC and ADB have also been used in shaping up and improving the system.

The construction of Gulpur project is carried out in accordance with the ESMS implementation handbook (Construction) of IFC which is based on the most common method Plan-Do-Check-Act cycle (PDCA). The system is based on following elements as shown below in Fig. 6.

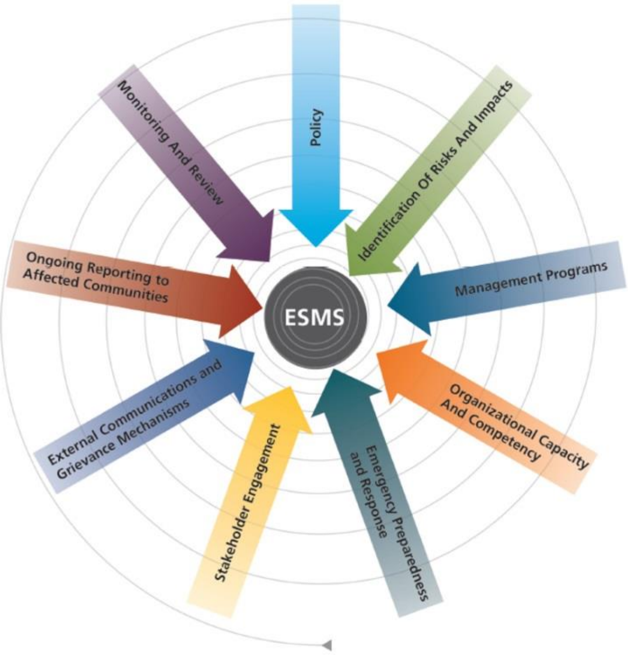

Fig. 6
Gulpur Hydropower Project – ESMS

5. STRATEGIC OUTCOME

After implementation of revised ESIA, land acquisition has been completed without any significant relocation. The initial results after implementation of plans developed for sustainability are very encouraging whereas hatcheries for critically endangered Kashmir Catfish and endangered Golden Mahaseer are under construction whereby a significant 'net gain' in the population of these species is expected. We expect that the concept of net gain implemented for addressing the environmental challenges while developing Gulpur HPP shall be the best solution for various other projects not only on Poonch River rather other rivers as well. This will set an international standard that how development and environmental protection can work together for sustainable development.

DISASTER COMPETENCE NETWORK AUSTRIA

Christian RESCH, Rainer PRÜLLER

*Managing Director DCNA, GRAZ UNIVERSITY OF TECHNOLOGY,
UNIVERSITY OF NATURAL RESOURCES AND LIFE SCIENCES VIENNA*

AUSTRIA

1. INTRODUCTION

The Disaster Competence Network Austria (DCNA) is a cooperation platform of universities and research institutions in the field of security and disaster research. The aim of the initiative is to transfer scientific knowledge into practice, through cooperative research and education activities carried out in collaboration with various stakeholders, as well as the provision of decision-relevant information in the event of a disaster.

2. ABOUT THE ASSOCIATION

The basic idea behind the DCNA initiative is to bundle scientific expertise in Austria in the field of disaster prevention and disaster research. The association acts as a networking platform and coordinating body for scientific institutions, companies and disaster management authorities at all levels. It is organized as a non-profit and open association under university management and distinguishes three different types of memberships. Ordinary members are all Austrian institutions in the field of scientific security and disaster research. Associate members are all Austrian institutions that are interested in DCNA activities and their support, but do not carry out any scientific research themselves. To further anchor disaster research across multiple institutions, there are strategic partnerships. These can be met with ministries, local authorities and international institutions that will pursue a common goal with DCNA. Meanwhile, the network has been expanded to include major players in disaster management and prevention (**Figure 1**).

Figure 1: Current DCNA members

The common denominator of all participating institutions is disaster prevention and appropriate preparation to potential emergencies. This large clip is drawn by DCNA in order to be equally available to research institutions and academia as well as stakeholders from the public and private sector.

3. ORGANIZATIONAL STRUCTURE

The organizational structure of DCNA includes the Board Members from the founding universities such as Graz University of Technology and University of Natural Resources and Life Sciences Vienna with their rectors holding the Chairmanship. A General Assembly is bringing together all network members and partners once a year. In addition to the management level, the implementation-oriented and scientific activities are carried out in different scientific working groups that are formed by experts from DCNA member organizations. Official meetings of the working groups are scheduled twice a year in spring and autumn for two to three days alternately at one of the various member institutions. A chairperson which is elected coordinates a specific working group. If needed, subgroups or project groups are set up for specific topics and demands. The five working groups within DCNA will be the content of the following sections.

3.1. MASS MOVEMENTS AND EARTHQUAKES

Mass movements are gravitation-related catastrophic events such as landslides, rock-falls or and avalanches. In the Alps, a large number of potential landslides threaten public infrastructure and settlement areas can be detected. The working group therefore devotes itself to the gravitational sources of danger in alpine regions with. As Earthquakes are not very likely to happen in Austria, but need scientific attention, they are taken into scientific consideration within this working group.

3.2. FLOODS

Flooding is the condition of waters where the water level is significantly above the mean level. In general floods can be predicted in advance, except in the case of flash floods. Risk areas of floods affect both inner and outer Alpine regions in Austria and beyond and are of high likelihood. That is why flooding is to be addressed within a separate working group.

3.3. EXTREME-WEATHER-EVENTS

Under extreme weather events, weather phenomena such as storm, hail, heat and late or extreme frost will be addressed in this group. These occur in hard-to-predict intervals and can only be modeled inaccurately. The main focus of this working group is therefore the prevention of these extreme weather events and its consequences (e.g. Forest fires, droughts…) for public authorities, insurance companies and agricultural decision-makers.

3.4. CRITICAL INFRASTRUCTURE AND INDUSTRIAL HAZARDS

The working group Critical Infrastructure and Industrial Hazards deals with the topics blackout, electricity, communication, traffic, chemical industry or nuclear power plants with their nuclear hazard potential. Process and Plant Safety is of high importance not only because of natural hazards that have high potential to trigger major industrial accidents.

3.5. DISASTER RISK MANAGEMENT

This working group deals with disaster risk assessment, implements needs planning and brings socio-scientific and economic aspects into civil protection. Furthermore, response planning and capacity needs are being addressed. These include among others the risk analysis of technologies, technology-related catastrophic events as well as the modeling of disaster consequences and the appraisal of the extent of damage.

4. RESEARCH AND TECHNOLOGY AREAS

For horizontal linking of the working groups among themselves, research and technology areas are defined. These fields are described in the following chapters.

4.1. MODELING & SIMULATION OF IMPACTS AND PROCESSES

By experimental determination of process-related factors and parameters, including experiments in the laboratory, processes from the five main topics of the DCNA are to be modeled. In the field of gravitational mass movements, the flow behavior is modeled in the laboratory as well as in the field. Interactions between structures and the acting processes are investigated. Hydro-mechanically coupled modeling of profound mass movements in the area of influence of large reservoirs is just as much a topic as the development of geological, climatic and kinematic models in the catchment areas of endangered slope areas. The simulation of impacts includes the analysis and evaluation of temporal and spatial dynamics of mass movements and their effects on infrastructure and populated areas. It is not the simulation of catastrophic events themselves, such as the forces occurring within an avalanche, in the focus of the investigation, but the simulation of the effects of avalanche, for example, the spill of road infrastructure or the destruction of protective forest above permanent settlements.

4.2. STATISTICS & ACTUARIAL SCIENCE

The insurance industry is exposed to the consequences of catastrophic events in most cases, which is why the interest of minimizing damage is an important tool for cost optimization. Due to very well documented claims over a very long time, the quantitative and qualitative data of the insurance companies can be a valuable source for the scientific processing of disasters. On the other hand, the insurance industry benefits from a large network of scientists to gain a greater understanding of the occurrence of disasters based on statistical and mathematical data. This knowledge will then again influence the pricing policy.

4.3. REMOTE SENSING, GEOINFORMATION & NAVIGATION

Remote sensing technologies are imaging techniques that can operate from different carrier platforms. Depending on the spatial and temporal resolution of the requested data, satellite imagery, aerial photographs, thermal surveys, highly accurate surface models from LiDAR and radar interferometry etc. are available. For example, remote sensing systems for protection forest monitoring with the detection of forest parameters can be used as the planning basis for protection forest management by various evaluation methods. After a catastrophic event, building damage and damage to infrastructure can be detected automatically by remote sensing-based data. In the event of a flood, a real-time detection of the flood stop line can be performed. The harmonization of this data is expediently implemented in a Geographical Information System (GIS). Within this GIS, conclusions can be drawn from the observations using geoinformation methods as well as the documentation of damage events. Navigation as part of this field of technology deals with outdoor and indoor navigation, whereby outdoor navigation part is often seen as a synonym for GPS. However, this would severely restrict research in the field of outdoor navigation, since independent systems, for example Inertial Measurement Systems (IMU) are also be developed using complex filter methods. Indoor navigation plays an important role in the field of robotics, for example. Since satellite-based positioning methods can not be used within buildings, indoor navigation technology has to be used. Autonomous robots in the object exploration of fire in buildings, must be able to navigate and move autonomously with the help of optical and acoustic sensors.

4.4. SENSORS & SENSOR CARRIERS

In order to prevent catastrophes, the establishment of a monitoring network is of crucial importance. Applied to the disaster research carried out within the framework of the DCNA, these are the engineering supervision of large-scale structures and the monitoring of non-slip slopes in the catchment area of infrastructure. Geodetic technologies and methods provide the means to cushion the impending catastrophe very promptly and initiate countermeasures. In this case, Unmanned System (UxS) based carrier platforms such as drones or robots can be used to meet the temporal resolution requirements to the data. Fires or the discharge of hazardous substances can be localized by means of thermal sensors or chemical detectors to be made available to field forces.

4.5. ARTIFICIAL INTELLIGENCE, COMMUNICATION & INFORMATION TECHNOLOGY

This technology group includes the construction of information systems, such as a river information system such as the "Danube River Information Service" as well as the construction and operation of communication technologies in the event of a disaster. Information systems are designed to allow interoperability between civilian and military organizations in disaster management and to provide an interface to government agencies and scientific institutions. Thus, it is possible for experts to assess damage potential and vulnerability.

4.6. RAW MATERIALS, PLANT AND BUILDING MATERIALS RESEARCH

Materials science and engineering is an interdisciplinary field that deals with the research and development of new materials (e.g. lighter, smarter…) to be used for individual protection and safety for first responder organizations for example. Furthermore, research on new materials to be used for collective protection measures such as building structures, are being addressed.

4.7. EDUCATION, TRAINING & OPERATION

DCNA members have the opportunities to get education and training within their research focus as well as trainings out of other DCNA-relevant fields of technology. In addition, DCNA members will be able to participate in large-scale disaster and response training sessions and provide their scientific expertise to the task forces during these test runs. Using the competence map of DCNA, participating institutions and scientists can present their expertise in the field of disaster research and are proposed to the requesting task force in the event of a disaster.

5. MOBILE DCNA-RESEARCHPLATFORM

In the past decade, there have been an increasing number of disasters in Austria, caused for example by floods, mudflows or large-scale gravitational movements. Dealing with these natural phenomena presents massive challenges to the public safety organizations. In the phases of disaster management and recovery, but also in the area of prevention, recent disasters and the increasing complexity of scenarios have shown that response organizations and decision-makers at all administrative levels grow a higher demand of scientific expertise and advice. For this reason, the University of Natural Resources and Life Sciences Vienna and Graz University of Technology have launched the "Disaster Competence Network Austria" to transfer scientific knowledge into practice. With the assistance of acute assignments as well as through cooperative research and educational activities carried out in cooperation with a wide variety of stakeholders, the DCNA platform offers, among other things, the following synergies and added value:

- Contributing to the preservation of human life by avoiding damage caused by disasters and their consequences
- Advisory body of decision-makers in public authorities and organizations at federal and state level

- Close coordination, cooperation and provision of expertise towards thematically related initiatives, such as state crisis and civil protection management
- Establishment of a reliable partner network for national and international research activities by networking and expanding existing structures
- Access to scientific issues initiated directly from the field
- Sharing existing and new infrastructure.

In order to be able to realize these added values, together with the creation of a common organizational structure, the development of the common infrastructure is absolutely necessary. Therefore, a mobile research platform is being developed. The aim of this cooperative project is to establish an infrastructure (analysis laboratory), which enables the researchers and experts of the DCNA network to make their expertise available locally and in real time during disaster events. This system will be modular in its basic technical structure:

- Information and communication modules
- Laboratory and analysis workstations
- basic technical equipment for field operation

With regard to sensors and analytics, the two scientific partners will equip the modules according to their respective scientific strengths. The aim is an integrated overall concept, based on the complementary strengths of the scientific partners and also coordinated with each other in terms of organization. A current focus of the mobile research laboratory will be the monitoring and analysis of gravitational mass movements, e.g. Landslides or potential rock and landslides. With the high-precision measuring systems introduced by the university partners and the selective new acquisitions (terrestrial laser scanners, terrestrial interferometry, drones equipped with multi-sensor systems, engineering geodetic measuring instruments) as a supplement to existing equipment, it will be possible to produce highly precise multi-temporal digital elevation models of affected areas to create and to observe mass movements continuously. Based on these measurement results and deformation controls, model calculations for risk and risk assessment can be carried out at the same time. The analysis of deformations in structures (e.g. piers, buildings, highways, dams…) represents another important application of mobile measurement and analysis units. The planned container systems, which are completed in terms of their equipment to form a complete system, are brought into use as a joint large-scale laboratory. Due to the complementary expertise of both universities, these interdisciplinary missions can increase the measuring and analysis capacities as well as the possibilities for the stationing of scientific staff in the field (number of jobs). The realization of the acquisition of the two container systems planned in the first half of the project requires great know-how about their requirements and design. The fire brigade and the army in particular have been using such systems for many years, and the universities can and do wish to draw on these experiences in the cooperation project. Within the framework of the project, a dedicated section will deal specifically with the technical design of the container systems.

Another section will focus on adapting the existing research infrastructure (contribution of universities to equipment and sensors) and the selectively planned new purchases to the concept of a mobile laboratory. Both specialist groups will cooperate closely with each other in order to develop and implement a technically, ergonomically and organizationally harmonized overall concept. Apart from the deployment scenario of a real loss event, this mobile infrastructure will offer many new opportunities in everyday university life. For the first time, the mobile research infrastructure offers the opportunity to pursue research-relevant issues away from the physical infrastructure and to put them into practice. In addition, a positive effect on the teaching is expected since the students can apply their acquired knowledge in practice. The main advantages of a mobile infrastructure are the following:

- Possibility of monitoring existing critical mass movements within the sphere of influence of settlement areas
- Possibility of effective hazard and risk assessment along infrastructure (railway lines, motorway routes, quarries)
- Increasing understanding of processes and triggering mechanisms by linking to local variables (such as precipitation measurements using weather radar)

Of course, the planned mobile infrastructure should not only be available to the applicants. Organizational integration into the Disaster Competence Network Austria ensures that this infrastructure is subsequently accessible to all users in the field of civil protection and disaster management.

The operation and the further expansion (new thematic emphases in relation to sensor technology and analytics) of the DCNA measuring and analysis laboratory is ensured. The expansion will take place through the integration of further universities.

6. CONCLUSION

The Disaster Competence Network Austria is combining scientific expertise in the field of disaster research and prevention in order to establish a closer cooperation between knowledge carriers and their stakeholders. The aim of the non-profit association is to transfer scientific knowledge into practice through cooperative research and educational activities carried out in conjunction with a wide range of stakeholders, as well as the provision of information and advice to decision-makers in the event of a disaster.

PERMANENT SAFETY ASSESSMENT OF DAMS, LEVEES, RESERVOIRS, WATERWAYS WITH FIBER OPTIC DISTRIBUTED SENSING

Régis BLIN, Daniele INAUDI

SMARTEC SA

SWITZERLAND

1. EARLY DETECTION AS A KEY FOR SAFETY MANAGEMENT

The growing demand of safety awareness, cost effective operations and effective maintenance has rapidly stimulated, in the last decade, the development of smart monitoring techniques capable of detecting early-stage events, thus preventing structures from major failures and leading to a better knowledge of the structure itself. In this publication, the aim is to concentrate on long-term, large-scale field applications on dams, dikes and levees, based on the presented distributed technology and sensors.

2. FIBER OPTIC DISTRIBUTING SENSING

2.1. TECHNOLOGY

The most developed technologies of distributed fiber optic sensors are based on Raman and Brillouin scattering. Both systems make use of a non-linear interaction between the light and the silica material of which a standard optical fiber is made. If light at a known wavelength is launched into a fiber, a very small amount of it is scattered back at every point along the fiber. The scattered light contains components at wavelengths that are different from the original signal. These shifted components contain information on the local properties of the fiber, in particular its strain and temperature. After an appropriate analysis of those signals, the system can therefore provide a calibrated strain or temperature reading at every meter along the sensing cable, as depicted on Fig. 1.

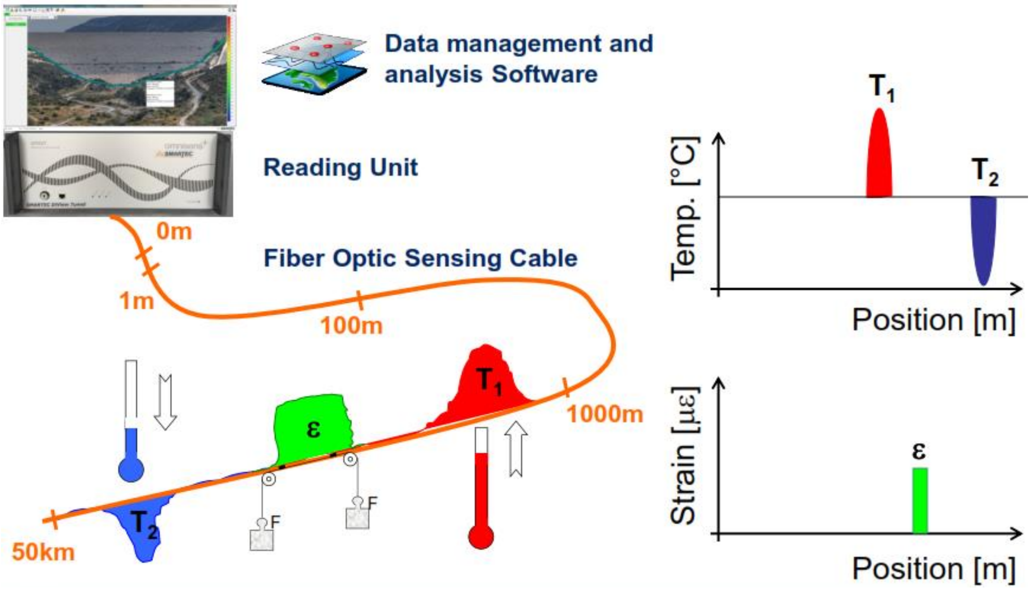

Fig. 1
Fiber Optic Distributed Sensing System

2.2. DATA MANAGEMENT

Direct data analysis based on distributed temperature or strain data has limitations and does not provides real-time data to the operator that often becomes overwhelmed by the amount of data he receives. It is therefore necessary to automate the data management and analysis process. The developed software displays measurement profiles, status maps of temperature or strain, evolution of the structure and events automatically recognized and logged by the monitoring system. All measurements are imported and stored into a single database and data is processed to apply calibrations and select zones of interest. Alarms are generated automatically, based on complex criteria (e.g. for leak detection). The user can than dig-down into raw data for deeper analysis, as shown in Fig. 2.

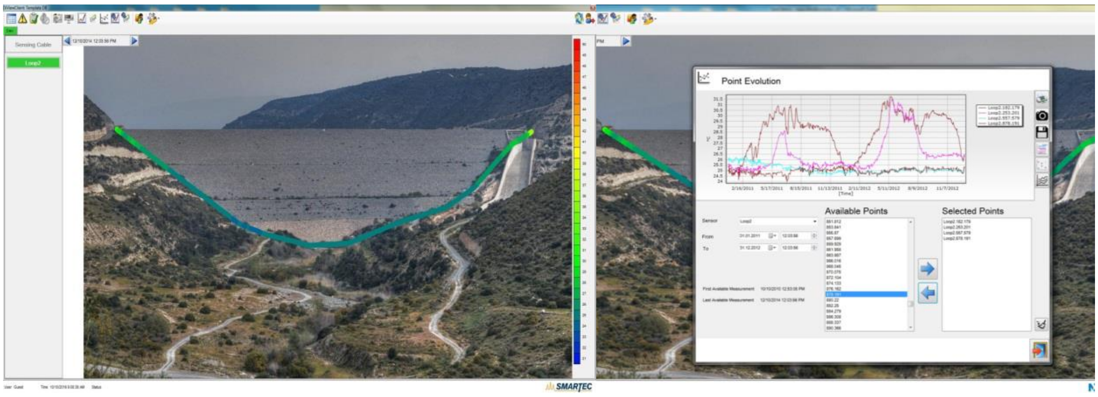

Fig. 2
Distributed Data - Strain and Temperature - Management and Analysis Software
Color coding representation (left) - Point evolution display (right)

2.3. BENEFITS

The scale, age and uncertainty of materials in the sometimes huge hydro engineering structures combine a difficult array of parameters for the responsible engineer to navigate when analyzing its structural integrity.

Traditional instrumentation based on localized point sensor is not sufficient to guarantee the detection of early signs of damage and localization of unknown events. Distributed fiber optic sensing allows the early detection, localization and sizing of defects and degradations such as seepages, leakages, settlements, shearing, cracks, abnormal joint movements, intentional tampering and over-flooding.

3. INFILTRATION DETECTION FOR DAMS, DIKES AND RESERVOIRS

A fiber optic distributed system for infiltration detection relies on Raman distributed thermal sensing and can work in two different configurations; the passive and active methods.

The so-called passive method relies on direct detection of temperature anomalies induced by seepage or leak. This method is typically used when a gradient of approximately 5°C between the leaking liquid and the sensing cable can be assured.

The so-called Heat Pulse Method or active method is on the other hand used when the gradient between the liquid and the sensing cable is negligible and smaller than 1°C. In order to ensure a reliable detection of the leak, the self-heating cable is heat up and forced to change its natural temperature. Heating is provided by flowing electrical current in copper wires of the sensing cable. When forced to change temperature the cable will need a certain time to arrive at a certain temperature, defined as T-heating, and as well a certain time to go back in its initial condition. Studying the cooling transient and the value of the maximum temperature reached during the heating phase the analysis software figure out automatically if some events are occurring.

Fig. 3
Sensing cable installation at Grand Ethiopian Rennaissance Dam (GERD)

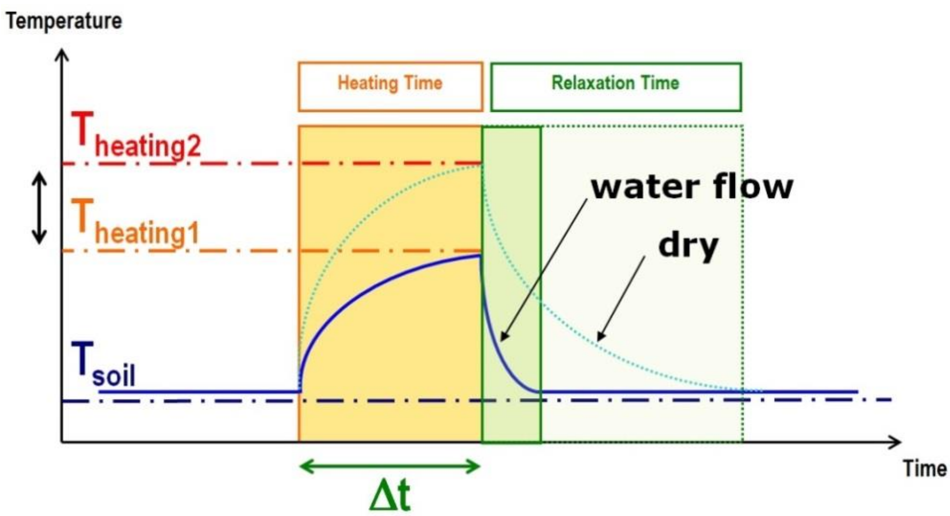

Fig. 4
DiTemp Heat Pulse Method working principle

As an example, a cable surrounded by still water will require more time to heat up, while a cable within flowing water will cool down more quickly.

3.4. APPLICATION: SIAH BISHEH UPPER DAM, IRAN

The Siah Bisheh Pumped-storage Hydroelectric Power Project is the first of this type in Iran. Located 125 km from Tehran it has an installed capacity of 1000 MW. The plant is intended to play a vital role in stabilizing the entire North Iran power grid, ensuring the safe operation of thermal power plants in the surrounding provinces.

The main aims of fiber optic instrumentation are seepage at plinth level and active detection system with Heat Pulse Method technique. Beside this direct detection, the monitoring system can offer an effective analysis of the evolution of the detected anomaly, and a way to define reasonable threshold and trigger alerts if they are overcome. Moreover fiber optic systems are easily integrated with already existing traditional / standard monitoring systems. Distributed sensing offers the unique capacity of locating precisely the event using only few distributed sensors.

Two independent systems are developed to monitor the existing dams. A dedicated control room where the instrumentation rack is located is specifically built on the crest of each dam (Fig. 5).

Fig. 5
Sensing cable installation at the plinth of the upstream face of the upper dam and one monitoring cabinet

The rack contains a display, the DiTemp unit with its accessories, the server PC where the analysis software is installed and the heating module necessary to heat up the cable at scheduled times. All the system is plugged into a network stabilizer and UPS in order to prevent general functionality in case of power failure.

Accuracy and repeatability tests were carried out during implementation phases (Fig. 6 and Fig. 7).

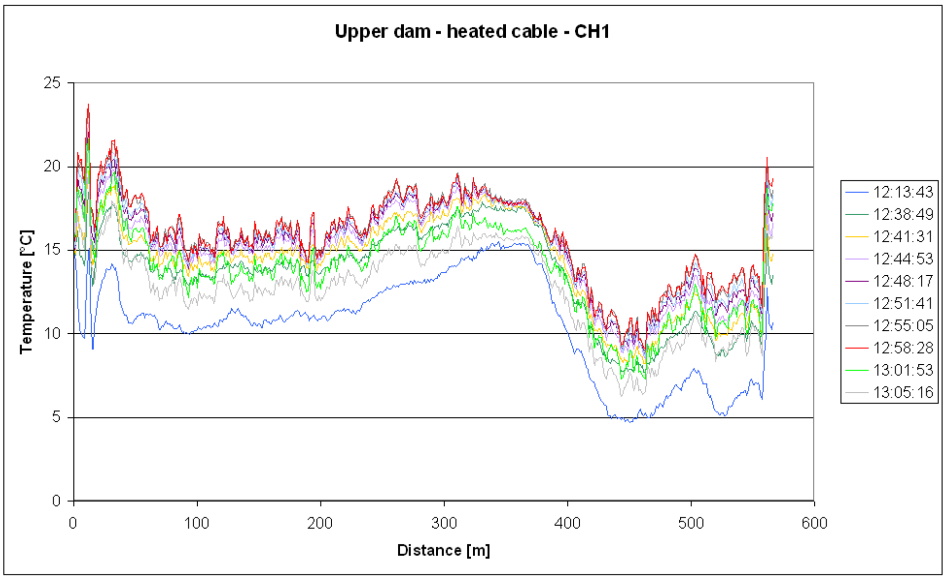

Fig. 6
Absolute temperature measurements during heating

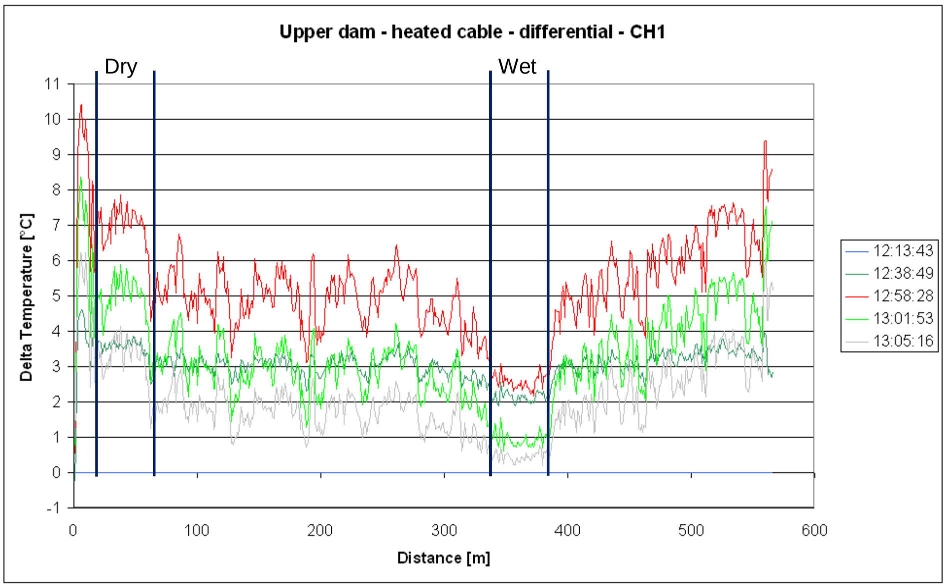

Fig. 7
Differential temperature measurements during heating

It is possible to evince how temperature resolution is about + - 0.2 °C. The initial section showing higher deviation refers in fact to cable section not yet concreted and exposed to the environment. Thanks to the customized visualization and analysis software it is possible to follow in real time any variation in the temperature profiles of the two sensing cable, launching a warning in case of any seepage or leakage.

4. DEFORMATION EARLY WARNING SYSTEMS

A fiber optic distributed system for deformation relies on Brillouin sensing and provides early detection of ground settlements and heaves, local cracks and internal erosion.

4.1. APPLICATION: I-WALL LEVEE – NEW ORLEANS (US)

The iLevees project ”Intelligent Flood Protection Monitoring Warning and Response Systems”, in the state of Louisiana, has the goal of providing an alerting and monitoring system capable of preventing early stage failure, both in terms of ground instability and seepage. The motivation for the monitoring system is to improve safety awareness, provide sensible information about levees’ status and conditions, before, during and after floods, and to avoid the tragic events like the ones that occurred following Hurricane Katrina in 2005. The project had the goal to monitor the levee wall, deformation and shear, and the surrounding soil, movements and water infiltration / seepage.

The particularity of the project was the installation technique adopted for the levee wall integration. In order to provide a good transfer of the acting forces from the wall to the sensor itself a good bonding strength shall be given: to do this it was decided to “cut” a groove all along the installed section, where the sensing cable was deployed and sealed by means of specific episodic resins (Fig. 8).

Fig. 8
Installation of sensor in a groove, on top of the levee wall section and in a trench

For the surrounding soil a more common ground embedding technique was chosen on the base of our previous returns of experience. Sensors are embedded between 0.5 and 1 m below the ground level, after compacting the trench, the sensors are deployed and covered with soft filling material. After this operation, the trench is back-filled and compacted.

An example of calculated deformation on the sensor placed on the top of the wall section I presented in Fig. 9. Deformation is plotted as a function of position along the wall and as a function of time.

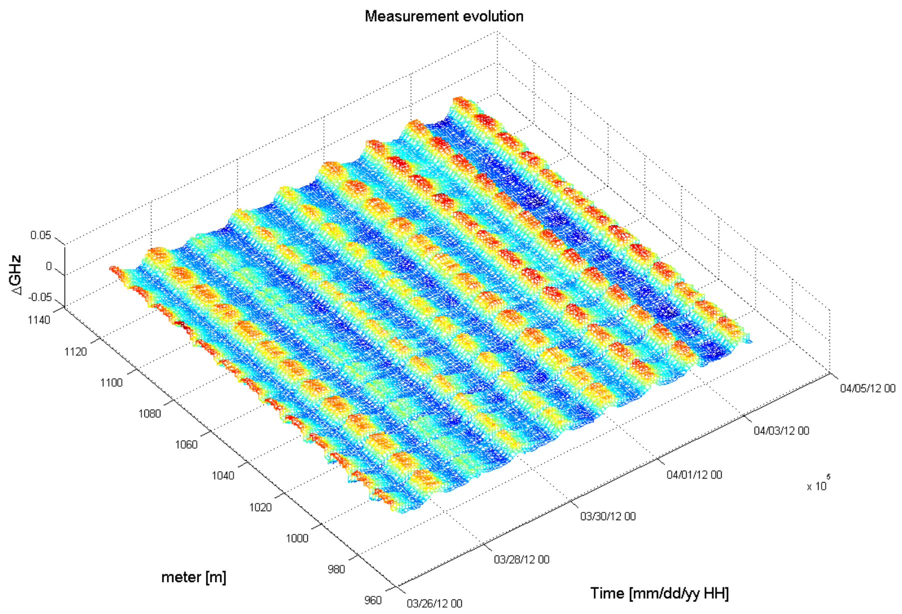

Fig. 9
Recorded deformations on a levee wall as a function of position and time

In the plot it is possible to observe the daily expansion-contraction cycles of the wall due to temperature fluctuations. It is also possible to localize the expansion joints along the levee wall that shows a different behavior. In case of an event along the levee section, a localized deformation peak will appear in the visualization software and would automatically trip an alarm.

4.2. APPLICATION: PENSTOCK MOVEMENT MONITORING PROJECT – NENDAZ (CH)

The penstock of an important mountain dam in the Swiss Alps, is subject to rock mass movements that can influence its mechanical performance (Jordan Papilloud 2015). In order to provide a safe installation, the penstock is made of several pipe sections welded together in order to form a more flexible pipe, thus allowing a higher degree of movement. Nevertheless a deformation monitoring system is necessary to detect any abnormal penstock deformation and penstock curvature. In addition to this, the penstock access tunnel is also affected by concrete cracking due to the water pore pressure and rock movements. A distributed strain monitoring system was selected because of its capability to monitor long lengths through a single cable, thus simplifying installation and increasing data density. A different installation technique is chosen for the 2 sections: in the penstock, where precise and accurate monitoring under water is required, the sensing cable (flat profile) is directly glued on the internal surface. The steel penstock is sand-blasted to offer a smooth and clean installation surface where 510 m, linear length, of sensing cable is glued along 4 different lines, Fig. 10.

Fig. 10
Strain sensing cable installation inside the penstock

On the other hand, for the access tunnel a mixed installation technique was selected: sensing cable was directly glued on concrete for most of its length, but fixed with stainless steel bracket where wide cracks were already visible and developing; this decision was taken in order to preserve sensor from breaking in case the crack keep developing, Fig. 11. This installation technique allows a precise and accurate monitoring over the whole length of this tunnel of approximately 70 m.

Fig. 11
Strain sensing cable installation on penstock access tunnel

After 3 years of monitoring, the collected results are in line and good agreement with the mathematical predictions and other geo-matic measurements provided by additional monitoring systems installed at site. A typical example of Strain distribution measured in the penstock access tunnel clearly shows the location of open developing cracks, peaks can be seen and easily localized along the sensing cable length, Fig. 12.

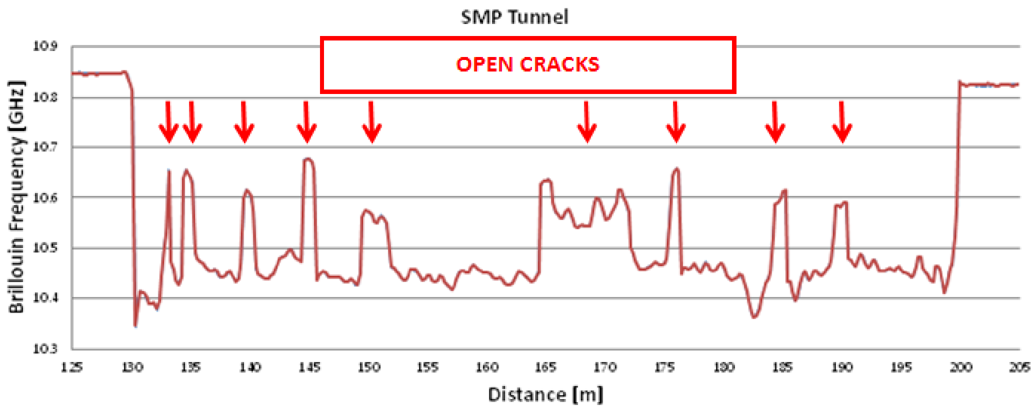

Fig. 12
Strain distribution measured along the penstock access tunnel

5. CONCLUSION

SMARTEC has instrumented more than 20 dams with fiber optic distributed sensing within the last 15 years. The use of distributed fiber optic sensors for the monitoring of civil structures and infrastructures opens new possibilities that have no equivalent in the conventional sensors system. Distributed sensing technologies have been applied on key hydraulic components such as penstock and waterlines.

Fiber optic distributed sensing is a recognized technology in dams engineering and meets todays goals of asset management. It overcomes limited capability of conventional sensors with reduction of maintenance expenses. Distributed sensing is often combined with fiber optic point sensors (temperature, piezometers) and data communications are fully compatible with plant DCS or SCADA system.

1. INTRODUCTION

Nowadays, the stepped spillway design has been widely used in many countries in the world due to the rapid development of RCC (Roller Compacted Concrete) dam which gives both structural and economical benefits. Although this concept existed for 3500 years (Chanson, 2010) the development is still growing from time to time. Peyras et al. (1992) mentioned that this type of spillway would gain economic mean approximately 20% compared to other types, the reason is because the ease of construction and design simplicity. Many studies has been done by several researcher specifically on this type of dam such as Rajaratnam (1990), Rice and Kadavy (1996), Yasuda and Ohtsu (1999), Chanson and Toombes (2002), Boes and Hager (2003), Gonzalez (2005), Takahashi et al. (2006), Hunt and Kadavy (2007, 2008), and Felder and Chanson (2008). Boes and Hager (2003) found that one of the advantages of this design is cheaper construction cost due to the decrease of stilling basin size. However, this concept has not been fully implemented in Indonesia. There are some weir structures that adopt this concept by using stepped shape on its spillway, however, it has not been implemented on dam construction.

Currently, the stepped spillway concept will be applied in Upper Cisokan Dam in Indonesia. The Upper Cisokan Dam is located at West Java Province on Cisokan River. Nevertheless, since this type of spillway is still new and has not been designed in Indonesia before, a physical model test is needed to be done to see the behaviour of the dam. We also found that research to study the pressure on dam spillway using pressure tranducer at hydraulic laboratory is still rare. The aim of this study is to have a proper design of stepped spillway which can be a good reference for further implementation of a stepped spillway. The experiments were conducted inside a hydraulic laboratory and the model covering the upstream reservoir, approach channel upstream apron of the spillway, dam, spillway and appurtenance structures (See Figure 1).

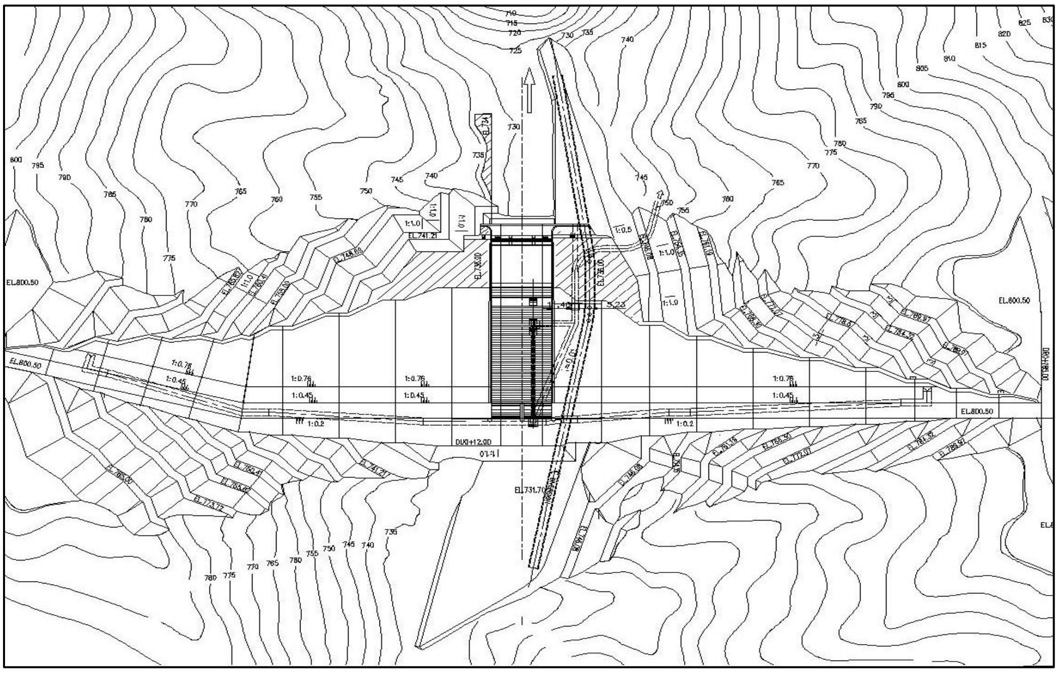

Fig. 1. Plan view of Upper Cisokan Dam

2. EXPERIMENTAL SETUP

The Upper Cisokan Dam spillway model is made as three-dimensional model covering the upstream reservoir, spillway and appurtenance structures (crest, chute channel and energy dissipator), and river in the downstream of the spillway. The experiment conducted at a hydraulic laboratory to observe the water profile, water pressure and scouring. The reservoir model in the upstream reach is made as a fixed bed model; it is constructed using of cement mortar and reproduced based on situation drawings. The reproduce upstream model is up to approximately 300 m upstream of the spillway. In particular for water pressure test, pressure transducers were installed inside the model to indicate the pressure measurement. In this experiment, there will be three scenarios; scenario 1 is the initial design where the downstream riverbed model is reproduced as a movable bed made by sand and left unprotected. Scenario 2 is a condition where the downstream protection material using stone riprap for downstream riverbed protection and arrange with u-shape. Scenario 3 is the condition where the downstream protection material is fully using stone riprap. The length of reach modelled is approximately 440 m downstream of the energy dissipator. The similarity in shape, dimensions, and roughness of the material in the prototype have closely resembled. It should be noted that the reproduction of shape and dimensions in the model is focussed in the shape and hydraulic measurements that influence the flow pattern and is intended to closely simulate the hydraulical field conditions as can be seen in Table 1. The geometric scale of Cisokan Upper Dam Spillway model is selected to be 1 to 33⅓.

Table 1
The Dimension of Upper Dam Spillway model

DIMENSION OF STRUCTURES	PROTOTYPE	MODEL
Height of dam	75.5 m	2.265 m
Width of dam crest	6.5 m	0.195 m
Height of spillway crest	71.50 m	2.145 m
Width of spillway crest	10.00 m	0.3 m
Height of end sill	21.2 m	0.636 m
Design discharge PMF	2.70 m	0.081 m
Design discharge 1000 years	300 m^3/s	46.77 m^3/s
Design discharge 100 years	185 m^3/s	28.84 m^3/s
Debit discharge 2 years	42.7 m^3/s	6.656 m^3/s

Fig. 2. Dam model in the hydraulic laboratory

3. EXPERIMENTAL OBSERVATION

3.1. WATER PROFILE ALONG THE SPILLWAY

Test of water surface profiles are conducted along the spillway, started from the crest through the stepped spillway and the energy dissipator using the design discharges. The water flow on stepped chute is known as the nappe, transition, and the skimming regimes (Yasuda 1997; Chanson & Toombes 2002). Based on the results, the flow from the crest spill smoothly and relatively well distributed, for low discharges the flow at the beginning of the steps are splash out of step, while for higher discharges the flow more smoothly over the stepped spillway. Since there are no changes in the upstream condition, the water profile is still the same in all scenario. Figure 3 shows that at the downstream of the center pier the flow is not smooth and splash over due to the rectangular shape of the downstream end of the pier.

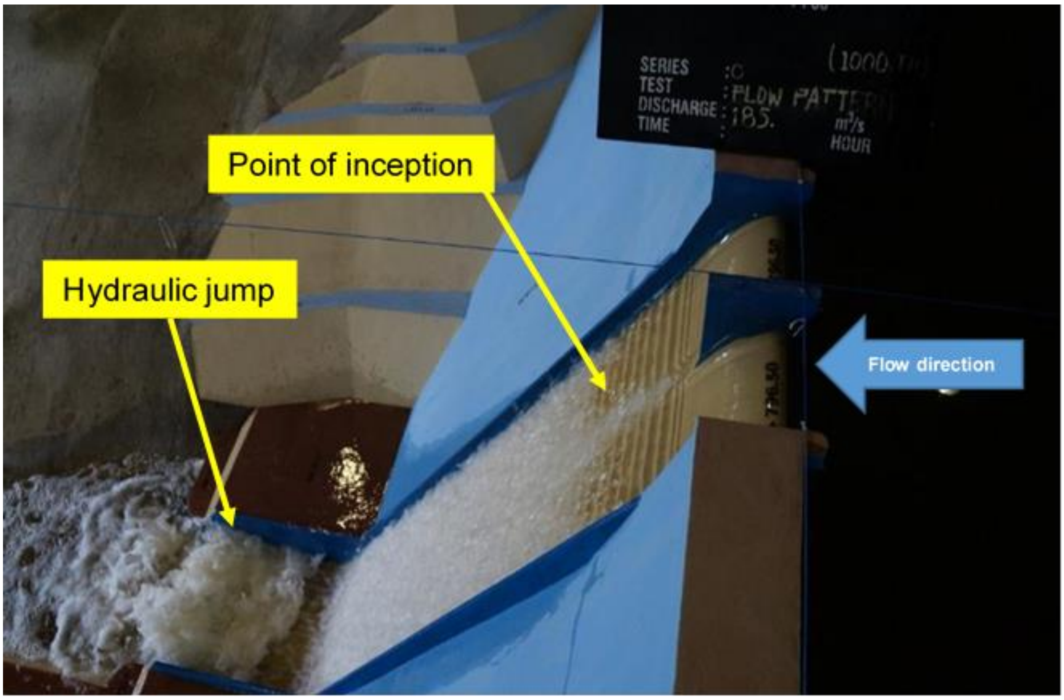

Fig. 3. Upper Cisokan spillway model with discharge $Q_{1000yrs}$

The inception point occurred and started to shift more downstream in regards of increased discharge from nappe to skimming regime. In particular for high discharge, the hydraulic jump occurred and seemed has not dissipated properly which may cause local scouring at downstream of the dam especially when the downstream area is not protected (see Figure 4).

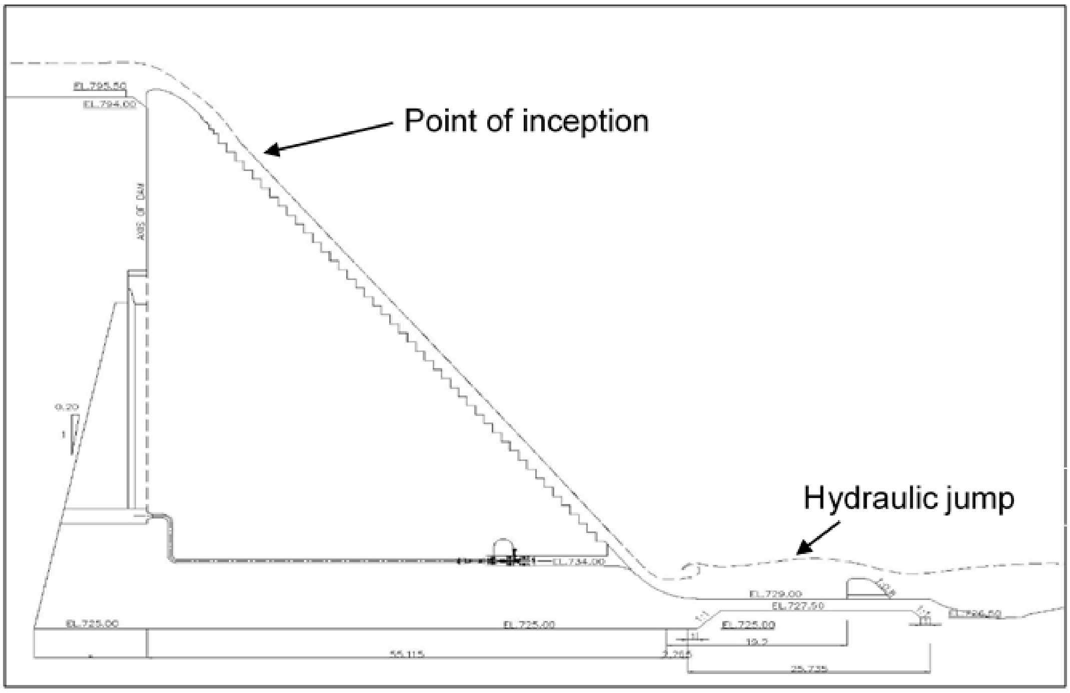

Fig. 4. Water profile with discharge $Q_{1000yrs}$

3.2. WATER PROFILE ALONG THE SPILLWAY

On this experiment, pressure transducers were installed on spillway to see the pressure characteristic during the observation using various discharges. The location of the transducers can be seen in Figure 5.

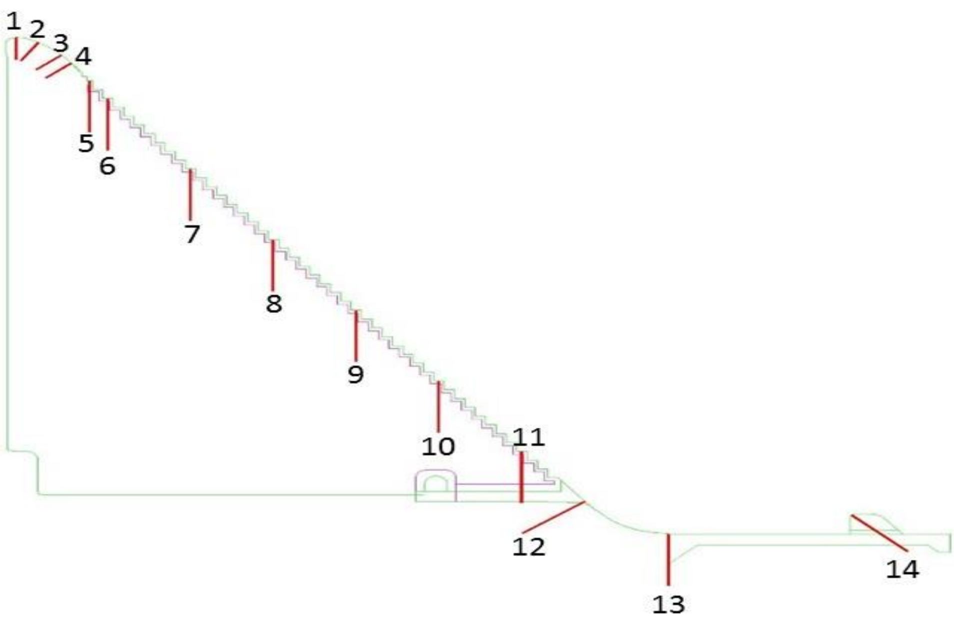

Fig. 5. Section view of pressure tranducer layout on dam spillway

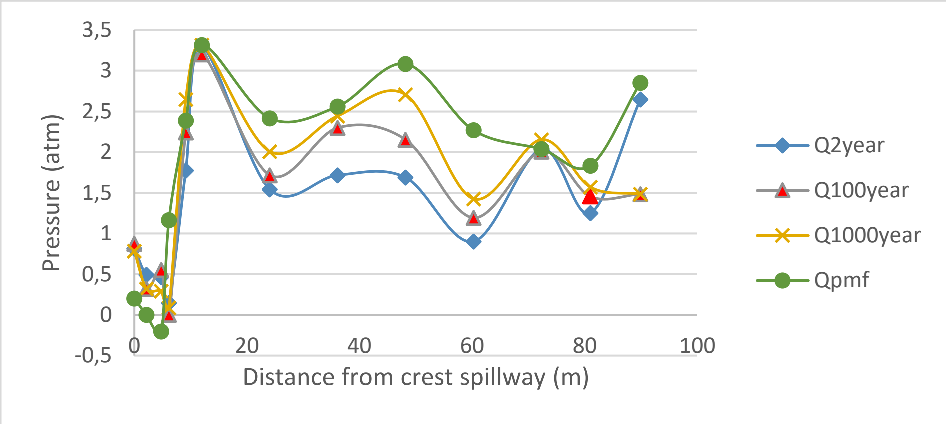

Fig. 6. Pressure distribution on dam spillway

Figure 6 indicates the pressure on each point of the location which described in Figure 5 where the transducers were installed. As can be seen that the pressure is vary along the spillway, some location has higher pressure due to turbulence and impact of the water with the stepped surface. The highest water pressure was shown at point 6 of tranducer location where the point of inception occurred. It is also found that negative pressure also occurred at point 3 of tranducer location where the transition zone from the smooth surface into stepped surface at Q_{pmf}. To avoid cavitation effects from this negative pressure, aerator can be implemented at the spillway to minimize the impacts.

3.3. SCOURING CONDITION

Scouring test were conducted for outflow discharge of period Q_{100yrs} = 133 m^3/s (See figure 7). Three scenarios were conducted, 1st scenario to study existing condition without downstream protection, 2nd and 3rd to study riprap protection.

Fig. 7. 1st scenario without downstream protection

Fig. 8. Upper Cisokan spillway model with discharge of Q_{100yrs}

Based on the experiment, the deepest local scour reaches –3 m measured from elevation El. + 729.00 m, located at the toe of downstream left and right wing walls as can be seen in Figure 9. This scouring phenomenon may harm the structure, therefore downstream protection is needed.

Fig. 9. Scouring condition at downstream of spillway (Scenario 1)

To minimize the scouring effect at downstream of the spillway, the kinetic energy dissipation needs to be optimized using stone riprap. Considering available material on site, stone riprap protection is recommended to use as downstream protection because there are many stone quarry. Scenario 2 was conducted at the laboratory, applying stone riprap with the diameter greater than 0,4 meters for downstream protection using U-shape pattern (See Figure 10).

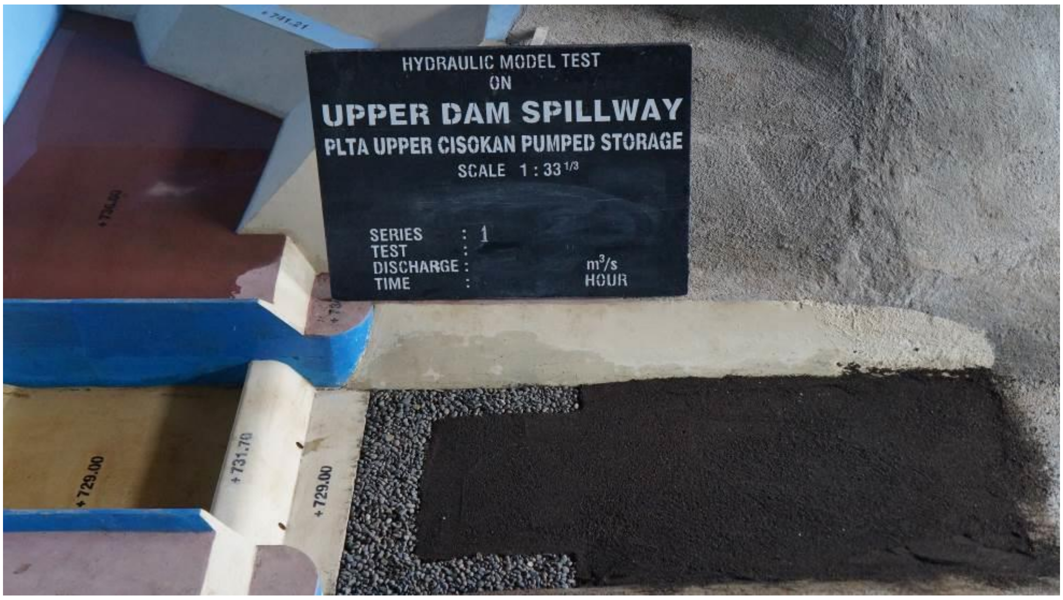

Fig. 10. Stone riprap for downstream protection (Scenario 2)

Various discharges applied to see the impact of the local scouring. According to the simulation results, there is a decline of maximum scouring depth from -3 meters in Scenario 1 to -1,5 meter in Scenario 2 as can be seen in Figure 11. This outcome shows that stone riprap protection is effective to use to reduce the impact of the scouring.

Fig. 11. Scouring condition at downstream of spillway (Scenario 2)

However, to protect and maintain the river bed downstream of the weir, Scenario 3 was applied by using fully stone riprap at downstream of the dam spillway. Based on the simulation, there was no scouring occurs (see Figure 12). Therefore, this condition can be preferred to be used as a final design of the dam in order to have a proper design of stepped spillway. Scouring comparison from 3 scenarios can be seen on Figure 13.

Fig. 12. Scouring condition at downstream of spillway (Scenario 3)

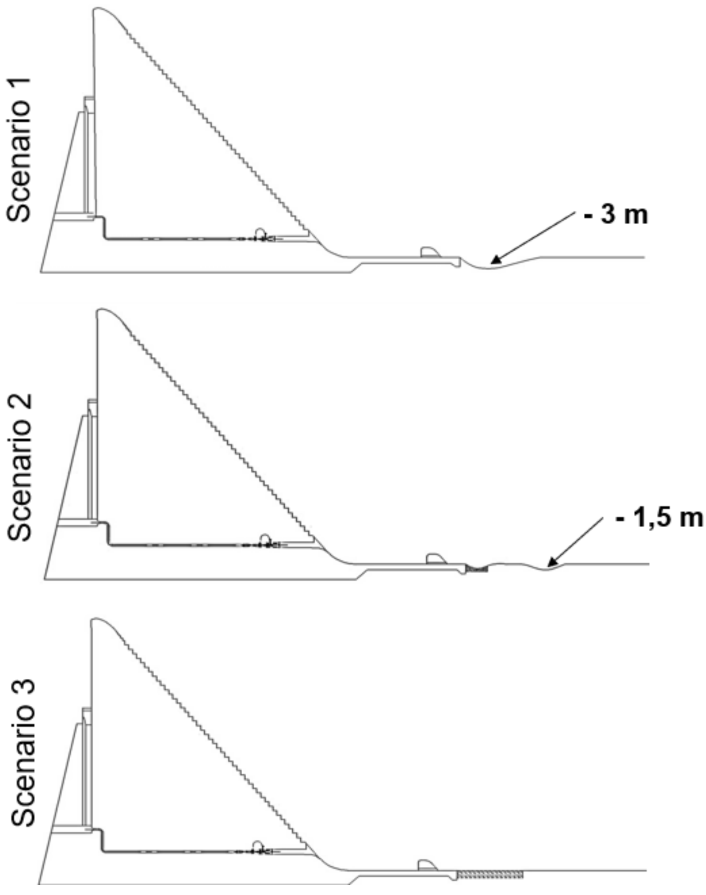

Fig. 13. Scouring comparison from different scenarios

According to the scouring results, scouring condition without downstream protection can be dangerous for the dam structure due to scouring problem. Downstream protection such as riprap can be a good solution for this issues as a transition zone from the massive structure and the river bed.

4. CONCLUSIONS

Upper Cisokan Dam was investigated using hydraulic laboratory experiments using various discharge. Based on the observation, it's known that water profile on stepped spillway at high discharge were dominant by skimming regime and already dissipated from the stepped chute to energy dissipator. Pressure distribution along the dam spillway is vary. It is also found that some negative pressure occurred. Therefore, if needed, aerator can be implemented to avoid cavitation effect. Based on its Froude number, the energy still not fully dissipated by the energy dissipator downstream of the spillway which may cause scouring. Hence, downstream protection such as riprap is needed to minimize the scouring effect. The final simulation shows that the stone riprap protection is effective to use to reduce the depth of the scouring from 3 meters into 0 meters. Ultimately, the stepped spillway can be implemented on the Upper Cisokan Dam after adding some additional treatment such as aerator and riprap protection.

5. ACKNOWLEDGEMENTS

The author also would like to thank Mrs. Yiniarti Eka Kumala for her valuable assistance that helped to improve the quality of this paper. Also for colleagues at Hydraulic Laboratory, Research Center for Water Resources, Ministry of Public Works and Housing for the support and opportunity to conduct dam investigation.

REMOTE INSPECTION OF SMALL DAMS AND LEVEES*

Bill SHERWOOD

Business Development, ASI MARINE, ST. CATHARINES

CANADA

1. INTRODUCTION

Inspections of small dams can present challenges that hinder comprehensive condition assessment. These can include health and safety of personnel, limited access to the inspection area, and water conditions. Each project brings unique complexities, so is important to assess and consider a range of technology and equipment. In this paper, we will review a project where methodology was amended to suit site conditions.

2. METHODS

The original proposed solution to complete this specific dam inspection was to utilize an inspection vessel equipped with sonar systems for data collection. However, as water levels were discovered to be too low for vessel operations, an alternative solution was required. Therefore, a comparative study of technology and equipment suitable for the project was analyzed. In the end, the project involved design and fabrication of an unmanned surface vessel (USV), which was identified as the safest and most adaptable platform for site conditions.

3. RESULTS

The result was an inspection that provided high-resolution georeferenced bathymetry expressed as point cloud data, crack detection, and spall crack size.

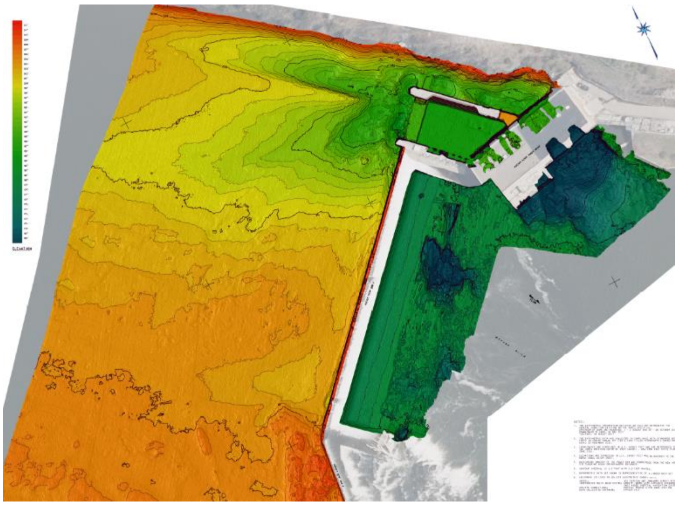

Fig 1. Bathymetric Contour Map of Dam Reservoir and Spillway

4. CONCLUSION

Underwater survey sites can present unique challenges, especially near dams where water level conditions can change dramatically. In the case of unforseen low water, access to key shallow areas can become impossible using manned vessels or even ROVs, both of which require sufficient draft to manouver. In the case of personnel on the water, safety is of course the primary concern. Shallow water is still dangerous. Work vessels can strike rocks or become grounded. It only takes about 20 cm of swift moving water to knock someone off their feet. Cold water only adds to the dangers. Additionally, sensors need to be deployed as close as is practicable to the water surface, and ROVs and the underwater portion of the hull of manned boats would partially block the sensor field. This would require additional manouvering to ensure coverage of shadow areas.

The USV solved these problems firstly by removing most of the danger to human life. Shoreside safety precautions were no less important, but overall the field aspects of this program was far safer and more efficient. Additionally, data collection was done more efficiently and to a higher consistent standard.

1. INTRODUCTION

Prestressed rock anchors have been installed in dams throughout the world since 1934. In the U.S., the first installation was in 1964. Since then, well over 400 case histories have been recorded by the authors [1] [2] [3]. Practice has evolved over the years, governed by, and reflected in, successive editions of the Post-Tensioning Institute's "Recommendations" documents. Since 1996, virtually all projects have been completed using what may reliably be referred to as "Permanent" anchor systems (i.e., with PTI Class I Protection) and responsive drilling, water testing, and grouting methodologies. However, older-vintage anchorage systems did not generally include corrosion protection systems which would be acceptable today, and did not generally provide the means to measure residual load or the state of corrosion in-situ. This is a challenge facing dam owners throughout the world, since early anchor technology was largely driven by a limited number of European post-tensioning suppliers operating internationally.

* COMMENT TRAITER LES ANCRAGES PRÉCONTRAINTES DE VIEILLISSEMENT DANS DES BARRAGES : UNE PERSPECTIVE NORD-AMÉRICAINE

2. THE EVOLUTION OF CONTEMPORARY PRACTICE

2.1 Referenceable Standard of Care

There is no standard, per se, for rock anchoring in the U.S. However, the current governing document is “Recommendations for Prestressed Rock and Soil Anchors,” Fifth Edition, 2014, published by the Post-Tensioning Institute [4]. This document, like its predecessors, was developed by a Committee of industry specialists and practitioners, an equal blend of consultants, contractors, suppliers, and regulators/ clients (Table1). The previous four editions (1980, 1986, 1996 and 2004) were in fact preceded in 1974 by the “Tentative Recommendations” document for the Prestressed Concrete Institute which, as the breakdown of Table 2 clearly illustrates, was principally a marketing and sales tool whose goal was to present illustrated applications to expand sales volumes of prestressing steel.

In this regard, it may be noted that, in the earlier days of practice in the U.S., anchoring was a technique pioneered by the post-tensioning suppliers themselves, subcontracting out to specialty geotechnical contractors the “dirty bits,” i.e., the actual drilling, water testing, tendon placement and grouting processes. This tendency was reversed by the early 1980’s: in the U.S. the geotechnical contractors win the projects, buy the steel and frequently rent the prestressing equipment.

Again it is reiterated that industry operates under a set of “Recommendations” provided by an ad hoc committee of a Trade Association, i.e., the Post-Tensioning Institute. However, for liability reasons, industry treats the Recommendations virtually as a standard, and it is very rare for any significant deviation to be found in Specifications or associated Method Statements. In the authors’ experience, the “Recommendations” constitute excellent, comprehensive and practical guidance, and stand in very favorable comparison with more rigorous European standards and guidelines.

The Recommendations do not provide guidance on the analysis or overall design of an anchored structure (e.g., selection of number and capacity of anchors, their length, spacing and inclination), for that is the responsibility of the Engineer-of-Record, using well established methods of rock mechanics and structural engineering. The Recommendations address the design, construction, testing and performance of individual anchors.

2.2 EVOLUTION OF PRACTICE

This is covered in detail in the papers contained in the References, and only a very brief summary is provided hereunder, insofar as the points have relevance to the assessment of aging anchors.

2.2.1 Design

Excluding, for the moment, the critical issue of corrosion protection, it may be concluded that most key elements of design have been little changed over the years, and so remain as described in Littlejohn and Bruce’s State of the Art Study [5]. It is tacitly assumed that load transfer mechanisms in and around the bond length are based on uniform bond distribution. Although inaccurate, this is a conservative assumption.

2.2.2 Construction Practices

While most drilling was done in early projects by coring (for fear of somehow damaging the dam, and to extract samples of bedrock in the bond zone), current drilling practice features rotary percussive methods, and especially Down-the-Hole Hammers (DTHH). Grout mix designs, grout blending (in a high speed, colloidal mixer) and placement (always via tremie) have changed only insofar as equipment has improved. Water pressure testing (and pregrouting if necessary) has always been of a high and conscientious standard, and this is of great importance when trying to evaluate the reliability of legacy anchors.

Equally important are the changes to the grouting/stressing sequence:

(i) Prior to the use of sheathing on the free length of the tendon components, the sequence was:
   - drill, water test (and pregrout and redrill if necessary),
   - place the tendon,
   - grout the bond zone,
   - stress, test and lock-off,
   - grout the free length.

(ii) After the use of sheathing on the free length of the tendon components, the sequence was:
   - drill, water test (and pregrout and redrill if necessary),
   - place the tendon,
   - grout the tendon completely,
   - stress, test and lock-off,
   - complete underhead grouting.

Most of the early anchors had tendons comprising a multitude (“bundle”) of 6 mm diameter wires (Figure 1). These wires were typically fully bonded to the concrete of the dam by the free length (secondary) grouting after prestressing and lock-off. Thus, such anchors have only grout for corrosion protection and cannot be lift-off tested to establish residual load in the tendon.

2.2.3 Stressing and Testing

Early stressing and testing procedures were surprisingly simple (given the sophistication of the original European post-tensioning specialists), and remained so in the U.S. until the 1996 Recommendations. Thus, it is typical that legacy anchors were quickly stressed to the Test Load in progressive steps, held there for a short period (but without a quantified creep criterion) and then destressed to the lock-off (or “transfer”) load. The benefits of progressive cycle loading, with well-defined criteria for creep and elastic analyses, cannot be exploited when evaluating contemporary records of legacy anchors, while Lift-Off Testing was optional and, in any case, of quite short-term duration (say 48 hours).

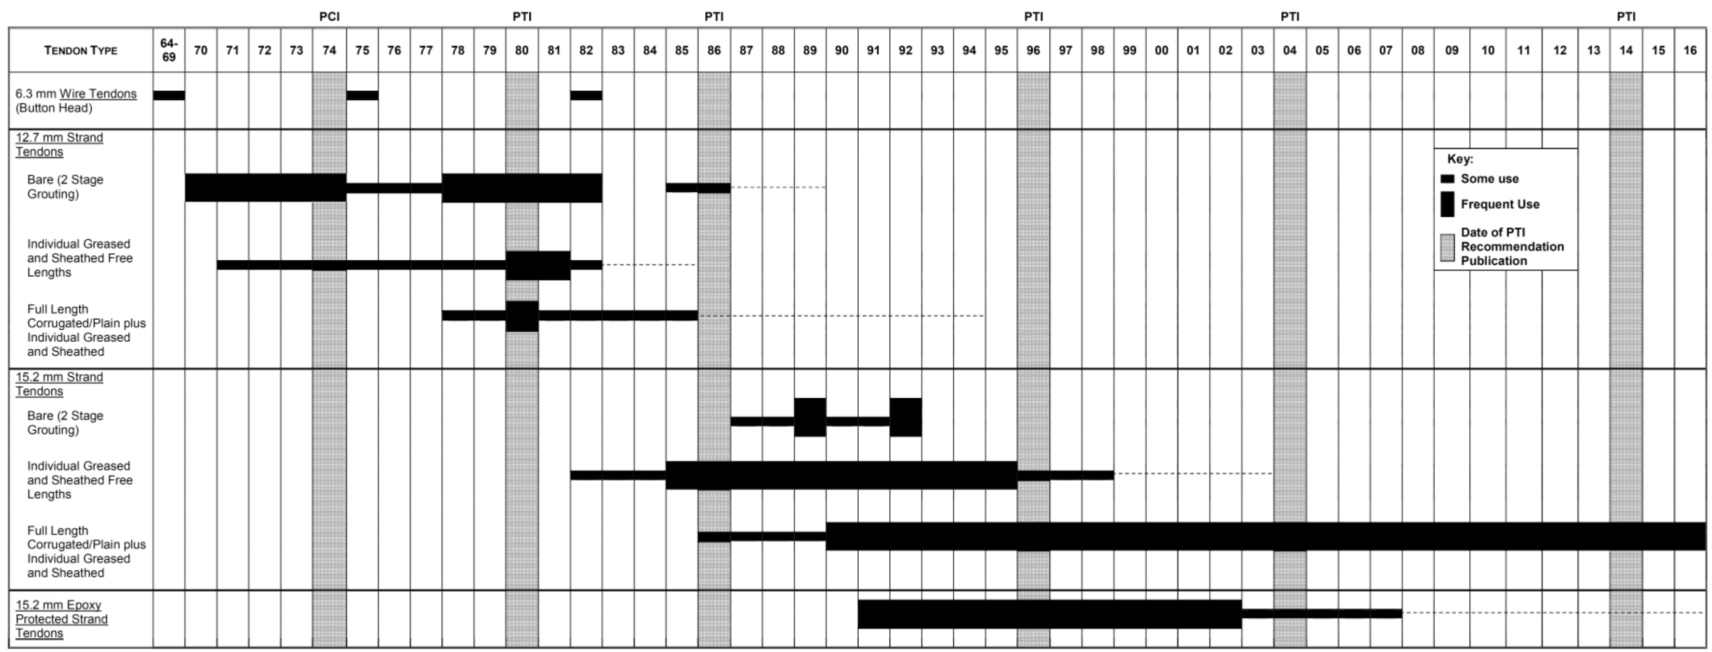

Fig. 1

The use of different tendon and corrosion protection types with time in N. American dams.

Note: Bar tendons have also been used in lower capacity anchors since the 1970's, with varying degrees of corrosion protection.

2.2.4 Corrosion and Corrosion Protection

References [1] and [2] provide an analysis of the PTI Recommendations to that point (i.e., including the 2004 version) and a summary of over 400 individual case histories. Note that the provisions of the PTI 2014 edition are sensibly the same as in 2004, while the database has recently been further updated [3]. It is extremely important in the context of legacy anchors to gain perspective of contemporary attitudes, and the development of these attitudes with time.

In summary, the anchor grout itself was regarded, during the early decades of practice, as an acceptable barrier to corrosion, for both the bond and free lengths. It was only with the 1996 version of the PTI Recommendations that full-length protection by at least one plastic sheath was required for permanent anchors, i.e., Class I protection, so matching contemporary standards of care in Europe (Figure 1).

3. CHALLENGES TO EVALUATING LEGACY ANCHORS

There are many challenges relating to the design and the construction of such anchors, and to practical/logistical aspects of condition assessment. These challenges are common to dam Owners and Regulators throughout the dam anchor world.

Firstly, it is clear that the majority of dam Owners and their consultants simply did not contemplate at the time of design and construction that long-term monitoring would be advantageous, let alone fundamental to risk management. The general philosophy was that anchors designed and constructed to the standards of the day would not corrode since the steel would be encased in grout, and placed into boreholes whose immediate proximity was pregrouted (to prevent water ingress and to prevent anchor grout loss). The anchor head itself was generally encased in concrete. Further, in acknowledgement that the tendon would naturally suffer long-term stress loss (principally due to relaxation), the post-tensioning specialists selected Lock-Off/Transfer Loads, which included an allowance for these losses, the magnitude and rate of which were well known from structural post-tensioning projects. Such elevated tendon stress levels, while (usually) still within the elastic response range (i.e., ≤ 80% fpu), would however increase the tendency for stress-induced corrosion to be initiated or accelerated under certain conditions. No provisions were made for installing restressable anchor heads.

Secondly, it was exactly these old methods which have now rendered lift-off testing unfeasible: without a developed free length, it is impossible to directly measure the residual load in the tendon, or to determine its distribution within the free length or, of course, the bond length.

Thirdly, it is often the case that the anchor heads are, for all practical purposes, inaccessible for any type of inspection or testing. In some cases, the functional anchor heads could be rendered accessible, but there would be a natural reticence to “probe too deeply” for fear of disturbing the anchor head – not so much from a load holding viewpoint, as the tendon is fully bonded below, but from the corrosion protection viewpoint. This is particularly the case with legacy anchors which do feature a greased and sheathed coating as a bond breaker to preserve the true free length even when surrounded by grout. In this case, the load is still maintained by the gripping wedges in the head (in the case of strands), or by the lock nut (in the case of bars), and attempts to expose such heads, or indeed to attempt, somehow, a lift-off test, would be inviting trouble.

Fourthly, strain gages or load cells of adequate reliability were simply not available to provide long-term monitoring capability, and indeed are still not available today. Compounding this issue is the stark fact that there is still no completely reliable, calibrated NDT Method that can be used to check the residual load, or the integrity, of wire or strand tendons, fully grouted or otherwise. It may be noted, however, that some recent methods are showing promise for bar tendon assessments.

Fifthly, contemporary construction records may not always be available for review and, even if they are, they may not contain vital pieces of information, the clues to the likely adequacy of the construction details to preventing long-term corrosion. A case in point here would be the static (bleed) and dynamic (pressure filtration coefficient) stability properties of the grouts: if either property were deficient, then bleed pockets would develop, especially in the tightly arranged "bundles" of wires so common in early legacy anchors.

Sixthly, it is not uncommon for Owners to consider somehow exhuming production anchors and then closely examining the tendon for signs of corrosion. Exhumation is feasible if the dam is being deconstructed for decommissioning. This is a relatively rare occurrence and of course is not an option for evaluating legacy anchors in dams required for extended, long-term service. Alternatively, it is technically feasible – if sufficient access exists to allow for the mobilization of a major piece of drilling equipment – to overcore the entire anchor and remove it for inspection. However, this is a very difficult and typically costly option since the drilling method must be precisely colinear with the anchor, and the tendon will not permit the anchor to be removed in convenient "runs," for example, of 1.5 or 3.0 m. Furthermore, the grout is typically damaged or lost in the drilling process, and the concern will remain if the particular anchor removed is actually representative in its condition of the others, or if any localized corrosion-induced damage will indeed be recognized.

As a final point, it is easy to be critical of the contemporary standards used in the design and construction of legacy anchors. However, at the time of their installation, design lives of 25-30 years were considered satisfactory, whereas some of these installations are now over 50 years old. "Modern" anchors (with Type I Corrosion Protection) are children of the late 1990's, and a great deal of knowledge has been accumulated since then fuelled, in part, by our current attitudes to risk assessment such as inherent in the Potential Failure Modes Analysis process.

4. KEY FACTORS IN RISK EVALUATION DURING A PORTFOLIO RISK ASSESSMENT PROCESS

In the case where an Owner is responsible for a number of projects dependent for stability on prestressed rock anchors, it is logical and essential to conduct a preliminary screening process to identify and prioritize the most worrisome projects. This is akin to the process first adopted by the U.S. Army

Corps of Engineers in 2005-2006 to allocate a Dam Safety Action Category (DSAC) number (I to VI) to each of its portfolio of over 600 structures. This categorization process then allowed attention to be paid to the “worst first” dams (i.e., DSAC I) in terms of the need for Interim Risk Reduction Measures (IRRM’s) to be emplaced pending the design and construction of Permanent Risk Reduction Measures in the form of Dam Safety Modifications (DSM’s). For the typical dam Owner, the number of dams to be evaluated can be reasonably covered by the same dedicated team, so assuring a very even-handed, and uniform quality of assessment of the portfolio. Such an approach has recently been adopted widely, including as an important example, by the Tennessee Valley Authority.

The Portfolio Risk Assessment process for aging anchors in N. America is a desk study in which the following steps should be taken, in sequence:

Step 1. Determine the date of anchoring, and the edition of the PTI (or ACI) Recommendations under which the anchors were installed. The following risks can be allocated as a “first cut”:

- All anchors installed prior to PTI (1986): High Risk
- Anchors installed 1986-1996 prior to PTI (1996): Moderate Risk
- Anchors installed post-1996 after PTI (1996): Low Risk

It should be noted that practitioners often continue to use an “old’ edition of PTI for say 2 years after the “new’ edition has been issued. So it would be prudent to amend the “High” category limit from 1986 to 1988, and the “Moderate” category from 1988 to 1998.

Step 2. Beginning with the oldest anchor project in the High Risk Group, very carefully examine all historical records for that project. In particular, the type of tendon (wire, bar, or strand) and the type of corrosion protection (if any, other than cement grout) should be identified. In addition, whether or not a free length actually remains or whether the free length steel is fully bonded to the concrete should be established, together with an understanding of the anchor head protection detail.

Anchors installed with no corrosion protection other than the grout are highest risk, together with anchors whose heads were encased in material other than grout or concrete (e.g., grease, or indeed without any protection). Anchors with no remnant free length, as typified by the multiwire “button head” tendons, cannot have their integrity or residual load measured, even if the heads are accessible.

The source details include the project specifications, the contractor’s method statement and construction records, construction photographs, and any information or observations on post-construction testing or performance.

For High Risk anchors, without sheathing or coating on the free length, a consideration of the intensity and quality of the pregrouting should be conducted. If none were conducted, the risk of long-term corrosion occurring is greater than if intensive pregrouting had been conducted.

Step 3. Beginning with the prioritized list created by Steps 1 and 2, review the original overall anchor design to judge exactly how vital the anchors are to overall stability, and how much overall prestress can be lost (to corrosion, relaxation and creep) before the structure does not meet contemporary standards of care, for sliding and/or overturning, or other loading conditions.

Step 4. Focusing, then, on the “High Risk” list created by Steps 1-3, the Owner/ Regulator must then make a risk-based decision regarding actions to be taken on these projects. Owners with a very low risk tolerance will elect to ignore the legacy anchors and replace them entirely (if space and access permit).

Owners who can tolerate a higher risk may elect for either partial replacement, or indeed for no further post-tensioning at all, and some type of “observation” strategy.

Step 5. Once the “High Risk” projects have been evaluated thus, then the same process can be applied to the “Moderate Risk” projects. Such projects may also afford the possibility of conducting lift-off tests provided the free length is sheathed, the anchor head is accessible, and the field testing will not adversely affect the structural performance of the locking assembly (especially for wedges for strands) or its corrosion integrity.

This process is summarized in the flow diagram (Figure 2) which focuses on high risk legacy anchors. Thus, a project which scores “high-high-high-high-high” in each risk category will have a more urgent need of further action/evaluation, than one which scores, for example, “high-high-high-moderate-low.” This figure only shows the flow path for the highest risk anchors.

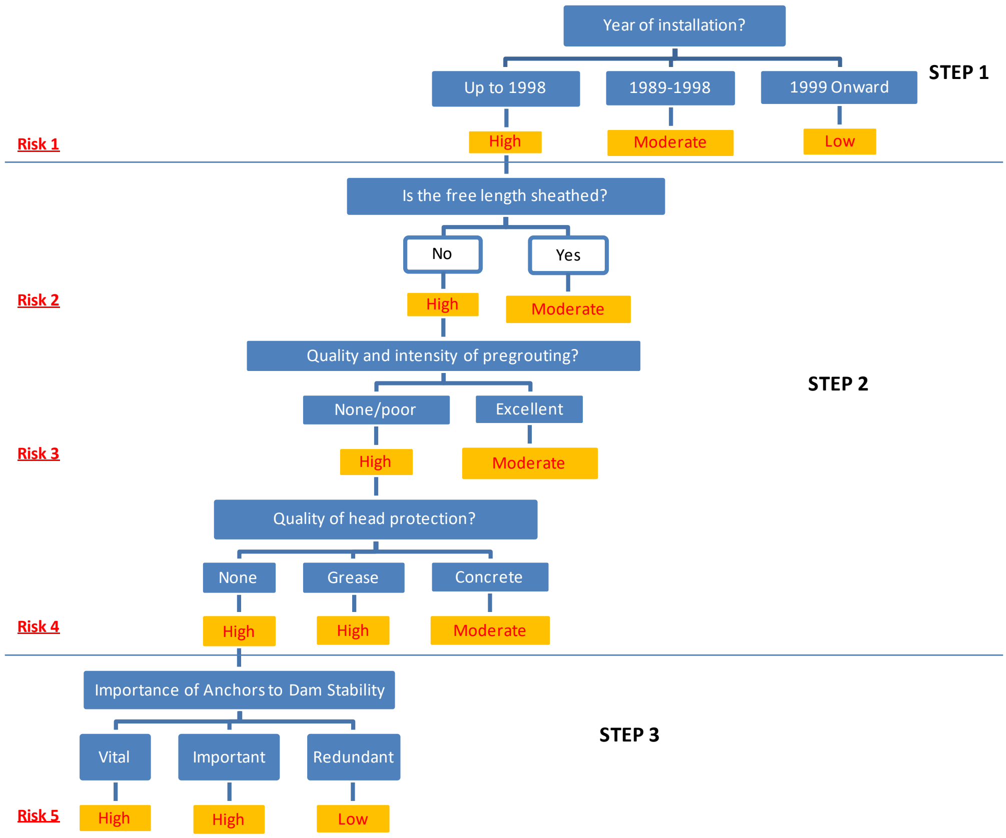

Fig. 2
Flow chart for screening portfolio risk assessment of aging anchors.

SUMMARY

The evolution of practice in the design and construction of prestressed rock anchors for North American dams is described. This provides background to the problem of assessing the reliability of aging anchors, principally those installed prior to 1996. This review is based on the results of a study of over 400 case histories of projects completed since 1964.

L’évolution de la pratique courante en conception et construction avec ancrages précontraints dans le roc pour les barrages nord-américains est décrite dans cet article. Il fournit le contexte du problème d’évaluation de la fiabilité des ancrages en service, majoritairement ceux installés avant 1996. Cette revue s’appuie sur plus de 400 études des cas des projets achevés depuis 1964.

1. INTRODUCTION

With global climate change, extreme events such as floods，rainstorm，typhoon，earthquake are frequent nowadays. Ten floods occurred in Yangtze, Huanghe, Huaihe, Zhujiang, Songhuajiang Rivers and 20 sub-rivers encountered extra-history floods in 2017. There are 27 typhoons in western pacific and 8 numbers landing on China in 2017. There are 8 times of earthquake extra 7 magnitude in the world and 19 times of earthquake extra 5 magnitude in China.

The above extreme events may lead dam incidents or even failure. More than 2000 reservoir dams were damaged following the Wenchuan earthquake of magnitude scale 8 in May 12, 2008. More than 3000 dams breached since 1954 in China. Overtopping, abnormal seepage, structural instability and earthquake are common dam accidents and major unexpected events.

2. EMERGEMCY MONOTROING

Dam safety monitoring following the unexpected events and accidents is essential for emergency action, which prevent or mitigate hazard, emergency inspection, monitoring techniques for the above extreme events and probable accident are studied below.

2.1. PRINCIPLE

Emergency monitoring should be rapid and efficient. The hereinafter should be followed.

(1) A detailed inspection and monitoring plan should be made in advance based on the dam danger type, dam danger consequences and risk degrees. The inspection and monitoring should be combined, and the related monitoring items should be monitored synchronously.

(2) Portable monitoring equipments should be the first selection for emergency monitoring, and the layout of monitoring equipments should be accessible and convenient. The technical performance of monitoring equipments can meet the requirements in extreme conditions. The installation of the instruments should minimize the impact on the safety of the project and avoid aggravating the occurrence of emergencies.

(3) The emergency monitoring methods should be fast, simple, practical, accurate and reliable. The automatic observation should be adopted to improve the efficiency and frequency of the monitoring if it is possible.

(4) The emergency monitoring frequency should be determined by the development speed and degree of the emergency, and the variation of observation values should be monitored. When the degree of emergency became more serious, the monitoring frequency should be increased.

(5) Information of the record should be normative and integrated, including emergency types, emergency degrees, weather conditions, monitoring items, monitoring methods, monitoring frequency, monitoring date, monitoring value, etc. Monitoring data analysis should focus on comparison of historical data and data after the occurrence of events.

2.2. DAM UNEXPECTED EVENT GRADING

Four grades of dam unexpected events are classified according to emergency degree and hazard consequence. The classification standard in China is show in Table 1. When the dam unexpected events grades determined by different standards are inconsistent, whichever is the highest.

Table 1
The classification standard of dam unexpected events

Grade Ⅰ	Grade Ⅱ	Grade Ⅲ	Grade Ⅳ
Reservoir water level surpass maximum flood level	Reservoir water level surpass design flood level	Reservoir water level surpass top of level of flood control	Reservoir water level surpass level of flood control
Fatal incidents uncontrolled, probably failure	Fatal incidents but can be controlled	Serious incidents convenient-controlled	Ordinary incidents convenient-controlled

Grade Ⅰ	Grade Ⅱ	Grade Ⅲ	Grade Ⅳ
More than 30 death loss	10~30 death loss	3~10 death loss	Less than 3 death loss
Economic loss more than 100millions RMB	Economic loss between 100millions and 50millions RMB	Economic loss between 50millions and 10 millions RMB	Economic loss less than 100millions RMB
Extraordinary serious social and environment impacts	Serious social and environment impacts	Greater social and environment impacts	Ordinary social and environment impacts

2.3. MONITORING ITEM FOR THE UNEXPECTED EVENTS AND ACCIDENTS

2.3.1. OVERTOPPING

Floods, insufficient discharge spillway, malfunction of gates, blocks on spillway may lead dam overtopping. Inspection should be focused on spillway, gates, and unstable slopes around spillway. Unmanned aerial vehicle (UAV) may be applied. Water level, rainfall, inflow and outflow discharge, deformation, seepage pressure and seepage discharge should be monitored, which is shown in Table 2. Spillway pulverization should be monitored during flood discharge.

Operation management problems such as gate and hoist can't work normally and spillway blocking problems resulted from big volume floater and spillway slope instability are major reasons for overtopping and even dam failure of embankment dams. Therefore, according to the weather forecast, when an extra-standard flood occurred, reservoir management department should immediately check that whether the dam, the bank slope close to the dam and the spillway slope have signs of erosion, crack, collapse and slide. Condition of the drainage facilities should also be checked, including whether the gate and the hoist can work normally, whether the spillway is blocked or not. The monitoring items for flood overtopping dam failure mode include water level, rainfalls, inflow and outflow discharge, deformation, seepage pressure, seepage discharge and discharge flood pulverization. Among them, water level, rainfalls, inflow and outflow discharge are the key monitoring items, while deformation and seepage are the important monitoring items, and other monitoring items can be monitored in a synchronized manner according to the actual situation.

Compared with satellite remote sensing and manned aircraft remote sensing, unmanned aerial vehicle(UAV) remote sensing technology has real-time transmission of large-scale image data, which is suitable for emergency inspection under flood condition.

In order to avoid the occurrence of overtopping, the flood water should be released by open the gate in time. But the pulverization caused by the flood discharge will affect the stability of the slopes on both sides of the spillway, so it is necessary to monitor the discharge flood pulverization.

Table 2
Emergency monitoring items for flood overtopping

2.3.2. ABNORMAL SEEPAGE AND STRUCTURAL INSTABILITY

Abnormal seepage and deformation may occur in dam. Variation of tendency should be more concerned during inspection and monitoring. Monitoring items for corresponding items are shown in table 3. Monitoring data should be analyzed in time.

Table 3
Emergency monitoring items for abnormal seepage and structural instability

2.3.3. EARTHQUAKE

The damages caused by earthquake are related with earthquake magnitude and distance from epicenter. ICOLD bulletin “Inspection of dam following earthquake guidelines” notes that dams around 25km, 50km, 80km, 125km and 200km from earthquake epicenter should be monitored for corresponding earthquake magnitude of 4.0, 5.0, 6.0, 7.0 and 8.0. Little dams are damaged below 4.0. Dams will be damaged seriously if magnitude in more than 7.0. Crack, leakage, structural deformation and landslide are the major seismic hazards .The monitoring item is shown in table 4.

Table 4
Emergency monitoring items following earthquake

2.4. MONITORING FREQUENCY FOR DIFFERENT ACCIDENTS

Monitoring frequency are suggested as the table 5 for overtopping, abnormal seepage and structural instability, earthquake.

Table 5
Emergency monitoring frequency for 1 day

Number	Monitoring item	Emergency degree			
		I	II	III	IV
1	Inspection	1	1~2	2~4	2~4
2	Water level	1~2	2~4	4~8	8~24
3	Rainfalls	1~2	2~4	4~8	8~24
4	Inflow and outflow discharge	1~2	2~4	4~8	8~24
5	cracks	1	1~2	2~4	4~8
6	Superficial deformation	1	1~2	2~4	4~8
7	Landslide surface deformation	1	1~2	2~4	4~8
8	Seepage pressure	1~2	2~4	4~8	8~24
9	Seepage discharge	1~2	2~4	4~8	8~24
10	Underground water level	1	1~2	2~4	4~8
11	Discharge flood pulverization	As required	As required	As required	As required
12	Seismic acceleration	Real time	Real time	Real time	Real time

Notes：Emergency degree include four levels namely Ⅳ, Ⅲ, Ⅱ, Ⅰ, ranging from low to high according to the degree of urgency and consequence.

3. CONCLUSION

(1) Dam emergency monitoring should be quickly and effectively, and combined with inspection. Emergency monitoring will not only consider increasing the monitoring frequency of existing monitoring facilities, but also consider the addition of temporary monitoring facilities for new dam deficiency. Monitoring data analysis should focus on comparison of historical data and data after the occurrence of unexpected events. Monitoring items are related to dam unexpected events or dam dangers as well as degrees of dam unexpected events.

(2) Inspection should be focused on spillway, gates, and slopes around spillway. Unmanned aerial vehicle (UAV) may be applied. Water level, rainfall, inflow and outflow discharge, deformation, seepage pressure, seepage discharge should be monitored. Spillway pulverization should be monitored during flood discharge.

(3) Variation of tendency should be more concerned during inspection and monitoring for abnormal seepage and structural instability. Monitoring items should be corresponding with dam incidents. Monitoring data should be analyzed in time.

(4) The damages caused by earthquake are related with earthquake magnitude and distance from epicenter. The monitoring item is focused on crack, leakage, structural deformation, landslide and seismic acceleration.

SUMMARY

Floods，rainstorm，typhoon and earthquake are extreme events nowadays，which may lead dam incidents or even failure. Dam emergency monitoring is an essential non-engineering measure in emergency action for incidents hazard mitigation. The paper analyzes the features of the above extreme events and probable accidents. Emergency inspection procedures, monitoring techniques are presented.

1. INTRODUCTION

As water utilization and demand for hydropower has expanded, the development of high dams containing large reservoirs have increased globally. Due to the high water head of a high dam with a large reservoir, vibrations caused by fluctuating flow loads generated by water energy can be transmitted underground to the surrounding area via the dam's foundations. Due to the "magnifying effect", vibrations can be enhanced when special ground conditions are present, an effect that will increase their impact on the surrounding environment [1]. Vibrations caused by high dam flood discharge, and their effect on the structural safety of surrounding buildings and the environment, as well as on the physical and mental health of the local population, have been recorded [2-4]. Therefore, research on this phenomenon is urgently needed.

Vibrations associated to high dam flood discharge have a close relationship with the hydrodynamic condition and dynamic characteristics of the discharge structures. As the mechanism of fluid-structure coupling vibration is fairly complex, the effective research method to solve the vibration problems induced by high dam flood discharge is to establish a fluid-structure interaction physical model through complete hydroelasticity simulation, and to undertake flood induced vibration tests [5-8].

In this study, by using a bottom-flow energy dissipation hydropower station in China as a case study, approaches to improve the traditional hydroelastic model for ground vibrations induced by flood discharge are proposed. The main factors influencing ground vibration intensity was studied by establishing a correlation system between the dam model and the actual ground in order to provide a theoretical basis to analyze vibrations and damping techniques for high dams.

2. EXPERIMENTAL PRINCIPLES

The hydroelastic experiment simulation of flow-induced vibrations simulates the fluid-structure interaction vibration system combined with "structure - water - foundation - dynamic load". The "dynamic load" input system similarity and the dynamic response similarity of structural systems are simultaneously required for the simulation, which means that the similarity of the hydraulic condition and the structural dynamic condition are simultaneously required [9].

The hydraulic similarity is the similarity of the "dynamic load" input system, and its essence is the similar law of fluctuating pressure in the hydraulic model designed by similar law of gravity. By comparing a series of scale model tests and prototype observations, it was found that the side fluctuating pressure, caused by flow separation or diffusion induced by the dramatic change of integral boundary and flow conditions, was mainly controlled by large-scale and low-frequency vortex motions. The large-scale vortex motion was successfully simulated in the model with a large enough Reynold's number, and fluctuating pressure can be extended to the prototype according to the similarity law of gravity. This conclusion can be drawn based on water fall model tests under different scales (Fig. 1), and analysis of the prototype observation data from the Ertan hydropower station, Yalong river, China [10] (Fig. 2).

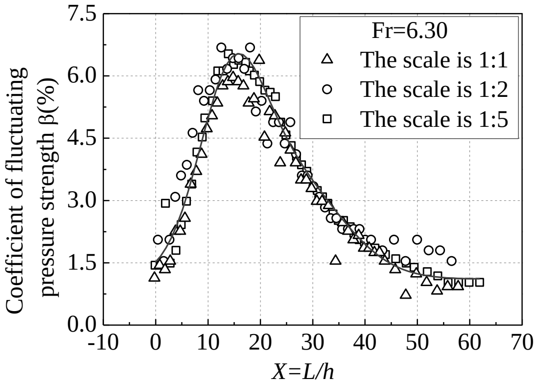

Fig. 1
Strength coefficient distribution of water fall fluctuating pressure

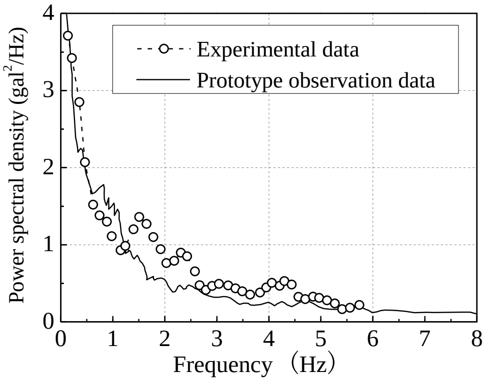

Fig. 2
Comparison between the prototype and model data of the fluctuating pressure frequency of the plunge pool in Ertan hydropower station (convert to prototype by gravity law)

The structural dynamic similarity, including geometric similarity, movement similarity and boundary similarity, refers to the similarity of the dynamic response of the structural system. This similarity is related to the frequency, vibration mode and damping of the structure.

According to the principle that the hydraulic similarity conditions is compatible with the structural dynamic similarity conditions, the hydroelastic model must adhere to the conditions of large density (λ_ρ = 1), a low elasticity modulus (λ_E=λ_L), an equal damping ratio (λ_ξ = 1), and an equal Poisson's ratio (λ_ν = 1) [11].

3. RESEARCH BACKGROUND

The high concrete gravity dam at Jinsha River, China, was selected to be the study dam for our investigation. This dam has a crest elevation of 384.00 m and a crest length of 909.26 m; the maximum height of the dam is 162.00 m. The dam body consists of 12 surface holes and 10 mid-level outlets which are alternatively arranged and divided into two symmetrical energy dissipation zones by the middle guide wall. This arrangement form is a typical layout for a high dam with energy dissipation via a hydraulic jump.

The minimum and maximum distance between the hydropower station and the nearest urban area downstream is 0.5 km and 2.5 km, respectively. According to observations, vibrations can be felt on the mountainside area near the county town downstream on the right bank, the vibration was magnified obviously in this region in the propagation process. Geological exploration results from the downstream area showed that the surface and foundation of that area consisted of sand layers and mudstones, respectively. An ancient channel with an average width of about 200 m was identified situated near the right-hand side of the mountain in the main urban area downstream; the maximum thickness of the covering layer over the ancient channel was 80 m. In comparison, the covering layer besides the ancient channel area covering layer of the other urban area had a significantly thinner thickness. The locations of the different regions are shown in Fig. 3.

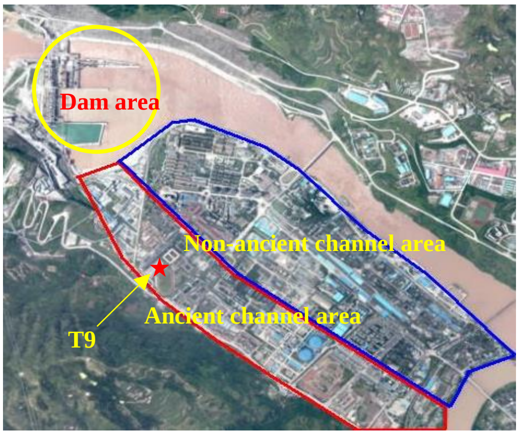

Fig. 3
Schematic diagram of each region in the hydropower station dam area and the downstream area

4. THE ESTABLISHMENT AND IMPROVEMENT OF HYDROELASTIC MODEL

4.1. THE ESTABLISHMENT OF HYDROELASTIC MODEL

Before making the hydroelastic model, the foundation plain fill was excavated and replaced, reinforcement treatment was undertaken using a C50 concrete foundation (7 m long × 7 m wide × 1.5 m deep); and a vibration isolation channel (0.1 m wide × 1.5 m deep) was created to reduce the influence of background vibration and vibrations caused by the water pump. In addition, in order to prevent background vibrations generated at the convergence between the upstream and downstream sections of the hydroelastic model from being transmitted to the transmission path, the upstream or downstream sections were connected using a rubber belt to form a flexible connection, thereby reducing the influence of external vibrations on the hydroelastic model. The location of the waterfall was also placed 7 m from the end of the downstream section of the hydroelastic model. Fig. 4 shows the vibration isolation and reduction measures used for our model.

Fig. 4
Vibration isolation and reduction measures of the model

A hydroelastic model of Xiangjiaba hydropower station with energy dissipation via a hydraulic jump was built on the test platform (Fig. 5). The geometry scale of the model was 1:80, and the simulation context included the overflow section of the dam, two stilling pools and a section of its foundation. According to the requirements of the model material property similarity law, synthetic rubber was used as the prototype material. The arrangement of the vibration acceleration measurement points located on the model are shown in Fig. 6.

Fig. 5
The hydroelastic model

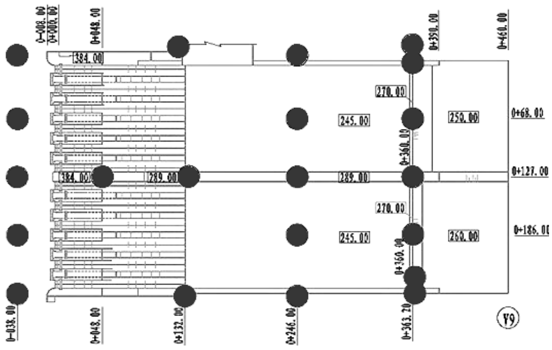

Fig. 6
Arrangement of the vibration acceleration sensor measuring points (the black dots indicating the position of the sensors).

4.2. SIMULATION EFFECT VERIFICATION

Taking the measuring points T9 (Fig. 3) with the largest vibration amplitude as an example, the 13 typical prototype observation conditions were calculated to correspond to the test model. The amplitude comparison between each measuring point of the model structure and T9 is shown in Fig. 6.

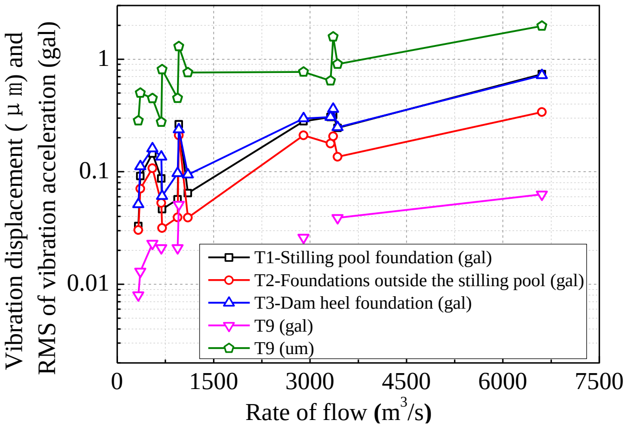

Fig. 6
Vibration comparison between each measuring point of the model structure and the prototype measurement point T9

Results show that the variation trends and patterns of vertical vibrations of each measuring point in the hydroelastic model were basically the same as those at T9. Firstly, the overall vibration intensity increased with an increase of the stilling pool flow; secondly, vibration intensity was sensitive to the route of discharge, with unfavorable routes of discharge resulting in an increase of vibration intensity.

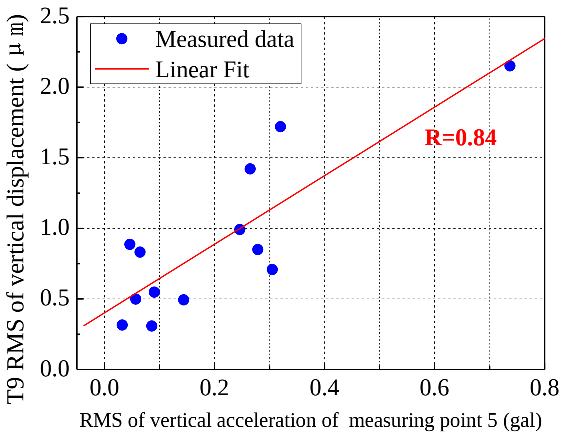

Fig. 7
Vibration correlation between the stilling pool base measurement point of the model and the prototype measurement point T9

Correlation analysis between vibration acceleration of hydroelastic model measuring points and vibration displacement of T9 (Fig. 7) show the coefficients between vibrations of the model stilling pool base and the prototype ground were 0.84. Furthermore, the correlation coefficient between the vertical acceleration of other measuring points in the model and measured vertical displacement, or vertical acceleration of T9, was high (0.71 ~ 0.89). These correlation coefficients indicate that the test results can effectively reflect actual discharge conditions.

5. THE EXPERIMENTAL RESULTS

When model verification effectiveness was undertaken, it was found that the vibration intensity of the downstream area had a close relationship with flood discharge volume and mode, such as the opening way of surface holes and mid-level outlets, the changing of the water level upstream or downstream, etc. Therefore, the influence of these factors on ground vibrations was studied by the principle of controlling a single variable factor. The vibration prediction results of measuring point T9 under the different influencing impact factors of the experiment are shown in Fig. 8 to 12.

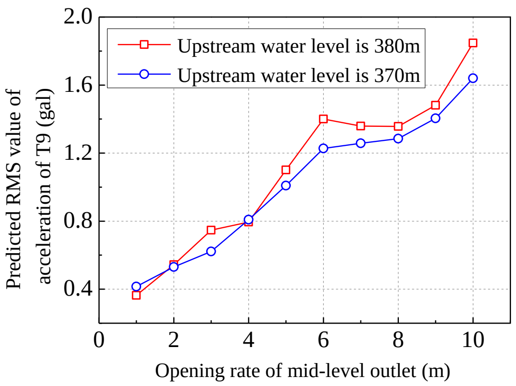

Fig. 8
Prediction results of vertical vibration acceleration of measuring point T9 with mid-level outlet discharge

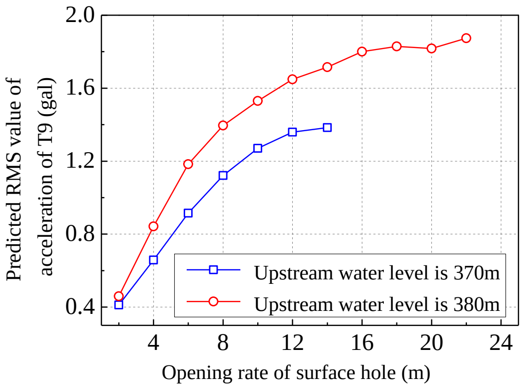

Fig. 9
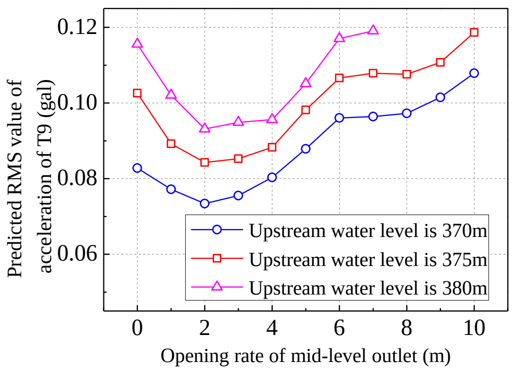
Prediction results of vertical vibration acceleration of measuring pointsT9 with surface hole discharge



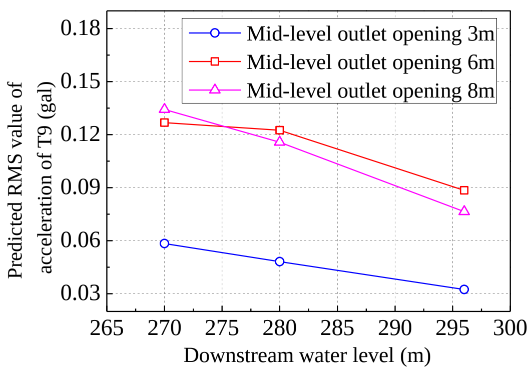


Fig. 10
Prediction results of vertical vibration acceleration of measuring point T9 with discharge from both surface holes and mid-level outlets

Fig. 11
Prediction results of vertical vibration acceleration of measuring points T9 with different downstream water levels

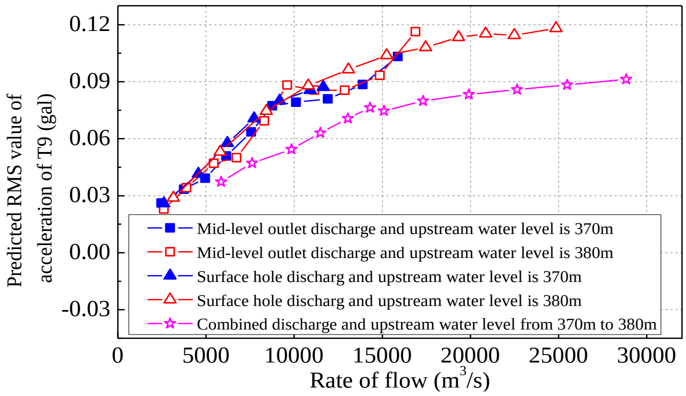

Fig. 12
Comparison of vibration conditions under different discharge modes

It can be seen in Fig.8 to 10 that there was a significant difference between vibration rules under different orifice opening modes. When the surface holes and mid-level outlets were operating, vibrations increased with an increasing in the degree of opening. The mid-level outlets had unfavorable operation ranges from about 5 m to 7 m. A relatively small fluctuating load could be generated at the orifice under both situations. There were no adverse operating conditions when discharging from surface holes, but the increasing range of vibration intensity decreased with a large degree of opening. When discharge occurred at the same time from the surface holes and mid-level outlets, ground vibrations were more sensitive to the degree of opening of the mid-level outlets. The vibration amplitude decreased significantly when the opening degree was between 1 m to 4 m. As can be seen from Fig. 11, the higher the downstream water level, the smaller was the vibration amplitude. While it can be seen from Fig.12 that a higher upstream water level resulted in stronger vibrations, the amplitude growth could be ignored when compared with the flow growth rate. In addition, with the same water flow rate, ground vibration intensity was the strongest when discharge occurred from the surface holes, followed by ground vibrations generated when discharge occurred from the mid-level outlets; an obvious adverse operating range can be identified. The strength of the vibrations generated with discharge from both the surface holes and mid-level outlets was significantly less than normal operating conditions with the same rate of discharge.

6. RESULTS AND DISCUSSION

The source of vibrations induced by flood discharge from the high dam and the factors affecting vibration intensity were examined based on the combination of a hydroelastic model and prototype observation data. The research findings from our study are:

(1) Before establishing the model, the foundation plain soil at the bottom of the model was reinforced by excavating it and replacing it with concrete, and a vibration isolation channel was set around the foundation. The convergence section between the hydroelastic model and the upstream/downstream sections were connected using a soft rubber belt to form a flexible connection. This adaptation effectively reduced the influence of external vibration sources on the hydroelastic model. Simulated discharge condition results inversed from the experimental model had the same change rule with actual measured ground vibrations, having a high correlation. The prediction results therefore accurately reflected ground vibrations.

(2) The orifice open and upstream and downstream water levels were the major influences on ground vibration intensity, thus controlling these factors and regulating the discharge modes, especially avoiding unfavorable operation ranges for the surface holes and mid-level outlets is beneficial in minimizing ground vibrations.

SUMMARY

Upstream and downstream vibrations generated by large volumes of flood water discharging from a high dam can potentially damage buildings and impact on the normal life of local populations. Modelling vibrations created by overflow conditions has enabled improvements for the traditional physical model, and the establishment of a correlation system by combining the model with prototype observations. In addition, the characteristics of vibration sources, as well as the factors influencing vibration intensities, were investigated. Our results show that establishing a hydroelastic model with vibration isolation and damping measures can simulate flood discharging conditions and accurately reflect ground vibrations through linear prediction. The vibration energy of the dam orifice was the primary vibration source of ground vibration, followed by the guide wall and stilling pool base slab. Findings from our investigation show that orifice open and upstream and downstream water levels were the major influences on ground vibration intensity, thus controlling these factors and regulating the discharge modes from a high dam will control the intensity of these vibrations.

1. INTRODUCTION

This study constructed a three-dimensional (3D) geo-mechanical model for the Xiaowan high arch dam, which simulated the topographical and geological features, the distribution of weak structural planes, the shallow relaxation unloading phenomena, and the dam reinforcement scheme. During the test, traditional model materials were used to simulate the dam body, the concrete reinforcement plug, and the mail rock mass of the abutment and foundation, whereas temperature-analogue materials were used to simulate faults F_{11}, F_{10}, F_5, F_{12}, F_{19}, and F_{20}. A small specially prepared rhombic block and thin block were used to simulate the shallow layer of the unloading rock body. The failure test was performed using the comprehensive method, which considers both the overloading and strength-reduction techniques.

2. METHODS

The combined overloading and strength reduction methods were applied in this test. The model failure test procedure is as follows. First, the model was pre-loaded and then the normal load level was applied. Afterward, the shear strength of the abutment rock faults, such as F11, F10, and F5, were reduced by approximately 20% by heating up the model materials. Finally, the overloading test was implemented until the dam instability caused the destruction of the dam abutment. The loads were applied successively in the following order as factors of the normal working load, P0: 1.2, 1.4, 1.6, 1.8, 2.0, 2.2, 2.4, 2.6, 2.8, 3.0, 3.3, and 3.5.

3. RESULTS

The asymmetry of the two-bank terrain and the geological condition of the dam abutments created an asymmetric trend of the displacement of the dam body. In the overloading stage, with an increase in overloading multiples, the displacement of the dam body continuously increased and had an asymmetric trend, which indicates that the displacement of the right arch abutment was slightly larger than that of the left arch abutment.

Under normal working conditions, the surface displacement of the abutments and resistance blocks of both the left and right banks was minimal, and there was no abnormal phenomenon. After K_p was increased to over 3.0, the surface displacements of both abutments increased rapidly and the change amplitude of the displacement curve increased. Furthermore, the measuring points near and around the arch abutment and at the fault outcropped points had abruptly increasing displacement and fluctuating displacement curves.

The primary reasons for the failure of the arch dam and foundation plane are as follows: in the later portion of the overload period, especially when the overloading coefficient K_p was over 3.0, the load born by the arch dam was large, and the geological condition of the two abutments had a large asymmetrical phenomenon. Furthermore, the resistance bodies of the two abutments had inhomogeneous deformation, and the width height of the river valley in the dam area was large. The beam direction effect of the arch dam was large, which caused fissures in the dam body and foundation plane.

Based on the analysis of the experimental data and results, the strength reserve coefficient K_1 is 1.2 and the overloading safety factor $K_2$was estimated to be 3.3-3.5, respectively, that is,

$$K_C = K_1 \times K_2 = 1.2 \times (3.3 \sim 3.5) = 3.96 \sim 4.2$$

Thus, the global safety factor K_C for the Xiaowan Arch Dam and foundation should be 3.96-4.2, which meets the present design requirement.

NORWAY

1. INTRODUCTION

Requirements for stability of concrete dams in the current Norwegian dam safety regulations are based on simplifications, which in many cases are conservative. As a result, rehabilitation works may be carried out on dams that are safe, but does not meet the safety requirements.

Norwegian dams have to meet a minimum safety standard, defined by a Factor of Safety (FoS). It is often assumed that the FoS includes all of the uncertainties in the calculations. However, how these variables affect the FoS are generally not known or not accessible. It is therefore a need to acquire more knowledge on how different assumptions affect the calculations of stability of FoS.

How different parameters affect the dam stability is essential in order to identify which parameters that are most important for stability and sensitivity of the overall dam safety. This knowledge is of particular interest in assessing existing dams. By gaining more knowledge about different parameters, it is possible to reduce the uncertainty connected to these parameters, and thereby reducing the overall uncertainty. This knowledge can thereby be used to reduce the calculated FoS without affecting the safety level of the dam.

In general, a probabilistic analysis would be suitable to identify these type of uncertainties. Due to a very limited budget, we had to use a different approach to the issue. Our selected method and the results from the calculations are described in this paper.

The calculations have been carried out on both concrete gravity dams and masonry dams. For simplicity, this paper only presents the results related to concrete gravity dams with a height > 8 m.

2. REQUIREMENTS FOR DAM SAFETY IN NORWAY

In Norway, dam stability is checked for both overturning and sliding.

Calculation of the sliding resistance require a safety factor of minimum 1.5 against normal design loads. For accident loads a minimum FoS of 1.1 is applied. If cohesion is included, a higher FoS is necessary. However, as this require documentation by testing, the cohesion is generally never included.

Safety against sliding is estimated with the shear friction factor method, where the FoS is generally defined as the following:

$$SF_{sliding} = \frac{\sum F_{horisontal\ capacity}}{\sum H_{horisontal\ load}} = \frac{\sum V \tan(\phi + \alpha)}{\sum H}$$

where ϕ is the fiction angle and α is the inclination of the foundation.

Stability against overturning for concrete gravity dams, is acceptable when calculations show that the resultant force is within the central dam foundation, so that it can be assumed pressure throughout the dam foundation.

To simplify the output of safety against overturning, the FoS is calculated instead of the eccentricity of the resultant force. Safety against overturning thereby defined as:

$$SF_{overturning} = \frac{\sum M_{stab.}}{\sum M_{destab.}}$$

3. METHOD AND ASSUMPTIONS

The calculations has been based on a computing tool for stability control, developed by Dr. Techn. Olav Olsen. To make the calculations more efficient, a script was developed with the programming language, Python. The script defines changes of different variables, and then generates calculations with these assumptions.

The result of the stability calculation of each parameter is presented graphically, where the resulting FoS is plotted against the varying parameters for each dam height. Variation in the FoS are shown for both sliding and overturning. This paper only presents a sample of the results that have been produced.

The method used, has proven to give a very powerful and flexible tool for estimating stability of all types of concrete dams with different variables. In total, the report has been based on approximately 7000 separate calculations with different variables.

3.1. VARIABLES

Assumptions of for the calculations are shown in the table below. "Initial values" are used to generate dam section as described in the next chapter.

Table 1.
Assumptions used for the computations

Variable	**Initial value**	**Min. value**	**Max. value**	**Step for calculations**	**Comment**
Friction angle	40°	35°	60°	1°	
Water level (H_w)	h	h – 1 m	h	0.01 m	h = Dam height
Self-weight (kN/m^3):	22	21	24	0.1	
Drainage constant (k)*	1.00	0.50	1.0	0.05	Changes in pore pressure defined by k and dx*.
Drainage position (dx)*	0	0.1H_w	0.5H_w	0.1H_w	
* Both the drainage constant (k) and the drainage position (dx) was changed, - see figure below (i.e. 6 * 11 = 66 different calculations for each dam height)					

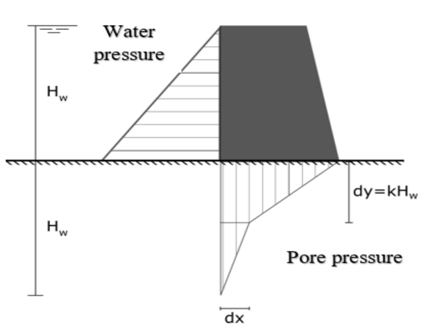

Fig. 1.
Illustration of assumptions to generate pore pressure.

3.2. GENERATION OF DAM SECTION

The dam-sections were generated, satisfying the following requirements:

- Compression throughout the entire foundation (i.e. the resultant force is within the central dam foundation)
- FoS against sliding equal to 1.0.

By changing crest width and downstream slope (see Figure 2) an optimal cross section was found using the “initial values” given in Table 1.

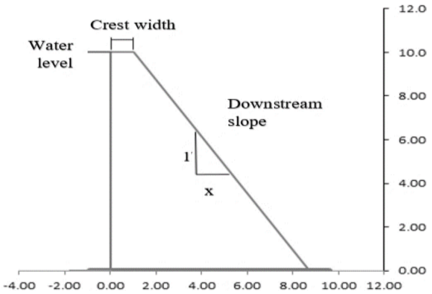

Fig. 2.
Dam section was selected by varying crest width and downstream slope.

It was not possible to generate a cross section that satisfied the assumptions mentioned above. Therefore, the required FoS against sliding was increased from 1.0 to 1.1 as shown in the table below.

Table 2.
Geometry and FoS for dam-sections generated.

Dam height [m]	Crest width [m]	Downstream slope [1:x]	FoS	
			Sliding	Overturning
8	0.81	0.77	1.1	1.5
10	1.01	0.77	1.1	1.5
12	1.21	0.77	1.1	1.5
14	1.41	0.77	1.1	1.5
16	1.61	0.77	1.1	1.5
18	1.82	0.77	1.1	1.5
20	2.02	0.77	1.1	1.5
25	2.52	0.77	1.1	1.5
30	3.03	0.77	1.1	1.5

The above table shows that optimization of the cross sections provided a minimum FoS of 1.1 against sliding and 1.5 against overturning, with the assumptions used. In presentation of the results, the FoS for the initial dam section was normalized. This implies that the computed FoS against sliding was divided by 1.1, while the results against overturning was divided by 1.5.

It can also be noted that when the friction angle was increased to 50º, the FoS against sliding increases to ~1.5, which is the same FoS as for overturning.

4. RESULTS

In this chapter, the results of the calculations with different variables are presented and discussed.

4.1. FRICTION ANGLE (AND ANGLE OF FOUNDATION)

Variation in friction angle is also valid for inclination of the foundation, since horizontal capacity is defined as $\sum V \tan(\phi + \alpha)$ (see chapter 2). The friction angle has no effect on the FoS against overturning.

The computations show that the FoS against sliding is the same for all different dam heights. This imply that friction angles is directly related to FoS, and that the dam height do not influence the results. This means that a change in the friction angle will give the same change of the FoS regardless of the dam height. This can, of course, also bee seen directly from the definition of FoS against sliding.

The friction angle will normally be conservative where the friction angle also “includes” possible cohesion and shear capacity due to rock surface roughness. This implies that the corresponding safety factor from friction, should be 1,0. The calculations carried out, also show that a conservative friction angle will result in a high level of safety that is not necessarily reflected in the computed FoS for the dam.

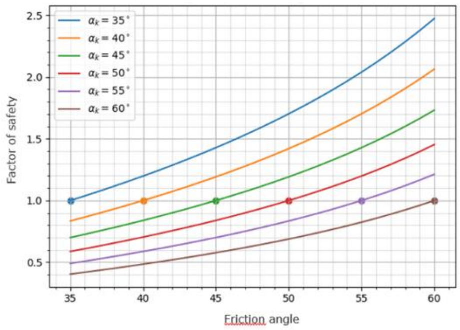

Fig. 3.
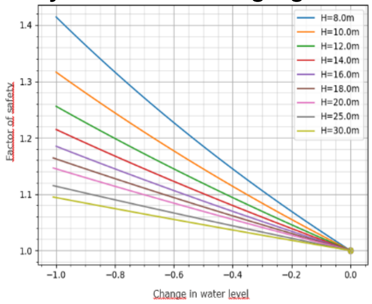
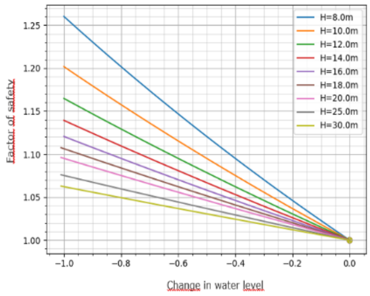
Correlation between FoS and friction angle. α_k is the initial friction angle where the different dam sections have a FoS = 1.0.

4.2. WATER LEVEL

How variations in the water level influence the FoS, will identify how sensitive the dam is to changes in flood water level. Changes in design water level can for instance be caused by changes in future flood calculations etc. How much this affects the safety in relation to different dam heights is calculated and presented graphically in the following figures.



Results for sliding



Results for overturning

Fig. 1.
Reduced water level (x-axis) vs. FoS for different dam heights (y-axis).

As shown in the above graphs, higher dams are, of course, less sensitive to changes in water levels than lower dams. This is summarized in the following table.

Table 3.
Effects of changes in water level on the FoS for different dam heights.

Change in water level	**FoS - Sliding**		**FoS - Overturning**	
	Dam height 8 m	**Dam height 30 m**	**Dam height 8 m**	**Dam height 30 m**
0,2 m	1,07	1,02	1,05	1,01
1,0 m	1,41	1,09	1,26	1,06

The table shows that changes in water levels have more influence on the FoS against sliding than FoS against overturning.

Dam height (i.e. static water pressure) is crucial for how uncertainties in flood calculation and flooding affect stability. When the dam height increases, changes in flood water have little significance for the dam stability.

As uncertainties in floods and operating levels will have different impact on the FoS dependent on the dam height, it is reasonable that these uncertainties are handled in the flood calculations and are not included in the FoS. For instance, a dam dependent on floodgates will have other uncertainties related to flood handling and flood levels than a dam with a free overflow spillway. This implies that the corresponding safety factor from static water pressure, should be 1,0.

4.3. Self-weight

The self-weight is essential for the stability of a concrete gravity dam. The calculations carried out show that variations in the self-weight is directly related to the FoS and the dam height does not influence the results.

JCSS, "Probabilistic Model Code", 2015, Table 2.1.1, recommends a coefficient of variation of 0.04 on self-weight. This corresponds to a load factor of 0.96, which imply a reduced self-weight from 24 to 23 kN/m^3. The correlation between a load factor of 0,96 and the FoS are shown in the table below.

Table 4.
Correlation between load factor and FoS.

	Load factor	**FoS**
Sliding	0,96	1,08 (=1/0.93)
Overturning	0,96	1,04 (=1/0.96)

A graphic presentation of the correlation between self-weight and FoS is shown below (blue line = sliding; orange line = overturning).

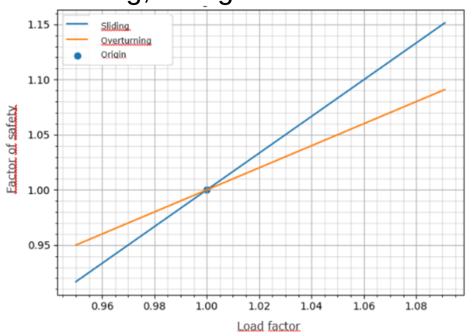


Fig. 5.
Load factor (x-axis) vs. FoS (y-axis) when the friction angle = 40º

The dam geometry also represents an uncertainty, which also can be illustrated by variating the self-weight. However, probabilistic analysis carried out on a gravity dam in Norway indicate that deviations in the geometry do not have a significant effect on the FoS.

4.4. Pore pressure

The pore pressure represents an uncertainty that can be difficult to predict and therefore difficult to quantify in terms of a specific FoS. This would imply that the pore pressure should be subjected to a relatively high FoS to take account of the uncertainty it represents.

In Norway, requirements for stability against overturning assume that the resultant force is within the central dam foundation. Thereby, a linear decreasing pore pressure can be assumed as there is pressure throughout the entire dam foundation. In addition, a check of accident load is required, where the resultant force should be upstream 1/6 of the dam foundation. In this case, full pore pressure can be assumed on the upstream half of the foundation (where there is no pressure on the foundation) and then linearly decreasing to the downstream side. The assumptions for design loads and accident loads are shown in the following figure.

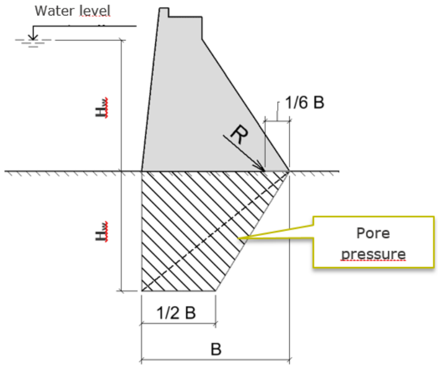

Fig. 6.
Maximum allowable pore pressure assumed for accident loads. Pore pressure distribution for normal design loads is shown as a dotted line.

The criteria for pore pressure distribution provides a logical correlation between the load effects from the dam and the resulting pore pressure for normal design loads. When there is pressure in the entire foundation, the bond between the concrete and the foundation can be assumed to be intact. Thereby, a linearly decreasing pore pressure under the dam will probably be a conservative assumption and generally contribute to a high safety level.

The additional check for accident loads provides an extra safety in case the pore pressure should be greater than assumed for normal design loads.

If the maximum permissible pore pressure for accident loads represents the uncertainty in the pore pressure distribution, the difference of pore pressure between design load situation and accident load situation may be defined as the corresponding load factor. This difference represents an increase in pore pressures of 43%, or a load factor of 1.43. The correlation between the FoS for design loads and accident loads can thus be expressed as shown in the following figure, where FoS = 1 represent a linearly decreasing pore pressure distribution under the dam.

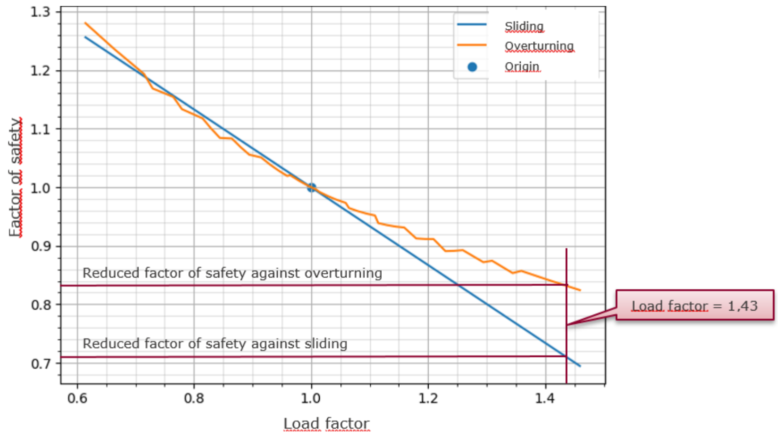

Fig. 7.
Computed correlation between load factor and FoS with changing pore pressure (blue line = sliding; orange line = overturning).

5. SUMMARY AND CONCLUSION

The following table summarizes the suggested FoS for each variable as discussed in this paper. Multiplying the different factors is assumed to represent the overall FoS.

Table 5.
Total FoS as a product of the individual safety factors.

Variable	FoS - Sliding		FoS - Overturning		Reference
	Design	**Accident**	**Design**	**Accident**	
Friction	1,0	1,0	Not relevant		Chapter 4.1
Water level	1,0	1,0	1,0	1,0	Chapter 4.2
Self-weight	1,08	1,08	1,04	1,04	Chapter 4.3
Pore pressure	1,40	1,00	1,20	1,00	Chapter 4.4
SUM	1,51	1,08	1,25	1,04	Overall FoS
Current FoS	1,5	1,1	N.A.*	N.A.*	
* Safety against overturning is defined by position of the resultant					

Elements constituting the total FoS given in the Norwegian dam safety regulations is not publicly available. The factors of safety suggested in the above table can, however, be used to justify the current requirements, but this has not been confirmed by the Norwegian dam safety authority.

How different parameters affect the dam stability is essential when assessing the degree of uncertainty of the calculations. This will make it easier to identify which parameters that are most important for the stability and that influences the ucertainties of the overall dam safety.

By improving the knowledge related to the individual variables, the uncertainties can be reduced and thereby reducing the overall required FoS for the dam in question. This is of particular interest in cases where existing dams do not meet the safety requirements.

It must be underlined that results in this report is valid with the given methodology and assumptions described in chapter **Fehler! Verweisquelle konnte nicht gefunden werden.** and **Fehler! Verweisquelle konnte nicht gefunden werden.**, and a validation of the results is recommended.

6. ACKNOWLEDGEMENTS

We would like to thank EnergiNorge that has supported this project, and thereby made this contribution possible.

7. REFERENCES

This article is based on a study documented in a report by EnergiNorge in Norwegian. When this article was written, the report was not published. The report will in time available on: https://www.energinorge.no/publikasjoner/

SUMMARY

The study presented in this paper is part of a lager Norwegian Research and Development project, named “Dam safety in an overall perspective” that is administrated by EnergiNorge. This is a joint project with participants from the Norwegian dam safety sector. One of the objects of this project is to look at alternative approaches to evaluate safety of existing concrete- and masonry dams.

This paper presents a study carried out to identify how different variables affect the estimated safety for dams. To do so, a series of calculations has been carried out to understand how the FoS is affected for a wide range of variables and assumptions.

The calculations have been carried out by combining a computing tool for stability calculations with a script that runs the calculations. This method has proved to produce a very powerful and flexible tool for computing stability with varying assumptions. In total, the report is based on approximately 7000 separate calculations with different variables

The study gives suggestions on how uncertainties related to loads and other assumptions can be represented in the overall FoS. The results can also be used to justify the current practice and safety level applied by the Norwegian dam safety regulations.

1. INTRODUCTION

Organizations have no choice but to use technology as a strategic resource to achieve their strategic goals, and this means that the concept of strategic alignment of development and technology makes sense. Undoubtedly, the most important component in the progress of organizations in today's world is technology. The lack of a development strategy to manage technology transfer is one of the problems for companies. In this study, first, effective indicators have been identified for development strategy development, and then, by assessing the quality of technology, the strengths and weaknesses of the company in each technology are determined, while specifying the proposed solution of the SWOT analysis (Matrix of Technology) and Grounded theory (Model Alignment) is done briefly.

2. RESEARCH METHODOLOGY

2.1. MAIN HEADING

One of the problems of domestic companies is the lack of a development strategy to manage technology transfer in technology transfer projects. Therefore, this research seeks to provide a method for developing a development strategy in order to identify the technologies that are in line with the needs of the country and provide solutions for the acquisition of the required technologies of the power plants. To this end, effective indicators have been identified for developing a development strategy. By devoting axes to each of the components, a framework for developing a development strategy has been designed. By drawing the technology map based on the external and internal dimension assessment by the quality performance of the technology and the model of the management of the technology requirements, while identifying the technological status of the company in each technology (the strengths and weaknesses), the key technologies of the company, as well as the competitive position of each technology (opportunities And threats) will be identified.

2.2. DETERMINE TECHNICAL CHARACTERISTICS AND MAP THE TECHNOLOGY

To this end, by first examining the contracts concluded between the employer and the manufacturing companies, the quality requirements and technical requirements that directly or indirectly influenced the construction of the power plant were identified. In the next step, a questionnaire was prepared for the first step, and from the 14 experts of the company, the employer was asked to provide an assessment on the weight of each of the demands and technical requirements, based on the questionnaire method [1]. Based on the analysis of the findings, the technical strength of the production capacity was 400 MW, 9; the water in the design reservoir was 100 meters; 7; the ability to manage the mechanical equilibrium system; 5; unit time at 150, 7 rpm; generator voltage 13.8 kV, 5, and the design of the plant's structure according to standard 9 [2]. Then, according to the principles of collective agreement and according to the grading (1-3-5-7-9), provide an assessment of the impact of each of the technical characteristics on the quality requirements and technical requirements of the design and construction of the power plant (Table 2 and 1).

2.3. FINDINGS

To determine the technological capability gap, the collected data was analyzed and the test results confirmed the existence of a technological gap for eight of the technologies. For this purpose, the level of existing capabilities and the level of capabilities required in each technology are specified. Then, the following test was carried out to test the technological capability gap in technologies with different required and existing capabilities [3].

There is no gap between the level of existing and required X technology technology: H0

There is a gap between the existing level of existing and required X technology technology: H1

Measurement of Indicators: For this purpose, a questionnaire was developed in three sections, the internal indicators including the technological gap, the duration of development and the cost of development, were examined in each part of the questionnaire [4]. The output of this step is shown in Table 3.

Table 3
The degree of technological gap in each of the technologies required for power plant design

Technology gap		Technology level of the item need	Available Technology level	Technology Title
Relative amount	Quantitative			
%12	10.16	11.33	1.17	Model simulation software
%5	4.00	11.83	7.83	Hydrostatic calculations software

%20	16.91	18.08	1.17	Wave Systems Damper
%20	16.67	18	1.33	Cavitation tunnel

2.4. DRAW A TECHNOLOGY MAP

In this step, the technology map is taken into account with regard to the component of the importance of technology as the horizontal axis (vector x) and the component of the technological gap as the vertical axis (vector y). Gaining a relatively high value in the component of the importance of technology for a particular technology suggests that the acquisition of this technology by the company is inherently competitive and, in addition to creating opportunity, avoids threats such as dependency on the source. Also, the relative value of the technology gap is considered to be the weak point in the technology [5]. The purpose of drawing up a technology map for the technology of designing and building a power plant in Karkheh Power Generation Company is to show the technological status of the company in each technology (strengths and weaknesses) and identify key technologies and determine the competitive position of each technology in comparison with other technologies. The survey (opportunities and threats) is shown in Figure 1 After determining these; we can adopt a suitable development strategy for the development and acquisition of each technology in the company.

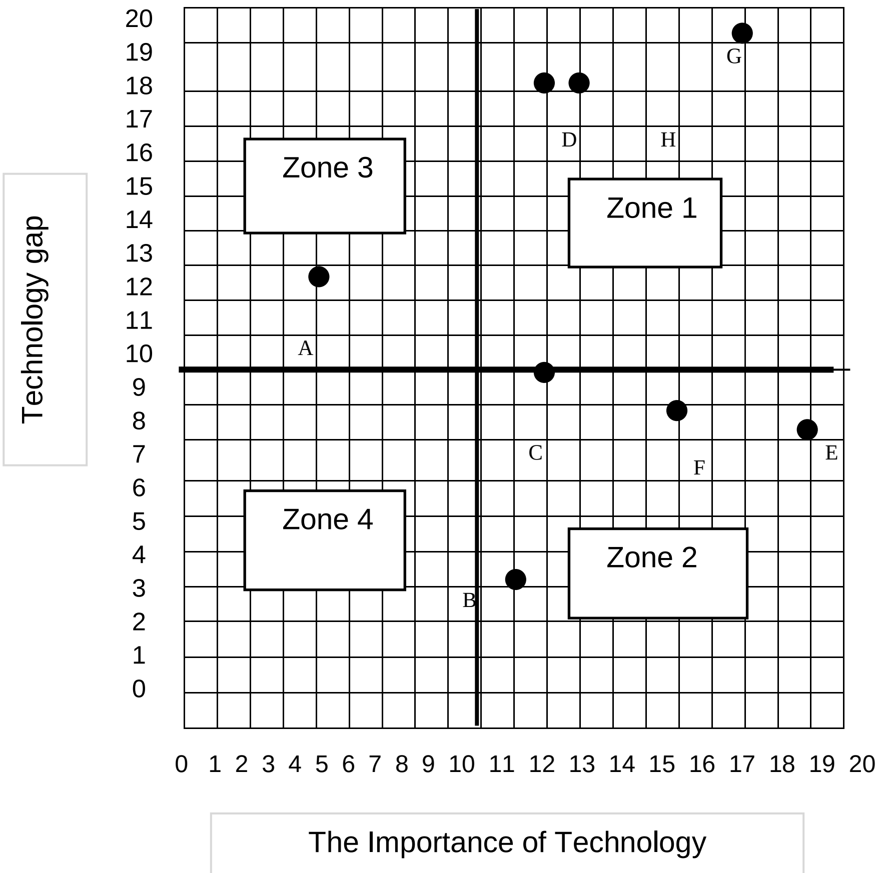

Fig. 1
Technology map area guidance for choosing a development strategy

3. PATTERN COMPILATION ALIGNMENT

3.5. GRENDD'S THEORY OF THEORY

In the present study, the theory of grounded theory (granddad theory) is used. One of the techniques of textual data analysis is the grounded theory that is a method of inducing the interpretation of recorded data about the social phenomenon-especially the data from interviews-to build theories about that phenomenon. In general, theories of theory focus on actions and social processes and ask questions about what is happening and how people react. It shows the impact of symbolic interaction and a social psychological approach that focuses on the meaning of human action. Background theory studies begin with open questions, and researchers assume that they may be aware of a small amount of meanings or concepts derived from participant actions. Accordingly, it can be said that, when there is little information about the subject studied and the creation of a respected scholarly theory, the research approach would be appropriate [6]. Using the method of theoretical sampling, 14 managers and experts of Karkheh Power Plant were interviewed. In this study, 14 managers and experts of Karkheh power plant were selected. The statistical sample of the research is reported in the following table in terms of education.

Table 4
Distribution of research samples according to education

Percent	Abundance	Education	Row
%28.57	4	Masters	1
%64.28	9	Masters	2
%7.14	1	P.H.D	3
%100	15	Total	4

The table of Pierre samples discern statistical study based on work histories have been reported.

Table 5
Distribution of statistical samples based on work experience

Percent	Abundance	Education	Row
-	-	Less than a year	1
%21.42	3	One to five years	2
%35.71	5	5 to 10 years	3
%42.85	6	10 Years up	4

The purpose of the coding is to create the relationship between the generated categories (in the open coding step). This practice is usually done based on the paradigm pattern and helps the theorist to make the theorizing process easy. The basis of communication in central coding is the expansion of one of the categories. In central coding, we encounter an organized set of code and initial concepts that results from an accurate and detailed review of articles and interviews in the open coding process. The focus of this phase is on codes and concepts rather than data. The main categorization (such as the idea or event) is defined as a phenomenon, and other categories are related to this major categorization. Cause conditions are events and events that lead to the creation and development of phenomena. The background to a specific set of conditions and intervening conditions refers to a wider set of circumstances in which the phenomenon is located. Action or counteraction strategies refer to actions and responses that occur as a result of the phenomenon, and ultimately-intentionally or unwillingly-these actions and responses to outcomes.

In order to explain the criteria and sub criteria of the process of aligning technology strategy with development strategy, the method of content analysis and theoretical coding technique was used from the data-foundation theory. For this purpose, firstly, using the open coding method, the concepts were classified in the interviews and documents based on the same topics, among which the main categories and subcategories of the process of alignment of the technology strategy with the development strategy were identified. The researcher categorized the title of "criterion" and subcategories related to them as "subclass". Then, in the form of axial coding using the paradigm pattern, the relationship between the criteria and the sub-criteria was established. Therefore, a research model that demonstrates how the criteria of the alignment pattern of technology strategy with the development strategy are related. Figure 4 illustrates the alignment pattern of technology strategy with development strategy. The explanation is that based on the pattern of alignment of the technology strategy with the strategy of development of alignment empowers including the maturity of the communication and the factors of management and exercise of power, strategic planning of technology and organizational architecture compatible with technology, participation factors, human resources (innovation, entrepreneurship, expertise, knowledge) and factors Distinctive merits that lead to the realization of the results of the alignment of the technology strategy with the development strategy.

SUMMARY

In this paper, a new approach to developing a strategy of alignment of technology and development strategy using Swat matrix technique and Granddad's theory of theory is introduced as a scientific innovation. For this purpose, development strategy analysis indicators were extracted and then an algorithm was developed for developing a development strategy with technology (proposed model). This model, in addition to determining the technological status of the company in each technology, can identify the key technology of the company and the competitive position of each technology. The basic assumptions of this model are: technology evaluation (identifying the strengths and weaknesses of the company in the field of technology) and improvement through the identification of performance aspirations, comprehensive evaluation and management flexibility. Innovation and features of the proposed model in the domain of 1) designing the proposed model, including: flexibility, ease and simplicity, multi-purpose, obtaining the information, and validity and reliability; and 2) management tool of the proposed model, including the tool for controlling development activities in line with the objectives Strategic and guidance for decision making.

RÉSUMÉ

Dans cet article, une nouvelle approche pour développer une stratégie d'alignement de la technologie et de la stratégie de développement utilisant la technique matricielle Swot et la théorie de la théorie de Granddad est présentée comme une innovation scientifique. A cet effet, des indicateurs d'analyse de stratégie de développement ont été extraits puis un algorithme a été développé pour développer une stratégie de développement avec la technologie (modèle proposé). Ce modèle, en plus de déterminer le statut technologique de l'entreprise dans chaque technologie, permet d'identifier la technologie clé de l'entreprise et la position concurrentielle de chaque technologie. Les hypothèses de base de ce modèle sont: l'évaluation de la technologie (identifier les forces et les faiblesses de l'entreprise dans le domaine de la technologie) et l'amélioration par l'identification des aspirations de performance, l'évaluation complète et la flexibilité de gestion. L'innovation et les caractéristiques du modèle proposé dans le domaine de 1) la conception du modèle proposé, y compris: la flexibilité, la facilité et la simplicité, la polyvalence, l'obtention de l'information, la validité et la fiabilité; et 2) l'outil de gestion du modèle proposé, y compris l'outil de contrôle des activités de développement conformément aux objectifs stratégiques et d'orientation pour la prise de décision.

ABSTRACT

Monitoring the long-term behavior of dams is key for addressing safety and serviceability issues. One challenge is to enable the detection of changes in the baseline response of the structure (i.e. anomalies) in real time, while mitigating false alarms.

The most popular data interpretation method for monitoring the long-term behavior of dams is the Hydrostatic-Season-Time model (HST; [1]). The HST performs a regression analysis to decompose a time series into three sub-components related to the hydrostatic effects (H), the thermal effects (S), and the baseline response of the dam (T). The main drawback of HST models, is that they are not dynamic; it means that once the model is built using a training dataset, it stops evolving as new data are collected over time. This is a limitation because the main objective of dam instrumentation/auscultation is to interpret non-stationary (i.e. abnormal) behavior in the baseline response. Moreover, the

* Comparaison entre les modèles Hydrostatique-Saison-Temps et les modèles Bayésiens Linéaires Dynamiques pour le suivi temporel du comportement des barrages

detection of anomalies typically depends on hypothesis testing or threshold-based procedures, which are prone to false alarms.

Bayesian Dynamic Linear Models (BDLMs) are a class of state-space models which are well suited for sequential inference [2]. BDLMs are capable to decompose time series into a set of sub-components, as HST does. In contrast with the HST technique, the behavior of the sub-components can vary with time, without the need to retrain the model. Recent applications have demonstrated the potential of BDLMs to track time-varying baseline responses of civil infrastructures from real dataset [3], and to detect anomalies [4].

This paper compares the HST and BDLMs techniques for the long-term monitoring of dams. This study presents a specific class of BDLMs based on the switching Kalman filter (BDLM-SKF). Two examples of application based on real displacement data recorded on a dam in Canada and simulated data show that BDLM-SKF is robust towards false alarms, and enable to interpret non-stationary time series. One feature of BDLM-SKF is its capacity to interpret the baseline after an anomaly occurs (i.e. when the dam returns to its normal behavior), without retraining the model. In contrast, HST model is prone to false alarms, and is unable to provide information about when an anomaly stops.

This study demonstrates that Bayesian Dynamic Linear models (BDLMs) outperform Hydrostatic-Time-Season (HST) modelling for monitoring the long-term behavior of dams, while providing the same level of interpretability. The main advantages of BDLM over HST model is its ability to interpret non-stationary time series and to detect change in the baseline response of the dam (i.e. anomalies) without being prone to false alarms.

INCREASE CONCRETE QUALITY IN DAM CONSTRUCTION DURING DESIGN AND EXECUTION PHASE

Andreas ZITZENBACHER, Massimo MAFFEZZOLI, Stefan SCHEUCHELBAUER

Doka GmbH

AUSTRIA

1. INTRODUCTION

The durability and service life of a dam structure is designed in an early stage of the planning phase. In order to achieve the planned target of concrete quality, monitoring during execution is one of the keys of quality management. For instance, in case of mass concrete structures one of the most important aspects is the monitoring of the temperature gradient and appropriate actions on site to avoid cracking and simply guarantee the concrete quality already during construction.

The ambition is to emphasize the importance how to optimize the combination of formwork expertise with superior material technology enabling a well-defined construction sequence between all relevant parties. Resulting in increased quality management and enhanced durability of the designated concrete structure.

2. THE METHOD

2.1. UNDERSTANDING – CONCRETE

Already in the project tendering and work preparation phase, the early strength development of individual concrete mixtures with different performance will be simulated with respective calibration and temperature assumptions. Necessarily, the intended concrete formulations can be re-adjusted.

For this purpose, the early strength development of the intended concrete type is used as a performance indicator that can be planned, measured and controlled with Concremote (=real-time concrete monitoring system). Doka Concremote is used as a method to optimize the construction process and thus significantly increase productivity on the job site resulting in secured cycle time and optimized concrete costs in the execution phase (= 'Concremote Value Engineering Methodology', figure 1).

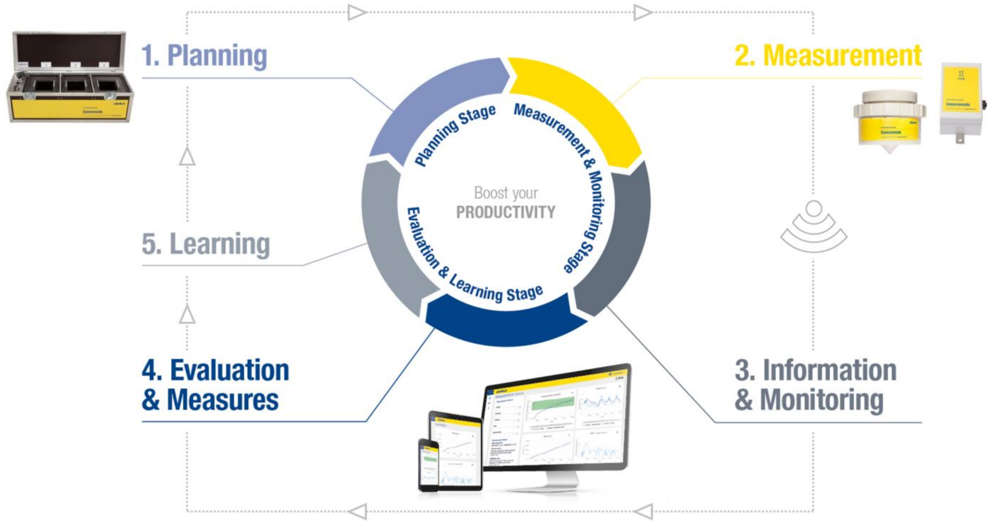

Figure 1: The Concremote Value Engineering Methodology

Ideally a construction company defines a concrete mix portfolio for example to consider ambient temperature changes (e.g. winter, summer, …) and other influences already before construction. In order to be able to create a portfolio of concrete mix designs a final design strength of specific structure member has to be defined by design engineers. To meet the requirements a wide set of scenarios for possible concrete mix designs are proposed for specific concrete structure ('scenario gaming', figure 2).

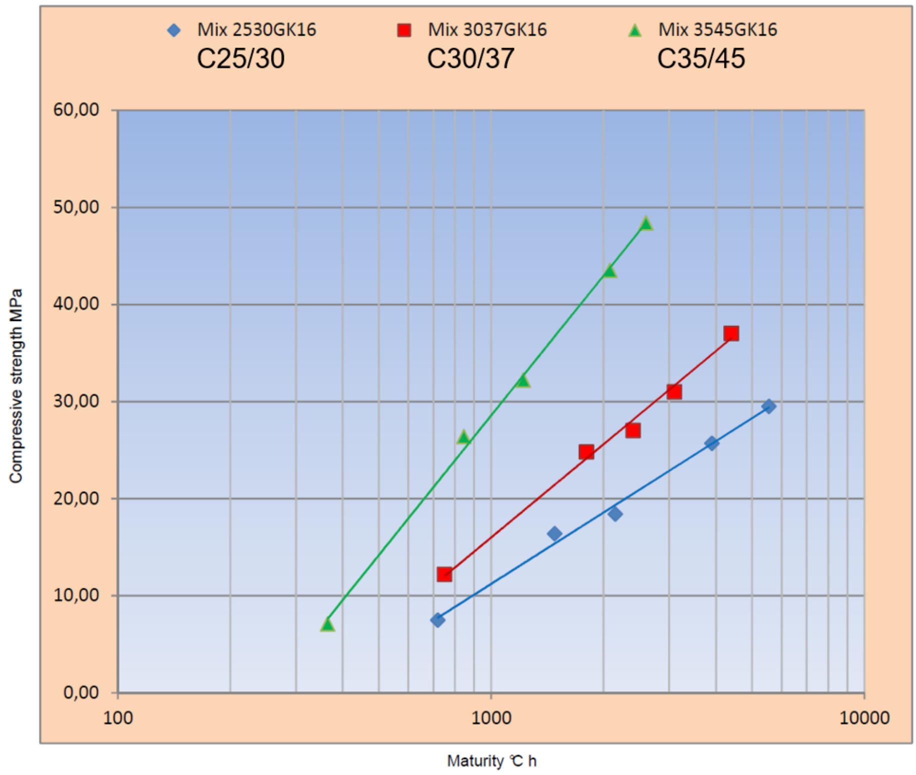

Figure 2: Portfolio of concrete mixtures

Part of the scenario gaming is the temperature simulation, which shows the temperature gradient in various points of critical structural members in a specific pouring section and also the influence to the adjacent building parts (see figure 3).

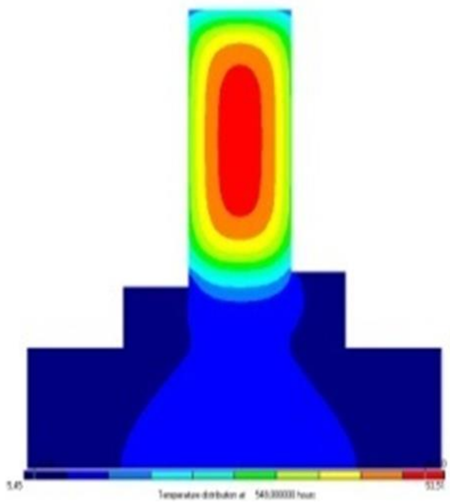

Figure 3: Simulation of the heat of hydration of a structural member

Once the optimized concrete mix portfolio is defined the project can go into the execution phase (transfer to real-time). Before the start of the construction phase each concrete mix design has to be calibrated in order to define correlation between compressive strength and maturity.

By measuring concrete temperature development using Concremote calibration boxes (figure 4), the maturity index of each concrete mixture is uniquely and directly related to its compressive strength and to the other concrete properties.

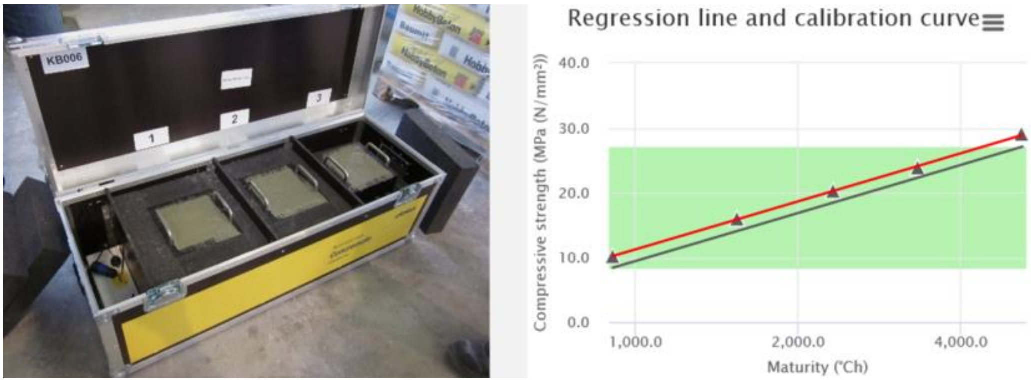

Figure 4: Concremote calibration box, calibration curve in the web portal

In the construction phase, the monitoring of the temperature and strength development by Concremote takes place in each critical concreting section. The reusable devices will be installed before pouring and the result will be monitored with the Concremote web portal (figure 5).

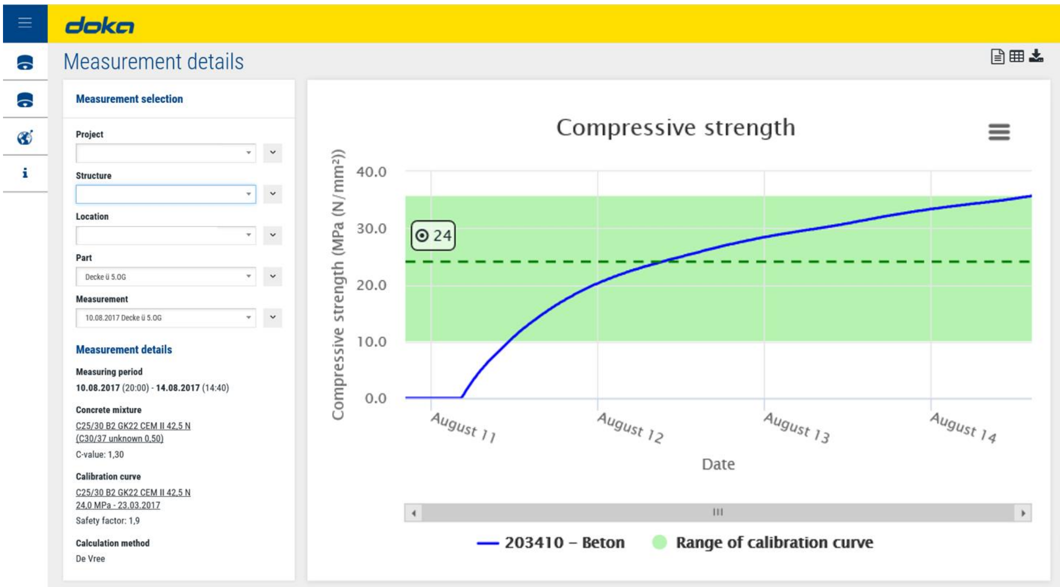

Figure 5: Concremote web portal – Real-time information (e. g. strength)

To enhance the quality of the concrete the curing is monitored and documented. As soon as a certain target value of compressive strength is reached formwork removal takes place. According to that, cycle times and commissioning quantities are reduced and the most optimized curing is obtained at the same time.

For mass concrete, e. g. dam structure, there is also the possibility to monitor the temperature gradient in a ‘Delta T’ diagram. The difference between core and surface temperature should be limited to enhance the concrete quality (less crack width). Concremote offers the possibility to control other external devices, like heating or cooling equipment. For this purpose, Concremote is able to switch-on and switch-of these devices automatically based on measured data.

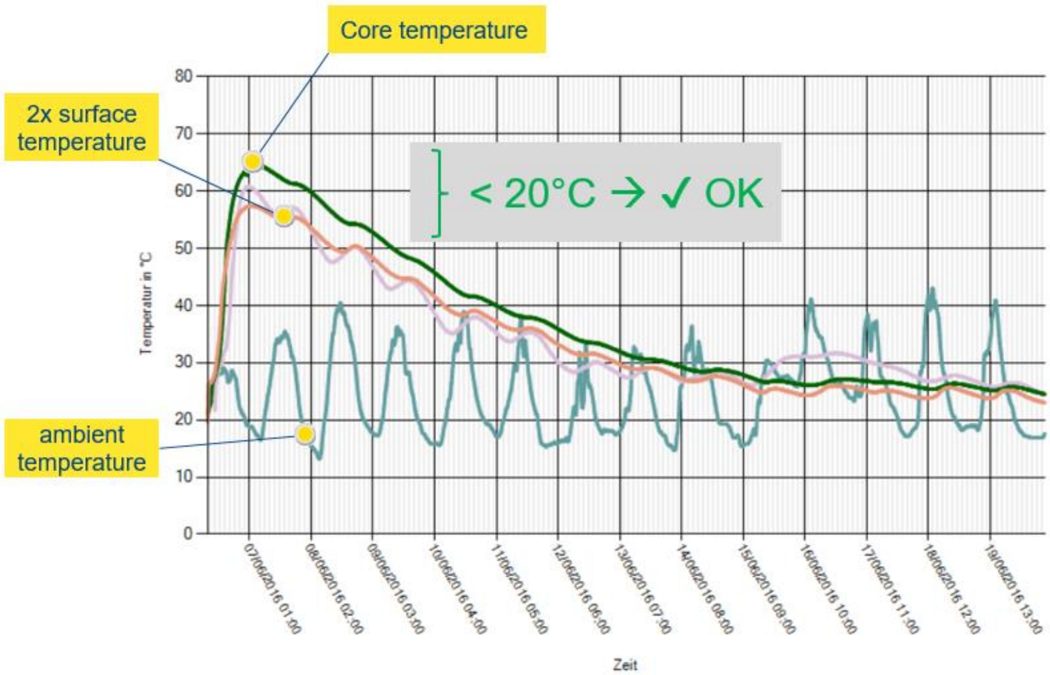

Figure 6: Temperature monitoring of CIP structure

Beside the benefits during design and construction phase, Concremote provides easy access for all stakeholders to the measurement data and a digital backup of all measured data.

In addition to the benefits of the Concremote Value Engineering Methodology, the combination with Doka´s formwork expertise will positively impact the durability and the service life of the designated dam construction.

2.2. UNDERSTANDING – FORMWORK

Understanding, the building and job site requirements as well as the clients' intention of the construction method, is one of the main subjects to discuss before talking about an optimized formwork solution. Different to the common procedure on standard projects, the construction method and the corresponding formwork solution for dam constructions shall be defined already in the design phase of a project in order to optimize the processes during execution phase.

The optimized formwork solution can be influenced for example by the geology, the geometry of the structure, the construction method as well as the construction schedule (see figure 7). Vice versa an optimized formwork design can influence the geometry of the structure (e.g. increased block size resulting in less construction and block joints), improve the construction method and speed up the construction schedule resulting in increased productivity and ideally reduced construction costs.

An optimized formwork solution means to meet the right balance between the influencers and the formwork or accordingly align the specifications on both sides in order to meet the project and client expectations and furthermore assure the demanded final quality of the dam structure.

Figure 7: Bykle Dam, Norway – influence of geology and geometry

At the beginning of a planning phase of a project we need to understand two main subjects:

- **What is being built?**
- **How is it being built?**

_Understanding - What is being built?

The reason for the question is to analyze the basics of the dam construction and forming the foundation for our future work on the concrete structure (e.g. consultancy, value engineering, ….).

Based on the project's unique requirements (**"what is being built"**, figure 8) a tailor-made formwork solution in combination with an optimized construction method between all main structures (e.g. dams, power houses, inlets, outlets, draft tubes or scroll cases) shall be the target of the communication between 'formwork solution provider' and the 'contractor'.

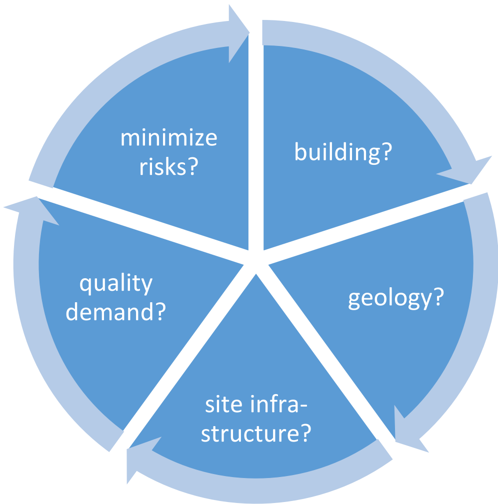

Figure 8: Influencers for optimized formwork solution (what is being built?)

Building: building designs often depend on the geology and surrounding job site conditions. Discussing the given settings in an early phase may result in simplifying the construction process with minor adjustments on the building designs and the pouring sequences.

Geology: type and size of dam structure is influenced by the geology. Most of the time earth and rockwork is influencing the time schedule of an entire project. Keeping the earth and rockwork to a minimum and compensate the mismatch with the concrete structure might be a possibility to save costs and time. Formwork versatility and optimized construction sequences provide the options of financial and time savings.

Site infrastructure: smooth and efficient construction process depend on a workable site infrastructure. Investing in service roads to shorten the paths for material handling or even the investment into an on-site concrete plant is positively impacting the final concrete result.

Quality demand: matching and assuring the exact concrete quality demand can have a major impact on the project budget. Reviewing the demand in an early phase provides the possibility to consider the measures to be taken in the execution phase.

Minimize risks: concrete joints or block joints pear a risk in regards to sealed joints and water tightness. Uncontrolled heat development in mass concrete may cause concrete cracking. In all event it will result in an impact on the project budget for repair works and maintenance. Also it may influence the durability and the service life of the dam structure. Optimize the volume of mass concrete with the corresponding pouring sequence in combination of concrete monitoring equals minimizing risks of unexpected costs.

Figure 9: Wudongde Dam, China

_Understand - How is it being built?

Figure 10: Influencers for optimized formwork solution (how is being built?)

Geometry: fundamental geometric conditions like wall jumps or inclination change in the resulting complexity, as well as the number of pouring sections and sequences, are essential for the selection of the right formwork systems.

Workflow planning: observing cycle times will have a considerable impact on the progress of the entire project. To ensure efficient workflow, detailed planning of system formwork, commissioning quantities, their reuse in additional construction sections within the project and personnel resources will be required for a positive impact on-site (= optimized time schedule).

Safety: developing a project-specific safety concept - from concrete monitoring with real-time measuring values or operating and repositioning formwork to stair towers and safeguards through to emergency planning.

Installation of embedment (reinforcement and water stops): it takes a significant portion of time to install reinforcement and water stops. A specific formwork solution considering any steel inserts or the installation of reinforcement ahead of time is drastically improving the formwork handling resulting in speeding up the time schedule.

Project budget: a solution customized to meet the project’s unique requirements saves resources, as well as time and money - due to quality-tested formwork systems and a holistic project solution.

2.3. WHAT DOES IT MEAN IN PRACTICE? (PROJECT PROCEDURE)

The project success does not only depend on selecting the right material. Guidance for the ‘big picture’ (= products, concrete, logistics and on-site services) from an expert **(Consultant)** can help to enable target oriented processes and assure to meet the demanded result. Consultancy from the very beginning produces a comprehensive solution for the entire production cycle of the dam structure.

Professional coordination **(Project Management)** in all involved processes and along the entire project is the foundation of having an influence on the concrete result. In other words, each individual process needs to be optimized, custom tailored and monitored in order to meet the project specific requirements. Just the sum of all involved processes and the learning of the monitoring is creating and assuring the final concrete result.

To sum up, the ‘big picture’, considering the influences from the concrete and concrete temperature & strength development in combination with an effective and efficient formwork solution, is providing the possibility to optimize the construction method resulting in increased concrete quality in dam constructions.

Figure 11: Hydro power plant Lehen, Austria

3. ADVANTAGES FOR CONSTRUCTION COMPANIES AND INVESTORS

Amidst the different options in power plant construction, there is one goal at the top of the list: producing energy as quickly as possible. Although the objective is formulated with utmost simplicity, the solutions for getting there are no less challenging.

The combination of formwork experience and concrete expertise of Doka allows the customer a ‘scenario gaming’ in the design phase of a construction project. During execution phase the ‘Concremote Value Engineering Methodology’ offers the possibility to use the most economic concrete mixture and to monitor the evolution of the temperature gradients in the concrete. The resulting benefits are a higher productivity during construction, higher concrete quality and financial savings during execution and the service life of a dam structure.

1. INTRODUCTION

Dam surveillance is crucial to minimize the risk of a dam failure. The International Commission on Large Dams (ICOLD) proposes guidelines to establish surveillance procedures, including instrumentation of sensors for monitoring and evaluating the data [1]. The overall assessment of dam safety comprises three major pillars: monitoring, visual inspections and checking & testing (Fig. 1). While special tests are due every one to five years, monitoring and visual inspections are required at frequent intervals.

A typical monitoring setup consists of a variety of sensors, each of which complements the other and contributes to the model analysis. The mathematical models also take into account the sensor limitations (e.g. sensitivity, accuracy) and thus give a good estimate on the reliability of the results. By contrast, visual inspections highly depend on the inspector's experience or performance. The resulting report, including photographs, drawings and comments, is subjective and may be incomplete and inaccurate, especially for the long-term documentation and inspection of the concrete surface of a dam's downstream side. Consequently, emerging technologies, as laser scanning and digital imagery, gain more and more attention for addressing these problems. A comprehensive three-dimensional documentation of the dam proved beneficial in deformation monitoring as well as for surface documentation. For this purpose, researchers focused on using Unmanned Aerial Vehicles (UAVs), carrying a Single Lens Reflex (SLR) camera

[2,3], cameras with telescopic lenses [4] and terrestrial laser scanners (TLS) in the past [5].

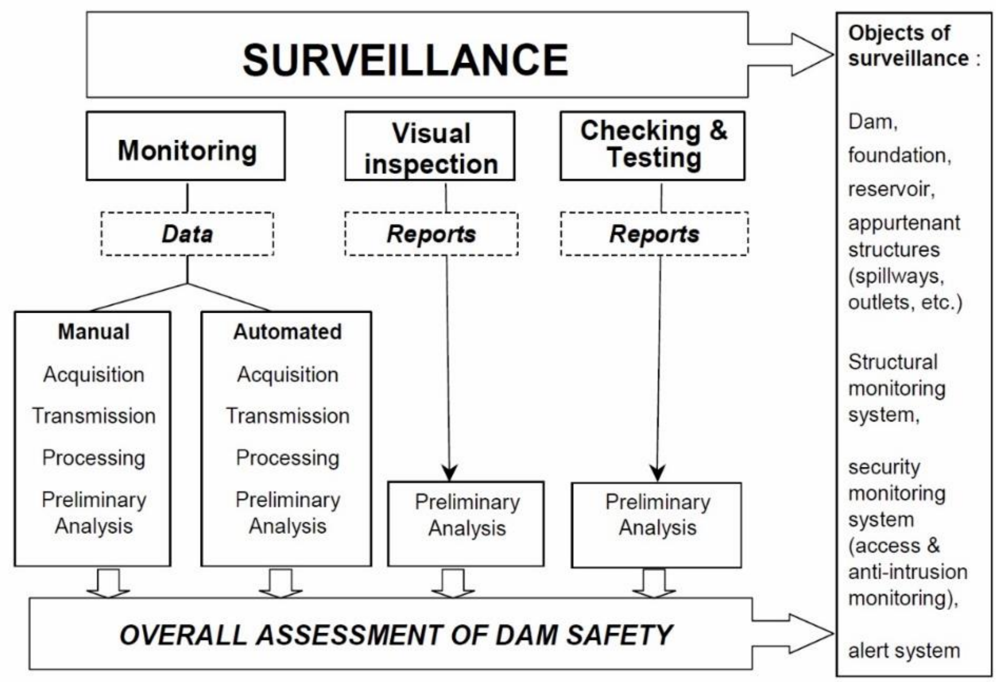

Fig. 1:
Dam surveillance as defined by ICOLD [1, p. 4]

The mentioned technologies imply highly sophisticated data acquisition and processing methods, requiring significant investments of money and time. For this reason, we propose a method, in which we use a sensor commonly used by dam operators in order to accomplish the same as by using UAVs and TLS. The recent developments of total stations (TS) [6] brought scanning and image functionalities, and thus opened up new fields of application such as surface mapping. In this paper, we present an approach for surface documentation and evaluation with modern total stations, which we apply to an Austrian arch dam. We present a workflow to compute a photorealistic three-dimensional model. Additionally, we introduce a novel system concept for automatic on-site detection and mapping of concrete deficiencies with high-resolution. By applying state-of-the-art processing techniques to the scan and image data and by exploiting the hardware features of the hybrid instrument, we demonstrate the potential for a surface monitoring solution. This solution enables merging the two major pillars of dam surveillance, monitoring and visual inspections. The proposed system enables change detection analysis of the dam’s surface and hence a novel tool to contribute to an objective overall assessment of dam safety.

2. VISUAL DOCUMENTATION OF DAM SURFACES WITH MODERN TOTAL STATIONS

2.1. DATA ACQUISITION

For geodetic monitoring with total stations, the competent surveyor establishes stable points with known coordinates in the dam's vicinity. These points ensure that observations of multiple epochs and/or setup points are referenced in a common coordinate frame. Regarding modern total stations, which enable scanning and imaging, this is a large benefit over TLS and SLR cameras, as point clouds are registered directly and image orientations are already known and stored when images are captured.

Within a predefined polygonal area, modern TS instruments take images and acquire the scan data autonomously. The scanning resolution is not critical, as the shape of concrete (arch) dams is regular and thus well known.

2.2. DATA PROCESSING

The process of combining geometry and texture content of an object's surface is denoted as surface mapping. The principle workflow for processing the acquired scan and image data to derive a textured 3D photo model is illustrated in Fig. 2.

The processing of the scan data (left box in Fig. 2) implies point cloud registration, filtering, outlier elimination and hole filling procedures. Based on the preprocessed point cloud, we compute a continuous digital representation of the surface with a combined approximation-interpolation method. We partition the data space into voxels, for which we compute characteristic points by averaging the respective points inside. This step provides a simple but effective approximation method and hence noise reduction.

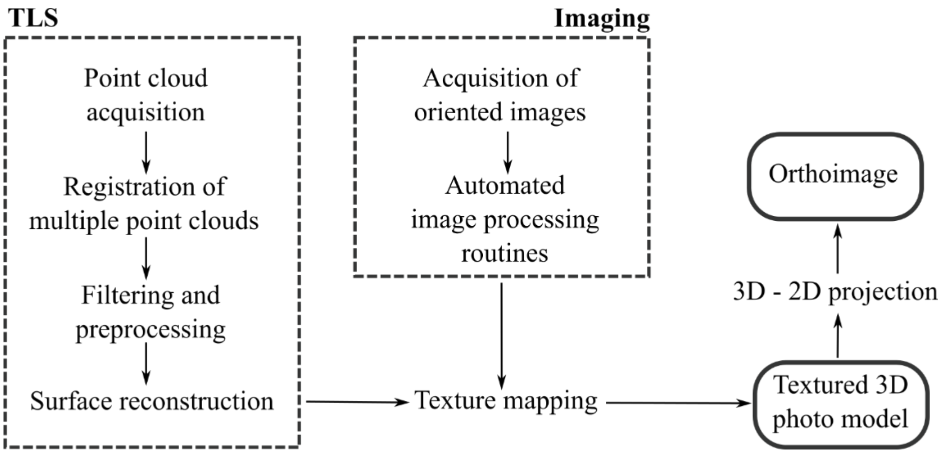

Fig 2:
Workflow to compute 3D photo models from scan and image data of TS

Eventually, we use 3D Delaunay triangulation to compute a triangle mesh, i.e. a set of triangles connecting the denoised point cloud.

Dependent on the properties of the captured images, we apply automated image processing techniques to reduce radiometric differences and thus to obtain a homogenous texture. Due to the knowledge about the orientation of each image, the textures are mapped onto the surface model, which is why this step is called texture mapping. As a result, a photorealistic representation of the dam's surface is obtained, which we then map onto a 2D plane to derive an ortho image with metric information.

2.3. FIELD STUDY AT AN AUSTRIAN ARCH DAM

To validate our approach, we performed practical measurements at the Drossen dam, which is located near Kaprun, Salzburg. It is 112 m high, has a crest length of about 360 m, and is thus one of the largest dams in Austria. Together with the Mooser dam, it impounds the Mooserboden reservoir.

Due to the large object-to-instrument distances (up to 200 m) and the scan range limitations, at least two setup points were required to cover the full dam. In order to speed up the data acquisition, we decided to use two total stations simultaneously set up at P_1 and P_2 (see Fig. 3 left). We used fixed points with known coordinates to reference measurements from both instruments in the national reference system.

We decided to use a Leica Multi Station MS50 and MS60. Both instruments use the same hardware for scanning and imaging. The instrument scans up to 1000 points per second with an accuracy of 2 mm at 100 m distance.

Fig 3:

Measurement site, overview image showing the two concrete dams of the reservoir Mooserboden (left, source: Verbund), illustration of the relevant components of the Multi Station MS60 (right)

The used instruments offer two cameras: the Overview Camera (OVC) and the On-Axis Camera (OAC). The OVC is a wide-angle camera with fixed focus and a large field of view (FOV) located above the telescope (see Fig. 3 right), whereas the OAC has a small FOV but benefits from the telescope's 30× magnification, providing image content rich in detail. Calibration of the OAC [7] gives an angular resolution of approximately 1.96″/px in horizontal and vertical direction, which corresponds to a spatial resolution of 1 mm at 100 m distance.

Altogether, we acquired point clouds with around 10 million points and 300 OVC photos completely covering the Drossen dam. The fully automatic acquisition of scan and image data took about 4 hours in total.

Fig. 4 displays the final 3D photo model of the Drossen dam.

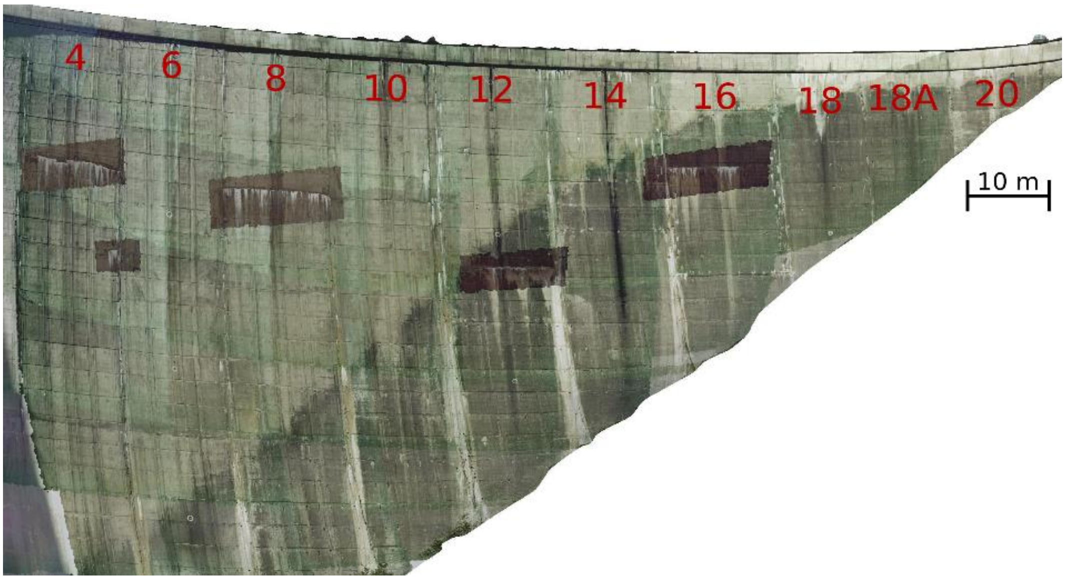

Fig. 4:
Textured 3D photo model of the Drossen dam

Apart from OVC images covering the complete dam, we captured OAC images of selective defects (dark ares of Fig. 4) and used them for texture mapping as well. Hence, large-scale textures and high-resolution textures are combined in one model providing a detailed documentation for areas of interest at relatively low memory capacity and computational cost. For defect regions, we generate ortho images with sequences of overlapping high-resolution OAC photos (see Fig. 5). While easy to handle, ortho images provide a valuable data basis for an objective assessment of the concrete's state. It is now possible to measure on the dam's surface without requiring direct access.

3. SURFACE MONITORING SOLUTION WITH TOTAL STATIONS FOR ENHANCEMENT OF VISUAL INSPECTIONS

3.1. METHODOLOGY

Large dams commonly show concrete deficiencies, which do not necessarily pose a risk to the structure's safety. Some of these deficiencies appear just after construction and do not change over time. Therefore, detection of any visual changes on the dam's surface is crucial. The objective is the development of an algorithm to automatically detect new defects and identify the extent of deterioration of existing ones. In principle, we exploit the spatial information of the TS and use images to derive semantic information for visual change detection. We divide our evaluation into two parts: the on-site detection and acquisition and the change detection analysis, which we perform in a subsequent step (see Fig. 6).

We developed an application to carry out all required work processes (remote control, processing) on-site on a standard laptop. After the user measures the contours of the dam's surface, the instrument starts full dam photo acquisition with the OVC. With image-processing techniques applied to the OVC images, we localize defect regions on the dam (cf. Section 3.2). The known camera model simplifies the combination of image content to spatial information, i.e. horizontal (Hz) and vertical (V) angles.

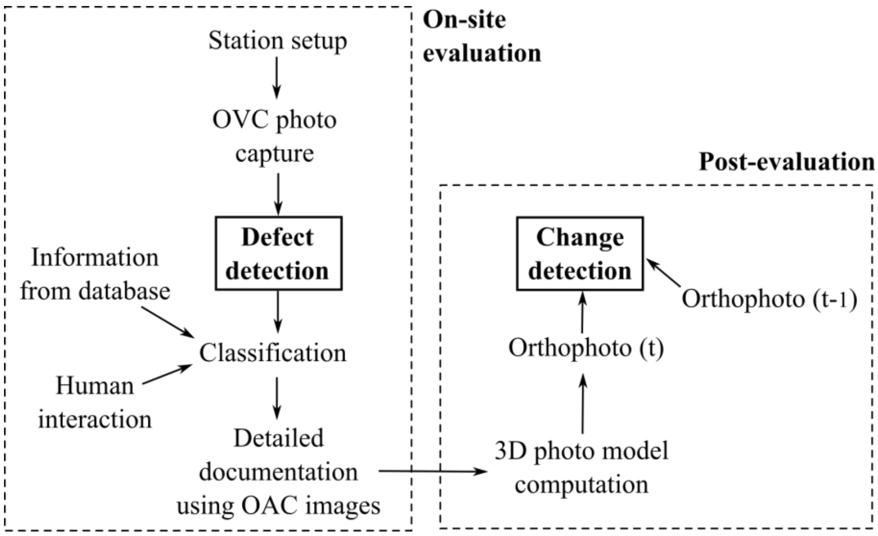

Fig 6:
Operating principle of the proposed surface monitoring solution

Afterwards, the application starts high-resolution scan data and OAC photo acquisition of potential defect regions. At this point, the operator can manually interact in order to minimize the time effort needed for data acquisition. However, to enhance the entire acquisition process, we propose an automatic classification procedure based on foreknowledge. Therefore, we establish a database containing coordinates of true defects as well as mistakenly identified defect regions in the past surveys. The results of the automatic defect identification is hence dependent on the scope of effort spent on labeling the data (in terms of spatial or semantic information).

3.2. IMAGE-PROCESSING FOR DEFECT DETECTION

In order to formulate an algorithm, which is capable to detect damages on the concrete surface based on OVC photos, knowledge about the visual appearance of defects is necessary. For example, white spots on a concrete surface usually imply sinter formation, which may result from cracking or block joint openings. Wet areas, pop outs and other deficiencies evoke recognizable visual irregularities. Consequently, we analyze the captured OVC photos on these characteristics.

While most researchers focused on detecting cracks from images [8, 9, and 10] in the past, we generalize our analysis to detect any kind of concrete deficiencies on a dam using the captured OVC images. Fig. 7 shows the intermediate results of the algorithm. Detailed information on the procedure can be found in [11]. The algorithm describes potential defects in terms of pixel coordinates of the bounding rectangle (Fig. 7d), which eventually gives the orientation angles for the TS (using the known camera model). This angle values are used to steer the TS and to capture high-resolution images of the potential defect areas. It becomes obvious that the complete data acquisition is automatable by using a modern TS and a database with spatial information on the dam's boundaries and apparent defects.

(d) Filtered and identified defects

Fig. 7:
Important steps of the defect detection algorithm

3.3. MONITORING VISUAL CHANGES

The detection of visual changes in images is a well-researched topic in the field of remote sensing [12]. Consequently, a wide range of approaches were developed for automatic unsupervised change detection analysis in the past years. However, it turns out that these algorithms are well suited not only for large-scale satellite images but also for high-resolution ortho images of concrete defects.

One approach is to compare the pixel intensities of two images by e.g. differencing, rationing or by image regression [12]. It is simple, easy to implement but is sensitive to the acquisition conditions. Therefore, it is essential to pre-process the data, i.e. to match the images in terms of radiometry and spatial coverage. We adopted the analysis of [12, 13] and focus on gray value differences in the ortho images.

We validated the algorithm by placing shaving foam near a concrete crack to simulate an increase of efflorescence. The approach proved suitable to detect the changes and even to compute the area of change. Nevertheless, changing lighting conditions pose a problem to the algorithm, requiring more investigations for establishing a fully automatic change detection analysis. However, it assists the dam engineer and provides quantitates to assess the dam safety objectively.

SUMMARY

In this paper, we presented a new approach for surface documentation using scan and image data of modern total stations. The proposed method is easy to perform for surveyors and requires less effort in data acquisition and processing compared to other measurement principles (e.g. documentation with UAVs).

The used total stations benefit from classic setup routines providing referenced point clouds and oriented images at the time of measurement. Hence, if stable points with known coordinates exist for referencing the measurements, the surveyor has to perform the time-consuming scanning process only once. It is thus possible to combine geometry acquired at the initial measurement epoch with photos captured at different measurement times to derive textured 3D models and ortho images.

We introduced a novel surface monitoring solution to address the risks related to visual changes on dam surfaces. By applying image-processing techniques to the acquired overview images, we automatically detect concrete deficiencies. With a database containing information from previous surveys, the system identifies newly emerged defects directly on-site. Subsequently, the instrument takes telescope images and scans dense point clouds of selective defects. As a result, the developed system provides multi temporal ortho images with high resolution, which we utilize to detect and to quantify changes on dam surfaces.

Our proposed approach delivers data, which is accurate, complete and objective. However, our system does not intend to replace the human inspector but it aims to provide a valuable data basis to enhance the safety assessment of large concrete dams.

Analyse Paramétrique de l'influence des effets flexuraux, deformation de cisallement et de rotation inertielle sur des barrage de poids en béton

1. INTRODUCTION

Dams have an important economic role, either as reservoirs or to increase the potential energy of water and generate electricity. However, due to the possible rupture; they have a high-risk potential, which imposes more rigorous analyzes and inspections. These structures can cause enormous worries because of the possibility of eventual collapse, with consequences for the environment, destruction of fauna and flora, and loss of human life.

In the literature, there are few researches that contemplate the behavior of the flexion and shear effects of the dam as a result of a simplification adopted on the representation of the problems that involves those structures. Theories of the equation of motion are distinguished, existing theories that include only the bending effect (Euler-Bernoulli theory), bending and rotational inertia (Rayleigh Theory) and bending, rotational inertia and shear deformations (Thimoshenko's theory). In general, such effects are more important as less slender the structure is. For plane state structures, the slenderness can be measured as the ratio of its width by length or height

The present study sought to analyze the influence of the consideration of shear effects and rotational inertia as well as to develop a code in the Python language based on the technique of finite differences. For the validation of the results based on the program, the outcomes of a supported beam were compared with those obtained by the Ansys v18 (finite element software).

For simplicity of calculations and numerical modeling, it is assumed that the dam can be modeled as a cantilever beam of variable section, using the hypothesis of plane strain state. Also, the properties of the material are homogeneous, isotropic, linear and elastic.

A parametric analytical study is developed to verify the influence of this consideration on the first five natural frequencies of a beam, admitted by simplification as simply. Then, several models of beams with different boundary conditions and width / length ratios are analyzed. Based on the program developed, it is obtained the results of the first five natural frequencies; then, graphs are drawn illustrating the influence of considering these effects for clamped beams.

The major studies that this article was based on: Anderson [1] studied the transverse motion of beams modeled in the Timoshenko manner for the case of time dependent boundary and normal loads. Clough [2] presents the theoretical dynamic analysis of continuous systems, in which theory this work is based on. Herzog [3] presents an approximate method of calculation using a shell platform and a series of approximations. Silva [5] studied a particular types of non-uniform cantilever beam structures as wedges and cones are vastly used in engineering practice.

2. THEORETICAL EQUATION OF DEEP BEAM NATURAL FREQUENCY

According to Pedroso [4], the vibration equation of a deep beam, with constant properties along its length, considering the flexural, shear deformation, and rotational inertia of the cross-section effects and am applied dynamic distributed load is given by Eq. [1]:

$$EI \cdot \frac{\partial^4 y}{\partial x^4} - \left(q - \bar{m} \cdot \frac{\partial^2 y}{\partial t^2}\right) - J \cdot \frac{\partial^4 y}{\partial x^2 \partial t^2} + \frac{EI}{\gamma} \cdot \frac{\partial^2}{\partial t^2}\left(q - \bar{m} \cdot \frac{\partial^2 y}{\partial t^2}\right) - \frac{J}{\gamma} \cdot \frac{\partial^2}{\partial t^2}\left(q - \bar{m} \cdot \frac{\partial^2 y}{\partial t^2}\right) = 0 \quad [1]$$

Where $\bar{m}$ is the mass by unit length; $\gamma = k' \cdot G \cdot A$, where k' the shear correction factor of the section, A is the section area and G is the transverse elastic modulus of the material; and $q = f(x, t)$ is the dynamic distributed load.

It is useful to state the meaning of each term in the Eq. [1]. The first term (Eq. [2]) represents the basic flexural theory (Euler's beam). The second term (Eq. [3]) represents the consideration of rotational inertia of the cross-section effect. The third term (Eq. [4]) represents the shear deformation effect. The fourth term (Eq. [5]), represents the coupling between the rotational inertia and shear effects.

$$EI \cdot \frac{\partial^4 y}{\partial x^4} - \left(q - \bar{m} \cdot \frac{\partial^2 y}{\partial t^2}\right) \quad [2]$$

$$J \cdot \frac{\partial^4 y}{\partial x^2 \partial t^2} \quad [3]$$

$$\frac{EI}{\gamma} \cdot \frac{\partial^2}{\partial t^2}\left(q - \bar{m} \cdot \frac{\partial^2 y}{\partial t^2}\right) \quad [4]$$

$$\frac{EI}{\gamma} \cdot \frac{\partial^2}{\partial t^2}\left(q - \bar{m} \cdot \frac{\partial^2 y}{\partial t^2}\right) \quad [5]$$

To obtain the mode shape function of free vibration, one can apply the separation of variables procedure to decouple the solution of Eq. [1] into a function of x (mode shape) and t (time-dependent amplitude) [2]. Assuming a harmonic response for the time-dependent amplitude, the application of separation of variables into Eq. [1] written for free vibration, i.e. $q = 0$, yields Eq. [6]:

$$\phi(x)^{IV} - a^4 \cdot \phi(x) + a^4 \cdot r^2 \cdot \phi(x)^{II} + \frac{\bar{m} \cdot \omega^2}{\gamma} \cdot [a^4 \cdot r^2 \cdot \phi(x) + \phi(x)^{II}] = 0 \quad [6]$$

Where $\phi(x)$ is the mode shape; $\phi(x)^i$ denotes the *i*-th derivative of $\phi(x)^i$ relative to x; r is the radius of gyration; and a is a convenient constant defined in Eq. [7]:

$$a = \frac{\bar{m} \cdot \omega^2}{EI} \quad [7]$$

For simplicity it is assumed a mode shape form of a simply supported beam, since analytical solution of Eq. [6] is complex for other support conditions. The validity of such supposition for gravity dams models will be further assessed. For a simply supported beam, the mode shape has the form [2]:

$$\phi(x) = X \cdot sin\left(\frac{m \cdot \pi \cdot x}{L}\right) \qquad [8]$$

Where L is the length of the beam; $m = 1, 2, 3, \ldots$ is a natural number that indicates the vibration mode; and X is a constant for generalization purposes. Substituting Eq. [8] in Eq. [6], one arrives in Eq. [9], after arithmetical manipulations:

$$\left(\frac{m \cdot \pi}{L}\right)^4 - a^4 - a^4 \cdot r^2 \cdot \left(\frac{m \cdot \pi}{L}\right)^2 \cdot \left(1 + \frac{E}{k'G}\right) + a^4 \cdot r^2 \cdot \left(a^4 \cdot r^2 \cdot \frac{E}{k'G}\right) = 0 \qquad [9]$$

Following Pedroso [4], for the first vibration modes the last term of the sum in the left-hand side of Eq. [9] can be disregarded since it can be proven to be very small when compared to the third term. With this consideration, Eq. [9] can be simplified to Eq. [10]:

$$a^4 = \beta^4 \cdot \frac{1}{1 + r^2 \cdot \beta^2 \cdot (1 + \gamma')} \qquad [10]$$

Where the terms β and γ' are defined as:

$$\beta = \frac{m \cdot \pi}{L} \qquad [11]$$

$$\gamma' = \frac{E}{k' \cdot G} \qquad [12]$$

From Eq. [10] it is possible to define τ as the correction factor for shear deformation and rotational inertia of the cross-section effects:

$$\tau = \frac{1}{1 + r^2 \cdot \beta^2 \cdot (1 + \gamma')} = \frac{1}{1 + r^2 \cdot \beta^2 + r^2 \cdot \beta^2 \cdot \gamma'} \qquad [13]$$

With Eq. [7], [10] and [13] one arrives at the Eq. [14]:

$$\omega_m^{f+s+r} = \left(\frac{m \cdot \pi}{L}\right)^2 \cdot \sqrt{\frac{EI}{\bar{m} \cdot L^4} \cdot \tau} \qquad [13]$$

With $m = 1, 2, 3, \ldots$ defining the vibration mode considered. Eq. [13] defines the natural frequency of a deep beam considering the flexural, shear deformation, and rotational inertia of the cross-section effects. It is interesting to observe the resemblance of Eq. [13] to the classical natural frequencies equation of Euler's beam: the only difference is the correction factor τ.

It is important to note that Eq. [13] is valid for a beam with constant properties along its length and only for its first vibration modes.

3. ANALYTICAL PARAMETRIC ANALYSIS OF SHEAR DEFORMATION AND ROTATIONAL INERTIA OF CROSS-SECTION EFFECTS AND DEVELOPMENT OF A FINITE DIFFERENCE METHOD ALGORITHM

From Eq. [13], making $\tau = 1$ one obtains the classical natural frequencies equation of Euler's beam, which considers only the flexural effect:

$$\omega_m^f = \left(\frac{m \cdot \pi}{L}\right)^2 \cdot \sqrt{\frac{EI}{\bar{m} \cdot L^4}} \qquad [14]$$

The division of Eq. [13] by Eq. [14] defines the parametric ratio between these two frequencies:

$$\frac{\omega_m^{f+s+r}}{\omega_m^f} = \sqrt{\frac{1}{1 + r^2 \cdot \beta^2 + r^2 \cdot \beta^2 \cdot \gamma'}} \qquad [15]$$

To perform the parametric analysis, consider a beam with cross-section height equal to h and Poisson ration ν. Substituting the definitions of Eq. [11] and [12] in Eq. [15], and performing some arithmetic manipulations, one obtains:

$$\frac{\omega_m^{f+s+r}}{\omega_m^f} = \sqrt{\frac{1}{1 + \frac{(m \cdot \pi)^2}{12} \cdot \left(\frac{h}{L}\right)^2 + \frac{(m \cdot \pi)^2}{5} \cdot \left(\frac{h}{L}\right)^2 \cdot (1 + \nu)}} \qquad [16]$$

The ratio $h \,/\, L$ is a typical measurement of the importance of considering shear effects in beams. The higher this ratio more the beam behavior approaches to deep beam rather than slender beam.

Due to the complexity of the analytical approach for the dynamic problem of clamped beams, with variable section, based on the theory of Timoshenko, the numerical approach of the problem is justified.

In the present work, it was used the Finite Differences Method (FDM), implemented using the Python programming language, to discretize the general dynamic equation of the Timoshenko beam in free vibration, presented in Eq [6].

The FDM is a method to solve differential equations that is based on the approximation of derivatives by finite differences. The approximation formula is derived from the Taylor series of the derived function. In Eq [6], the differential operators of fourth and second order can be replaced by finite expressions of FDM.

After a mesh convergence study, it was chosen to use a 30-node model in all simulations made in this work.

The first validation of the implemented algorithm was done comparing the analytical results for a typical simply supported beam with constant cross-section, given by the parametric equation presented in Eq. [13], with the numerical results. Considering a typical beam, it is obtained the parametric curves that associate the variation of the h / L ratio, measure of beam depth, to the relation between frequency obtained by Euler's theory and Timoshenko's theory. The results are presented in Figure 1. It is observed a good conformity between the analytical curves and the numerical ones, obtained by the algorithm implemented.

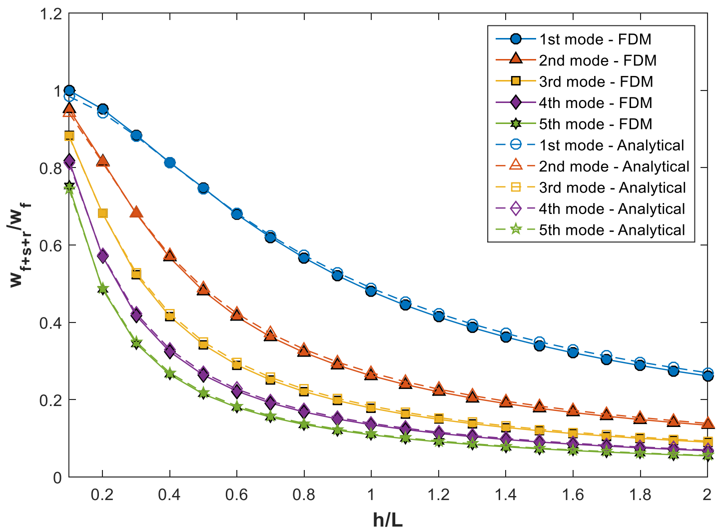

Figure 1: Analytical and numerical results for the ratio between the natural frequencies of Timoshenko and Euler theories, for a simply supported constant cross-section beam.

The analytical results, in general, presents a greater impact of the effects of Timoshenko, denoting that the numerical model implemented produces a more rigid model. However, such behavior is expected from numerical models if compared to analytical results.

In addition, a validation was also made through the comparison with a finite element model developed in Ansys software. In this case, a cantilever beam, with constant section and typical properties, was modeled both in the finite element software and using the FDM algorithm.

It is possible to observe an acceptable approximation between the results, validating the implemented algorithm through the comparison with Ansys, which besides being a consecrated software, uses a stronger formulation (finite elements) than the finite differences.

It is important to note that, as the h / L ratio is increased, making the beam more rigid and the Timoshenko effects more important, the FDM implemented formulation differs more and consistently in all modes from the formulation of finite elements. The results via FDM present visibly more rigid models, with higher natural frequencies, which evidences the difficulty of the implemented modeling to correctly capture the real behavior of the beam.

However, due to the consistency of this increase over all modes, the algorithm is considered as valid for a parametric and qualitative investigation of the effects of Timoshenko on clamped free beams with variable cross-section

4. PARAMETRIC ANALYSIS OF A CANTILVER BEAM WITH VARIABLE CROSS-SECTION

As already presented, the dam dynamic problem can be analyzed, in an initial study, as a cantilever beam with variable cross-section, based on the plane strain state hypothesis. In this section, the FDM algorithm is used to evaluate the impact of shear deformation and rotary inertia consideration on the natural frequencies of a clamped-free beam, representing a dam in plane strain state.

For all analyzes performed, the following properties of the material were used (Table 1):

ρ (kg/m³)	2400
Young's modulus- E (GPa)	20
Poisson coefficient	0.2

Table 1: Properties of material

First, a beam with constant section is analyzed, to identify only the influence of the shear deformation effects and rotational inertia on the section.

For this, three analyzes are made: two with only one of the effects acting, and a third considering all the effects, including the coupling. The Figures 2, 3 and 4 present the results. The first frequency was not included due to an unexpected behavior, which will be further discussed.

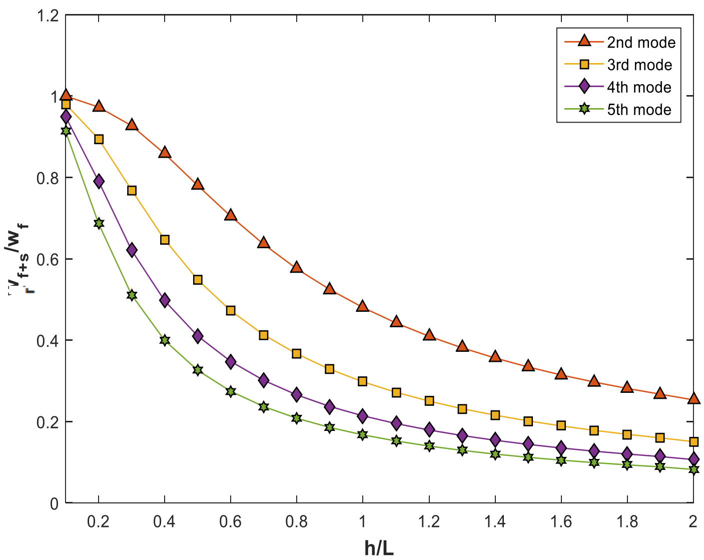

Figure 2: Ratio between the natural frequencies of Timoshenko and Euler theories, for a cantilever beam with constant cross-section, considering only rotary inertia effects.

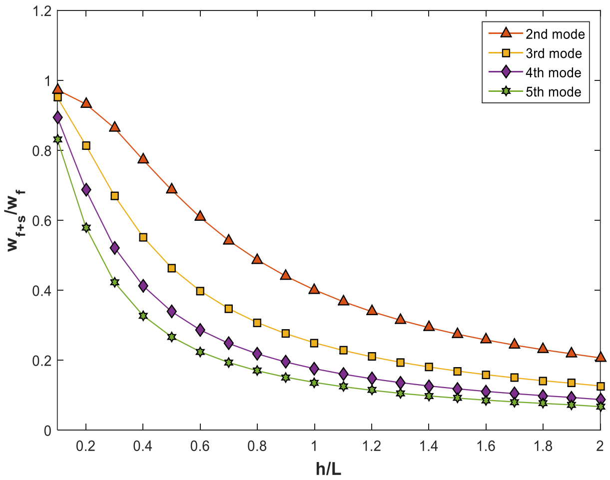

Figure 3: Ratio between the natural frequencies of Timoshenko and Euler theories, for a cantilever beam with constant cross-section, considering only shear deformation effects.

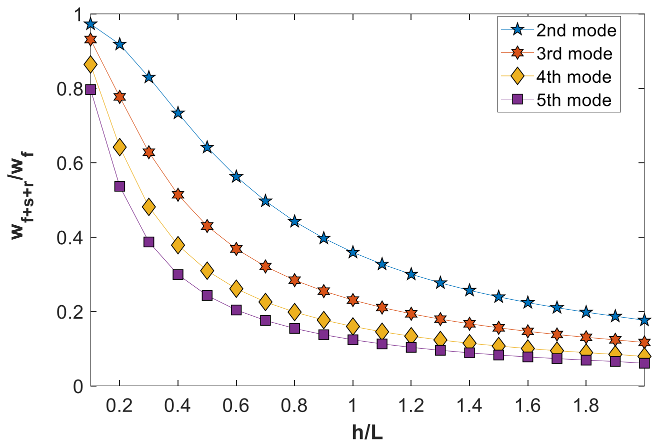

Figure 4: Ratio between the natural frequencies of Timoshenko and Euler theories, for a cantilever beam with constant cross-section, with all effects.

In the analysis, it was noted that the behavior for the first frequency differs from that expected: the consideration of the Timoshenko theory effects made the beam behave more rigid in the first natural frequency, resulting in ratios higher than the unity. Such behavior is contrary to the very nature of considering such effects, which is achieving a more realistic behavior, considering additional effects that induces a more flexible model.

Although the consideration of only the rotational inertia produced values ratios below the unity for the first frequency, the consideration of shear deformation and all effects, including coupling, caused the Timoshenko beam to produce more rigid results. Thus, it was chosen to disregard the analysis of the first frequency which, although it is the most relevant in the dynamic study of structures, could not be well represented by the algorithm developed, either due to the implementation made or by inaccuracies of the Finite Differences Method, since it could not be identify the source of such difference.

The other frequencies, however, presented well-formed and expected behaviors, comparable to results obtained in test models in Ansys. Thus, the analyzes with variable section are also only done for the frequencies of the second to the fifth mode.

For the case of variable cross-section, it is analyzed various relations h/L, being h the height of the base cross-section of the beam (or dam base width in plane strain state) and L the length of the beam (or dam height in plane strain state). The top cross-section height is fixed as half of the base cross-section (Figure 5).

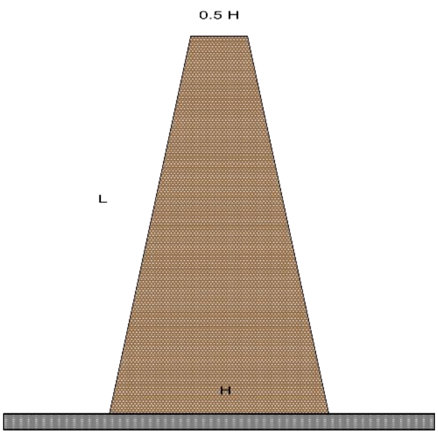

Figure 5: Geometric values used in the variable cross-section study.

The results for the variable cross-section case are presented in the Figure 6.

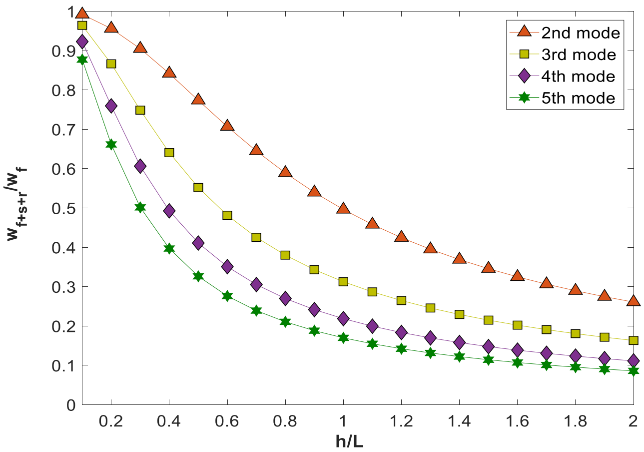

Figure 6: Parametric results for a cantilever beam with variable cross-section.

Comparing the results of variable cross-section with those for constant cross-section, presented in Figure 4, it is observable that the variable cross-section induces higher ratios, i.e. the Timoshenko effects tend to be slightly less present. For the same h / L ratio, the frequency ratios for all modes are higher for a variable cross-section than for the constant cross-section case.

5. CONCLUSION

The aim of this study is to observe the influence of considering the effects of shear deformation and rotational inertia in the dynamic analysis of a dam, modelled as a homogenous clamped beam.

The aim of this study is to observe the influence of considering the effects of shear deformation and rotational inertia in the dynamic analysis of a gravity dam, modelled as a cantilever beam with variable cross-section. This simplified dynamic analysis can serve as a preliminary evaluation of the dam's structural behavior and support additional detailed studies.

A parametric analytical study is developed, based on a simply supported beam model, to obtain first insights on the matter. Sequentially, a numerical analysis using a FDM implementation in Python is presented and used to study the cantilever beam with variable cross-section case.

Various studies are presented aiming to validate the FDM implementation: comparison with the simply supported analytical results and finite element models in Ansys. A satisfactory approximation is observed, appropriate enough for the qualitative and exploratory purpose of this work.

The study of the cantilever beam with variable cross-section presented an unexpected behavior for the first frequency. The consideration of Timoshenko theory induced a more rigid model than Euler theory, which is not acceptable, since the introduction of shear deformation and rotary inertia adds flexibility to the model. The source of this behavior could not be tracked, and it is supposed to arise from the implementation or numerical error of the formulation used. Even though the first mode is of most interest in the dynamic analysis of structure, the analysis was carried on with the second to fifth modes, since their consistent behavior still permits the objective of an exploratory and qualitative evaluation regarding the Timoshenko effects on plane strain dynamic analysis of dams.

1. INTRODUCTION

The high arch dams are usually located in the narrow valley with steep terrain. The construction space of the storehouse is limited, the construction process is complicated, the construction methods are complex and the operations cross each other. Which makes difficult to layout construction equipment, reduce work efficiency, and even generate security risks. Therefore, how to scientifically formulate construction plans, avoid collisions and rework, and achieve efficient and safe construction of storehouse are the focuses by all parties.

According to the research [1-3], the rationality plan is directly relate to the successful implementation of the construction process. In the research about construction of time-space collisions, Hu Zhenzhong [4-6] integrated BIM and 4D technology to build structural collisions and security collision detection system. Wu Hao [7] integrated GNSS/GIS to guide cable cranes safety monitoring platform to achieve the cable crane safety operation analysis. Li Xuefeng[8] etl built cable machine and tower crane operation anti-collision system for Long Kai Kou hydropower. Xiao Zhihuai [9] combine GPS, rotating decoder and high-speed data acquisition card technology to design a dam building equipment anti-collision system. Wu Binping [10] cable machine analysis the selection of randomness and uncertainty of cable cranes, based on the edge of the limited criteria and space collisions to simulation cable cranes for arch dam. Wang Renchao [11] using spatial analysis and collision identification technology proposed a variety of construction conditions of cable casting interference and joint simulation of the rules. Ren [12] proposed a mobile crane real-time anti-collision system.

In order to analysis the time-space collision in the process of pouring of the storehouse. It is necessary to figure out the basic construction procedure and activities logical relationship, then to simulate and analyze the plan implementation process, and find out the origin of collision and propose adjustment method to avoid collisions and improve construction efficiency [13-16].

To solve the above problems, the time-space evolution model of storehouse entities is established. Then analyzes the mechanism, classification and effect of the collision of storehouse construction entity. The time-space collision simulation and detection analysis model for the storehouse based on the pouring behavior simulation model were established. The results shows that this model can provide a scientific basis for the analysis and optimization of storehouse.

2. TIME-SPACE EVOLUTION MODEL OF STOREHOUSE CONSTRUCTION

In the construction of high arch dam, efficient construction machinery is usually apply to complete the work. Since there are many contents works on the storehouse surface, different types of construction machinery are required to cooperate with each other. However, the operation modes and efficiency of different machines are different. Therefore, it is necessary to establish the time-space evolution model of different mechanical surface activities to analyze the construction state such as operating status and running trajectory and so on.

The entity in the storehouse can abstract as a mass point, and its trajectory changes with time in the three-dimensional Euclidean space [17-18] is a spatial curve. The point trajectory is divide along the curve according to a certain time step Δt. Based on the trajectory of the point in the coordinate system, the point begins to move along the space curve from point Pt at the time t and arrives at the point P_{t+1} at time t+1, $r(s_t)$ and $r(s_{t+1})$ are the arc lengths of the curves at Pt and P_{t+1}, respectively. As shown in Fig.1, the velocity and acceleration of the point moving along the curve can express as:

$$v(t)=ds(t)/dt \quad [1]$$

$$a(t)=dv(t)/dt=d^2s(t)/dt^2+(ds(t)/dt)^2 \quad [2]$$

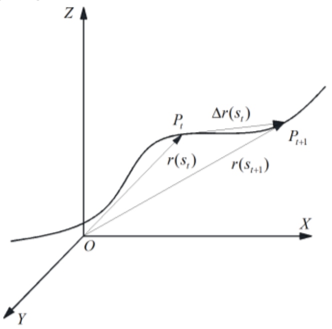

Fig. 1
Time-space path diagram

According to the above description, the time-space evolution model of construction entity in the construction space can describe by motion equations, motion trajectories, velocities and accelerations and so on. By establishing the construction space coordinate system, the entity position transformation can express as a single-valued continuous function of time t:

$$P(t)=[x(t)\ \ y(t)\ \ z(t)] \quad [3]$$

The rotation angle around the x-axis, y-axis, or z-axis is express as:

$$O(t)=[ox(t)\ \ oy(t)\ \ oz(t)] \quad [4]$$

In order to express the construction entity's translation and rotation in virtual environment, the vector $r(t)=[p(t)\ \ o(t)]^T$ is defined to represent the position and direction of the entity at a certain moment. When the construction entity moves, the time is from t_1 to t_2, its direction and position changes from $r(t_1)$ to $r(t_2)$. Through the above matrix transformation operation, the three-dimensional spatial movement characteristics of the entity in the construction space can describe.

3. CONSTRUCTION COLLISION DETECTION AND ANALYSIS

3.1. COLLISION CLASSIFICATION AND EVALUATION INDEXES

According to entities state, all entities can divide into active entities and passive entities. The position of active entity changes constantly with time. The position of passive entity remains stationary. Therefore, the collision can be simplified into two types:1) Collision between active entities;2) Collisions between active and passive entities.

Through the observation and statistical analysis of high arch dam construction process, statistics show that the main types of collisions in construction are show in Table 3.

Table 3
Collision types and description

Collision Type	Explanation
Collision 1	Among cable cranes
Collision 2	Among bucket and surface machine
Collision 3	Between bucket and dam body
Collision 4	Between bucket and temporary structure
Collision 5	Between bucket and other hoists
Collision 6	Among machines in the storehouse
Collision 7	Between machines and dam structure

The collision means that two entities overlap in the same space at the same time. Different degrees of overlap cause different collision effects. Therefore, the degree of overlap can quantify by the indicators with following indexes:

(1) The space area of collision (Sc). Two entities have intersection in space when collisions take place, and the degree of collision can measure intuitively by the calculated area of intersection.

(2) The space ratio of collision (Sr). The space ratio means the ratio between the space area of collision and the original entity, because the entity of Collision gets different damage in the collision, this index can reflect influence extent between the two collisions.

(3) The continuance of collision (Dc). The continuance means the overlap time of two entities in the space, which reflect the influence of working procedure, if the continuance is long, and it maybe influence the project schedule.

(4) The duration ratio of collision (Ds). The duration ratio means the ratio between the continuance and the set time, and determine the adjustment will be necessary or not according to this index.

3.2. CONFLICTS IMPACT ANALYSIS

After the above indicators are analysis, the collision impact to the project can divide into the following types.

(1) Significant Effect. Significant effect usually caused by the breakdown of key equipment during construction. Key equipment cannot work normally, so the construction cannot carry out.

(2) Great Effect. Great effect caused by some troubles of construction equipment due to collision, but it can be solved by analyzing and eliminating the troubles in a certain time, but it may be delay the project schedule more or less as the long solving time.

(3) General Effect. Suspend the construction for a short time because of collision, but some simple processing can solve it, and it influences the project for a short time.

(4) Slight Effect. Collision leads to the put-off of construction date of the following activities, but the normal construction can be assuring by simple adjustment or delay of the process, and it has no effect on the whole schedule.

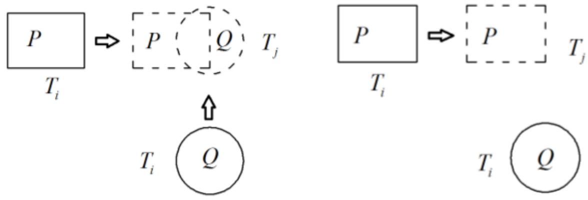
(5) No Effect. Although there is collision, the degree is subtle and it has no effect on construction entities and schedule.

3.3. COLLISION ADJUSTMENT MECHANISM

The adjustment of collisions can operate by time and space.

1) Time adjustment mechanism

The time adjustment is to change the running time parameters of the entities in the system to make the corresponding trajectories of the entities change to avoid the collision. As shown in Fig.2.



（a）before （b）after

Fig. 2

Diagram of Time Adjustment Method

2) Space adjustment mechanism

Space adjustment is to change the position of entity to avoiding collisions. It obey the following principles: 1) active entity moves priority; 2) spacious entity moves priority.

3.4. CONSTRUCTION COLLISION DETECTION METHOD

In this paper, the bounding box detection method is apply to detect the collision of entities in the virtual scene. Different entities adopt different forms of bounding boxes to satisfy detection accuracy and efficiency in this paper.

Collision detection base on the change of the state of each entity in the storehouse, and the change of the state of the storehouse entity follows a certain rules. The simulation of the storehouse construction process can base on the movement status and movement mode of each entity.

In order to make the construction process efficient and safe to implement, this paper takes the construction process of the storehouses as the main line, simulates the operation of the construction equipment in the pouring activities as the basic unit in the virtual scene, and analyzes the process collision detection and effect in the simulation process. Finally, the simulation results are record to analysis and optimize the construction process. The workflow as shown in Fig.3.

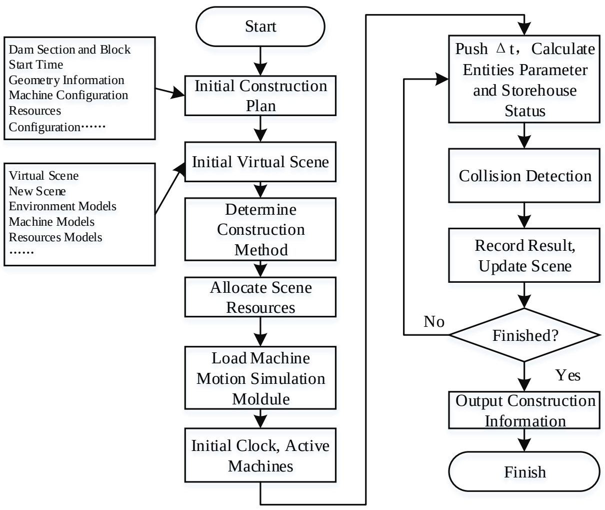


Fig. 3

Simulation process of surface in virtual scene

4. CASE STUDY

A project is located in the southwest of China. The max dam height is 285.5m. The dam body is divide into more than 2000 storehouses. One of a construction storehouse is take to simulate the process. The block located in 7# section layer 38, height 512.0m~518.0m. The volume is 3069 m^3, the storehouse area is about 1023 m^2. In initial plan, five cable cranes, five lateral unloading cars, two scrapers and two vibrators is arrange.

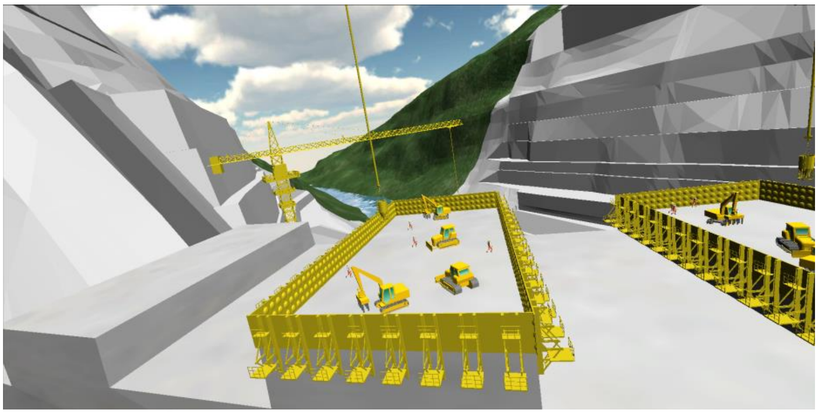

Fig. 3

A construction surface scene

When the cable crane operation speed are v_1 =(7.5m/s,3.5m/s), v_2=(6.5m/s,3.0m/s), v_3=(5.5m/s, 2.5m/s), the best operation path into the storehouse as shown in Figure 7.

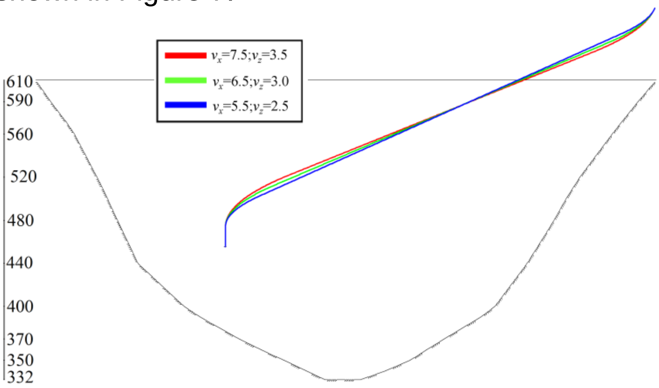

Fig 4

Optimized Cable Crane Path

After deduction of scene simulation, the total pouring time is 26.2h. The operation parameters of every cable crane is count and list in Table 4 (before optimization). In addition, the collision result as shown in Table 5. The statistic results demonstrate that collisions are mainly cause by cable crane, which also reduce the efficiency. By analysis the layout of cable crane, crane 2#~4# are located upward of block, crane 1# and 5# may effect by middle cranes. Thus, a new plan is carry out by reducing the cable crane number, and simulate again. The work time of each cable crane is list in Table 4 (after optimization). The total pouring time reduced to 23.23h.

Table 4.
The Working Time of Cable Cranes Before and After Optimization (Min)

No	Before optimization					After optimization				
	Times	Volume	Working time	Total time	Efficiency	Times	Volume	Working time	Total time	Efficiency

Collision 6	8	Avoid
Collision 7	19	Avoid

5. CONCULUSION

In this paper, according to the collision problem in high arch dam construction process, the model of time-space evolution model for entities in the storehouse is establish first. Then, the type and effect of the collision are analyze and the collision detection and adjustment mechanism was established. At the same time, a dynamic adjustment and optimization model of the construction scheme was established. At last, a case study is carry out according to a real practice, and the results shows that the method proposed in this paper can effectively provide a scientific basis for decision-making of construction projects.

SUMMARY

To resolve the time-space conflicts in pouring concrete of high arch dams, this paper first analyzes the state transition of construction entities in a three-dimensional space, and develops a time-space evolution model and description method of the entities. Then, the transition process examines generation and classification of the conflicts and their effect is examined and a mechanism of space-time adjustment to the pouring procedure is established. Finally, a conflict detection mechanism is construct by simulations of concrete pouring. We have achieved simulations of the pouring procedure in the virtual scene and developed an optimization model for dynamically adjusting the construction scheme. Application to a practical case of concrete pouring shows that this method can provide detailed data for a pouring procedure before its implementation and hence it would help analyze the feasibility and security of a construction scheme.

1. INTRODUCTION

Satellite SAR (Synthetic Aperture Radar) is one of remote sensing technologies which makes it possible to measure distributions of ground surface deformations over a wide area, and it has been commonly used to evaluate crustal displacement due to earthquakes and volcanic activity, as well as landslides.

Recently, researches on external deformation measurements for dams using satellite SAR data have been conducted [1] to [8]. For the purpose of technological development to contribute to the rationalization and efficiency of dam deformation measurements, the authors have already shown the external deformations of five rockfill dams using satellite SAR data [6]. The authors have found that the satellite SAR produced external deformation measurements which were with an accuracy of about 5 mm when compared with the external deformation measurements obtained by GPS or electro-optical survey.

This paper reports on the results of external deformation monitoring of nineteen rockfill dams in Japan using satellite SAR data. The external deformation of dams for about two years by satellite SAR was measured and compared with other existing geodetic measurements such as GPS or electro-optical survey.

2. EXTERNAL DEFORMATION MONITORING OF NINETEEN ROCKFILL DAMS USING SATELLITE SAR DATA

2.1. OUTLINE OF NINETEEN ROCKFILL DAMS AND SATELLITE SAR DATA FOR STUDY

Fig. 1 shows the locations of the dams for study. Table 1 shows main specifications of nineteen rockfill dams and observational data of satellite SAR for study. In Table 1, ASC and DSC mean ascending and descending orbits of satellite SAR shown in Fig. 2, respectively. A total of 135 scenes of SAR data was used.

ASC : Ascending, DSC : Descending
*1 : Rockfill dam part of combined dam

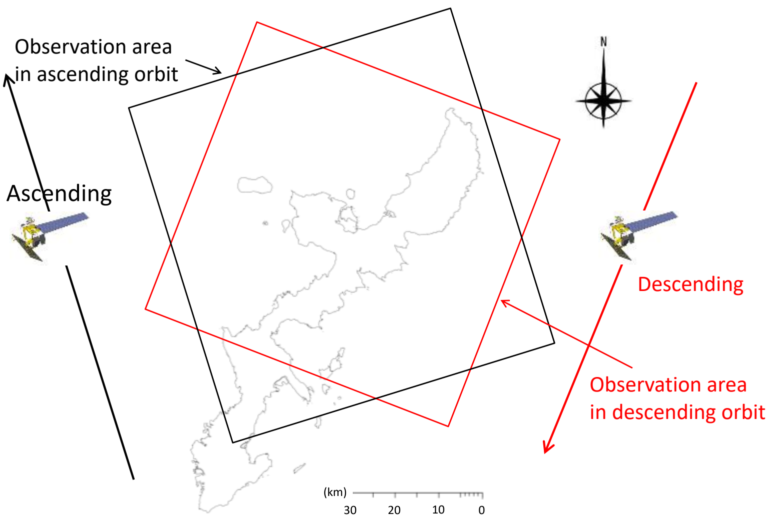

Fig. 2
Ascending and Descending Orbits and Observation Areas

In this paper, we used satellite SAR data obtained by Advanced Land Observing Satellite 2 (ALOS-2) with a Phased Array L-band SAR (PALSAR) sensor (hereinafter referred to as "ALOS-2") [9]. ALOS-2 was launched by Japan Aerospace Exploration Agency (JAXA) in January 2014 and is currently operated. The wavelength and the spatial resolution of the ALOS-2 are 23.6 cm and about 3 m, respectively.

In addition to SAR data, 2 m Digital Elevation Models (DEM) of study areas by Laser Profiler (LP) were used as initial dam body shapes to improve external deformation accuracy.

2.2. EXTERNAL DEFORMATION MONITORING USING SATELLITE SAR DATA

Fig. 3 shows external deformations of nineteen rockfill dams by satellite SAR in the line-of-sight direction from the first SAR observation to the last SAR observation day shown in Table 1. The red arrows in Fig. 3 show the observation directions of the ALOS-2. From the results of preliminary examinations, the multi-look [10], [11] for noise reduction of SAR data was set at 2 x 2 pixels (a spatial resolution of about 5m) in this paper, and the distributions of external deformations in Fig. 3 are expressed with a spatial resolution of about 5 m. Negative values in Fig. 3 mean that the dam surface deforms away from the satellite and it is almost the same direction of settlement of the dam. In the case of Dam N in Fig. 3, which showed a relatively large amount of external deformation, it was clarified with electro-optical survey after the Kumamoto earthquake in April 2016 that there had been settlement of several centimeters due to the earthquake, and earthquake-induced settlement was well measured by satellite SAR.

In order to evaluate the accuracy of satellite SAR based external deformation monitoring, Fig. 4 shows root mean square error (RMSE) distributions at existing GPS or electro-optical survey measurement points. RMSE is calculated using Eq. [1].

$$RMSE = \sqrt{\frac{1}{n}\sum_{i=1}^{n}(u_{SAR} - u_0)^2} \qquad [1]$$

Where n is the number of satellite SAR data, u_{SAR} is the external deformation measured by satellite SAR, and u_0 is the external deformation measured by GPS or electro-optical survey, respectively. If GPS data has been obtained, RMSE in Eq. [1] is calculated from the differences of external deformations between SAR and GPS measurement values at the GPS measurement points. If no GPS data has been obtained, external deformations by electro-optical survey at the SAR observation days were estimated by linear interpolation of two electro-optical survey data and RMSE was calculated from the differences of external deformations between SAR and electro-optical survey at the electro-optical measurement points.

Most RMSE values show less than 5 mm in Fig. 4 and it means that external deformations by satellite SAR have good accuracy by comparing to GPS or electro-optical survey.

Fig. 5 shows the comparisons of temporal changes of external deformations by SAR and GPS/electro-optical survey at the existing geodetic measurement points on the crests in the maximum cross sections of nineteen studied dams. Although there were small variations among the results between

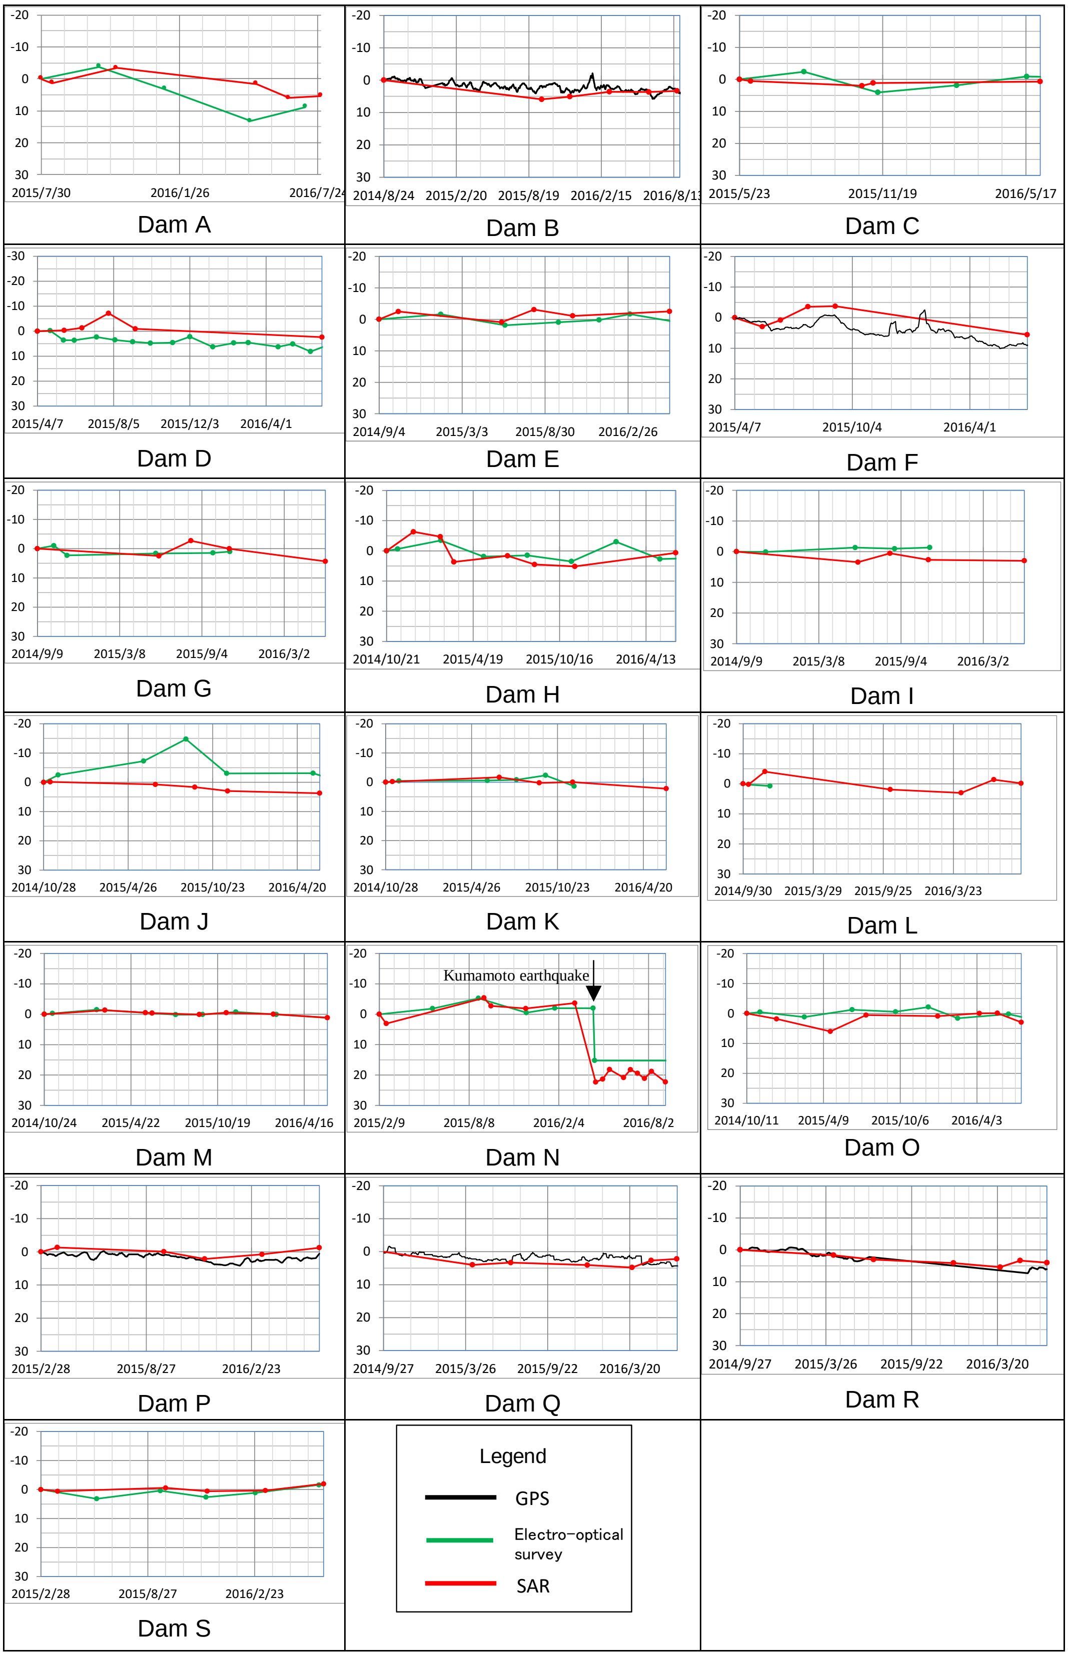

Fig. 5
Comparisons of external deformations between SAR and GPS/electro-optical survey at crests of maximum cross sections

SAR and GPS/electro-optical survey, the results of satellite SAR based external deformation measurements agreed well with the results by GPS or electro-optical survey. In the case of Dam N in Fig. 5, which showed a relatively large and sudden settlement by the Kumamoto earthquake in April 2016, earthquake-induced settlement was well measured by satellite SAR.

Table 2 shows the average RMSE on upstream, crest and downstream surfaces and all existing geodetic points of nineteen rockfill dams. Although there are some variations among the results of RMSEs in Table 2, more than half of the average RMSEs are less than 5 mm and most values are less than 10 mm. On the other hand, several RMSEs in Table 2 show more than 10 mm and the RMSE of the downstream surface of Dam N shows more than 20 mm. It is well known that deterioration in accuracy of SAR based deformation measurements occurs when ground surface is covered with vegetation [10]. Because downstream surface of Dam N has been covered with vegetation, it leads to the relatively large RMSE of downstream surface of Dam N. Table 2 shows that external deformation monitoring using satellite SAR data is generally accurate, but we must pay attention to factors that cause reduction of the accuracy such as ground surface vegetation.

3. CONCLUSION

With the aim of carrying out a development of satellite SAR-based external deformation measurement of rockfill dams, this paper focused on nineteen rockfill dams in Japan. A total of 135 scenes of satellite SAR data was used over a period of nearly two years from late 2014 to early 2016 for study. External deformations of nineteen rockfill dams were measured by satellite SAR and compared with existing GPS or electro-optical survey data. The average RMSE of nineteen rockfill dams between SAR and existing geodetic measurements was about 5 mm. As earthquake induced settlement up to several centimeters was also well measured by satellite SAR data, satellite SAR data is useful both in normal times and after earthquakes. In order to conduct accurate external deformation measurements using satellite SAR data, it is important for us to pay attention to factors that cause reduction of the accuracy such as ground surface vegetation.

Because we find that the satellite SAR based external deformation measurement of rockfill dams is accurate and useful, we will continue our research to put our research results into practical use.

ACKNOWLEDGEMENTS

This research has been supported by the Strategic Innovation Promotion Program (SIP) of the Cabinet Office, Government of Japan. We would like to thank to dam management offices in Japan which provided valuable data for our research.

SUMMARY

It is important to develop a new method of effective and efficient monitoring of dams such as external deformation measurement of embankment dams. External deformations of nineteen rockfill dams in Japan using satellite SAR data were measured in about two years, and the results of external deformations using SAR data were compared with those by GPS or electro-optical survey data. We found that the results of external deformations using satellite SAR data agreed well with those by existing geodetic data and the average error of the external deformations between SAR and existing measurements was about five millimeters. Although external deformation monitoring of rockfill dams using satellite SAR data is generally accurate, it is important to pay attention to factors that cause reduction of the accuracy of satellite SAR based deformation monitoring such as ground surface vegetation.

1. INTRODUCTION

The Mavčiče concrete gravity dam, part of the corresponding hydro-power plant, was built on the Sava River, in central Slovenia (see Fig. 1), in 1986. It has a maximum structural height of 38.5 m, and the dam crest has a length of 149 m. The concrete dam structure consists of an erection bay, a machine hall, and two spillways, followed by an embankment dam (see Fig. 2). The total capacity of both spillways, which are closed by radial gates with flaps, is 3,200 m^3/s. The reservoir, which contains 10.7 hm^3 of water, has a length of 7.0 km and the surface area of 1.0 km^2, whereas the catchment area of the reservoir is 1,480 km^2 [1, 2].

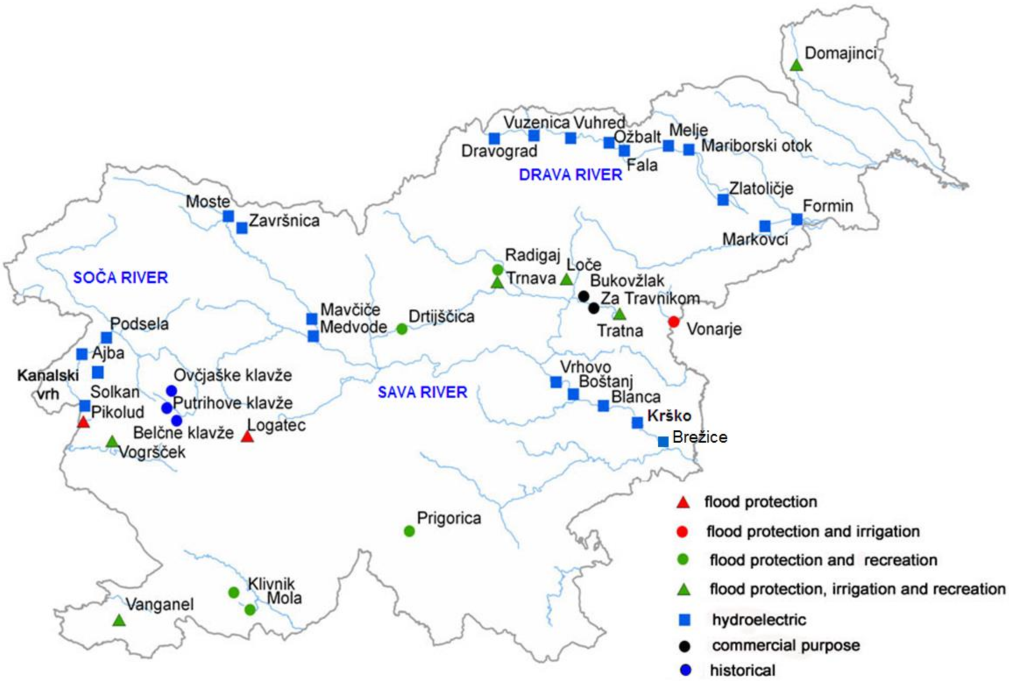

Fig.1
The locations of large dams in Slovenia

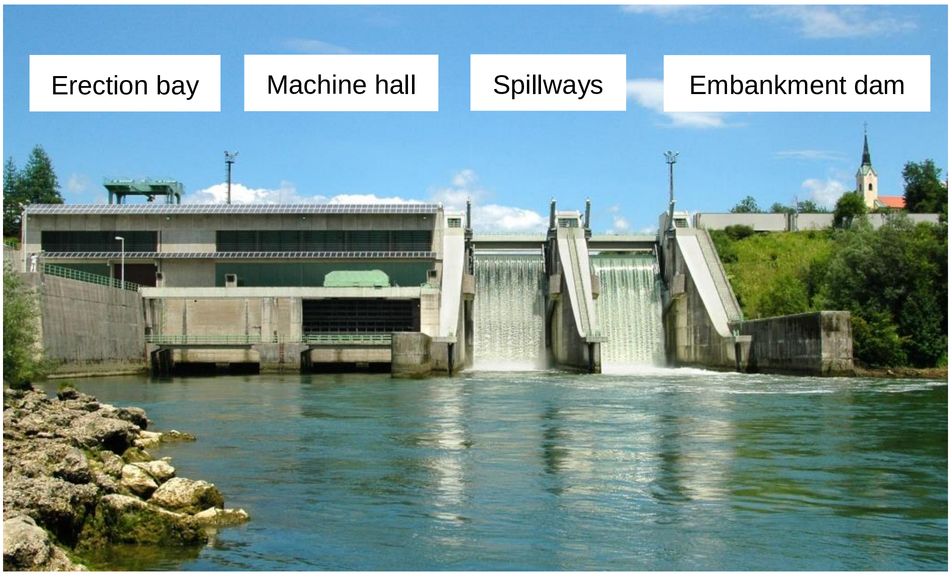

Fig. 2
View of the Mavčiče Dam

2. FOUNDATION OF THE DAM

Most of the Mavčiče Dam is founded on permeable Quaternary conglomerate bedrock, so that a cut-off grout curtain had to be constructed to a depth of up to 60 m below the ground surface, i.e. up to 296 - 302 m above sea level, where a layer of impermeable Oligocene marine clay occurs. The foundation of the machine hall is, for instance, at the altitude of 309.50 m. However, the erection bay, which is located on the right bank of the dam, is founded on a layer of gravel backfill, up to about 25 m thick, which lies on top of the conglomerate bedrock. The upper courtyard, which is located behind the erection bay, has an altitude of 348.00 m, whereas the lower courtyard, which lies in front of the erection bay, is located 10.75 m lower, i.e. at the altitude of 337.25 m [3]. The foundation of the right portion of the dam is presented in Fig. 3.

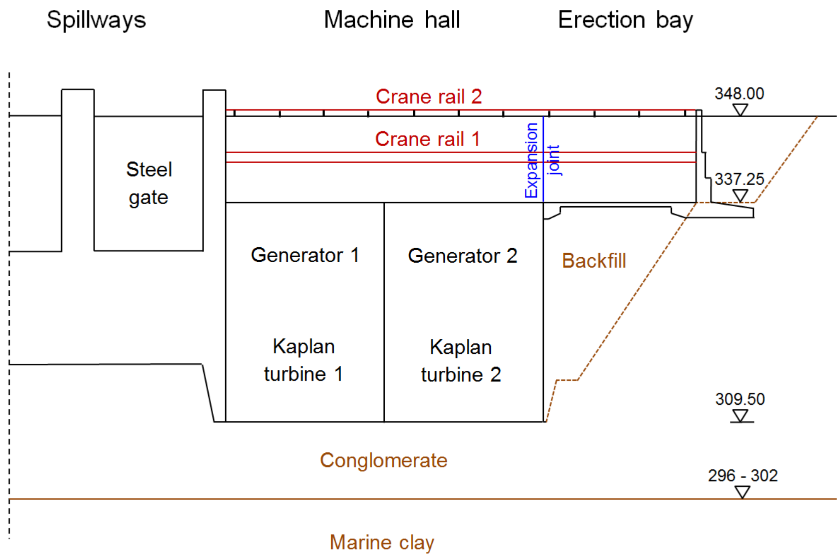

Fig. 3
The foundation of the right portion of the Mavčiče Dam

3. MONITORING SYSTEM OF THE DAM

Long-term manual technical monitoring of the behaviour of the dam began in 1986, at the time of the dam's completion, and included all necessary types of measurements and inspections. In 1999 to 2000 the supplemented monitoring system of the detailed behaviour of the right bank of the dam was established, which included twenty-six points for the vertical displacement measurements. Eighteen of these points (indicated by 1 to 10 and by A to H) were located in the upper courtyard, whereas the other eight points (indicated by 11 to 18) lies in the lower courtyard (see Fig. 4).

Because of the need for more accurate determination of the state of the dam, an automatic measurements of several parameters, mainly hydrostatic and partly hydrodynamic, began in 2003. In 2005 an automated monitoring system for determining the dynamic response of the dam to strong earthquakes, i.e. when the peak ground acceleration exceeds 0.05 g, was established (see Table 1).

Monitoring system of the Mavčiče Dam behaviour includes: deformation measurements (vertical, horizontal and relative displacements, see Fig. 4), visual inspections (structural, geotechnical), groundwater measurements (piezometric levels, uplift pressures, temperatures, specific electrical conductivities) and measurements of external loads on the dam. The latter are carried out in the reservoir, in the stilling basin, in the dam itself (including the inspection gallery and the crest of the dam), as well as on the ground surface about 150 m downstream from the dam [4, 5]. Automatic parameters are shown in Table 2.

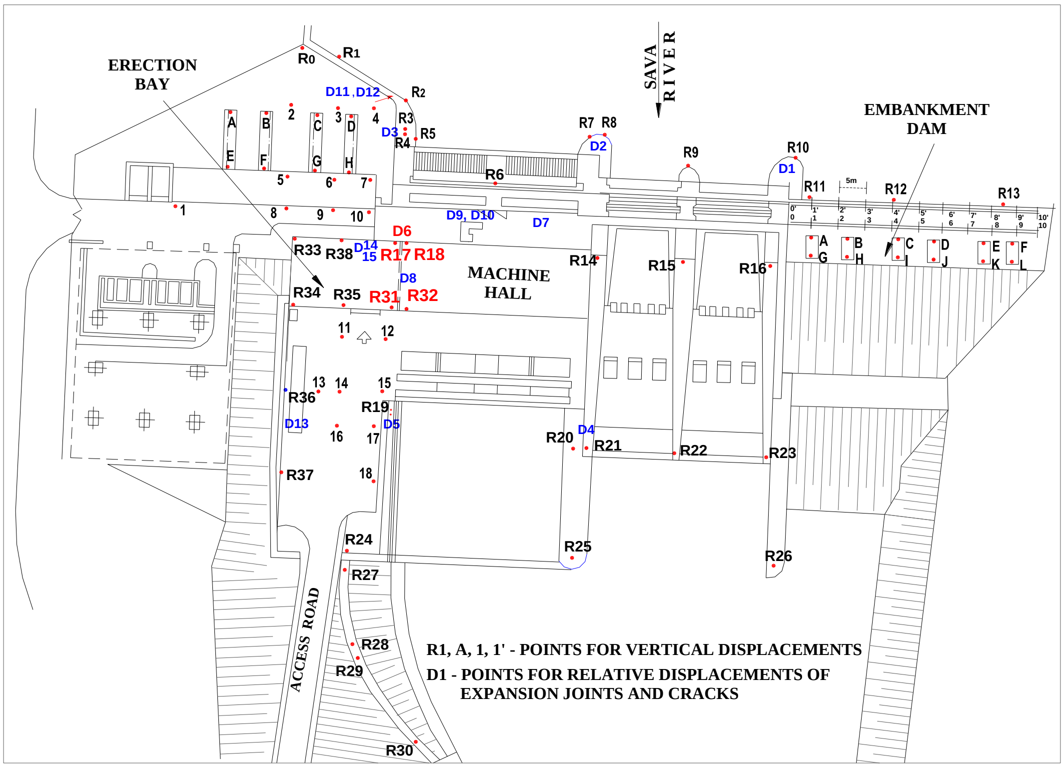

Fig. 4
The monitoring system for measurements of vertical and relative displacements

Table 1
The establishment of the technical monitoring system

Year	Established monitoring activity
1986	Manual measurements and visual inspections
1999 - 2000	Additional deformation measurements (right bank)
2003	Automated measurements (hydrostatic, partly hydrodynamic)
2005	Automated measurements (dynamic - strong earthquakes)

Table 2
Automatic measuring parameters for monitoring the behaviour of the dam

Type	Location	No.	Measuring parameter

External loads	Reservoir and stilling basin	1	Water level, temperature, specific electrical conductivity
	Crest of the dam	1	Air temperature, acceleration
	Inspection gallery	1	Air temperature, acceleration
	Dam structure	1	Concrete temperature
	150 m downstream	1	Acceleration

4. RESULTS OF MONITORING, INVESTIGATIONS AND ACTIONS

In general, the results of measurements and visual inspections did not show any abnormalities. However, this was not the case for the erection bay located on the top of the backfilled right bank of the dam, where the results of measurements of vertical displacements showed increasing settlements [6]. By 1999, i.e. over a period of 12 years, these settlements had increased to 22 mm (see Fig. 5). These results were confirmed by measuring the relative displacements of expansion joint D6, located between the erection bay and the machine hall (see Fig. 6).

The results of investigations, by drilling three research boreholes (one in the upper courtyard and two in the erection bay) in 1993, and another six such boreholes (four drilled in the upper courtyard and another two drilled in the lower courtyard) in 1996, indicated that the settlements were the consequence of the secondary consolidation of the backfill, and probable also due to scouring of fine material from the backfill. Due to the resulting differential settlements, the crane rail which connects the erection bay to the machine hall, as well as the crane rail which is located along the crest of the dam, became non-functional, and needed height corrections (see Fig. 7). For this reason rehabilitation works of the backfill and of the substratum of the right bank of the dam were performed between September 1999 and August 2000, using 50 m long grouted boreholes (see Fig. 8). This grouting was performed using a combination of water reactive polyurethane and a cement-bentonite mixture [7]. Measurements performed since than have shown that the settlement rate of the erection bay has slowed down slightly (by 2017, i.e. over the last 17 years, the settlements had increased by up to 8 mm, see Fig. 5), but from the point of view of the operation of the two crane rails the settlement process needed to be stopped.

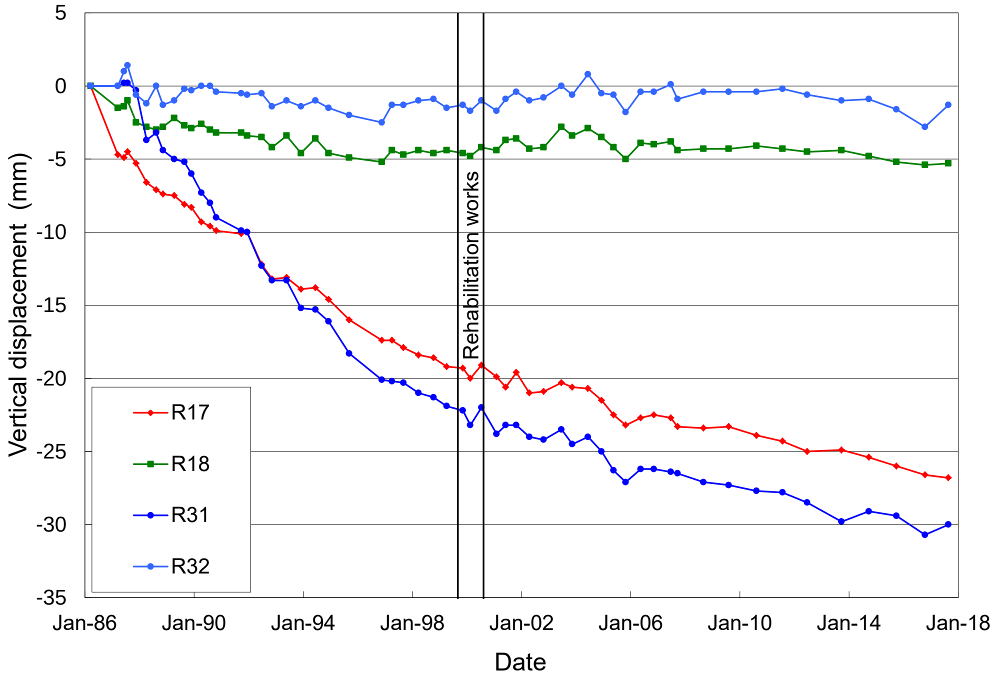

Fig. 5
Vertical displacements of the erection bay

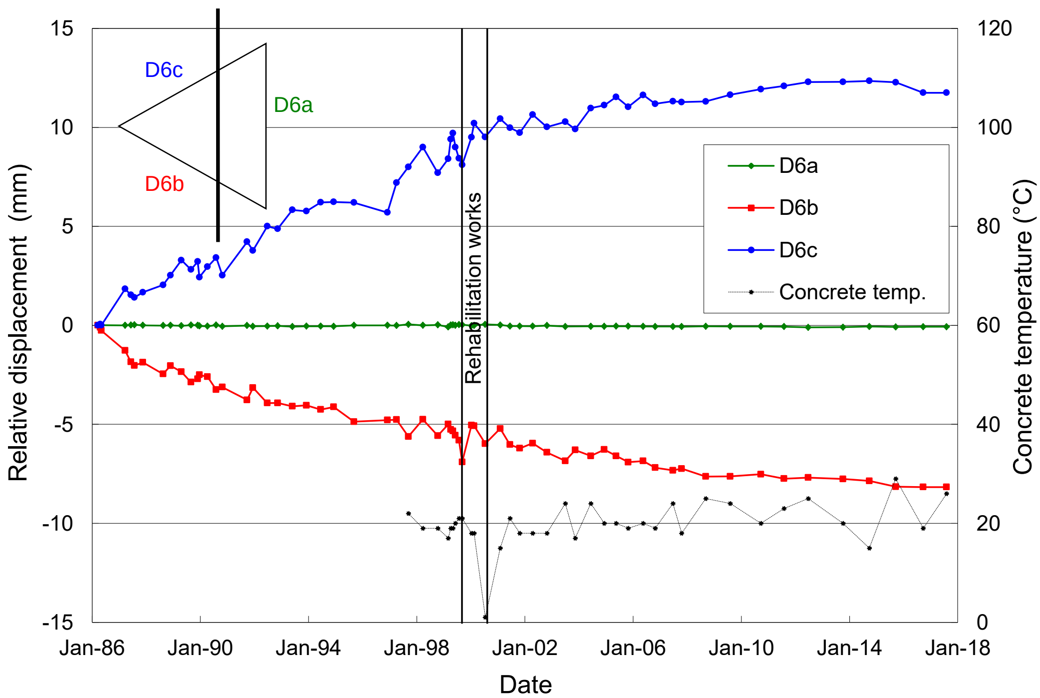

Fig. 6
Relative displacement of expansion joint D6

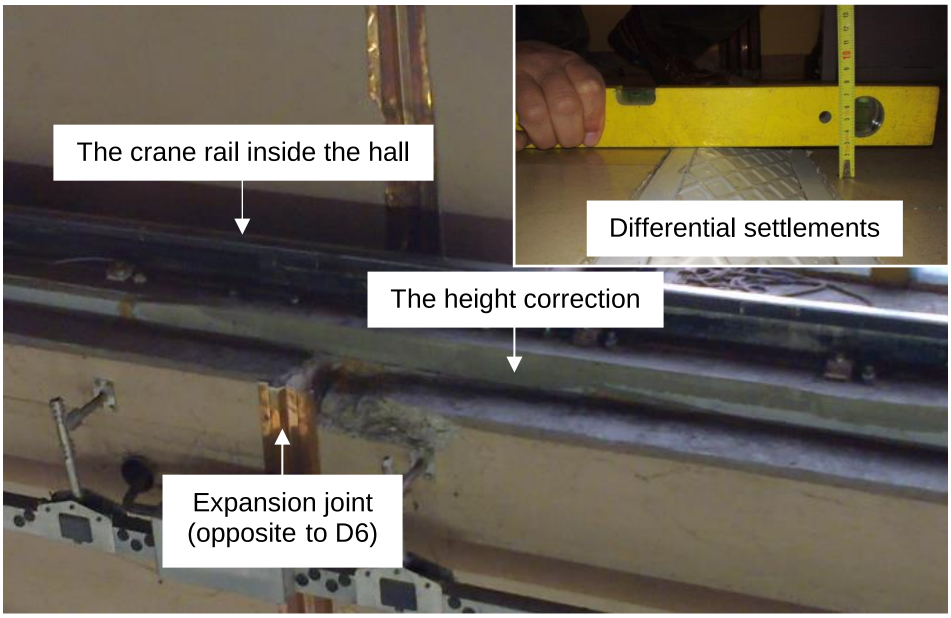

Fig. 7
Height corrections of the crane line inside the erection bay

Fig. 8
Rehabilitation works at the right bank of the dam

The results of the vertical displacement measurements at eight points in the lower courtyard, since the end of rehabilitation works in 2000, showed settlements up to 8 mm, which is similar as in the case of the erection bay. Since 2000, the settlements at ten points in the upper courtyard did not reach 8 mm, whereas at the remaining eight points the settlements reached locally even up to 32 mm.

Additional investigations, involving the drilling of two research boreholes in the upper courtyard, 28.0 m and 30.0 m in depth, as well as appropriate field tests (soil and rock classification, groundwater level, standard penetration test) and laboratory tests (particle size distribution curve, water permeability coefficient) carried out on 21 samples, were performed between November 2015 and March 2016. According to the results of these most recent investigations, the newer settlements were the consequence of additional scouring of fine material from the backfill [8].

5. CONCLUSIONS

In the years following the Mavčiče Dam completion in 1986, the results of measurements of vertical displacements showed increasing settlements of the erection bay at the right bank of the dam, and therefore the differential settlements according to the adjacent machine hall, which resulted to uselessness of both crane rails, which needed height corrections. After investigations, involving the drilling of research boreholes, as well as appropriate field and laboratory tests in 1993 and 1996, the rehabilitation works of the backfill and the substratum of the right bank of the dam were performed in 1999 and 2000. Since even after the rehabilitation works, the settlements of the erection bay continued to increase, additional investigations, involving the drilling of two research boreholes as well as suitable tests (soil and rock classification, groundwater level, standard penetration test, particle size distribution and water permeability coefficient) were carried out in 2015 and 2016. The results of these investigations showed that the settlements measured in the recent years were the outcome of the additional internal erosion of the backfill.

In order to achieve a final solution to the problem of the subsidence of the erection bay, additional rehabilitation works of the backfill and substratum of the right bank of the dam, by grouting the permeable zones, would be needed in order to stop both the scouring of fine material from the backfill, as well as any internal erosion of the cavernous conglomerate at the base of the backfill. The latter concerns the long-term stability of the right bank of the dam with potentially serious results.

1. INTRODUCTION

Bottom outlets (BOs) are a key safety feature of high-head dams. Their main purpose is the regulation and – if required - a fast drawdown of the reservoir water level in case of floods, structural damage of the dam or maintenance works. Additional purposes include residual flow release, flood diversion or sediment flushing. The large energy heads at the gate lead to a high-speed free-surface flow in the BO tunnel with flow velocities up to some 50 m/s for high dams. These large flow velocities and the high turbulence levels lead to considerable air entrainment and air transport, possibly resulting in negative pressures in the BO. This can cause problems with gate vibrations, cavitation and flow chocking. Sufficient air supply via an aeration chamber can mitigate these problems. Available design equations for the required air demand to prevent excessive negative pressures are based on scale model tests and prototype measurements. Most of these equations express the air demand β as a function of the Froude number at the vena contracta F_c. However, measured and predicted β-values show a large scatter. Some of the scatter can be explained by the different flow patterns. The remaining scatter can be explained with the neglect of crucial parameters in the design equation like the air vent loss coefficient ζ or the tunnel length L. This project aims to investigate the

* *Aération des vidanges de fond: Résultats des essais sur modèle à échelle réduite et des mesures en prototype*

effect of those parameters with small-scale model tests. The employed scale model exceeds most previous model studies in terms of energy head H_E and water discharge Q_w. Nevertheless, scale and model effects still need to be addressed carefully. Detailed prototype data are crucial for the validation and upscaling of model results. Therefore, this project additionally includes air demand measurements at three bottom and one middle outlet(s) in southern Switzerland.

2. SCALE MODEL TESTS

2.1. MODEL SETUP AND INSTRUMENTATION

A physical bottom outlet model was built at the Laboratory of Hydraulics, Hydrology and Glaciology (VAW) at ETH Zurich (Fig. 1a). Two pumps provide a maximum energy head at the gate of $H_E = 30$ m w.c. at a water discharge of $Q_w \approx 600$ l/s. The rectangular sharp-crested gate is 0.2 m wide, 0.25 m high and the downstream tunnel extends to a height of $h_t = 0.3$ m (Fig. 1b). The horizontal BO tunnel has a maximum length of $L = 20.6$ m which can be varied due to detachable elements. The aeration chamber is connected to a circular air vent of diameter $d = 0.15$ m which can be throttled with an orifice plate to vary the loss coefficient ζ of the whole aeration system. A similar air vent is located at the tunnel end to measure the airflow into or out of the tunnel. All channel walls consist of PVC or acrylic glass with a hydraulic roughness of $k = 0.003$ mm.

Q_w is measured with an inductive flow meter with an accuracy of ±0.5% of the measurement value (MV) and ±0.4 l/s absolute error. The air flow velocity in the air vent $U_{a,o}$ is measured with a thermal anemometer while the air flow velocity at the tunnel end $U_{a,u}$ is measured with a bidirectional vane anemometer. The thermal anemometer has an accuracy of ±2.5% of MV and the vane anemometer has an accuracy of ±1.5% of MV ±0.2 m/s. From the measured velocity, the air discharges $Q_{a,o}$ and $Q_{a,u}$ are computed assuming a logarithmic velocity profile. The cross section above the air-water mixture is blocked with a gate at the tunnel end. Consequently the air has to be supplied through the second air vent which allows for a precise measurement of $Q_{a,u}$. A total of 40 relative pressure sensors with a measurement range of ±100 mbar and an accuracy of ±1 mbar are installed at the invert and the soffit along the tunnel centerline to measure both the water (subscript *w*) and air pressures (subscript *a*), respectively.

The following parameters were varied in the model tests: The relative gate opening a/a_{max} was increased from 0.1 to 1 in steps of 0.1. For each a/a_{max}, H_E was varied from 5 to 30 m w.c. in steps of 5 m w.c. and six ζ-values were tested, $\zeta = 0.7$, 2.7, 9, 19, 28 and 57. All parameter combinations were tested for tunnel lengths of $L = 20.6$, 12.6 and 6.6 m. Combinations of $H_E > 20$ m w.c. and $\zeta > 10$ could not be measured due to strong flow pulsations. Large relative gate openings of $a/a_{max} > 0.8$ led to a drowning of the aeration chamber and were thus excluded from the measurements.

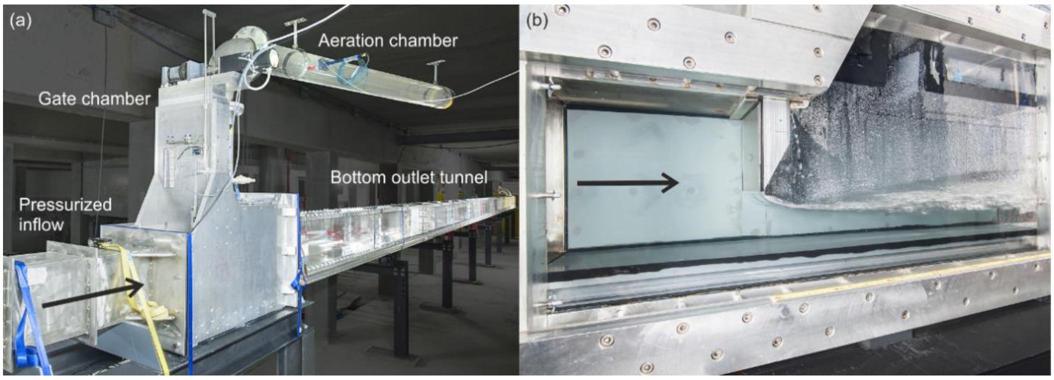

Fig. 1
(a) Physical scale model of a bottom outlet at VAW, (b) gate chamber
(a) Modèle à échelle réduite d'une vidange de fond à la VAW, (b) chambre de la vanne

2.2. AIR DEMAND IN MODEL TESTS

The air discharge $Q_{a,o}$ through the aeration chamber increases with increasing H_E and attains a maximum for moderate relative gate openings 0.4 ≤ a/a_{max} ≤ 0.6 (Fig. 2a). The maximum is shifted towards smaller a/a_{max} for increasing H_E.

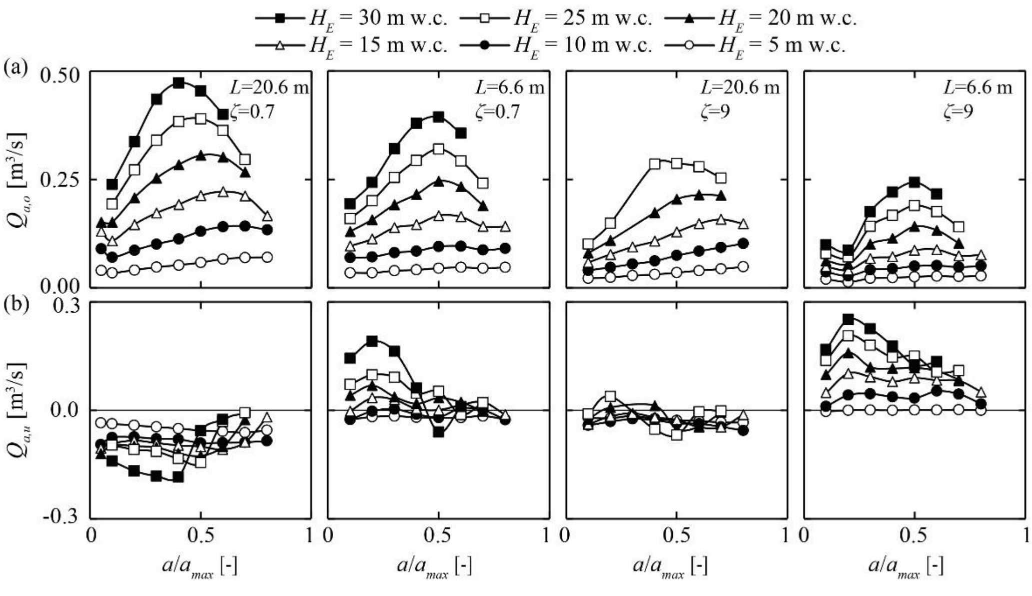

Fig. 2
(a) $Q_{a,o}$ and (b) $Q_{a,u}$ for different values of a/a_{max}, H_E, L and ζ
(a) $Q_{a,o}$ et (b) $Q_{a,u}$ pour des valeurs différentes de a/a_{max}, H_E, L et ζ

The sudden increase of $Q_{a,o}$ for $a/a_{max} \approx 0.05$ is caused by the transition to spray flow. At large a/a_{max} the air flow rate is decreasing again, especially for large H_E. This is due to the transition to foamy flow with the tunnel almost flowing full at the tunnel end. The reduced cross-sectional area above the air-water mixture for foamy flow allows less air to be dragged along with the flow. $Q_{a,u}$ is negative for moderate a/a_{max}, low ζ value and long tunnel, indicating a net air flow out of the tunnel at the downstream end. For foamy flow conditions $Q_{a,u}$ increases to zero, whereas spray flow leads to a slight decrease of $Q_{a,u}$ (Fig. 2b). An increase in ζ drastically reduces $Q_{a,o}$, while simultaneously increasing $Q_{a,u}$, resulting in a net air flow into the tunnel from the downstream (Fig. 2). The decrease in $Q_{a,o}$ and the increase in $Q_{a,u}$ are even more pronounced for short tunnels as air can enter more easily from the downstream tunnel end.

The minimal air pressure in the gate chamber $p_{a,min}$ depends on $Q_{a,o}$ and ζ. With all other parameters kept constant, an increase in ζ leads to a simultaneous decrease of $Q_{a,o}$ and $p_{a,min}$. The magnitude of decrease of each quantity in turn depends on a/a_{max}, H_E and L.

3. PROTOTYPE MEASUREMENTS

3.1. TEST SITES

The two BOs of the arch dam Malvaglia and the BO and middle outlet (MO) of the arch dam Luzzone in the Canton of Ticion, southern Switzerland were equipped with measurement devices. All outlets are usually operated once a year to flush sediments out of the reservoir. Additionally, a mandatory function test requires the test of small gate openings once a year. All three outlets are equipped with sluice gates. Luzzone features a maximum static head $H_{o,m}$ of 224 m w.c. for the BO and 120 m w.c. for the MO. Malvaglia has two BOs, an old and a new one with $H_{o,m}$ = 94 m w.c. and $H_{o,m}$ = 91 m w.c., respectively. The new BO was specifically built to flush sediments from the intake vicinity. The old BO features a circular tunnel with a diameter of d = 4.3 m, whereas the new BO has a 2 m wide, 2.5 m high horseshoe profile. Both outlet tunnels join a common outlet tunnel (d = 5.6 m) to which the spillway is also connected (Fig. 3). The tunnel conjunction is well aerated what leads to effective tunnel lengths of L = 67 m and L = 82 m for the old and new BO. Up to now only measurements during a function test in Malvaglia could be conducted.

3.2. PROTOTYPE INSTRUMENTATION

The instrumentation applied at Malvaglia Dam and their accuracy are listed in Table 1, and a sketch of the measurement setup is shown in Fig. 3.

The following parameters were measured:

- $Q_{a,o}$: To measure the air flow velocity $U_{a,o}$ in the air vent, vane anemometers were mounted at two locations in the center of the air vent cross section. $Q_{a,o}$ was calculated assuming that the measured velocity $U_{a,o}$ corresponds to 110% of the mean air velocity in the air vent.
- p_a: Absolute pressure sensors were installed in both gate chambers, in the middle of both tunnels and at the tunnel conjunction.
- Air velocity at the end of the outlet tunnel $U_{a,u}$: Bidirectional vane anemometers were installed in the upper half of the tunnel cross section at the end of both tunnels to measure air flowing out of or into the BO tunnel.
- Air temperature T_a: Temperature sensors were installed at two locations in the air vent; in the horizontal part and at the end of the air vent in the new BO.

Additionally, video cameras were installed in both gate chambers and at the tunnel conjunction.

Table 1
Overview on measurement devices and accuracy, symbols refer to Fig. 3

Symbol	Type	Name	Range	Accuracy
U1, U2	unidirectional vane	Höntzsch ZS25-mn120	1.4 - 120 m/s	± (1.5% of MV + 0.6 m/s)
U3 - U5	bidirectional vane	Höntzsch ZSR25-mn120	–60 - 60 m/s	± (1.5% of MV + 0.6 m/s)
U6, U7	bidirectional vane	Schiltknecht Air	–40 - 40 m/s	± (1.5% of MV + 1 m/s)
P1 - P5	absolute pressure sensor	Keller PAA-26 W	700 - 1200 mbar	± 2.5 mbar
R	flow direction indicator	VAW-made	0 - 360°	± 2°
T1, T2	Air temperature	Arthur-Grillo MTA90-P	–30 - 40°C	± (0.25% of MV + 0.15°C)

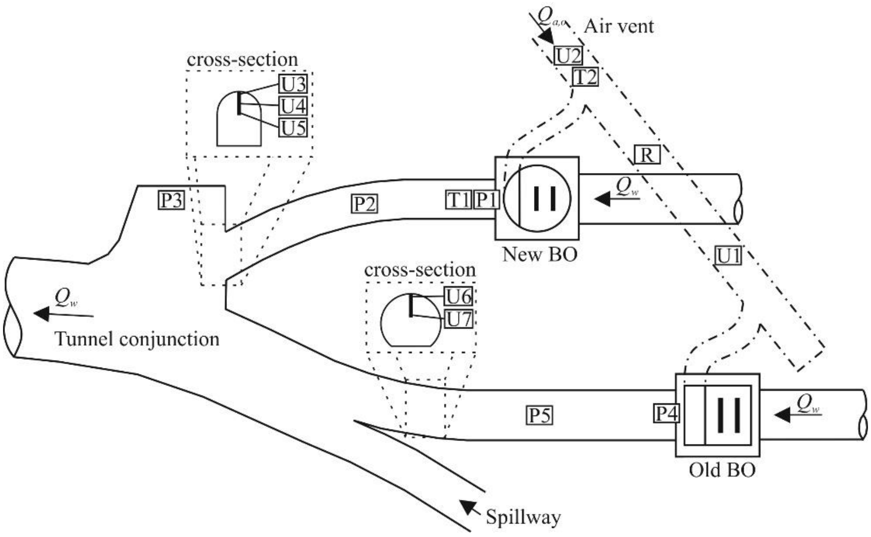

Fig. 3
Sketch of the measurement setup at Malvaglia Dam (not to scale)
Esquisse de la configuration de mesure au barrage Malvaglia (pas à l'échelle)

Two different gate openings were tested for both BOs: a = 0.05, 0.1 m for the old BO and a = 0.1, 0.2 m for the new BO, respectively. Only one BO was in operation at a time. The reservoir water level varied from 980 to 980.9 m asl. during the test, resulting in an average static pressure head of H_E = 84.7 m w.c. for the old BO and H_E = 81.6 m w.c for the new BO. An average air temperature T_a of 9°C was used to calculate ρ_a, resulting in ρ_a = 1.12 kg/m³ at ~900 m asl. To show the overall trend, the measurements were averaged over 5 s in the following figures. Additionally, the original 10 Hz measurements are shown as thin lines. To calculate characteristic numbers (e.g. β, ζ), the measurement were averaged over the duration of each gate opening. ζ was calculated as $\zeta = 2\Delta p_a/(\rho_a U_{a,ov}^2) - 1$, where Δp_a is the air pressure drop in the gate chamber $\Delta p_a = p_a(t{=}0) - p_a(t)$. The Q_w-values for the calculation of $\beta = Q_{a,o}/Q_w$ were provided by the dam operator.

3.3. Results of bottom outlets Malvaglia

Table 2 summarizes the measurement results and Fig. 4 shows detailed results for the new BO. If only the new BO is in operation, an equal amount of air is supplied through the air vent and the old BO tunnel (U1 and U2 in Fig. 4a). $U_{a,o}$ is slightly higher for a = 0.1 m compared to a = 0.2 m. This can partly be explained by the transition from spray flow to free-surface flow for a = 0.2 m (Fig. 5). The sudden rise in $U_{a,o}$ during the closing of the gate is also caused by a more intense spray formation for a < 0.1 m. For spray flow, i.e. a = 0.1 m, air is flowing out of the tunnel end, whereas for a = 0.2 m air is entering the tunnel from downstream (Fig. 4b). $U_{a,u}$ is significantly lower than the air-water mixture velocity of ~12 m/s (estimated after [1]). The drop of p_a is clearly visible in the gate chamber (P1) and to a lesser extent after half of the tunnel length (P2) (Fig. 4). At P1, more pronounced pressure transients were observed, particularly during gate closure, whereas these transients have already disappeared at P2. No considerable variation in pressure can be observed in the tunnel conjunction (P3), showing that the conjunction is sufficiently aerated from downstream.

Table 2
Overview of the measurement results in Malvaglia

name	Q_w [m³/s]	a [m]	a/a_{max} [-]	F_c [-]	$Q_{a,o}$ [m³/s]	Δp_a [mbar]	ζ [-]	β [-]
new BO	2.5	0.1	0.08	52	17.7	5.2	2.6	7.1
new BO	5.0	0.2	0.15	36	15.0	3.9	2.8	3.0
new BO	2.5	0.1	0.08	52	17.1	6.3	3.7	6.8
old BO	2.4	0.05	0.03	61	15.2	7.5	5.8	6.3
old BO	5.0	0.1	0.06	43	27.1	23.7	5.8	5.4
old BO	2.4	0.05	0.03	61	11.7	4.5	5.9	4.9

For the old BO no transition to free-surface flow was observed for the larger gate opening a = 0.1 m. On the contrary, the old BO showed an even stronger spray formation for a = 0.1 m (Fig. 5). Consequently $Q_{a,o}$ increased with increasing a for the old BO.

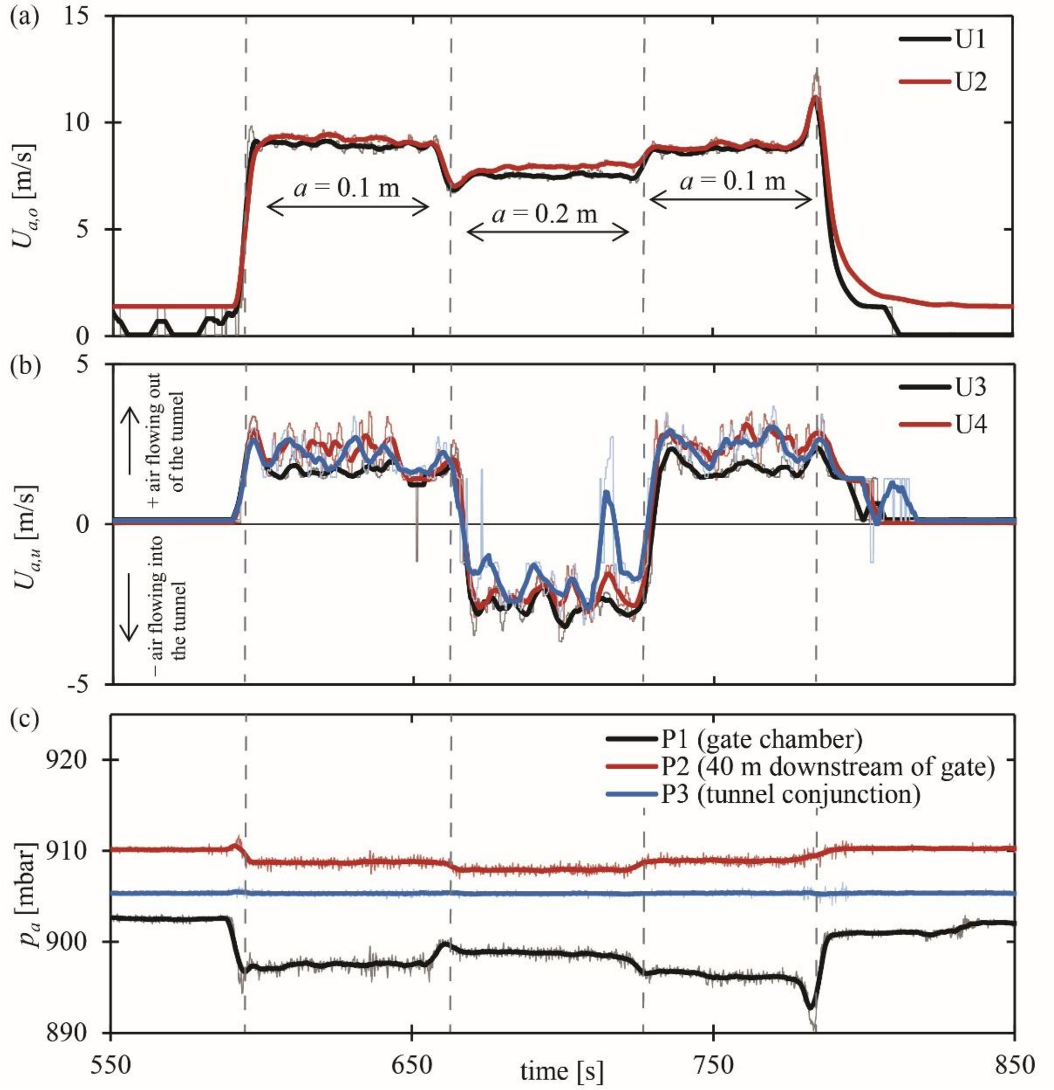

Fig. 4
Measurements for the new BO (a) $U_{a,o}$, (b) $U_{a,u}$ and (c) p_a at different locations
Valeurs mesurées pour la nouvelle VF (a) $U_{a,o}$, (b) $U_{a,u}$ et (c) p_a aux lieux différents

4. DISCUSSION

Both the model and prototype data demonstrate the significant influence of the flow pattern on $Q_{a,o}$, $Q_{a,u}$ and p_a. The scale model data also clearly show the importance of L and ζ for the aforementioned quantities. The importance of ζ is also supported by the prototype data, i.e. the fact that the new BO exhibits larger β-values than the old BO despite smaller F_c and less intense spray can be attributed to the smaller ζ-value.

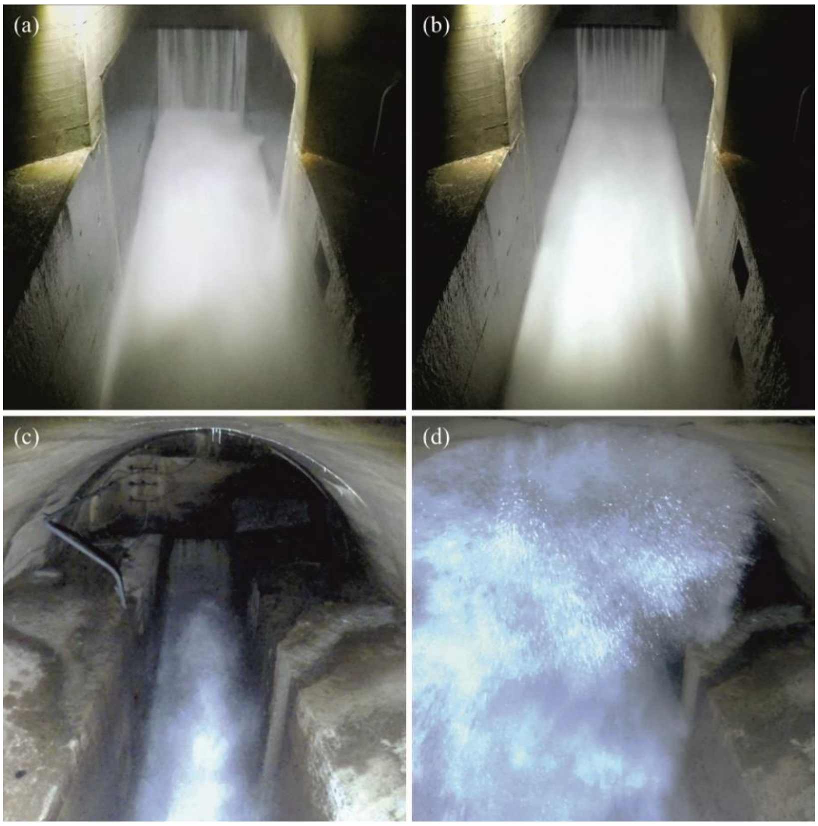

Fig. 5
Bottom outlet sluice gate in operation (a) new BO a = 0.1 m, (b) new BO a = 0.2 m, (c) old BO a = 0.05 m and (d) old BO a = 0.1 m.
Vanne de vidanges de fond (VF) en opération (a) nouvelle VF a = 0.1 m, (b) nouvelle VF a = 0.2 m, (c) vielle VF a = 0.05 m and (d) vielle VF a = 0.1 m.

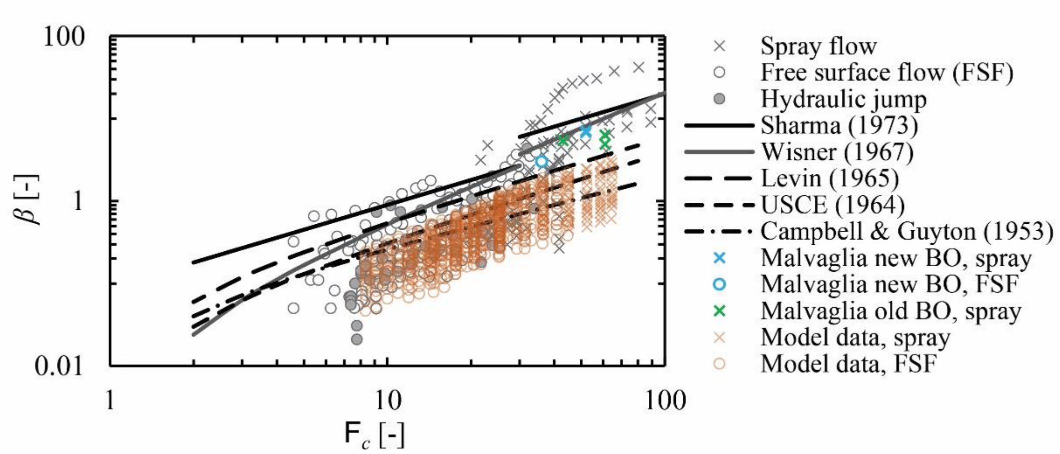

Fig. 6
Comparison of prototype data from literature [2] and design equations with model data and new prototype measurements
Comparaison des mesures en prototype de la littérature [2] et des équations avec des mesures du modèle à échelle réduite et nouvelles mesures en prototype

The new prototype air demand data are moderate to high compared with existing prototype measurements (Fig. 6, [2]). The large scatter in the model data is due to the varying ζ and L. Actually the model data for a given combination of ζ and L is reasonably described by a power law relation $\beta = a\mathrm{F}_c^{\,b}$, where a, b are dependent on ζ and L. While the model data shows a good agreement with existing prototype data and equations for free-surface flow, the model data tend to underestimate β for spray flow conditions. Indeed the gas Weber number and the Ohnesorge number indicate that the secondary disintegration of droplets is subject to scale effects i.e. the spray is less pronounced in the model. Additionally the model sluice gate has no gate slots which are a main cause for spray formation [8].

5. CONCLUSIONS

A systematic physical scale model study on the air demand of bottom outlets was performed. The results show that the air demand decreases with increasing air vent resistance and decreasing tunnel length. The flow pattern has a decisive influence on the air demand with the maximum air demand occurring for spray flow. The highest air discharge was observed for free-surface flow. New prototype measurements conducted in two bottom outlets in Switzerland support the main findings of the scale model test. Differences were observed for spray flow conditions, where the local gate geometry plays a crucial role.

ACKNOWLEDGEMENTS

The first author is funded by the Swiss National Science Foundation (SNF, Grant No. 163415). The prototype measurements are financed by the Lombardi Engineering Foundation and kindly supported by the dam operator Ofible. The project is embedded in the Swiss Competence Centre for Energy Research – Supply of Electricity (SCCER-SoE).

SUMMARY

Bottom outlets (BOs) are a key safety feature of high-head dams. The high-speed free-surface flow in the BO tunnel leads to considerable air entrainment and air transport, resulting in negative pressures in the outlet tunnel. Current knowledge does not allow a coherent design of the air vent needed to mitigate problems due to negative pressures as e.g. gate vibrations and cavitation. Extensive model test conducted in this project showed that: (i) the flow pattern strongly influences the air demand with spray flow resulting in maximal values; (ii) the air demand decreases with increasing air vent loss coefficient, while the air pressure consequently decreases; and (iii) a shorter tunnel length reduces the air demand as air can enter more easily from the downstream end. New prototype data collected in two BOs in Switzerland support these findings.

Des vidanges de fond (VF) sont des structures importantes pour des grands barrages. L'écoulement à surface libre à grande vitesse mène à l'entraînement et transport de l'air résultant en pressions négatives dans le conduit. La connaissance actuelle ne permet pas une conception cohérente du conduit d'aération lequel est pourtant nécessaire pour atténuer les problèmes de vibration des vannes et de cavitation. Des expériences extensifs sur modèle à échelle réduite mênés dans ce projet ont montré le suivant : (i) le régime d'écoulement influence fortement la demande d'air avec un maximum pour le régime « spray », (ii) la demande d'air diminue pour une augmentation du coefficient de perte du conduit d'air tandis que par conséquent la pression diminue et (iii) un conduit plus court diminue la demande d'air parce que l'air peux entrer plus facile par la fin du conduit en aval. Les résultats principaux des essais sur modèle à échelle réduite sont soutenus par des nouveaux essais de prototype.

1. ABSTRACT

Jatigede Dam is a rock fill dam located on Cimanuk river, West Java province, Republic of Indonesia which is one of Multipurpose dam and second biggest in Indonesia with 114 m height and about 980 Mcm of reservoir volume. To perform the initial filling of the reservoir, the inlet of the diversion tunnel must be closed and followed by plugging work. Systematically, Jatigede Dam diversion structure with a diameter of 10 m, starting from Inlet Diversion Conduit along

61.454 m connected with Tunnel along 546,221m and Outlet tunnel ends at Plunge pool.

There are two types of plugging done that is Primary plugging along the 17,74 m the starting position of the conduit and Main plugging along the 41 m at the core of the dam.

Immediately after closing of closure gate on August 31, 2015, Engineer will confirm the area where is in the right bank of Plunge Pool up to front of Tunnel Outlet is satisfied to use for access and material loading area from above. After closure gate, lining concrete of tunnel at position grout stopper shall be cut by using electric grinder to make groove for fixing of the Steel Galvanized Plate. After the completion of the installation of Steel Galvanized Plate, so Grout Pipes, including Riser Pipes, Backfill pipes, and T-type Socket are installation and fixed firmly by U-bolts at 10 cm center to center at the correct position from Grout Pipe. Drainage pipe is installed at the bottom of tunnel before 1st stage of concrete placing then Shut-off gate, tied with a wire rope of 12 mm diameter, is installed at the upstream end drainage pipe.

Forms are installed and firmly fixed together by using wooden timbers, anchor bars tension bars to avoid displacement or deformation. All supports wooden timbers and anchor bars at upstream of forms for all lift (up to 5th layer of A1 Block) shall be installed and firmly fixed prior to the placing concrete. Cooling pipe was constructed for each Block. All cooling pipes are tested for the leakage under the pressure of 3.5 kg/cm2. The cooling water will be continuously provided by pump through the cooling pipes from the time of placing concrete until the concrete temperature comes down to 26oC. The discharge of water shall be controlled not to exceed 50oC of the concrete temperature. If necessary the water temperature shall be controlled by ice.

1. ABSTRACT

Royal Irrigation Department (RID) announces that an integrated geophysical investigation can provide useful information for the earthen dam inspection. Nondestructive geophysical techniques; Electrical Resistivity Imaging (ERI), Multichannel Analysis of Surface Wave (MASW), and Ground Penetrating Radar (GPR) have a great potential in identifying subsurface deficiencies and the results are intuitively acceptable.

In relation to these activities, subsurface characteristics of particular interest must be inferred from the physical properties of clay core. Low or high resistivity range means relative moisture in embankment material and implies the homogeneousness of impervious clay core. The shear wave velocity measured by MASW can be numerically converted to undrained shear strength, implying the bearing capacity of compacted clay. The GPR image clearly reveals partial settlement of freeboard zone at the upper part of the old earthen dam as well as the area covered by filled material, if there was any treatment in the past.

Integrated interpretation of the three results together with several field evidences can help verifying the current condition of the old earthen dam. The applicable techniques are applied to twenty six earthen dams of RID for a five-year research project, and finally, exhibit a flowchart for the old earthen dam inspection by using integrated geophysical techniques. Solutions and recommendations from the research lead to big changes in maintenance and/or retreatment program of the RID dams in the present day.

Keywords— Dam inspection, GPR, MASW, Resistivity.

1. INTRODUCTION

The main branches of Cemented Material Dams (CMDs) are shown in Fig.1. Although CMD allows both the construction of admirable gravity dam bodies on weak rock foundations and the employment of low specific materials as aggregates for the dam body, it has more uncertainties than conventional RCC and CVC regarding design. On the other hand, one of the biggest advantages in designing CMDs is the uniform and typical geometry of the dam section, which permits the development of parametric solutions. Therefore, Performance-Based Design (PBD) using a probabilistic approach could be a proper strategy for this type of dam. In this paper, the advantages of this method are described.

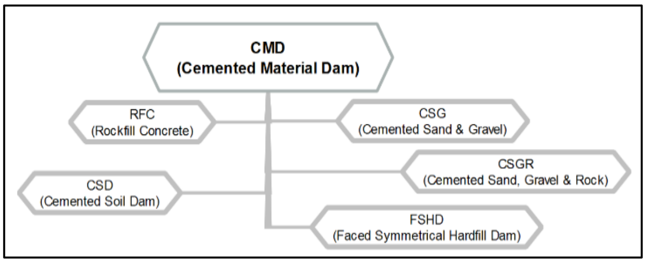

Fig. 1
Cemented Material Dams

Three CMDs, currently being constructed under the supervision of ABFAN consulting engineers in Iran, are used in the case study for the proposed probabilistic approaches. The detailed specification of these dams is presented in the authors' previous papers [1], however, a brief specification of "Dasht-e-Palang" dam which is most referred to in this paper is described for convenience.

"Dasht-e-Palang" is a composite of Gravity and Earthfill dam type, under construction in the south of Iran (Fig.2). The project objective is to provide drinking, industrial and agricultural water:

• Maximum height: 56 m
• CMD part crest length: 350 m. Earthfill part crest length: 680 m
• CMD part crest width: 4 m. Earthfill part crest width: 8 m
• Upstream and downstream slope of the dam body: 0.7 h / 1.0 v
• Hardfill volume: 540,000 m^3. CVC volume: 150,000 m^3
• Earthfill volume: 950,000 m^3

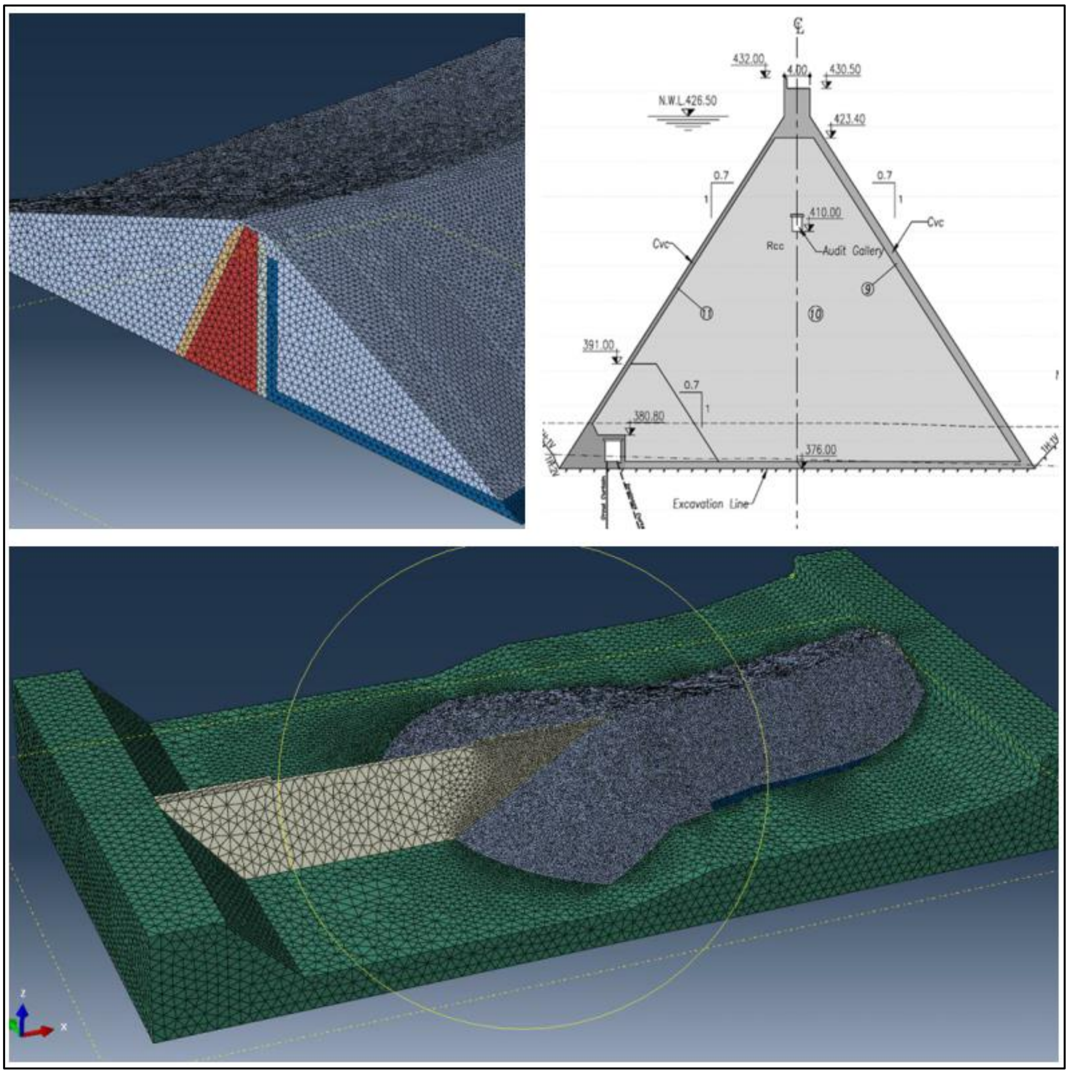

Fig. 2
"Dasht-e-Palang" dam (A composite of CMD & Earthfill)

2. VARIATIONS IN AGGREGATE GRADING~~'~~S

One of the most important benefits of CMDs is the ability to adopt raw and even low-quality materials around the dam site [2], which causes unavoidable variations in aggregate grading and the physical properties of Hardfill materials on the other side. Segregations at Hardfill placement are another defect that could occur in this regard. A solution to reduce these variations and mitigate such segregations is dividing the raw materials in two or three stockpiles. Sand~~s~~ and gravels will then be mixed with pre-specified proportions to produce the best fit of aggregate grading compared to the optimum curves. Obviously, this process will lead to the production of some excess aggregates that can be crushed and used again if desirable. Applying the probabilistic method will be of significant help in order to obtain the optimum sieve number of fractions and mixing proportion since the varieties in the samples are unknown. This method can be summarized in the following steps:

- Providing adequate samples of raw materials in the different locations of the borrow area and at different depths of each pit.
- Generating the remaining portions instead of the finer material grading tables.
- Generating a huge series of aggregate grading tables (e.g. more than 10000) based on the probabilistic approach (one may use a numerical method instead of probabilistic distributions to generate a new series).
- Changing the above-mentioned series from the “residue” percentage curves to “finer” percentage curves.
- Selecting the base sieve numbers for aggregate fractioning and the proportion of mixing~~,~~ in a way that the best fit to the desired curves is obtained with minimum excess materials.

As a case study, the application of this method in the "Kahir" dam project will be discussed:

Riverbed aggregates with MSA=50mm are selected as the raw materials, and the natural grading curves are shown in Fig. 3. The aim is to simplify the construction procedure by reducing the aggregate production process.

Date	Number of sample	Fluctuations range in curves (Min&Max)			
		Sand(%) (0-5)	Fine Gravel(%) (5-25)	Coarse Gravel(%) (25-50)	Passing #200
2013/01	3	28-38	36-41	20-36	8-9
13/02	9	25-48	34-41	14-34	5-11
13/03	2	31-37	41-47	22-23	6-7
13/05	6	33-41	36-47	14-25	7-11
13/06	9	34-45	38-41	16-24	7-11
13/07	9	40-48	33-42	12-27	8-10
13/09	2	40-45	38-40	15-23	10
13/10	3	36	36-46	18-28	8-10
13/11	6	35-46	36-44	12-28	9-13
13/12	5	31-42	40-50	16-22	9-12

Min-Max	70	25-48	33-55	7-36	5-22
Ave	70	39	42	20	10

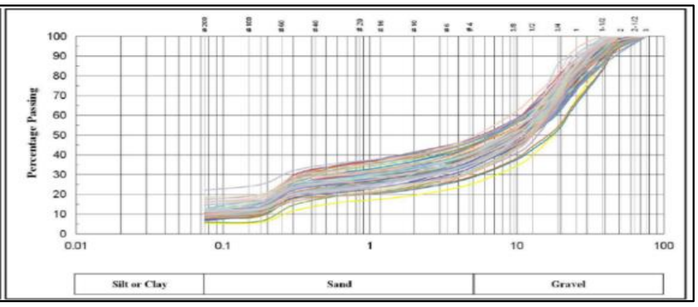

Fig. 3
Grading curves of raw materials

Performing the above-mentioned method, many variants have been studied. Based on the natural grading curves, about 10,000 probabilistic curves have been generated, each subsequently divided in two parts on the selected dividing sieve, e.g. #5, #12 or #25**.** Afterwards, each division has been mixed with various proportions (25%, 35%, 45% and 55% of the finer portion as shown in Fig. 4). The produced curves have been compared to the desired aggregate curves and the optimum values have been selected in the end. The optimum selection is elaborated as follows:

The total aggregates are separated into fractions by sieve #16 (in other words, we separately have 0-12mm and 12-50mm) with a mixing proportion of 45-55%.

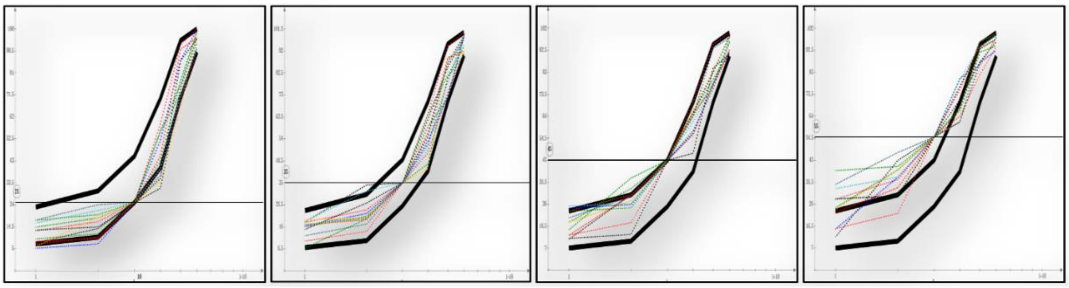

Fig. 4
The grading curves of aggregates for different proportions

3. CMDs FOUNDED ON WEAK ROCKS

CMDs are more compatible with their foundations with respect to RCC and CVC gravity dams, which comes at the price of weaker foundations and hindering the estimation of proper and precise rock engineering parameters (shear strength and modulus of deformation), and also the type of the rock in the basement may varies in each location (Fig. 5 shows the rock lithology profiles in Dasht-e-Palang Dam).

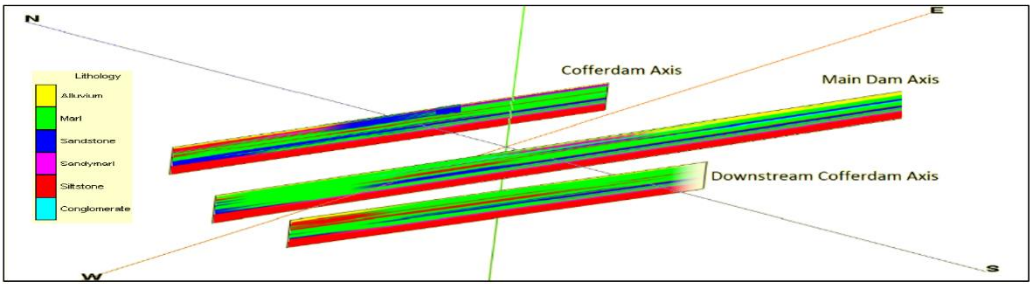

Fig. 5
Different rock properties along the longitudinal axis in Dasht-e-Palang dam

Uncertainties in shear strength parameters will cause uncertainties in the sliding stability of the dam body. Similarly, uncertainties in the rock deformation modulus will cause the stress values in the dam body and foundation to experience variations. Exerting the “minimum” shear strength parameters is a conservative and costly design approach on one hand, and exerting the “mean” values may not be safe on the other. Therefore, studying the stability and stresses in the dam body and foundation would require a huge amount of rigid body stability and finite element analysis, making the final decision-making difficult. This is where applying the probabilistic method comes as a great advantage. In the following, utilizing this method to calculate the sliding stability is described, and its application to determine the modulus of deformation is explained in the next section.

Initially, consider the shear strength parameters of Dasht-e-Palang dam. An evaluation of the rock mechanics parameters based on a vast range of studies is presented in the table shown in Fig. 6 (left). The first step is to perform a stability analysis on different optional pairs of cohesion and friction angle, which will result in a calculable sliding safety factors. Obtaining this data matrix and performing a probabilistic analysis (finding the interpolation of SFs between each node of cohesion and the friction angle), the distribution of SFs can be plotted. In addition, by selecting the minimum desired safety factor, the probability of failure and the adequacy of the dam body geometry will be yielded according to Fig. 6 (right).

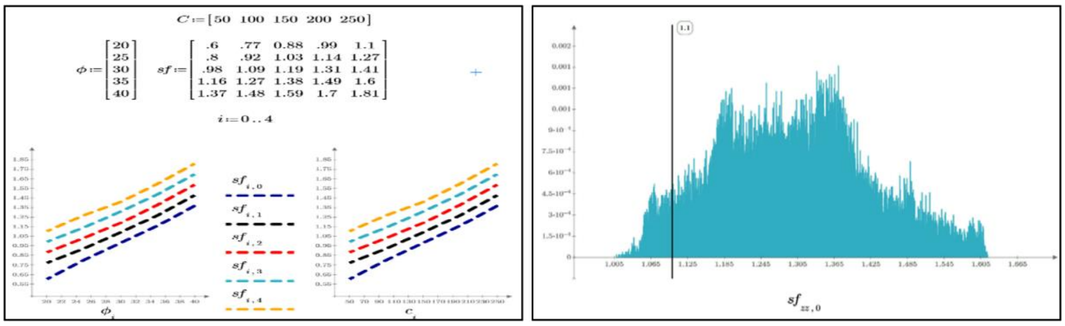

Fig. 6

Safety factors against sliding (left), the distribution of safety factors (right)

4. CONSTRUCTION SIMPLICITY

Even though the construction simplicity of CMDs is a key asset, it could also cause a number of challenges to the prediction of the material behavior, the highly layered dam body amongst them. The bonding between the Hardfill layers is generally less than the RCC layers due to the following reasons:

- The total cement content is low.
- Treatment between successive layers is not necessary.
- There is no need to bedding mortars between layers.
- More segregation occurs compared to RCC.

For example, some cores from the Kahir dam project are demonstrated in Fig. 7. As clearly indicated in this figure, undesirable bonding is observed between the Hardfill layers.

Fig. 7
Core samples from the Kahir Hardfill dam

From the aforementioned facts, we can elicit that the layered behavior of the dam body under loadings (which affects the mass modulus of the dam body deformation) should not be neglected. As also discussed in the next section, the estimation of the modulus of deformation must be sufficiently close to reality in order to give valid stress analysis results. Among the available approaches to overcome this challenge in finite element method, one is to model the layers of the dam body one by one, and considering their interfaces using the appropriate approach [6]. Although this method is more reliable than ignoring the multilayer properties of the materials, performing this complicated method is far more time-consuming and thus impractical, especially in dynamic loads. Two other approaches based on the probabilistic approach are discussed here:

1- The strength properties of the CMD layers are reduced in the direction normal to the layers. Employing the mechanics of multilayered or composite materials, we can define an orthogonal material with two different moduli in two perpendicular directions. The parameters which the derived formulas require (the shear and normal stiffness between successive layers) are unknown variables and need large-scale experiments that may not be feasible in regular Hardfill dams. To solve this issue, performing a dilatometry test in the constructed Hardfills will help gather useful data. A set of estimations are also available in rock mechanics [3], including the following equation:

$$E_i := \left(\frac{1}{E_r} + \frac{1}{Th \cdot K_n} \right)^{-1} \qquad [1]$$

Where "Th" and "Kn" are the layer thickness and the normal-stiffness, respectively. Assuming the Hardfill layer thicknesses and the normal stiffness of the layers equal to 30 cm and an estimated value of 13 for K_n, we will have $E_v = 0.3 * E_i$ and $E_h = E_i$.

2- A wide range of studies have been done on finding the relationship between the intact modulus (E_i) and the mass modulus (E_m) in rock mechanics [4], most of which apply a reduction factor to E_i in order to obtain E_m. A simple equation proposed by Bieniawski [5] relates the two moduli using RQD as follows:

$$E_m := E_i \cdot \left(10^{.0186 \cdot RQD - 1.91}\right) \qquad [2]$$

Another method is to relate the reduction factor to RMR [4], which could be rewritten in terms of RQD in layered dam bodies.

$$\frac{E_m}{E_i} = \frac{1}{100} \cdot \left(0.0028 \cdot RMR^2 + 0.9^{\frac{RMR}{22.82}}\right) \qquad [3]$$

The RQDs of Hardfill cores are variable along the dam body, not perfectly precise and containing uncertainties, which makes a probabilistic approach necessary. Exerting RQD distribution of cores will enable us to calculate the modulus of the Hardfill using the relations above. The application of these probabilistic distributions of E to the finite element method will be discussed in the next section. Whereas the stress results in the dam body and foundation are directly dependent on the "modulus ratio" of Hardfill to rock and independent from the single values of E, it is clear that utilizing the same method and data to estimate E in both rock mechanics and dam analysis will result in a better estimation of stress values in the dam body.

5. CHARACTERISTIC COMPRESSIVE STRENGTH

More "variations" occur in the compressive strength and the modulus of elasticity of Hardfill compared to RCC projects, which results in unknown stress distribution in the structure. Determining the characteristic compressive strength for Hardfill dams is of great importance since it plays the main role in the total cement usage of the project. Therefore, a probabilistic approach to determine the optimum compressive strength is proposed in this paper.

All of the stresses in the dam body must be compared to allowable stresses considering various load combinations. A new stress distribution with respect to the load combination is obtained as shown in Fig. 8 (middle) for each value of $E_{(c)}$ or $E_{(Hardfill)}$. By performing finite element analysis for different values of $E_{(Hardfill)}$ and finding the highest compressive stress generated in the structure (and transforming tensile stresses into equivalent compressive stresses), a fitted curve for input $E_{(Hardfill)}$ against the maximum compressive strengths is resulted according to Fig. 8 (left). It is inferred from the figure that each f'_c of the Hardfill material will produce an initially unknown $E_{(Hardfill)}$. Assuming that this relationship is characterized as curve R in Fig. 8 (left), it is clear that the intersection of these two curves may be the desired f'c, considering the safety factors for the stresses. It is worth noting that the stress values depend on the ratio of $E_{(Hardfill)}$ to $E_{(rock)}$. However, we will consider the $E_{(rock)}$ values equal to 1 GPa for simplicity.

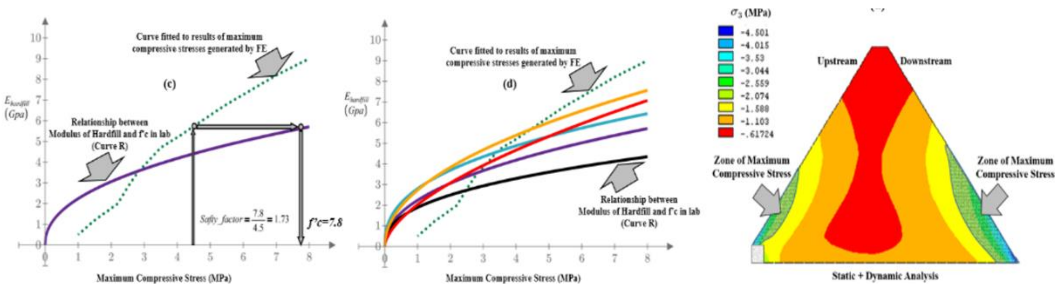

Fig. 8
Modulus of deformation vs. compressive strength

As indicated in Fig. 8 (middle), if a satisfactory fixed curve is not obtained for the relationship between Ec and f'c of Hardfill, each sample of the Hardfill material may generate a different curve, which in turn yields a different stress safety factor. The challenge is coming up with a way to find a minimum f'c for Hardfill that also satisfies the allowable safety factors.

The following factors are presumed to affect the output results:

- The relationship between f'c and Ec in lab tests
- Estimating the modulus of the "Hardfill mass" (Discussed in the section 4)
- The probabilistic parameters of the rock foundation (Discussed in the section 3)

The formulae of the probabilistic functions are defined as follows:

$$E_{mass} = f^*\left(f'_c, E_{rock}, \frac{E_m}{E_i}\right) \qquad [4]$$

$$\sigma_{max} = g^*(E_{mass}) = g^*\left(f^*\left(f'_c, E_{rock}, \frac{E_m}{E_i}\right)\right) \qquad [5]$$

$$\frac{f'_{c_i}}{\sigma_{max_i}} = Safety\_factor_i \qquad [6]$$

The probabilistic formulation for the relationship between f'c and Ec can be put this way:

$$E_c := a \cdot f'c^b \qquad [7]$$

Were there enough tests available to relate E to f'c, we could stablish a probabilistic formula instead of a fitting curve with a low coefficient factor. Nevertheless, we are obliged to assume "a" as a random normal distribution (with μ=3.5 and σ=0.5) and "b" equal to 0.5 based on the vast experiment results in lean RCCs.

Constructing a mathematical model to perform a probabilistic analysis, we will obtain the output in the form of the density distribution of the stress safety factors. To gain the optimum f'_c, we should constantly change f'_c as an input to find a distribution of the stress safety factors with the allowable failure percentage (for example 20% is acceptable for most gravity dams).

Performing the analysis on Dasht-e-Palang dam, the application of the method mentioned above will result in the graphs shown in Fig. 9. Trial and error yields that assuming a normal distribution for f'_c of the samples with a mean of 7 MPa (known as f_{cr}) and a variation coefficient of 30% (i.e. a standard deviation of 2.1 MPa), we will have a f'_c equal to 7-0.824*2.1=5.2 MPa. Performing tests to determine E in the lab will make a more accurate estimation of f'_c possible.

Dasht-e-Palang dam probabilistic analysis results

6. CONCLUSIONS

CMDs simplify the method of construction at the cost of causing uncertainties in the analysis and design of the dam. Applying an approach based on probabilistic methods with the concept of performance-based design will enable us to overcome these unwanted variations. In this paper, using a probabilistic approach in the designing process of three CMDs (currently under construction) has been described. The main benefits are listed as follows:

1- Minimizing the variations of aggregates in the Hardfill using an optimal method for screening and fractioning without any crushing.
2- More authentic estimation of the effect of weak rock parameters on the sliding safety factors of the dam body.
3- Better estimation of the layered properties of the CMD body.
4- Using less cementitious material by optimizing f'_c.

ACKNOWLEDGEMENTS

The authors would like to give special thanks to A.Mohammadi and R.Erami from Bushehr Regional Water Authority (BRWA) for their kind contributions.

SUMMARY

Cemented material Dam (CMD) on weak foundation has more challenges than other types of gravity ones. Variations in rock properties in the foundation, natural aggregates and simplicity in construction which results in more inhomogeneities in dam body will cause a lot of uncertainties which is a paradox in design. Performance Based Design using a probabilistic approach may be a proper way in this type of dam.

Using this probabilistic method, uncertainties on estimating the modulus of deformation of foundation is considered, variations in aggregate grading's has been reduced by finding the optimum sieve number of fractions, the layered behavior of dam body which is an inherent specification of CMD's, the relationship between modulus of deformation of Hardfill versus compressive strength and finally finding an optimum characteristic compression of dam body is well defined by a new proposed method in this paper.

1. INTRODUCTION

Analysis and design of geotechnical structures continue to face many uncertainties, which make it difficult to choose the appropriate design parameters. In the conventional design, engineers are trying to cover the uncertainties involved with a relatively high safety factor. considering high safety factor leads to construction of conservative design of foundations so that in spite of high cost, due to ignoring the effect of uncertainty, engineering judgment should be very difficult. Selecting geotechnical parameters of soil, due to uncertainties in the field, has always been one of the most challenging issues in geotechnical engineering.

Due to the uncertainties involved, it can be pointed out that considering constant parameters in soil analysis is not reasonable and the best solution to consider uncertainty in the soil is using probabilistic approach. Statistical parameters include the mean, coefficient of variation, and the density function of all parameters. The probabilistic analysis consists of methods that consider the effect of uncertainties on input parameters and determine the response regarding the uncertainty level. Some of these methods can be stated as reliability analysis method.

Reliability analysis method makes it possible to quantify the uncertainties involved in the problem. It also determines safety factor according to the degree of uncertainty and acceptable risk. Reliability analysis can be considered as an alternative to the definitive methods and makes engineering judgment easier [1].

2. EFFECT OF FLOW RULE ON THE BEARING CAPACITY COEFFICIENTS

Bearing capacity of the soil is the maximum load pressure that soil can tolerate at the moment of the failure. The most common methods used to determine the bearing capacity of foundations are limit methods so that these methods can be divided into three basic types of limit equilibrium method, method of stress characteristic and limit analysis.

Limit analysis method determines the upper and lower collapse load by theory of plasticity. In this method if the upper and lower limit give the same result, then it will be the exact solution of the problem. Researchers investigate foundation bearing capacity using different methods in the literature. One of the famous theories is known as Terzaghi bearing capacity theory. Terzaghi defines ultimate bearing capacity of foundation according to Eq. 1 [2].

$$Q_u = CN_c + qN_q + 0.5B\gamma N_\gamma \quad [1]$$

where N_c, N_q, N_γ are bearing capacity factors which are dimensionless and can be computed by friction angle, φ. B is the foundation width, and γ is unit weight. Also in this equation q is surcharge pressure and C is soil cohesion. Michalowski (1997) [3] estimated to calculate bearing capacity of a foundation using the upper bound approach which is applied to determine bearing capacity of a dam foundation on granular soil without surcharge pressure ($C = 0 \ , q = 0$). In Michalowski estimation, the substantial influence of the dilatancy angle on limit load was also considered. It is worthy to note that limit theorems are based on rigid-perfectly-plastic behavior that follow the associated flow rule.

It should be noted that the soil used in this paper is coarse; the soil cohesion, therefore, is set zero. Furthermore, surcharge pressure has not been taken into account, i.e. the third term of the bearing capacity equation, qN_q, becomes zero. Accordingly, the bearing capacity equation of Michalowski can be written as below:

$$Q_u = 0.5B\gamma N_\gamma \quad [2]$$

Concerning associated flow rule, the yield function is equal to the potential function [28]. Assuming Mohr-Coulomb yield criterion and associativity, the aforementioned statement renders the equality of yield surface. Although the associated flow rule leads the limit theorems , the theorems based on which limit analysis of stability problems can be well carried out to be developed [29], granular soils often dilates under deviatoric loads in an angle much less than the friction angle. Therefore, it seems to be more or less inaccurate assuming associativity, and non-associated flow rule, instead, should be considered in order to increase the accuracy of the assumptions.

$$\mathrm{T} = \sigma \tan \varphi + \mathrm{C} \qquad [3]$$

Mohr-Coulomb criteria can be modified for non-associated problems as follows [3]

$$\mathrm{T} = \sigma \tan \varphi^{*} + \mathrm{C}^{*} \qquad [4]$$

where:

$$\tan \varphi^{*} = \frac{\sin\varphi\cos\psi}{1 - \sin\psi \sin \varphi} \qquad [5]$$

To make a rational and proper judgment to calculate the third term in Eq.1, limit analysis is employed. The advantage of this approach is that a clear distribution weight of the components of the soil, cohesion, and surcharge in bearing capacity formula is considered. N_{γ} factor for non-associated flow rule is obtained from the perspective of the limit analysis. N_{γ} factor values are shown in the following table for smooth and rough foundations and for different dilation angles as the part of the friction angle. It is worth re-mentioning that by the use of limit analysis, it is possible to obtain numerically estimated N_{γ} values, tabled below as the results of Michalovski (1997); the most reasonable curve fits would be achieved in the next step, required for the reliability analysis.

Table 1
N_{γ} for smooth foundation (non-associated flow rule)

$(\varphi^{*\circ})$	N_{γ}		
	$\psi = 0.5\varphi^{*}$	$\psi = 0.25^{\circ}$	$\psi = 0$
0	0	0	0
5	0.18	0.18	0.18
10	0.7	0.693	0.683
15	1.894	1.842	1.773
20	4.261	4.028	3.734
25	8.931	8.064	7.058
30	18.309	15.442	12.457
35	37.606	28.798	20.849
40	78.649	52.772	33.306
45	169.436	95.428	50.924
50	379.868	170.386	74.614

Table2
N_{γ} for rough foundation (non-associated flow rule)

$(\varphi^{*\circ})$	N_{γ}		
	$\psi = 0.5\varphi^{*}$	$\psi = 0.25^{\circ}$	$\psi = 0$
0	0	0	0
5	0.127	0.127	0.126

10	0.419	0.415	0.413
15	1.027	1.001	0.966
20	2.225	2.107	1.962
25	4.597	4.156	3.646
30	9.353	7.899	6.385
35	19.134	14.667	10.642
40	39.937	26.834	16.958
45	86.045	48.385	25.886
50	192.66	86.4	37.876

As shown in Tables 1 and 2, non-associativity has a negligible effect on N_γ for internal friction angles below 25 degrees but it becomes more significant for larger friction angle. The numerical solutions can approximate N_γ factor for each dilation angle in smooth and rough foundations. Results are given for both rough and smooth footings. for rough footings:

$$N_\gamma = e^{0.66+5.11\tan\varphi^*}\tan\varphi^* \quad [6]$$

For smooth footings:

$$N_\gamma = e^{5.11\tan\varphi^*}\tan\varphi^* \quad [7]$$

3. RELIABILITY ANALYSIS METHODS

In reliability analysis, there are three specific categories including analytical, approximate and simulation methods which can be used in different conditions based on their drawbacks and advantages. The analytical methods consider probability density functions of input parameters mathematically defined and the performance function (e.g. safety factor), integrated over input variables; accordingly, probability density function of the performance function can be determined. The drawback of these methods is that they are limited to problems with few numbers of stochastic variables. However, it is possible to assess the probability feature of the problems using ideal mathematical viewpoint. It is worth mentioning that few studies have been done using analytical methods of reliability analysis in view of their mathematical complexity. Jointly Distribution Random Variables (JDRV) approach is the one utilizes mathematical techniques [4-7] by numerical integration in order to find probability distribution function (PDF) of performance function, but it is not able to consider correlation coefficient between stochastic parameters.

However, approximate solutions compute the probability of events with some indicators such as mean value and variance of input stochastic parameters. It should be mentioned that conventional approximate solutions are based on three methods: First Order Reliability Method (FORM) [8], First Order Second Moment (FOSM) [9] and Point Estimation Method (PEM) [10]. Each of them uses several simplifying assumptions for prediction of failure probability that somewhat reduces the accuracy. Furthermore, approximate solutions estimate the mean and variance of performance function; but they do not provide any information concerning the shape of its PDF. Therefore, the probability of events can be determined merely based on the assumed PDF for performance function by usually using normal distribution function. Recently, most of the reliability analysis, especially in the study of liquefiable soils, have been done using these methods [11-21].

Finally, it is worth noting that simulation methods are somewhat more accurate comparing with the previous ones. By the use of these methods, it is possible to predict the probability of event by simulating stochastic input parameters and implementing in repetitive calculations. The striking feature of these methods is that they can be used in complex mathematical problems, where the closed-form solution of which is not possible [22]. Thanks to the development of computer technology and available personal computer, application of these methods has been increased significantly in engineering problems. Monte Carlo simulation method is one of the most applicable methods, which will be discussed in the next section [1].

4. MONTE CARLO SIMULATION METHOD

In Monte Carlo Simulation (MCS), a mathematical or empirical operator $F(X)$ with the variable X ranging from x_1 to x_n is continuously calculated in which the operator (s) are random or have uncertainty with prescribed probability distributions [22-23]. MCS is actually an accurate reliability analysis method, applicable for collapse problems including slope stability, retaining walls and foundations [24-25]. In the analysis, stochastic values for input parameters are chosen; afterwards, the probability density function of stochastic parameters – which include any shape but normal, log-normal and beta distribution functions are generally implemented based on the characteristics of the stochastic variables, used to obtain the performance function. It is worth mentioning that the current procedure is repeated so far as proper statistical distribution for performance function is obtained enabling the user to determine the mean and standard deviation of performance function and, finally, prediction of the probability of events. Generally, this method consists of four steps as follows [25]:

1. Generating stochastic values for each of stochastic variables according to assigned probability density function.
2. Computing performance function using a proper deterministic method based on generated values in previous step.
3. Repeating steps 1 and 2 for as many times as required.
4. Determining probability distribution function of performance function and calculating the probability of events.

The number of required Monte Carlo trials is dependent on the level of confidence in the solution and the amount of stochastic variables. Based on the statistical theory, Eq. (8) has been recommended for the number of iterations [25]:

$$\mathrm{N} = \left(\frac{\mathrm{d}^2}{4(1-\varepsilon)^2}\right)^{\mathrm{m}} \qquad [8]$$

where N is the number of Monte Carlo trials, d is the normal standard deviation corresponding to the level of confidence, ε is the desired level of confidence and m is the amount of stochastic variables. Table 3 represents some confidence level (ε) with corresponding standard deviation (Std) with regard to the number of stochastic variables.

Table 3
Standard deviations according to confidence levels

confidence level (ε)	Standard deviation(std)
80%	1.282
90%	1.645
95%	1.96
99%	2.576

To generate random numbers, often probability distribution functions that generate numbers betwen zero and one are used such as uniform probability distribution function. Then using Eq. 9 these numbers are converted to numbers with standard normal probability distribution.

$$\mathrm{N_1} = \sqrt{-2\ln \mathrm{R_1}}\cos(2\pi \mathrm{R_2}) \quad [9]$$

R_1 and R_2 are random numbers generated using uniform distribution and N_1 is an independent random number generated using standard normal distribution. This process will be continued until enough random numbers are generated. The generated random numbers have mean of zero and standard deviation of one. To convert numbers with standard normal distribution (N_i) to numbers with the normal distribution having the mean of μ_x and the stress standard deviation of σ_x (X_i), Eq. 10 is applied.

$$\mathrm{N_1} = \sqrt{-2\ln \mathrm{R_1}}\cos(2\pi \mathrm{R_2}) \quad [10]$$

$$\mathrm{X_i} = \mu_\mathrm{x} + \mathrm{N_i}\sigma_\mathrm{x} \quad [11]$$

In Eq. 10, X_i is a generated random number with normal distribution that is used in the calculation of the performance function and N_i is a random number with standard normal distribution. The presented equations are provided for the case that random numbers are generated independently.

5. CALCULATION OF THE BEARING CAPACITY OF DAM FOUNDATION USING MONTE CARLO SIMULATION METHOD

In this method, the foundation bearing capacity can be analyzed for various performance levels and soil bearing capacity is calculated depending on the desired level of confidence. Probabilistic analysis for bearing capacity of dam foundations using Monte Carlo simulation and uncertainty parameters is calculated.

Among input variables, the friction angle is considered as random variables and (ψ), (γ) and (B) are constant. The number of iterations to simulate is set to 200,000 times, also the coefficient of variation of soil friction angle is considered 15% [26, 27].

5.1. NUMERICAL ANALYSIS

In this section, to demonstrate the efficiency of the proposed model to analyze the bearing capacity of foundation, a numerical example is assumed. In the example a foundation with a width of 2 meters and granular soil with the unit weight of 19 $\mathrm{kN/m^3}$ are considered. Also The average of dilation angle (ψ) is assumed to be 6°. In calculating the definitive bearing capacity, the average friction angle is considered 25 degree.

Safety factor in different iterations is calculated and the frequency graph of ultimate bearing capacity is shown in Figures 1 and 2. As can be observed the curve is continuous and follows the log-normal probability distribution function. In Figures 3 and 4 the procedure of calculating allowable bearing capacity with a confidence level of 90% are illustrated.

Ultimate bearing capacity of foundation using Michalowski method is obtained 92.5 kN for smooth foundations and 176 kN for rough foundations.

If the dam foundation with the assumed specifications is analyzed using Monte Carlo method, the cumulative distribution graph of bearing capacity could be as Figures 1 and 2. To select the allowable bearing capacity of foundation, regarding the desired confidence level, cumulative distribution graph of bearing capacity can be selected. it can be concluded that the confidence level required for structures is about 90 to 98%.For example, a confidence level of 90% indicates that 90% of simulated items have more bearing capacity than the allowable bearing capacity. According to Figures 3 and 4 allowable bearing capacity of smooth foundation due to the 90 percent of confidence level equals to 48.2 kN and for rough foundation this value is 95.9 kN.

By comparing the allowable values and ultimate bearing capacity regarding confidence level of 90%, it can be pointed out that safety factors for smooth and rough foundations are obtained 1.92 and 1.83 respectively. According to the above explanation, it can be stated that the method of reliability analysis to calculate the bearing capacity of foundations is more reliable that certain methods, because in addition to reducing construction costs, this method handles the uncertainties that are also quantified.

6. CONCLUSIONS

Reliability analysis methods, which consider uncertainties and estimate the probability of bearing capacity, can facilitate the engineering judgment.

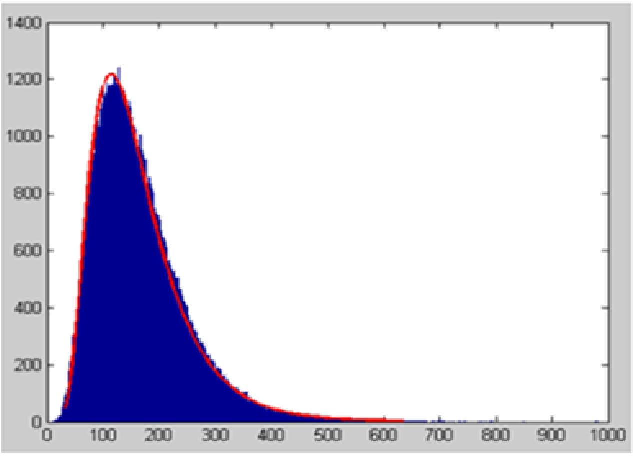

Fig. 1
Frequency diagram of ultimate bearing capacity of smooth foundation

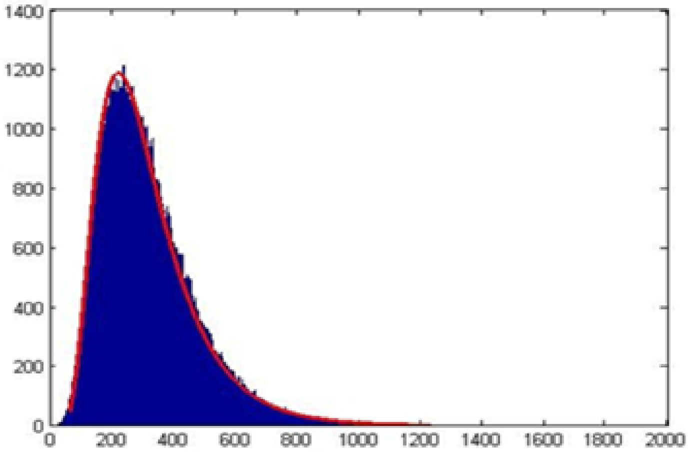

Fig. 2
Frequency diagram of ultimate bearing capacity of rough foundation

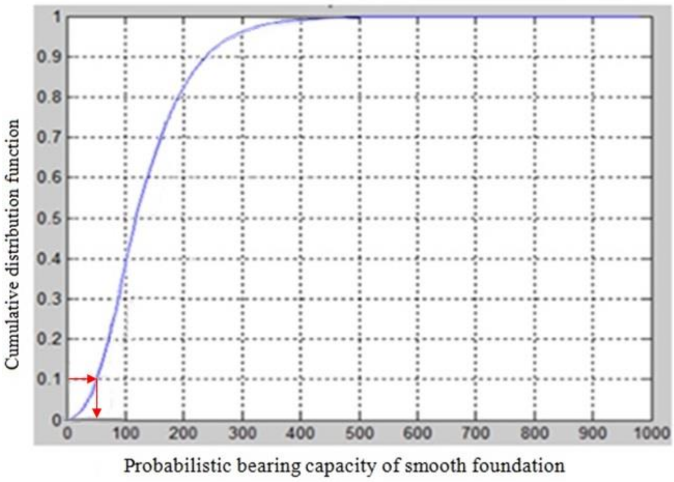

Fig. 3

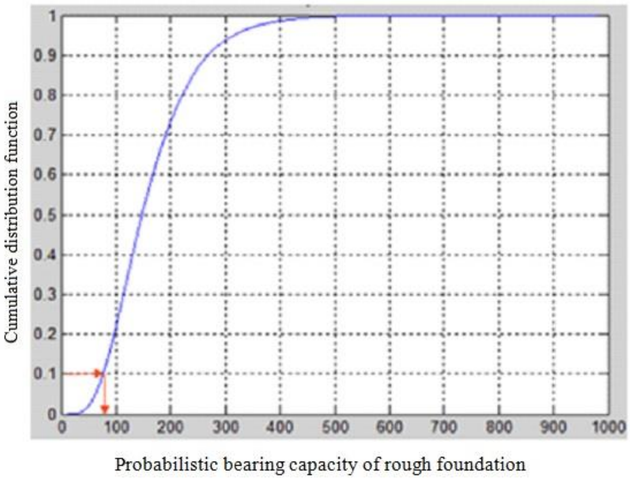

Fig. 4
Probabilistic bearing capacity of rough foundation

In this paper, Monte Carlo's simulation method as one of the reliability analysis methods is used to investigate the influence of the variation of friction angle (φ) on the reliability of dam foundations. In this regard, the performance function is built with Michalowski's equation. In the presented research, based on the results, the following conclusions are drawn:

1. For foundations on granular soils, the probability of failure of foundation is more sensitive to the variation of friction angle of soils, since the COVs of main parameters of bearing capacity like the friction angle (φ) is considered.
2. The proposed probabilistic approach accounts for parameter uncertainty of soil friction angle, and enables bearing capacity to be quantified in the form of a cumulative probability distribution function that provides bearing capacity predictions corresponding to certain reliability levels. This indicates the importance of adopting probabilistic analysis in favor of the factor of safety. It was also shown that the developed probabilistic method can be used to predict bearing capacity of dam foundation for reliability levels of 90% and 95%.
3. The results obtained from Monte Carlo's simulation method and deterministic method indicate that the deterministic method is not reliable enough in comparison to the probabilistic results.
4. A numerical example was given to illustrate the use of Monte Carlo's simulation. The results indicate that the suggested factor of safety of 3 that usually used by available deterministic models is conservative. However, it seems not to be economically beneficial.
5. A substantial influence of the dilatancy angle on N_γ is found and this is a reason for concern. Since the non-associativity of plastic deformation of soils is usually not accounted and especially in high levels of friction angle, is usually an essential phenomenon in soils under applied loads. Taking into account the reliability analysis with non-associativity, one can highlight the aim of the current study.

SUMMARY

To a great extent, an accurate prediction of the bearing capacity is considered to be a common practice in geotechnical engineering. Analysis and design of geotechnical structures continue to face with many uncertainties which make it difficult to choose the design parameters. Mostly, the uncertainties are pertinent to unreliable deterministic soil characteristics. Use of a deterministic approach for soil specifications may result in either underestimation or overestimation of the soil shear strength in problems dealing with limit loads. Therefore, the traditional deterministic limit load methods, e.g. the conventional limit analysis and slip line methods could not capture a reliable estimation of the bearing capacity. In order to examine the parameters involved in the estimation of bearing capacity of foundations, it is required to take in to account the uncertainty nature of the soil to perform the reliability analysis. In the analysis, the effect of probabilistic input parameters on the limit loads is considered. As a matter of fact, the reliability analysis makes it possible to be able to quantify the uncertainties involved.

In this study, the reliability analysis of the bearing capacity of dam foundations was carried out via Monte Carlo simulation with the focus on the uncertainty associated with the friction angle. To do so, the upper-bound limit analysis was employed assuming the deterministic friction angle. The formulation and the general computational procedure were kept exactly as the one introduced by Michalowski (1997). As it is obvious, the non-associativity of plastic deformation of soils is a significant factor in limit load problems. In the current study, the substantial influence of the dilatancy angle on N_γ was also examined. As a conclusion, appropriate safety factors based on reliability analysis are suggested leading to economical advantage of the design of geotechnical structures.

ABSTRACT

Primary purpose of water recources development in Indonesia is water supply for various needs. Therefore, various efforts are made by the government to solve the problem. One of the efforts in planning phase, is water resources infrastructure development of Cipanundan Dam at Cirebon District .

The physical model spillway of Cipanundan Dam is made on a scale of 1: 20, some scenarios of debit flow based on design flood discharge Q_2, Q_{25}, Q_{100}, Q_{1000}, and Q_{PMF}. The construction of three dimensional model of Cipanundan Dam is built by using Froude model criteria, because this criteria model is the closest to field condition.

Flow testing on Cipanundan Dam spillway model is expected to provide parameters of hydraulic test results in laboratory that will determine optimal dimensions of the spillway and complementary structure building, so that it can be used as basic work for the next stage.

The results of the hydraulic flow obtained from the test model still needs a further study that is to model the flow condition when it returns to the river and to map scouring pattern in the downstream stilling basin.

Keywords: Cipanundan, test model, hydraulic parameters

1. BACKGROUND

Cipanundan Dam is a dam that is subjected to irrigate the irrigation area in Kabupaten Cirebon and planned to construct soon. Dam reservoir area is located in Cipanundan river valley, at el. +26 m until el.+50 m extended from south to north. Cipanundan Dam axis is located between two hills, stratched along Cipanundan river.

Type of Cipanundan Dam is homogenous soil type, dam height is about 24 m dan dam length is about 511 m. Spillway Cipanundan Dam located on the right toe with overflow type, and stilling basin type is USBR type 2.

2. PURPOSE AND OBJECTIVES

The purposes of the hydraulic test model spillway of Cipanundan Dam are:

1) To establish the idea of planning in terms of hydraulic aspects (flow design and sediment transport) by studying and investigating the flow symptoms and parameters that occur.
2) To study and verify the layout of spillway designed to obtain hydraulic design properly,
3) To determine of optimum type, form and dimension of energy dissipator and appurtenance structure,

The objective of this hydraulic test model spillway of Cipanundan Dam is to provide a refined recommendation based on hydraulic aspect, so that deviations may occur during desgining, it can be eliminated from the test model and will obtain the most optimal hydraulic structures dimension. All of these stages are to guaranty of dam safety and function.

3. PROTOTYPE DATA

Prototype data of Cipanundan Dam are as follows:

a. **Main Dam**

- Type	:	Homogeny Embankment
- Crest dam elevation	:	+ 46,80 m
- Crest width	:	7,50 m
- Slope	:	Upstream = 1 : 3,00 Downstream = 1 : 2,50

b. **Spillway and Appurtenance Works**

■ **Spillway works**

- Type	:	Ogee
- Crest dam elevation	:	+ 44,00 m
- Crest width	:	17,50 m

■ **Transition Channel**

- Length	:	26,50 m
- Width	:	hulu = 17,50 m hilir = 8,50 m
- Elevation	:	hulu = + 38,00 m hilir = + 37,25 m
- Basic slope	:	0,028302

■ **Chute**

- Length	:	47,65 m
- Width	:	8,50 m
- Basic slope	:	0,278069

■ **Stilling Basin**

- Type	:	USBR Type II
- Length	:	30,00 m
- Width	:	8,50 m

4. DESIGN FLOOD DISCHARGE

Based on analysis, it is known that the design flood discharge is based on flood routing through reservoir. So for test model Cipanundan Dam, is used the outflow discharge from the debit of Q_2, Q_{25}, Q_{100}, Q_{1000}, and Q_{PMF}. The design flood discharge data are as follows:

Table 1.
Design Flood Discharge

Return Period	Inflow Discharge (m^3/s)	Outflow Discharge (m^3/s)
2	27,40	8,47
5	31,80	10,00
10	42,20	14,63
25	50,70	18,48
50	55,60	21,16
100	60,90	24,96
200	68,30	27,93
500	79,00	33,30
1000	83,50	36,71
PMF	193,80	112,63

5. MODEL CONSTRUCTION

The construction of three dimensional model of Cipanundan Dam is built by using Froude model criteria, because this criteria model is the closest to field condition. Furthermore, with various consideration it has been established that the scale model used is 1 : 20, undistortion.

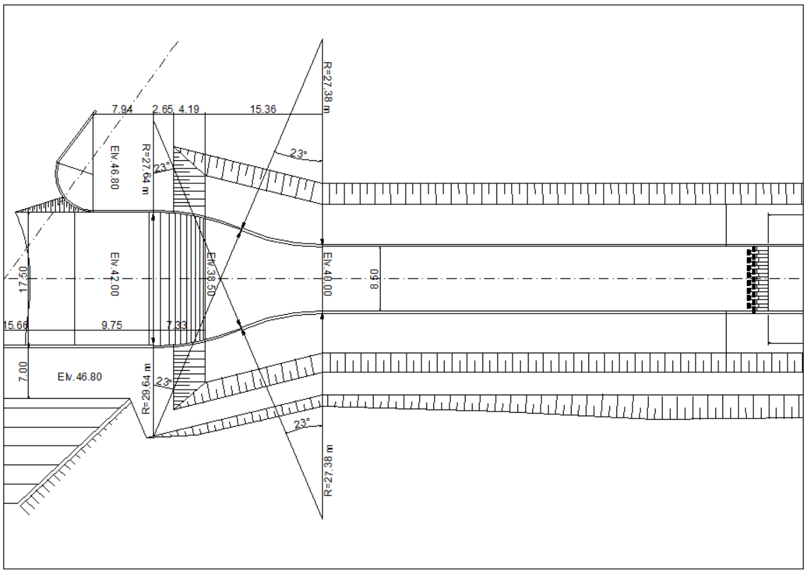

Figure 1.
Layout of Spillway Cipanundan Dam

6. SCENARIO OF TESTING

In order to achieved the test model objectives, the test scenario are carried out as follows:

1) Testing of spillway weir capacity,
2) Investigation to examine the design of spillway structure to follow the designed discharge as expected,
3) Investigation to improve and refine spillway structure design and their component,
4) Investigation of impacts on dam construction

Based on the test scenario above, to support test program, the model is made with two types of riverbed and riverbank, they are:

1) Reservoir model with fixed riverbed and fixed riverbank (Fixed Bed Model), is a model with riverbed and riverbank made from mixed of sand and cement to obtain similarity of roughness,
2) Downstream river model with movable riverbed and movable riverbank (Movable Bed Model), is a model with riverbed and riverbank made from loose material fine sand to imitate riverbed and riverbank material in prototype that can be eroded.

Figure 2.
Test Model Of Cipanundan Dam

Figure 3.
Prototipe of Spillway Works, Chute dan Stilling Basin

7. TEST MODEL RESULT

Results from spillway hydraulic test model of Cipanundan Dam are as follows:

1) The flow conditions on the transition channel are relatively good and there is no crossing flow,
2) The flow conditions on energy dissipator up to Q1000 discharge, still form hydraulic jump,
3) The effectiveness of the energy dissipator is functioning optimally

8. CONCLUSION

The results of the hydraulic flow obtained from the test model still needs a further study that is to model the flow condition when it returns to the river and to map scouring pattern in the downstream stilling basin. It is necessary in order that the results of modelling can gain the most optimal condition.

9. ACKNOWLEDGEMENT

The authors would like to thank to Dam Center and Dam Safety Unit, Directorate General of Water Resources, Ministry of Public Works and Housing for the authorization to publish the main result of the present study. The authors would also like to express the gratitude to Dam Safety Unit and Cimanuk Cisanggarung River Basin Authority as the institution who built the dam for having made this fruitful collaboration possible.

1. INTRODUCTION

Mae Suai is the second RCC dam in Thailand which is situated in Chaing Rai province, in the northern region as shown in Figure 1. It was constructed on the Mae Suai river during 1999 and 2002 for irrigation. The storage capacity is 73 Million cubic meter. The dam is a composite dam consisting of the RCC dam in the middle part of the dam to be the spillway and the earth dam on the both abutments because of the foundation condition. View of Mae Suai Dam is shown in Figure 2. The maximum height of dam is about 59 m and the crest length is 400 m. The site plan and section of dam as shown in Figure 3. The foundation of the RCC was excavated to the sound rock. Grouting has been done as necessary. The RCC section uses as an overflow spillway. The RCC section is surrounded with the earth dam. The earth dam extends to both sides of the abutment. Core trench has been excavated in the foundation and to the abutments. There are RCC blocks on the crest of earth dam at the downstream side because of earthfill volume and height of spillway's downstream wall reduction.

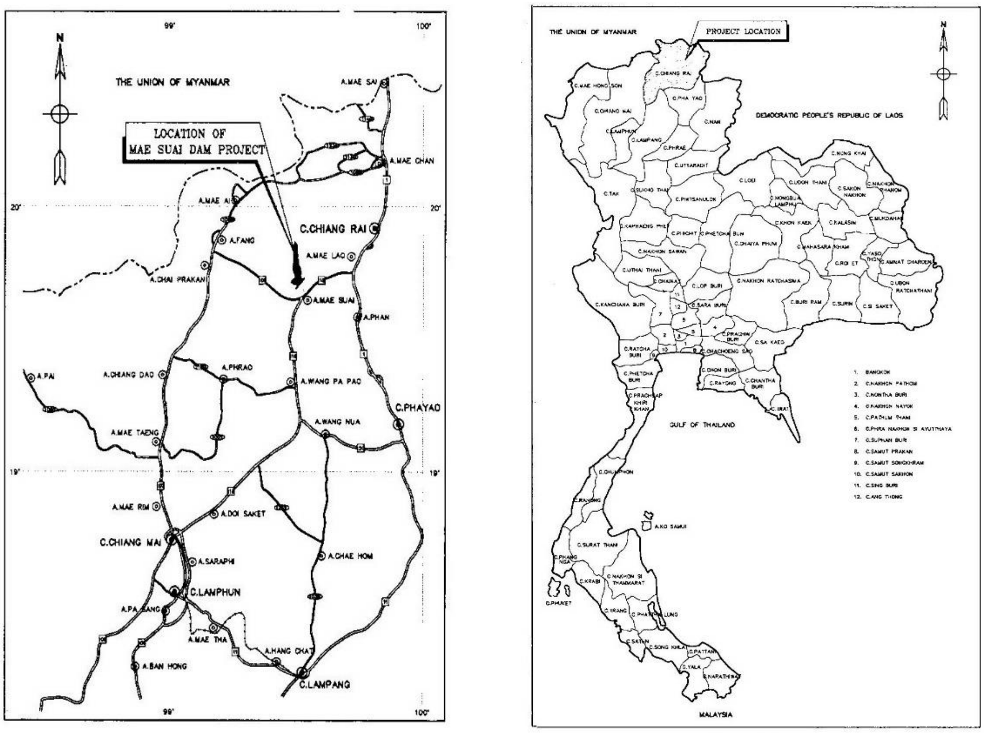

Fig. 1
Location of Mae Suai Dam Project

Fig. 2
View of Mae Suai Dam

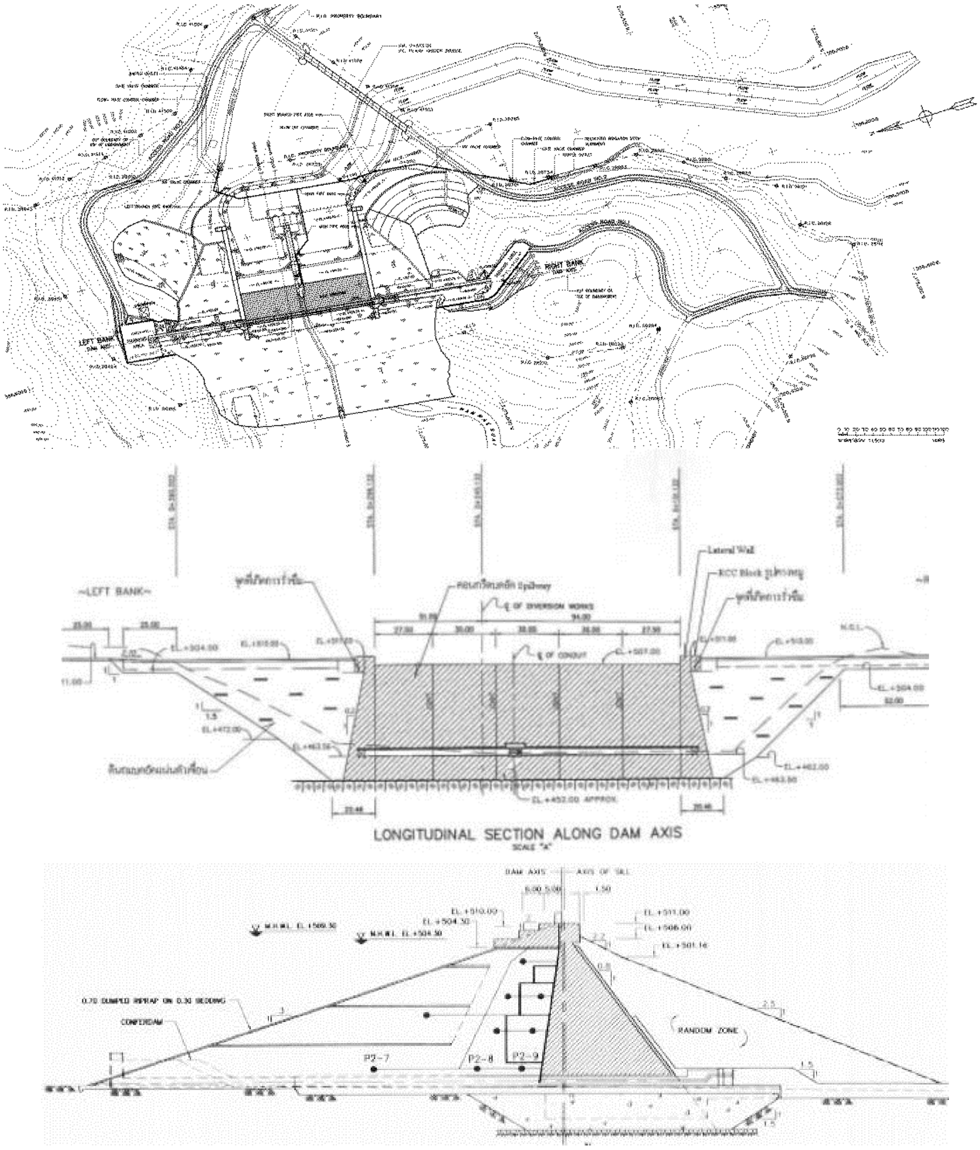

Fig. 3

Site Plan, Longitudinal and Typical Section of Mae Suai Dam

2. DAM CREST SETTLEMENT AND LEAKAGE PROBLEM

The differential settlement between the RCC spillway and the earth dam is occurred causing the cracks and gaps at the RCC blocks. In the first filling, the water overtopped the spillway and flow through the cracks and gaps. The leakage was observed at the downstream crest near the contact area between the RCC part and the earth zone part as shown in Figure 4. They are repaired by the impervious membrane covering at the upstream surface of RCC blocks, the leakage is reducing but stilling. The downstream population worried about the safety of the Mae Suai dam especially in case of earthquake.

Fig. 4
Leakage occurred near the joint between RCC and earth fill, the differential settlement is clearly seen

3. CHIANG RAI EARTHQUAKE AND RESPONSE OF DAM

Fears of an earthquake have deepened after 6.3 magnitude earthquake hit the province in May of 2014. The epicenter to the dam site is 18 km. However, the epicenter of the aftershock is closer to the dam site. Mae Suai Dam is located in the active faults zone as shown in Figure 5. The dam experienced the strong ground motion and the accelerometer at the right abutment recorded the maximum PGA of 0.33g. Fortunately, the seismic force did not affect the Mae Suai Dam. The dam performed well. There is some crack observed in the concrete cover of the RCC block on the crest of the dam. The crack is much above the maximum water elevation therefore the safety is not to be concerned. Especially, the RCC block that seen some cracks is the part that not related with the stability of the dam.

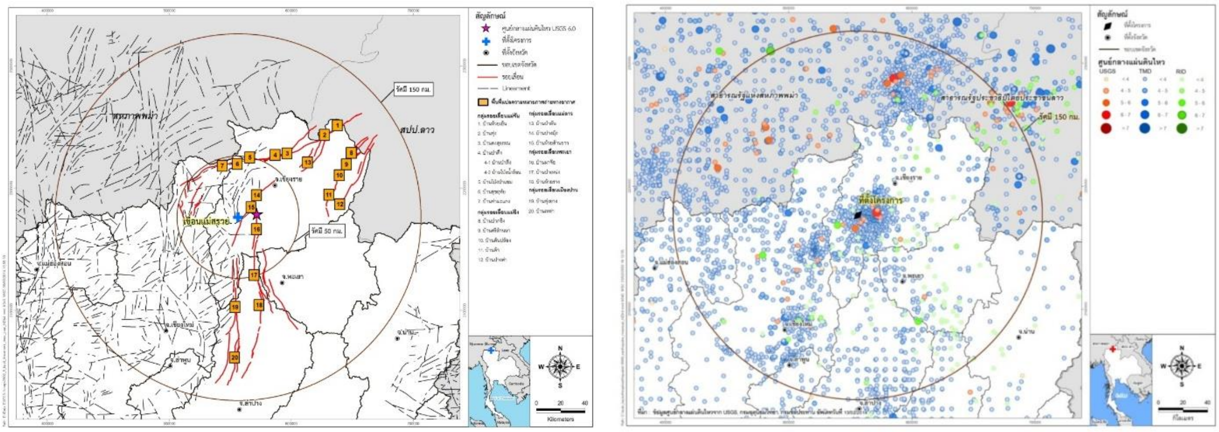

Fig. 5

Active Faults and Earthquake Epicenter near the Dam Site

Even though the dam is performed well according to the engineering evaluation, however the people who lives downstream of the dam are very concerned about the safety of the dam. This is because they thought that the cracks of the concrete covered of the RCC block may lead to the leakage just like what they had experienced before. The concerns became a panic and serious since the community required that the dam shall be removed. Several meetings were set up to discuss about the practical solution and the consensus are to keep the water storage to be lower than 60% until the dam has been fully repaired.

4. EMERGENCY ACTION PLAN

However, people at the dam downstream still worried over the incident. Besides, there was not any study, plan, prevention measures or risk surveillance in terms of surplus discharge and dam break, which caused faster flood and more damage to life and property. Then, the Royal Irrigation Department had studied the dam break of Mae Suai Reservoir Project in terms of surplus discharge, causes of damage of dam and appurtenant structures which may cause flood and flood severity and characteristics, as well as to complete action plan to cope with the dam break.

4.1. FLOOD CONDITIONS AFTER DAM BREAK

The study of flood conditions based on dam break is aimed at applying the result of flood conditions and the flood flow period to the preparation of action plans in case of emergency to cope with situations arising in the event of dam failure. Three dam failure events are identified: flood loading, static loading and earthquake loading.

[1] Flood loading is analyzed to obtain the maximum flood boundary. The study of six case studies found that the most severe flood case that is caused by the failure of mae suai dam in case of the pmf to mae suai reservoir and the 10,000-year return flood in downstream or mae lao river basin areas. Flood conditions of case study are shown in figure 6. The flooded area is about 181 km^2.

[2] Static Loading is analyzed to determine the flood boundary in case of dam failure by considering that water levels and downstream or Mae Lao River Basin areas are normal and no overflow occurs. The study result revealed that flooded areas are less than the first event. where the reservoir water is at normal high water level. Flood conditions are shown in Figure 7. Flooded areas are about 102 km^2.

[3] Earthquake Loading is analyzed as a scenario to consider impacts of dam failure in the event of earthquakes and in case of the 10,000-year return flood in downstream or Mae Lao River Basin areas. The study result shows that flooded areas are the same as case 1

4.2. AREAS AFFECTED BY DAM BREAK

The boundary of areas affected by floods due to failure of Mae Suai Dam will change in accordance with characteristics and severity of dam failure in different scenarios. As a result of hydraulics analysis using mathematical models in preparation for flood maps, Mae Suai dam failure is analyzed in various scenarios to study flood conditions, the boundary of affected areas and severity so that damages can be assessed by using flood map data overlapping with area condition data.

The analysis of different case studies indicated that the failure of Mae Suai Dam in case of flood conditions results in the most flooded areas as shown in Figure 8. Affected areas include both banks of the Mae Suai River from the area below Mae Suai Dam to the confluence of the Mae Lao River and both banks of the Mae Lao River from Ban Thung Yao, Si Thoi Sub-district, Mae Suai District to the confluence of the Kok River. The boundary of flooded areas in each area depends on topography and drainage potential of the Mae Suai and Mae Lao Rivers in that period. Flooded areas cover some areas in five districts of Chiang Rai Province – Mae Suai, Mae Lao, Phan, Mueang Chiang Rai and Wiang Chai districts and four municipalities: Wiang Suai, Mae Suai, Mae Lao and Pa Ko Dam sub-district municipalities.

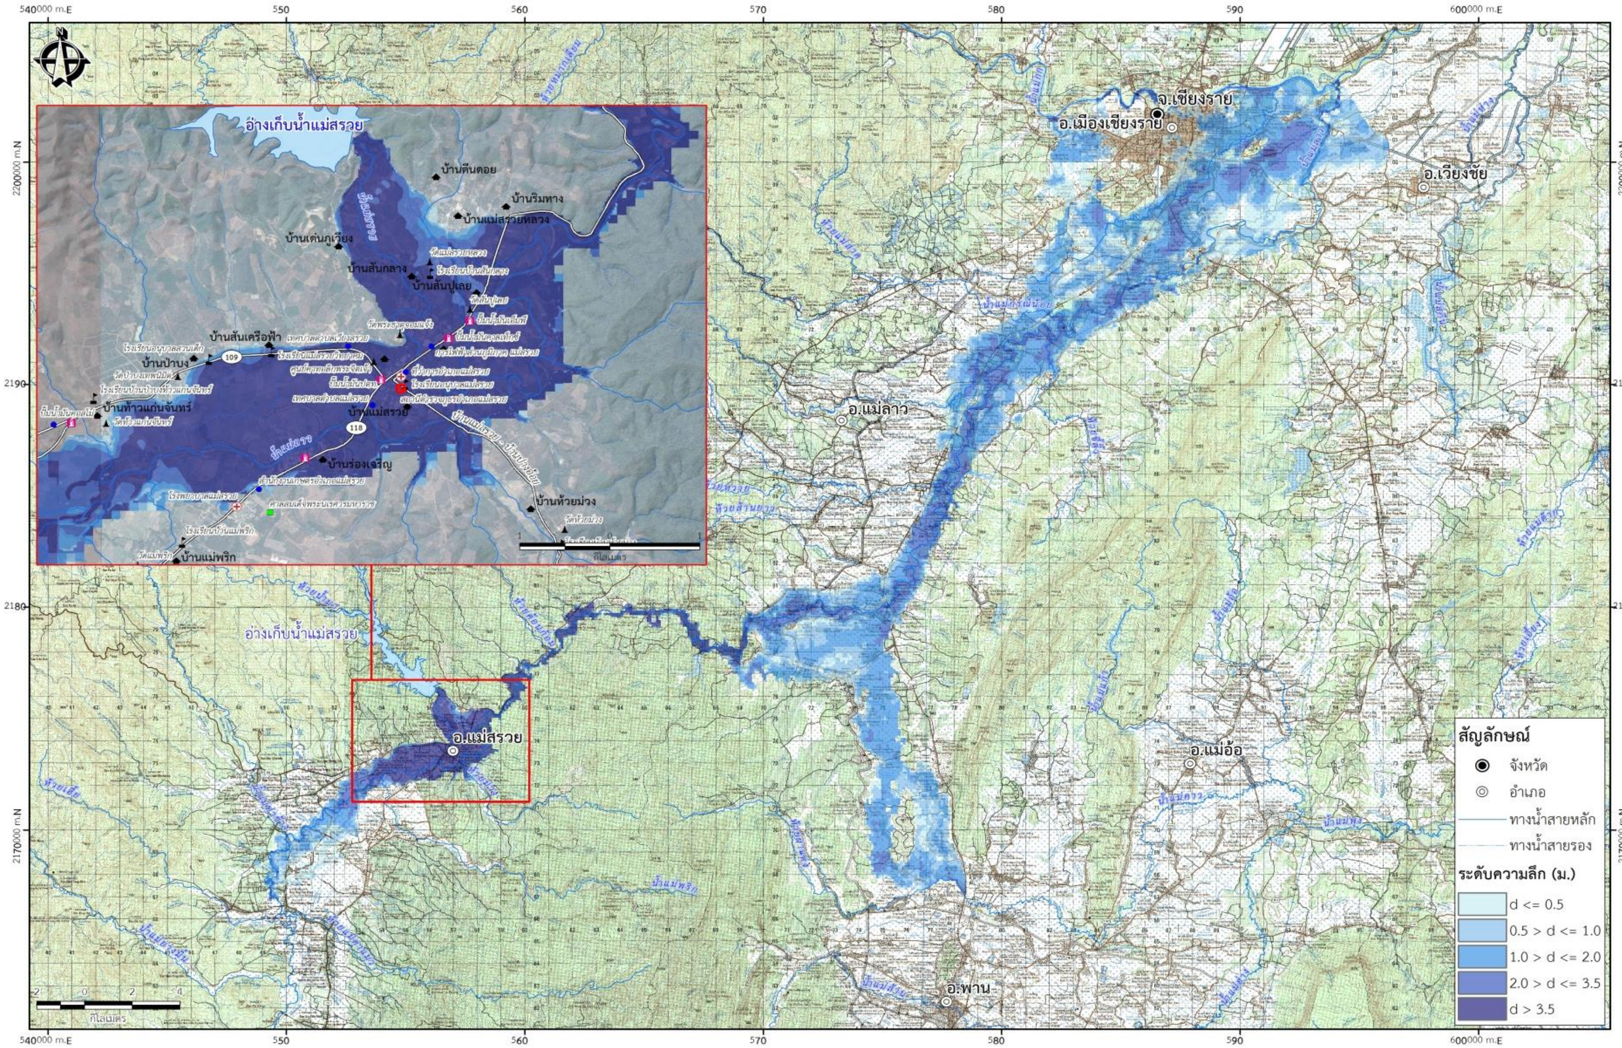

Fig. 6

Flood Map Analysis in Case of PMF Flood and Failure of Mae Suai Dam

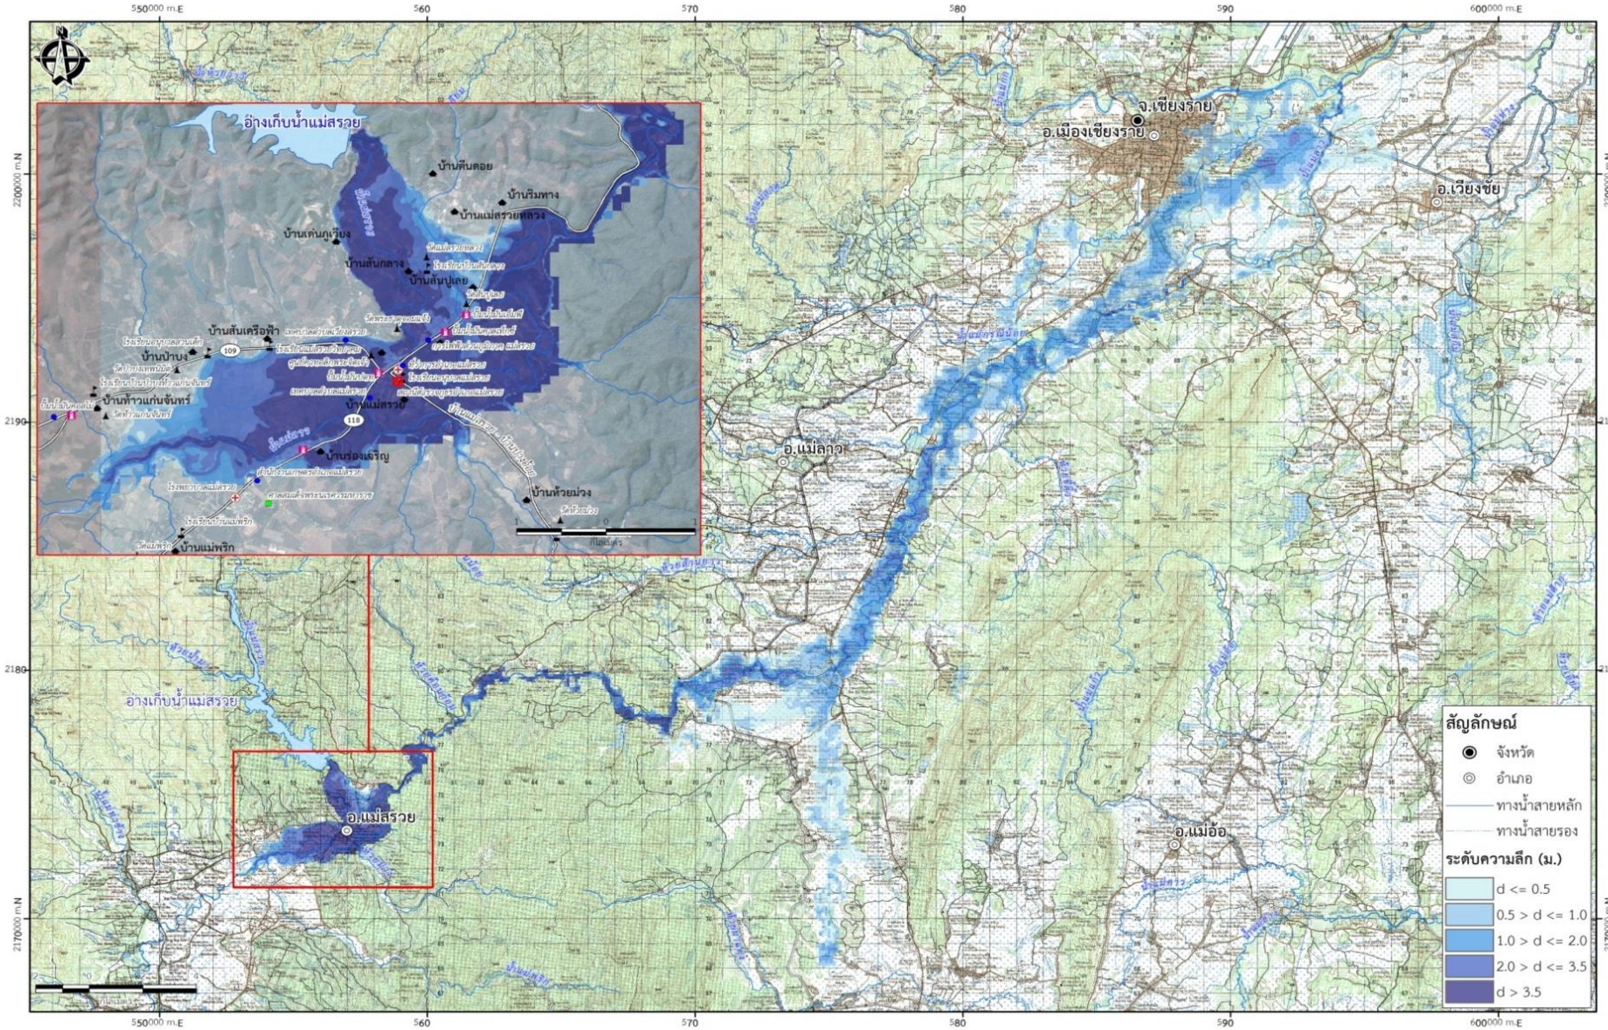

Fig. 7

Flood Map Analysis in Case of Maximum Storage and Failure of Mae Suai Dam

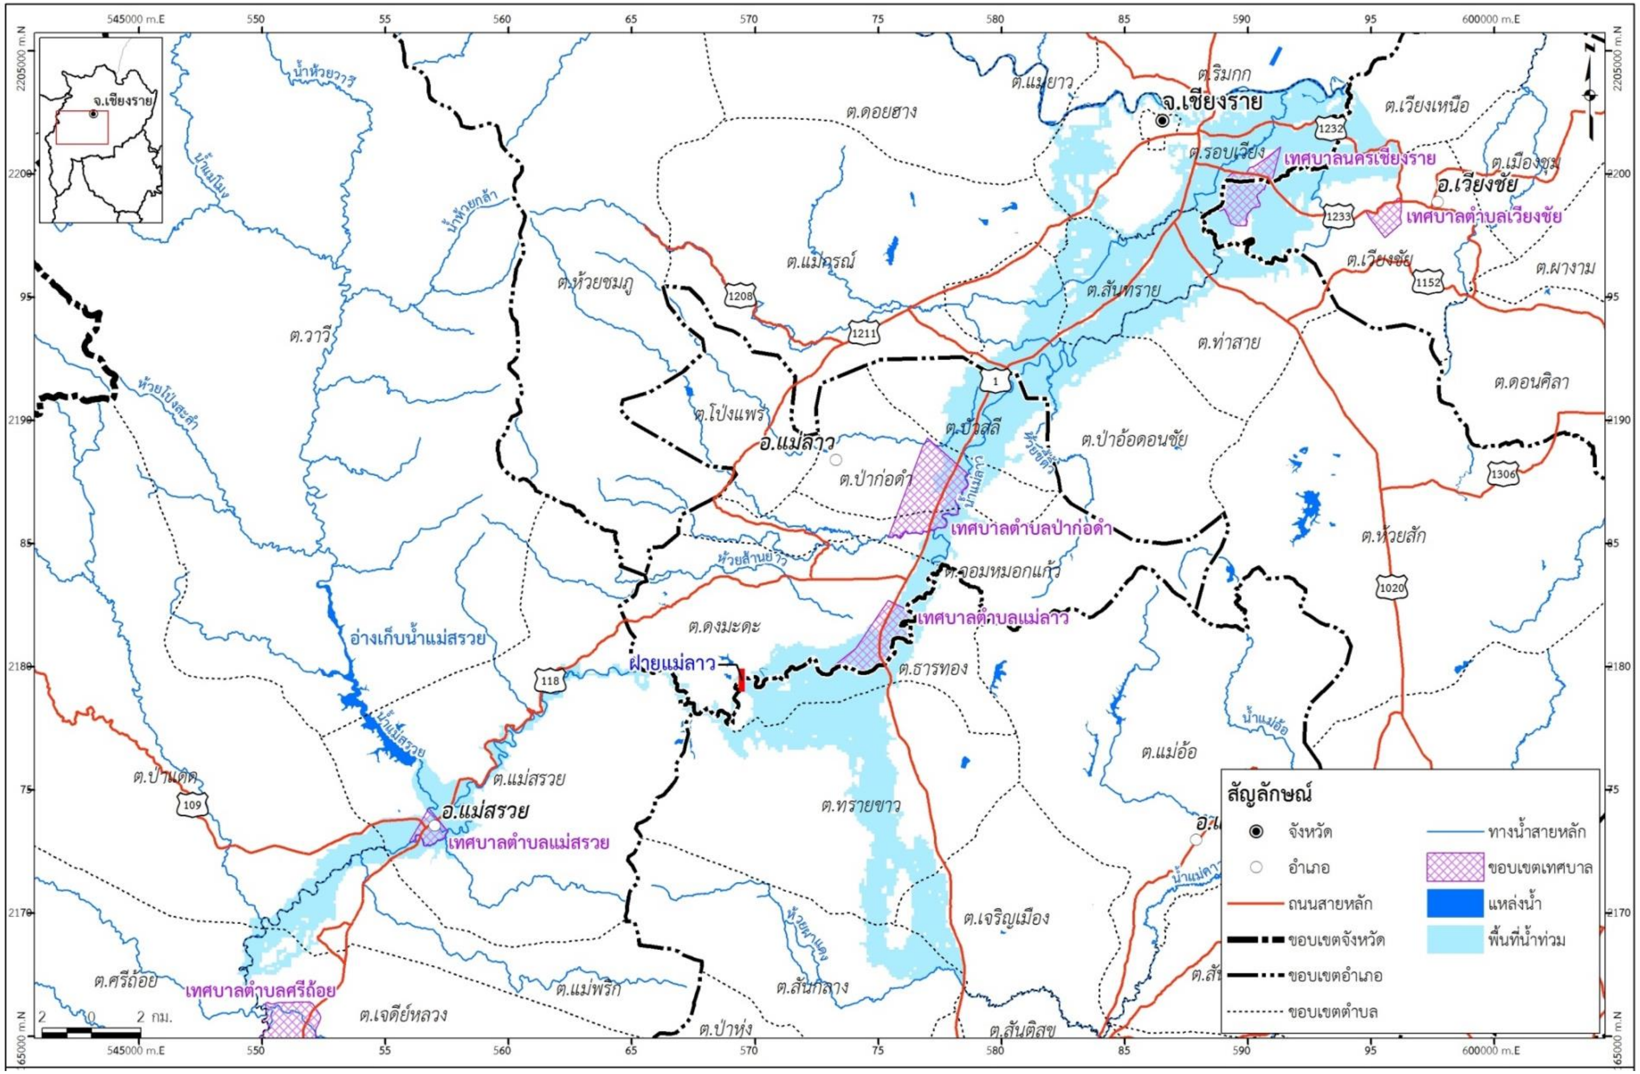

Fig. 8

Flooded Area in Case of Failure of Mae Suai Dam

Areas that may be affected or risk areas due to emergency cases of dams or much drainage from dams include dam downstream areas along both banks of the Mae Suai River in Mae Suai District to the confluence of the Mae Lao River, where floods will also take place. The boundary of risk areas in each event of emergency cases of Mae Suai Dam varies according to flood conditions as a result of the analysis. This depends on the reservoir water volume at that moment, inflow, dam failure types and the existing flood conditions in dam downstream areas prior to the incident. It is summarized as follows:

Zone 1 (downstream of Mae Suai Dam-Ban Rim Thang)

The severity of floods will be very high, especially in Ban Rim Thang, in which Zone 1 ends .There are a mountain pass and a narrow waterway .As a result, flood water levels are very high .Therefore, warning should be issued to people immediately and houses and buildings should not be constructed along the banks because this may cause harm to lives and properties.

Zone 2 (Ban Rim Thang-Mae Lao Weir)

In Zone 2, the severity of floods will be very high because of a narrow mountain pass throughout the area. As a result, the overflow from the Mae Lao River will occur. However, the population in the area is not dense. Warning should be issued to people to evacuate to higher grounds as specified. The wave will take about 2-3 hrs to travel to this area.

Zone 3 (Mae Lao Weir-the confluence of the Mae Kok River)

According to the analysis of all cases, Zone 3 will not face much risk because flood levels will be low or about 0.5-1.0 m. It will take about 4-9 hrs in total for waves to travel. This may not affect people’s way of life. It is not necessary to move people to higher grounds. People in such area should monitor the situation closely and cooperate with agencies concerned or seek how to prevent impacts caused by floods.

4.3. ACTION PLAN FOR UNUSUAL CONDITION DAM SAFETY

Generally, when uncommon situations occur, for example, downpour, earthquakes, landslides in reservoirs, the officers in charge of dam maintenance have to examine and evaluate the dam conditions immediately. If unusual conditions or damage of the dams, appurtenant structures or control devices are found, the officers have to report the conditions to the dam safety section to analyze the causes and provide solutions as well as the prevention and monitoring measures intensively. The action plan for the Mae Suai dam safety in unusual conditions can be summarized as follows:

1] In case of downpour or unusual flood; excessive downpour over 200 mm within 24 hours, continuous downpour over 48 hours or flood that causes water levels in reservoirs change rapidly (over 30 cm per hour), the operation approach will be as below:

[1] Analyze and evaluate the volume in the reservoir that will increase from the rainy storm .

[2] Examine the gate control system of the dam and appurtenant structures .

[3] Check the conditions of dam foundation, the seepage of the dam and the possibility of landslides in the reservoir area .

[4] Monitor and examine the abnormality of the dam and appurtenant structures.

[5] In case that the water level in the reservoir cannot be controlled, resulting in rapid overflow over the dam crest and the dam is likely to break down, evacuation of people from the project area should be implemented immediately as well as the notification of related agencies located at the downstream.

2] Earthquakes may impact dams and can cause unusual conditions to the dams. In case of earthquakes, the inspection of the dams and appurtenant structure conditions after the earthquakes is recommended.

Dam conditions and seismic response will be measured by using the dam instruments, such as Survey Monument, Piezometer and Accelerograph, which are already installed.

Normal Level: An earthquake takes place more than 200 km away from the dam and does not certainly cause any effects to the stability of the dam.

Alert Level: An earthquake of magnitude and distance according to ICOLD (1988), or an earthquake which causes ground acceleration at the foundation and is severe enough to cause a few impacts to the dam, occurs) for example, the accelerograph responds the seismic waves of > 0.02g to <0.2g, which does not cause damage to the dam.(

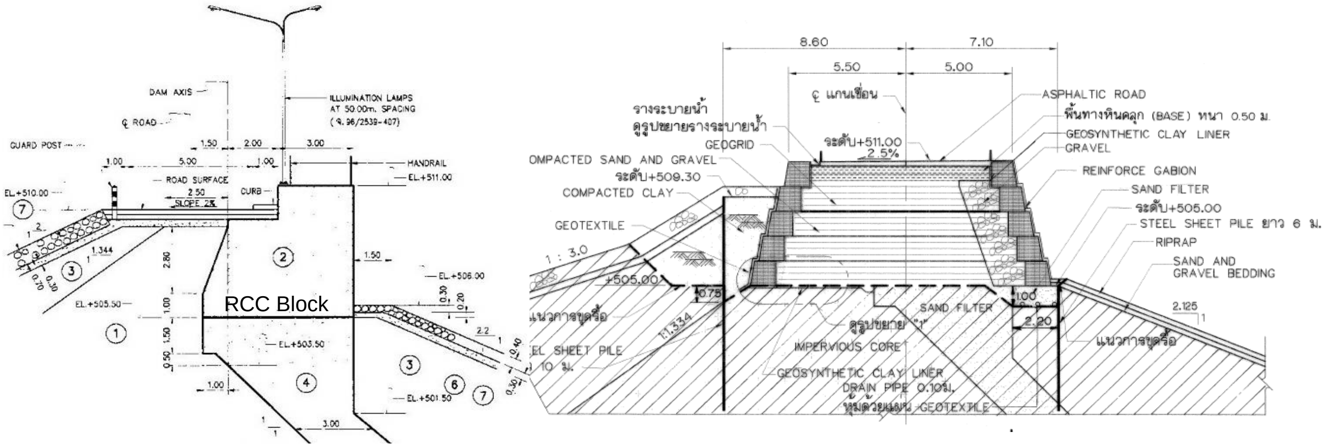
Alarm Level: The earthquake generates ground acceleration of >0.2g at the dam foundation or the magnitude and the distance of the earthquake from the dam according to Sadigh)1997('s energy attenuation model causes the ground acceleration of 0.2g at the dam foundation, which is serious enough to cause damage to the dam.

3] In case of landslides in a reservoir, the inspection and the evaluation of landslide locations and sizes is recommended, including the massive waves that may cause overflow to the dam crest .Scrap, rock and soil mass which block the water flow should be moved out .It is recommended to inform the dam safety section to evaluate the damage of the dam and appurtenant structures.

5. DAM REHABILITATION

Moreover, Royal irrigation department decided to rehabilitate Mae Suai dam. Repair works shall be able to solve the leakage problem and make the dam to perform well with the future earthquake. The dam rehabilitation will be done in two parts. First, the RCC blocks on the earth dam crest will be removed and replaced by the flexible and vibration resistance structure. The GRS wall with the cutoff sheet pile will be used as shown in Figure 10. GRS wall consists of reinforce gabion. The gabion wall is anchored to the gabion in the opposite side in order to provide additional confining pressure near the slope face and hence increasing the strength of compacted sand during the earthquake. Hot dipped galvanized steel sheet pile will be placed on both side of the GRS wall. Sheet piles will work as a water tightness barrier. In addition, it designed to minimize lateral movement that may cause from the weight of new GRS wall to the exiting soil below the cut level.

And the second is to build the 3 m diameter tunnel as the additional outlet to control the water level for flood management. The existing outlet diameter is 1.5 m that is small and the maximum discharge is about 30 cms. It is difficult to manage flood because the reservoir volume of Mae Suai Dam is less than the average annual inflow. Adding the new outlet tunnel should be done as shown in Figure 11. The maximum discharge capacity is about 100 cms that less than the capacity of the downstream river.



Existing Rehabilitation (GRS Wall)

Fig. 10
Dam Crest Rehabilitation Detail

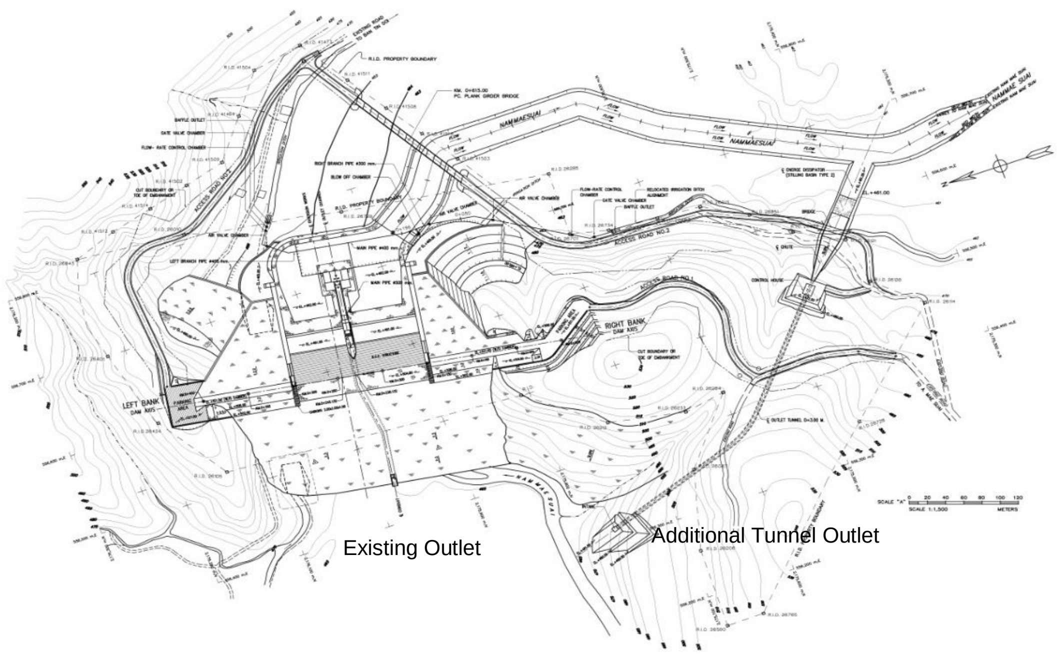


Fig. 11
Additional Outlet Tunnel

6. CONSTRUCTION PROGRESS

The construction of dam rehabilitation started on August 2017. The construction schedule is 20 months so it will be completed on March 2019. The construction is dam crest and spillway rehabilitation that cost is about 100 million baht. In the first part of the schedule, the construction is RCC block and dam crest removal. The photo of construction is shown in Figure 12.

Fig. 12
The Photo of Construction

7. SUMMARY AND KEYWORDS

1] It is not avoidable to have a large differential settlement between the high earth fill zone and rigid rcc or concrete zone, therefore we should avoid having this whenever possible.

2] Even though the leakage occurred but the dam shall be safe since it flows through the rcc material in which suffusion flow might not be able to occur and the leak occurred near the dam crest where hydraulic head is low.

3] Cracks in the rcc crest block due to the earthquake may not be harmful in the engineering point of view. However, for the community who lives downstream, unnecessary worries posted to them.

Therefore, the rigid and brittle rcc crest block will be replaced with the more flexible grs wall.

4] After dam rehabilitation is completed, the mae suai dam reservoir will be full storage.

Keywords: dam, roller compacted concrete dam, leakage, rehabilitation, seismic resistance, emergency plan

RUSSIA

1. INTRODUCTION

The report includes information on the state policy of Russia in the sphere of the safety and reliability of dams, on other laws and standard legal acts and on organization of surveillance of dams.

2. SAFETY MAINTENANCE LEGISLATURE OF RUSSIA

In Russia the maintenance of safety and reliability of hydraulic structures is obligatory to their owners or operators. The control of its quality is a state function implemented by federal executive authorities.

One of the basic laws in the sphere of safety and reliability of hydraulic structures is the Federal Law "On the safety of hydraulic structures" [1], which was adopted 20 years ago. According to this law, maintenance of safety of hydraulic structures includes development and implementation of measures aimed to prevent possible failure.

The Federal Law “On the safety of hydraulic structures” requires the following documents to be developed by the owners of hydraulic structures:

- hydraulic structure safety declaration — a document, in which the hydraulic structure safety is substantiated and measures concerning its safety control are defined according to its class during the whole life-cycle of the structure from designing to conservation or demolition; the safety of every hydraulic structure, whose failure can lead to an emergency, must be declared;
- hydraulic structures safety criteria—the limiting values of quantitative and qualitative factors of the hydraulic structure condition, representing the allowable failure risk of the structure and being accepted by federal authorities, who are in charge of government supervision of the safety of hydraulic structures;
- the amount of harm that can be done to the life or health of individuals, to the property of individuals or legal persons caused by the failure of the hydraulic structure;
- the plan of measures concerning maintenance and advancement (if needed) of the required level of safety.

These documents undergo public examination, are accepted by hydraulic structures supervision authorities and coordinated with the Ministry of Emergency Situations of Russia regional authorities. When accepting the safety declaration, supervision authority sets its validity period, which cannot exceed five years. On the grounds of the accepted safety declaration, the supervisory authority issues the permission for operation.

According to adopted classification, a hydraulic structure can have one of the following safety levels: normal, reduced, unsatisfactory (low) and dangerous. For hydraulic structures with “normal” safety level, the safety declaration and operation permit are issued for five years. When the safety level is “reduced”, both documents are issued for four years. Hydraulic structures with unsatisfactory safety level both safety declaration and operation permit cannot be issued for the period longer than three years. The exact period is specified by expert commission depending on the circumstances which caused safety reduction. If a hydraulic structure’s safety level is “dangerous”, supervisory authorities do not accept safety declaration and operation permit is not issued. In this case the owner must as soon as possible develop and implement measures aimed to gain an acceptable safety level. For the period of implementation, the design operation mode can be limited and supervisory authorities intensify their control over such structures. Safety declaration must be revised within six months after detection of the following circumstances:

- changes of operating conditions, which influence on the safety of hydraulic structures;
- damages and emergencies;
- changes of emergency management conditions.

Supervisory authorities have the right to withdraw operation permit in case the safety declaration was not submitted on time.

First of all the safety level of hydraulic structure depends on its operational status. According to the Federal Law [1], the owner of hydraulic structures must develop their safety criteria. Diagnostic parameters (settlements, flow rates, hydraulic gradients, etc.) of structures are compared with corresponding safety criteria to identify their operational status. In Russia two levels of safety criteria are used: K1—precautionary level, K2—minimum allowable level.

Under current legislation, the owner of hydraulic structure or its operator (in case the structure is state or municipally owned) must provide financial guarantee of civil liability. Civil liability in case of damages caused by failure of hydraulic structure, except force majeure, is guaranteed by funds of the owner or operator and by insurance. According to the Federal Law, the civil liability risk is subject to compulsory insurance for the whole period of hydraulic structure's construction and operation. The terms and conditions of insurance are regulated by the Federal Law "On Compulsory Insurance of Civil Liability of the Owner of a Hazardous Object for Inflicting Damage as a Result of an Accident at the Hazardous Object" [2].

The financial guarantee is set according to the results of estimation of possible loss suffered by third parties (natural or legal persons or their property) in case the hydraulic structure fails [5]. The estimation, which is fulfilled according to special methodology, is submitted to the supervisory authority called Rostechnadzor together with the safety declaration. The financial guarantee should be indexed (increased) every year depending on the inflation rate. The process is fulfilled by the owner in accordance with the change of the consumer price index [7].

The safety declaration justify the whole complex of measures aimed to maintain and enhance (if needed) the safety level set by building codes and standards.

The Federal Law [1] stipulates the following responsibilities of the owner:

- To control the parameters of hydraulic structures themselves, natural and technogenic influence, assess the safety of hydraulic structures and if needed, to analyze causes of its decrease;
- To develop safety criteria and specify them timely;
- To inspect the structures regularly;
- To operate the structures according to active codes and standards;
- To develop and implement measures aimed to maintain technically sound state of structures and their safety;
- To develop safety declarations and submit them to supervisory authorities.

Thus, current legislature of Russia covers all the stages of life-cycle of hydraulic structures, including design, construction, operation, closure and demolition. This legislative system includes the assessment of operational safety, ability of the owner to eliminate emergencies and failure risk estimation. The system also includes organization of supervision which is fulfilled by state authorities.

3. CASE STUDY: SAFETY AND RELIABILITY MANAGEMENT SYSTEM OF RUSHYDRO PLC

As a case study let us describe the hydraulic structures' safety and reliability management system used in RusHydro PLC. The goal of this system is to provide the required level of safety and reliability of hydraulic structures throughout their lifecycle in the most cost-effective way. Implementation of the system allowed RusHydro PLC:

To manage the whole set of hydraulic structures operated by the company using evidence-based and cost-effective measures, taking into account contemporary methods;

To use both technical and organizational and if needed, social measures of safety management;

To enter foreign market of design, development and implementation of safety management systems, including non-power hydraulic structures.

Today JSC RusHydro has its own Analytical center for the safety of hydraulic structures and their basic equipment, which help to ensure that the best possible decisions devoted to safety management, reliability and efficiency, are made. The structure of Analytical center includes the Executive office, its branches and research institute.

Major activities of the Analytical center includes:

- Monitoring of hydraulic structures and their equipment;
- State assessment;
- If needed, development of changes to mid-term and long-term production and R&D programs and technical policies;
- The control of compliance with the safety and reliability requirements;
- Taking part in declaration of safety and safety criteria development, drawing up the list of priority measures aimed to support and enhance the safety level within the period between declarations.
- The current activity of Analytical center made it possible:
- To predict the state of hydraulic structures and their equipment and if needed, to develop measures aimed to enhance it;
- To create the hydraulic structures database, this made it possible to compile the experience of state monitoring and to harmonize R&D programs;
- To unify methods of safety assessment and control used by different hydraulic facilities and to develop model solutions;
- To develop uniform format of reporting of the state of hydraulic structures used by their technical managers, uniform requirements and standards of state assessment, certificates and safety criteria.
- To minimize the gap in competencies of the staff of different hydraulic facilities by development of their skills, taking part in monitoring and state assessment, making of annual reports, etc.

SUMMARY

Thus, today in Russia at the governmental level hydraulic structures failure risk management systems are being adopted into theory and practice. These systems make it possible to provide acceptable failure risk with optimal correlation between the costs of failure risk reduction measures and the benefits of hydraulic structures. RusHydro PLC is one of the leaders of hydraulic structures failure risk management systems development and implementation.

SUMMERY

The safety assessment of a dam requires a wide range of information that is acquired from monitoring systems. Usually, there are many instruments equipped in the dam and its surroundings for monitoring the water level, temperature, deformation and other aspects. The behavior of the dam structure depends on the synergy of multiple factors. It is therefore necessary to detect the significant indicators that have a greater influence on the dam performance. In this paper, a monitoring model based on principal component analysis (PCA) and radial basis function (RBF) neural network is put forward to analyze the displacement trend of the concrete dam. The method of principal component is used to reduce the dimension of the dataset and simplify the multi-correlation of the components. On the basis, the in-situ monitoring displacement and the extracted components is taken as the input of the RBF neural network to build the forecasting model. An example analysis based on the proposed monitoring model is performed on a prototype concrete dam, and the results show that the proposed model is reasonable and practical.

Keywords: Gravity dam; Monitoring; Numerical model; Safety

1. INTRODUCTION

Dam safety assessment has received much attention since the end of the last century. The safety assessment of a gravity dam requires a wide range of information that is acquired from monitoring systems. Usually, there are many instruments equipped in the dam and its surroundings for monitoring the water level, temperature, deformation and other aspects. Now, with the progress of monitoring technology, the current measurement technology has advantages of high precision, good stability and strong sensitivity. But the response of dam structural behavior is the result of multi-factor synergies. So it’s necessary to extract the main factors, which influence the dam performance, and in the meantime analyze their development trend.

The positive analysis models are a fundamental component of dam safety systems. They provide an estimate of dam response faced with a given load combination. Then the calculated value can be compared with the actual measurements to draw conclusions about dam safety. The statistical models based on monitoring data have been used for decades for this purpose since 1955. In particular, the hydrostatic-season-time models are fully implemented in engineering practice.

In recent years, powerful tools such as neural networks are used by some scholars to analyze the observed data for interpreting the complex systems. But the multicollinearity issue among the components will influence the generalization ability and prediction accuracy of the model.

In this paper, a monitoring model based on principal component analysis (PCA) and radial basis function (RBF) neural network is put forward to analyze the displacement trend of the concrete dam. The principal components of the displacement monitoring data of the dam is extracted and reconstructed by PCA. On the basis, the method of the RBF neural network is used to predict the displacement trend of dam body.

2. PCA-RBF NEURAL NETWORK

During the operation period, usually, there’s a large amount of dam monitoring data accumulated, including displacement, temperature, water level and so on. The large amount monitoring data provides a good basis to analyze the dam behavior and is very important in the diagnosis. But massive data can also be a problem for analysis. It’s necessary to separate the useful information from observation and find out the main factors that affect the dam performance.

The PCA is used to reduce the dimensionality of m components including hydraulic components, temperature components and irreversible components. Then the measured displacements and the n extracted principal components $(n < m)$ are trained in the RBF neural network to make predictions. The main steps are shown in Fig. 1.

2.1. PRINCIPAL COMPONENT ANALYSIS

All Generally, there are many related variables involved during the process, and too many input variables will increase the complexity of the calculation. PCA is a kind of analytic method that can transform massive factors into some concentrate ones (principal components). The new principal components are the linear combination of the original variables, which can reflect the information of the original data to the greatest extent. The main steps are as follow:

(1) If there are a variables and each one has b groups of data, a two-dimensional matrix $(X_{ij})_{a\times b}$ can be formed. Then the matrix $(X_{ij})_{a\times b}$ can be standardized to matrix $(X'_{ij})_{a\times b}$;

(2) Calculate the correlation coefficient matrix $(R_{ij})_{b\times b}$ of the standardized matrix $(X'_{ij})_{a\times b}$;

(3) Calculate the eigenvalues λ_i $(i=1,2...p)$ and corresponding eigenvectors l_i $(i=1,2...p)$ of the correlation coefficient matrix $(R_{ij})_{b\times b}$. Arrange p eigenvalues λ_i from the largest one to the smallest one;

(4) Calculate the variance contribution rate and the accumulated variance contribution rate of each principal component;

(5) Select the principal components according to the accumulated variance contribution rate.

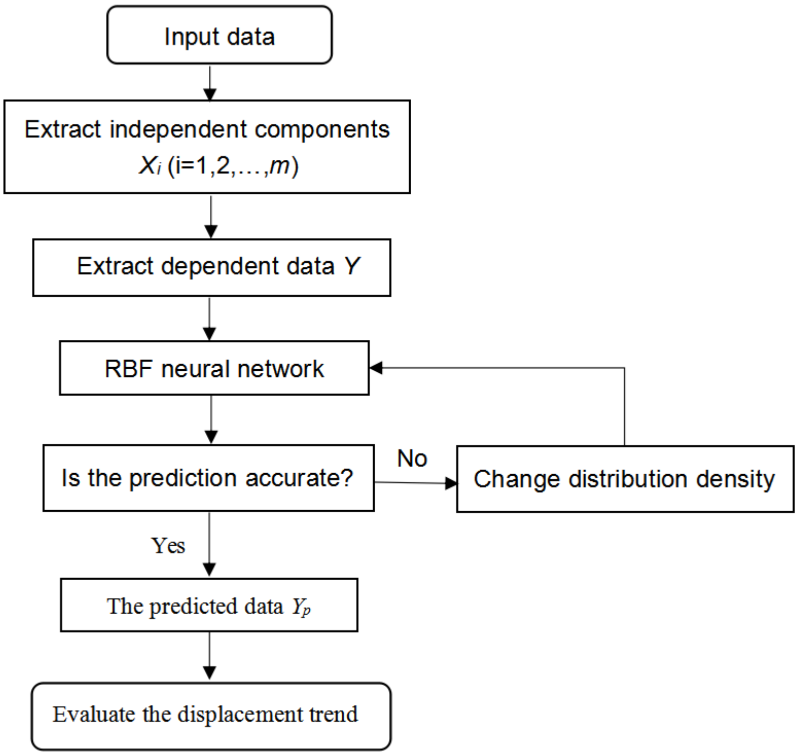

Fig. 1

Process of PCA-RBF neural network

2.2. RBF NEURAL NETWORK

RBF neural network is a kind of three-layer feedforward neural network, including input layer, hidden layer and output layer. The network uses radial basis function as the "base" of the hidden element. By this method, the input vector can be directly mapped to the hidden layer. The transformation from the input layer to the hidden layer is nonlinear mapping, and the transformation from the hidden layer to the input layer is linear mapping. The network is nonlinearly mapped from the input layer to the output layer, but the output layer is linear to the adjustable parameters. Thus, the weights of the network can be directly solved from the linear equations, which can effectively improve the learning efficiency of the network and avoid falling into the local minimum.

Generally, Gaussian function is chosen as the activation function of the hidden layer, and the output of the each hidden layer is:

$$a_{ij} = \exp\left(-\left\|c_j - x_i\right\|^2 / 2\sigma_j^2\right) \ , \ \ j = 1, 2, \ldots, N \qquad [1]$$

where c_j is the central value of the Gaussian function corresponding to the j hidden layer unit; σ_j is the central width of the Gaussian function corresponding to the j hidden layer unit; N is the number of the total nodes of the hidden layer.

3. ENGINEERING APPLICATION

3.1. BACKGROUND

A hydropower station is located in Cambodia, and the water-retaining structure is a RCC gravity dam. The crest elevation of the dam is 153.00m, the bottom elevation is 41.00m, the maximum dam height is 112.00m, and the width of the crest is 6.0m. There is a folding point located upstream at 145.00m elevation with the slope of 1:0.75.

This RCC gravity dam has 10 sections from the left bank to the right bank. In order to monitoring the horizontal displacements of the dam foundation, six reversed pendulums (numbered IP1~IP6) were installed symmetrically at abutment sections (at EL153m, EL120m, and EL88m). Two reversed pendulums (numbered IP7~IP8) were installed at riverbed sections (at EL43m and EL60m).

In this section, the monitoring data of IP4 from September 2, 2014 to December 7, 2017 is analyzed as an example: the 126 groups of data from September 2, 2014 to June 24, 2017 are set as the training sample and the 21 groups of data from July 7, 2017 to December 7, 2017 are set as the testing samples.

3.2. SELECTION OF PRINCIPAL COMPONENT

The main components of the displacement at the measuring points can be identified as a linear combination of three effects: the hydraulic component $\delta_H(t)$, the temperature component $\delta_T(t)$ and the irreversible component $\delta_\theta(t)$.

$$\delta = \delta_H(t) + \delta_T(t) + \delta_\theta(t) \qquad [2]$$

The hydraulic component $\delta_H(t)$ is related to the types of concrete dam. In this example, three factors are selected as: $X_1 = H - H_0$, $X_2 = H^2 - H_0^2$ and $X_3 = H^3 - H_0^3$.

H_0 represents the water level of the initial monitoring day and H represents the water level of the current monitoring day.

The multicycle simple chord factor is chosen as the temperature component $\delta_T(t)$:

$X_4 = \sin\frac{\pi t}{365} - \sin\frac{\pi t_0}{365}$, $X_5 = \cos\frac{\pi t}{365} - \cos\frac{\pi t_0}{365}$, $X_6 = \sin\frac{2\pi t}{365} - \sin\frac{2\pi t_0}{365}$, $X_7 = \cos\frac{2\pi t}{365} - \cos\frac{2\pi t_0}{365}$.

t_0 represents the initial monitoring day and t represents the current monitoring day.

There are four factors selected as the irreversible components $\delta_\theta(t)$: $X_8 = \theta - \theta_0$, $X_9 = \ln\theta - \ln\theta_0$, $X_{10} = \frac{\theta - \theta_0}{\theta - \theta_0 + 1}$, $X_{11} = 1 - e^{-(\theta-\theta_0)}$.

θ_0 is $t_0/100$ and θ is $t/100$.

The above-mentioned 11 components are analyzed by PCA, and the results are shown in Table 1 and Table 2.

Table 1

The eigenvalue and contribution rate of the components

Component	Eigenvalue λ_i	Variance contribution rate/%	Cumulative variance contribution rate /%
1	4.429	40.264	40.264
2	2.852	25.923	66.187
3	1.223	11.121	77.308
4	0.907	8.250	85.558
5	0.733	6.666	92.224
6	0.577	5.241	97.465
7	0.237	2.151	99.616
8	0.202	0.181	99.797
9	0.015	0.132	99.929
10	0.007	0.067	99.996
11	0.000	0.004	100.000

Table 2

Load coefficients of the principal components

Component	X_1	X_2	X_3	X_4	X_5	X_6	X_7	X_8	X_9	X_{10}	X_{11}
Y_1	0.670	0.650	0.663	0.499	0.085	0.460	0.292	0.736	0.822	0.835	0.806
Y_2	0.715	0.737	0.720	0.162	0.154	0.372	0.298	0.434	0.535	0.527	0.498
Y_3	0.055	0.057	0.029	0.133	0.682	0.368	0.747	0.091	0.074	0.073	0.142
Y_4	0.045	0.075	0.107	0.529	0.615	0.378	0.278	0.026	0.065	0.067	0.033
Y_5	0.019	0.005	0.016	0.639	0.311	0.252	0.240	0.295	0.109	0.050	0.068

According to the results, the variance contribution rates of the principal component Y_1, Y_2, Y_3, Y_4 and Y_5 are 40.264%, 25.9234%, 11.121%, 8.250% and 6.666% respectively. The cumulative variance contribution rate of the first five principal components is 92.224%. It is shown that the former five principal components can reflect more than 90% of information from the original 11 components. Therefore, the first five principal components are selected as the input variables of the model. The expressions of the five principal components are as follows:

$$Y_1 = -0.670X_1 - 0.650X_2 - 0.663X_3 + 0.499X_4 - 0.085X_5 + 0.460X_6 + 0.292X_7 + 0.736X_8 + 0.822X_9 + 0.835X_{10} + 0.806X_{11} \quad [3]$$

$$Y_2 = 0.715X_1 + 0.737X_2 + 0.720X_3 + 0.162X_4 - 0.154X_5 - 0.372X_6 - 0.298X_7 + 0.434X_8 + 0.535X_9 + 0.527X_{10} + 0.498X_{11} \quad [4]$$

$$Y_3 = 0.055X_1 + 0.057X_2 + 0.029X_3 - 0.133X_4 + 0.682X_5 - 0.368X_6 + 0.747X_7 - 0.091X_8 + 0.074X_9 + 0.073X_{10} + 0.142X_{11} \quad [5]$$

$$Y_4 = 0.045X_1 + 0.075X_2 + 0.107X_3 + 0.529X_4 + 0.615X_5 + 0.378X_6 - 0.278X_7 - 0.026X_8 - 0.065X_9 - 0.067X_{10} - 0.033X_{11} \quad [6]$$

$$Y_5 = -0.019X_1 - 0.005X_2 + 0.016X_3 - 0.639X_4 + 0.311X_5 + 0.252X_6 - 0.240X_7 \\ +0.295X_8 + 0.109X_9 + 0.050X_{10} - 0.068X_{11} \quad [7]$$

3.3. RBF NEURAL NETWORK

RBF neural network was created and the calling format is:

$$net = newrb\left(P, T, spread\right) \quad [8]$$

where P is the input item, T is the output item, and spread is the distribution density of radial basis functions.

Five principal components are selected as the input items of the neural network:

$$P = \left(Y_1, Y_2, Y_3, Y_4, Y_5\right)^T \quad [9]$$

The displacements prediction data are chosen as the output item of the neural network, that is:

$$T = \left(y_p\right)^T \quad [10]$$

3.4. COMPARISON

In order to verify the prediction effect, the PCA-RBF neural network model is compared with the multivariate regression analysis statistical model in this section. The above-mentioned 126 sets of data are used as the sample, and the multivariate regression function is shown as follow:

$$Y_s = 0.449 + 0.157X_1 + 0.002X_2 + 3.49e - 05X_3 + 0.227X_4 - 0.092X_5 - 0.354X_6 \\ +0.191X_7 + 0.15X_8 + 0.147X_9 - 0.919X_{10} - 0.812X_{11} \quad [11]$$

The training and prediction results of the two models are shown in Fig. 2. The determination coefficient (R2), mean-square error (RMSE) and mean absolute deviation (MAE) are defined as (12) ~ (14), where $y_s(i)$ is prediction value and $y(i)$ is measured value. The results are listed in Table 3, and the comparison results of the residuals is shown in Fig. 2.

$$R^2 = \frac{[\sum_{i=1}^{N}(y_s(i) - \bar{y}_s)(y(i) - \bar{y})]^2}{\sum_{i=1}^{N}(y_s(i) - \bar{y}_s)^2 \sum_{i=1}^{N}(y(i) - \bar{y})^2} \quad [12]$$

It is shown in Fig. 2 that the displacement prediction line of the PCA-RBF neural network model is more close to the measured displacement line, and the prediction effect is better than that of the statistical model.

As shown in Table 3, the RMSE and MAE of PCA-RBF neural network at training stage are 0.288 and 0.201 respectively, and are 0.702 and 0.548 at the prediction stage respectively, which are all smaller than those of statistical models. The R2 of the PCA-RBF neural network model at the training stage and the prediction stage are 0.959 and 0.910 respectively, which are both larger than those of the statistical models. In addition, with the comparison of the residual results of Fig. 3, the prediction effect of the PCA-RBF neural network model is more accurate.

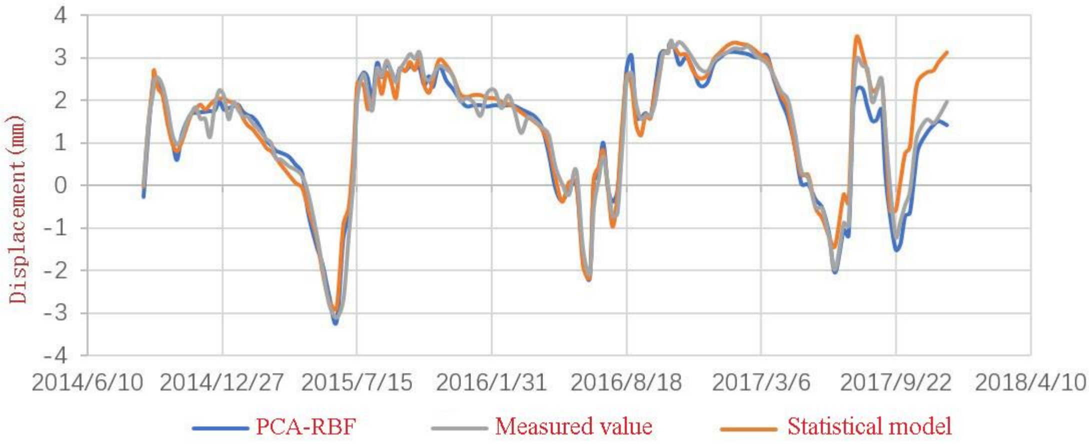

Fig. 2

Comparison of training and prediction effect

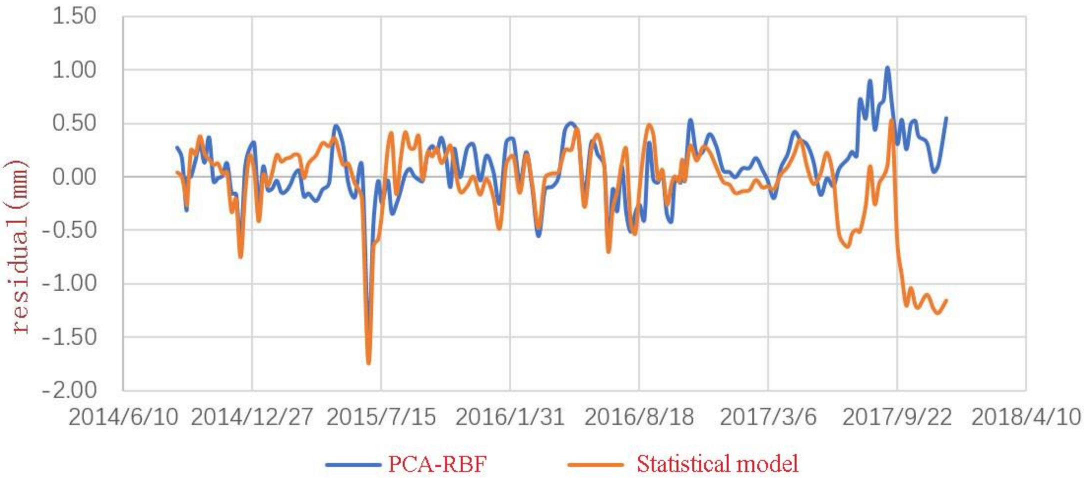

Fig. 3

Comparison of the residual

Table 3

Evaluation of the related parameters

Stage	Model	R^2	RMSE/mm	MAE/mm
Training	PCA-RBF	0.959	0.288	0.201
	Statistical	0.958	0.293	0.209
Prediction	PCA-RBF	0.910	0.702	0.548
	Statistical	0.869	0.827	0.696

4. CONCLUSION

In this paper, a monitoring model based on the principal component analysis (PCA) and radial basis function (RBF) neural network is put forward to predict the displacement trend of the concrete dam. And an example analysis based on the proposed model is performed on a prototype concrete dam. The conclusions are as follows:

(1) The PCA-RBF prediction model reduces the data redundancy and eliminates the multiple correlations among the components. And this model can predict the displacement trend of the concrete dam well.

(2) Compared with the statistical model, the PCA-RBF neural network model has higher prediction accuracy for the displacement trend of concrete dam, and can be applied in practical projects.

ACKNOWLEGMENTS

This research has been greatly supported by the National Key Research and Development Plan (Grant No. 2016YFC0401601), Postgraduate Research & Practice Innovation Program of Jiangsu Province (KYCX17_0436) and the Fundmental Research Funds for the Cental Universities (2017B623X14).

SAFETY ASSESSMENT FOR LARGE RESERVOIR CONSTRUCTED FOR DOMESTIC WATER NEAR URBAN AREAS AND A CASE STUDY

Hasan TOSUN

Professor, Engineering Faculty, ESKİSEHİR OSMANGAZI UNIVERSITY

TURKEY

1. INTRODUCTION

Increasing demand for water results to construct large reservoirs in or near urban areas. Same situation can be resulted by extending settlement area around reservoirs, which were constructed many years ago. Therefore, dams with large reservoirs, which are located in or near urban areas, have a high-risk potential for downstream life and property. In other words, a problem on public safety can raise up for people and live life on downstream for urban areas.

Safety assessment is a most significant concept for large reservoir, especially constructed in or near urban area. It is clear that there are mainly two important factors acting on total risk for dam structures. These are (1) the seismic hazard rating of dam site and (2) the risk rating of the dam and appurtenant structures. The seismic hazard of a dam site can be based on the peak ground acceleration. This value derived from the defined design earthquake produces the main seismic loads. For a preliminary study, the existing map of seismic zones can be used to estimate the seismic hazard of a dam site. The risk rating of the dam should be based on the capacity of the reservoir, the height of the dam, the evacuation requirements, and the potential downstream damages. In general, the seismic and risk ratings are evaluated separately for ICOLD method. However, BUREAU method combined these two factors to define the total risk factor for dam structure.

In the study six dams, namely Alacatlı Kutlu Aktas, Balcova, Gordes, Guzelhisar, Tahtalı and Urkmez dams in Kucuk Menderes and Gediz basins, were considered. These dams are maibly utilized for providing domestic water of Izmir Metropolitan Area. In 2017, The water demand was totally 225 millon cubic meter for this area. The 42.3 percent of this demand was provided by surface water, which are impounded in the reservoirs of dams mentioned above while others provided by groundwater resources. This paper deals with an evaluation of seismic hazard and local site effects for large dams and evaluates six large dams, which have a height from river bed between 20.3 m and 89.0 m in the Kucuk Menderes and Gediz basins (Table 1).

Table 1. Physical properties of dams considered for this study.

No	Dam	Basin	Height from river bed (m)	Completed Year	Volume of embankment (hm^3)	Volume of reservoir (hm3)
1	A.Kutlu Aktaş	K.Menderes	15.3	1997	0.28	16.61
2	Balcova	K.Menderes	63.4	1980	1.11	7.76

2. MATERIALS AND METHODS

For this study seismic study has been carried out by deterministic and probabilistic seismic hazard analyses. The deterministic seismic hazard analysis (DSHA) considers a seismic scenario that includes a four-step process. It is a very simple procedure and gives rational solutions for large dams because it provides a straightforward framework for the evaluation of the worst ground motions. The probabilistic seismic hazard analysis (PSHA), which is widely used for dam sites, considers uncertainties in size, location and recurrence rate of earthquakes. For the seismic hazard analysis of each dam site, all possible seismic sources were identified and their potential was evaluated in detail, as based on the guidelines given by [1] and the unified seismic hazard modeling for Mediterranean region introduced by [2]. Four separate predictive relationships for horizontal peak ground acceleration were used for this study [3,4,5 and 6].

Some institutions have defined some earthquake levels for dynamic analysis of dam structures. In this study, earthquake definitions given by FEMA were considered for seismic hazard analyses [7]. The Operating Basis Earthquake (OBE), which was defined by means of the probabilistic methods mentioned above, is the earthquake that produces the ground motions at the site that can reasonably be expected to occur within the service life of the project. MDE is normally characterized by a level of motion equal to that expected at the dam site from the occurrence of deterministically evaluated MCE. Safety Evaluation Earthquake (SEE) is the level of shaking for which damage can be accepted but for which there should be no uncontrolled release of water from the reservoir. Author states that most of large dams in Turkey were analyzed by using these definitions in past. ICOLD [8] also some earthquake definitions for dynamic analysis of dams. Author mentions these definitions more detail on their research [9].

Some methods are used to quantify the total risk factor of a dam. One of them considers the seismic hazard of the dam site and the risk rating of the structure separately [10[]. According to this method, the seismic hazard of the dam site regardless of type of dam, can be classified into four groups from low to extreme. This is a quick way for rating the seismic hazard. The hazard class of a dam site obtained from this method provides a preliminary indication of seismic evaluation requirements. Other one is Bureau method, which considers various risk factors and weighting points to quantify the total risk factor (TRF) of any dam [11]. In this methods the TRF depends on the dam type, age, size, downstream risk and vulnerability, which depends on the seismic hazard of the site.

For all analyses throughout this study, the peak ground acceleration was determined by two methods discussed above, only the results obtained by DSHA. All procedures mentioned above can be executed by the DAMHA program that is working on the basis of geographic information system (GIS). For total risk of dams, two different methods mentioned above are used for all dams considered for this study.

3. ANALYSES AND RESULTS

Dam designers in Turkey believe the fact that embankment dams, which are well compacted according to the specification, are suitable type for regions having high seismic activity. Whereas it is a well-known fact that strong ground shaking can result to instability on embankment and loss of strength at the foundations. Additionally, active faults, which are very close to the foundation of dams, have the potential to cause damaging displacement of the structure.

Most of the existing dams considered for this study are under near source effect [12]. ICOLD defined the near-field motion, which is ground motion recorded in the vicinity of a fault [8]. In this specification, a correlation between radius of near field area and earthquake magnitude is suggested as based on the cases on West United States. Author established limits of near-field motion for the investigation area. According to this model, the maximum magnitude of the earthquakes ranges from 5.7 to 6.7 and the minimal distance to fault segment is between 1.1 and 3.1 km for five dams (Table 2). The last one, namely Alacati Kutlu Aktas dam, is not under near field motion with minimal distance to fault segment is 10.1 km. The 83.3 percent of dams considered for this study has a minimal distance, which is less than 3.1 km to an active fault. In other word, all dams with exception of Alacati Kutlu Aktas dam, are not far away 10 km to active faults.

Table 2. The results of deterministic seismic hazard analyses

No	Dam	Deterministic Method *			
		Maximum earthquake M_{max}	Minimum distance, R_{min}	Mean PGA + 50 %	Mean PGA + 84 %
1	A.Kutlu Aktaş	6.1	10.1	0.116	0.189
2	Balcova	6.1	2.4	0.288	0.450
3	Gordes	6.7	1.1	0.442	0.702
4	Guzelhisar	6.7	3.1	0.409	0.642
5	Tahtali	5.7	1.9	0.277	0.431
6	Urkmez	5.7	1.7	0.310	0.482

The results of the DSHA are given in table 2. In this table, M_{max} is the maximum earthquake magnitude in M_w and R_{min} is the minimum distance to fault segment. Mean PGA + 50% and Mean PGA + 84% are mean peak ground acceleration at the 50^{th} percentile and Mean Peak Ground Acceleration at the 84^{th} percentile, respectively.

A detailed study was performed to identify all possible seismic sources for the seismic hazard analyses of the dam sites, as based on the macro seismo-tectonic model of Turkey. The National Disaster Organization and other Institutes prepared the map for general use. But it was modified by the author and his co-workers to use for dam projects at the Earthquake Research Center in Osmangazi University. Local geological features and seismic history were also taken into account to quantify the rate of seismic activity in dam sites. As a result of detailed evaluation, total area covering all basins was separated into four seismic zones. These seismic zones and historical earthquakes are given in Fig. 1. These zones including faults and earthquakes occurred in the basin along last 100 years. The number of earthquakes having a magnitude on the basis of surface wave (Ms), which is greater than 4.0, is 1455. The numbers of earthquakes with Ms that are greater than 6.0 are 34 for dam sites.There is no earthquake having a magnitude greater than 7.0 in the basin.

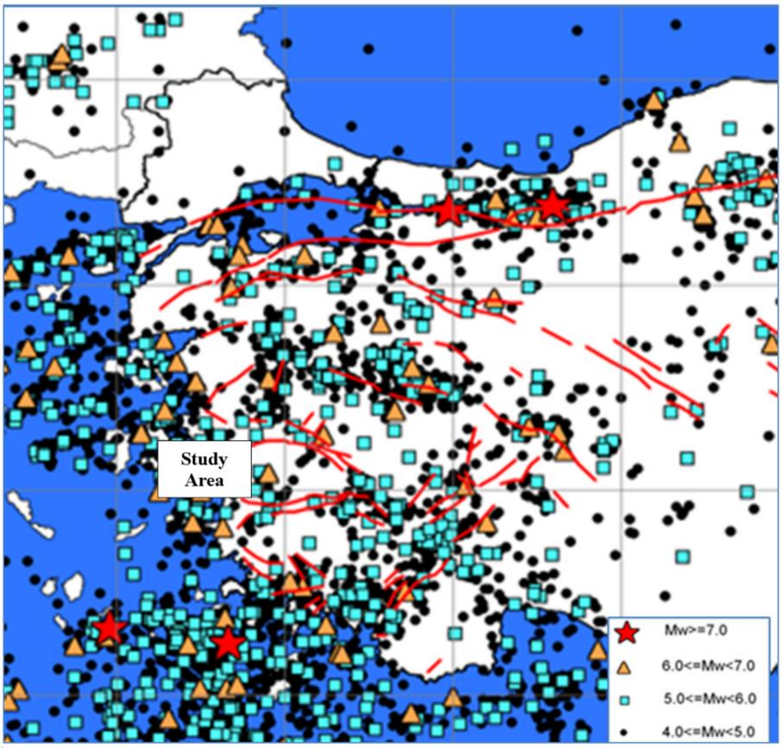

Fig. 1. Energy sources and earthquakes in west Anatolia region of Turkey.

The deterministic analyses indicate that peak ground acceleration (PGA) changes within a wide range. The PGA values ranges from 0.116g to 0.442g for the mean Peak Ground Acceleration at the 50^{th} percentile and from 0.189g to 0.702g for the mean Peak Ground Acceleration at the 84^{th} percentile given in table 2. According to the updated DSI guidelines, the PGA values at the 84^{th} percentile should be taken into account for five dams analyzed throughout the study, when considered deterministic approach (DSI, 2012). For only Alacati Kutlu Aktas dam, the PGA values at the 84^{th} percentile shoud be considered Table 3 shows the summary of DSI seismic guidelines for dynamic analyses.

Table 3. Selection of Design Earthquake as based on risk classification [13]

Hazard Analysis		Deterministic Method	Probabilistic Method
Class	Hazard Ratio		
I	Low	50 %	T_R = 224 years (*)
II	Moderate	50 %	T_R = 475 years
III	High	84 %	T_R = 975 years
IV	Very high	84 %	T_R = 2475 years

(*) Tr = Return time

The seismic hazard analyses were performed for six dams throughout this study. The results with total risk of each dam are given table 4. All dams with exception of Alacatı Kutlu Aktas dam are identified in class of IV with extremely high hazard rating. One dam site have moderate hazard rating and are identified as hazard class of II. ICOLD [10] state that if the PGA value is greater than 0.25 g and the energy source is closer than 10 km from the dam site, it is classified as hazard class IV with hazard rating of extreme. For eleven dams, the distance from dam site to active faults, which are given on updated seismic maps, ranges from 1.1 km to 3.1 km. The large dams of basins, which are under the influence of the near-field motion, have been constructed to very close to active segments of the horst-graben fault system in west Anatolia, which were determined after 2013.

Table 4. Total risk of dams considered for this study.

No	Dam	Hazard Analysis		Total Risk (ICOLD,1989)			Total Risk (Bureau, 2003)		
		Class	Hazard Ratio	Risk factor	Risk class	Risk ratio	Risk factor	Risk class	Risk ratio
1	A.K. Aktaş	II	Moderate	30	III	High	163.4	III	High
2	Balcova	IV	Very high	34	IV	Very high	187.6	III	High
3	Gordes	IV	Very high	36	IV	Very high	155.6	III	High
4	Guzelhisar	IV	Very high	36	IV	Very high	158.3	III	High
5	Tahtali	IV	Very high	36	IV	Very high	186.6	III	High
6	Urkmez	IV	Very high	32	IV	Very high	188.5	III	High

Throughout this study, two methods have been considered to quantify the total risk for dam structures. In DSI guidelines, total risk factor depends to reservoir capacity, height, evacuation requirement and potential hazard (DSİ, 2012). According to DSI Guidelines all dams are categorized in III and IV risk classes with high and very high risk rating. Following Bureau's method, all large dams are classified in risk class III, a high-risk rating. In Bureau method, the values of the TRF range from 96.5 to 208.6. This means that there is no dam having a risk classes of I and II for all dams considered for this study. Author thinks that the solution obtained from Bureau method is more rational than that of the DSI guidelines.

4. DISCUSSIONS

There are six large dams located in Izmir Metropolitan Area for providing domestic water. Four of them are located on the turbidities of Kucuk Menderes river while other two were constructed in Gediz basin. The earthquake safety and total risk of these dams are evaluated more detail as given below.

Alacatı Kutlu Aktas Dam is a earthfill dam 15.3-m high with a total embankment volume of 280 000 m^3. It is located on Hirsiz river in Kucuk Menderes basin. Its construction was finished in 1997. When the reservoir is at operation stage with maximum water level, the facility approximately will impound 16.60 hm^3 of water with a reservoir surface area of 2.55 km^2. It is mainly designed to provide domestic water with annual capacity of 3.0 hm^3. The side slopes of main embankment is 3.0H:1V for upstream and 2.5H:1V for downstream (H=horizontal and V=vertical) (Fig. 2). On the section there is a central impervious zone, which is composed of impervious clay and a transition section of sand, gravel and small-sized crushed rock was designed over rockfill materials (Figure 2). The shell fill in downstream and upstream parts is composed of semi-pervious clayey material. The alluvium on river bed was removed before beginning the construction of the main embankment. The seismic hazard analyses performed throughout this study indicates that this dam is less critical dam within the Izmir Metropolitan Area. It will be subjected to a peak ground acceleration of 0.116 g by an earthquake of 6.1 magnitude and it is only 10.1 km far away from an active fault given in new seismo-tectonic map of Turkey in 2013. Its TRF value is 163.4 and it is identified as risk class of III. The 21-years old embankment is in excellent condition.

Balcova dam is a rockfill dam on Ilica River in the Izmir Metropolitan Area. It has a 63.4 m height from river bed. When the reservoir is at maximum capacity, the facility impounds 7.76 hm^3 of water with a reservoir surface area of 0.69 km^2. Its construction was finished in 1980. It was designed to provide domestic water with annual capacity of 12 hm^3. The crest length is 231 m and the side slopes of main embankment is 3.5H:1V for upstream and 3.0H:1V for downstream (H=horizontal and V=vertical) (Fig. 3). On the section there is a central impervious core, which is composed of compacted impervious clay and a transition section of sandy and gravelly aggregates was designed between the core and semi-pervious soils. The alluvium on river bed, which is composed of different size of river bed material, was removed before beginning the construction of the main embankment According to the seismic hazard analyses of this study, it will be subjected to a peak ground acceleration of 0.288g by an earthquake of 6.1 magnitude and its embankment is only 2.4 km far away from an active fault given in new seismo-tectonic map of Turkey in 2014. Its TRF value is 187.6, and it is identified as risk class of III. This 37-year old earthfill embankment is in excellent condition, but it cannot meet current seismic design standards. Additionally, it is under near-field motion. Therefore, its seismic upgrade should be provided soon.

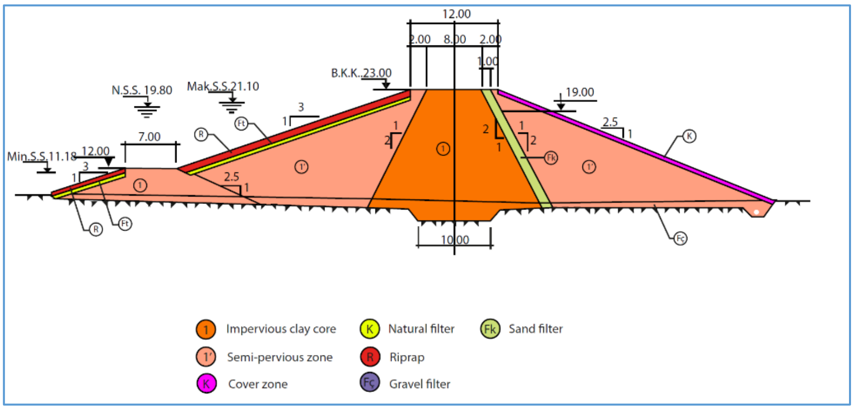

Fig. 2. The maximum cross-section of embankment of A.Kutlu Aktas dam [14]

Fig. 3. A general view from Balcova dam.

The Gordes dam is a concrete faced rockfill dam with a 82.9-m height from river bed. It was located on the Gordes River near Golmarmara County. When the reservoir is at maximum capacity, the facility impounds 448.46 hm^3 of water with a reservoir surface area of 14.06 km^2. Its construction was finished in 2010. It was designed to irrigate land of 14 890 ha land and to provide drinking water for İzmir city. The main embankment consists of crushed rock and transition zone to concrete face. The upstream and downstream fills are large-sized crushed rocks at which the most durable and high strengthened ones are located on the outer part of the shell. The crest width is 10 m and the side slopes of main embankment is 1.5H:1V for upstream and 1.4H:1V for downstream (H=horizontal and V=vertical). According to the seismic hazard analyses of this study, it will be subjected to a peak ground acceleration of 0.442 g by an earthquake of 6.7 magnitude. [9] introduce more detail information about its earthquake safety and total risk.

Güzelhisar dam is a rockfill dam 89-m high with a total embankment volume of 3 210 000 m^3. It is located on the Guzelhisar River in Gediz basin. Its construction was finished in 1982. When the reservoir is at operation stage with maximum water level, the facility approximately will impound 158.00 hm^3 of water with a reservoir surface area of 5.8 km^2. It was mainly designed to provide industrial water for a national chemistry company. The crest width is 10 m and the side slopes of main embankment is 2.5H:1V for upstream and 2.0H:1V for downstream (H=horizontal and V=vertical). On the section there is a central impervious core, which is composed of compacted low-plasticity clay and a transition section of sand, gravel and small-sized crushed rock was designed between the core and rockfill materials for downstream part. The downstream shells are composed of large-sized crushed rocks. The alluvium on river bed, which is composed of mixtures of fine to large size grains, was removed before beginning the construction of the main embankment. The seismic hazard analyses performed throughout this study indicates that Guzelhisar dam is one of the most critical dams within the basin. Detail assessment about its earthquake safety and total risk are introduced by [9].

Tahtalı dam is a rockfill dam on Tahtalı River near Gumuldur County in the Izmir Metropolitan Area. It has a 54.4 m height from river bed. When the reservoir is at maximum capacity, the facility impounds 306.6 hm^3 of water in its reservoir. Its construction was finished in 1999. It was designed to provide domestic water with an active volume of 287 hm^3. Fig.4 shows a general view from Tahtali dam. On the section there is a central impervious core, which is composed of compacted impervious clay and a transition section of sandy and gravelly aggregates was designed between the core and semi-pervious soils. The alluvium on clay core was removed before beginning the construction of the main embankment. A low-strength concrete wall was constructed for providing impermeability in dense aluvional soil. According to the seismic hazard analyses of this study, it will be subjected to a peak ground acceleration of 0.277g by an earthquake of 5.7 magnitude and its embankment is only 1.9 km far away from an active fault given in the updated seismo-tectonic map of Turkey. Its TRF value is 188.6 and it is identified as risk class of III. It is at second place after Gordes dam when regarding the total capacity of reservoir and one of the most critical dams in Izmır Metropolitan Area. This 19-year old earthfill embankment is in excellent condition, but it cannot meet current seismic design standards. Additionally, it is under near-field motion. Therefore, its seismic upgrade should be provided soon

Fig.4. A general view from Tahtali dam

Urkmez dam is a earthfill dam on Urkmez River near Seferihisar County. It has a 32.0 m height from river bed. When the reservoir is at maximum capacity, the facility impounds 7.92 hm^3 of water with a reservoir surface area of 0.61 km^2. Its construction was finished in 1991. It was designed to provide water for irrigation of 370 ha and drinking water with annual capacity of 0.78 hm^3. The crest length is 428 m and the side slopes of main embankment is 3.0H:1V for upstream and 2.5H:1V for downstream (H=horizontal and V=vertical). On the section there is a central impervious core, which is composed of compacted impervious clay and a transition section of sandy and gravelly aggregates was designed between the core and pervious coarse grained soils. The alluvium under clayey impervious core, which is composed of different size of river bed material, was removed before beginning the construction of the main embankment According to the seismic hazard analyses of this study, it will be subjected to a peak ground acceleration of 0.310 g by an earthquake of 5.7 magnitude and its embankment is 1.7 km far away from an active fault given in the updated seismo-tectonic map of Turkey. Its TRF value is 188.5, and it is identified as risk class of III. This 37-year old earthfill embankment is in excellent condition, but it cannot meet current seismic design standards. It will be under near-field motion during earthquake. Therefore, its seismic upgrade should be provided soon.

5. CONCLUSIONS

For the large dams within the Izmir Metropolitan Area, the seismic hazard rating of the dam site and the risk rating of the complete structures were determined and possible modes of failure were estimated. This paper summarizes the seismic hazard and total risk analyses of six large dams, which are located on two basins in Turkey, as based on a preliminary study. The study identified that five of them are under near source effect. As a result of this study, 83.3 percent of dams has extremely high of risk class while others are classified in high risk class. Therefore, detail seismic hazard analyses should be performed for these structures as based on the updated seismic data and design code under circumstances of the study of a national safety program for dam. In other words, these dams must be re-analyzed by selecting appropriate seismic parameters. Rehabilitation design and construction measures, if necessary, may follow after in cases where the dams are found deficient seismically.

SUMMARY

Large reservoirs, which are located in or near urban areas, pose a high-risk potential for downstream life and property. Safety assessment requires for existing dams having large reservoirs built in the settlement area. There are some metropolitan provinces, which are under threatening of earthquakes. One of them is Izmir Metropolitan Area with five million people. Major earthquakes with the potential of threatening life and property occur frequently here. There are six large dams for providing domestic water for Izmir province. These are namely Alacatlı Kutlu Aktas, Balcova, Gordes, Guzelhisar, Tahtalı and Urkmez dams. The investigation area is structurally cut by numerous faults, which are resulted by horst-graben system in west Anatolia. The seismic hazard analyses have indicated that peak ground acceleration changes within a wide range (0.116 g and 0.442 g) for the six dam sites of this area. This study indicates that most of these large dams have high-risk class in the metropolitan area.

ABSTRACT

This study presents mechanical and durability aspects of using different waste fillers including Iron powder, Iron concentrate, Coal and Coke Powder, which cannot be reused at industry process. (samples from different parts of the Jalalabad Iron Ore Concentrate Plant and Zarand Coking Plant, Kerman, Iran) as well as mineral powder filler as a control sample to replace 3% and 6% of coarse and fine natural aggregates content in RCC combination. Absorption, compressive strength, workability and non-segregation of grains investigated for the concrete specimens. The experimental results showed that RCCs of iron ore- powder filler contents with 6% of the weight of coarse and fine natural aggregates had higher values of 28 days compressive strength and minimum 24-hour water absorption about 2.22%. Generally, the fillers of iron ore concentrate factory including iron ore filler and concentrate filler have better results in improving the mechanical and transitional properties of roller concrete, due to rounding of aggregates, comparing by the case of carbonaceous compounds extracted from the coking plant, including Coke and coal fillers. In addition to that, using this type of waste in concrete may has more environmentally efficient, because this helps to remove some parts of wastes and protects the environment.

1. INTRODUCTION

In order to achieve economic self-sufficiency, it is important to control the floods and surface water through the construction of dams which considered essential and infrastructural since water supply has always been a fundamental human need for agriculture, industry and drinking water.

In the early 1980s, conventional concrete dam construction methods replaced by the roller compacted concrete method. RCC dams use embankment dams construction's method, which is based on using heavy equipment machinery. Usage of heavy equipment machinery for constructing concrete dams, leads to development of RCC dams which despite the short construction time, they have the reliability of conventional concrete dams. Also, RCC dams are an economical competitive choice over embankment dams. Construction cost of RCC dams is less than conventional concrete dams as well as embankment dams. It is because of material saving, fast construction, less costly spillway, less risk of coffer dam overtopping and shorter and smaller size of diversion conduit [1].

In addition to economic benefits, the RCC is considered as a ‘‘green” concrete because the cement consumption in the RCC is lower as the RCC mixtures are normally designed with leaner binder content. Mineral admixtures are used extensively in RCC mixtures. The use of large amounts of mineral admixtures improves durability, reduce adiabatic temperature rise of concrete, construction costs, and gas emission accompanied with the manufacturing of cement clinker. Class F and Class C fly ashes, slag, and natural pozzolan have been used as mineral admixtures in the RCC [2].

Coarse aggregate size has a significant influence on the degree of RCC compaction in small layers and less effect in relatively thicker layers especially when large vibratory rollers are employed. The coarse aggregates with maximum-size diameter greater than 76 mm are seldom used in the RCC manufacturing because they cause problems in the layers spreading and compaction. However, the use of coarse aggregates with maximum-size diameter finer than 75 mm reduces the volume of voids and produces more cohesive mixture [3].

Waste coking and iron ore concentrate plant, which is not reusable, is normally deposit causing obvious environmental problems; so use of these materials effectively in concrete, make them valorized. A mass of small particle also produced due to the process of iron ore concentrate production, which usually does not have the ability to become concentrate, and is deposit. The waste Coke, consisting of non-consumable materials commonly used in particles smaller than 1 cm in diameter, are discharged as waste and disposed of in garbage dumps.

This waste called coal in input materials, and called coke in exhaust materials. Applying the aggregates smaller than 75 microns (sieve NO. #200), if not plastic, can be a useful solution for reducing the free space among fine-aggregates. Typically, the use of about 2 to 8 percent of aggregates smaller than 75 microns in pavement roller concrete is common (ACI 325.9 R) [4].

This study includes three consecutive parts. In the first part, materials and instruments were prepared and initial tests were performed to establish material properties. In the second part, material properties were checked with codes and proper mix design were defined by testing several initial mix designs. In the last part, main specimens were prepared and tests were conducted on 7, 14, 28, 42 and 90 days specimens.

In this research, we used nine mix designs based on 140 kg/m^3 cement type-II and Iron ore powder, Iron ore concentrate, Coal Powder and Coke as filler materials passing sieve no. #100 (0.15>) by replacing 3% and 6% of coarse and fine-aggregate content. Finally, the results compared with mineral powder filler as control sample. In order to study the durability and mechanical properties of concrete; maximum density, VB time, compressive strength on 7, 14, 28, 42 and 90 days and 24-hour absorption of specimens on the day 28 were investigated.

2. EXPERIMENTAL PROGRAM

The material properties of the concrete mixture used in this experimental study has given in the following.

2.1. MATERIALS

2.1.1. Aggregate

Of 0–6, 6–12 and 12–25 mm grain size aggregate used in this study have been widely used in the civil projects in Kerman for years, provided from Gloomak Region. The aggregate grade was designed as existing between the curves of 2-4-3-A and 2-4-3-B defined in journal No. 55 Iran Standards [5]. The properties of these aggregates are presented in Table 1 and Figure 1, 2. The gradation curves of mixed aggregates consisted of coarse-aggregates (12-25 mm) (33%), fine-aggregates (6-12 mm) (22%) and fine-aggregates passing sieve No. 4 (4.75mm) (45%) compared with the limits set by ACI 207-5R standard, which presented in Figure 3 [6].

3.2. SPECIMENS

In total, nine different concrete mixtures given in Table 7 prepared. Cylindrical samples used with height of 30 cm (12 in.) and diameter of 15.2 cm (6 in.). Samples made in three layers by vibrating method with Vebe table following the USBR 4906 [12]. Totally 72 specimens were made with 140 kg cement materials per cubic meter. Amount of 3% and 6% of total coarse and fine-aggregate materials were replaced by fillers in different mix design to investigate the effects of different amount of fillers. The results are shown on table 7.

Table 7. Mixing ratio (kg/m3)

$\frac{W}{C}$	Weight of water	Weight of fine-aggr.	Weight of coarse-aggr.	Weight of coarse-aggr.	Type of filler	Weight of filler	Weight of Cement	Specimens No.
0.8	112+34	945	460	690	6% mineral powder	130	140	RCC-1
0.8	112+34	945	460	690	6% iron concentrate	130	140	RCC-2

0.8	112+34	945	460	690	6% iron powder	130	140	RCC-6
0.8	112+34	945	460	690	6% coal powder	130	140	RCC-7
0.8	112+34	945	460	690	3% mineral powder+3% coal	65 + 65	140	RCC-8
0.8	112+34	945	460	690	3% mineral powder+3% coke	65 + 65	140	RCC-9

Compressive strength test, workability test by VB time, water absorption test and compacted concrete density tests were conducted at the ages of 7, 14, 28, 42 and 90 days.

4. EXPERIMENTAL

4.1. VB TIME

A modified Vebe apparatus was used to determine the workability of mix designs. The results showed on table 8.

Table 8. Workability Results

Specific gravity of fresh concrete (gr/Cm^3)	VB Time (sec)	Specimens No.
2.298	18	RCC-1
2.336	18	RCC-2
2.191	105	RCC-3
2.395	15	RCC-4
2.326	16	RCC-5
2.361	38	RCC-6
2.205	40	RCC-7
2.251	36	RCC-8
2.229	36	RCC-9

4.2. 24-HOUR WATER ABSORPTION

24-hour Water absorption test on concrete specimens was performed according to ASTM C642 standard. The results showed in figure 4.

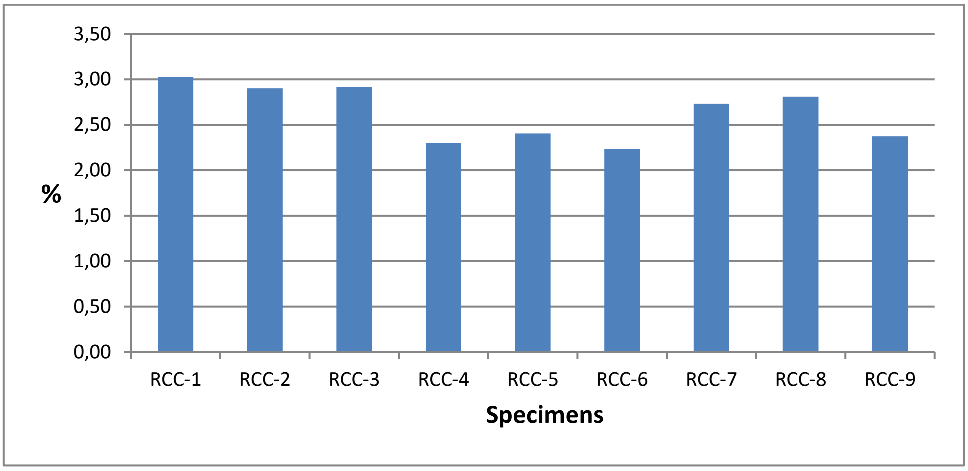

Fig. 4
24-houre water absorption

4.3. WEIGHT OF MASS

The specific density of concrete depends on the specific weight of the sand and the porosity of the roller concrete mass. There are a few air vents in roller concrete, varying between 0.5 and 5%, which reduces the action of compacting. The results showed in figure 5.

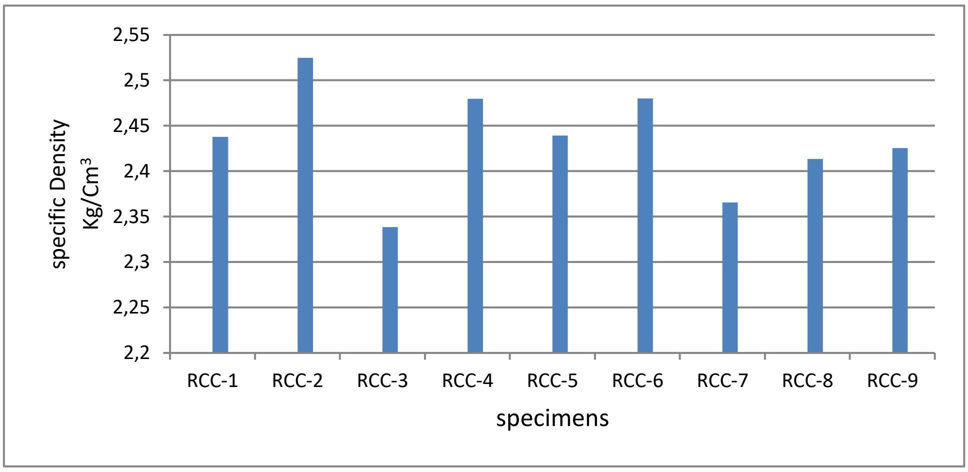

Fig. 5
Specific density of specimens

4.4. CONCRETE COMPRESSIVE STRENGTH

Compressive strengths results of the various mixes for ages of 7, 14, 28, 42 and 90 days presented in Fig. 6 to fig. 8. Comparatively to the reference concrete, at twenty days old, the increase in compressive strength was in the mix design for RCC6 with 6% iron ore powder filler. In a study, Friedin (2005) proved that the high levels of CaO and SO_3 in the ash of wind makes the wind ash have a good cement property and therefore gradually increases the compressive strength [13].

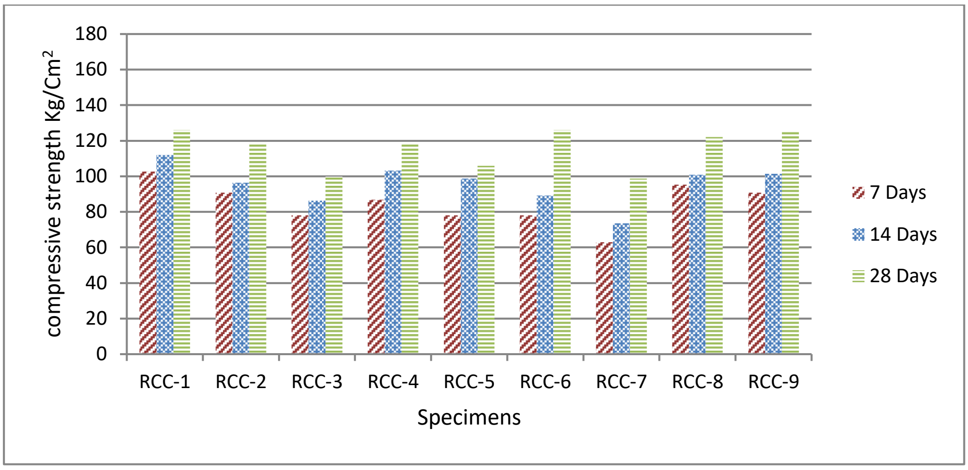

Fig. 6
7, 14, 28-days compressive strength resultes

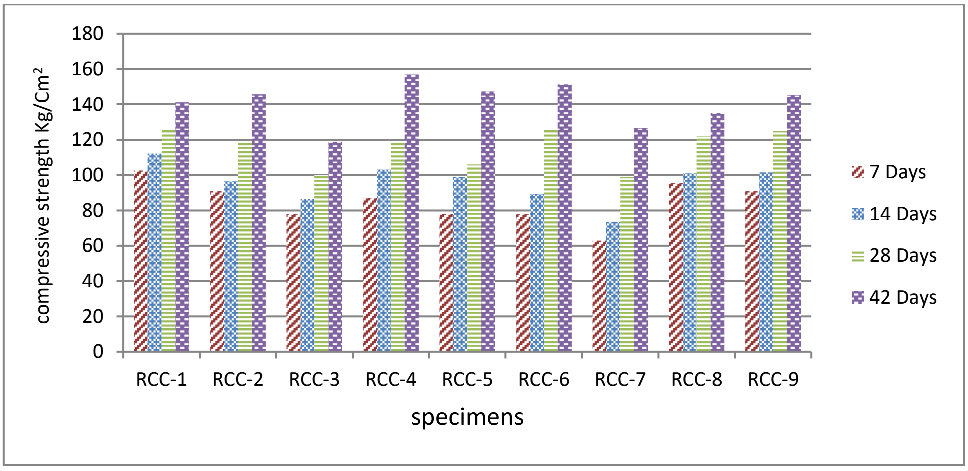

Fig. 7
7, 14, 28, 42-days compressive strength

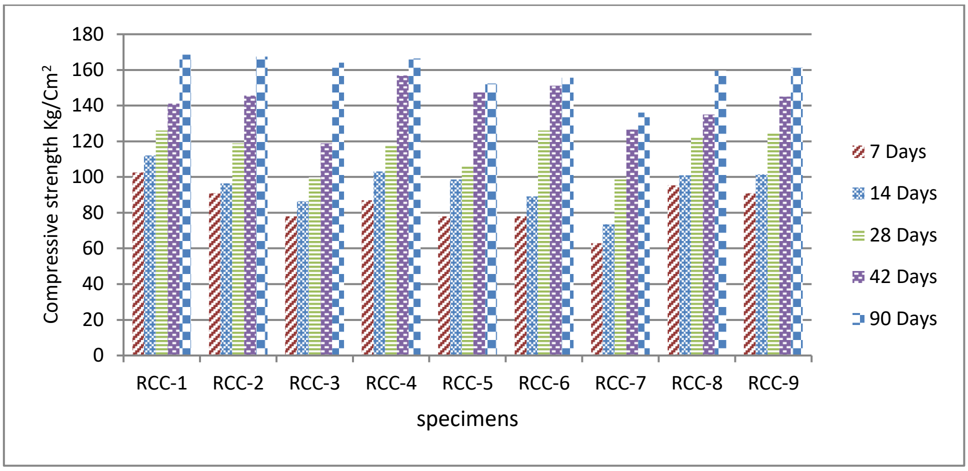

Fig. 8
7, 14, 28, 42, 90-days compressive strength

5. CONCLUSIONS

In this research, different fillers from coking and iron concentrate plants (passing sieve No. #100) made up of 6% of the aggregate's weight, and 3% of the filler along with 3% of the mineral powder filler has been used and investigated. The purpose of this study was to analyze the effect of various fillers on the roller concrete properties, concrete mechanical properties and its permeability. The results indicated a significant change in the mechanical properties and durability of the roller compacted concrete.

1. Using a high water percentage caused the segregation, which prevented by use of fillers to some extent. According to the design and time of VB, the optimal water-cement ratio was obtained in amount of 0.8 .
2. The highest 7-days compressive strength of concrete related to the RCC1 mixing design with the mineral powder filler indicated increasing compressive strength at the early ages.
3. The highest 28-days concrete compressive strength related to the RCC6 mixing design with Iron Ore Powder Filler indicated an increase in the final strength of the concrete at an advanced age by the filler.
4. The lowest compressive strength growth over time (90 days) observed in RCC1 and RCC3 mixing designs made with 6% mineral powder filler and 6% coke filler, which to some extent indicated that these fillers were not very effective in the cement hydration.
5. The best performance of compressive strength up to 28 days is related to the RCC6 mixing design containing 6% Iron Ore Powder Filler, which at the ages has more compressive strength and performance similar to that expected from Pozzolans.

6. The results of 24-hour water absorption of specimens showed that the minimum water absorption related to the RCC6 mixing design with iron ore-powder filler, with amount of 2.24%, which is acceptable and ideal for dam construction projects.
7. The lowest VB time measured in the study related to the RCC4 mixing design with 3% mineral powder filler and 3% iron ore concentrate with amount of 15 seconds.
8. By studying the results of the filler's chemical tests, iron ore powder knew to be close to the pozzolan group type F.

6. ACKNOWLEDGMENT

Funding for this study was provided by MANA Construction Company.

IRAN

ABSTRACT

Inspection and Monitoring of dams as well as data analysis and interpretation has a critical role in the field of dam safety. Surveillance and Monitoring programs on dams provide information for evaluating the dam`s performance with respect to design intent and expected behavior.

Sabalan dam is an 89 m high rock-fill embankment with central clay core constructed in the north west of Iran and has been operated since 2006.

The dam instrumentation system comprises variety of piezometers, total stress cells, settlement meters and inclinometers that are installed along 5 cross sections. In this paper, instrumentation scheme of Sabalan dam are described. Then the safety of the dam during operation is evaluated through the surveillance reports which have been prepared from records of the whole monitoring system.

The results indicated that the stability of the dam satisfies the safety requirements. The percentage of settlement is within the reasonable range and also stress and pore water pressure graphs indicate safety of the dam. Detailed results of the study are demonstrated through the text.

ABSTRACT

Emptying facilities of high dams play an important role for overhauling during operation period and lowering water level in case of emergency so as to reduce risk of the whole projects. Based on summarizing of present design status of reservoir emptying, the key technology problems of lower discharge facilities are analyzed firstly. Secondly, this paper puts forward that characteristics of reservoir and projects as well as hydrologic conditions should all be considered when emptying design to help choosing a reasonable emptying scale and depth. At the last, this paper indicates that the basin cascade dispatching and forewarning, manage systems of dams safety adapting to construction and economic level, as well as dams lifecycle safety management and risk distinction system suited to national conditions, should all be established as soon as possible, in order to minimize risk of basin cascading dams failure.

KEY WORDS

reservoir emptying; lower discharging; underwater overhaul; emergency management; basin cascade

PREFACE

Till 2017, more than 20 super high dams over 200m have been built or were under construction in China, which play an important role in the national economy development. After reservoirs impounding, it not only bring up benefit of flood controlling, irrigation and generating electricity, etc., but also pose a threat to downstream areas. There's no dam failure of large reservoirs occurred in China since 1980s, stood tests of big flood in 1998 and Wenchuan Earthquake in 2008, Ya'an Earthquake and so on. Especially Zipingpu CFRD of 156m height which is only 17km far from the epicenter of Wenchuan Earthquake and Shapai RCC arch dam of 132m height which is 30km far from that in 2008, were both in good conditions [1]. In general, construction, operation and management of large reservoirs and high dams in China are all standard, and keep safety under designed situation [2].

However, along with more and more higher dams constructed, people are more and more worried about the losses and influence of public safety, social stability, and economic development coursed by dams' failure. In recent years, some new laws and legislations of security management in China put forward new requirements and research subjects to emergency management when dams suffer extraordinary floods, extremely strong earthquakes, or catastrophic geologic disasters. So, we have to reexamine the emptying design of large reservoirs constructed, summarize the key technology problems of reservoir emptying, and bring out some suggestions about how to improve the ability of emergency.

PRESENT EMPTYING ABILITY OF LARGE RESERVOIRS IN CHINA

Emptying facilities were set up in most of high dams in China to lower water level in case of emergency or dam damage. Table 1 and table 2 shows emptying abilities of primary high earth-rockfill dams and high concrete dams, respectively.

Table 1
Emptying abilities of primary high earth-rockfill dams

Three Gorges	181	393	145.0	17.54	171.5	56.36	10

The two tables above indicate that, most reservoirs can be discharged more than half water head and 70% capacity which are mainly affected by hydrologic conditions, reservoir topography, dam height and design of emptying facilities. Storage capacities emptying ratios of those reservoirs located in alpine and narrow valleys are usually larger, such as Shuibuya CFRD and Wudongde arch dam. On the other hand, water head emptying ratios of those reservoirs located in wide valleys are usually larger, such as Three Gorges and Bashan dam. Specially, storage capacities emptying ratios of some reservoirs with special topography can reach up to 95%, while water head emptying ratios of those are just about 60%, such as Pubugou, Tianshengqiao I. As most of high dams with 300m height are located in alpine and narrow valleys in southwestern China, it is difficult to emptying the water head of reservoirs. In addition, the emptying time cost varies a great deal for different reservoirs.

KEY TECHNOLOGIES OF LOWER DISCHARGE FACILITIES

The most effective measure to emptying reservoirs is via lower discharge facilities, the key technologies of which are an important breakthrough of emptying design, including enhance emptying ability, shorten emptying time, routine maintenance, hydraulic problems and downstream protection.

ENHANCE EMPTYING ABILITY

Due to technology limitations of sluices and hoists, the intake elevation of emptying facilities cannot be set too low. The water head before the sluice of emptying facilities should not be greater than 120m usually, maximum 160m; otherwise the sluice will bear too large thrust. The water head and capacity been emptied are both limited. So it is very necessary to research the feasibility and rationality of lowering the intake elevation of emptying facilities.

SHORTEN THE EMPTYING TIME

Because of restriction by water thrust on sluice gate, the size of emptying tunnel cannot be designed too large and the discharge flow of it is limited. So the emptying time is too long sometimes to ensure the safety of projects. Such as Lianghekou project, the sluice gate size of emptying tunnel is 8m by 10m, while the water head before the gate reaches 125m, which need 87 days to discharge to designed emptying water level in dry season. So it is necessary to consider hydrologic conditions of both flood season and dry season as well as project investment to research the arrangement and structures of emptying facilities and then shorten the emptying time. The emptying facilities in China are designed considering the requirements of emptying for overhaul under exceptional circumstances in dry season.

ROUTINE MAINTENANCE OF EMPTYING FACILITIES

Usually, the emptying facilities cannot be used until the reservoir water level falls to a very low level. Most of them are rarely used and have very few chances to operate and be maintained. So it should be pay attention to how to make sure the emptying facilities can operate normally at key time. In addition, the intake of emptying facilities should not be set too low because of sediment deposition.

The intake elevation of bottom emptying outlets of Xiaowan arch dam (Fig. 1) is 1080m, which can be partly or must be totally opened when the reservoir water level is lower than 1160m or between 1160m and 1186m, respectively, and cannot be used when the water level is higher than 1186m. Nevertheless, as a multi-year regulating reservoir, the designed dead water level and flood season limited water level are 1166m and 1236m, respectively, much higher than 1186m. So it is obviously that the bottom emptying outlets have almost no chance to operate and be inspected.

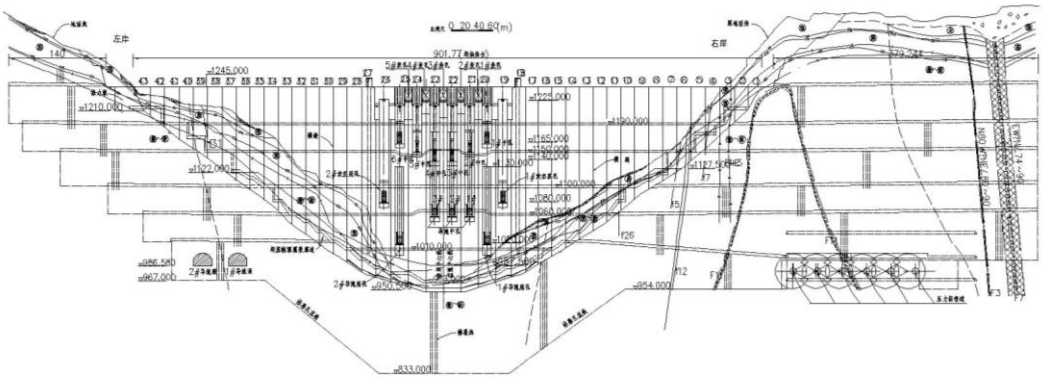

Fig. 1
Upstream vertical unfold view of Xiaowan arch dam

HYDRAULIC PROBLEMS AND DOWNSTREAM AREAS PROTECTION

The elevation of emptying facilities is much lower than any other discharge facilities. So the hydraulic problems such as high water level, high speed flow and cavitation when reservoir emptying, especially emergency emptying, along with energy dissipation and erosion control problems as well as investment should all be took into account. On the other hand, man-made extraordinary flood should not occurred in the downstream areas even if emergency emptying.

SUBJECTS NEED TO BE FURTHER RESEARCHED ABOUT EMPTYING DESIGN OF HIGH DAMS

The emptying requirements and process are much complex and some factors should be considered in the emptying design, including the relationships and requirements of integral safety degree and the water level for overhaul, hydrologic characteristics and downstream area flood control, arrangement conditions and sizes of emptying facilities as well as reservoirs slope stabilities when emptying. Through comprehensive and thematic analysis, a proper emptying ending water level and emptying facilities scale should be chosen to satisfy the dam overhaul requirements, ensure dam safety risk acceptable and prevent dam failures or other secondary disasters.

DAM INTEGRAL SAFETY DEGREE

The water thrust acted on concrete dams can be reduced by lower down the reservoir water level, which is very effective to increase the stabilities of dam foundation and dam abutment. In case of emergency, the first consideration is to enhance the dam integral safety degree as soon as possible, though that may cause excess concrete tensile stress at some local areas.

On the other hand, in case of non-emergency, it's better not to lower down the reservoirs water level too much to avoid excess concrete stress and crack, especially arch dams, to which, the temperature load is a kind of particularly sensitive load. In fact, majority loads of water thrust act on the higher part of arch dams. The total water thrust of Xiaowan arch dam with the height of 294.5m reaches 18 million tons. And half of the thrust act on the top 40m of the dam, while the other half act on the bottom 250m height left. So the integral stability of Xiaowan arch dam is enough safe after discharging to the designed emptying ending water level even if there is still 139.5m water head left.

The safety of embankment contains dam slope stability and seepage stability. When the anti-seepage is damaged, the seepage gradient of dam body behind the anti-seepage can be significantly reduced while the downstream slope stability been increased by lower the reservoirs water level, no matter earth core dam or concrete faced rockfill dam (CFRD).

DAM OVERHAUL CONDITIONS

Foundation galleries are usually set up in concrete dams, especially high dams. So the cracks in the upstream surface of dam body and seepage of dam basement can be handled by grouting in the foundation galleries, without emptying the reservoirs. However, some concrete dams developed cracks penetrating from upstream surface to foundations, which caused dam uplift pressures and leakage increase. In this case, the cracks have to be repaired by emptying the reservoirs instead of grouting only, such as Konbrien arch dam in Austria.

The key problem of embankment dams is overhauling conditions of anti-seepage systems. For earth core dams with foundation galleries, the effects of supplementary grouting under high water head are usually not good if the anti-seepage systems are damaged. So it is need to lower the reservoirs water level to reduce the seepage pressure and velocity in order to achieve good grouting effect. For CFRD, the biggest challenge is how to overhaul the broken seepage system. Clay blanket under the emptying ending water level is designed to protect the anti-seepage systems. But there are still some problems. The leakage position of Baiyun CFRD in Hunan province was just below the clay blanket, so the reservoir has to be emptying and clay blanket be dug out to overhaul the broken concrete face. Some research suggest that do not set clay blanket on the concrete face for convenience of overhaul. In the near future, the dam examine and overhauling may not be limited by the water depth along with the development of intelligent robots and detection technologies in deep water.

COMBINATION OF EMPTYING AND DISCHARGE FACILITIES

Usually, the intakes of emptying facilities are set too low and do not used to discharge flood or silt. Most of them are rarely used and have very few chances to operate and be maintained. So they may not be able to operate in case of emergency. Thus it should be considered to combine the emptying facilities and routine discharge facilities so as to increase the operating frequency of emptying facilities. Thereby examine their status and repair them if necessary to ensure dams stabilities.

EMERGENCY EMPTYING STANDARD AND MANAGEMENT

(1) Emergency emptying standard
Different from overhauling emptying, extreme disaster at any time of the year must be considered in emergency emptying. Longtan dam for example, two bottom emptying outlets with the size of 5m by 10m were designed to discharge flow of 3210m3/s, 20-year return flood in dry season. However, if it is need to emptying 5-year return flood of the whole year emergently, the flow up to 14400m3/s, 4 more bottom emptying outlets with the same size should be designed, which will increase the investment in great deal. So, it is not economical and reasonable to solve the emergency risk only depending on emptying facilities. It should be deeply researched to choose a proper standard of emergency emptying.
(2) Dam emergency management
In case of extreme disaster or other risk, the reservoirs water level must be lower down rapidly, which may cause man-made extraordinary flood and bank slops stability problems. For example, the maximum discharge flow of Xiluodu arch dam reaches 49000m3/s, which will wreak destruction to downstream banks. Obviously, a professional emergency management institute at the national level should be set to decide whether to empty and discharge to which water level.
So, it is necessary to develop risk assessment mechanism and risk management technology, manage dam safety in case of emergency at the basin cascade and national level, and improve the dam safety management level [3].

SUMMARY

Based on summarizing of present design status of reservoir emptying, the key technology problems of lower discharge facilities are analyzed in this paper, and then some subjects need to be further researched are discussed.
(1) Reservoir emptying is to discharge the reservoir to a proper water level in order to keep the dam stability instead of discharging the entire reservoir.
(2) It is very important and effective to set emptying facilities to lower down the water level in emergency. Characteristics of reservoir and projects as well as hydrologic conditions should all be considered when emptying design to help choosing a reasonable emptying scale and depth.
(3) The key technologies of lower discharge facilities should be further researched in the future to break though the limited factors.
(4) The basin cascade dispatching and forewarning, manage systems of dams safety adapting to construction and economic level, as well as dams lifecycle safety management and risk distinction system suited to national conditions, should all be established and improved in order to minimize risk of basin cascading dams failure.

1. INTRODUCTION

Visual inspection is a visual inspection of ground and water inspection objects, such as dam surfaces, auxiliary buildings, ridges and reservoir cliffs, hydro mechanical equipment, instrumentation and so on. Reservoir Manager Ir. H. Djuanda performs visual inspections twice a year for dams located in his working area, which are around May - June at the time of the high water reservoir and November - December at the time the water level is low.

Visual inspection conducted includes inspection of dam Ir. H. Djuanda in Purwakarta District. The purpose of the visual inspection work is to find out as early as possible about the current state of the field on dams, complementary buildings and facilities for the purpose of encountering unusual things (anomalies) and / or symptoms that may threaten the safety of the dam so that immediate precautions are taken and risk reduction to the safety and safety of dams.

Visual inspection work consists of a series of inspection activities on dam bodies, complementary buildings, hilltop, rim (roving) reservoirs and the surrounding dam environment. Matters inspected during the visual inspection of the dam include cracks, seepage, leaks, basins, springs, burrows, erosion of surface erosion, abrasion scouring, excessive plant growth, top straightness, bulge or slope subsidence or berm, animal burrows of rip-rap quality deterioration as well as other slope protective materials. As for the concrete buildings are examined for cracks, crushing, dissolving, leaking, indication of deterioration of quality or chemical reaction, and or the damage caused by erosion and cavitation, the reliability of construction connections.

Based on the method of implementation, the inspection is divided into two types: visual inspection and underwater inspection. Visual inspection is a visual inspection of ground and water inspection objects, such as dam surfaces, auxiliary buildings, ridges and reservoir cliffs, hydromechanical equipment and so on. The work of this inspection is a work performed by visual inspection method based on the March 2003 Safety Dam Inspection and Evaluation Guidelines published by the Ministry of Public Works. The steps taken against a finding on the ground during the visual inspection are S I M P L E i,e:

a. Sketch: Drawing / Sketch that describes a finding in the field.
b. Investigate: Investigate further on a finding in the field.
c. Measure: Measuring dimensions of a field findings such as cracks, avalanches, leakage discharge and so on.
d. Photograph: Take a picture / photo of a finding in the field.
e. Locate: Marking the location / place of a find in the field is associated with easily recognizable objects such as shear, piezometer, Observation Well and so on.
f. Engage: Engage experts or engineers who are experienced in visual inspection to be a resource person in consultation every problem that exists.

The tools and materials commonly used in visual inspection at Ir.H.Djuanda Dam include : Four-wheeled vehicles, camera, handy cam, meter tool 50 m and 5 m, stationery, handbags, cranes and steel cages as a means to descend to the bottom of the spillway during Hollow Jet Valve inspection, belt safety (Safe Belt) for Hollowjet Valve inspection, buoy (Life Vest) for Rim Reservoir inspection, boat (Speed Boat) for inspection Rim Reservoir, handheld GPS (Global Positioning Tool).

1.1. DAM IR. H. DJUANDA

Located approximately 100 km southeast of Jakarta and 60 km northwest of bandung, Ir. H. Djuanda dam is a new urugan dam with clay core, irin (Rock Fill with Inclined Clay Core). It has four saddle dam (saddle dam), namely the saddle dam of Pasir Gombong Barat, Pasir Gombong Timur, Ciganea, and Ubrug. The main spillway shaped tower type of morning glory, which at the bottom also functions as a powerhouse, as “Fig.1”.

Fig.1
Ir. H. Djuanda Dam

To assist in the event of a shortage of supply from downstream through the power cord, two irrigation supply channels (hollow jet valve) are available on the eve of +49 m.dpl, see as “Fig 2 and Fig.3”. Based on the result of the year 2000, the volume of TMA +107 m.dpl (normal pool level) of 2.448 million m3 with the puddle area of 81.3 km2. The dam was built in 1957 and completed in 1967 on the Citarum River, with a catchment area of 4,500 km2, while the catchment area directly to the reservoir after the construction of Saguling and Cirata Dam in the upper reaches 380 km2.

Ir. H. Djuanda dam is a multipurpose dam, function as a hydropower plant with installed capacity of 187.5 MW, flood control in Karawang regency and Bekasi district, irrigation for 242,000 hectares of rice field in north coast of West Java, water supply for brackish water fishery cultivation along the west coast of West Java covering an area of 20,000 hectares and tourism.

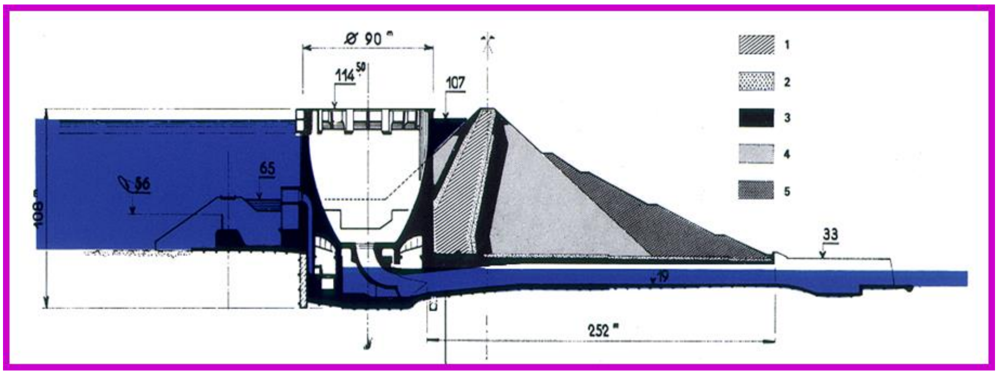

Fig.2
Profile of the main Dam Ir. H. Djuanda

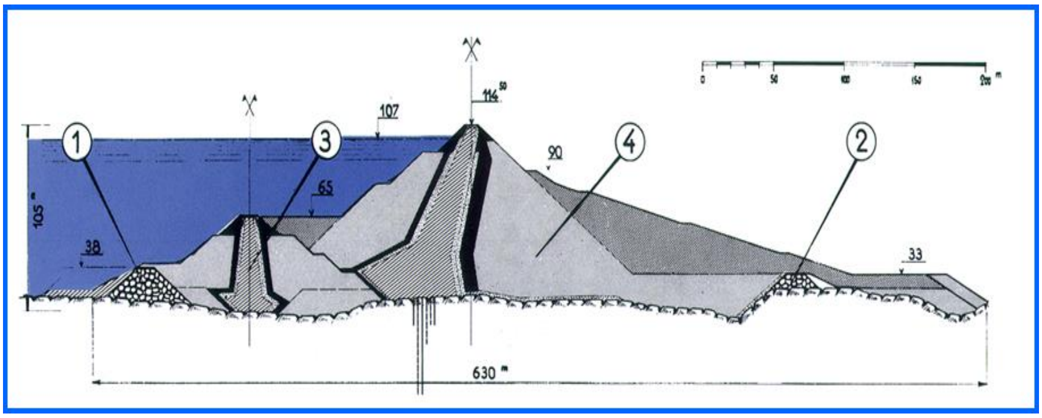

Fig.3
cross Section of the main Dam Ir. H. Djuanda

1.2. PASIR GOMBONG SADDLE DAM

Pasir Gombong saddle dam is a type of Homogenous Earth Fill dam with cover using andesite and some places using chimney drain. Elevation of the saddle hose +114.5 m.dpl. sand dunes sands west of 1950 m long, 19.0 m high maximum and sand dunes sands east of eastern with a length of 400 m, maximum height 15 m.

1.3. CIGANEA SADDLE DAM

The Ciganea saddle dam is a Homogenous Earth Fill type dam similar to the Pasaj Gombong Strip Dam with a cover using andesite rocks and in some places using Chimney Drain. Peak shedd elevation +114.5 m.dpl. the length of this saddle dam is 330 m, the maximum height is 12.5 m.

1.4. UBRUG SADDLE DAM

The Ubrug saddleback is also a Homogenous Earth Fill type dam similar to Pasir Gombong saddle dam with a cover with andesite stone and in some places using Chimney Drain. Peak shed elevation +114.5 m.dpl. The length of this saddle dam is 550 m, the maximum height of 17 m is equipped with an overflow auxiliary. Overflow aids at the Ubrug Saddle Dam has 4 (four) doors with a width of 12.4 m, elevation of overflow floor +102 m.dpl with abundance capacity 2000 m3 / sec.

2. IR H. DJUANDA VISUAL INSPECTION

Based on the results of visual inspection and observation of the dam body and its complementary building, that in general the dam Ir. H. Djuanda relatively good and normal, with the condition of findings in the field, among others:

1. On the hillside there are several rip-rap rock spots happening dislocations, and found grass and shurbs plants growing on the sidelines of rip-rap stones.
2. On the slopes downstream on the sidelines still visible grass and shrubs that grow, the frequency of grass that needs to be reproduced so that the roots of the plant does not penetrate the body of the dam that could be the outlet of water seepage on the lining wall structure and lining paving blocks access road to the dock.
3. Generally the condition of instrumentation in the main dam is relatively good, but on OW5 protective wall made of concrete slab looks damaged and not closed. The accelerometer installed in the Access Gallery of the tool is damaged, the error sign continues and the voltage indicator panel shows 5.4 volts which should be +/- 11 volts. The condition of the surface monument has small damage to the slope 9surface monument) which is located at the upper lining of the dam top.
4. Conditions of drainage channels in some places at the foot of the dam and downstream areas appear to be clogged with soil, moss and grass so that the water flow cannot flow smoothly and inundated.
5. Rip-rap conditions are generally good, but need to be weaned and additions around the C2 sliding mark downstream.

3. TOWER MAIN TOWER AND ACCESS GALLERY INSPECTION

Based on visual inspection and observation of the main spillway tower, Access Gallery and its complementary building. In general the condition of the main spillway tower and access gallery is relatively good and normal, with the condition of findings in the field, among others:

a. The connection between the plates on the bridge ladder has already started to loose due to run out by rust. And at some point bridge paint floor has begun to fade, the handrail and steel rope reinforcement on the right and left side of the bridge looks still pretty good.
b. There are cracks in the 3 concrete joints under the rails. Found the wild vegetation around joint 9 then on joint 11. Three Dimension Instrument (3D) Joint Apparatus looks rusty start and surface pin is not flat. The 3D Joint Apparatus protective cover is largely unlocked because the lock nut is missing. The sliding mark on the shoulders of the tower must be re-painted because the

paint has begun to fade. Home / Box AWLR (automatic Water Level Recorder) SESAME must be repaired.

c. The condition of the ladder that is on the wall inside the spillway looks rusty.
d. The wet location or seepage trace is found in joint G0. The concrete connection is observed by 3 (three) Dimension Joint Apparatus. The condition of the former leakage monitoring tool in joint 0 that is Rive Droite (RD) and Rive Gauche (RG) still looks stagnant due to drainage of seepage see page clogged, If will be measured discharge leakage RD and RG must first pumped. Therefore the measurements of the RD and RG leakage discharges are now done in a new place through two pipes connected directly to the directional pipe steering join 0. The sliding benchmark in the Access Gallery is mostly without a protective cover.
e. In the ceiling space re-cavitation occurs on the concrete wall that has been done with the addition of using cement. Corrosion section contained in the cooling pipe casing on the staircase entering the ceiling has not been repaired.
f. In the left sump Pit found cracks in the concrete wall, concrete and concrete floor joints drainage see page (sump pit) left, so the concrete floor is relatively slippery when skipped.
g. The condition of the right collecting drum space (sump pit) mostly cavitation, moist and wet. The wet location is found almost in all the right (sump pit) areas, so the concrete floor is relatively slippery when skipped.
h. The condition of the bouchon, the tap (gate valve) to open the waterway has been consumed by corrosion. Condition of concrete wall, and concrete connection experience cavitation, moist and wet. Wet locations and puddles are found only on the side of the baton wall around the entrance hall.
i. The intake room of the riva pump is inundated about 2 meters deep and needs to be addressed immediately because of mild corrosion.
j. The old cracks in the majority of concrete are found in the interior walls of the circle and a small part is found in the exterior circle but the condition does not change significantly.
k. The old vapor that forms the cavity to the right of the tailrace (about 20 m to the left of OW IC748) has been repaired by means of the extraction and compaction of the material.
l. Elevators contained in the access gallery is not working and severely damaged (high corrosive) as well as around the elevator door area often leaks. The protective cable cover (concrete plate) at the top of the tower is partially cracked.

4. SADDLE DAM INSPECTION

4.1. PASIR GOMBONG BARAT SADDLE DAM

Generally the condition of Pasir Gombong Barat Saddle dam relatively good and normal with visual observation conditions as follows:

a) Avalanche / sliding in downstream profile 32 and profile 17 handling not entirely.
b) Some of the stucco slabs are plastered and there are many streaks.
c) In the downstream area there are many rushes on the drainage especially the lining of the stone pairs.
d) Water supply to basecamp does not exist.

4.2. Pasir Gombong Timur Saddle Dam

Generally, the condition of Pasir Gombong Timur Saddle Dam is relatively good and normal with visual observation conditions as follows:

1) The old erosion occurring in the original soil near the R42 and R44 profiles still has not been handled. There is still a wet / muddy area that has not formed a puddle on the original soil to the left of the R46B shear and the wet area around the R42b shear. There is erosion on the hillside to the left of the dam hill slope caused by water abrasion.
2) In the downstream of Pasir Gombong Timur saddle dam still found many surface erosion on the original soil.

4.3. Ciganea Saddle Dam

In general, the saddle cave dam conditions are relatively normal and normal with visual observation conditions as follows:

1) Drainage holes in the hills and downstream of the saddle dam are partially clogged up by soil deposits and garbage.
2) Some parts of the lining of the upstream and downstream of the saddle dam are still visible damage to the stone pairs.
3) Wild grass and shrubs are seen along the top of the saddle dam, on the sidelines of the ripa-rap of the upstream slope and downstream slope.
4) Livestock poultry found in some places on the original soil downstream of the saddle dam.

4.4. Ubrug Saddle Dam

In general, Ubrug saddle dam conditions are relatively good and normal with visual observation conditions as follows:

1) There are cracks along the 11 meters wide 50 cm in 30 between the c.10 -c.11 segment.
2) There is still original soil erosion near the downstream drainage next to the emergency spillway.
3) The protective building of the instrumentation apparatus in the downstream area of the partially damaged partition (rock pairs on the loose wall) and part of the protective cover is lost.
4) Drainage system overgrown with weeds and there is damage to the lining of stone pairs.
5) The position of the right collector building is not suitable, the drainage channel is higher than the position of the container tub.
6) Grasses and herbaceous plants are still visible in several places on the sidelines of the hill and downstream of the dam, rip-rap hillsides and rafting downstream.

5. RESEVOIRS RIM INSPECTION

In general the condition of the reservoir rim is relatively good and normal with the visual observation conditions as follows:

1. Found water vegetation in the form of water hyacinth in Cimanggu area.
2. There are many patches of illegal floating net cages in the Pasir Gombong Barat, Madang, Kertamanah, Pagadungan - Sukasari, Sukasari - Sodong, Cilendi and Jamaras – Tajur Sindang area.
3. More and more fishing rafts on the edge of the reservoir between the main dam – pasir gombong and Pagadungan area.
4. More and more non-permanent buildings and floating buildings in the puddle area and side of lake reservoir Sukasari, Cidadap, Cimanggu, Bojong, Warung Jeruk, Cilangobar, Sindang, Ciganea - Ubrug area, which is used by the community to trade and as a place of residence that has the potential to produce waste is relatively large.
5. Found erosion and landslides and landslide potential in the right bluff that is wide enough around the outlet Cirata reservoir.

CONCLUSION

Ir. H. Djuanda Dam is one of the largest dams and the first multipurpose dam in Indonesia. The dam with an area of 8,300 ha was built by the French franchise contractor Compagnie francaise d'entreprise in 1957 and completed in 1967, with a water potential of approximately 12.9 billion m3 / year. The capacity of this dam is 2.44 billion m3.

Visual inspection of large dams Ir. H. Djuanda is a routine activity undertaken in the context of monitoring activities on dam safety. Visual inspection is done periodically and continuously to get the latest visual data about the condition of Dam Ir. H. Djuanda. Visual inspection is important because not all changes in the condition and behavior of the dam can be described from the measurement or reading of the instrument. This visual inspection is done twice a year i.e May - June at high water level and November - December when the water level is low.

Visual inspection activities consist of a series of inspection activities on dam bodies, complementary buildings, hilltop, rim (roving) reservoirs and the surrounding dam environment. Matters inspected during the visual inspection of the dam include leakage, basement, springs, evaporator, erosion eruption, surface erosion, scouring, abrasion, excessive plant growth, top straightness, protrusion or subsidence of slopes, animals, deterioration of rip-rap quality as well as other slope protective materials. As for the concrete buildings are examined for cracks, crushing, dissolving, leaking, indication of deterioration of quality or chemical reaction and or damage due to erosion and cavitation, the stability of construction joints.

The method of inspection implementation is divided into 2 types: visual inspection and underwater inspection. Visual inspection is a visual inspection of the ground and water inspection objects, such as dam surfaces, auxiliary buildings, ridges and reservoir cliffs, hydro mechanical equipment and so on.

Based on the results of visual inspection and observation of the dam body, main spillway towers, access galleries, saddle dam bodies, reservoir reefs and complementary buildings that are generally in relatively good condition and normal.

Barbara BRINKMEIER
PostDoc at the Unit Hydraulic Engineering, UNIVERSITY OF INNSBRUCK

AUSTRIA

1. INTRODUCTION

The safety and reliability of dams and weirs depend – among other things – on the functionality and reliability of the gates, which are used to control the flow. Various design approaches exist in different countries. In Germany and Austria and numerous other countries, the so called (n-1) – condition has to be met when designing the gates of dams and weirs [1]. This deterministic design concept aims at a safe discharge of the design flood, assuming one gate is out of operation. Typically, the return period of the design flood is of the order of 100 years for weirs and 1.000 to 5.000 years for the spillways of large dams.

In addition to the above mentioned design flood, which has to be discharged through (n-1) gates, typically a much higher ´check flood´ has to be passed through the weir or spillway in a safe way. In Germany this ´second design flood´ (or ´check flood´) has a return period of 1.000 years for large weirs and 10.000 years for large dams, whereby all available openings and outlets can be used for flood discharge. The specific design rules for the safe passage of the ´check flood´ vary significantly between different countries.

In many cases the (n-1) concept ensures a very robust and safe hydraulic design of weirs and spillways weirs. The probabilistic approach behind this concept is that the coincidence of a blockage of two or more gates with a design flood is very unlikely.

Anyhow, there remains a number of aspects which cannot be taken into account with this very clear and simple (n-1) - approach, among other things

- the number of gates
- the type of gates
- the revision concept
- the steering units (inter alia reliability and type)
- the power supply (inter alia redundancy).

In many cases existing weirs and less frequently existing spillways do not fulfil the (n-1)-criteria. Many of them were carefully investigated and upgraded with additional measures (e.g. additional lifting units). For proofing the reliability of these structures despite the missing possibility of passing the design flood through (n-1) gates a more sophisticated method using the (n-*a*)-concept [2] is being used since decades. The parameter '*a'* considers both the revision and the malfunction of the gates. Under favourable conditions '*a'* can accommodate values lower than 1.0.

The event tree concept presented below can be considered as a base for a future alternative way for determining and proving the reliability of gated weirs and spillways if the (n-1)-criteria cannot be fulfilled. It should be understood as a useful supplement to the very robust (n-1) design method. The event tree concept does not strive to replace any check flood design cases.

2. EVENT TREE CONCEPT

2.1. BASICS

A new design approach, that has the potential to replace respectively to complement the (n-1) condition, was developed at the University of Innsbruck in cooperation with different partners. It is based on the idea, that the required level of safety is determined at the beginning of the design process. For example, it is accepted for weirs, that the maximum operation water level in the reservoir is exceeded with a probability of 0.01 each year (return period of 100 years).

The design has to take into account four variables: the number of gates, the total capacity of the weir respectively the spillway of the dam, the duration of 'critical works', where the gates or their drive systems are under revision and not available for flood discharge, and the probability of the malfunction of one gate. Empirical values for the latter two variables have to be defined carefully. Within the scope of this critical step of the conceptual work for the event tree concept data gained from literature, experiences of the operators and fundamental considerations concerning the overall safety level have to be taken into account.

The present paper will explain the basic design approach in detail. Detailed recommendations for the numerical values of the related variables for the duration of the critical works and the probability of the malfunction of on gate will be given after a period of detailed investigations, comprehensive discussions and sound verifications.

Generally, the event tree concept can be applied for all kind of weirs and spillways with very different gated and not gated openings. Anyhow, within the scope of the present work the presentations, relations and equations are related to gated weirs and spillways with an optional number of gates of the same size and type.

2.2. EVENT TREE

The key of the event tree concept is the consequent presentation of the events, which can happen if a flood approaches a weir or a spillway (Fig. 1). In a first differentiation it has to be checked whether the gate or weir field is blocked due to critical works.

The variable $d_{C,G}$ describes the number of days of ´critical works´ per year for one gate. Critical works are definied as works during which an ad hoc opening of a gate would not be possible. Hereby any kind of inspection, revision and replacement works have to be taken into account.

The value $\alpha_{C,G}$ (Eq. 1) shows the probability that one specific gate is being blocked by critical works at any time. If n is the number of gates, consequently p_B describes the probability that one of the n existing gates is being blocked by critical works at any time (Eq. 2.).

It can be ruled out that more than one gate is being blocked by critical works at the same time.

$$\alpha_{C,G} = \frac{d_{C,G}\ [d]}{365{,}24\ [d]} \quad [-] \qquad [1]$$

$$p_B = n \cdot \alpha_{C,G} \quad [-] \qquad [2]$$

Within the scope of a second and much more comprehensive differentiation it has to be checked whether it is possible to open every single gate during a flood event. In order to enable this evaluation the probablity of a malfunction of one gate has to be defined. Consequently the related statistical parameter p_F describes the fundamental probability that it is not possible to open one gate at any time. In order to allow a much better understanding of this parameter its reciprocal value '*f*' shall be used (Eq. 3). This means that in an estimate, which has to be very much on the safe side, one specific gate has to be considered as not properly working within the scope of each f^{th} gate opening. Gates, where little or no external forces are needed for opening (e.g. flap gates oder rubber dams), will show much higher values of '*f'* compared to other gates like radial gates or even slide gates, where the function of mechanical steering units and a power supply are mandatory for a successful opening.

$$p_F = \frac{1}{f} \quad [-] \qquad [3]$$

By using the two newly introduced paramters p_B and p_F a complete event tree in the case of an approaching flood can be set up (Fig. 1). Typically the probabilities of the occurance of two of even three gates not working properly will be very little. Anyhow, for the purpose of a universally applicable approach these very unlikely scenarios shall be kept at that time. The event tree can be set up for an optional number of gates (greater than 1). The example shown below (Fig. 1) shows the potential szenarios for a weir with four gates.

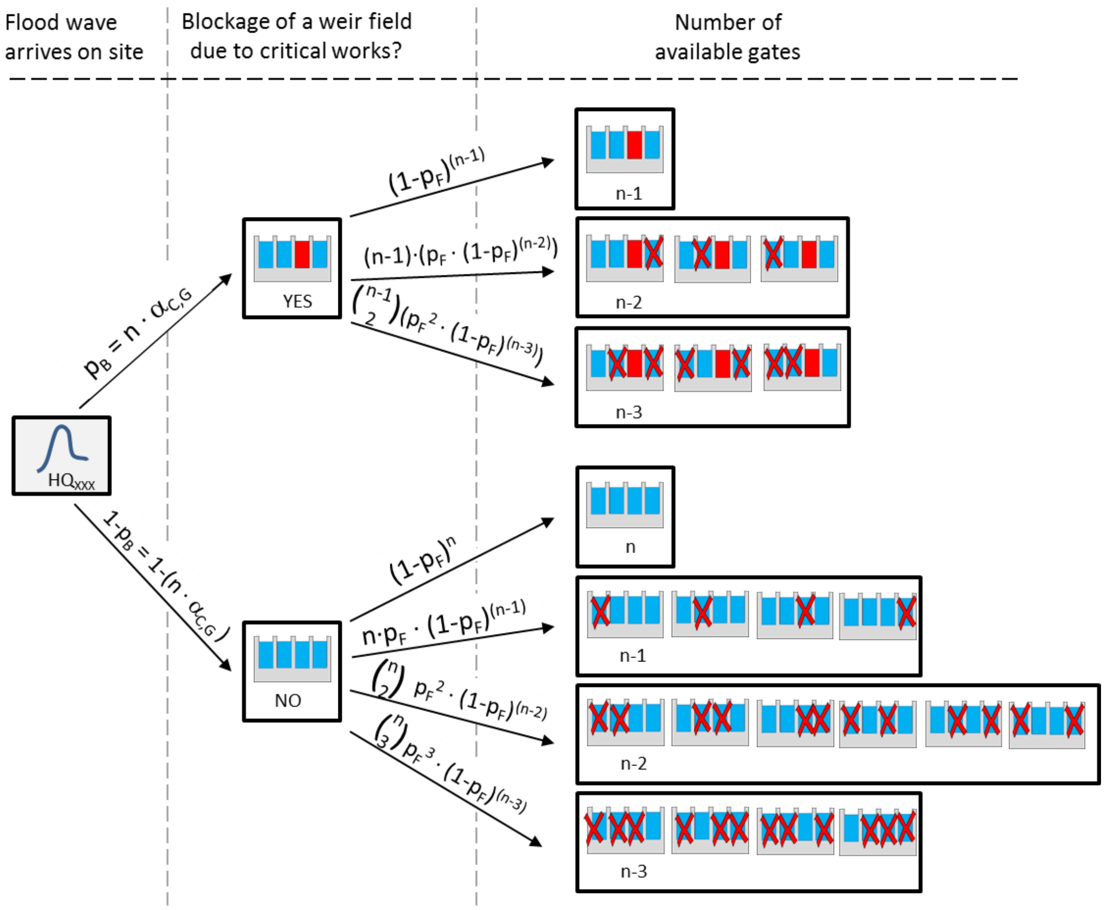

Fig. 1
Event Tree (Example for a weir with four gates and a design flood with a return period of 100 years)

2.3. Statistical Description of The Failure Probability

In a next step it is required to determine the probability p_D of a hydraulic respectively hydrological ´failure´ by considering all scenarios shown in the set-up of the event tree (see above). Hereby ´failure´ is defined as the exceeding of the maximum operation water level in the reservoir. Practically this situation is far away from a structural failure of the concrete structure of the weir or the related embankment dams. The additional freeboard respectively the vertical distance between the maximum water level and the dam crest or the top edge of the sealing element will not be considered directly within the scope of the event tree concept.

To enable a statistical description of the related probability p_D it becomes necessary to determine the return period of the maximal possible flows passing through the weir respectively spillway in all relevant scenarios [Q_n, Q_{n-1}, potentially also Q_{n-2} and Q_{n-3}] defined within the scope of the event tree. This can be done either by applying site specific flood statistics or simplified statistical approaches based on typical statistical characteristics (e.g. HQ_{50}, HQ_{100}, HQ_{1000}). The reciprocal values of these return periods lead to the related probabilities $p(Q_n)$, $p(Q_{n-1})$ etc..

By merging these expressions and relations with the event tree it becomes possible to formulate a simple but long equation for the determination of the ´failure probability´ p_D (Eq. 4).

$$
\begin{aligned}
p_D \;=\; & (1-p_B)\cdot(1-p_F)^n \cdot p(Q_n) \qquad [4] \\
& + \left[p_B\cdot(1-p_F)^{(n-1)} + (1-p_B)\cdot n\cdot p_F\cdot(1-p_F)^{(n-1)}\right]\cdot p(Q_{n-1}) \\
& + \left[p_B\cdot(n-1)\cdot p_F\cdot(1-p_F)^{(n-2)} + (1-p_B)\cdot\binom{n}{2}\cdot {p_F}^2\cdot(1-p_F)^{(n-2)}\right]\cdot p(Q_{n-2}) \\
& + \left[p_B\cdot\binom{n-1}{2}\cdot {p_F}^2\cdot(1-p_F)^{(n-3)} + (1-p_B)\cdot\binom{n}{3}\cdot {p_F}^3\cdot(1-p_F)^{(n-3)}\right]\cdot p(Q_{n-3}) \quad [-]
\end{aligned}
$$

3. OUTLOOK

By referring the above introduced failure probability p_D to the required safety level in the specific load case (e.g. a return period of 100 years for passing the design flood through a weir) it will become possible to determine the required capacity of the weir respectively the spillway. Hereby the site specific conditions (duration of the critical works and the probability of the malfunction of a gate) have to be taken into consideration. This procedure based on the event tree concept enables an adequate determination of the safety level at different sites under very different conditions (e.g. number and type of gates). The biggest challenge for their successful application will be the appropriate determination of suitable input parameters on the safe side.

1. INTRODUCTION

The necessity of dam construction is prima facie principle in arid or semiarid regions. As an inevitable consequence in dam construction, unnatural slopes around dam body and reservoir are formed and usually devoid of vegetation. Failures of those slopes can have a significant cost. Translational failure is defined as linear movement along a bedding plane or a soil layer lying near to the surface. Such movements are normally fairly shallow and parallel to the surface [1].

Vegetation surely affects hydrological and mechanical properties of slopes related to slope stability and shallow landslide triggering. The most important and general problem is a shallow seated instability of a slope [2]. Based on the complexity of soil-plant mechanical interactions, the quantification of root mechanical reinforcement remains a challenge. On the other hand, considering the failure mode and uncertainty in geotechnical and vegetation parameters, it seems that using probability theory in slope analysis is inescapable. The aim of this study is evaluation of increased shallow landslide resistance of a slope due to vegetation considering uncertainty of related parameters. With reliability analysis it is possible to quantify the uncertainties involved in the problem and to determine safety factor according to the degree of uncertainty and acceptable risk.

2. UNCERTAINTY AND RISK

In contrast with some engineering fields dealing with man-made materials, geotechnical engineers deal with geometries and materials provided by nature. These natural conditions are unknown to the designer and should be inferred from limited and costly observations. The principal uncertainties have to do with the accuracy and completeness with which subsurface conditions are known and with the resistances that the materials will be able to mobilize. The uncertainties in geotechnical engineering are largely inductive: starting from limited observations, judgment, knowledge of geology and ecology, and statistical reasoning are employed to infer the behavior of a poorly-defined universe [3].

In engineering contexts, risk is commonly defined as the product of probability and consequence, or expressed another way, risk is taken as the expectation of adverse outcome. Risk assessment provides proper opportunity to experts with considering uncertain data related to slope safety decisions, to evaluate qualitative and quantitative assessment of slope safety. Hence, experts finally take appropriate economical and practical decisions. Quantitative risk assessment includes risk analysis, risk assessment and management. Risk management is consideration of the risk analysis along with risk control that threatens safety. Risk control is one of important parts of safety management, which includes review of alternatives in dealing with risks such as risk mitigation, risk acceptance and risk avoidance[4,5].

3. VEGETATION EFFECT

To assess the safety of a slope to prevent human casualties and economic losses, it is necessary to find out the ways in which soil and vegetation interact. The most important and general problem is a shallow seated instability of a slope, that is at depth of around 0.5-2 m below the ground surface and that this is in fact the most widespread form of slope failure particularly in embankments [2]. Depending on the potential slip surface, the factor of safety (FOS) varied from 2.8-3.7 and 1.8-2.0 for unrooted soil. When the mean value of the FOS increased significantly for surface depth of 0.3m, albeit as distance progresses to a depth of 1.2m these benefits diminish [6]. The stability of slopes is governed by the load, which is the driving force that causes failure, and the resistance, which is the strength of the soil-root system [7]. Based on Coppin and Richards (1990), main influences of vegetation on the stability of the slope segment are from enhanced soil cohesion due to soil reinforcement by roots and tensile root force acting at the base of the slip plane [8]. The FOS for a slope may be calculated using the infinite slope model [1] by Eq. 1.

$$FOS = \frac{c+(\gamma z-\gamma_w h)cos^2\beta\ tan\varphi}{\gamma\ z\ sin\beta\ cos\beta} \qquad [1]$$

Where c: cohesion of the soil (kN/m^2); z: depth to shear plane (m); h: height of ground water level above shear plane (m); γ: density of soil (kN/m^3); γ_w: density of water (kN/m^3); β: slope angle (º) and φ: angle of friction (º). The modified equation for translational failure on an infinite slope taking the effects of vegetation into account is defined by Eq. 2.

$$FOS = \frac{(c_R)+\{[(\gamma z-\gamma_w h)+W]cos^2\beta+Tsin\theta\}tan\varphi+Tcos\theta}{[(\gamma z+W)sin\beta+D]cos\beta} \qquad [2]$$

Eq. 2 incorporates four additional variables defined as: c_R: the enhanced shear resistance due to roots (kN/m^2); T: tensile root force acting at the base of the shear plane (kN/m), W: surcharge of the vegetation (kN/m^2) and D: wind loading parallel to the slope (kN/m).

to ascertain these variables, a set of experimental studies were carried out [7]. The values of parameters are selected based on that experiment and worst case scenario demonstrated in Table 1.

Table 1. Values of variables

Parameter	γ	γ_w	Z*	h	W	D	φ	c	c_R	T
Value	11	9.81	0.1-0.5	0.5	0	0	16	10	10	5

* Maximum depth of roots of grass and forbs is usually no greater than 0.5 [9].

Employing Eq.1 and 2 for reliability analysis, several assumptions are made. The weight of the surface vegetation and its subsequent normal force on the soil are quantified as W, the surcharge. This surcharge is included in the calculation primarily due to the plausibly high force exerted on soils by trees, in this paper W has been assumed to be zero as the surcharge exerted by grass is likely to be very small and of little consequence. The tensile root force for the grass is selected based on literature [10]. The wind loading force, D, is chiefly concerned with the effect of 'wind throw'. In the case of grass, the surface area upon which wind can act is small in comparison to trees, additionally grasses tend to be flexible and unlikely to transfer a great deal of force to the roots. The angle between roots and slip plane, θ, has been taken to be equal to that of the slope angle, β, as it was assumed that roots had grown in a gravitonic manner.

4. RELIABILITY AND MONTE-CARLO SIMULATION

Reliability analysis deals with the relation between the loads a system should carry and its ability to carry those loads. Both the loads and the resistance may be uncertain, so the result of their interaction is also uncertain. Reliability analysis of a system means evaluating the probability of satisfactory performance of that system under specified conditions and given time. The engineering design is to create a balanced relation between optimization of maximum safety and minimum cost. Any method in design satisfying both aspects is very precious. These methods are identified as techniques for determining the reliability of system.

Today, it is common to express reliability in the form of a reliability index, which can be related to a probability of failure. The reliability index β provides a more meaningful measure of stability than the FOS. Geotechnical engineers have long recognized that FOS has little physical meaning and that the choice of a satisfactory value is fraught with difficulty. Conversely, the reliability index describes safety by a number of standard deviations (i.e. the amount of uncertainty in the calculated value of FOS) separating the best estimate of FOS from its defined failure value, that is to say 1.0. It is a more explicit approach.

β is the number of standard deviations by which the expected value of the factor of safety is away from the unsatisfactory performance condition, or the factor of safety equaling one. Obviously larger reliability index indicates the higher confidence of slope safety [11,12]. The reliability index can be computed by Eq. 3.

$$\beta = \frac{m_{FOS} - L}{\sigma_{FOS}} \qquad [3]$$

where m_{FOS} is the mean factor of safety, L is a limit state value usually equal to 1 and σ_{FOS} is the standard deviation of the factor of safety [13].

To determine the reliability index β, Monte Carlo simulation can be employed. Monte Carlo simulation is a method for iteratively evaluating both stochastic and deterministic systems using randomly generated points to cover the range of values that enter into a calculation. It is just one of many methods for analyzing uncertainty propagation where the goal is to determine how random variation, lack of knowledge, or error affects the sensitivity, performance, or reliability of the system being modelled. To perform such a study, the data analyst generates a random value represented by a probability density function, for each uncertain variable and performs the calculations necessary to yield a solution for that set of values. This gives one sample of the process. The trials are repeated many times, giving many samples of the process. Once a large number of runs have been completed, it is possible to study the output statistically and to obtain values of means, variances, probabilities of various percentiles, and other statistical parameters. Considering safety factor, repeating process continues until a distribution of factors of safety sufficient to define the probability of failure. Regarding to this, the probability of failure and reliability index is calculated [11,14].

5. ANALYSIS

Employing Monte Carlo simulation, a Python code is developed to evaluate the vegetation effect on slope stability. Discrete values of each variable interacting with slope stability are randomly selected from its probability distribution. Those distributions are depicted in Fig. 1 and 2. Using a set of such discrete values, a value of the performance function FOS is then obtained. This process is repeated many times. The accuracy of the results increases as the number of simulations is increased. Application of Monte Carlo simulation in geotechnical engineering and its extension to correlated variables has been demonstrated by Nguyen and Chowdhury [15,16].

Such uncertainties have systematic components. Systematic uncertainty includes statistical error in the mean due to insufficient number of tests or observations (small sample size) and bias in measurement methods. Over relatively short distances, the value of a geotechnical parameter may vary far more from the mean value than it does if averaged over relatively long distances. Thus, estimating the standard deviation of a geotechnical parameter requires careful analysis of data. Therefore, in this paper the Monte Carlo method was adopted to evaluate the stabilizing effect of vegetation in order to improve the economic efficiency as well as conserving environment.

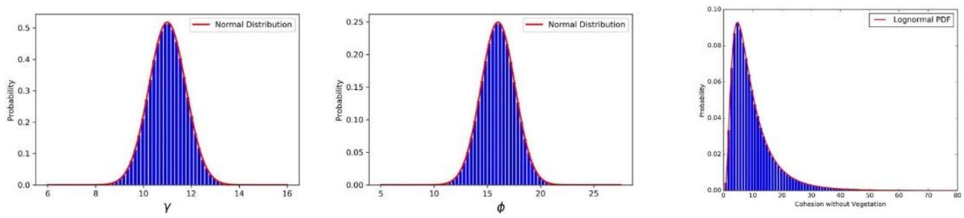

Figure 1. Probability distribution functions for parameters in unrooted system

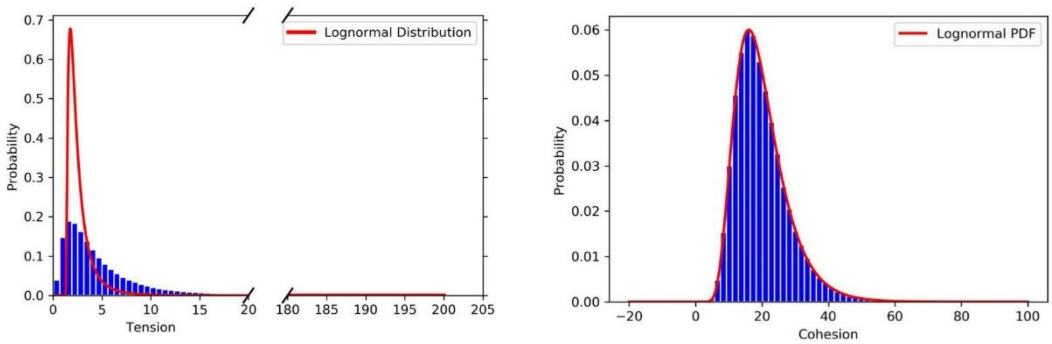

Figure 2. Probability distribution functions for additional parameters in rooted system (T and c_R)

Depend on the desired level of confidence in the solution, as well as the number of variables being considered, the number of required Monte Carlo trials is calculated from Eq. 4.

$$N = [\frac{d^2}{4(1-\varepsilon)^2}]^z \quad [4]$$

Where N is number of Monte Carlo trials, ε is the desired level of confidence (0 to 100%) expressed in decimal form, d is the normal standard deviation corresponding to the level of confidence illustrated in Fig. 3 and z is number of variables [17]. The standard deviation is considered 1.645 (with the level of confidence equal to 90%), subsequently the number of Monte Carlo trials will be about 20000000 for 4 variables (i.e. T, c, φ and λ).

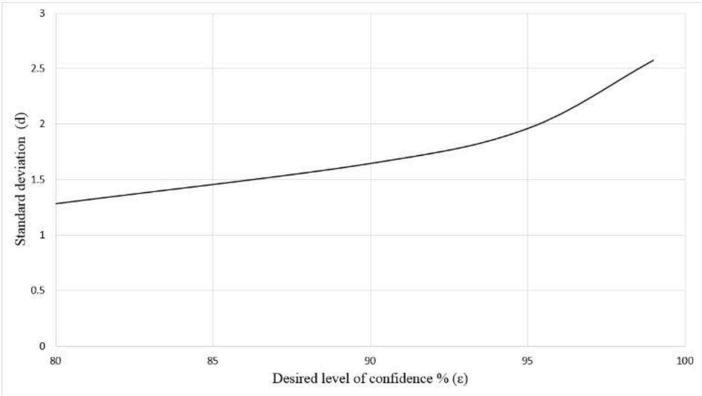

Figure 3. Standard deviations versus confidence levels

6. RESULTS AND CONCLUSION

Probability density function (PDF) and cumulative distribution function (CDF) diagram are plotted for without vegetation slope in Fig. 4 and 5.

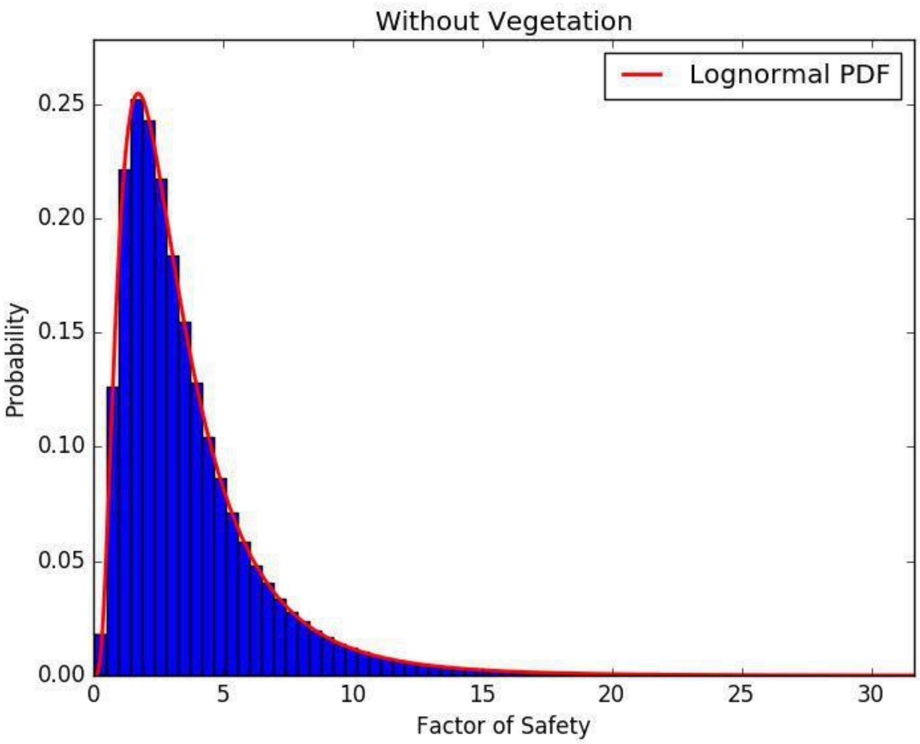

Figure 4. Probability density function of FOS for slope without vegetation

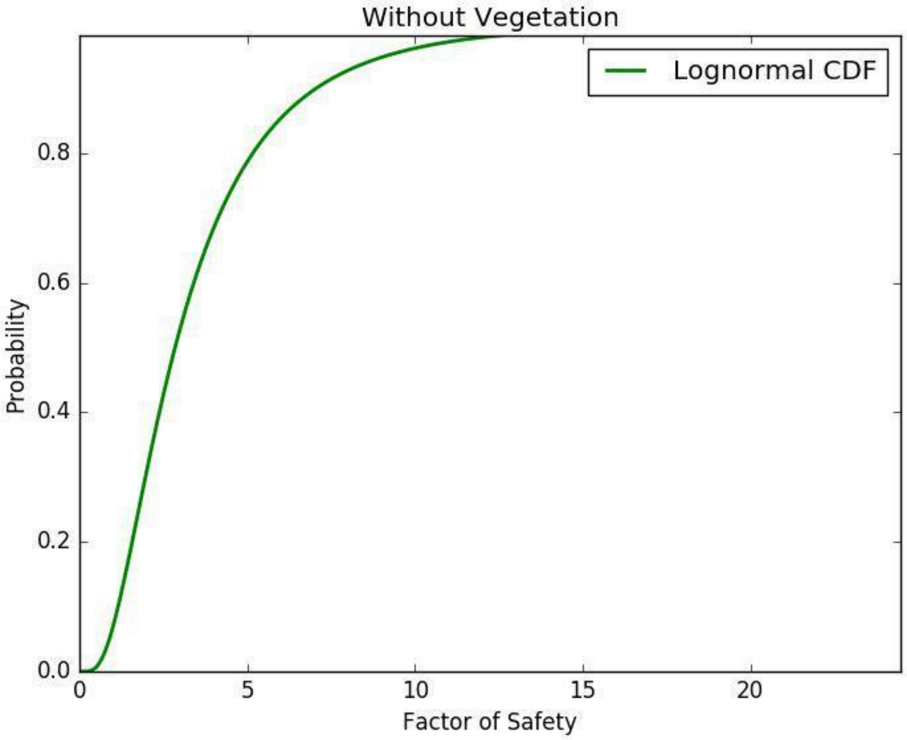

Figure 5. Cumulative distribution function of FOS for slope without vegetation

From these figures, it is observed that there is a chance for instability. For better illustration, failure probability is depicted in Fig. 6.

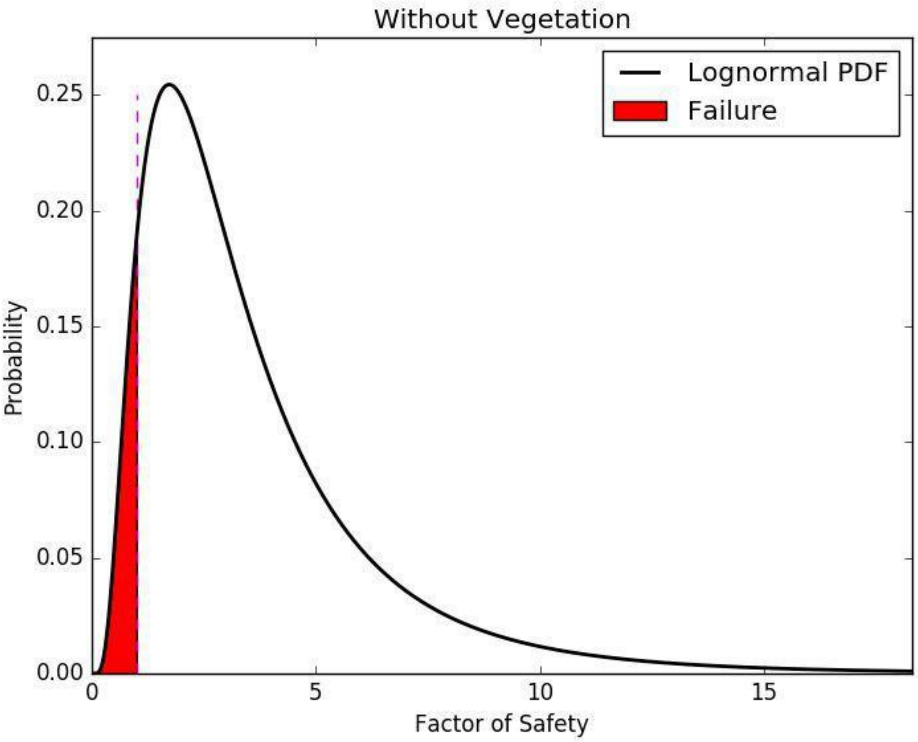

Figure 6. Probability density function of FOS considering failure

Correspondingly, PDF and CDF diagram of SOF in slope with vegetation are plotted in Fig. 7 and 8. Nevertheless, in contrast with the former diagrams the probability of failure is zero. It is demonstrated that vegetation has a stabilizing effect.

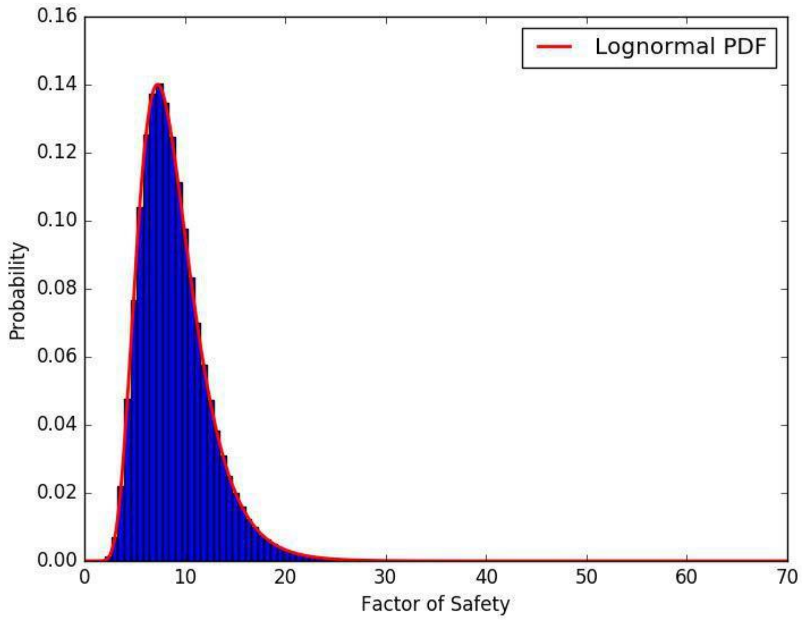

Figure 7. Probability density function of FOS for slope with vegetation

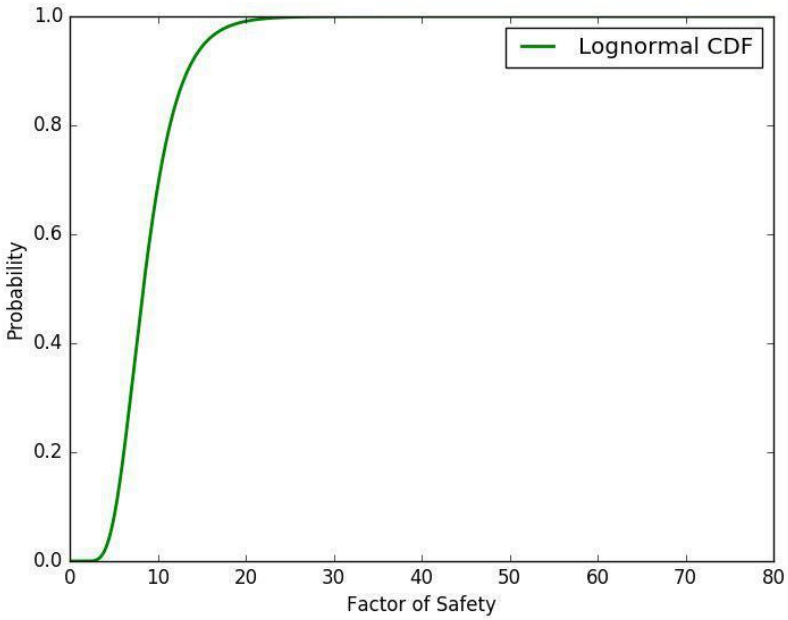

Figure 8. Cumulative distribution function of FOS for slope with vegetation

Comparing these diagrams, it is conspicuous that taking vegetation into account, FOS is significantly increases in the latter case.

For instance, the probability of FOS more than 5 is about 20% in slope without vegetation, yet, that is more than 90% in slope with vegetation. This is a substantial increase.

Based on PDF diagrams, the amount of m_{FOS} and σ_{FOS} are ascertained for both with and without vegetation system. Using these values, the reliability indexes against instability are as Table 2. There is a significant increase in the reliability index.

Table 2. Reliability index for both systems

System	m_{FOS}	σ_{FOS}	β
Without vegetation	2.841	2.027	0.907
With vegetation	8.372	1.440	5.166

Considering geotechnical uncertainty, the aim of this paper is to investigate the reliability of relationship between vegetation and slope stability in order to assess its benefits. A probabilistic analysis approach (Monte Carlo method) based on limit equilibrium employing Python programming was developed using random samples for each parameter generated. The overall results indicate that vegetation roots have a considerable stabilizing effect on the slope, limited to the rooting depth. It is appeared that through a matrix of tensile fibers, enhanced soil cohesion has a significant effect on slope stabilizing and the shallower the location of the sliding plane, the bigger the impact of vegetation.

SUMMARY

Landslide and lateral spreading may have severe impact on natural and man-made environment and there is a global concern about their prevention and mitigation. The resistance level of a slope against landslide depends on the materials and the properties it of which is composed. In this paper, enhanced shallow landslide resistance of a slope due to vegetation is investigated. Considering the failure modes and uncertainty in geotechnical parameters, it seems that using probability theory in slope stability is inevitable. Regarding the effect of vegetation phenomenon in diminishing the probability of failure and increasing the stability of reservoir slopes, it is necessary to evaluate slope safety level by conducting reliability analysis. Employing Monte Carlo simulation, a python code is developed and the effect of vegetation is investigated by limit equilibrium analyses. The results demonstrate that vegetation roots have a significant stabilizing effect on the slope, limited to the rooting depth. The reliability index substantially increases due to vegetation.

1. INTRODUCTION

The Republic of Indonesia is the largest archipelago country in the world about 13,466 large and small islands. Indonesia is straddling along the equator, situated between the continents of Asia and Ausralia and between the Pacific and the Indian Oceans. Lies between 95º - 141º East Longitude and 6º North to 11º South Latitude.

Currently, the number of watersheds in Indonesia is 131 river basins. This amount consist of 5 across the country, 29 across the province, 29 national strategic, 53 across districts, and 15 cities watersheds spreading around the country that more than 5,800 rivers, 500 natural lakes and 214 dams. Indonesia has 2 (two) seasons : dry and rainy seasons. Dry usually occurs from June to September and the rest is rainy season. The average annual precipitation varies 1,5000 mm in eastern region to 2,600 mm in the west.

Indonesia is the country that has huge water availability, it is about 3,909.6 billion m3/year about 2530 km^3 (no. 5^{th} water resources in the world). Although Indonesia include 10 water-rich country, but because of the season variations and spatial imbalances in water availability, requires good management of water resources availability specially in dry season such as constructing dam.
Beside having many benefits, dams construction also keep potential hazards that can endanger the lives at the downstream. The dams failure can cause major flooding and damage in the downstream area.

In accordance with Minister Regulation No. 27 / PRT / M / 2015 on Dams, dam safety role is intended to realize the orderly development and utilization of dams so be worthy of a technical or non-technical aspects from the design, construction, operation, decommissioning stages in order to prevent or reduce the potential failure risk of the dams construction with criterias are as follow:

a. Dam with 15 (fifteen) meters height or more, measured from the deepest foundation;
b. Dam with 10 (ten) meters height up to 15 (fifteen) meters, measured from the deepest foundation with the following provisions:
    1) The length of the dam crest at least 500 (five hundred) meters;
    2) The capacity of the reservoir at least 500,000 (five hundred thousand) cubic meters; or
    3) Maximum flood discharge at least 1,000 (one thousand) cubic meters per second; or
c. Dams with special difficulty on the foundation or dams designed with new technology and / or dams that have high hazard classification.

2. DAM DEVELOPMENT IN INDONESIA

Many dams in Indonesia are very old. It was built before Mid 80’s, some dams were even built before 1950, during the colonial time. Based on Minister Regulation No. 27 / PRT / M / 2015 on Dams, Indonesia has 214 dams are categorized as large dam until 2017. The latest dams that are on going in 2017/2018 are:

1. Bener Dam, Yogyakarta
2. Semantok Dam, East Java
3. Temef Dam, East Nusa Tenggara
4. Tigadihaji Dam, South Sumatera
5. Pamukkulu Dam, South Sulawesi
6. Margatiga Dam, Lampung
7. Sidan Dam, Bali

These dams are constructing specially for irrigation purpose, while for fulfill the national electricity demand, Indonesia has prepared 33 new dams integrated with National Hydroelectric which is expected to produce electricity of 2,300 MW by the State Owned Enterprise or private. And all dams development must go through the process of certification or approval in accordance with Minister Regulation No. 27 / PRT / M / 2015 on Dams.

3. DAM SAFETY APPROVAL PROCEDURE

3.1. GENERAL

In order to minimize the risk of dams development, each stages of Dam and reservoir construction and operation should be implemented based on dam safety conception of and the rules of dams safety contained in various norms, standards, guidelines and manuals to improve the usefulness of the source function water resources, water preservation, control of water damage, and the safety functions of tailing.

Dam safety concept in Indonesia was adopted by dam safety concept from Swiss Dam. The idea of dam safety concept is best provided when due consideration is given to the following tenets:

a. Structural safety, safety against structural, hydraulic, and seepage failure;
b. Operation, maintenance and monitoring; and
c. Emergency action plan.

In order to review the safety of the dams, the dams construction in Indonesia must obtain a license or approval, including:

1. Design.
   This permission / approval is intended to obtain technical design aspect. In this process also can be obtained the construction approval if the documents requirement attached.
2. The construction in preparation for reservoir initial impounding.
3. The reservoir initial impounding in preparation for the dam operation.
4. Decommissioning of the dam functions.

This permission / approval is filed if dams have been completed its life time.

3.2. DAM SAFETY ORGANIZATION

As stated in Ministerial Regulation Number 72/PRT/1997, in order to carry out the dam safety, Minister of Public Works and Housing was assisted by dam safety organization consisting of Dam Safety Commission and Dam Safety Unit.

Dam Safety Commission (DSC) provides recommendation and suggestion to the minister in charge of dam safety activities and responsible to the minister. The tasks of dam safety commission are as follow:

a. Giving the recommendation about dam safety to the minister in every phase of dam development such as design, construction, operation, rehabilitation, and dam closure.
b. Evaluating Dam Safety Unit activities in order to suggest to the minister
c. Preparing the accountability report to the minister

Dam safety commission member consists of representative of government and state-owned company as the owner of the dam, professional association and another government agency related to dam appointed by minister. The chairman of dam safety commission is Director General of Water Resources.

Based on structural organization, Dam Safety Unit is under Directorate General of Water Resources, Ministry of Public Work and Housing. The main duty of dam safety unit is to provide support about dam safety to DSC.

The tasks of Dam Safety Unit are as follow:

Provide guidance to technical regulations field of dam safety. Providing permit approval process and dam safety to all elements of the owners of their dams and reservoirs.

Implement programming and budget, regulations, guidelines and technical guidance to dam safety and performance evaluation.

Carry out periodic inspections, inspections extraordinary / special dam inspection and evaluation of data.

3.3. DAM SAFETY LISENCE

There are some steps to do to have dam safety license in every phase of dam development. After the construction finished, there are another dam safety license for rehabilitation or removal of the dam. As mentioned above, that the member of DSC come from various institution based on their competency. So, the discussion about dam safety could be as detailed as could be for making sure the dam is safe.

Here the explanation about the process of dam safety license. In figure 4, dam safety license start with sending application from the dam owner to the Minister c.q. Director General of Water Resources as the chairman of Dam Safety Commission. The report about dam should be sent to DSU to have first assessment. After that, the DSC, DSU and dam owner inspect the dam site and discussed it.

After inspection, the DSU reviewing the inspection result whether the reports are appropriate or not. If everything is going fine, then DSU, DSC, dam owner, consultant and/or contractor will take DSC technical meeting. In this meeting, it discussed about dam safety based on regulation, standard, guideline and manual in technical consideration.

After the dam owner complete the suggestion at the technical meeting, then the process continue to plenum meeting. The DSC members who attend the plenum meeting vary from some other institution, such as environmental, electricity, and geological agency, which are related to dam safety. If all the process is finished, the DSC would give recommendation to the minister. Then the minister will issue the license of dam safety. The documents which are sent to dam safety unit in order to get dam safety license in every phase of dam development and management will be brief explained below.

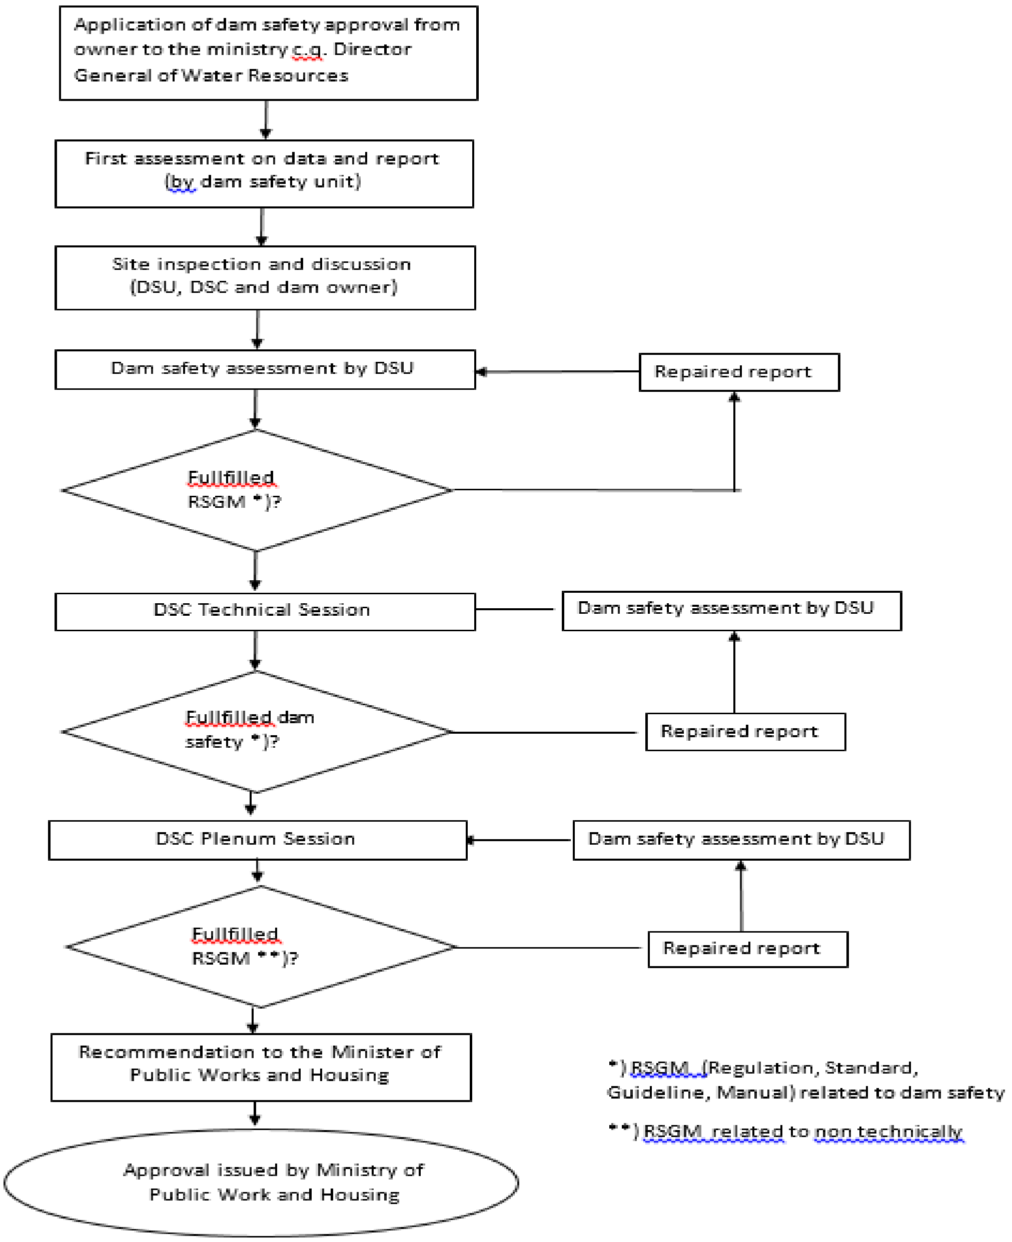

Figure 1.
Dam Safety License Flowchart

3.3.1. Design

The documents should be sent to Dam Safety Unit in this phase are:

A. Administrative requirements

   1) License of water uses
   2) Environmental license
   3) Land Acquisition and Resettlement Action Plan Report
   4) The location of dam should be stipulated in Urban Land Use and Spatial Plan

B. Technical requirements

   1) Feasibility study documents, which are contain of: main report, executive summary report, and another report which is support the feasibility study.
   2) Detail design documents, which are contain of: main report, criteria design, executive summary report, design note, design calculation, survey and investigation, hydrological report, model test report, construction method report, technical specification, operation and maintenance plan, budget plan, design drawing, etc.
   3) Detail design review (if available)
   4) Photos of dam location, borrow area and quarry area.

3.3.2. Impounding

The documents should be sent to Dam Safety Unit in this phase are:

1) Technical geology report based on the result of foundation excavation and additional investigation (if available)
2) Foundation treatment report
3) Alteration design report, including any judgment why the design should be changed (if available)
4) Quality control report, including test
5) The result of hydro mechanical equipment test in factory or in site, and also dry and wet test report
6) Project completion report. If the reports in number 1) to 5) are included in this report, so they didn't need to submit separately.
7) Surveillance program report include the result of instrumentation reading along the construction
8) Emergency action plan, flood warning system and the socialization to the downstream population
9) Impounding plan
10) Operation and maintenance organization include training for the operator
11) As built drawing
12) Construction photos

3.3.3. Operation

The documents should be sent to Dam Safety Unit in this phase are:

1) Result of instrumentation reading from construction until the latest reading
2) Dam behavior analysis based on instrumentation reading in number 1) and also inspection result in dam, reservoir and its vicinity, and appurtenance structure
3) Operation and maintenance manual which is has been adjusted based on the actual condition
4) Hydro mechanical operation report
5) Incidents and accidents report, such as earthquake, sliding, excess seepage, etc.
6) Executive summary report from impounding
7) Photos

3.3.4. Dam Closure

The documents should be sent to Dam Safety Unit in this phase are:

1) Detail planning about termination, demolition of dam (if needed), including environment restoration, and safety of the environment. If the dam body and its appurtenance structure didn't demolished, so maintenance and monitoring plan should be prepared include the operational organization.
2) Stability analysis for dam which is not demolished
3) Detail investigation about consequences or impact about dam removal for hydrology condition and hydraulically at the dam site
4) Environmental impact
5) Drawing
6) Photos

4. CONCLUSION

Approval of the construction and management of dams in Indonesia is divided into four phases, namely the approval of design and construction, the initial charge, operation, and closure dam. This is intended to minimize the risk of dam failure and function in accordance with the purpose of development as well as to ensure the safety of the dam.

5. ACKNOWLEDGEMENT

The authors would like to thank to Dam Safety Unit, Directorate General of Water Resources, Ministry of Public Works and Housing and INACOLD for the authorization to publish the main result of the present study.

1. NTRODUCTION

The Ahmadbeiglu Storage Dam site is located in Ardebil province (northwest of Iran) on the Meshginchay River. The main objective of the Ahmadbeiglu Storage Dam construction is to store for supplying water needed for agriculture, environmental and partially supply Meshginshahr domestic water demand.

Ahmadbeiglu Dam site is located at the upstream of several villages with more than 1000 population and failure of this dam will result in loss of human life, extensive property damage to homes and other structures, thus, ahmadbeiglu Dam is high risk.

In the spring of 2017, during the excavation of clay core foundation in the right abutment from elevation 980 m, seepage through this abutment observed. Since foundation behavior, especially soil foundations can significantly affect the stability of this kind of dams and internal erosion /piping through the soil foundation or along dam body-foundation is one of the leading causes of embankment failure, a technical team organized to evaluate the internal erosion potential and risks.

The potential of internal erosion through soil foundation can't be completely modeled or analyzed, the probability of this phenomena occurrence were evaluated by using the soil foundation strata, sealing method of dam and foundation, the results of dam and foundation analyses in different loading conditions (in this paper, the analysis is limited to static loading condition), evaluation of hydraulic gradient and finally the dam and foundation behavior after reservoir filling.

2. DAM AND DAM SITE DESCRIPTION

According to the geological studies, the right abutment of this dam is composed of two parts in terms of lithology. The upper part is weathered tuff in form of layered soils including clay, clayed sand and silty sand and then covered with variable thickness of fine-grained alluvial terraces (the thickness is between 3m and 20 m). The lower part is pyroxene andesite rock that is completely weathered and then moderate weathered pyroxene andesite. The foundation in left abutment is low to moderate weathering pyroxene andesite and consists of alluvial deposits of maximum 8.0 m thick in the middle of the valley.

As it previously mentioned, the right abutment is critical due to its strata. Thus, in this paper, the right abutment is our subject. In order to determine the soil foundation strata, permeability and density of the soils, ground water table and finally geotechnical parameters for dam design, geotechnical investigation including field and laboratory tests in 6 boreholes and 7 test pits in this abutment was performed in the feasibility and detail design studies.

According to the Unified Soil Classification System (USCS), and results of field and laboratory tests on the samples of the right abutment, the foundation soil is often in CL classification, soils with classification of SC, CH, SC-SM, SP-SM and SM have been observed as layer between soils with CL classification. The right abutment strata has been presented in Fig. 1.

The fine grained soils of the right abutment is considered as dense and very dense soils based on the results of Standard Penetration Test (SPT), Since the No. of SPT tests (N) are more than 30 and 50.

In order to determine the permeability coefficient of right abutment fine-grained material, lefrance tests were performed in one-meter stage with maximum 2.0 m intervals by using constant and falling head method. Corresponding to the results of lefrance tests, the average permeability coefficient of soils is 1.0e-6 cm/s and the variation of permeability coefficient is very low. Based on the lefrance tests, the right abutment fine-grained soils have been classified as low to very low permeable soils.

The maximum hydraulic gradient is 25 degree toward to the Meshginchay River. The ground water level has been presented in Fig.1.

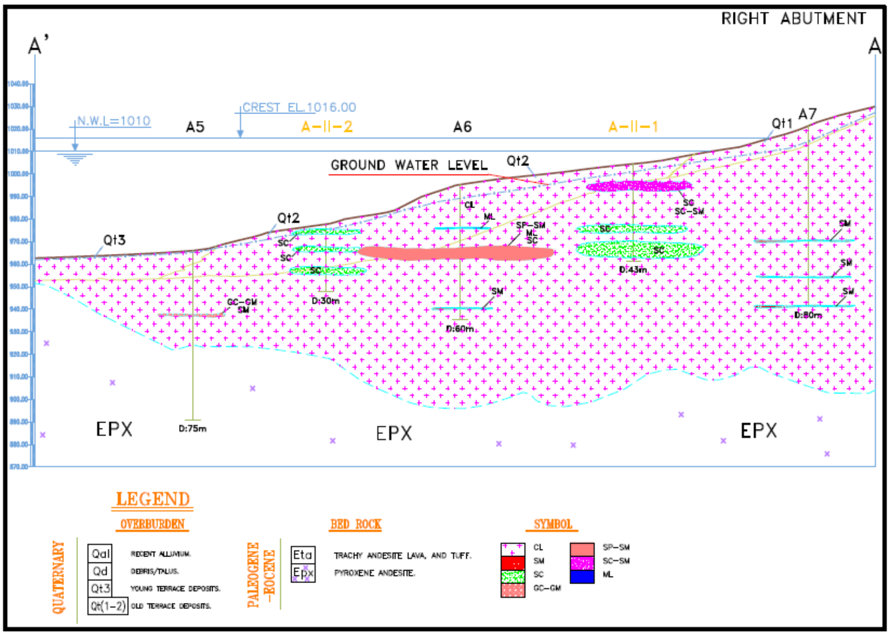

Fig.1.

The right abutment strata along dam axis

By considering the geological and geotechnical investigations and analyses of laboratory and field test, the right abutment strata, the alluvial terrace under clay core foundation in right abutment must be removed and replaced by a key trench as sealing element since the fine grained material of this abutment is generally classified as low to very low permeable material.

Ahmadbeiglu Dam and cofferdam are both earth fill with vertical clay core. Minimum, normal and maximum water levels in the reservoir are levels 971.5 m, 1010.0 m and 1013.3 m, respectively. The total reservoir volume is 27.4 Mm3. The dam crest is 10 m wide and 528 m long at elevation 1016 m. The maximum dam height is 58 m from riverbed and 65 m from foundation. The upstream slope is 2.5 H to 1.0 V from dam crest to elevation of 991 m, which corresponds to the stabilizing berm with 10 m width, then, continue with the same slope to natural ground. The downstream slope is 2.0 H to 1.0 V. The upstream and downstream slopes of cofferdam are 2.5 H to 1.0 V and 2.0 H to 1.0 V, respectively.

3. INTERNAL EROSION RISK ANALYSIS METHODOLOGY

The internal erosion risk analysis in right abutment of Ahmadbeiglu earth fill dam has been carried out in accordance with the methods of ''Dam Safety Risk Analysis Best Practices, 2009''. In this paper, the risk analysis is limited to evaluation of internal erosion in normal operation and the other loading condition (flood and seismic loading) has not been considered.

The risk analysis process consists of a) Identification of failure modes b) Estimation of probability of dam failure due to each failure modes c) Dam failure consequence d) Risk prioritization and risk control. It should be noted that, in this analysis, only life loss has been considered as dam failure consequence.

The probability of dam failure due to internal erosion has been determined based on event tree methods. In this method, all failure modes due to internal erosion are broken down in two four phases; initiation of erosion, continuation of erosion, progression of erosion and detection and finally breach. Thus, the probability of dam failure has been obtained by using below equation [1];

$$P_F = P_{Load} \times P_{Initiation} \times P_{Continuation} \times P_{Progression} \times P_{Detection} \times P_{Breac} \quad [1]$$

3.1. IDENTIFICATION OF FAILURE MODE

The failure of embankment dams by internal erosion or piping has been evaluated in three different modes including piping through embankment, piping through foundation and piping from embankment nto foundation.

3.1.1. *Assessment Of The Probability Of Dam Failure Due To Internal Erosion Through Soil Foundation (PF1)*

In order to evaluate the internal erosion through soil foundation, determination of soil classification and existence of continues layer in dam foundation is the first step. As it was mentation, in feasibility and detail design study, the foundation soil is classified as CL, SC, CH and layers of SC-SM, SM and GC-GM. In this stage, three bore hole which are located in upstream, axis and downstream of dam body has been drilled for determining of the soil classification, existence of continues layered soil and also permeability of the soil.

According to the results of field and laboratory tests, the foundation soil is often in CL classification; soils with classification of SC, SM, and ML have been observed as layer between soils with CL classification and these layers are approximately continues layer. In addition, the plasticity index (PI) of these layer is less than 7.0 (PI<7). Thus, internal erosion in soil foundation with continues cohesionless layer may initiate and progress due to backward erosion or suffusion (erosion of fine soils into adjacent coarse soils). The evaluation of internal erosion has been presented as following;

3.1.1.1. Initiation of backward erosion

In order to estimate the initiation of internal erosion by backward, the following issues have been evaluated;

- Estimation of heave occurrence probability at the toe of the embankment dam when reservoir is at normal level;

The probability of heave occurrence should be considered in areas of a thinner confining layer with a distance of 2 x dam height at downstream of dam toe. In order to estimate the probability of heave occurrence, the hydraulic gradient at toe of dam and critical hydraulic gradient should be determined. The hydraulic gradient at toe of dam can be calculated by using piezometers reading or results of seepage analysis and the critical hydraulic gradient are calculated by Terzaghi equation (1960). The gradient at the toe of dam in right abutment has been obtained from the results of seepage modeling ($i = 0.4$) and the critical gradient is equal to 0.9. The probability of heave occurrence has been estimated as 0.01 by using the judgment probability table and hydraulic gradient at the dam toe.

- Estimation of backward erosion occurrence probability with heave occurrence

The initiation of backward erosion is depended on the hydraulic gradient under the main part of dam. The other factors are particle size distribution/uniformity coefficient, permeability of the soil and the geometry of dam and foundation. According to the results of seepage analysis, the gradient is 0.4 and the uniformity coefficient is more than 6 ($C_u>6$), thus, the probability of backward erosion with heave occurrence is estimated as 0.1.

- Estimation of backward erosion occurrence probability without heave occurrence

For this purpose, the main factors are average hydraulic gradient, uniformity coefficient and permeability of continues layer. By considering the gradient equal to 0.4 and $C_u > 6$, the probability of backward erosion without heave occurrence is estimated 0.02.

From the results of the above assessment, the probability of initiation of backward is estimated 0.0208.

3.1.1.1.1. Continuation of backward erosion

In order to evaluate the continuation of backward erosion, the filtered or unfiltered exit should be assessed. In Ahmadbeiglu Storage Dam, the exit point of seepage is unfiltered but a blanket drain and toe drain system is present. In this dam, a low permeability layer is existent between blanket drain and erodible layer. By considering the mentioned condition and using probability judgment tables, the probability of erosion continuation is estimated 0.25.

3.1.1.1.2. Progression of backward erosion

In order to assess the probability of erosion progression, the following issues have been considered;

- Probability of the forming a roof of a pipe (PR); the roof of a pipe can be formed by layers of soil in the foundation which are cohesive or have high fines content. The erodible soil in foundation has been classified as SM, ML and SC with fine content more than 15%, thus, the probability of forming a roof of a pipe has been calculated as 0.7.

- Probability for no limitation of the flow (PL); the flow limitation can be performed by zoning within the dam, cutoff wall or other sealing elements in dams or foundation. In Ahmadbeiglu dam, the sealing element in right abutment is key trench. Therefore, the probability of no limitation has been considered as 0.01.

Thus, the probability of progression of erosion through the layered foundation has been calculated as 7e-3 (PP =P_R x P_L).

3.1.1.1.3. Probability of detection, intervention and repair fail

Determination of water level at the downstream of dam by using readout of observation well and open standpipe piezometer during construction show that the water level is normal. For more safe, four open standpipe piezometers in the downstream shell and right abutment and eight observation wells in downstream of dam body and right abutment have been installed in this stage besides the other instrumentations of dam body and foundation. By considering the installed instruments in dam body and foundation in right abutment and frequency of inspection (weekly or every two weeks), it is likely that the intervention on dam and right abutment would be successful. The probability of the intervention and repair not to be successful is considered unlikely (P=0.1).

3.1.1.1.4. Probability of breach in the layered soil foundation

Dam breach could be occurred by the following mechanisms in this dam;

- Breach by instability of downstream slope; since there is a blanket drain in downstream and downstream shell is free-drain material, so, the pore pressure will dissipate and the probability of breach by instability of downstream slope is estimated 0.02.

- Breach by sinkhole development; for this purpose, the loss of freeboard due to the settlement of embankment induced by the loss of foundation material should be determined. Since the settlement of dam is less than 1% dam height (according to the stress-strain analysis results), and freeboard is equal to 6 m, the freeboard at the time of failure is calculated 5 m, so breach by sinkhole develop is estimated 0.01.

The probability of breach in layered soil foundation due to the above mechanisms and engineering judgments has been estimated as 0.03.

3.1.1.2. Initiation of erosion by suffusion/internal instability in a cohesionless layer of foundation

Suffusion, or internal instability, involves the erosion of finer particles from the matrix of coarser soils, under the seepage gradient in the soil. For assessing the suffusion/internal erosion of soils, the particle size distribution and hydraulic gradient are the main factors. By using Fell and Wan (2004) method, and considering the particle size for D15 (0.08mm), D60 (0.3mm), D90 (0.8mm), the erosion initiation by internal instability is not possible in right abutment.

3.1.2. *Assessment of the probability of dam failure due to internal erosion from embankment into foundation (PF2)*

3.1.2.1. Initiation of erosion from embankment into foundation

In order to assess the erosion initiation from embankment into foundation, the existence of a coarse layer in the base or sides of key trench, initiation of scour or initiation of core material erosion by hydraulic fracture due to arching in a narrow key trench should be evaluated.

The probability of existence of a coarse layer in the base of key trench has been estimated as 0.5, by using the geology studies, mapping and photographs taken during construction. According to the results of laboratory tests on samples of the fine borrow area (clay core material), the material is not susceptible to erosion. The results of seepage analysis in a section located in right abutment showed that the maximum hydraulic gradient in the core-foundation contact is 1.4 that is less than allowable value. Therefore, the probability of initiation of scour in core-foundation contact in spite of existence of coarse layer and unfiltered exit is estimated as 0.01.

In addition, according to the results of static stress-strain analysis, occurrence of hydraulic fracture due to arching in key trench with slope 2H: 1V is very unlikely (p=0.005). However, the probability of initiation of erosion from embankment into foundation has been calculated 0.01.

3.1.2.2. Continuation of erosion from embankment into foundation

In order to evaluate the probability of erosion continuation from embankment into foundation, the presence of filter/transition zone in downstream of core or filtered and unfiltered exit should be determined.

As previously mentioned, the exit point in Ahmadbeiglu dam is unfiltered but there is a very low permeable layer between erodible layer and blanket drain. Also, there is a filter in downstream of clay core which the D15 filter ranges between 0.2 to 0.7 mm. According to reference [5] for some, excessive and continuing erosion, D15 filter should be between 0.7 to 5, 7 to 12 and 12 to 33 mm, respectively. By considering the mentioned factors, the probability for continuing for erosion has been estimated as 0.01.

3.1.2.3. Progression of erosion from embankment into foundation

For assessing the progression of erosion from embankment into foundation, the possibility of forming roof of the piping path and restriction of the flow in piping path in upstream of dam should be determined;

- *Probability of forming the roof of the piping path (P_R);*

For progression of erosion from embankment into foundation by forming a roof of a pipe path, the core material and erodible layer of soil foundation must be capable of forming and holding the roof of a pipe. The fine content of core/soil foundation (% passing sieve #200, 0.075mm), the plasticity of the soils and the saturation of the soil are the most important factors in forming a roof. According to the grading curve of core material, the fine content of core material is between 30 to 85 % , the average plasticity index is 23 and the fine content of erodible layer of foundation is >15 %. Therefore, by using the reference table and the material characteristic, the probability of forming a roof has been calculated as 0.9.

- *Probability for no limitation of the flow (P_L);*

In this dam there is a filter and transition zone with fine content < 5% that cannot support a roof in upstream side of core, and also, the hydraulic gradient in upstream side of core is less than 1.0, thus, the probability of no limitation of flow is estimated as 0.01.

However, by considering the results of above assessment, the probability of progression of erosion from embankment into soil foundation is obtained 0.009 ($P=P_R \times P_L$).

3.1.2.4. Breach in the embankment or from embankment into foundation due to erosion

In order to assess the probability of breach in the embankment or from embankment into foundation due to erosion, the following aspects should be evaluated;

- Breach by instability of downstream slope;

For this purpose, the pore pressure rising or dissipation in downstream shell should be evaluated. In this dam, there is a filter and transition zone in downstream of core, the downstream slope is 2H: 1 V, and the fine content of downstream shell is < 8 %. Thus, the probability of breach by instability of downstream slope has been estimated as 0.02.

- Breach by sinkhole development;

The probability of breach by sinkhole development is estimated as 0.01 since the clay core material is well graded and the plasticity indices are low to medium, therefore, the core material is not susceptible to form a large void in dam and finally form a sinkhole.

The probability of breach in embankment or from embankment into foundation due to erosion has been calculated as 0.03 by using the results of above assessment.
Finally, the probability of dam failure by erosion from embankment into layered soil foundation is 1.35 e -8.

3.1.3. *Assessment of the probability of dam failure due to internal erosion through embankment (PF3)*

3.1.3.1. Initiation of piping through embankment

According to the results of laboratory tests on samples of fine borrow areas, especially clay size fraction and plasticity index, the probability of erosion initiation by backward or suffusion through embankment is negligible. But, erosion can initiate by concentrate leakage in low stressed zones which may be caused by differential settlement and arching or high permeability zone due to poor compaction. According to the static stress-strain analsis of Ahmadbeiglu dam, evaluation of arching and hydraulic fracturing, and construction quality, the probability of erosion occurrence in this dam is estimated as 0.02.

3.1.3.2. Continuation of piping through embankment

As it was mentioned, a protective filter in downstream of clay core is present with D15 between 0.2 and 0.7 mm. According reference [5], the probability of continuing erosion has been considered as 0.01.

The probability of progression, failure to detect, breach is the same as for erosion from embankment into foundation. Therefore, the probability of failure due to erosion through embankment has been estimated as 5.4e-9.

4. CONCLUSION

According to the geology and geotechnical studies, the results of field and laboratory tests and the dam site investigation, the right abutment of this dam site has been considered as layered soil foundation and the internal erosion was the most important factor in dam failure. In order to assess the probability of dam failure due to erosion, three failure modes have been evaluated as failure by erosion through layered soil foundation, erosion from embankment into soil foundation and erosion through embankment.

All failure modes have been assessed (reservoir is considered to be in normal level) and the probability of their occurrence have determined. In order to categorize the internal erosion risk, f-N event chart has been used. On the f-N chart, f and N represent the annualized failure probability and the estimated life loss associated with an individual failure mode, respectively. The f-N chart has been presented in Fig.3.

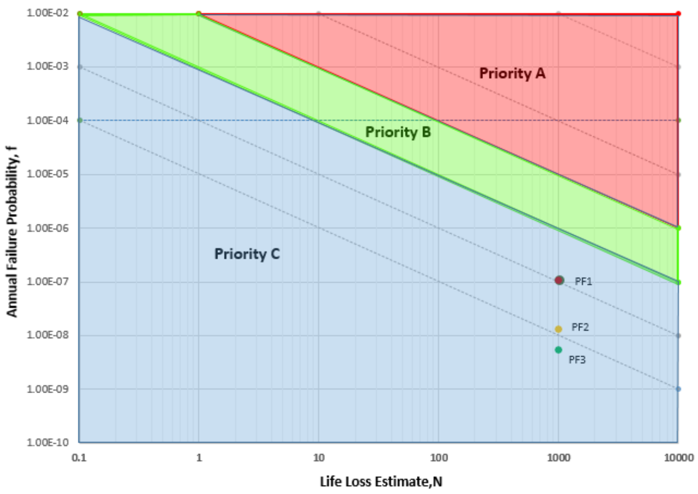

Fig. 3.
The f-N diagram of risk analysis results

Where;

Priority A- Justification to take expedited action to reduce risk

Priority B- Justification to take action to reduce risk

Priority C- Diminishing justification to take action to reduce risk

As it can be seen, the most critical risk comes from erosion through layered soil foundation (PF1), but all the risks of dam failure by erosion in right abutment of Ahmadbeiglu dam is in Priority C that indicate a reduced justification for risk reduction action related to these failure modes.

For increase safety, in addition to the instruments of dam body and foundation in right abutment, instruments such open standpipe piezometers (at the downstream of clay core and foundation) for checking pore water pressure in foundation and downstream of clay core and observation wells (at the downstream of dam body and right abutment) for evaluation ground water level at the downstream and right abutment have been installed.

ACKNOWLEDGEMENTS

The authors appreciate the cooperation of the Ardebil Regional Water Authority and Pooyab Consulting Engineers. The authors would also like to acknowledge Engineer Nosratollah Mostofi, the head of geology department of Pooyab Consulting Engineer, for providing of geological information of Ahmadbeiglu Storage Dam Site.

1. INTRODUCTION

The Yangtze River flows for 6,300 kilometers. It is the third longest river in the world. The Yangtze River Basin is a world hot spot of biodiversity, inhabited by over 400 fish species, of which some 350 are freshwater fish and up to 156 are endemic fish (Cao, 2011). Human activities such as water engineering and reclamation have led to changes in the aquatic inhabit, which then affect the reproduction and multiplication of aquatic organisms; the destruction of aquatic communities in turn affects the environment that humans depend on for survival. At present, the major hydroecological risks facing the Yangtze River Basin include decline in aquatic biodiversity, partial loss of biological habitats, water pollution, and reduction in river connectivity.

2. DECLINING AQUATIC BIODIVERSITY

2.1. REDUCTION IN SPECIES NUMBER

The Yangtze River is a wide diversity of unique species, when flooding occurs, provides us with abundant aquatic organisms. Flooding may be a disaster for human beings, but it provides us with precious hydropower. Dams and sluices are extensively built in the middle and lower reaches to control flooding; and tens of thousands of dams are built to meet the excessive demand for hydropower. Besides, excessive demand has given rise to overfishing in open waters. As a result, the pristine Yangtze River ecosystem was damaged. Many species are threatened with extinction and biodiversity faces an unprecedented crisis. The middle and lower reaches was once abundant in *Lipotes vexillifer,Neophocaena phocaenoides*, *Tenualosa reevesii*, *Lucpobrama macrocephalus,* and *Longjaw grenadier ancho.* Today, *Lipotes vexillifer* and *Lucpobrama macrocephalus* are hard to find. *Tenualosa reevesii* has dropped significantly since the 1970s, falling to a record low in the early 1980s. Few *Longjaw grenadier ancho*, once the main fishing target, has been spotted in recent years (Li Sifa 2001). *Neophocaena phocaenoides* resources are being exhausted from about 2,700 in 1991 to about 550 in 2015 (*Bulletin of Fishery Ecology in the Yangtze River Basin (Trial)*, 2015). Compared with the 1970s, fish species of Dongting Lake and Poyang Lake decreased by 33.7% and32.6%, and the proportion of migratory fish decreased by 47.1% and 53.6%. In 1970's, 336 and 310 bird species once lived around Dongting Lake and Poyang Lake, but surveys conducted in recent years showed that only 70-80 species have survived. Since the 1990s, the number of endangered species has seen a dramatic increase.

2.2. SHRINKING POPULATION

Yangtze River Basin is the most important producing area of freshwater fish in China (Yu, 1988a). The fish catches reached 450,000,000kg in 1954, accounting for 72% of the total national freshwater catches. It dropped to over 200,000 tons in the early 1980s, accounting for only about 60%. In recent years, it has maintained about 100,000,000 kg.

The production of semi-migratory fish of black carps, grass carps, silver carps, and bighead carps in rivers and lakes also dropped significantly. In 1964-1965, the annual average egg-laying amount of the Four Major Chinese Carps in the mainstream of the Yangtze River reached 115 billion. In 1981, it fell by 85% to 17 billion (Liu and He, 1992, Survey Groups of the Four Major Chinese Carps' Spawning Sites in the Yangtze River, 1982).

The natural fishery yield of Dongting Lake and Poyang Lak once reached a record high of 55,000,000kg. In 2015, it dropped to 28,000 tons in Dongting Lake and to 25,000 tons in Poyang Lake. The proportion of the Four Major Chinese Carps decreased from 21.0% to 6.61% and from 12.7% to 3.1% in Dongting Lake and Poyang Lake.

2.3. MINIATURIZATION AND HIGH MORTALITY AMONG INDIVIDUALS

In the 1970s, the average weight of two brass gudgeon species living in the Three Gorges Reservoir was about 500g (Ding, 1987). In 2000, the average weight of the two gudgeon species dropped to 276g and 208g, respectively (Chen et al., 2002). During 2005-2006, the average weight of two gudgeon species dropped further to 131g and 171g (Wu et al., 2007). The average ages of the Four Family Carps were 2.34, 2.10, 2.13, and 1.77 years. Compared. with the data of the 1970s, fishery catches size was down significantly, and most of them were medium or small-sized young fish (Chen et al., 2002).

In Poyang Lake, small-sized commercial fish are on a general rise, and individuals tend to be younger and smaller. In 2007, there were about 12 major commercial fish species in the survey, those lake-inhabiting species such as carps, crucian carps, yellow-head catfish, and catfish are the main fishing targets, accounting for 71.3% -77.26% of the catches. The majority were 1-2 years old, accounting for 76% of the total catches.

2.4. DEGRADATION OF GERMPLASM RESOURCES

In freshwater aquaculture, population blend has led to the degradation of germplasm resources. As a result, over fishing, breeding parents generally tend to be small-sized. Typical examples include silver crucian carps "giving only one times birth" to multiply and germplasm degradation among *Eriocheir sinensis* due to germplasm blend. Moreover, these degraded germplasm resources face the ecological risk of hybridization when they meet natural populations in the Yangtze River. As is the case with invading alien species, so far no relevant mechanism for assessing ecological risk is available in the country.

3. PARTIAL LOSS OF ENVIRONMENTAL CONDITIONS IN HABITATS

For many reasons, wetland degradation in the Yangtze River Basin has been severe for over half a century, and wetlands as important habitats of fish and waterfowl are gradually losing their environmental conditions. According to statistics, more than 1/3 of the lake areas, up to130km^2, in the middle and lower Yangtze River have been reclaimed since1949. More specifically, Dongting Lake dropped sharply from 43.50 km^2 to the current 26.25 km^2; Poyang Lake decreased from 52km^2 in 1949 to the current 29.33 km^2. Apart from this, almost all riverine wetlands in the middle and lower Yangtze River have been reclaimed, and about 12.13 km^2 of wetland has been affected.

Changes have occurred in fish composition and structures after the impoundment of the Three Gorges Reservoir. In 1997-2002, 127 fish species were commonly spotted. In 2005-2006, 108 fish species were surveyed. In 2017, only 71 fish species were discovered, accounting for only 31%-33% of the endemic fish at the upper Yangtze River. Some rapid-loving fish, such as *Coreius* *guichenoti*, *Rhinogobio cylindricus*, and *Rhinogobio ventralis*, migrated from the still-water sections of the reservoir area to the flowing-water river sections of the upper reaches of the river indication of the shrinking habitat space and an indirect cause of population reduction among these fish (Wu Qiang et al., 2007).SHRINKING POPULATION

4. INCREASED WATER POLLUTION AND LAKE EUTROPHICATION

According to statistics, sewage discharge in the Yangtze River Basin has risen from 12.7 billion m^3 in the early1980s to the current level of 15 billion m^3, accounting for about 40% of the national total. Urban sewage treatment is inefficient, and a large amount of untreated sewage is discharged into various water bodies, causing varying pollution. The middle and lower reaches of the Yangtze River, 4, 000 lakes here are larger than $0.5km^2$. Five most famous freshwater lakes are located in the economic development zone in China. 5.6% are oligotrophic, 44.4% are mesotrophic, and 50% are eutrophic. More than half of them, especially those in suburban areas, have been affected by eutrophication. Taihu, Chaohu, and Dianchi Lakes are typical heavily polluted lakes (*China Environmental Quality Report*, 2011). For a vast majority of the lakes in the Yangtze River, sluices and embankments separate them from rivers. Poyang and Dongting Lakes are the only large lakes that are still linking to the River.

5. REDUCED RIVER AND LAKE CONNECTIVITY

Today, it has a lake area of about 15,200km2 in Yangtze River, which accounts for 1/5 of the national area. Historically, more than 100 lakes larger than 10km2 originally connected with rivers. Since the 1950s, due to massive construction of water conservancy projects and artificial reclamation, the longitudinal, horizontal, and vertical connectivity of the river systems in the Yangtze River Basin has been, in varying degrees, damaged.

5.1. RECLAMATION AND SLUICES AFFECTED RIVER-LAKE CONNECTIVITY

For a vast majority of the lakes in the Yangtze River, sluices and embankments separate them from rivers. Poyang and Dongting Lakes are the only large lakes that are still linking to the River

Table 1 Factors Affecting the Connectivity between Lakes -Rivers in the Middle and Lower Yangtze River

Lake Name	Year of Blocking	Reason for Blocking	Lake Name	Year of Blocking	Reason for Blocking
East Lake	1930	Reclamation	Wang Lake	1975	Embankment
Caisang Lake	958	Reclamation and Embankment	Chihu Lake	1983	Embankment
Taibai Lake	1942	Embankment	Saihu Lake	1983	Embankment
Datong Lake	1951	Reclamation and Embankment	Junshan Lake	1959	Sluice
Huanggai Lake	1959	Embankment	Wuchang Lake	1959	Sluice

Zhangdu Lake	1954	Sluice	Chaohu Lake	1959	Sluice
Daye Lake	1970	Sluice	Gucheng Lake	1971	Sluice

5.2. THE DAMS AFFECTS THE UPPER STREAM-DOWNSTREAM CONNECTIVITY

Dozens of migratory species, such as *Coreius heterodon*, *Coreius guichenoti*, *Leptobotia elongata*, migrate to the middle and upper reaches to lay drifting spawn. Most of their spawning grounds are distributed in the upstream, and their eggs drift dozens or even hundreds of kilometers to the lower reaches for fattening. Another good example is the typical river-lake migratory species of "four major Chinese carps". By 2005, 45,694 reservoirs of various types had been built in the Yangtze River Basin. Dam construction obstructs the migration routes and blocks the migration passageway between the feeding zone and reproduction zone, preventing fish from effectively completing their life history and often resulting in serious decline in resources for these fish species. If these fish do not have spawning grounds in the main channel below the dam, the effects can be very serious and even lead to their extinction.

5.3. LOSS OF LONGITUDINAL AND VERTICAL RIVER CONNECTIVITY

An integrated river ecosystem includes riverways, floodplains, deep pools, shoal patches, and tributaries. During the flood season, fish follow the flow and swim to bottomland to spawn, forage, and avoid hazards. Reservoirs and Dams cut off the link between rivers and bottomland or floodplains, limits the horizontal spread of water flow, and results in decrease in horizontal river connectivity and habitat loss for aquatic organisms. In addition, transforming rivers into channels and cutting off curves have completely changed the basic landform of meandering rivers, and the pattern in which rapid and slow flows alternate disappeared. The regular geometric changes on the cross-section also altered the pattern in which deep pools and shoal patches alternate. As the habitats heterogeneity was reduced, aquatic ecosystems were changed and biological diversity was reduced accordingly. This is embodied by shrinking areas of riverside vegetation and plants, reduced biodiversity in micro-habitats, altered spawning conditions for fish, changes in the habitats of birds, amphibians, and insects, or disappearance of shelters, which may lead to reduced populations and the extinction of some species.

6. EXISTING PROTECTIVE MEASURES FOR AQUATIC ECOSYSTEMS

6.1. LAWS AND REGULATIONS

By 2005, 9 laws on the protection of the ecological environment and 15 laws on the protection of natural resources has enacted, and more than 660 regulations and local laws have enacted and passed. Seven fish species in the Yangtze River Basin are under national-level protection, the first-class protected animals Dabry's sturgeon, Chinese sturgeon, and Chinese paddlefish; the second-class protected animals huchobleekeri, Chinese high fin banded shark, trachidermusfasciatus, and anguillamarmorata (Law of the People's Republic of China on the Protection of Wildlife, 1989); 69 fish species are included in the China Species Red List at or above the endangered level; aquatic animals listed under first-class protection include Yangtze River Dolphin, finless porpoise, and bank beaver, giant salamander etc. are under second-class protection.

6.2. CONSERVATION AREAS AND ACHIEVEMENTS

By 2004, 561 nature reserves have been established in the Yangtze River Basin, covering a total area of $32.88\times10^4 km^2$, accounting for 18.3% of the Basin area. Among them, 59 are state-level with an area of $22.89\times10^4 km^2$; 202 are provincial-level with an area of $6.44\times10^4 km^2$; 59 are aremunicipal-level with an area of $1.74\times10^4 km^2$; 241 are county-level nature reserves with an area of $1.81\times10^4 km^2$. Nature reserves are distributed along the upper reaches and the mainstream as well as at the mouths. So far, a network of diverse nature reserves with a rational layout and complete functions has taken shape in the Yangtze River Basin.

In order to effectively protect and make rational use of aquatic germplasm resources and promote the sustainable development of fishery, the Ministry of Agriculture has selected a number of fishing and breeding areas as well as major growth and breeding areas such as spawning grounds, feeding grounds, overwintering fields and migration routes as protected areas of aquatic germplasm resources. Until 2017, there are 228 national conservation areas of aquatic germplasm resources in the Yangtze River Basin.

6.3. ARTIFICIAL BREEDING AND RELEASE

As Artificial breeding and release is an important measure to mitigate the adverse impact of water engineering on aquatic resources, breeding and release stations are often correspondingly planned while the hydropower stations is under construction. In response to the decline in fishery resources, the Ministry of Agriculture organized long-term, systematic release activities mainly in the middle and lower reaches of the Yangtze River. The released offspring seeds are normally provided by local fishery production organizations. Among them, seed multiplication and stock seed farms of aquatic germplasm resources play a significant role. According to incomplete statistics, the Yangtze River Basin has 26 stock seed farms and seed multiplication farms.

6.4. RESTRICTIONS ON FISHING

Restricting fishing is the core of fishery resources management on the Yangtze River. The policy was released by the Ministry of Agriculture since 2002. The enforcement scope of the policy of closed fishing season on the Yangtze River sections in 10 provinces (cities) with a total length of more than 8,100 km. Specifically, the mainstream, the tributaries, the Poyang and Dongting Lake areas. During the closed fishing season(February 1 to April 30 above Gezhou Dam; April 1 to June 30 below Gezhou Dam), all the fishing activities are banned.

According to the research results of Shi Weigang et al. (2005), after the implementation of the fishing ban, species diversity index increased significantly and stabilized in the Anhui and Jiangsu sections from 2001 to 2004. The CPUE (catch per unit of effort) in some sections of the river increased significantly, the CPUE of coiliaectenes rebounded, and resource degradation was stopped. The ecological effects of the spring ban on the protection of fishery resources in the middle and lower reaches of the Yangtze River are noticeable, and the interspecific structure of the fishery resources was improved to a certain extent after the implementation of the spring ban.

6.5. FISH PASS STRUCTURES

In 1958, China designed its first fishpass at Qililong Power Station on the Fuchun River. In 1960, the first newly opened fishpass was built near Xingkai Lake and it has a total length of 70m and a width of 11m, and initial operations were successful (Song Dejing et al., 2008). The construction of Yangtang Fishpass in 1980 has taken the design and research on fish pass structures in China's fish collection system. For example, according to statistics gathered in 1982, the total number of fish that passed through the fishpass was 759,325 (77d, 1464h), and 571,143 (77d, 1415d) passed through the fish collection system in the plant, accounting for 75% of the total number of fish that passed through (Wang and Guo, 2006).

With the further development of water conservancy and hydropower projects in China since 2000, more attention was given to the research on the restoration of fish migration routes. A number of fish pass structures are under construction or have been completed, such as the Shangzhuang Reservoir Fishpass in Beijing, the Xinglong Fishpass on the Hanjiang River, the Pengshui Hydropower Station Fishpass on the Wujiang River, the fishpass on the Pearl River and Shiquan River(Hu et al., 2008). According to incomplete statistics, China has built more than 40 fishpasses in various types of water conservancy projects, most of which are built on low water head dams.

7. CONCLUSION AND SUGGESTIONS

The development of the Yangtze River Economic Belt, supported chiefly by the Yangtze River golden waterway, is in full swing. This will undoubtedly place the maintenance of the Yangtze River's biodiversity and the protection of the water environment under unprecedented pressure. We need to analyze the current crisis from a historical perspective because biodiversity in today's Yangtze River system is not inherent but a product of evolution. The subtropical monsoon climate is the basis of the unique biota of the Yangtze River, and the East Asian monsoon climate is the result of the uplifting of the Qinghai-Tibet Plateau, at least it strengthens the monsoon. These major climatic and geological events are important basis for the evolution of biodiversity. They reveal the uniqueness and ecological needs of the ichthyofauna, as well as how species diversity is maintained. The knowledge of the historical contributing factors to species diversity is essential to understanding why human activities have led to a significant loss of biodiversity in water systems. We need to understand the space-time continuity (eg, connectivity of rivers and lakes) and the integrity of ecological processes (eg, hydrological processes, temperature processes) needed by each species to accomplish life histories. Accurate prediction of what species are endangered is hard to come by, not to mention saving them. Our target goal is to rehabilitate or re-naturalize damaged ecosystems, which, though basically impossible in large rivers, is still worth the effort because it at least delays or reverses the decline of some aquatic animals or the danger of extinction facing them (Xie Ping, 2017).

SUMMARY

The Yangtze River flows for 6,300 kilometers. It is the third longest river in the world. The Yangtze River Basin is a world hot spot of biodiversity, inhabited by over 400 fish species, of which some 350 are freshwater fish and up to 156 are endemic fish. Increasing human activity in the Yangtze River Basin has led to changes in the habitats that aquatic organisms inhabit, which then affect the reproduction and multiplication of aquatic organisms; the destruction of aquatic communities in turn affects the environment that humans depend on for survival.

The major hydroecological problems and risks facing the Yangtze River Basin today include decline in aquatic biodiversity, partial loss of environmental conditions in biological habitats, aggravation of water pollution, and reduction in river connectivity. The decline in biodiversity is reflected mainly in decrease in species number, shrinking of population, miniaturization and high mortality rate among individuals, and degeneration of germplasm resources. The main reasons leading to the decline in biodiversity include reclamations, sluices, or embankments that reduce the connectivity of rivers and lakes; the construction of reservoirs across rivers lowers upstream-downstream connectivity; embankments turn rivers into channels, resulting in loss of vertical connectivity.

In the face of the hydroecological problems and risks prevalent in the Yangtze River Basin, China has, over the years, enacted 9 laws concerning ecological improvement and environmental protection, 15 laws for the protection of natural resources, and over 660 regulations at all levels of government. In addition, efforts at natural conservation have been redoubled, such as promoting the development of protected areas and taking measures like artificial fecundation, release of fish, restricting fishing, and construction of fish pass facilities. However, as development projects in the Yangtze River Basin continue to grow, existing measures may not be able to delay or reverse ecological recession and more time is needed to test them.

1. INTRODUCTION

The failure of dams with large reservoirs can be the cause of catastrophic accidents with very important losses of human lives and of material and environmental assets. For these reasons, the safety control of these constructions is regulated and followed by national authorities, considering the structural, hydraulic-operational and environmental aspects. In Portugal, the national authority is technically helped, with the dams that involve major risks, by the National Laboratory for Civil Engineering (LNEC).

The structural safety control of dams begins in the design phase and ends only with its decommissioning. This control is based on regular inspections and on the comparison between monitoring data, obtained through the instrumentation installed according to the monitoring plan (defined during the design phase and updated during the dam's lifetime), and results of models, usually numerical ones, considering the most important characteristics of the structures, such as the geometry and the material properties, and the main actions.

The first filling of the reservoir, as a load test for the real operational conditions of the dam-foundation-reservoir system, requires special monitoring. The safety control activities during this period are very important not only to avoid accidents and incidents, but also to acquire knowledge about the structural behaviour of the dam which will be a reference during its lifetime. The safety regulations of almost all developed countries determine special monitoring programmes during this particular phase.

This paper presents some relevant results of the structural safety activities performed during the first filling of the reservoir of Baixo Sabor dam. After a brief description of the dam and its construction, the monitoring system, the monitoring plan during the first filling of the reservoir and some important results of tests carried out for the characterization of the material rheological properties are presented. The interpretation of the monitoring results is based on their comparison with results of a numerical model that simulates the structural behaviour of the dam and its foundation.

2. BRIEF DESCRIPTION OF THE DAM

2.1. BAIXO SABOR HYDROELECTRIC SCHEME

The Baixo Sabor hydroelectric scheme, in which the dam is integrated, is located on the Sabor river, in the north eastern part of Portugal. The scheme was designed and built by EDP Produção [1], and has been operated by this company.

The scheme mainly consists of the dam, the underground powerhouse, excavated in the rock mass of the right bank, which includes the water intakes and the headrace tunnels upstream, as well as the tailrace tunnels downstream. The total installed power capacity is 171 MW, using two reversible units.

The rock mass, on which the scheme was built, is of a good quality granite. However, it showed heterogeneous characteristics along the dam insertion surface as well as in the underground structures.

2.2. DAM CHARACTERISTICS

The dam is a double curvature thick arch dam (Fig. 1) with 123.00 m high and a crest development and thickness of 505 m and 6.00 m, respectively. The crest and the normal water level (NWL) are at elevations 236.00 m and 234.00 m, respectively. The structure is divided into 32 blocks with approximately 15 m width near the right and the left banks and with 17 m width in the central blocks. The blocks are separated by vertical contraction joints, which were grouted to obtain a monolithic structure, after forced cooling of the concrete blocks. The dam has six horizontal inspection galleries spaced 20.00m in elevation. The reservoir volume is of about 1095 hm^3 for the NWL [2].

Fig. 1
Aerial view of Baixo Sabor dam after the first filling of the reservoir

2.3. DAM CONCRETE

The dam has a total concrete volume of, approximately, 670,000 m^3. The 32 blocks were cast in 2.0 m height layers. The placement of concrete began in 2011 and ended in 2013.

The cementitious materials were Portland cement CEM I 42.5R and a class F fly ash. The fine and the coarse aggregates were granitic, obtained by crushing the rock from a quarry located on the right bank of the river, upstream. The concrete mixtures presented in Table 1 correspond to the concretes most used in the dam.

Table 1
Dam concrete compositions

Constituents (kg/m^3)	Face concrete	Core concrete
Cement I 42.5R	130	110
Fly ash	130	110
Fine aggregate 0/4.75 mm	637	640
Coarse aggregate 4.75/150 mm	1293	1414
Admixture	1.04	0.88
Water	133	124

For the dominant dam’s concrete, the following BaP creep law was adjusted, considering the results of a set of “in situ” and laboratory tests [3],

$$J(t,t_0) = \frac{1}{40.0}\left(1 + 3.2(t_0^{-0.35} + 0.05)(t - t_0)^{0.12}\right) \qquad (GPa^{-1}) \qquad [1]$$

which is represented in Fig. 2 for three ages of loading, as well as the corresponding relaxation curves obtained through numerical inversion. Mention must be made to the fact that the concrete presents low creep rates for high loading ages.

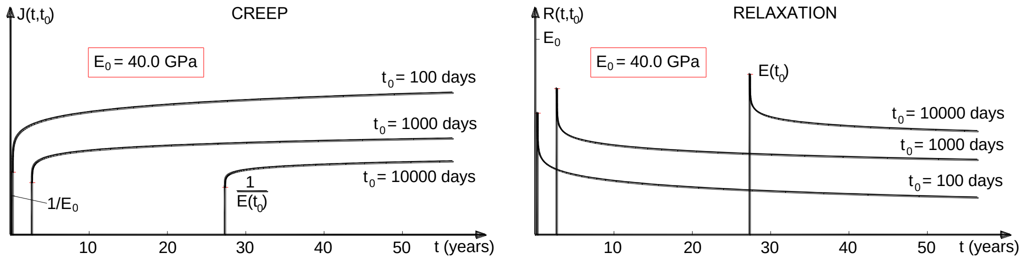

Fig. 2
Creep and relaxation curves of the dominant dam's concrete

2.4. MONITORING SYSTEM

The dam monitoring system allows the evaluation of the actions and the determination of the thermal, structural and hydraulic responses [4], by measuring (in brackets the total number of measurement instruments are indicated): i) the upstream and downstream levels, by staff gauges and water level recorders; ii) air temperatures, in an automatic weather station; iii) uplifts, by means of a piezometer network (41) installed in the drainage gallery; iv) horizontal displacements, by coordimeter bases installed at the intersection of the 5 plumb lines with the inspection galleries; v) horizontal displacements by 3 traverses on galleries; vi) vertical displacements, by precision geometric levelling on the crest and on 4 galleries; vii) vertical and horizontal displacements of the rock mass foundation, by rod extensometers (16) installed also in the drainage gallery; viii) joint movements, using electrical resistance devices for measuring the movement of joints (152) and three-dimensional baselines (103); ix) temperatures in the dam's body, by electrical resistance thermometers (52), by devices for measuring the movement of joints, by strain meters and stress meters; x) strains, by groups of one, five or nine Carlson strain meters (265); xi) stress, by stress meters (10); xii) water pressures in the concrete, by pressure cells (6); and xiii) discharged and infiltrated flows, by foundation drains (216) and measuring weirs (18). The dam is also equipped with 3 creep cells, for evaluation of the concrete deformability over time, a GNSS system to measure displacements (4 antennas, 1 reference station and 3 stations on the crest), a seismic monitoring system (6 triaxial accelerometers, 3 near the foundation and 3 on the upper central zone) and a dynamic response monitoring system (20 accelerometers installed on the upper galleries).

3. ANALYSIS AND INTERPRETATION OF THE STRUCTURAL BEHAVIOUR

3.1. STRUCTURAL MODEL

The dam behaviour was analyzed and interpreted on the basis of the monitoring results and of a continuous structural model (because no significant movement variations were observed in the contraction joints during the first filling). The structure of the dam was approximated by a set of supposedly continuous and homogeneous blocks, considering 30 monthly construction stages, with a rheologic behaviour of the concrete characterized by expression (1) and by Poisson ratio ν_c=0.2. The rock mass foundation was divided in 7 zones of different deformability, as a function of the results obtained from the geomechanical characterization [2] and “in situ” seismic tomography tests [5]. The Poisson ratio was assumed with a value of ν_f=0.2 for all the zones. No time effects on the foundation behaviour have been considered.

The finite element mesh (Fig. 3) has a total of 14854 nodal points for 2795 isoparametric cubic 20 nodes finite elements (1067 elements of the dam’s body and 1728 elements of the rock mass foundation). The dam’s body has 3 elements across the thickness. The spans and the shapes of the surface spillway were explicitly represented in the finite element mesh.

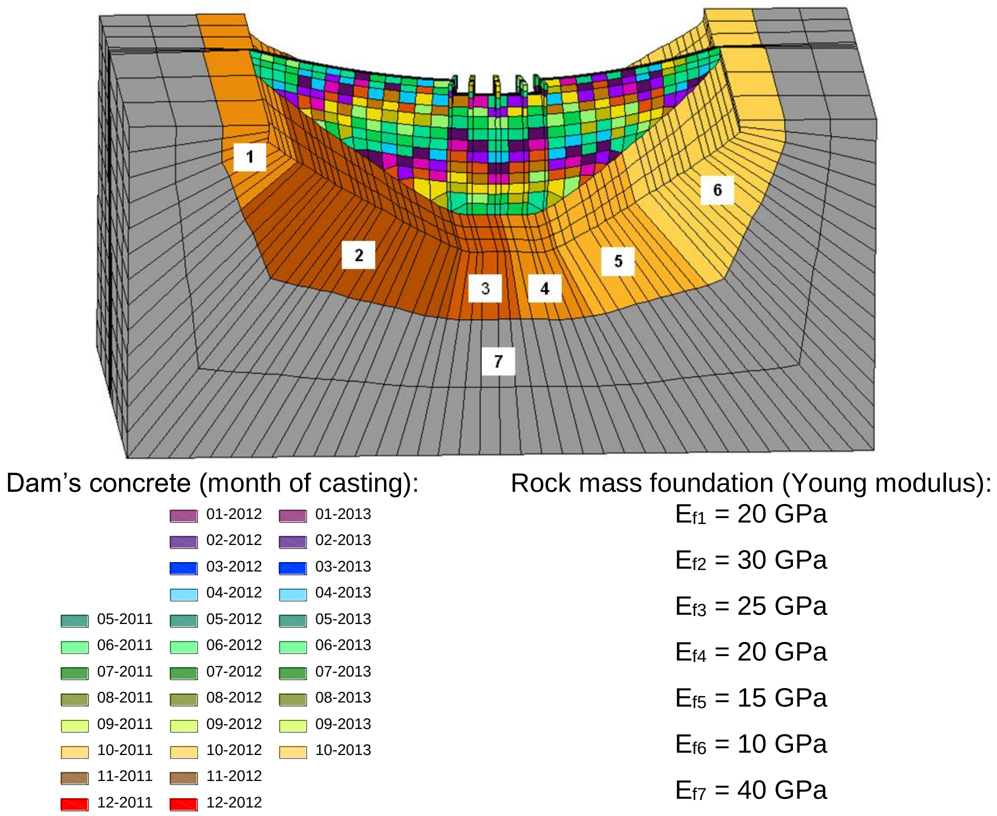

Fig. 3
Dam-foundation finite element mesh considered in structural analysis

3.2. ACTIONS VARIATION DURING THE FIRST FILLING OF THE RESERVOIR

The specific monitoring plan for the first filling of the reservoir defined a set of stages at which the filling was suspended to do general observation campaigns and to perform the dam's behaviour evaluation [6]. The first filling of the reservoir began in December 2013, was interrupted in 3 main intermediate filling stages (FS1, FS2 and FS3, at water levels 180 m, 206 m and 224 m, respectively) and in 2 stabilization levels (SL1 and SL2, at water levels 216 m and 231 m, respectively), and was completed in April 2016 (FS4), when the NWL reached an elevation of 234 m (Fig. 4). The first filling lasted about 28 months.

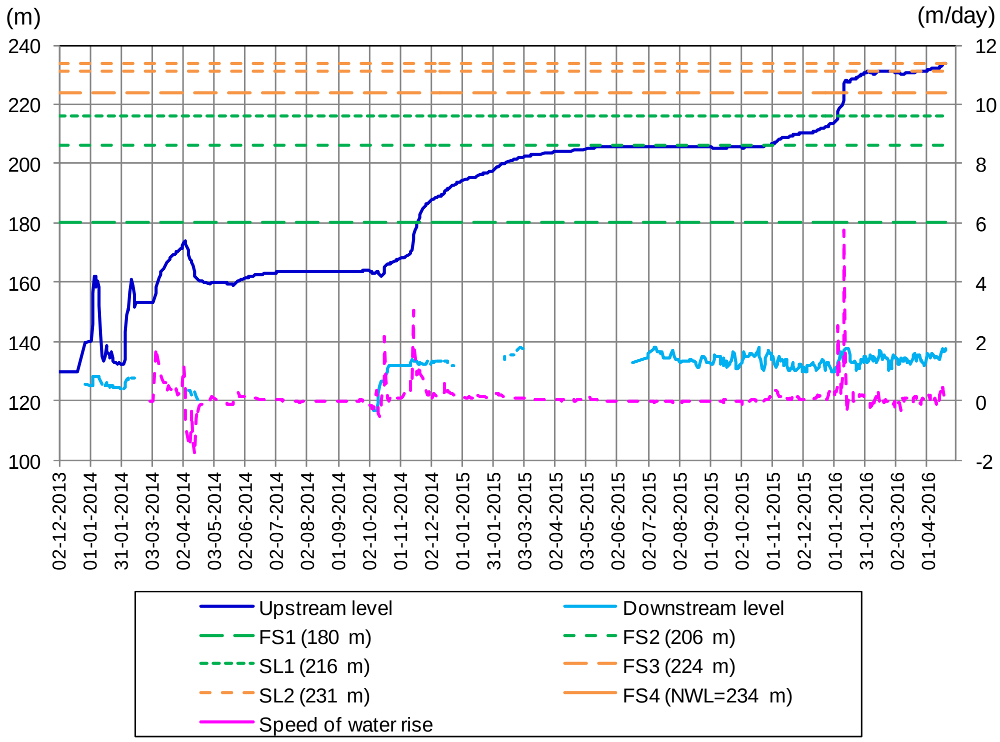

Fig. 4
Water level variation during the first filling of the reservoir

As the uplifts had small variations during the first filling, the water loads were represented only by hydrostatic pressure increments on the upstream surface of the dam, considering γ_w=10 kN/m^3.

The thermal variations in the dam's body were computed from the monitored temperatures in concrete, air and water, considering a numerical procedure to spread the observed values in a set of discrete points to all the mesh nodes of the dam's structure. Fig. 5 represents, as examples, the temperature fields observed in two stages of analysis, August 2014 and December 2015. A linear thermal dilation coefficient was considered for the concrete α=1.1x10^{-5} /ºC.

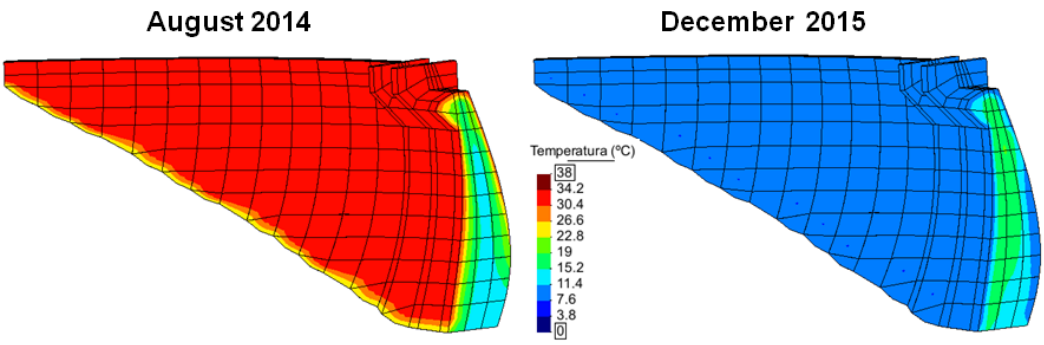

Fig. 5
Temperature fields observed in dam's body in two stages of analysis

The analysis comprises of the first filling period and a subsequent operation period until late January 2017. Actions due to water pressure and thermal variations were discretized fortnightly.

3.3. SOME RELEVANT RESULTS

In Fig. 6 and Fig 7 the horizontal displacements observed over time (from July 2014 to January 2017) for the central plumb-line at elevations 233.10 m and 170.2 m, respectively, and the correspondent computed horizontal displacements, considering the effects of water pressure, thermal variations and creep, are represented. The great influence of the thermal variations on the structural response and the very good agreement obtained between observed and calculated displacements should be pointed out. Concerning the displacements values measured and computed in other points of the dam, good adjustments were also obtained.

Fig. 8 shows the displacements measured and computed on the subvertical rod extensometer EF9, located downstream on the bottom of the central block 17-18 at 116.3 m elevation, from July 2014 to January 2017. In this case the agreement is not so good. The global shape of the displacements evolution over time is similar, but the monitored displacements are about twice the calculated ones. On most rod extensometers the adjustment achieved was better, but in some of them the adjustment was of the same type.

For the data of other types of monitoring devices good agreements were also obtained, demonstrating the good performance of the dam and the adequacy of the models considered for the analysis and interpretation of the observed behaviour.

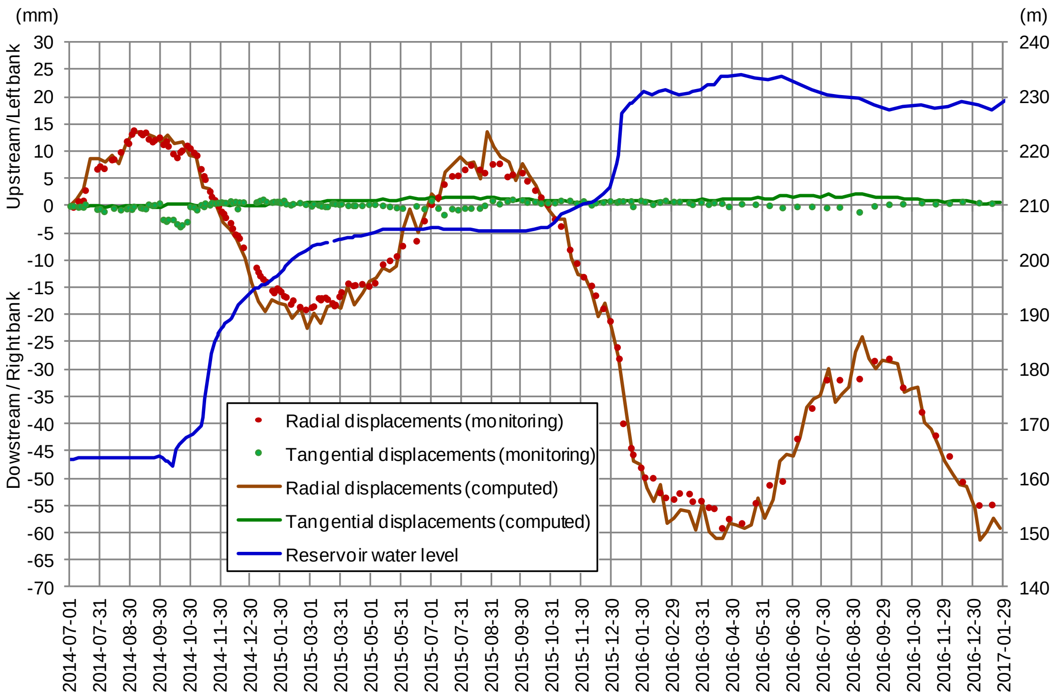

Fig. 6
Central block 17-18 horizontal displacements at 233.1 m elevation, measured on the plumb line and computed from July 2014 to January 2017

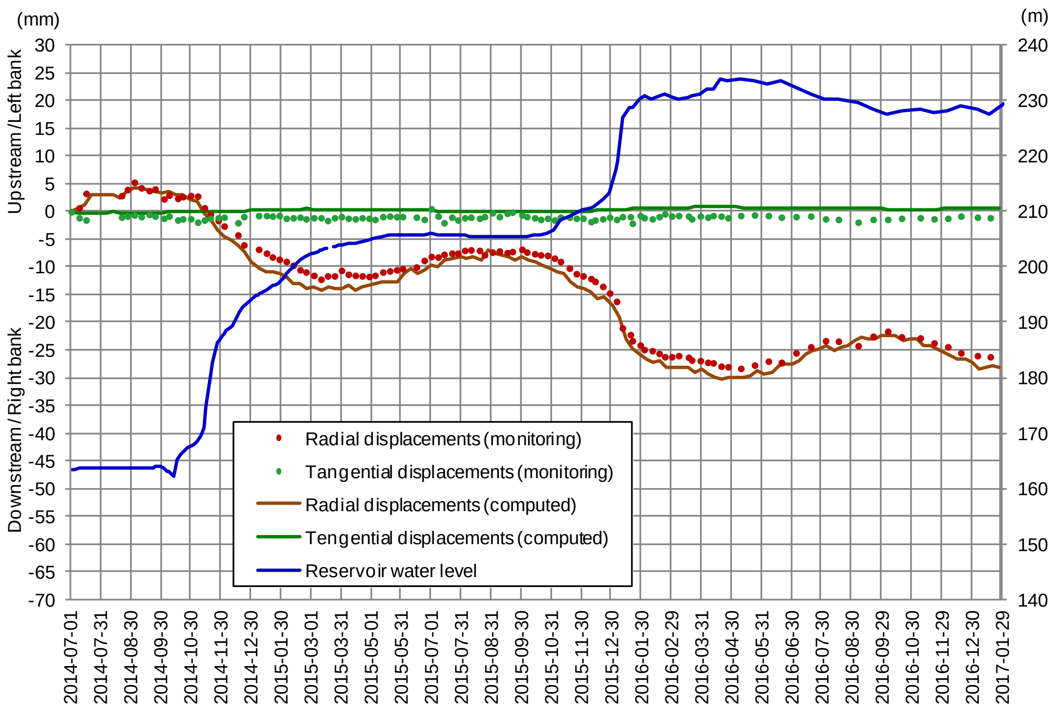

Fig. 7
Central block 17-18 horizontal displacements at 170.2 m elevation, measured on the plumb line and computed from July 2014 to January 2017

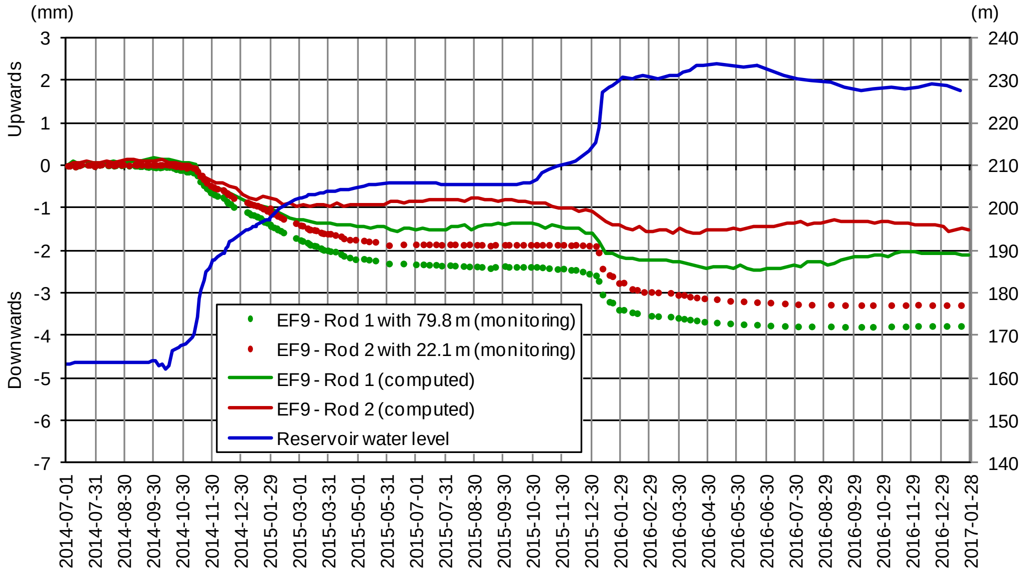

Fig. 8
Displacements measured and computed on the subvertical rod extensometer EF9, located downstream on the bottom of the central block 17-18 at 116.3 m elevation, from July 2014 to January 2017

4. CONCLUSIONS

The mathematical methodologies used to analyse and interpret the structural behaviour of the Baixo Sabor dam during the first filling of the reservoir have proven to be adequate for the intended purposes, in particular regarding to the consideration of both the instantaneous and the differed effects of the main loads, namely the hydrostatic pressure and the temperature variations. Mention should be done to the suitable evaluation of the deformability characteristics of the dam's concrete and of the rock mass foundation, as well as the thermal variations in the dam's body, that allowed a good adjustment between the monitoring data and the structural model results.

The adequate planning of the first filling of the reservoir and the results of both the inspections and the behaviour analysis and interpretation made it possible to carry out a proper monitoring and safety control of the dam during this critical period. The overall results obtained show the good performance of the dam and constitute a reference state for the observation and safety control of the dam over time.

SUMMARY

The first filling of the reservoir, as a real load test, is a crucial stage in the dam's lifetime. During this phase the safety control, based on the continuous monitoring, according to a specific observation plan, is required for the early detection of any abnormal behaviour. The structural modelling is also important to allow a coherent interpretation of the causes-effects relationships.

The paper describes the relevant aspects of the monitoring procedures and of the analysis and interpretation of the Baixo Sabor dam's behaviour, an arch dam with 123 m high and 505 m long at crest (designed, built and operated by EDP Produção), during the first filling of its reservoir (with a volume of about 1095 hm^3), which took place between December 2013 and April 2016.

The characterization of the materials' properties (concrete and rock mass foundation) and of the actions and responses during the first filling, as well as the structural model used to simulate the structural behaviour, are presented. This model, developed by LNEC, included a 3D representation of the dam and its rock mass foundation and it was analysed by the finite element method, considering the actions time evolution and the concrete viscoelastic behaviour.

A good agreement between the monitoring results and those obtained through the mathematical modelling was achieved, which confirmed the good performance of the dam and the modelling adequacy during this important stage.

1. INTRODUCTION

Nam Theun 1 (NT1) dam is a 180 m high RCC curved gravity dam situated in Lao PDR. The dam is equipped with four gated spillway bays and a bottom outlet, both terminating at flip buckets as energy dissipaters. To prevent any dam foundation undermining, tailwater level increase and blockage of the draft tube gates as a result of erodible material being deposited at the powerhouse located circa 300 m downstream of the dam, a pre-excavated plunge pool was designed within the river just downstream the spillway and bottom outlet.

This paper describes the step-by-step methodology applied for design and functionality checks of the proposed pre-excavated plunge pool downstream the dam.

2. PLUNGE POOL DESIGN CRITERIA

A pre-excavated plunge pool is proposed for NT1 project in order to prevent uncontrolled progression of the scour towards the dam foundation and the formation of a mound of scoured material at the powerhouse tailrace area. This would cause higher tailwater levels affecting the energy production.

The spillway is designed to safely discharge a Probable Maximum Flood (PMF) of 30,200 m^3/s without causing serious damage to the permanent works, whereas the design of the pre-excavated plunge pool focusses on the serviceability of the powerhouse, justifying a 100-year return period as a design basis. For this event the design of the pre-excavated plunge pool shall not allow for any major erosion process by the released water of the spillway and the bottom outlet.

3. SCOURING EVALUATION USING EMPIRICAL FORMULAE

For the hydraulic design of NT1 a theoretical analysis has been coupled with laboratory investigations. The theoretical analysis is based on (semi-) empirical scour depth formulae, the main parameters of which are the duration of the spillway operation, the specific discharge (per meter width) and the head. Other parameters are air entrainment in the jet, the rock characteristics and the tailwater depth. Martins, Chian, Mason and Veronese equation modified by Yildiz and Üzücek have been used to estimate the ultimate scour depth. For NT1 spillway jets, average scour depths in the range of about 45 m to 80 m below tailwater level were achieved for 30-year flood to PMF. Mason and Modified Veronese yielded high range values while Chian and Martins gave lower closer values.

4. PHYSICAL MODEL QUALITATIVE SCOURING TESTS RESULTS

The hydraulic studies of the spillway jets and plunge pool were carried out using 1:80 (overall dam) and 1:60 (partial of three chutes) reduced scale physical models, adopting Froude similarity, built at the Asian Institute of Technology (AIT) in Bangkok, Thailand. The 1:80 overall model reproduces a part of the reservoir and of the dam, the entire spillway (sill, gates, chute, flip buckets), the plunge pool and the powerhouse tailrace together with a downstream river reach for implementing the downstream tailwater condition.

The spillway model, built in PVC and mortar, was designed to accommodate modifications and several alternatives for the flip buckets (varying the lip angle and provision of dents). Erosion in the plunge pool was studied using a movable bed. With such non-cohesive material good predictive results are expected for the scour depth, but not for its horizontal extents. Therefore the banks were modelled rigid. To minimize the scour depths in the plunge pool, the spillway flip buckets were fitted with dents. The flow patterns for different alternatives of buckets are illustrated Fig.1.

Fig. 1
Hydraulic performance of the flip bucket before and after the modification
(Q=4,200 m^3/s; “baffle blocks” = dents)

The dents scatter the jet trajectories. This not only favours the energy dissipation but also better regulates the backward currents, thus reducing the maximum scour and the risk of erosion towards the dam toe. The shape and the depth of the scour holes formed by flows from both buckets alternatives are shown in Fig.2.

5. PLUNGE POOL LAYOUT (OUTLINES & DEPTH)

The plunge pool depth design is based on the results of physical model tests and estimates from empirical approaches. Based on this, the excavation level of the plunge pool invert was set at 105.0 m asl which ensures passage of a 100-year flood without any major plunge pool damage.

To be on the safe side, the upstream face of the pre-excavation was designed based on jet trajectory calculations that take into account the considerable effect of the air resistance. In contrast for the downstream side –

potentially affecting the powerhouse tailrace – this influence was omitted, which approximately corresponds to the model test trajectories.

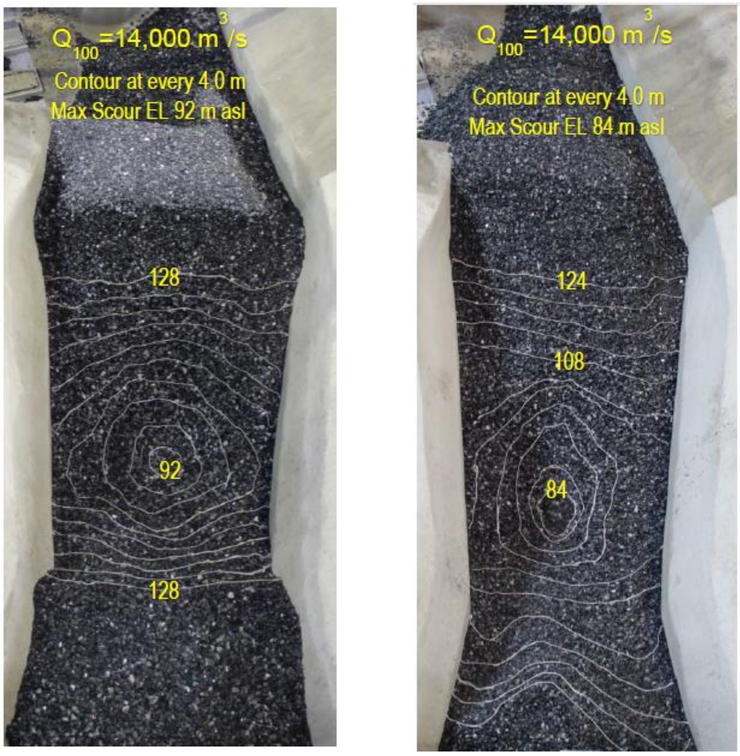

Fig. 2
Scour patterns at plunge pool for flip bucket options with (left) and without (right) dents

The plunge pool forehead general slope including the widths of the berms were such designed to avoid rotational and erosive flow patterns, as e.g. threating Kariba dam in Zambia. In the framework of the Kariba plunge pool scour mitigation studies, a similar adjustment of the forehead slope was recommended as a countermeasure based on physical and numerical modelling [1]. The layout of the pre-excavated plunge pool of NT1 is shown in Fig.3.

6. JETS CHARACTERISTICS BEFORE AND AFTER IMPACTING THE PLUNGE POOL SURFACE

A parallel method to assess the nature and hence the erosive potential of a plunging jet has been developed by researchers such as Ervine et al. [2] and Castillo [3, 4] which is based on two major processes (see Fig. 4).

First, when travelling through the air the jet develops increasing instability and corresponding turbulent surface disturbances. These gradually reduce the thickness of the solid core of the jet. Beyond the "jet break-up length" L_b the solid core has vanished. The jet then consists of blobs of water that disintegrate into finer drops. It is considered no more “developing” but “developed”. The decision is made on the parameter L_b/H with H being the jet falling height.

Fig. 3
Pre-excavated plunge pool model together with installed pressure sensors

Second, when the jet – developed or not – plunges into the pool it forms a new core of a thickness B_j, no longer solid this time. This core is gradually reduced by turbulent mixing with the surrounding water. After a distance of 4 B_j the core is dissipated. In case the ratio Y/B_j – Y being the pool depth – is larger than 4, the pool is considered “deep”, otherwise “shallow”.

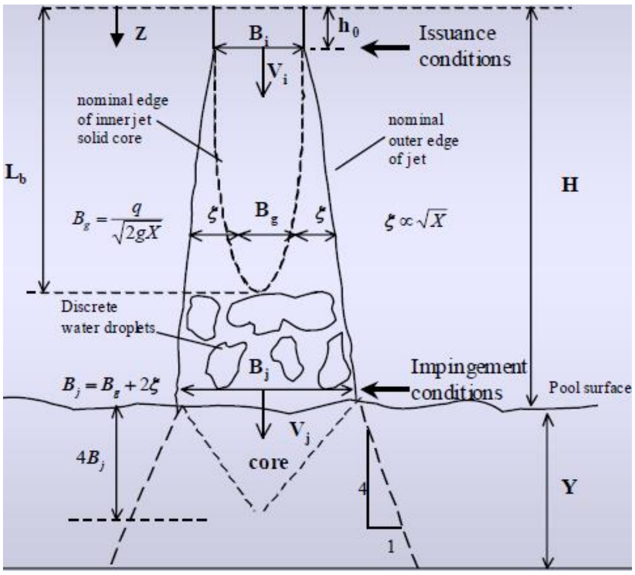

Fig. 4
Impingement jet analysis according to Castillo [4]

Based on these two distinctions Castillo [4] classified four types of jet conditions realized before and after entering the plunge pool:

a) undeveloped jet $H/L_b < 1$, shallow pool $Y/B_j < 4$
b) developed jet $H/L_b > 1$, shallow pool $Y/B_j < 4$
c) undeveloped jet $H/L_b < 1$, deep pool $Y/B_j > 4$
d) developed jet $H/L_b > 1$, deep pool $Y/B_j > 4$

Applying Castillo's approach [3], the jet break-up length was calculated and it was found that the disintegration occurs before the impact on the plunge pool water surface. Thus, a certain amount of energy will be dissipated in the air. The existence of dents on the buckets shall improve and guarantee the degree of jets' aeration and disintegration. Considering the jet's issuance characteristics, travelling length, falling heights and the tailwater levels at the plunge pool for NT1 case (Table 1), the jets can be classified as type (d) which implies developed (disintegrated) jets condition in the air and a deep pool situation.

Table 1
NT1 spillway design flood jet characteristics at issuance section and before/after impacting the plunge pool surface

Flood	q [m²/s]	Y [m]	Tu	L_b [m]	H [m]	H/L_b	B_j [m]	Y/Bj
100-year	134.9	55	0.035	95	125	1.3	7.1	7.8

7. PRESSURES REGISTERS AND INTERPRETATION

The pressures at the invert and berms of the pre-excavated plunge pool have been measured by means of low range industrial pressure sensors (10 Hz).

The impact pressures time series on the pre-excavated plunge pool bed and berms for Q_{100}=14,000 m^3/s are plotted in Fig.6. The flow pattern along the plunge pool area during model test is shown in Fig. 7.

According to Bollaert and Schleiss [5], the scouring process in plunge pools is the result of the interactions of the three phases water, rock and air. Moreover, the highly turbulent nature of the flow and the resulting pressure fluctuations on the water-rock interface and inside rock fissures make appropriate scaling very difficult in hydraulic modelling. Thus, the applicability of Froude-based reduced-scale models is limited and shall only be used as qualitative indication.

The impact of the plunging jets on the proposed pre-excavated plunge pool invert and berms are evaluated using a fixed bed, by measuring the pressures induced by the water jets through electronic transducers. Then, the parameters of the dynamic pressure distribution on the plunge pool surfaces such as mean dynamic pressure (C_p), RMS (root of mean square) (C_p') fluctuation, maximum and minimum peak fluctuations (C_p^+ and C_p^-) were analysed and compared to the values available in literature.

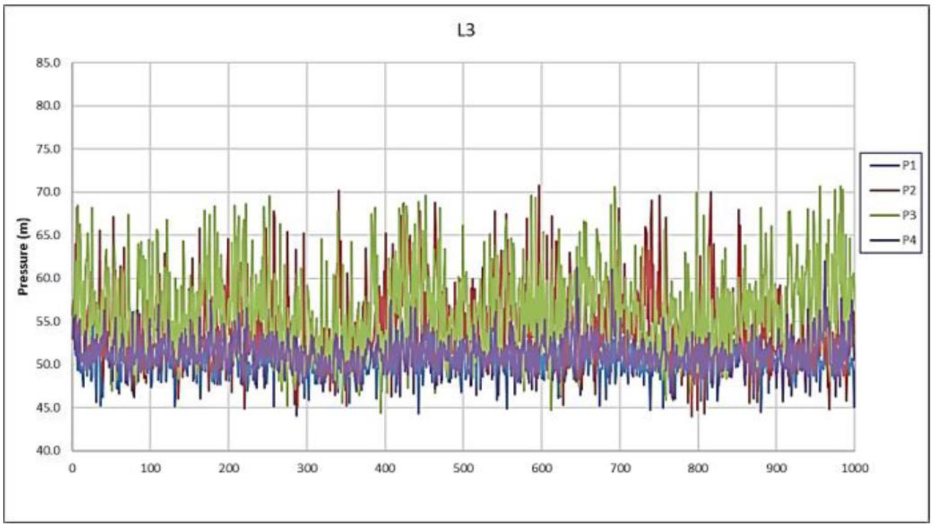

Fig. 6
Measured bed pressures on the pre-excavated plunge pool (Q100=14,000 m^3/s)

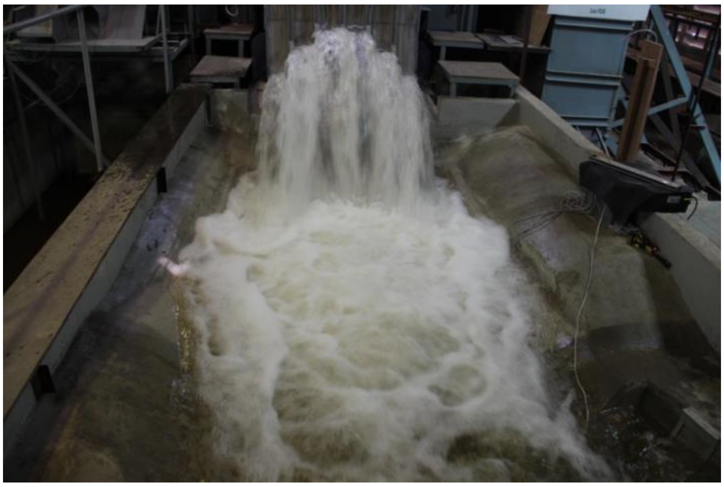

Fig. 7
Pre-excavated plunge pool in operation (Q_{100}=14,000 m^3/s)

The mean, RMS fluctuating and extreme peak dynamic pressure coefficients available in the literature for several different jet and plunge pool conditions are shown in Fig.8 and Fig.9.

The NT1 plunge pool design flood jet processed data is plotted on the relevant graphs. According to the values shown, it can be concluded that the design flood jet is of a developed one while the plunge pool water cushion regarding the corresponding tailwater level was classified as a “Deep Pool”. This confirms the results of the calculations and classifications of the jet already performed in Section 6.

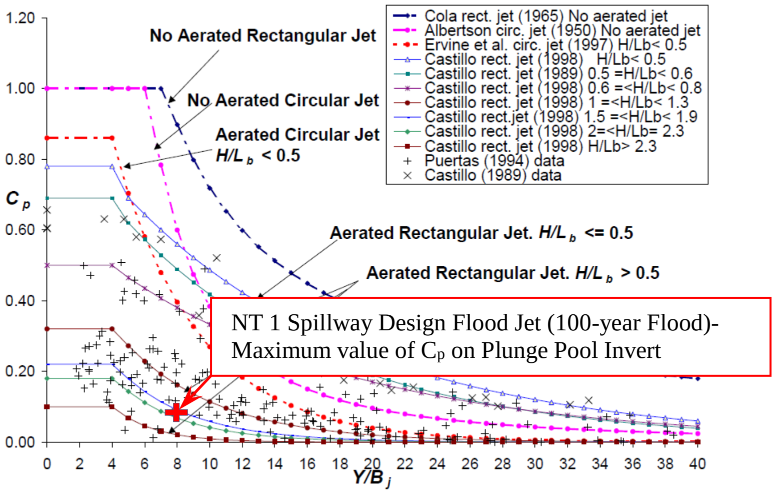

Fig. 8
Mean dynamic pressure coefficient [4]

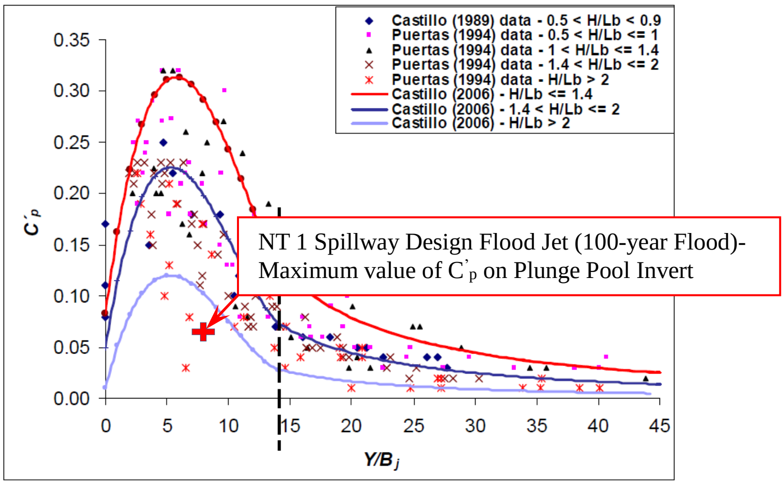

Fig. 9
Fluctuating dynamic pressure (RMS) coefficient for rectangular jet [4]

8. CONCLUSION

A practical methodology for design of NT1 pre-excavated plunge pool has been applied. In the beginning, the ultimate scour depths due to spillway plunging jets are estimated using empirical relationships as well as qualitative scouring tests in physical model. In the next step, the pre-excavated plunge pool was designed for a flood frequency referring to the serviceability of the powerhouse. Then, the dynamic pressures on the plunge pool invert and berms were recorded and the according dynamic pressure coefficients were calculated.

Comparing the range of the pressure coefficients for NT1 plunge pool case with those available in the literature shows that the NT1 proposed pre-excavated plunge pool shall be deep enough to not be eroded in an extensive area deeper than the proposed invert level of 105.0 m asl by its design flood jet.

Also, the calculations show that the spillway jets for all range of floods shall be fully developed before impacting the plunge pool surface which will reduce the erosive power of the plunging jets. Provision of the dents on flip buckets, which are not embedded in the disintegration length relationships, shall further improve the jets disintegration and aeration.

10. SUMMARY & KEYWORDS

Nam Theun 1 is a hydropower plant under construction in Lao PDR, located about 170 km east of Vientiane. The scheme comprises a 177 m high RCC curved gravity dam. The flood release structures including the plunge pool at the dam toe need to be designed to withstand the high dynamic loads and is one of the major hydraulic design issues. In order to reduce the scour depth, the spillway flip buckets will end at different elevations and will be equipped with baffle blocks that will spread the jet and improve its aeration.

In addition, the presumable scour depth and the required pre-excavation are important design parameters both with regard to the powerhouse tailwater conditions, the serviceability of the powerhouse itself and the dam safety. Several methods were used to estimate the presumable scour depth for different return periods and to design the plunge pool pre-excavation for the 100-year design flood.

At first classical scour formulae were applied. Second a physical model was built at AIT in Bangkok. This was used to investigate further the behaviour of a movable gravel bed, mainly in order to compare the effect of the above mentioned scour reduction measures, as well as to investigate the pressure fluctuations in the pre-excavated area. The pressure data was analysed in terms of the mean dynamic, RMS, maximum and minimum pressure coefficients at the proposed pre-excavation invert and berms. The jet characteristics just before impacting the plunge pool water cushion surface were determined. These results were used to evaluate the residual energy and scouring potential at the plunge pool invert and berms. The chosen approach containing empiric formulae combined with physical model testing allows for as suitable design of the challenging flood evacuation system of the Nam Theun 1 hydropower scheme.

Nam Theun 1 est un aménagement hydroélectrique en construction au Lao, situé 170 km à l’est de Vientiane. Il contient un barrage-poids arqué de 177 m d’hauteur. Le système d’évacuation des crues incluent une fosse de dissipation en aval de l’ouvrage qui est dimensionné de façon à résister aux importantes pressions fluctuantes. Son dimensionnement est critique. Afin de mieux distribuer et aérer les jets d’eau ainsi que de réduire la profondeur de l’affouillement, les chutes de l’évacuateur de crue se terminent par des cuillères de dissipation à différentes élévations équipées de dents de dissipation. Par ailleurs, le potentiel d’affouillement et la pré-excavation de la fosse de de dissipation sont des variables d’entrée clés influencent les niveaux d’eau et le bon fonctionnement de l’usine à l’aval ainsi que la stabilité du barrage. Plusieurs approches ont été utilisées dans le but d’estimer la profondeur d’affouillement pour des crues de différentes périodes de retour et de dimensionner la pré-excavation correspondant à une crue centennale.

D’abord, des approches empiriques ont été utilisées. Ensuite, un modèle réduit a été construit et exploité au laboratoire AIT de Bangkok dans le but d’étudier l’impact des jets sur un lit mobile avec et sans la mise en œuvre des mesures de correctives pour en mesurer l’efficacité et de mesurer les pressions fluctuantes dans la fosse de dissipation. La moyenne dynamique, le RMS ainsi que les coefficients de pression minimum et maximum ont été mesurés sur les bermes et en surfaces de la zone pré-excavée. Les caractéristiques du jet juste avant de pénétrer la surface de la fosse de dissipation ont été étudiées afin d’évaluer l’énergie résiduelle âpres impact ainsi que le potentiel d’affouillement au pied du barrage. La méthodologie choisie basée sur l’application de formules empiriques combinées avec les résultats obtenus grâce à modèle hydraulique réduit ont permis un dimensionnement hydraulique satisfaisant du très complexe système d’évacuation des crues de l’aménagement de Nam Theun 1.

1. ABSTRACT

Typhoon-induced storm surge along with heavy rainfall has been recognized as the most frequently reported hazards for water-related hazards in South Korea. Moreover, it has been widely acknowledged that the frequency and intensity of typhoons (or abnormal low-pressure system) are likely to increase over time due to the potential impact of climate change. There are 14,000 small reservoirs in South Korea and various issues related to the reservoir safety. A hydrologic reservoir risk analysis requires a systematic process to ensure dependency relationships among key hydrologic variables (e.g. precipitation,

[*] *A DEVELOPMENT OF HYDRAULIC-HYDROLOGIC RISK ANALYSIS MODEL FOR SMALL RESERVOIRS BASED ON BAYESIAN NETWORK*

discharge and water surface level). However, the existing reservoir risk approach showed a limitation in assessing the interdependencies across the variables. In this context, this study proposed a Bayesian network based reservoir risk analysis. Based on the basic information of reservoir, various failure modes was first identified and the failure modes are then translated into nodes in the Bayesian network framework. The failure probabilities of the each node were estimated quantitatively by integrating limit state equations, which are composed of a set of random variables. Moreover, we investigated an integrated Bayesian network model to estimate overtopping risk from water surface level rise informed by climate change scenarios. A further discussion on the role of the uncertainty for overall risk is provided. This proposed procedure will help to effectively introduce the risk analysis for reservoirs safety in Korea.

1. INTRODUCTION

Stress can be transmitted effectively between FRP and concrete, which is the key for FRP-concrete to effectively improve the bearing capacity of the reinforced structure. Numerous tests and engineering projects have shown that the failure of FRP-concrete tends to be caused by the de-bonding of FRP-concrete interface or local failure along the interface of the concrete [1,2]. Consequently, the bond performance of FRP-concrete interface directly determines whether the reinforced structure will succeed. Under most external load conditions, this interface tends to be in the state of shear stress. Currently, there are four types of experimental study to test bond performance of FRP-concrete interface, which is simple-shear test, double-shear test, beam test and corrected beam test. Simple-shear test and double-shear test are most common for their specific and simple stress state. This essay adopts single-shear test to deeply discuss and research on the mechanical property and bond mechanism of FRP-concrete.

Van Gemert [3] researched the bond performance of steel-plate reinforced concrete structure through double-shear test for the first time in 1980. Besides, he presented the values of maximum shearing stress and average shearing stress, and the transmission law of stress distribution and calculation formula of steel plate-concrete interface. Later, based on simple-shear test, Sharma [4] and his fellows focused their research on the influence of the effective bonding length of FRP-concrete interface on the bond strength. When above shear tests measured the stress strain of steel plate or FRP plate, they stuck large quantities of strain gauges on the plate surface alongside the length direction of plate and then read the value of strain gauges, used to calculate the local average bond shearing stress and local slippage. However, many test outcomes have shown that the constitutive relation of bond slippage derived from above tests cannot demonstrate satisfying law because the material components of concrete and the cracks caused during tests were randomly distributed. Furthermore, when the strain gauges were adopted for measurement, there would be certain difference between the strain values read from the strain gauges at the measurement points and the actual strain values because of the limit on measurement gauge length [5,6]. Therefore, we should find a brand-new measurement method which can accurately measure the overall deformation of FRP plate.

DIC (digital image correlation) was put forward by one Japanese scholar-Yamaguchi [7] and two American scholars-Prof. Peters and Prof. Ranson [8] independently in the 1980s. The research thought of Yamaguchi [7] was to adopt laser beam to irradiate to object surface to form speckles and to measure the peak value of relevant function of light strength before and after the object was deformed. In the meanwhile, he derived the object displacement based on relevant theories, thus achieving the real-time measurement of small deformation in small regions. Prof. Peters and Prof. Ranson [8] used computers and image scanning devices to acquire the speckle diagram before and after the object was deformed. In addition, they found out the extreme value of correlation coefficient through iterative algorithm on the grey field before and after the object was deformed, thus obtaining the displacement field and stress strain field inside the closed regions and then acquiring the deformation field through boundary integral equation.

This experiment measures the surface deformation of FRP plate with the assistance of relevant advanced digital image technologies and can overcome some limitations of above tests quite well, thus eliminating some disadvantages of strain gauges. Besides, this experiment analyzes the stress transmission in different de-bonding stages through careful observations of FRP-concrete de-bonding process, thus establishing the de-bonding law of FRP-concrete interface and providing technical instructions for the disposal of FRP-concrete bonding interface in real hazard elimination and reinforcement projects.

2. DIRECT SHEAR BETWEEN FRP - CONCRETE BONDING INTERFACE BASED ON DIC

2.1. EXPERIMENTAL APPARATUS

All tests are conducted on equipment which is autonomously designed and manufactured. This equipment consists of following parts: upper baseboard with four holes, lower baseboard with eight holes, four pieces of steel bars with screw-thread, two pieces of baffles welded with small steel bars (as clamping chuck for lower pull head connection testing machine), upper pull head and fixture.

2.2. SPECIMENS

(1) concrete sample

Eight pieces of concrete cube specimens are poured in one batch with a strength of C30, a size of 100mm in length, 50mm in breadth and 300mm in height. Grinding papers are used to polish the concrete surface to be measured. In addition, dry cleaning cloth is used to clean the surface.

(2) FRP Plates

Yao Jian [9] and his fellows pointed out that when the breadth ratio between the FRP plate and concrete was equal or higher than one fourth, the de-bonding development process before the specimen damage can hardly be observed. The failure happened all of a sudden with no pre-signs. Therefore, the breadth of FRP plate is set as 20mm. The length of plate is determined by the sum of different bonding length and clamping length in accordance with the testing requirements.

(3) The bond between concrete and FRP plates

The cut concrete specimen and FRP plate are bonded with resin adhesive. The bonding lengths include eight different types: 80mm (Type SS-80), 90mm (Type SS-90), 100mm (Type SS-100), 110mm (Type SS-110), 120mm (Type SS-120), 150mm (Type SS-150), 160mm (Type SS-160) and 180mm (Type SS-180). Stick FPR plate to the concrete surface to be measured with resin adhesive and use rollers to squeeze the bubbles out. Place weight on FRP plate for three days to guarantee that FRP plates are totally stuck with concrete. When the adhesive completely sticks the concrete specimen and FRP plate tightly, install the specimen on the equipment and conduct the test.

2.3. EXPERIMENTAL APPROACH

This experiment adopts optical measurement technique to measure the deformation of FRP plate surface. In order to acquire speckles for optical measurement, two colors-black and white, are sprayed on the surface to be measured respectively. Connect the data line of optical measurement camera with the computer, observe the computer screen, and adjust the height and focal length of camera until the speckles on FRP plate can be clearly seen. Set the photograph frequency as five pics per second. Place the installed testing equipment fixed with FRP plate-concrete specimen on the 10t testing machine. Adopt monotonic loading mode under displacement control, the tensile speed is 0.03mm/min. The model diagram of direct shearing equipment and the diagram of direct shearing equipment are shown in Fig. 1.

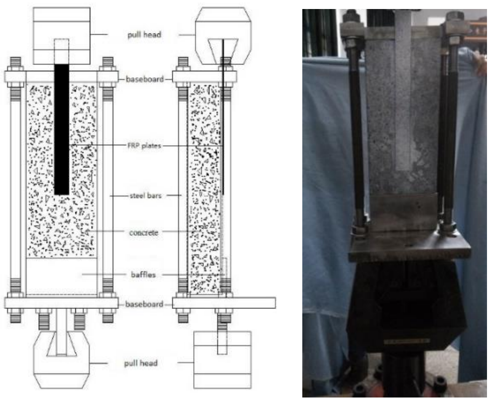

Fig. 1 Direct shear apparatus model

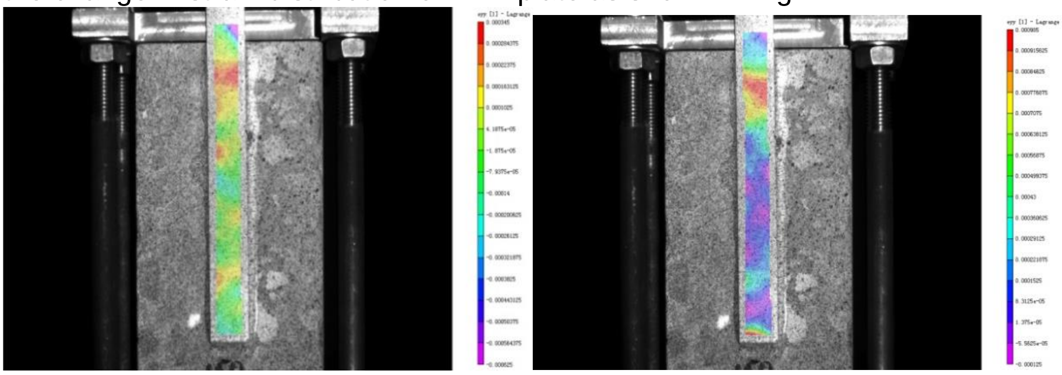
3. EXPERIMENTAL RESULTS AND ANALYSIS

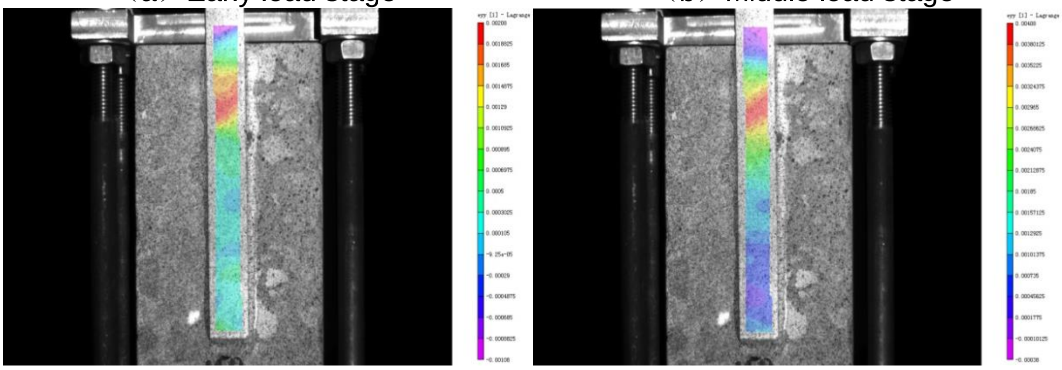
3.1. EXPERIMENTAL RESULTS

(1) Experimental results observed by optical measurement

If we choose to observe the strain of specimen in the vertical direction, we can obviously see the strain distribution of FRP plate at different time. Take the strain distribution of specimen SS-150 at different time for example and analyze the change in strain distribution of FRP plate as shown in Fig. 2.



（a）Early load stage （b）Middle load stage



（c）Later load stage （d）Extreme load stage

Fig. 2 The strain distribution of the FRP plates at different times in the sample ss-150

The de-bonding of FRP reinforced concrete bonding interface can be divided into following three stages as shown in the Fig. 2:

(1) Early load stage: the strain on each part of FRP plate is very small. The peak value of strain, which is measured in a small region around the load end, which is $\varepsilon_{yy}=0.000345$. As the load increases, when the peak value of strain reaches 0.000985, the strain in its neighboring regions exceeds 0.000779 and the position of peak value of strain basically remains unchanged.

(2) Middle load stage: as the load continues to increase, the peak value of strain ($\varepsilon_{yy}=0.00208$) keeps increasing while its position moves towards the free end of FRP plate. The overall strain of plate increases compared to early load stage. The minimum value of strain is 0.0005 and is measured at the free end of FRP plate. There is very small strain in the regions between the plate center and the free end, ranging from 0.0001 to 0.0003.

(3) Later load stage: the position of peak value ($\varepsilon_{yy}=0.00408$) of strain basically remains unchanged compared to middle load stage and the strain of free end only reaches 0.001.

3.2. EXPERIMENTAL DATA ANALYSIS

(1) Load - displacement curve of specimen

The load - displacement curve of specimens can be obtained from the data of the test machine, as shown in fig.3 (for example, specimen ss-120).

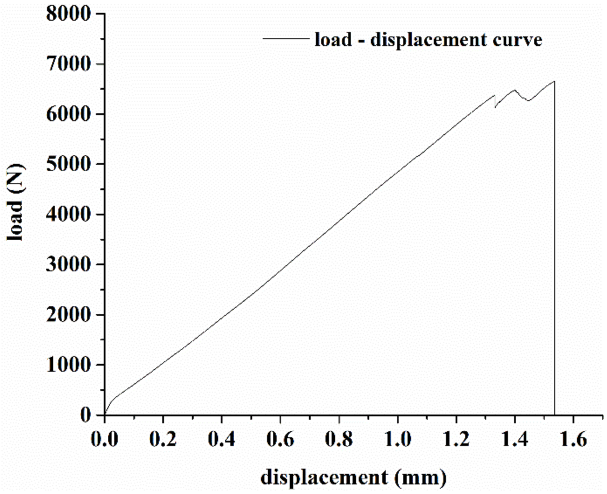


Fig.3 The load-displacement curve of the specimen ss-120

(2) Extreme bearing capacity, slippage of load end and failure mode measured in the test

Collect each specimen according to the extreme capacity of interface (direct shearing strength) as shown in Fig. 4.

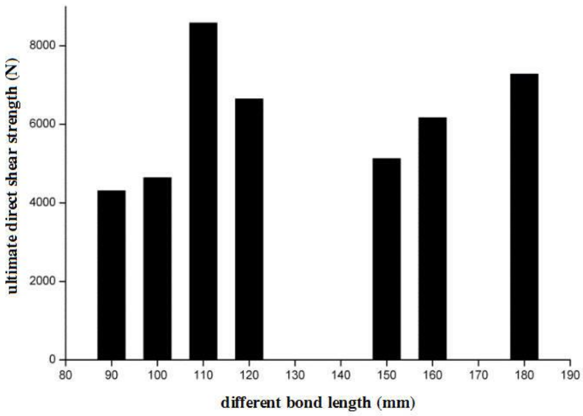

Fig. 4 The ultimate direct shear strength distribution of FRP- concrete specimen with different bond length

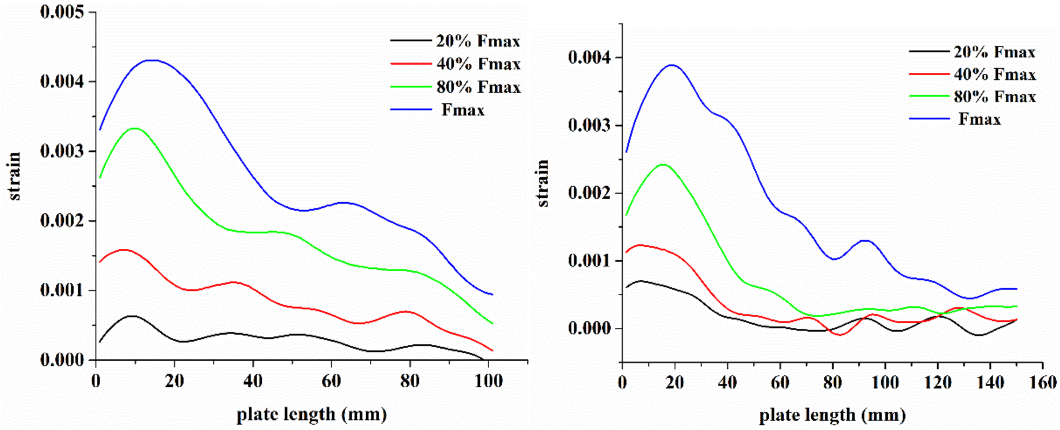
We can see from Fig. 4 that except for specimen SS-80, with the bonding length increases, the extreme bearing capacity of interface firstly increases (the bonding length is 110mm) and then demonstrates stable trend. Although the bonding length of specimen SS-80 is only 80mm, its extreme bearing capacity of interface is quite high. It might be that the FRP plate is stuck right at the place with concentrated coarse aggregate and there is relative little mortar in this part. As for specimen SS-110, its extreme bearing capacity of interface is highest, which can also be attributed to above reason.

(3) Strain distribution of FRP plates surface

Ali-Ahmad [10] and his fellows pointed out that when the test of bonding performance of FRP-concrete was conducted, the FRP plate remains in the elastic range and the strain distribution of FRP plate surface can reflect the strain distribution of FRP-concrete bonding surface quite well. Analyze the data collected by DIC and select the strain distribution of FRP plate alongside the plate length direction of specimen SS-100 and SS-150 at different load time (which means different load stages)-20%, 40%, 80% and 100% of extreme load.



（a）SS-100 specimen （b）SS-150 specimen

Fig. 5 The strain of FRP plate in different loading moments

We can see from Fig. 5 as follows:

(1) During the stage of 20% to 40% of extreme load, the strain increases obviously except for the region within 40mm from the load end. There is not much increment in strain at other positions on the FRP plate. So we can conclude that the effective bonding length of FRP-concrete is about 100mm or slightly lower than 100mm;

(2) With the external load continues to increase, the overall strain of FRP plate increases and the free end begins to transmit shearing strain stress towards the concrete surface. However, the strain value is relatively smaller compared to other parts.

(3) With the load increases, the strain keeps increasing while the position of peak value of strain moves forward little by little, which indicates that the FRP at original positions of peak value of strain starts de-bonding away from the concrete surface gradually until the external load reaches the maximum shearing stress which the FRP plate and concrete can withstand. When there is no subsequent FRP plate sharing this external load at the free end, the de-bonding failure happens to the specimen.

Collect the strain distribution of each specimen at extreme load as shown in Fig. 6.

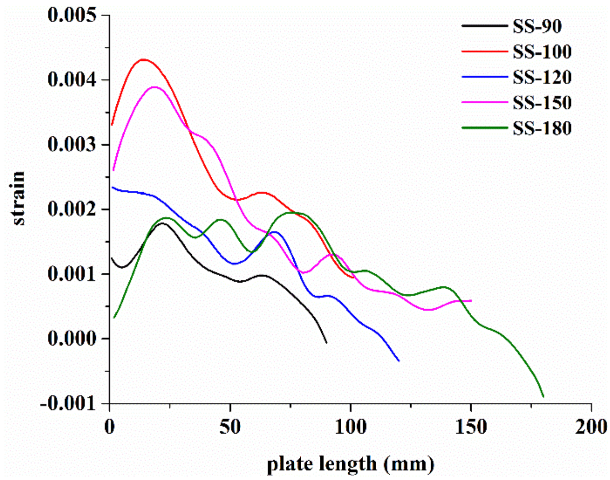


Fig.6 The strain of FRP plates along the plate length at the limit load

We can see from Fig. 6 as follows:

(1) The strain distribution law of FRP plate of each specimen is consistent.

(2) The maximum strains of specimen SS-120 and specimen SS-180 are relatively small for influence of clamping chuck of testing machine.

(3) Apart from some factors that influence the test results, and combined with the analysis of FRP-concrete specimen of each plate length, we can predict that: the maximum strain of each specimen under extreme load increases as the bonding length of FRP plate increases; the strain distribution law curve along the length direction of plate extends outwards as the bonding length of FRP plate increases.

3.3. COMPARISON WITH THE FORMULA OF THE SHEAR BOND STRENGTH MODEL OF CHEN - TENG

The Chen-Teng [13] anti-shear boding strength equations based on fracture mechanics theories and experimental outcomes are adopted to compare with the testing outcome. Fig. 7 shows the comparison between the ratio of FRP plate stress and its tensile strength σ_{frp} / f_{frp} and the ratio of bonding length of FRP plate and effective bonding length l_{frp} / l_e during de-bonding failure in direct shearing tests.

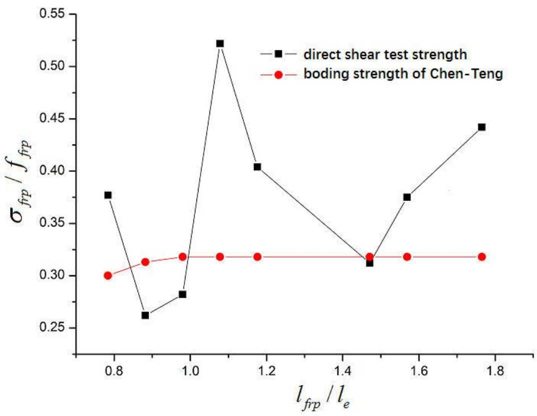

Fig. 7 The bond strength of different bond length in direct shear test

We can see from Fig. 7 as follows:

(1) While the bonding length-l_{frp} is equal to 150mm, the testing outcome can agree well with the calculation outcome.

(2) While the bonding length-l_{frp} is equal to 90mm, 100mm and 160mm, the difference rate between the testing outcome and the calculation outcome is about 15%.

(3) While the bonding length-l_{frp} is equal to 80mm, 110mm, 120mm and 180mm, the difference between the testing outcome and the calculation outcome is relatively big and higher than 25%.

3.4. EFFECTIVE BONDING LENGTH OF FRP PLATE - CONCRETE SPECIMEN

Sharma [4] and his fellows put forward the concept of “effective bonding length” based on the results that the bonding strength of FRP-concrete will not keep increasing as the bonding length of FRP plate increases. Chen and Teng[13] put forward the calculation formula for effective bonding length through plenty of tests. The effective bonding length of FRP plate-concrete specimen is roughly estimated through analysis of strain-plate length, and compared with the Chen-Teng effective bonding length.

In the discussion about specimen SS-100 and SS-150 in Chapter 3.2, it has been demonstrated that the effective bonding length of this batch of FRP plates is roughly estimated to be about 100mm. The effective bonding length calculated by Chen-Teng formula is:

$$l_e = \sqrt{\frac{E_{frp} t_{frp}}{\sqrt{f_c^{'}}}} = \sqrt{\frac{256000 \times 0.2}{\sqrt{0.76 \times 30}}} \approx 103.5mm$$

On this basis, it is indicated as follows:

(1) The analysis of strain-plate length curve can be estimated the effective bonding length of FRP plate-concrete indeed.

(2) The effective bonding length calculation formula proposed by Chen-Teng is re-verified by amount of analysis.

4. CONCLUSION

The direct shear and de-bonding test of FRP-concrete specimen are conducted by autonomously developed testing equipment. With the assistance of advanced DIC (digital image correlation) technology, the strain distribution on the FRP plate surface of FRP-concrete specimen is accurately measured. Besides, the surface strain distribution law of FRP plate alongside the length direction of plate and the bonding strength of specimen are researched. Furthermore, it reveals the de-bonding failure process of concrete interface and draws following major conclusions:

(1) The shear strain stress of FRP plate and concrete interface is not evenly distributed, the de-bonding starts from the load end and presents itself as brittle failure.

(2) The strain-plate length distribution of FRP plate indirectly reflects the bonded quality of specimen and corresponds to the strength error reflected by the calculation outcome of Chen-Teng formula.

(3) The effective bonding length of FRP plate is estimated by analyzed the surface strain distribution of FRP plate along the length direction. The determination of effective bonding length of FRP plate in project applications means a lot for reducing reinforcement costs and construction work load.

1. INTRODUCTION AND BACKGROUND

Regular dam safety evaluations are performed on Swedish dams according to the voluntary Dam-Safety Guidelines (RIDAS). Due to recent revisions, deficiencies in structural and hydraulic performance are routinely discovered leading to dam safety upgrades (Yang *et al*. 2010, 2014). These shortfalls include rock erosion downstream, status of embankment dams, spillway stability and functions of mechanical and electrical systems in addition to spillway discharge capacity (Ygland *et al.* 2012, Bond et al. 2014).

Both Långströmmen and Ramsele are among the candidates for spillway upgrade and renewal.

Långströmmen is located on the River Ljusnan in Mid Sweden and was commissioned in 1961. The facility includes more than 2,5 km of embankment dams, owned by the power producer Fortum. The tallest dam sections are placed near the spillway, rising to a height of 29 m. The full retention reservoir level (FRRL) is +279.55 m, with 35 cm of regulation amplitude. Its power plant has two Francis turbines with a gross head of 31.3 m and a turbine flow rate of 100 m^3/s. Its annual power production exceeds 250 GWh. dams.

Ramsele hydropower plant, owned by Uniper, is located on Faxälven in Northern Sweden and was commissioned 1958. The dam is a 440 m long buttress dam about 40 m high. The full retention reservoir level (FRRL) is +223.50 m, with 50 cm of regulation amplitude. The power station has three Francis turbines with a total output of about 160 MW, a gross head of 79.2 m. Its annual power production is about 870 GWh.

Figure 1 shows the location of Långströmmen and Ramsele.

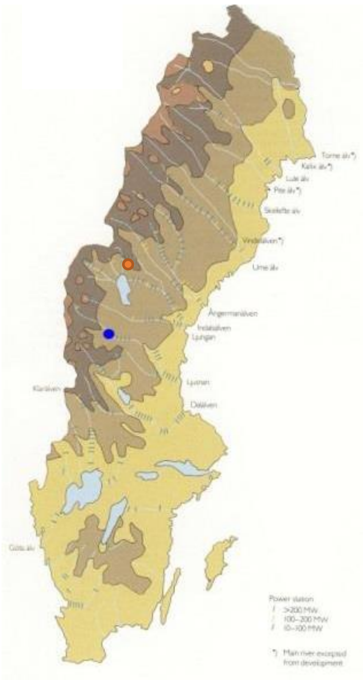

Figure 1. Map of Sweden showing Ramsele (Red) and Långströmmen (Blue)

Figure 2: Downstream view of the spillway at Långströmmen prior to dam safety upgrades (Norconsult, 2014).

Figure 3: Aerial photo of Ramsele dam and spillway (Norconsult, 2015).

2. RESULT OF SAFETY EVALUATIONS

The Swedish Guidelines for Design Flood Determination, classify dams into two categories depending on the consequences of a dam failure ().

Table 1: Classifications of dam failure consequences and corresponding design flood.

Design flood category	Class I	Class II
Dam failure consequence category	Loss of human life, damage to vital infrastructure, etc.	Property and infrastructure damage,.
Hydrological modeling technique	Extreme precipitation combined with heavy snowmelt and saturated soils	Frequency analysis
Return period, years	> 10 000	>100

Both Långströmmen and Ramsele are classified as high-hazard dams, or Class I, implying that a 10 000 year flood must be safely passed. Not only does this signify that the floodwaters must be evacuated without exceeding the maximum design water level thereby jeopardizing the structural integrity of the embankment dams.

It also means that the spillways must be designed with energy dissipators and sufficient downstream riprap to avoid backreaching erosion.

2.1. DISCHARGE CAPACITY

Prior to the dam safety upgrades, the capacity of the spillway at Långströmmen was 1670 m^3/s, while the updated design flood was close to 2500 m^3/s, an additional 830 m^3/s (50 % increase). Due to the very limited active reservoir volume, this leads to a water level increase of 1.8 m above the FRRL, which is 1.45 m above the central moraine core of the embankment dam. For an embankment dam, this is unacceptable.

When the dam was built, in the 1950s, the design flood was about the same as the 100 year-flood, but with today’s hydrological methodology the design flood has a return period of about 10 000 years, hence the 50 % increase.

For Ramsele, its existing spillway with a capacity of 800 m^3/s, was able to safely handle the updated design flood of 910 m^3/s. The additional 110 m^3/s results in water levels 50 cm higher than the FRRL to discharge the flood, which still is *under* maximum design water level as the central moraine core of the embankment dam extends another 1,6 meters. This gives the spillway sufficient capacity to evacuate the full volume of the floods, even accounting for wind drag buildup and waves.

2.2. EROSION DOWNSTREAM OF SPILLWAY

At Långströmmen dam, inspections have uncovered damages in the bedrock and concrete adjacent to the rock downstream of the spillway. Diving inspection uncovered that bedrock had been jacked up and washed away during flood episodes downstream the ski jump. Repairs were instigated, but rock erosion at the existing spillway was not handled in the project presented– the focus was on increasing the discharge capacity by adding the new spillway and designing it for safe passage of the design flood.

Downstream of Ramsele’s left spillway chute, extensive rock erosion has occurred even though the spillways are rarely used. Before being re-built in 2017, the spillway had no engineered energy-dissipation at all, and the hydraulic conditions were non-favorable. There were reasons for apprehension concerning backward erosion, under the existing spillway chute. As no redundancy exists regarding discharge alternatives, it is of utmost importance that all three gates can be used without limitations regarding rock erosion, at a design flood event.
One outcome from the latest dam safety evaluation was to introduce restrictions regarding usage of the left spillway, since discharge could possibly

threaten the integrity of the dam. Figure 4 shows the eroded area downstream the left spillway chute.

Figure 4 Eroded area (marked red) downstream of the left chute at Ramsele (Norconsult, 2014).

2.3. Rehabilitation Options

In order to fulfill the design requirements cost-effectively, a number of rehabilitation options were studied in separate feasibility studies for both dam facilities.

2.3.1. Långströmmen

The following alternatives were evaluated, with the objective to increase the total discharge capacity (Ygland et al, 2012):

1. Modifications of the existing timber spillway by lowering its threshold
2. A new spillway to the right of embankment 5
3. A new spillway between embankments 4 and 5
4. A new spillway in combination with a siphon spillway
5. An emergency spillway with an erodible dam section
6. An emergency spillway with an automatically regulated flap gate

7. An overflow spillway with a fixed sill
8. An overflow spillway with a fixed sill combined with raise in the impervious cores
9. Modifications of the existing overflow dams.
10. An emergency spillway with Hydroplus fusegates
11. An emergency spillway with Hydroplus combined with raise in the impervious cores

Other factors, such as risks for flooding during construction combined with cofferdams, availability of reservoir for flood regulation during construction including debris and ice, erosion risk in the downstream area, impacts on the dam facility etc were weighed in.

The feasibility study favored construction of a new spillway (alternative 2) as the final option for the dam rehabilitation. The spillway was given a width of 18 m, with a sloping chute of ~80 m, followed by a stilling basin.

2.3.2. Ramsele

With a more limited objective of preventing further backward erosion near the dam, the following overreaching approaches were evaluated

- accepting some erosion but stop it from threatening the dam (undermining)
- accepting some erosion but move it to a safe distance from the dam
- introducing energy dissipation structures

Based on the approaches above, the following measures were evaluated:

1. Classic stilling basin
2. Rock reinforcements (rock bolts)
3. Prolongation of the existing spillway chute
4. Cuf-off wall immediately downstream of the existing chute
5. A few different combinations of No. 2 - 4.

The obvious factors that affect the evaluations of the alternatives for Ramsele was cost-efficiency as well as the overall risk reduction and impacts of construction on the existing dam.

The feasibility study recommended the third alternative. The prolongation had a linear slope, covering the entire length of the erosion pit ending with a cut-off wall anchored into bedrock. This construction would achieve both goals of limiting backward erosion threatening the dam body as well as relocating erosion areas to a safe distance from the dam.

3. HYDRAULIC MODEL STUDIES

For both spillways a physical model was constructed to assist in the detailed design of the waterways. The initial design of the models was supported by 2D computational hydraulic models to limit the scope of modeling necessary.

3.4. Initial Hydraulic Model Långströmmen:

Prior to detailed design, hydraulic models have been constructed at Vattenfall's hydraulic laboratory in Älvkarleby, Sweden (Yang *et al.* 2015). A 25 m long model, as shown in figure 5**,** was constructed at a scale of 1:60 with the objective of testing the following:

1. Impact of bathymetric features upstream that creates complex flow patterns during high floods.
2. The new spillway is situated some 350 m from the existing one with a small cross-section. This creates a velocity head that needed examination.
3. The flow behavior in the reservoir (point 1) and the head loss between the existing and new spillways (point 2) impacts the new spillway's threshold and discharge capacity.
4. The energy dissipater design of the new spillway.

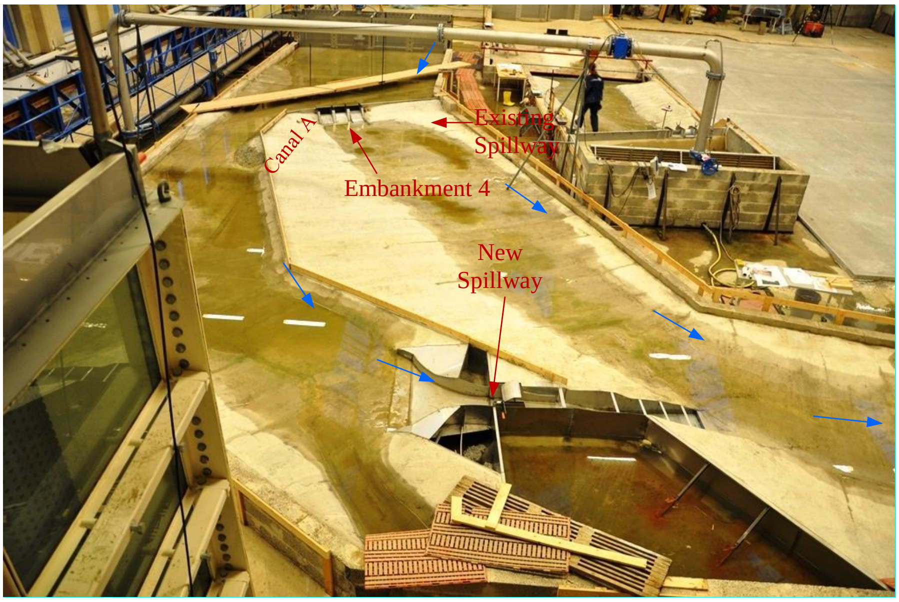

Figure 5: Hydraulic model of Långströmmen dam, scale 1:60

One of the main tasks of the model was to determine the final threshold of the new spillway. The lower the threshold, the higher capacity but also increased velocities downstream which impacts riprap design.

Results from two-dimensional modeling (2D) in the pre-study concluded that the reservoir levels needed to be increased to successfully evacuate the new design flood, since too high velocities would occur otherwise in the channel between the existing spillway and the new one.

In order to achieve acceptable velocities at FRRL, an extensive excavation of the mentioned channel is needed, and it is not likely to get a permit for this with respect to environmental aspects. Figure 6 shows the results from the 2D-modeling: a comparison between FRRL and FRRL+0.75.

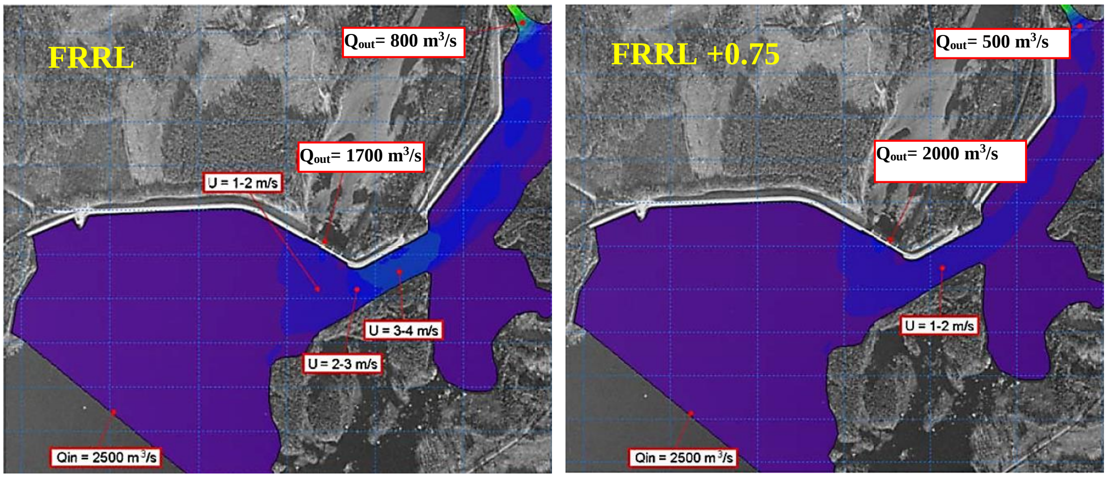

Figure 6: Reservoir flow patterns at FRRL and FRRL+0.75 m

The new spillway is designed with a stilling basin to reduce the risk of erosion in the river bed downstream the spillway and dams. Several configurations of the stilling basin were examined in terms of its floor elevation, end-sill elevation and basin length. Its placement was mainly governed by the hydraulic requirements to produce a stable hydraulic jump. It is also restrained by the geological conditions as it mainly will be excavated from existing bedrock.

Figure 7 shows the final layout of the basin, with a diverging shape downstream and a floor length of 40 m. The length of the sloping chute is about 80 m. The floor is placed at el. +255 m; the end sill is situated 6 m higher. The basin is 30 m wide at its downstream end.

Figure 7. Final design of new spillway’s stilling basin

One-dimensional numerical modelling of the river flow showed that the difference between water stages at low and high floods is significant. Therefore, the governing condition for the basin design corresponds to a downstream water level that results from the full discharge through the new spillway, with the existing spillway closed. In figure 8, the energy dissipation is shown at a discharge of 475 m^3/s merely from the new spillway.

Due to the low downstream water stage, the end-sill location should be placed as close as possible to the river course. A too large distance would not help hold up the basin water level and form a proper hydraulic jump, as the high-velocity outflow from the basin pushes away the water in the river. The end sill location is, to some extent, limited by the terrain and the rock quality of the river bank.

Figure 8. Energy dissipation at 475 m^3/s from the new spillway,
with the existing spillway in the closed position.

3.5. REVISED DESIGN DURING CONSTRUCTION

Later, during the construction of Långströmmen, the design needed to be revised due to issues such as poorer rock quality than expected as well as to excavate additional rock from the stilling basin to supply material for the reinforcement of the embankment dams. The well-known fact that CFD has difficulties in correctly modeling the complex flows in a stilling basin led to the construction of a physical models initially.

However, as the physical model no longer existed, Computational Fluid Dynamic-modelling (CFD) was used to evaluate impacts of proposed changes designs. The CFD-model was only used for relative evaluation, by comparing qualitative results from different designs. First, the design preferred in the physical model tests was tested in the CFD-model and later compared with the design motivated by the requested changes in design [9].

Figure 9 and figure 10 show results from the CFD-modeling.

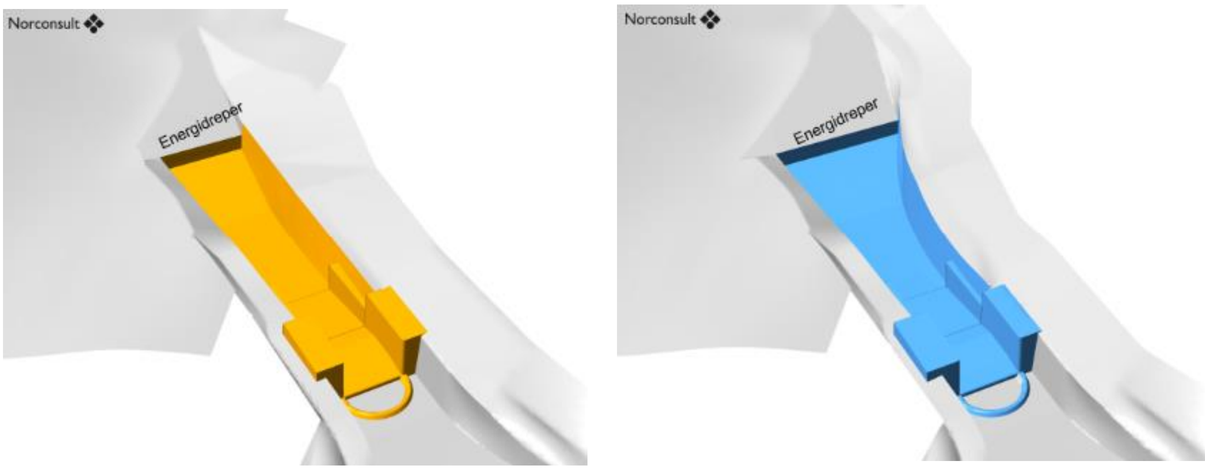

Figure 9: Left: Preferred design of spillway channel / stilling basin. Right: Alternative design, due to request for rock excavation (Norconsult, *2015.*

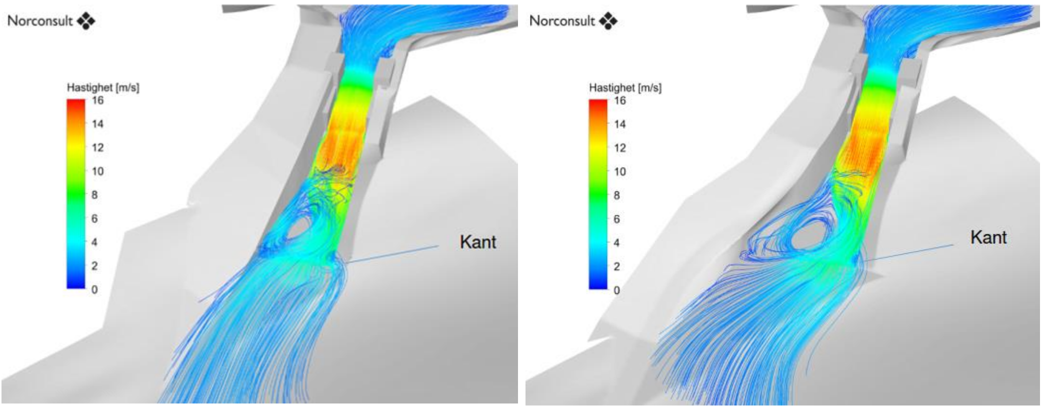

Figure 10: Results from CFD-calculations with preferred design (left) and the alternative design (right), (Norconsult, 2015).

The results show that the alternative design, with a more diverging shape downstream, generates a larger eddy that compresses the jet. This leads to higher velocities and thus, less effective energy dissipation in the stilling basin. However, it was concluded that the increased velocity was acceptable, and the alternative design was approved.

3.6. Initial Hydraulic Model Ramsele:

Similarly, a physical model was built for Ramsele (Billstein et al. 2016), with the main objective to attain optimal design of the prolongated spillway chute. All three spillway chutes were included in the model, since it was necessary to examine various configurations of gate openings, as well as operation of the left chute, see figure 11 below. It was also of some interest to determine the total discharge capacity of the dam facility.

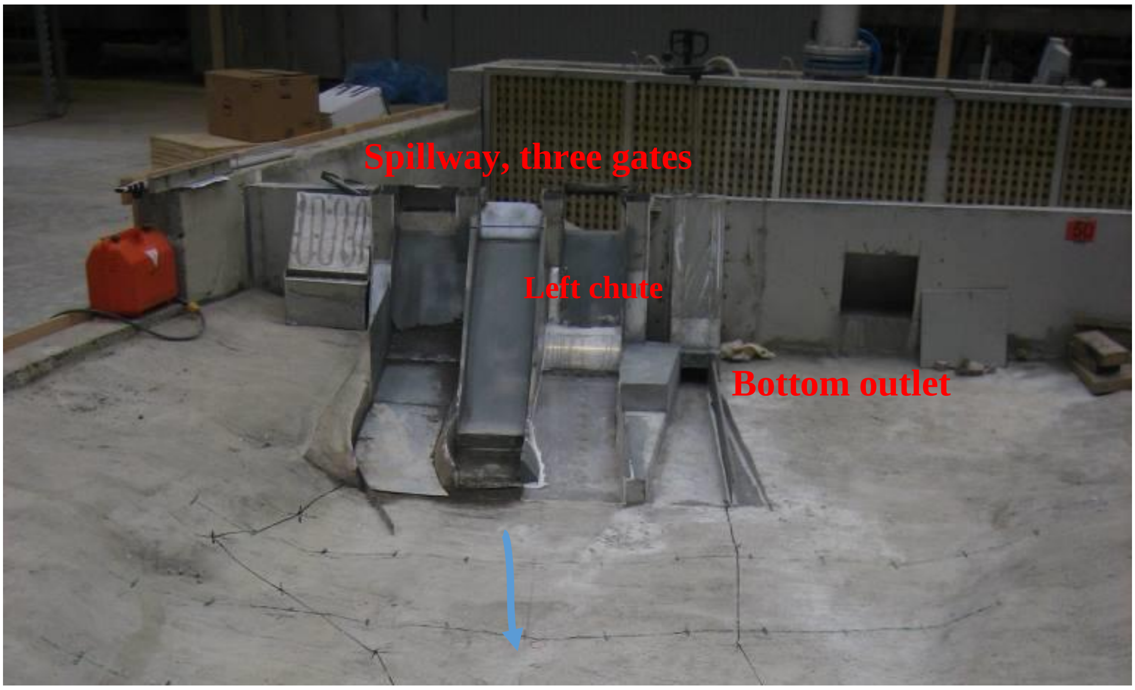

Figure 11: Hydraulic model of Ramsele dam, scale 1:50, with the proposed prolongated left chute (Vattenfall R&D, 2014)

3.6.1. *Spillway Discharge Capacity*

The discharge capacity of all three spillways was determined by physical modeling, and was found to agree with the original design values.

3.6.2. *Energy dissipation / prevention of rock erosion*

The planned design of the prolongated chute was included in the physical model upon which a number of tests were done, including measurements of velocity and wave activity along the slopes at the sides. During the testing phase, an alternative design was proposed: a shorter prolongation with a ski-jump at the end. The design change was chiefly motivated by cost reduction, as the construction length could be decreased by 30% to about 35 m.

This new design was chosen for further testing with a focus on optimizing the ski-jump design – jet throw length, location of the impact zone etc. The updated design flood also demanded for the guide walls to be heightened, and the model tests were used for optimization of this. Figure 12 shows model testing for the left chute, with the final design of the ski-jump.

Figure 12: Ramsele, left spillway – proposed shortened ski jump design (Norconsult, 2016)

4. VERIFICATION OF HYDRAULIC PERFORMANCE IN THE PROTOTYPES

After the completed construction of the planned measures, discharge tests are carried out according to accepted international guidelines. Ramsele has already been completed, and here photogrammetry was performed for the spillway channel before the discharge test, focusing on the area where the jet from the ski-jump plunges. This resulted in a topographic model, and if the procedure is repeated in the future after some discharging has occurred, the models can be compared for evaluating erosion propagation. Figure 13 shows a drone photo from the discharge test.

Upon completion of the last gate structure at Långströmmen, similar tests will be performed here. Aerial filming by drone is to be supplemented with water level measurements in order to verify the downstream water level during discharge. The readings will be compared to the physical model, and also the fluctuation of the water level.

Figure 13: Drone photo from first discharge test, after completed construction (Norconsult, 2016).

5. CONCLUSION

Both Långströmmen and Ramsele are high-hazard dams where recent dam safety revisions have uncovered deficiencies in their spillway structures. Whether the defects are in spillway capacity or in the structure downstream where scouring can erode the foundations of dam and spillway, one needs to fully understand the forces in play prior to designing the spillway structure.
In this, the value provided by physical modelling has been underscored in both projects by findings during the project life.

In Långströmmen, discoveries on site necessitated a revamp of the design.
In Ramsele, the discoveries were in the model phase and the design could be adapted parallel to the model tests.

In ideal worlds, the physical models should be kept until the project has been completed successfully. However, as large physical models are costly to keep for extended periods of time, the approach described in the Långströmmen project can be a way forward.

Numerical modeling is already used to enhance physical models in conceptualization by narrowing the scope of modelling. Långströmmen shows a way where CFD can be used to project parameters beyond the scope of the initial physical model.

Acknowledgements

The study of the dam upgrades reported in this paper is performed for power producers Fortum and Uniper, in Sweden. Vattenfall R&D, are acknowledged for their contributions to the hydraulic model tests. 1. ABSTRACT

Djuanda Dam is the largest dam built in Citarum River, located about 80 km toward southeast from Jakarta the capital city of Indonesia.

Djuanda Dam Jatiluhur is a multipurpose dam with a design-capacity volume of 3 billion m3, and based on the latest bathymetri measurement results has a storage capacity of approximately 2.5 billion m3.

This dam has a concrete cylindrical-shaped spillway called morning glory with a diameter of 90 meters and a height of 105 meters. The maximum capacity of this spillway is 3,000 m3 and also equipped with two irrigation outlets of which capable to release 195 m3/s water on normal water level.

This spillway is integrated with the powerhouse and connected with the access galery and tailrace tunnel, and make it as the only infrastructure to

* *LE COMPORTEMENT DE LA STRUCTURE DE DÉVERSEMENT DE DJUANDA DAM JATILUHUR INDONÉSIE*

release water from this dam so that the operation and maintenance of this spillway structure is very important.

The shift of the dam body construction toward the upstream than the planned has shifted the center of gravity of the dam causing the concrete fracture connecting the spillway-structure with the access gallery. This cracks then named as join 0. The water leakage from this cracks are collected and channeled into the drainage channel to monitor the quantity and the quality of leakage. The leakage monitoring activity conducted every two weeks.

There are 37 points of surface marker installed in this morning glory spillway-structure, 3 points placed on the top floor of the morning glory spillway-structure, 3 points on the floor in the powerhouse. While on the wall of the powerhouse is placed 31 points of surface marker, 11 mounted on the inside wall named interior circle, and 20 others mounted on the outside wall named exterior circle. The monitoring activity by measuring the movement of these surface markers conducted every month.

The measurement of the spillway-crest on 14 spillway-windows has conducted twice, on August 2001 and on October 2017.

Based on surface-marker monitoring results, this spillway has experienced movement and the monitoring data record shown the average cummulative settlement is 11 cm, and the largest cummulative settlement reached 15 centimeters at the point of window number 12, with elevation 106,8438 meters above sea level.

The movement of this spillway is influenced by the elevation of the reservoir water level (RWL), when the elevation of the RWL reach the normal elevation the spillway-structure moves down, and vice versa.

The movement of the spillway-structure also impact to the leakage at join 0. The leak is still monitored until now and it shown the largest discharge of 190 ml per second. The water quality of the leakage is monitored and did not indicate it carry the embankment material, visually it looks clear and clean.

1. INTRODUCTION

Bell-mouth spillways are not a common type of spillways in the Czech Republic. One of the oldest bell-mouth spillways is situated at the Jirkov Dam (Fig. 1). When compared to other spillways of this type, an unusuall solution was used for the intake and the circular bottom end of the vertical shaft. The physical model was built in order to clarify the hydraulic conditions during flood flows.

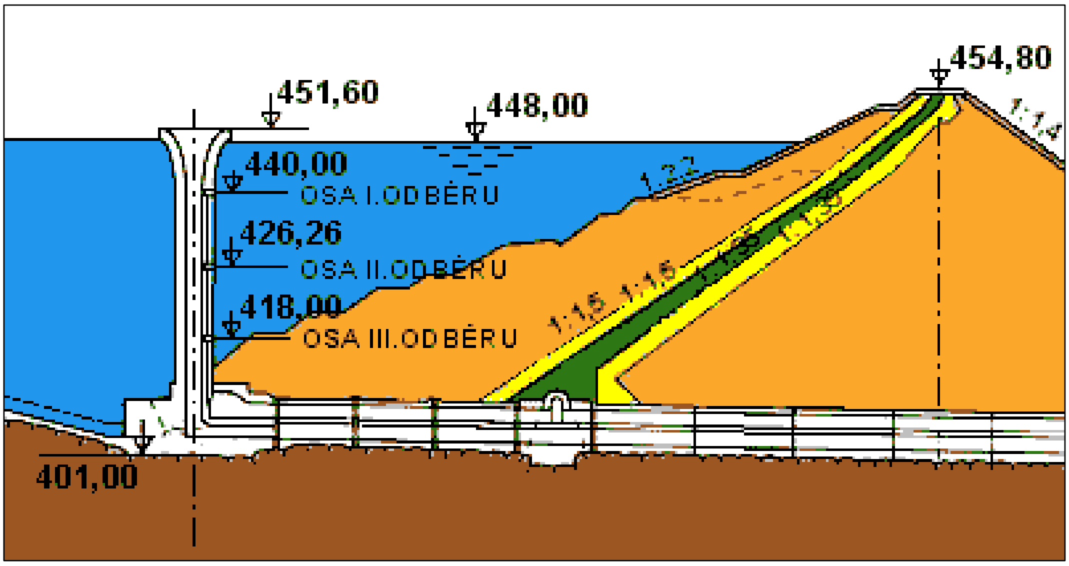

Fig. 1
Cross section of the Jirkov Dam

2. JIRKOV DAM

2.1. DAM

Jirkov Dam is located in the North-west part of the Czech Republic. It was constructed between 1960 and 1965. It is a rockfill dam sealed by the impervious clay core. The dam is equipped with the bell-mouth spillway structure at the upstream toe of the dam that is combined with two bottom outlets and three water abstraction intakes at different levels. Water from the bell-mouth spillway and the bottom outlets is conveyed to the outlet tunnel that ends at the downstream toe of the dam. The upper part of the tunnel structure forms an access to the bottom outlets.

Perpendicular to the tunnel is the injection gallery that goes along the whole dam at the foundations level. In recent years a grout curtain was constructed from the injection gallery in order to seal the seepage that had been observed.

2.2. BELL-MOUTH SPILLWAY

The overflow piers of the Jirkov Dam bell-mouth spillway were constructed rather small in size compared with similar structures at other dams. The piers also force water to rotate in the opposite direction. The water falls to the vertical shaft and then flows to the outlet tunnel via the sharp perpendicular bend that was suspected to limit the capacity of the whole object.

3. RESEARCH ASSIGNMENT

The unusual spillway intake setup led to the research that was carried out by the Civil Engineering Faculty of the Czech Technical University in 2015 and 2016 [1]. The research was ordered by the dam operator Povodí Ohře, state enterprise. The aim of the research was to assess the existing layout and propose optimized design. The research was carried out using the physical model of the bell-mouth spillway that extended from the top of the structure to the end of the spillway tunnel at the downstream toe of the dam.

The physical model was used to derive the rating curve of the spillway and particularly to find the level flow at which the undesirable hydraulic effects occur. It was also used to design and verify suitable modifications to the intake of the bell-mouth spillway, to the bottom end of the vertical shaft and to join of the bottom outlets to the spillway tunnel.

The physical model was built using the Froude similarity, it was considered that gravity and inertial forces are dominant and effect of remaining forces such as kinematic viscosity are small. The model was built in laboratories of the Czech Technical University in Prague, Faculty of Civil Engineering at a 1:20 scale. Setup allowed to measure not only flows, but also vibrations and pulsations. Pressure sensors were used to measure all hydraulic phenomena, which occurred on the model and particularly the dynamic effects of water flow on the structure.

Firstly, the measurements were carried out on the model of the original design and then modifications reflecting the knowledge gained on the modelling of similar bell-mouth spillways were proposed and tested. In particular, the attention focused on the optimization of the shape of overflow piers and the rounded bottom end of the vertical shaft.

3.1. REMOVAL OF OVERFLOW PIERS AT THE SPILLWAY INTAKE

The existing design of the overflow piers (Fig. 2) does not ensure stable spiral inflow to the vertical shaft and sufficient air supply even at low flow rates of 1 in 2 years return period. The inflow into the vertical shaft is strongly affected by the piers and the pressure pulsations were observed. These pulsations generate an unwanted load on the spillway and the shaft structure.

Fig. 2
Model of the original design with 4 overflow piers

In order to improve the hydraulic performance of the existing spillway the overflow piers were removed (Fig. 3).

Fig. 3
Model of the bell-mouth spillway without overflow piers

3.2. IMPROVEMENTS TO THE BOTTOM END OF THE VERTICAL SHAFT

The existing bottom of the vertical shaft has a sharp perpendicular bend (Fig. 4, left). As the water falls vertically to the bottom of the shaft, it forms an aerated turbulent flow cushion that extends downstream to the spillway tunnel. This cushion starts to be significant for 1 in 20 years flow.

The rounded bottom of the vertical shaft was proposed (Fig. 4, right). The model revealed that the aerated cushion has diminished significantly. The energy loss is much smaller and the velocity vector is oriented towards the direction of the outlet tunnel. The aerated cushion at the bottom of the shaft was formed for much higher flow exceeding 1 in 100 years return period.

Fig. 4
Rounded bottom end of the vertical shaft
Existing design (Q_{10}) Updated design (Q_{10})

3.3. COMBINED EFFECT OF THE SPILLWAY AND BOTTOM OUTLETS

The physical model allowed testing the effect of combined bell-mouth spillway and two bottom outlets operation. This scenario was tested for the extreme flow of 1 in 1000 years and it was found that the space at the junction of bottom outlets and the spillway tunnel is more aerated, when bottom outlets are in operation (Fig. 5). The use of bottom outlets at extreme flow rates is not recommended based on the model results. These flow rates surcharge the spillway shaft and unfavorably reduce the capacity of the whole hydraulic system.

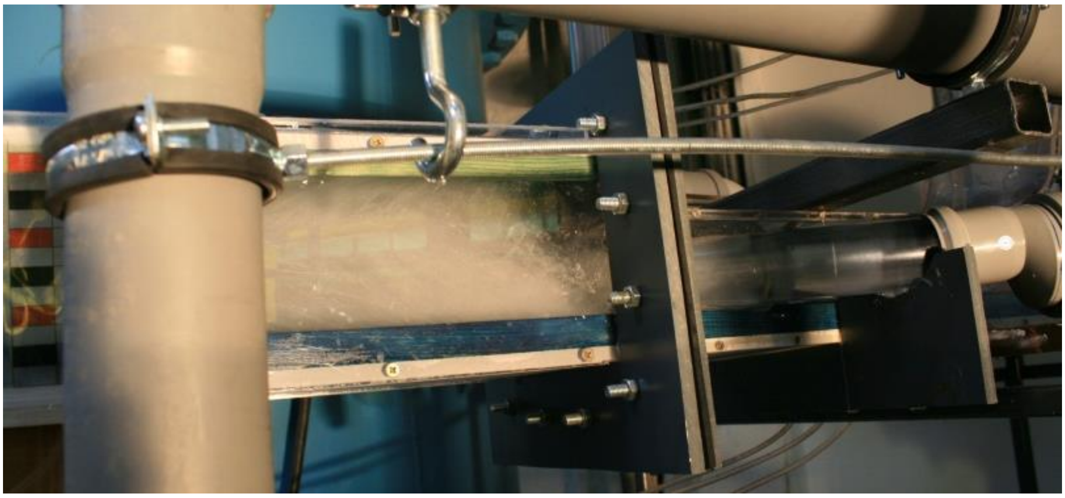

Fig. 5
Bottom left outlet pipe in operation

3.4. EFFECTS ON SPILLWAY CAPACITY

Rating curve was derived for the existing design (Var 1), on the improved design after the removal of the existing overflow piers (Var 2) and on the improved design with the rounded bottom end of the spillway shaft (Var 3). The comparison of rating curves representing the three modelled cases as well as the existing rating curve that is present in the operating manual can be seen in Fig. 6.

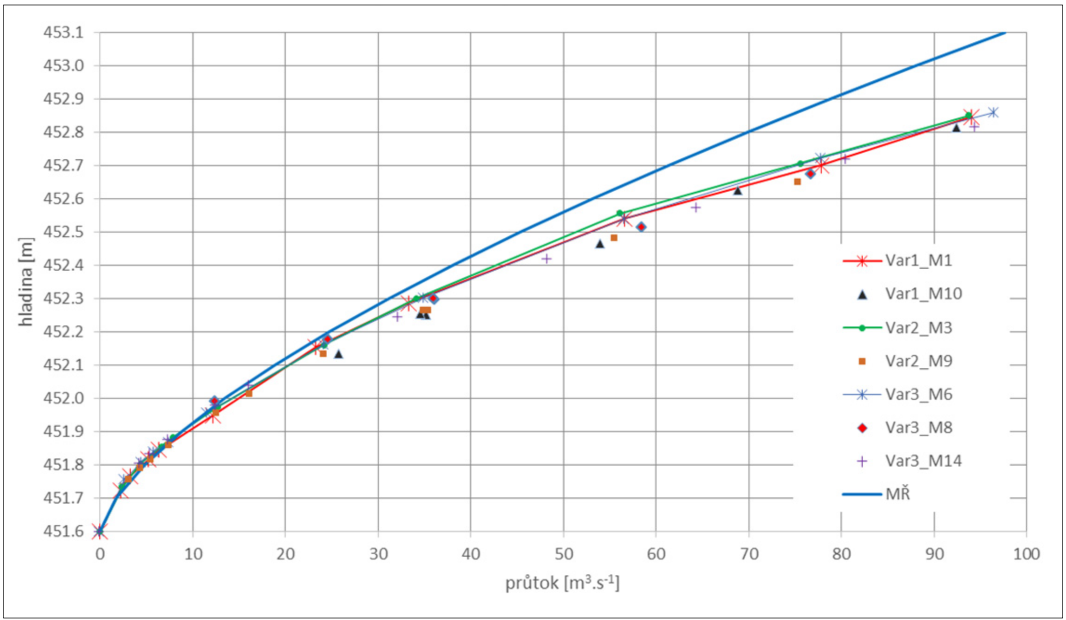

Fig. 6
Rating curve comparison

Curves derived by the physical model do not differ significantly; however, the plot shows the significant difference between the operating manual rating curve (labelled MR) and the models.

As the very small difference between the modelled rating curves suggests, the proposed design improvements do not affect the capacity of the structure significantly. However, it was proved by the physical model that the removal of the overflow piers improve water supply conditions at the vertical shaft and partly eliminate pulsations and decrease the hydraulic load on the structure, while the rounded bottom end of the vertical shaft prevents the existence of the extremely turbulent flow in the spillway tunnel downstream of the bend.

The original capacity of the Jirkov Dam spillway prior the reaching the undesired hydraulic conditions regime was assessed to be 95 $m^3.s^{-1}$, while the improved design capacity is 124,6 $m^3.s^{-1}$. This capacity is higher than 1 in 10 000 years flow which meets the Czech national standards for dam safety.

3.5. FURTHER IMPROVEMENTS OF SPILLWAY INTAKE

When the existing overflow piers were removed, research for a new design was carried out. The aim was to further eliminate the pressure pulsations on the spillway structure while not decreasing the capacity of the spillway.

A design of five-piers based on the similarity with other existing bell-mouth spillways was proposed and tested (Fig. 6). The six piers variant was also considered but it resulted in increase in pressure pulses throughout the tested flow range.

Fig. 7
Model of bell-mouth – designed overflow piers

SUMMARY

This paper presents the hydraulic research of the existing bell-mouth spillway at the Jirkov Dam in the Czech Republic and the improvements proposed to increase the hydraulic performance of the structure.

Proposals comprise the new design of the overflow piers and the rounding of the bottom of the vertical shaft. The improvements were proposed and tested on a physical model by the Czech Technical University in Prague, Faculty of Civil Engineering.

Rating curve was derived for the existing spillway design as well as for the proposed layouts. Proposed layouts showed an improvement, particularly the capacity of the existing Jirkov Dam spillway prior reaching the undesired hydraulic conditions was assessed to be 95 $m^3.s^{-1}$, while the improved design capacity is 124,6 $m^3.s^{-1}$. This capacity is higher than 1 in 10 000 years flow which meets the Czech national standards for dam safety.

1. INTRODUCTION

This paper presents the main characteristics of the automated structural monitoring system of Baixo Sabor dam and addresses a proposal for the definition of triggers for the physical quantities measured through the use of an automated data acquisition system (ADAS).

The defined triggers for the physical quantities will be linked to an Internal Early Warning Control System of the dam, allowing the early identification and notification of potential abnormal situations to the entities responsible for the dam safety.

In operation since August 2016, the ADAS of the Baixo Sabor dam defined by EDP allows the measurement of several quantities used for the safety control, analysis and interpretation of the dam behaviour, such as: horizontal and vertical displacements, movements of joints, strains, uplift pressures, foundation displacements, seepage, concrete and air temperatures, and reservoir water level, among others.

The measurements, obtained through the use of the ADAS developed and installed by Prointega Ingeneria, are sent to the gestBarragens system, which is the LNEC and EDP data processing and management system used for monitoring, diagnosis and safety control of dams.

2. THE BAIXO SABOR DAM

Baixo Sabor is a 123 m high concrete arch dam, 505 m long at the crest, designed, constructed and operated by EDP, located in the northeast of Portugal in Sabor river (a tributary of Douro river). The first filling of its reservoir, with a volume of about 1095 hm^3, took place between December 2013 and April 2016.

Fig. 1
Overall view of the Baixo Sabor dam

2.1. THE MONITORING SYSTEM OF THE BAIXO SABOR DAM

In accordance with the best technical practices, the monitoring system of the Baixo Sabor dam aims at the evaluation of the loads, the characterisation of the rheological, thermal and hydraulic properties of the materials, and the evaluation of the dam structural response.

The monitoring system of the Baixo Sabor dam consists of several devices which make it possible to measure quantities such as: concrete and air temperatures, reservoir water level, seepage and leakage, displacements in the dam and in its foundation, joint movements, strains and stresses in the concrete, and pressures, among others [1].

The system used for the measurement of the reservoir water level comprises a high precision pressure meter, which provides a record of the water height over time, and a level scale. The air temperature and humidity are measured in an automated weather station.

The concrete temperature is measured in 52 electrical resistance thermometers distributed across the dam thickness of several blocks. The location of the thermometers was defined taking into account the set of the others electrical resistance devices (strain gauges, embedded jointmeters and strain gauges) that also allow the measurement of the concrete temperature.

The foundation temperature is measured in 13 temperature sensors distributed in several rod extensometers.

Displacements are measured using an integrated system that includes 5 pendulums, 24 rod extensometers and geodetic observations. The relative movements between blocks are measured by 103 superficial and 152 embedded jointmeters.

The deformation of the concrete is measured with electrical strain gauges arranged in groups, distributed in radial sections, allowing the determination of the stress state through the knowledge of the deformation state and of the deformability law of the concrete. The drained and the infiltrated water are measured in the drainage system which includes 216 drains and 19 weirs. These last devices differentiate the total quantity of water that flows in the drainage gallery in several zones of the dam. The measurement of the uplift pressure in the foundation is performed by a piezometric network that comprises 41 piezometers.

2.2. THE AUTOMATED MONITORING SYSTEM OF THE BAIXO SABOR DAM

A real-time data acquisition system for the auscultation instrumentation (ADAS) has been installed at Baixo Sabor dam, allowing the measurement of the following physical quantities [2]:

- Horizontal movements based on the pendulum method through the use of optical telecoordinometers (4-20mA signal);
- Vertical movements through rod strain meters with position transducer, vibrating wire type;
- Discharges through level gauges with ultrasonic sensors (4-20mA signal);
- Pressures through piezometers with pressure transducers, vibrating wire type;
- Relative movements between blocks through 3D jointmeters with position transducer, vibrating wire type, located in the inspection galleries;
- Relative movements between blocks through 1D jointmeters with resistance transducer, Carlson type, embedded in the concrete dam body;
- Concrete strain through strain meters with resistance strain meter transducers, Carlson type, embedded in the concrete dam body;
- Concrete temperature through thermometers with resistance thermometer transducers, Carlson type.

In addition, the weather station has been integrated into the automated data collection system by communicating the automation server with the station logger.

As a complementary system, a high precision Global Navigation Satellite System (GNSS) has been installed. It allows the displacements measurements of 3 points located at the dam crest, both horizontally and vertically, using an external pillar as reference, allowing to obtain post-process results working every hour, 4 hours and 24 hours. In this last case, a sub-millimeter precision is obtained.

For real-time monitoring and for the analysis of all the information, ADAS auscultation software has been installed, with customised developments for this project. This software allows real-time monitoring of the system, generation of graphs and reports and alarm management, among other functionalities, operating on a multiuser Web environment, allowing several technicians to work on the system at the same time.

The structure of the ADAS is based on industrial decentralised periphery automation, in this case composed of a main box that houses the PLC (Programmable Logic Controller) provided with a touch panel with remote connection, and four secondary boxes, racks, all connected in a ring via optical fibre and secure power supply via batteries. Equipment with galvanic isolation and surge arresters has been placed at strategic points to make the system more robust. The GNSS communicates via optical fibre with the main box, which is connected to the server installed in the control and emergency room where the GNSS and ADAS software is installed.

The touch panel of the main box enables the parameterisation and supervision work on the dam, as well as stopping logs for maintenance work and alarm management. As all the equipment is in the same network, the panel can be remotely accessed from any box, thus allowing the monitoring and parameterisation of the instrumentation from other galleries where there are automation boxes, making these tasks much easier.

The communication between the instrumentation and automation box is performed with multi-wire shielded sheaths from each device to the box, thus avoiding interconnection boxes, all channelled in separate trays of the power supply sheaths, avoiding electromagnetic noise and guaranteeing the quality of the signals.

All the instrumentation is adapted to be able to make a parallel manual reading, allowing data contrast and validation of both systems. The equipment is all standard, allowing easy maintenance and rapid device replacement times. The system is already equipped for an expansion of about 20%.

2.3. MEASURING RANGE OF UPLIFT PRESSURE, MEASURED THROUGH PIEZOMETERS

The automated measurement of uplift pressure is performed through 25 piezometers as presented in Fig. 2.

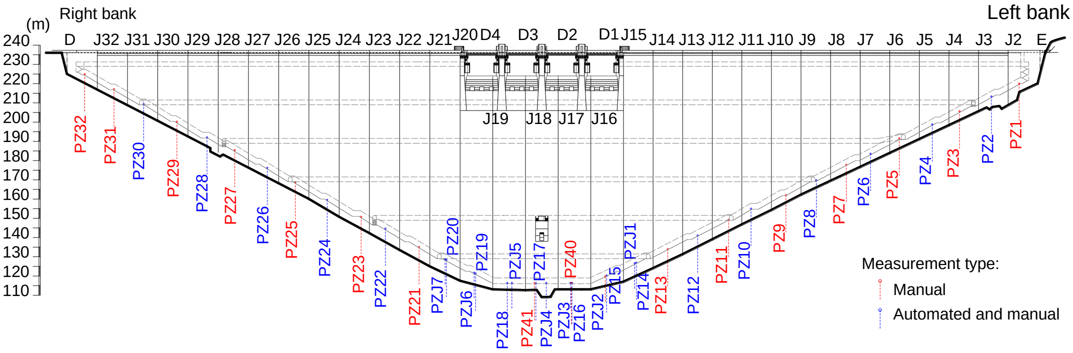

Fig. 2
Location of the piezometers

The automated measurement of the uplift pressure along the dam foundation is performed by vibrating wire piezometers, Geosense VWP-3000, converting fluid pressures on a sensitive diaphragm into a frequency signal and then into a uplift pressure unit (m H2O), Fig. 3.

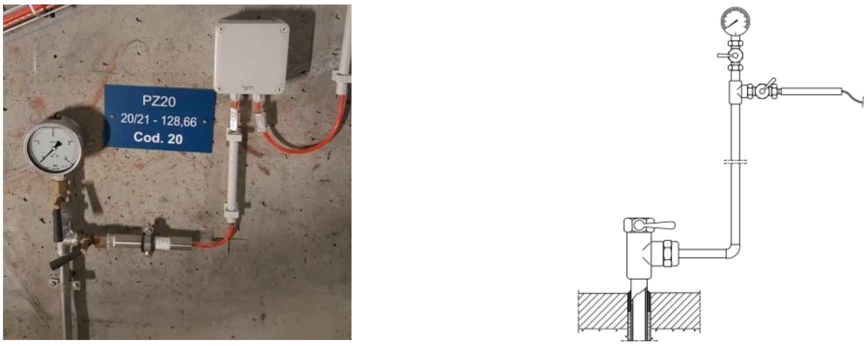

Fig. 3
Piezometer with automated readings.

The main features of the vibrating wire piezometers VWP-3000 type, presented in Table 1, are suitable for the environmental conditions and the expected maximum range of the instrument, equal to 70 m H2O, which is considered adequate.

Table 1
Piezometer VWP-3000 type, main features

Pressure range	0 – 690 kPa
Resolution	0.0255 %FS
Accuracy	0.1%FS
Non-Linearity	<0.5%FS
Temperature range	-20 to 80 ºC
Thermal effect	<0.05%FS/ºC

The uplift pressure measuring range in terms m H2O, for the 3 piezometers with more significative measurements, is presented in Table 2.

Table 2
Piezometer measuring range from January 2015 to December 2017

Designation	PZ8 (169m)	PZ12 (138.86m)	PZ14 (126.62m)	PZJ1 (125.9m)
Max (m H2O)	36	19	28	20
Min (m H2O)	13.2	0	1.9	2.7

(elevation of the measurement points is shown in curved brackets)

3. TRIGGER DEFINITION BASED ON THE OBSERVED BEHAVIOUR

The definition of triggers for the uplift pressure measured through use of the piezometers is presented in this work. In order to show the proposed methodology, only the analysis of the uplift pressure measured in the PZ14 (126.6m) is presented. In the case of uplift pressures, the manual measurement was possible since September 2014 (time period more than two years) and the automated measurement was possible since July 2016 (time period less than one year). For these reason, manual measurements were used for the trigger definition. The data analysed corresponds to a period between January 2015 and December 2017, resulting more than 123 observations (manual measurements). The time evolution of the reservoir water level, air temperature and uplift pressure (manual and automated measurements) in the referred PZ14 (126.6m) are presented in Fig. 4. The readings were collected every two weeks for manual measurements and every hour for automated measurements. Among the different loads acting on concrete dams, it is usual to distinguish, as the most important ones for structures in normal operation, the hydrostatic pressure and the air temperature variation, Fig. 4.

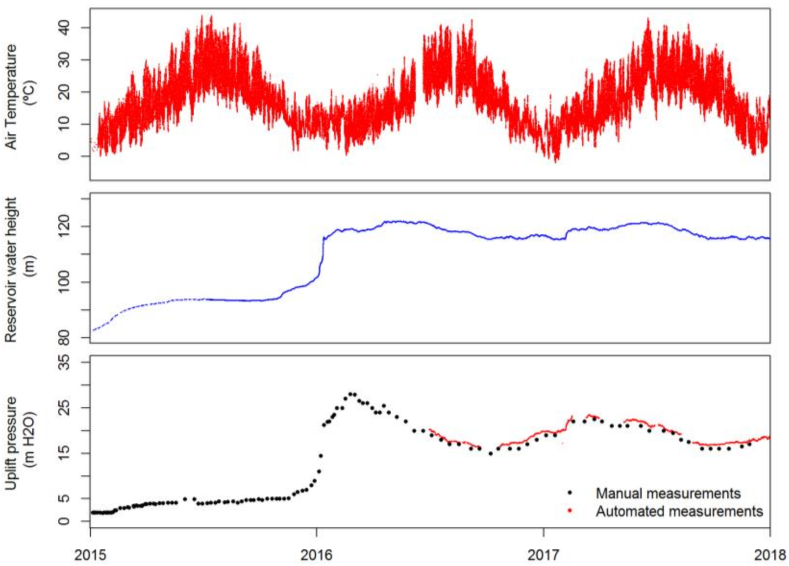

Fig. 4
Uplift pressure in the PZ14 (126.6m), reservoir water level and air temperature along time

The structural response of, for instance, the uplift pressure, is strongly related to the corresponding variation of the reservoir water level. The manual measurements presented in Fig. 4 were used for the computation of the Hydrostatic Season Time (HST) models [3,4,5] presented in this work.

In this case study, the HST model with the best performance for the uplift pressure regarding the manual readings of the piezometer $y^{HST,\ PZ14\ (126.6m)}$ was obtained as the sum of the hydrostatic pressure term $\beta_1 \times h^4$ (where h is the reservoir water level height and can vary between 0 and 123 m) and the temperature terms $\beta_2 \times cos(d) + \beta_3 \times sin(d)$ to represent the effect of the annual thermal variation of the temperature (where $d = 2\pi \bullet j/365$ and j represents the number of days between the beginning of the year, January 1, until the date of observation, $0 \leq j \leq 365$). The time effect did not seem to have a significant importance in the period examined by this study. The regression coefficients of the quantitative models obtained are $\beta_1 = 1.342 \times 10^{-7}$, $\beta_2 = 1.2512$ and $\beta_3 = 1.3459$, with $k=-6.049$; being the HST model represented through the Eq. (1).

$$Y^{HST,\ PZ14\ (126.6m)} = \beta_1 \times h^4 + \beta_2 \times cos(d) + \beta_3 \times sin(d) + k \quad (1)$$

The effects of hydrostatic pressure variation based on the reservoir water level variation, the thermal effect due to temperature variations (considered as a proportional attenuation of the air temperature changes with a phase shift), the residuals* (k), the HST model prediction and the confidence intervals (based on 3 and 6 standard deviation, corresponding to 99.73% and 99.99% confidence levels, respectively) are presented in Fig. 5.

The regression parameter estimates for the HST models, regarding to the uplift pressures, for the piezometers PZ8, PZ12, PZ14 and PZJ1, are presented in Table 3.

Table 3
Regression parameter estimates for the HST models regarding to the uplift pressure obtained through the piezometers

Designation	β1	β2	β3	k	σ (m H2O)
PZ8 (169,0m)	$1.107X10^{-7}$	1.218	1.305	6.852	2.15
PZ12 (138,9m)	$8.504X10^{-8}$	-0.084	1.996	-5.774	2.47
PZ14 (126,6m)	$1.342X10^{-7}$	1.251	1.346	-6.049	1.71
PZJ1 (125,9m)	$8.395X10^{-8}$	0.941	1.127	-2.111	1.39

* *Besides the information related to any possible anomalous phenomena, the residuals contain information related to errors (measurements and model) and other unknown effects.*

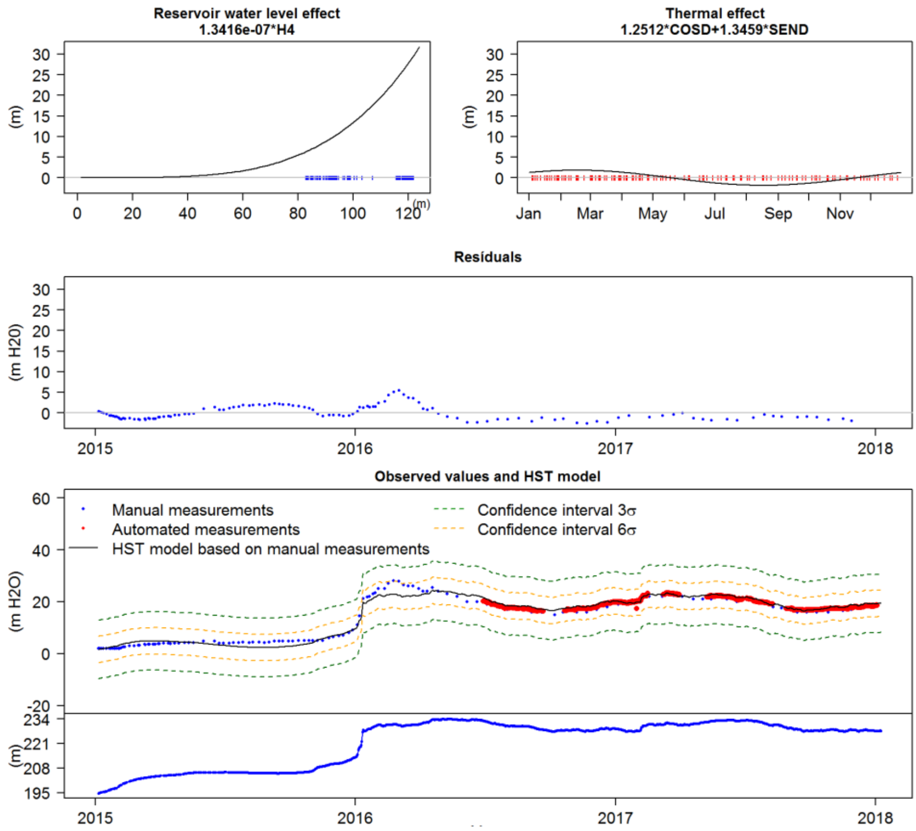

Fig. 5

HST model for the uplift pressure measured in the PZ14 (126.6m), $y^{HST,\ PZ14\ (126.6m)}$

4. DEFINITION OF TRIGGERS FOR THE AUTOMATED MEASUREMENTS

Currently, the ADAS auscultation software includes a control panel that allows the definition of four different constant triggers (LL, L, H, HH – Low Low, Low, High, High High respectively). Users associated with the dam are notified when any trigger is activated. These messages are sent to ADAS auscultation software, being possible to see the warning in several synoptics that's allows the analysis of the dam behavior in real time (Fig. 6) and sent to the mobile phone of the users.

Based on the analysis of the results:

- The minimum positive value obtained from the confidence interval 6σ was considered for LL and the minimum positive value obtained from the confidence interval 3σ was considered for L;
- The maximum value obtained from the confidence interval 3σ was considered for H and the maximum value obtained from the confidence interval 6σ was considered for HH.
- The value proposed during the design phase (percentages of hydraulic head less than 33,3 %) was considered for.

Despite the use of these triggers, an additional type of trigger will be defined to detect short time variations with more accuracy. Based on the fact that automated measurements are recorded each two hours, the hypothesis that between two consecutive measurements (at time *i* and time *i-2h*) small variations are expected can be considered adequate. In fact, the use of 3σ as criteria regarding two consecutive automated measurements showed to be adequate, based on the records of manual and automated measurements, (this type of trigger is represented with the black colour in Fig. 7).

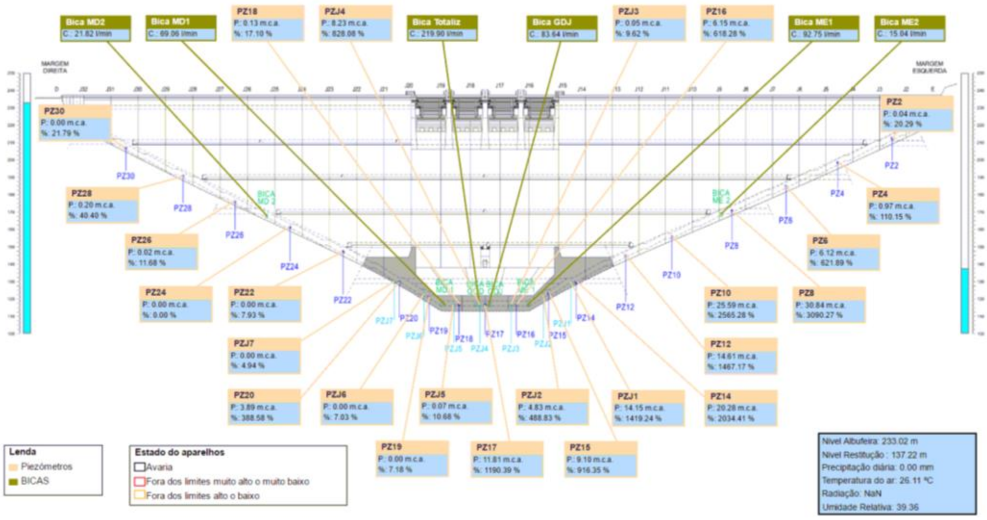

Fig. 6
Synoptic example: Uplift pressures and discharges measured in the Baixo Sabor dam

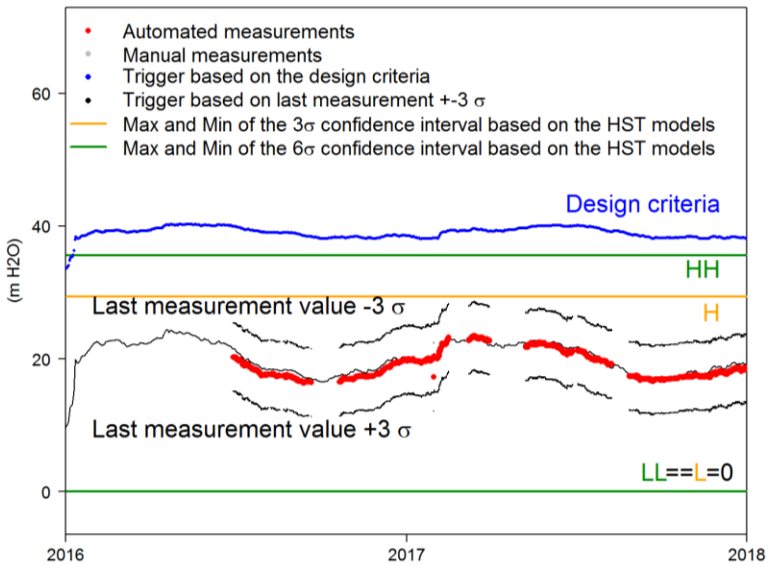

Fig. 7
Triggers used for the assessment of the uplift pressure measured in the piezometer PZ14 (126.6m)

The final results for each trigger are presented in Table 4.

Table 4
Trigger considered for the assessment of the uplift pressure

Designation	LL (mH2O)	L (mH2O)	H (mH2O)	HH (mH2O)	$Abs(\Delta_{(i)-(i-2h)})_{max}$ (mH2O)
PZ8 (169,0m)	0	6.2	39.2	45.7	6.5
PZ12 (138,9m)	0	0	23.1	30.5	7.4
PZ14 (126,6m)	0	0	30.0	35.1	5.1
PZJ1 (125,9m)	0	0	21.7	25.9	4.1

5. FINAL REMARKS

According to the recent trends in automatic monitoring dam systems having in mind the safety control in real time, the ADAS installed in the Baixo Sabor dam includes internal early warning control system allowing early identification and notification of potential situations to the entities responsible for dam safety.

In this work, a methodology to the definition of triggers for the physical quantities observed in automated monitoring systems of the Baixo Sabor dam was presented.

The definition of triggers for the uplift pressures measured on piezometers was performed through the use of HST models and measurement data. The proposed methodology are being used to the definition of the triggers for other physical quantities measured through the automated monitoring system.

Although the importance of physical installation of the systems, it should be noted that the exploitation of ADAS total capacities also involves the incorporation of suitable software for the analysis and validation of the results obtained, based on representative models of the dam behaviour.

So, it can be concluded that the automated monitoring system installed in the Baixo Sabor dam, with internal early warning control system, has a relevant contribution to assure an effective safety control of the dam.

1. INTRODUCTION

The Gambiri diversion dam is located at east of Kunar province, near the Asadabad city on the Kunar river, eastern Afghanistan "Fig 1". This project falls within a region of very high seismicity, in the eastern sector of Alpine- Himalaya orogenic belt. In order to estimate the ground motion parameters a comprehensive seismic hazard analysis was performed. This paper gives first a brief overview of the seismo-tectonics of the region and the seismicity. The methodology followed to obtain the peak ground acceleration, response spectra and design accelerograms for different design levels is then described together with selected results.

2. SEISMOTECTONIC SETTING AND HISTORICAL SEISMICITY

As recent deformation continues in the Alpine- Himalaya region, moderate-to-large magnitude, potentially damaging earthquakes are common. Earthquakes in this region will likely cause serious damage, not only from strong ground shaking and faults rupturing the ground surface, but also from liquefaction, lateral spreading and extensive landslide.

Fig. 1

Location of the Gambiri diversion dam site in the eastern Afghanistan.

The data necessary for the seismic hazard analysis were obtained from a survey of the type, location and characteristics of seismic sources, especially faults. Information obtained from earthquake catalogues gave input on the historical seismicity of the region. The catalogues were also used as a basis for probabilistic analyses of earthquake ground motions. The area surveyed for assessing the seismicity comprised a circle with a radius of about 300 km from the site. Epicenters in this region are shown in "Fig 2".

Most of the major faults in the study area follow an NE-SW trend. The Konar- Nari Fault was identified as major active fault. The strongest historical earthquake relevant to the Badakhshan district of northeast Afghanistan is the event of 1832 with an estimated magnitude Ms 7.4. This event can be ascribed to the activity of the central Badakhshan.

3. ESTIMATION OF PEAK GROUND MOTION PARAMETERS

3.1. SEISMICITY PARAMETERS

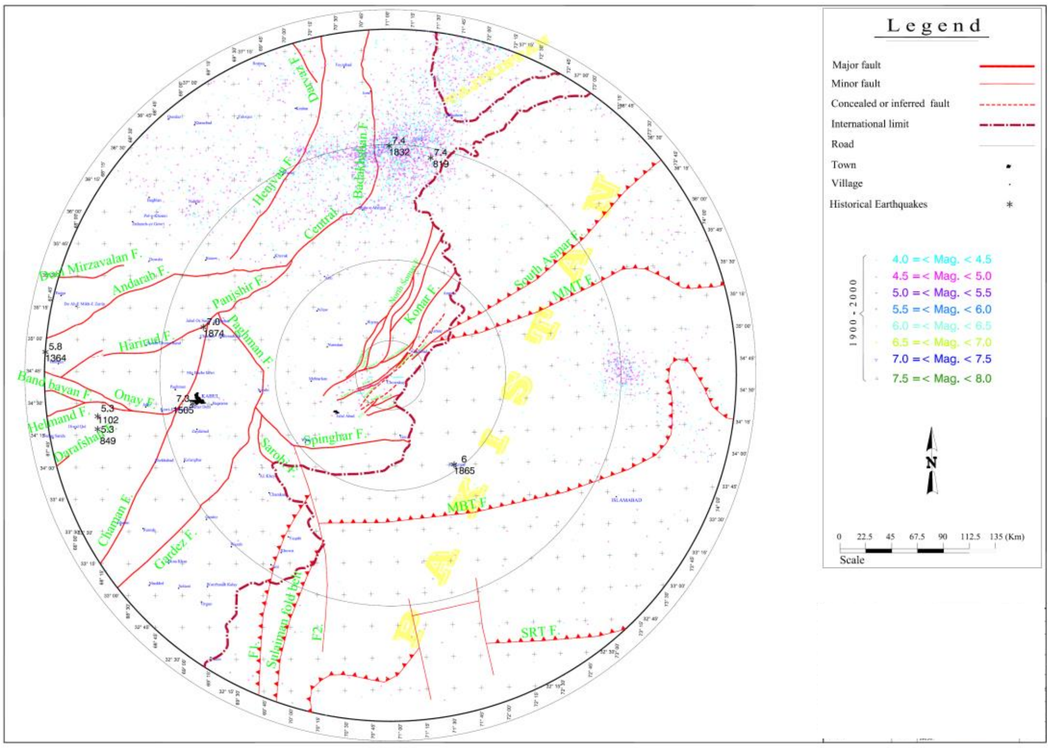

Fig. 2
Location of earthquake epicenters within a radius of 300 km around the site

The estimation of the maximum magnitude (Mmax) and recurrence relationships was performed using by both of the classical approach of Gutenberg & Richter [1] and of the Kijko-Sellevoll method [2].

The advantages of using both of these methods are containing the largest earthquakes and containing data sets which are complete from different thresholds of magnitude upwards. The method can also consider gaps when records in the catalogue are missing and uncertainties in earthquake magnitudes.

3.2. ATTENUATION RELATIONSHIPS

Seismic loads imposed on a dam structure such as power plant by ground motions are usually expressed as peak values of ground acceleration, velocity, and displacement. The peak ground acceleration (PGA) is often used to quantify the seismic hazard for a structure. The values of ground motion parameters (Y) at a site (Include PGA) are estimated by so-called attenuation laws which in their simplest form are expressed as "Eq. [1] ".

$$\log Y = \log f_1\,(\text{magnitude}) + \log f_2\,(\text{distance}) + .. + \varepsilon \qquad [1]$$

Attenuation of ground motion depends on many factors such as the fault mechanism, site geological conditions, thickness and type of overburden, etc. The most recent attenuation laws have also taken into account these effects. For this study the relationships of Campbell & Bozorgnia [3], Ambraseys and Douglas [4], Boore et al. [5] and Mahdavian [6] were used.

3.3. GROUND MOTION DESIGN LEVELS

Four ground motion levels were considered to define the seismic design requirements for the power plant and appurtenant structures. These design levels are partly defined by International Committee of Large Dams [7] and Building and Housing Research Center of Iran [8]. The basic idea is to allow for certain damages during an earthquake of a relatively long return period compared to the lifetime of the structure but not to endanger people's life. The four ground motion levels are defined in following on.

3.3.1. Operating Basis Level (OBL)

The Operating Basis earthquake is expected to occur during the lifetime of the dam. The OBE represents the level of ground motion at the dam site which no damage is acceptable. In this study recommended return period of occurring of the OBE is about 150 years.

3.3.2. Design Basis Level (DBL)

Ground motions of this level are expected to occur during the lifetime of the power plant. Some minor damage to structures and equipment is accepted but they must remain functional. A PSHA is the most suitable method to establish this level and a return period is about 500 years (usually 475 years).

3.3.3. Maximum Design Level (MDL)

This level of ground motions has a low probability of occurrence with a return period of about 1000 years. The dam and appurtenant structures shall be able to resist these ground motions but larger damages are accepted. Safety related devices, such as spillway gates, must remain operational. PSHA is most appropriate to establish values for this ground motion level.

3.3.4. Maximum Credible Design Level (MCL)

This level is defined as the largest ground motion that can reasonably be expected at the site from a nearby seismic source or on the basis of the seismic history and tectonics of the region. The DSHA is considered the most appropriate approach to estimate ground motion levels for this scenario. The dam and appurtenant structures may sustain irreparable damage but the uncontrolled release of reservoir water must be prevented. In this study Return Period of occurring of the MCE is more than 2000 years.

For Gambiri diversion dam site, return periods of 200, 500 and 2500 years were considered for the OBL, DBL and MDL respectively and using the 84th percentile of the distribution.

3.4. PROBABILISTIC SEISMIC HAZARD ANALYSIS (PSHA)

PSHA allows the use of multi-valued or continuous events and models to arrive at the required description of the earthquake hazard. Ground motion levels are expressed in terms of probabilistic estimates such as the probability of occurrence of the PGA for a given period of time. The method also allows quantifying the uncertainty of the ground motion parameters. Two models were considered, the seismic point source model and the seismic line source model.

3.4.1. Seismic Point Source (or Poisson) Model

This is the oldest approach employing probabilistic tools. The earthquakes are modeled as point sources considering magnitude, epicenter and focal depth. Events are considered independent of each other. The use of this model is advantageous for situations where the identification of faults in an area is difficult and where large and frequent earthquakes have occurred near the site. However, the method cannot consider uncertainties in magnitude and epicentral distance nor does it accept historical earthquakes in the calculations. Since there are numerous large historical earthquakes around the Gambiri diversion dam site, results obtained by this model are believed not to be reliable and they are used for reference purpose only. Calculations were performed using the Gumbel type I distribution function [9].

3.4.2. Seismic Line Source Model

This model better fits the many line sources (faults). It can be treated by the well-known software SEISRISK III [10]. Input parameters required include: geometry and location of each seismic source (fault, source zones, including uncertainty), attenuation relationships, and seismicity parameters β and λ (used in the 5 distribution function of the doubly truncated Gutenberg-Richter equation

[1]). The main output obtained from this program is the probability of a ground motion parameter (PGA or spectral acceleration) not being exceeded during a fixed period of time at the site.

For estimating the seismic potential (maximum magnitude) of a fault the Wells & Coppersmith relationship was used which is based on worldwide data [11]. Calculations were carried out for return periods between 100 and 2500 years. In order to obtain a weighted average of the results calculated with the three attenuation laws, a logic tree approach with three branches was applied. Selected results are shown in "Table 1". The values obtained from the line source model were considerably higher than those derived from the point source model.

Table 1
Values of PGA obtained from PSHA using line source model

Design level	Return period (year)	Dam site	
		Peak ground acceleration (g)	
		horizontal	vertical
OBL (84th percentile)	200	0.30	0.18
DBL (84th percentile)	500	0.394	0.245
MDL (84th percentile)	2500	0.455	0.290
MCL (84th percentile)	Deterministic	0.64	0.53

3.5. DETERMINISTIC SEISMIC HAZARD ANALYSIS (DSHA)

The purpose of the DSHA is to find the worst possible scenario among all the possible seismic sources related to the studied site. The analysis comprises four steps: (1) Identification of the active faults closest to the site, (2) determining the maximum earthquake that could be generated by these faults, (3) selection of appropriate attenuation laws, and (4) determination of the hazard at the site. The maximum values of PGA were calculated for twelve faults or fault segments affecting the dam site using the same attenuation laws as for the PSHA. The distance to the seismic source was taken as the closest distance to the vertical projection of the rupture for Campbell & Bozorgnia [3], Ambraseys and Douglas [4], Boore et al. [5] and Mahdavian [6] laws. A weighted average was calculated using a logic tree approach. The results are given in "Table 2".

4. ESTIMATION OF RESPONSE SPECTRA

For design and analysis of structures a convenient way to express ground motions is the response spectrum which gives the maximum response (acceleration, velocity, or displacement) of a simple oscillator to the ground motion.

Table 2
Values of PGA obtained from DSHA (in fractions of g)

Fault name	Distance (km)	M	Dam site			
			horizontal		vertical	
			50%	84%	50%	84%
Harirud	7.8	7.6	0.362	0.580	0.240	0.416
Konar- Nari	1.2	7.3	0.40	0.64	0.312	0.533

The oscillator has the same period of vibration as the fundamental period of the structure. The maximum response is plotted versus the undamped natural period or the natural frequency. Site-specific response spectra are derived from ground motions arising from distinct, well-identified seismic sources in the region considered.

For Gambiri diversion dam site, different methods were chosen to calculate the specific response spectra, namely: (1) probabilistic method using the line source model, (2) deterministic method using active faults in the site area, and (3) statistical method using existing strong motion records. In the following these three methods are briefly described.

4.1. RESPONSE SPECTRA FROM LINE SOURCE MODEL

Some of the attenuation laws used in the PSHA are also frequency dependent. These laws were used to establish so-called Uniform Hazard Spectra or Equal Probability Spectra. On such a spectrum curve each point has an equal probability of exceeding a ground motion parameter (acceleration, velocity, displacement). By means of the logic tree procedure weighted averages of the spectra can be derived.

4.2. RESPONSE SPECTRA FROM DETERMINISTIC MODEL

This model is used for the estimation of the response spectrum for the MCL. The ground motions at a site are estimated deterministically for a selected earthquake scenario. After having determined the earthquake magnitude of a specific seismic source and the closest distance to the site, the site ground motions are estimated using ground motion attenuation laws. The response spectrum is then calculated within a certain range of periods. 50th and 84th percentile values can then also be computed for different damping values.

4.3. RESPONSE SPECTRA FROM STATISTICAL ANALYSIS

In this method, originally proposed by Kimball [12], a suite of strong motion records is statistically treated. These records should originate from earthquakes with similar distances to the rupture source and the magnitude should be of the same order as the target magnitude. Some corrections for differences in site conditions may also be needed. The steps are as follows:

• Selection of suitable strong motion records having magnitudes and distances to the source similar to the target parameters of the earthquake.

• Adjustment of the records for differences in magnitude, distance, faulting mechanism, and other parameters between site-specific conditions and the conditions existing at the site of the record

• Performing a statistical analysis of the adjusted response spectra of the collected records to obtain the target values of the site-specific spectrum. The median (50th percentile) and the median plus one standard deviation (84 percentile) are then selected as DBL and MDL levels respectively. For Gambiri diversion dam sites, site-specific ground motions for distance ranges (about 30 km) similar to the target magnitude were calculated and statistically analyzed. "Fig. 3 and 4" show the horizontal and vertical design response spectra recommended for OBE, DBE, MDE and MCE for this project.

"Fig. 5" shows a comparison between Horizontal components of response spectra estimated by statistical and probabilistic methods with together. The amplitudes of recommended OBE, DBE and MDE response spectra estimated by statistical method are good coordinated with 150, 500 and 1000 year response spectra estimated by probabilistic method respectively.

Response spectra based on statistical processing for horizontal component

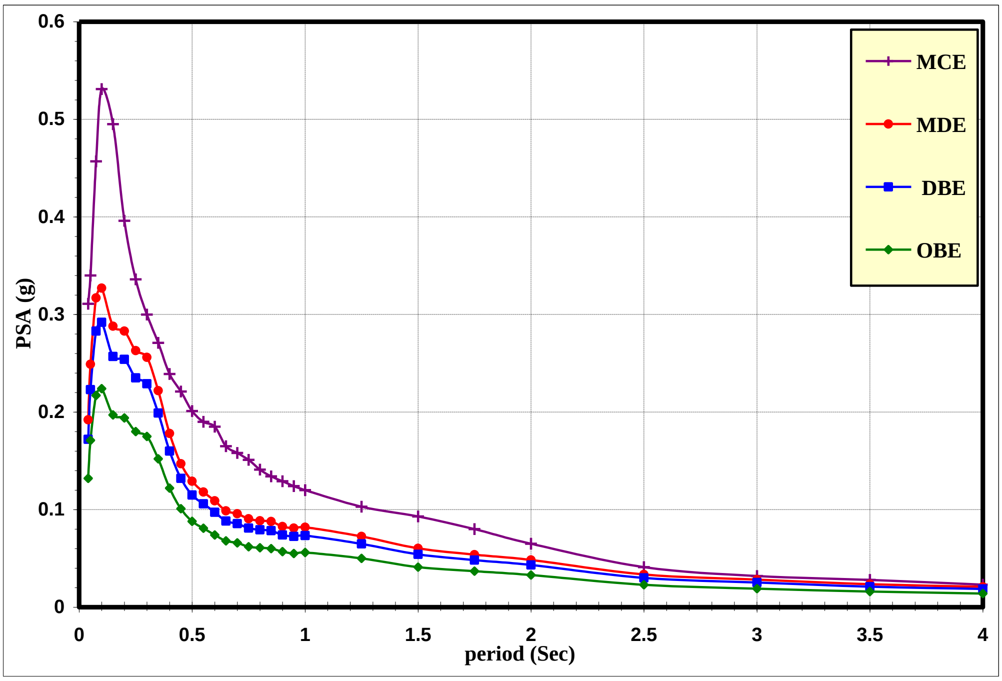

Fig. 4
Response spectra based on statistical processing for vertical component

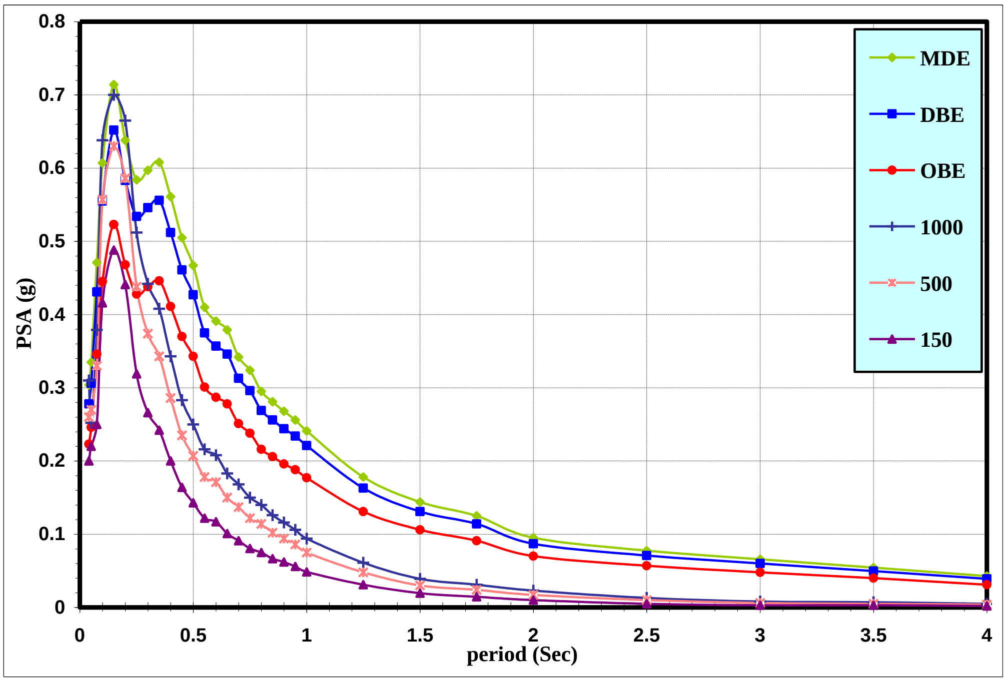

Fig. 5
Comparison between response spectra based on statistical & probabilistic processing for different periods

5. CONCLUSION

The seismic hazard at the Gambiri diversion dam site has been estimated by means of probabilistic and Deterministic methods to obtain the ground motion levels for the design of the dam and appurtenant structures. The dams and relevant structures are designed for the median (84th percentile) of the maximum credible level (MCL). This yields peak ground acceleration of 0.64 g in the horizontal and of 0.53 g in the vertical direction. Response spectra were produced for the design of concrete structures and acceleration-time histories, compatible with the design site-specific response spectrum, for the design of the dams and slopes. The study area has experienced numerous large historical and 20th/21st century earthquakes with Ms between 0.4-7.6. Often earthquakes in this region cannot be related to a mapped surface faulting and they occur between the branches of the major faults. The Konar- Nari fault was considered as the most dominant structure in the deterministic analysis. Smaller faults around the sites are considered non-active or with low seismic potential. Considering that events of surface faulting may be separated by quiescent periods of 3000 to 5000 years, the choice of more conservative ground motion values derived from the Konar- Nari fault is justified.

1. INTRODUCTION AND BACKGROUND

Among the 1200 dams classified in Switzerland, 167 are large dams according to ICOLD standards. The Swiss Federal Office of Energy (SFOE) is entrusted with the overall supervision of the enforcement of the legislation, which comprises the development of the safety concept and dam safety requirements published in form of Guidelines. The SFOE is also entrusted with the direct safety supervision of the 217 largest dams in view of their impounding head, storage capacity and hazard potential for the population in the area downstream of the dam. These are categorized into 124 concrete dams, 66 embankment dams and 27 run-of-river hydropower plants. The latter are deemed to be in the interest of public safety mainly for their relevant storage capacity.

With the new Dam Safety Legislation in Switzerland (2012), large run-of-river hydropower plants along main rivers became subjected to in-depth safety assessments under the direct supervisory authority of the SFOE based on the specific Enforcement Guideline of the Dam Safety Legislation (2015). The Swiss dam safety concept, apart from continuous surveillance, maintenance and emergency planning also entails such periodic in-depth safety assessments. This consists in a review of hydraulic and structural actions (static, flood and seismic) for all water-retaining structures and safety-critical appurtenant components of such an installation, including lateral embankments or dams within the storage area. Present structural, hydraulic, hydrogeological, geological, steel-structural and process control technology state of all above components require an assessment, as well as implemented surveillance and maintenance practices. If necessary, based on actual scientific and technical state of knowledge, improvements are recommended and may be set into practice.

Two case studies of multi-technical in-depth safety assessments for run-of-river hydropower plants along the Aar river are presented in this paper.

2. LEGAL FRAMEWORK FOR THE IN-DEPTH SAFETY ASSESSMENT OF WATER-RETAINING INSTALLATIONS ALONG THE AAR RIVER

The Aar river with its 295 km is the longest river that both rises and ends entirely in Switzerland by descending 1’845 m from the Swiss Alps to its junction with the Rhine river. There are more than 20 hydropower plants along its course (Fig.1).

The Enforcement Guideline of Dam Safety Legislation specifically referring to the construction and operation of large run-of-river hydropower plants along the Aar river was published in 2015 [1] and covers 11 hydropower plants under the direct supervision of the SFOE.

The scope of the Enforcement Guideline is to clarify and practically-deepen the legislation of water-retaining installations and to supplement the dam safety guidelines [2, 3] specifically for these types of installations in order to accomplish the in-depth safety assessment. The methodology can also be adopted to smaller installations, which are not directly SFOE-supervised but by direct supervision of the cantons.

The in-depth safety assessment end-product is a report which contains multi-technical chapters based on specific qualitative and quantitative evaluations as stepwise presented in the following paragraphs.

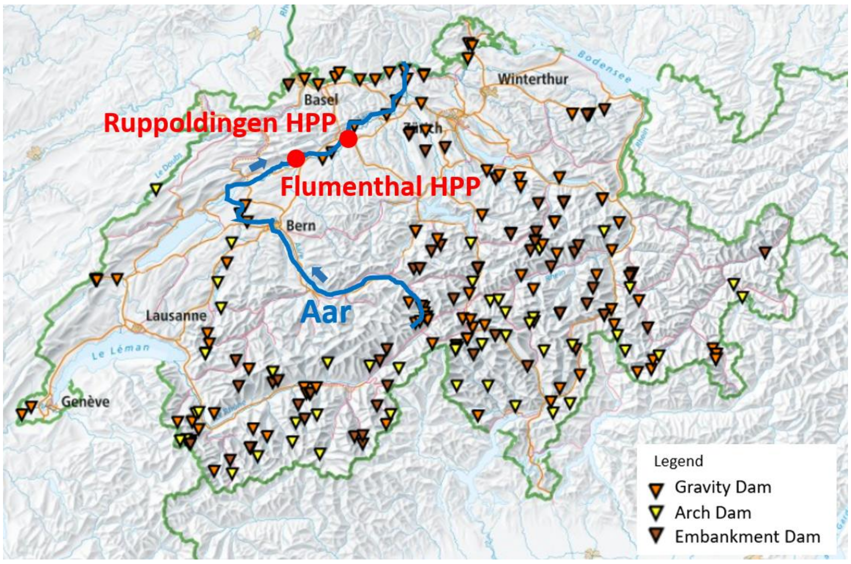

Fig. 1
The Aar river cuts through Switzerland from South to North. The two case studies are highlighted among the 217 SFOE-supervised dams [after 4]

3. CASE STUDIES: FLUMENTHAL AND RUPPOLDINGEN HPPS

Main descriptive features of the two large run-of-river plants case studies are summarized as follows:

Year of Construction	1970
Head water level	426.0 m a.s.l.
Number of turbines	3 Kaplan bulb turbines
Impounding head	9.0 m
Storage capacity	> 500’000 m^3
Capacity	25 MW
Av. annual production	146 GWh
Main water-retaining components	3 radial-gated weirs, each 12.50 m wide 2 piers, each 5.0 m wide Powerhouse (W x L): 46 m x 46 m Left and right abutment guide walls

Year of Construction	2000
Head water level	397.2 m a.s.l.
Number of turbines	2 Kaplan bulb turbines
Impounding head	5.93 m
Storage capacity	2'300 million m^3
Capacity	23 MW
Av. annual production	115 GWh
Main water-retaining components	4 radial-gated weirs, each 14.50 m wide 3 piers, each 4.0 m wide Powerhouse (W x L): 37 m x 62 m Left and right abutment guide walls

3.1. DOCUMENTATION AND ARCHIVES

The plant's operator is responsible to maintain for each plant an archive with below indicated relevant plans and reports. These archives constitute an essential input basis for the in-depth safety assessment.

- Design and as-built plans and information of as-built material's properties based on QA&QC data collected during construction
- Structural, hydrological and hydraulic analyses
- Geotechnical investigations and geological observations
- Plant operational reports
- Annual inspection and monitoring reports
- Reports on maintenance and functional tests of relevant appurtenant structures
- Accident and operating anomalies reports
- Surveillance manuals, O&M manuals and Emergency planning reports

3.2. ASSESSMENT OF ALL WATER-RETAINING AND SAFETY-CRITICAL APPURTENANT STRUCTURES BASED ON EXISTING DOCUMENTATION AND VISUAL INSPECTION

After achieving overview of the plant's relevant documentation, the team of civil, mechanical and electrical engineering experts and a geologist expert perform on-site visual inspections and a present state final qualitative evaluation. In accordance with the Enforcement Guideline, all water-retaining and safety-critical appurtenant structures of the installation are inspected and evaluated, which include:

- Structural inspection of the weir, powerhouse and gates
- Geological inspection: foundation, lateral embankments or dams and potential slope instabilities within the storage area, natural hazards and groundwater
- State of the monitoring instrumentation and safety-critical appurtenant structures such as drives, control technology, power supply and emergency diesel generators.

3.3. INSTRUMENTATION AND MONITORING PROGRAM

The aim is to assess whether the existing monitoring instrumentation is adequate for the facility. As there are no binding rules on the required type and number of instruments, the judgment is left to an experienced engineer.

For both plants, the deformation monitoring relies mainly on geodetic measurements. It was checked that sufficient monitoring points are available, the points are situated well distributed over the plant and that sufficient fix points are available on both abutments and at appropriate distance from the structures to be monitored. The number of fix points shall guarantee a redundancy in case a fix point is lost e.g. due to construction works. In Ruppoldingen, piezometers are installed under the weir and the powerhouse. As a result of the assessment, it was recommended to consider the installation of additional piezometers in the right abutment to monitor a possible flow around the weir and underlying sheet pile wall through the abutment. In Flumenthal currently no piezometers are available. Based on conservative structural stability calculations, it was assessed whether this state can be further tolerated or the installation of piezometers must be recommended to monitor the uplift pressure for both the weir and the powerhouse.

For both plants, the water level monitoring instruments are assessed as complete, with redundant measurements of the head and tail water levels with both, automatic readings and staff gauges. This is considered as a basic installation for any run-of-river plant.

The instrumentation monitoring is complemented with regular bathymetric surveys which focalize in the downstream area on potential scouring of the weir's stilling basin, in the upstream area on possible sediment depositions. With these surveys and with regular opening of the weir gates for checking its functionality it is ensured that the gates can be opened anytime required.

In addition to the instrumentation array installed, the frequency of the measurements and treatment of the read values was evaluated. It was concluded that the implemented procedures including the back-up of the data is well organized.

3.4. SAFETY-CRITICAL APPURTENANT STRUCTURES AND CONTROL TECHNOLOGY

The aim is to assess the reliability of the weir gate's control technology under unusual and extreme conditions. In a run-of-river plant the functionality of the weir gate is of vital importance to avoid overtopping the weir and overflowing of the river banks upstream of the weir.

This chapter of the safety assessment describes the control technology of the weir gates, which is under normal conditions fully automated to maintain the head water at the concessionary level. In case of failure of the automatic control and concurrent rising of the headwater level, a backup control system is taking over to open the weir and avoid overflowing. As an alternative or if the backup system should fail, the weir can be operated manually from the control room in the powerhouse or from a separate control station at the weir site.

Both plants have a power supply from their own production. In case of failure of the internal power supply, it can be switched to external supply or supply from the emergency diesel generator.

The outcomes from the seismic safety assessment demonstrated that the weir structure and powerhouse, which house the hydraulic system, will remain intact. The hydraulic system is therefore with high probability operable also after an earthquake has occurred. In case of failure of the hydraulic aggregate, in Ruppoldingen a fix installed backup aggregate is available. In both plants, a mobile emergency aggregate with its own diesel generator is available. This allows opening of one gate at the time.

Regular trial runs of the backup systems including moving of the gates with the help of these systems ensures that for both plants, the equipment is well maintained and the personnel is well trained to use the equipment even in emergency situations. The assessment could conclude that sufficient redundancy is available to safely open the weir gates also under unusual and extreme conditions.

3.5. STRUCTURAL SAFETY ASSESSMENT

In this chapter, the safety of all water-retaining structures, i.e. weir, gates and powerhouse are quantitatively assessed. This requires verification of structural stability (sliding, overturning and buoyancy), structural and foundation stress analyses and behavior against reviewed operational and hazard scenarios (load cases). Head and tailwater levels for the same load cases considered at the time of design were updated based on latest hydrological data. The post-earthquake functionality of the gates needs also to be verified.

Hazard scenarios and load cases

In order to start with the structural safety assessment, the specialist engineer defines the operational and hazard scenarios (load cases) according to the Enforcement Guideline: usual, unusual (1000-year return period flood while one weir opening blocked for maintenance) and extreme (probable maximum flood and 5'000-years return period earthquake respectively). Other hazard scenarios to be evaluated either quantitatively or qualitatively are erosion due to high velocity flows, abrasion due to debris transport, impact due to floating debris, sediment deposition on the gates, jamming of gates due to floating debris, rapid water level changes due to rapid closure of the turbines or of the control technology.

Flood safety assessment

The safe passage of a 1000-year return period design flood has to be guaranteed with sufficient freeboard and under the assumption that the gated discharge work of largest capacity is blocked ("n-1 rule"). In this case no damage and no uncontrolled overflow must occur. The "n-1 rule" also applies to side embankments or dams in the vicinity of the installation. For Flumenthal and Ruppoldingen, 1'400 m^3/s and 1'550 m^3/s are considered respectively.

The probable maximum flood (PMF) must pass the dam without causing it to surpass its critical water level, i.e. level above which stability may be impaired. Overflow and uncritical damages of the installation are allowed. The PMF is evaluated 20% higher than the corresponding 1000-year design flood for each plant.

Seismic safety assessment (SSA)

The seismic evaluation earthquake (SEE) for these large run-of-river installations is assessed on the basis of a 5'000-year return period for all water-retaining and safety-critical appurtenant structures of the installation as evaluated during visual inspection. The main objective of the SSA is to protect the population against loss of life and property damage. To fulfill this goal, the main and sole minimal requirement for the SEE is that no failure with uncontrolled release of water occurs (in accordance to ICOLD 2016 [5]), i.e. non safety-critical damages, such as permanent deformations or structural sliding are allowed if the main objective is fulfilled.

The SSA applies also to the gates, that could suffer partial or total failure with uncontrolled water loss. Their functionality, which has to be rapidly restored after the earthquake, has to be verified. The 1'000-year return period earthquake applies to side embankments or dams in the vicinity of the installation.

Methodology

Major seismic input parameters for SSA are: PGA, duration, site-independent (standard) response spectra and acceleration time-histories. The horizontal PGA in accordance to the SEE return period is derived by means of an empirical intensity-acceleration equation and based on seismic hazard maps (isolines of MSK intensity) published in 1977 [6].

The derived PGA becomes the scaling value of normalized subsoil class-dependent standard response spectral shapes [7] which simultaneously act in the two horizontal and in the vertical directions. Vertical PGA is computed as 2/3 of horizontal PGA. For Flumenthal and Ruppoldingen, PGA of 0.155 g (duration 13 s) and 0.17 g (duration 14s) are considered respectively.

Geological conditions of riverbeds are usually characterized by a sequence of gravelly, sandy, silty layers above sound bedrock. Therefore, site-dependent response spectra needed to be evaluated at Ruppoldingen HPP (Fig. 2). The presence of a 5.5 m thick fully saturated sand layer above bedrock with averaged granulometric curve with good fit into potential liquefiable sands required evaluation of liquefaction potential based on SPT tests outcomes, available from the geotechnical investigations performed during the construction time (Fig.3).

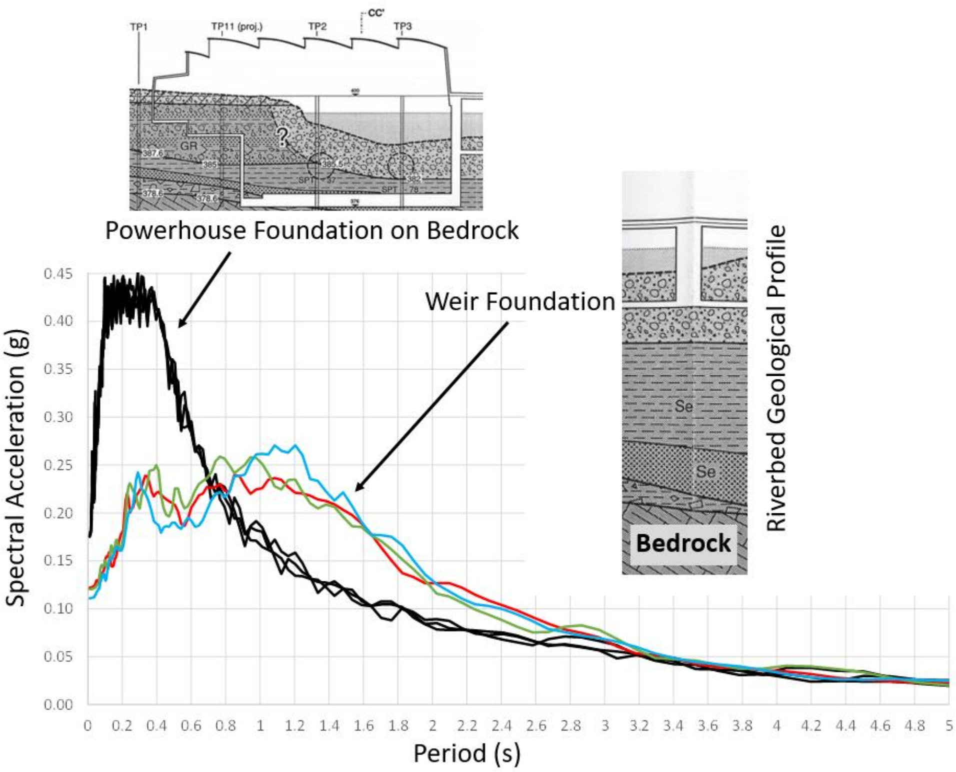

Fig. 2
SSA performed with site-dependent response spectra below weir foundation and below powerhouse foundation on bedrock at Ruppoldingen HPP

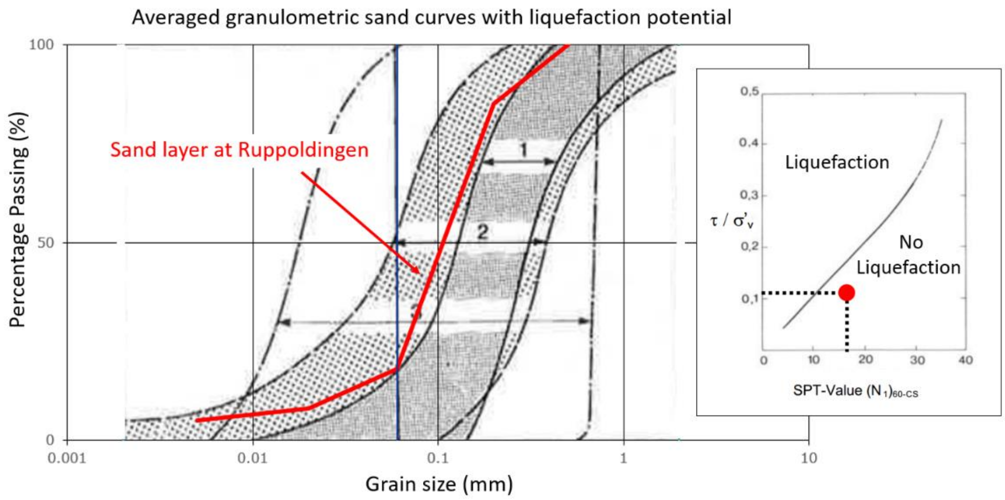

Fig. 3
Liquefaction potential evaluation based on SPT tests at Ruppoldingen HPP [after 8,9]

Computation procedures for water-retaining structures

The Guidelines require to setup a 3D FE model which includes one pier and a left and right half field of the weir structure and the extended sub-soil. The actions of non-modelled elements such as bridges and gates are implemented in order to consider a realistic dynamic behavior for the SSA. The water-structure inertial interaction is modelled by introducing additional incompressible masses on the structure according to Westergaard's method (Fig. 4). The bedrock mass is neglected, therefore only the soil-structure kinematic interaction is considered in the model. The powerhouse for both HPPs, as a water-retaining structure, is modelled also with a 3D FE model. The radial gates of the weir were manually back-calculated with the updated load cases, thanks to the available steel-structural analyses reports from the original design phase.

Material parameters

The Enforcement Guideline requires as a minimum the static characterization of the structural and geotechnical materials based on laboratory or in-situ tests. These are also accepted if available from the construction time. Required parameters for example would be concrete compression strength, reinforcement density and sub-soil seismic wave velocities.

Structural dynamic characterization of the materials is obtained either from specific dynamic laboratory tests or derived from the static values, e.g. for concrete based on following empirical relationships for the elastic modulus E_d = 1,25 E_s, compressive strength f_{cd} = 1.5 f_{cs} and tensile strength f_{td} = 1,5 $f_{ts} \leq 4$ MPa. In general, the weir body and the sub-soil are modelled as linear-elastic, isotropic with viscous damping (e.g. 7% for reinforced concrete).

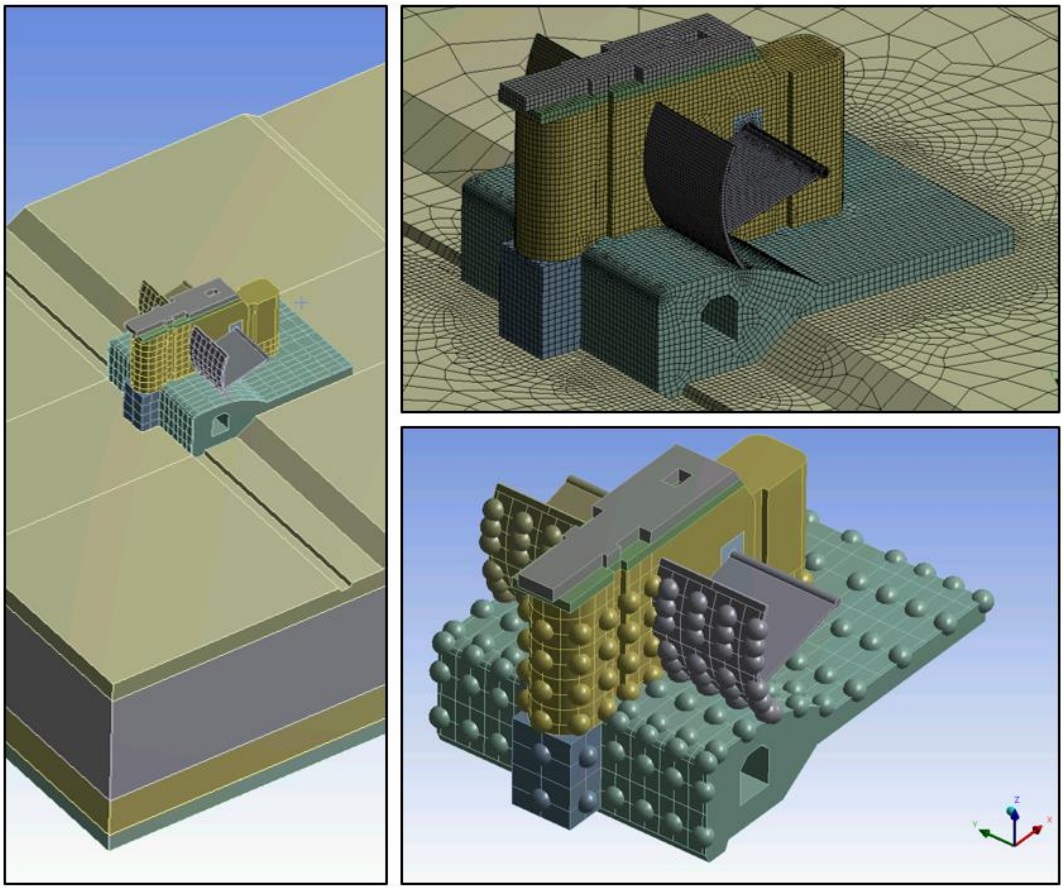

Fig. 4
3D FE numerical model of the weir structure of Ruppoldingen HPP

Final Structural Safety Assessment

The stability, structural and foundation stress and deformation of the weir structure for both HPPs are verified with the updated static and dynamic load cases. The maximal seismic-induced deformation of the pier is considerably smaller than the lateral 30 mm rubber sealed joint between the radial gate and the pillar. Therefore, the post-earthquake functionality of the gates is guaranteed. The radial gate of Flumenthal showed small seismic-induced yield deformations of the flap gates in downstream direction. This would in the worst case lead to a water release due to slight opening of these lateral joints. This however can be recovered within a short time.

The stability analysis of the massive powerhouse structure results in safety factors higher than required.

4. CONCLUDING REMARKS

A multi-technical in-depth safety assessment is performed for large run-of-river hydropower plants along the Aar river, in Switzerland.

The two plants dispose of continuous surveillance (regular function tests of all safety-critical installations and equipment and yearly inspections by external experienced engineer), continuous update of an archive with relevant documents, continuous structural maintenance, adequate monitoring instrumentation and redundant control technology. Further, as all operational and hazardous load cases meet the requirements, it is allowed to conclude that safety of both plants is guaranteed in accordance to the Swiss Dam Legislation.

A team of experts (civil, mechanical and electrical engineers and geologists) can perform straightforwardly a total in-depth safety review of such hydropower plants within a reasonable timeframe.

ASPECTS CONCERNING AGEING OF EMBANKMENT DAMS

Ronald HASELSTEINER

Department Manager Hydraulic Engineering, BJOERNSEN CONSULTING ENGINEERS

GERMANY

1. INTRODUCTION

The process ageing defines the timely change of the behaviour of embankment dams. These changes are caused by biogenic, geogenic, anthropological or climate factors. The ageing processes may occur periodically, temporarily, steadily, or even suddenly. These ageing processes can cause harm and can initiate failure processes and can lead to a total failure.

Different definitions of ageing are available, and were developed within the different engineering faculties. Generally, ageing depicts a deterioration process and, frequently, is treated hand in hand with the long-term behaviour of dam structures.

Particularly, embankment dams, which were designed without safety margin or show design deficits, are sensitive to long-term deterioration effects. Ageing can affect all materials and all parts of embankment dams. Research and science frequently focus on single processes such as the behaviour of dispersive clays, but those single processes are rarely put into an overall context such as life cycle considerations.

Life cycle considerations or management may support risk management approaches as well as may shed light on the obligations of the owner during the different operation periods and life spans of dams (Fig. 1).

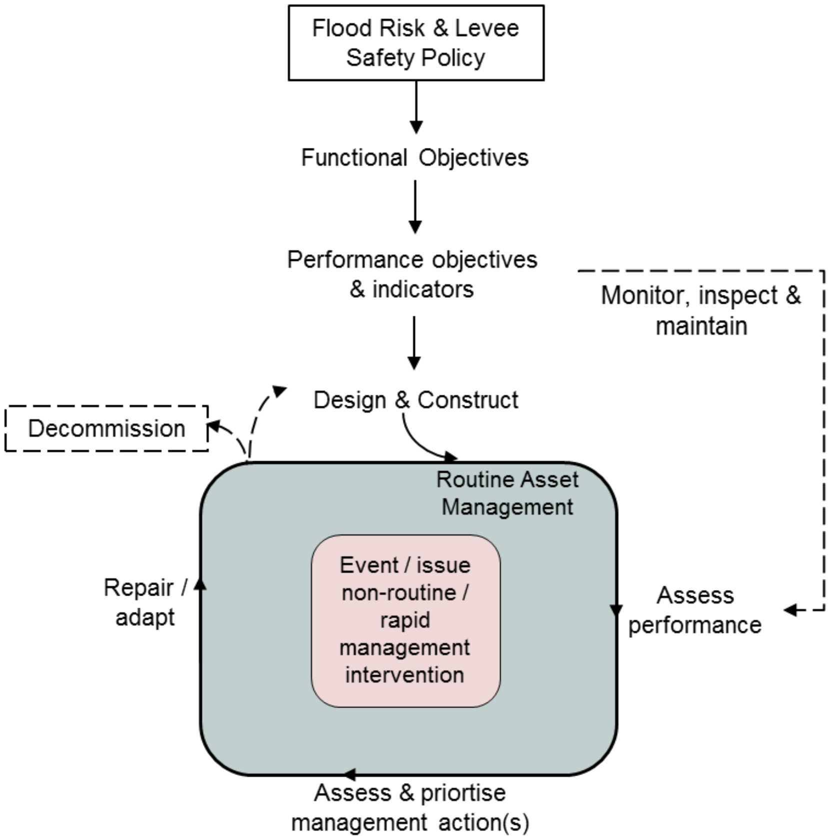

Fig. 1
Life Cycle Management of Levees (according to [1])

2. DEFINITION AND PROCESS CLASSIFICATION

An accurate, general valid definition for the term “ageing” for engineering structures, especially embankments dams, is hard to find in literature. Some authors provide definitions for special applications [2] [4] [5].

The term “ageing” defines the time-dependent alteration of characteristics of structures or materials. In this context the deterioration of characteristics is usually analyzed which leads to a deterioration of the structural behaviour in terms of stability, serviceability, and durability. In contraction to this general approach ageing processes may also lead to an improvement of material characteristics and structural behaviour as discussed in [3], such as the hardening of concrete sealings/barriers and the clogging of cracks in sealings.

A definition is given in the ICOLD bulletin No. 93: *“For the purposes of this therefore, ageing is defined as a class of deterioration associated with time-related changes in the properties of the materials of which the structure and its foundation is constructed. Excluded are the effects if exceptional events. Under* *normal conditions during the operation of structures ageing will usually affect the performance requirements, and then later affect the safety if corrective measures are not taken."* [4]

A similar definition is used by the USSD: *„The aging of dams, constructed of earth and rockfill material, as defined herein is due to time-related changes in the properties of the materials of which the structure and its foundation are composed."* [5]

In [6] the term ageing is related to natural processes, whilst damage is considered to be originated in man-made activities. Since also natural events may lead to damage, this distinction may not be valid for all kind of deterioration processes, which have to be considered in the context of embankment dams.

Typical ageing processes for embankment dams are listed below:

- Rooting of sealings/barriers of embankment dams with an increase of permeability
- Rooting of filter elements with an decrease of permeability
- Freezing-thawing-circles and drying of soils and natural sealings leading to cracks
- Particle breakage by saturation or stresses
- Upcoming woody vegetation close to or on the embankment
- Changing of design fundamentals such as hydrology (climate change) or design risk level which outdates the performance and required safety of the dam
- Sedimentation of reservoirs
- Etc.

3. LIFE CYCLE CONSIDERATIONS

The consideration of life-cycle management of engineering structures is more and more showing practical relevance. Generally, phase models are established as shown in Fig. 1 and Fig. 2.

In practice usually the phases design, construction and operation/maintenance are considered. For supervision and documentation, usually annual reports are prepared on the behalf of the owner [7] [8].

In the context of life cycle management the service life span of dams plays an important role. Life span and ageing interact. The stronger the ageing effects, the shorter the life span of an embankment dam. For embankment dams a life span of 50 to 100 years may be assumed [9].

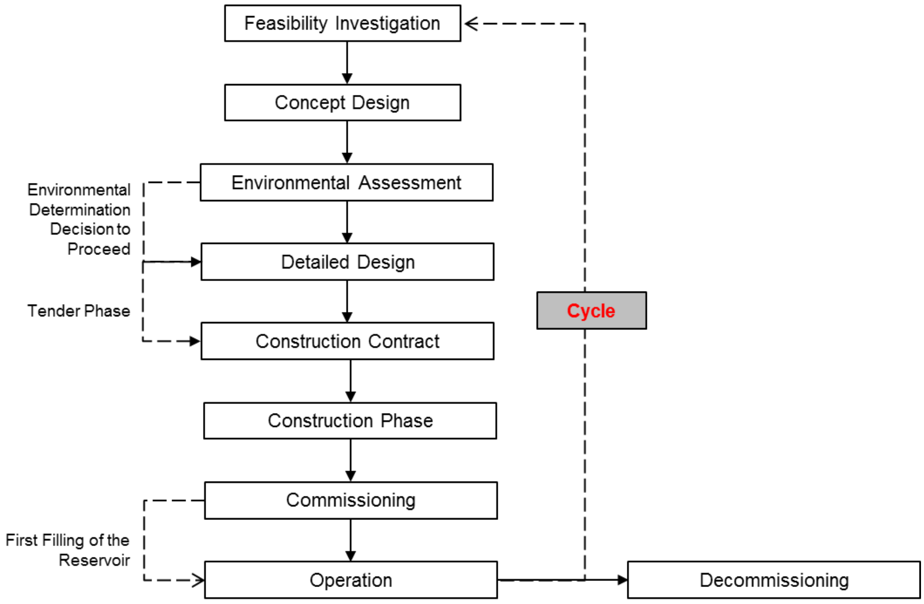

Fig. 2
Life cycle phases for dams

4. LONG-TERM BEHAVIOUR OF EMBANKMENT DAMS

The long-term behaviour of large embankment dams are assessed by analyzing of measurement data derived from the observation of deformation, stresses, pore water pressures, and seepage flow. Changes of material characteristics have to be determined by direct probing and testing in field or in the laboratory.

According to ICOLD Bulletin No. 93 [4] ageing processes and its effects are usually formed by the listed terms:

- Deformation
- Decrease of shear strength
- Pore water pressure increase
- Erosion/suffusion processes
- Surface erosion processes
- Deterioration of construction material characteristics

Escpecially creeping and consolidation processes contribute to long-term deformations. Embankment and rockfill dams which are constructed according to modern dam construction criteria show a totel settlement of less than 1.0 % of the dam height. The long-term settlement are frequently obtained after decades of operation.

The time-dependent deformation may lead to cracking, relocation of stresses or other effects along material borders so that the behaviour under hydraulic load and seepage forces may be affected which may lead to hydrodynamic soil deformation such as suffusion and erosion [10]. The increase of pore water pressures may result from ageing of selaings, drains, filters or changes in the underground.

5. ALTERATION OF MATERIAL BEHAVIOUR

For the construction of embankment dams and levees natural soils, geosynthetics, natural and articifical sealings, concrete, asphalt, etc. Are applied as summarized in [11]. All materials are subject to ageing. Corresponding to the type of material and the intensity of the loads and influences ageing is affecting the characteristics more or less strongly. The influencing factors are listed below:

- Freezing and thawing
- Seepage/saturation
- Wind
- UV-radiation
- Heat
- Biological impacts by animals
- Anthropene long-term behaviour
- Etc.

These influencing factors need to be assessed for the specific types of materials which are used in embankment dams and levees such as:

- Low permeable soils and natural sealings
- Artifical sealings
- Filter, drains and high permeable soils
- Geosynthetics
- Concrete

The listed materials and the related aspects of ageing are discussed in detail in [12].

6. EFFECTS ON THE DAM BEHAVIOUR AND DESIGN

The process of ageing starts with the construction or with the storing of materials which shall be used for construction. In practice the end of construction (EoC) is usually used as a reference date to determine the ageing period.

In ICOLD bulletin No. 93 [4] the first five years after EoC are not counted for ageing. Therefore, ageing starts five years after EoC according to [4] since all damage that occurs before is considered to be originated in construction shortcomings.

The monitoring and detection of ageing processes are evident in order to assess the dam behaviour correctly. For large embankment dams with permanent reservoirs the measurement of the seepage conditions is of first priority and has to be usually done by the Owner (see [13]). For embankment dams and levees which are only impounded temporarily a continuous surveillance is frequently considered to be not required. For small embankments and small levees frequently no monitoring is conducted [11] [14].

Under favourable conditions the ageing process will not reveal considerable deterioration effects during the life span of the structure. But, e.g., if the embankment dam was designed without safety margin so that with proceeding ageing the limit equilibrium conditions are reached and exceeded. This results in an overload of the system and potential failure. The safety margin should be assessed so that the design requirements are also fulfilled at the end of the service life span of the dam. The dam will subsequently suffer from damages, acceleration of ageing, and finally from failure.

Therefore, a safety margin should be considered to cover ageing effects. This safety margin should be also integrated in the specific technical guideline and codes. Not only material degradation should be integrated but also foreseeable processes, such as sedimentation, an increase of hydraulic loads, etc.

The safety margin should be established by the selection of adequate design parameters such as permeability, shear strength, etc. Generally, for all high risk large embankment dams it is recommended to consider a safety margin and not to design it at “the limit equilibrium border”.

In Fig. 3 the effect of ageing on the design approach is shown. Depending on the starting design approach and the influence of ageing the dam may reveal an under or over design during the operation period until the life span is reached. The under design shows an unacceptable risk; the over design reuqires the utilization of more resources but are welcome in consideration of safety reasons. A conservative design should be applied if the dam’s behaviour during the life span shows uncertainties which cannot be assessed reliable.

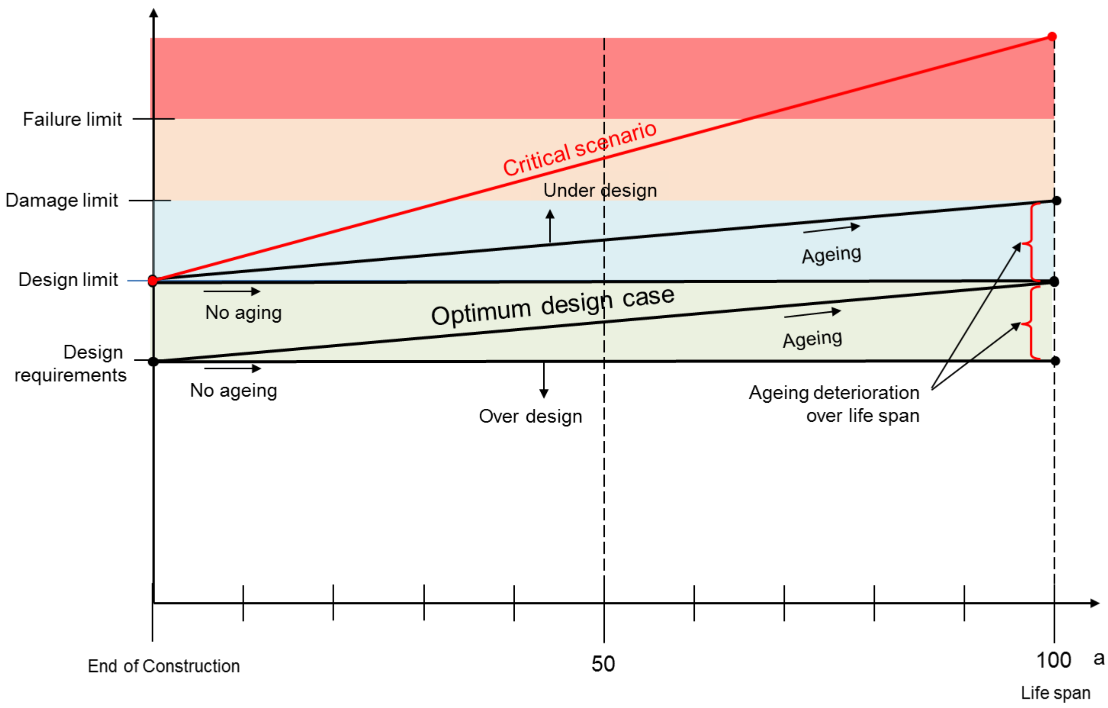

Fig. 3
Effect of ageing during design in consideration of the life span

7. MEASURES

Maintenance works have to be conducted annually. The existing vegetation needs to be controlled and cut according to the design and operation requirements. Small damage has to be refurbished. All ways, roads and access options need to be kept functional in order to guarantee access also in critical situations such as MDE or extreme floods. As soon as the structure does not comply with the engineering standards and codes a need for action exists and the owner is obliged to corresponding measures within a given realization period. This period is not a fixed number but should correspond to the practical periods for the preparation of the detailed dam safety reports which is five to ten years.

Various measures can be taken to upgrade the embankment dam in form of emergency action, partial rehabilitation works or a general upgrade. Rehabiliation works aim on the re-establishment of the former conditions. An upgrade shall improve the performance of the structure [15].

Embankment dams frequently suffer from an inadequate seepage situation, insuffucient slope stability or lack of dam height. Therefore, many measures are focussed on the installation of new sealings/barriers and the placement of drains and filters at the downstream toe in order also to stabilize the downstream slope.

For the heightening of a dam frequently little concrete walls are placed in the dam crest if the overall stability allows to tdo so. The heighting can also be realized by earh-moving techniques which results also in an adaptation of the downstream slope or parts of it.

Upgrading measures may reach from simple earth-moving methods to a complete demolition and reconstruction of the embankment dam. The extent of required works strongly depends on the grade of damage or ageing that orrured. An early detection is favourable in order to minimize the employment of required resources.

SUMMARY

An overview of different definitions for ageing is given. Generally ageing depicts a time-dependent alteration and deterioration of material characteristics and/or the complete dam structure.

Internationally accredited life cycle approaches are shortly discussed. In modern dam management life cycle considerations are state of the art starting with the design phase.

The ageing of typical materials, such as clay, geotextiles, concrete, etc. is an important aspect to assess the ageing of complete structures. The long-term behaviour of soils and the underground is more difficult to assess or to predict than the behaviour of artificial materials such as concrete and geosynthetics. For latter materials ageing was investigated in the past precisely.

Recommendations for the design are provided as well as counter measures against the deterioration effect of ageing on the structure. A safety margin should be considered within the design phase in the context with stability analysis and serviceability aspects. The sooner negative ageing effects are detected, the earlier countermeasures can be taken. Early measures are generally cheaper and more efficient than trying to rehabilitate a severely damaged embankment. Measures reach from easy works which can be handled during maintenance routines to a complete demolition and re-construction of the embankment dam.

1. INTRODUCTION

With any major spatial developments (construction projects) it is necessary to analyse both anthropogenic environmental impacts as well as the impact of the environment on the planned structure [1]. One of the technical basis in environmental impact assessment concerning developments in and near rivers and in their impact zone is to analyse the runoff regime, which indicates the difference between the existing and the planned state of water flows, depths, velocities, erosion, etc. Physical and mathematical hydraulic modelling is a commonly established practice to ensure that flood and erosion hazards remain the same, or are even mitigated, and to plan and optimize the expected end situation. In the planning stage of the construction and during the construction itself, neither the analysis of the situation in the individual construction phases nor the impact of temporary facilities and measures (e.g. access roads, bridging structures) must not be neglected or deficient. It can be the case that compared to the completed structure, particularly in major and complex projects, intermediate construction phases can have significantly more adverse impacts on the runoff regime and therefore on flood and erosion hazards of the construction site and other users in space. A hydraulic analysis to determine the extent of flood, velocity or erosion forces flow distribution, and the changes in the entire runoff regime in the area in question is used to determine any potential hazards and adjust or optimise the planned construction phases of the individual structures and accompanying developments, so that risks and costs are reduced.

The hydraulic analysis results of the individual phases allow us to assess the risks under transitional, changing spatial conditions compared to the condition prior to the construction and that after its completion. If excessive deterioration of the condition in a certain construction stage is identified, mitigation measures can be put in place to prevent hazard and risk increase or other measures are provided for, i.e. different stages of implementing structures and developments.

The planning and implementation of construction phases for the Brežice HPP, which was in the meantime put into regular operation, will be shown based on extensive experience in siting the HPP chain on the Lower Sava, as an example of siting a complex infrastructure facility in an alluvial plain area. Using prescribed spatial planning procedures, site selection and placement of the facilities and accompanying developments necessary for the HPP's operation (river reservoir levees, HPP dam structures, etc.) were carried out along with the many investments planned by other users or developers in the area. Along with this initiative (HPPs), under the National Spatial Plan the siting of developments in public interest was underway, such as updating and upgrading the existing and the construction of new levees and other flood risk reduction developments, developments of sustainable outflow sections of tributaries, improvement of riparian areas, provision of replacement habitats, etc. At the same time many initiatives regarding future land use emerged, including more intensive agricultural land use, various economic activities, and leisure facilities (e.g. a rowing trail).

When balancing the complex system of infrastructure facilities, accompanying developments, and various initiatives in the impact area there was an interplay of many requirements, restrictions, and conditions, which were consistent with each other, conflicting, or indifferent. They reflected the goals of many approving authorities and entities directly included in the spatial development project as well as other participants who take part indirectly but for whom it was assumed that the envisaged developments might, in one way or another, impact their established rights or development goals, and initiators who, upon the HPP chain completion, recognised the opportunity to carry out new or accompanying activities in the area.

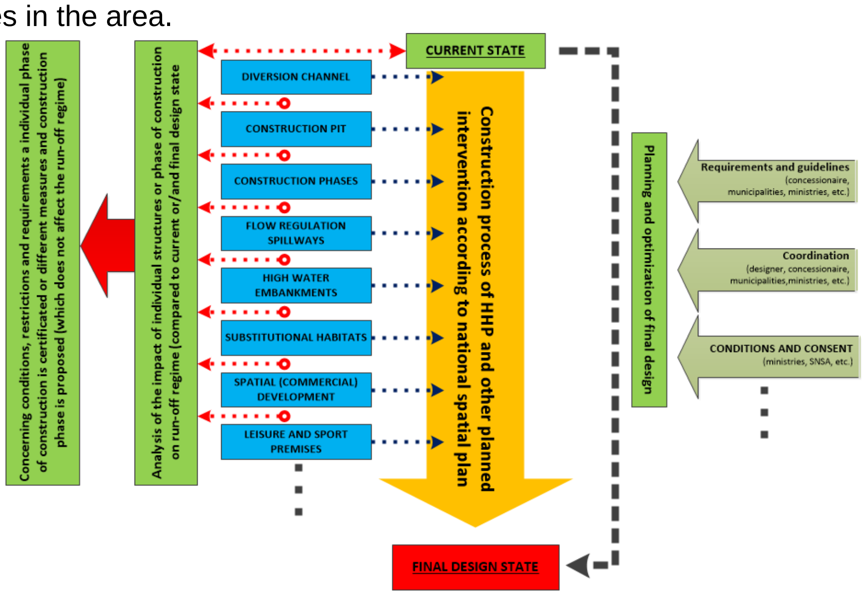

Fig. 1: Conceptual illustration of the activities in stepwise construction planning

For the HPP chain it is also necessary to analyse the morphological, hydrological and hydraulic, and anthropogenic impacts due to the complexity of the retention area, as they could potentially affect the runoff conditions at the border with the Republic of Croatia. In the downstream country such analyses were conducted in public procedures carried out in Integrated Environmental Impact Assessments. In such demanding interventions, the use of numerical modelling only is not sufficient, therefore the hydraulic analysis of the runoff conditions prior to and upon the construction of the HPP chain (Krško, Brežice, Mokrice) involved the use of hybrid hydraulic models [2-4]. By extensive modelling the locations of reservoir levees, size and locations of flood water overflow structures, HPP spillway structures, and other accompanying developments, including roads and economic structures, were analysed and optimised.

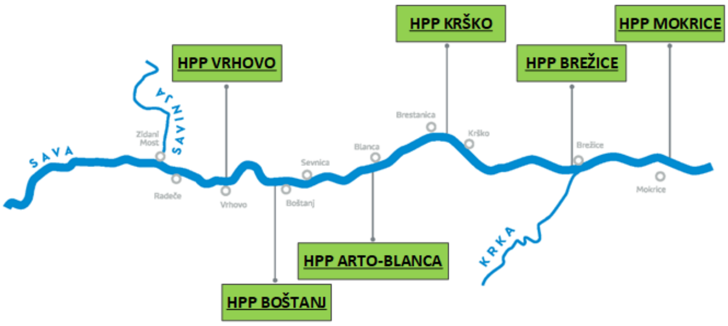

Fig. 2: Locations of HPPs on the Lower Sava River. HPPs Vrhovo, Boštanj, Blanca, Krško, and Brežice are completed, while the Mokrice HPP is in the final design stage.

For the planned situation of the area at the Brežice HPP, where there also is the Krško Nuclear Power Plant (NPP) located at the Sava, it is also necessary to check the fulfilment of all the strict safety requirements regarding the operation of NPP Krško, including the analysis of the conditions during the Probable Maximum Flood (PMF). An overview of the key interventions in the National Spatial Plan area concerning the Brežice HPP is shown in Figure 2.

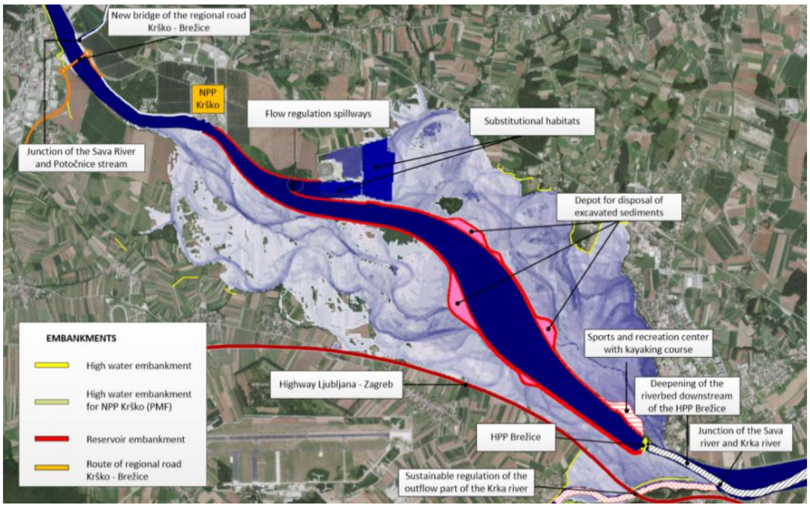

Fig. 3: The run-of-river Brežice HPP facilities with many accompanying measures are shown in terms of the existing flooding situation of the areas along the Sava River between Krško and Brežice at $Q_{100,HW}$.

The preparations for the HPP chain construction took a long time, while over the recent few years intensive analysis concerning the design and implementation of the selected solutions took place. In the individual phases of construction, which took several years, the runoff conditions gradually changed, therefore the previous runoff conditions in the HPP impact area were analysed. Good cooperation with the HPP design engineer and competent authorities was essential to identify relevant or unfavourable scenarios of flood (and other) events to be investigated hydraulically, and to review and evaluate the interim calculation results.

2. HYDRAULIC MODELLING – BREŽICE HPP

The advantage of numerical modelling over physical models is that it is easier to change the geometry and boundary and operational conditions, but unfortunately in the most complex cases it still does not achieve the necessary robustness of results compared with physical models. Therefore, hybrid hydraulic modelling (HHM) was used, which applies the manner of modelling (physical/numerical) that is the most relevant in a particular case. In this case, we applied conventional and distorted physical models for flood areas and various structures, while for the numerical analyses of runoff conditions in the entire area the combined one- and two-dimensional (1D-2D) software MIKE FLOOD was used. The appropriate numerical simulation of the faster 1D flow in the Sava River channel and the slower 2D flow in floodplains was achieved by an extensive calibration in relation to the previous flood events and simulations of conditions in the physical model. The 1D module applied allowed for simulation of the impact of various structures and operational dynamics according to the temporal dynamics of the flow from upstream areas. This enabled a hydraulic analysis of the situation in the wider areas (the entire HPP impact zone) as well as modelling of immediate areas (e.g. the construction pit area) and of individual structures (e.g. spillways).

To analyse the flow conditions in the HPP's immediate areas during the individual construction phases fully-2D modelling was applied, e.g. using the hydraulic software tool CCHE2D [5], which allowed for detailed analyses of velocity fields in critical areas. This tool is well calibrated, too; the same boundary conditions were applied for the HPP's immediate area as well, i.e. the flow conditions from the wider site analysis using HHM. Such case in shown in Figure 3 where left, based on an orthophoto image, the immediate zone of the HPP Brežice construction pit is shown, while on the right the numerical mesh of the same area for 2D analyses is shown.

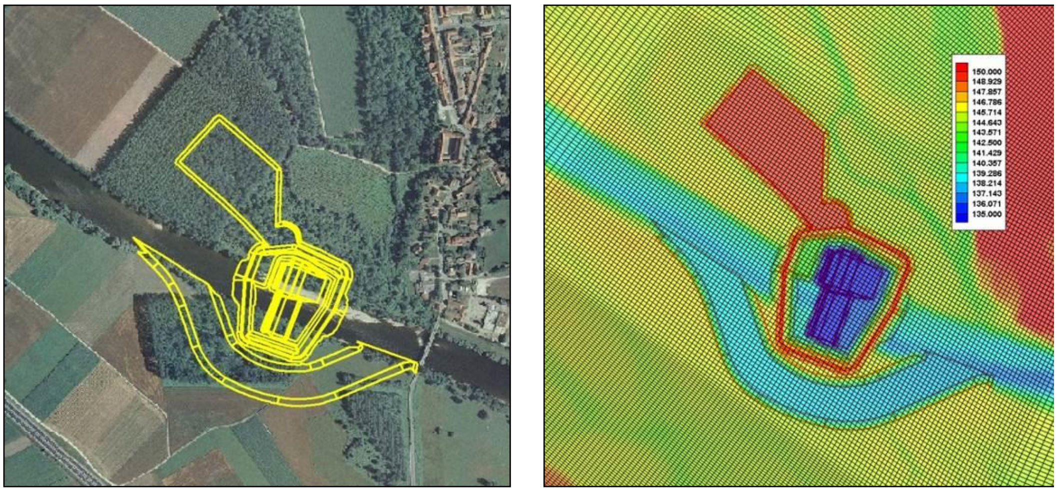

Fig. 4: Left – an orthophoto image with the developments in the HPP Brežice construction pit site; right – the same site captured using the numerical mesh of the 2D hydraulic model [4]

A physical model in a scale of 1:45 was also built for this case and the conditions in the plant's immediate area were analysed to an extent allowed for by the characteristics of the installations at the Institute for Hydraulic Research. It comprised the area of the entire HPP construction pit with a diversion channel and the Sava River reach 600 m downstream the envisaged dam location. Flow and velocity fields, water levels for dimensioning cut-off barriers at the construction pit and erosive action in riverbanks and the channel during the construction [6].

Fig. 5: Physical model of the HPP Brežice construction pit (Hidroinštitut, 2011). In the diversion channel the remains of the sand left from studying sediment transport capacity are evident

The coupling of physical and numerical modelling is reflected both in determining the boundary conditions for the physical model from investigating the wider area and the additional calibration of the numerical model to analyse the immediate vicinity of the construction pit and the diversion channel used both for checking the velocity field and/or erosion risk during higher discharges than those enabled by the physical model.

3. ANALYSIS OF SCENARIOS OF GRADUAL INTRODUCTION OF SPATIAL DEVELOPMENTS

During the construction of infrastructure systems many intermediate situations occur, as the individual work phases have different temporal dynamics. Therefore, many situations, i.e. scenarios, emerge, where it is necessary to check whether the individual combinations of (intermediate, temporary) measures do not excessively deteriorate the conditions in space. Such cases are, for example, the study of the impact of the construction pit with the diversion channel in combination with the impact of disposal sites with the material dredged from the construction pit or the determination of the optimal construction of levees along the reservoir. All intermediate conditions were compared in relation to the flow conditions at various discharges to those prior to construction, to remove the responsibility for anthropogenically enhanced flood risk.

For high-discharge conditions the flood risk rate was checked, where the development of the construction pit and the diversion channel shape was taken into consideration, as determined using the physical model, which allows for a discharge capacity of approx. 1800 m^3/s. The focus of the physical modelling was the conditions during the construction, e.g. the removal of abrupt changes in the riverbanks, which could lead to vortices that could reduce the throughput of the diversion channel [5]. The choice of locations of temporary disposal sites and the site for disposing of excess material was affected by spatial restrictions, optimisation of construction works, and particularly the requirement to not increase flood and erosion hazard.

When determining the sequence of constructing the individual sections of the embankments along the reservoir, from Krško to Brežice, the main goal was to preserve, as long as possible, the communication between the main channel and floodplains, to preserve the inundation’s retention function. Therefore, the embankments were first constructed in the areas where at Q_{100} the communication of the Sava water flow with the inundation was smallest or only local. The calculations showed that the parallel (simultaneous) construction of embankments on the left and right banks preserved the flows on the left and right inundations, while the embankment built in one bank only would cause increased spilling and a rise in water levels in the inundation on the opposite bank. The calculations also confirmed that already the construction of the embankments in the lower part of the reservoir improved the flood safety of the Ljubljana–Zagreb motorway.

These calculations took into account the implementation of other, accompanying interventions (e.g. replacement habitat), therefore the spatial situation changed gradually, while in some cases the impact of the individual spatial interventions was analysed. The calculation results for the individual scenarios allowed for the design of (temporary) mitigation measures to improve the runoff conditions (lowering of water levels, lower surface erosion, etc.) in the areas where flood risk could increase during the construction.

At the construction pit edges the risk of influx of water into the pit was studied to support the analyses of the design engineer regarding the justification of the degree of protection, i.e. to preserve the construction pit dry. The final decision was reached based on the relevant impacts of the separate interventions as well as on the impact of all the interventions together on the runoff conditions in the following combinations of the Sava and Krka discharges:

Steady flow for simultaneous occurrence of discharges $Q_{20,Sava} = 2900\ m^3/s$ and $Q_{Krka} = 80\ m^3/s$. and

Steady flow for simultaneous occurrence of discharges $Q_{100,Sava} = 3750\ m^3/s$ and $Q_{20,Krka} = 453\ m^3/s$.

The Sava River discharges are taken from the hydrological study from 2011 [7] and the 20-year return period discharge of the Krka River after the study from 2004 [8].

4. RESULTS AND DISCUSSION – BREŽICE HPP

Based on the calculations, the impact of the intermediate conditions during the construction was determined by comparing the water levels in the characteristic points, as a difference between the situation during the implementation of the individual phases and the condition prior to the start of construction. According to the various land uses and other boundary conditions, water levels were compared in 43 points in the Brežice impact area (Figure 6).

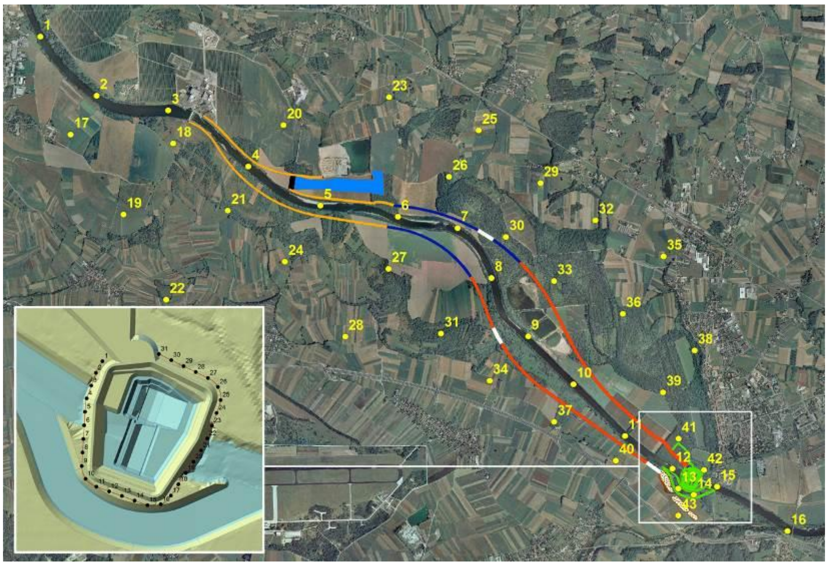

Fig. 6: Locations of points where the water levels were compared to identify the impact of the construction pit and the diversion channel during high-flow conditions

By analysing the differences in the water levels any potential adverse impacts during the construction are determined, so as not to excessively increase flood risk, deteriorate or even disable the functions of infrastructure facilities, or even put the stability of levees at risk, etc. 2D velocity analyses allow for assessing (the changes in) erosion risk in the wider flood area.

4.1. Impact of the HPP Brežice construction pit and the diversion channel on the runoff regime

Prior to HPP construction, the occurrence of a 100-year return period event (3750 m^3/s) would result in a quarter of the entire discharge (approx. 900 m3/s) flowing along the right floodplain between the Sava River and the Ljubljana–Zagreb motorway. The location of the construction pit and the diversion channel considerably change the velocity field; as the area of the construction pit is excluded from the flow, throughput is decreased, and the currents are redistributed, causing also a different distribution of depths, velocities, erosion, etc. To minimise the costs of dredging the diversion channel, the best location for the disposal site would be as close as possible to the channel, but the proposed location for the disposal of the material on the right bank would further narrow the already-narrow cross-section. The increase in water levels would increase flood hazard upstream, while, in the narrow cross-section and downstream part, the increased velocities or shear stresses would increase the erosion hazard on agricultural land and the motorway. At the discharges investigated, the mere construction of the construction pit would cause a rise in water levels in the left and right floodplains by up to 45 cm, the effects of which would diminish about 2 km upstream; this would require the construction of dikes near some settlements even in the initial stages of constructing HPP Brežice. The overall impact of the construction pit and the disposal sites would be sufficient to cause flooding of the motorway at a 100-year return period event. The disposal of the material dredged from the diversion channel at the right floodplain would partially obstruct the return of water from the right retention toward the confluence of the Sava and Krka rivers, which would increase the flood hazard vulnerability of the settlements upstream, along the Krka River.

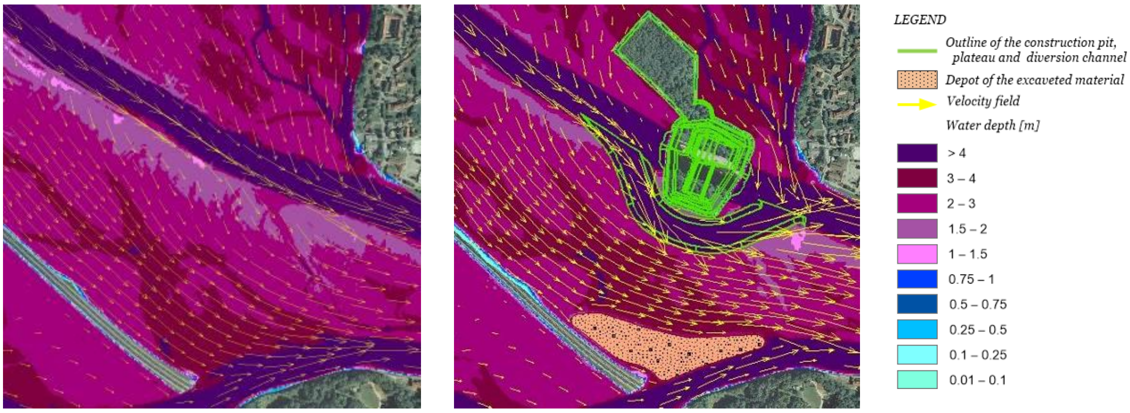

Fig. 7: Comparison of the velocity field and depths for the condition prior to the construction and the final location and shape of the disposal site for the material excavated from the construction pit and the diversion channel at a 100-year return period event.

In terms of costs and flood safety the relocation of the disposal sites upstream from the construction pit would be more suitable, where the cross-section of the right retention (floodplain) is large enough while the impact of the disposal sites would be smaller. Nevertheless this was not possible due to the archaeological site, where the investigations were conducted throughout most of the HPP construction. For other disposal sites on the right bank of the Sava the calculations showed that the critical point in constructing the weir and levees occurs at the narrowing between the construction pit and the Ljubljana–Zagreb motorway, therefore the only option was to remove the disposal sites as far as possible from the Sava River to the left bank of the Krka River. Figure 7 shows the final shape of the disposal site for the total quantity of the material dredged from the diversion channel. The shape is adapted according to the streamlines in the right inundation at the construction pit.

In this way, the disposal site in the corner between the left bank of the Krka River and the motorway embankment would temporarily function as a levee to avert the intrusion of the water from the Sava River into the Krka. This would already in the construction phase decrease the flood hazard of the settlements along the Krka River, as was demonstrated in a previous study [4] about levees along the left bank of the Krka River. In the case of a high-water event during the Brežice HPP construction the water level of the Krka River below the motorway bridge would decrease by up to 50 cm relative to the situation prior to the construction.

Figure 8 shows the conditions in 2014, at the Sava River discharge of approx. 2000 m^3/s.

Fig. 8: Photograph of the construction pit site and the diversion channel during high water in September 2014 (discharge approx. 2000 m^3/s) (source: 24ur.com).

The surface water formations confirmed the accuracy of the hydraulic analyses. During the event at locations under higher pressure//load//burden due to spiral water current in the diversion channel some erosion damage was caused in the banks of the diversion channel, while the safety of the construction pit was not at risk.

4.2. CHANGES IN RUNOFF CONDITIONS IN THE INDIVIDUAL PHASES OF CONSTRUCTING EMBANKMENTS AT BREŽICE HPP

The calculated conditions for the situation with the construction pit and the diversion channel provided a starting point when trying to find the best sequence of constructing embankments along the reservoir, i.e. such that would minimise any further negative impact on the situation, or even mitigate the situation, particularly along the Ljubljana–Zagreb motorway. The condition prior to the start of works at HPP Brežice provided another basis. The selection of various sections of the dike, various building sequences, etc., provided several scenarios, of which 16 cases were analysed, which addressed the individual developments or temporary conditions in space. Due to their extensiveness, the descriptions of the variants are not provided here. Roughly, they can be divided into four phases as follows: (1) Construction of embankments upstream the weir; (2) construction of embankments from NPP Krško downstream and construction of a flood control relief system; (3) construction of embankments in the middle part, and (4) closing of outflow openings in embankments and the inlet into the diversion channel (Figure 9).

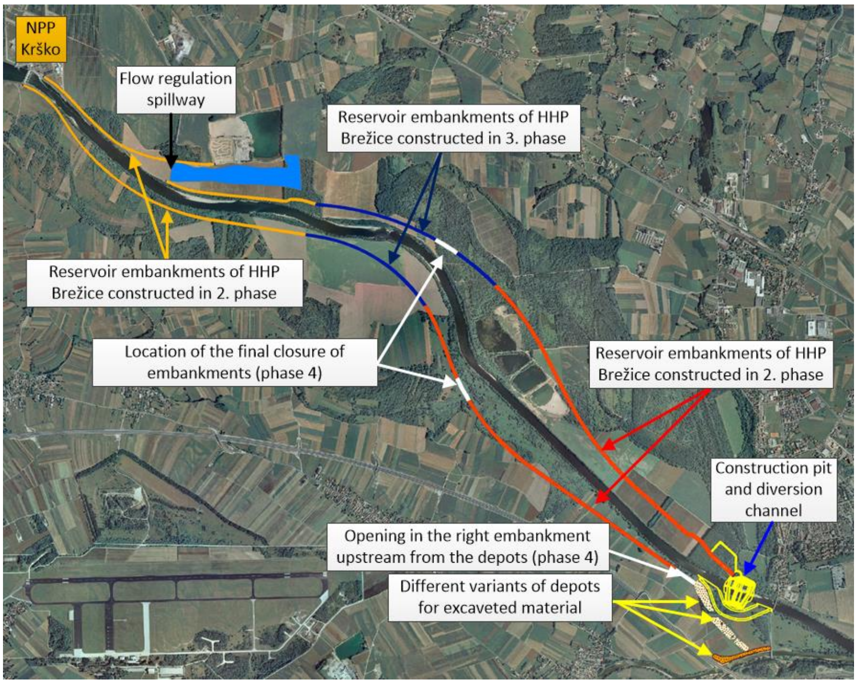

Fig. 9: Basic division of construction phases of building HPP Brežice embankments

In the first phase the embankments at both Sava River banks are built from the HPP weir upstream, with an opening on the right bank at the construction pit due to the inflow into the diversion channel and the upstream outflow opening, which allows for outflow into the right inundation, to preserve the processes as in the existing situation when floods flow from the channel to the retention. The construction of embankments, in fact, obstructs the outflow of water from the channel to floodplains, which would increase the discharge between the already built embankments toward the cross-section at the construction pit. In high-water situations the discharge at the retention, and thus water levels (and flood risk), would decrease, while higher discharge toward the construction pit would require the construction of higher levees along the pit.

Based on these analyses, the second stage involved the building of embankments from NPP Krško dam downstream, including the relief system for retention of peak discharges in the left inundation. After the completion, the latter is fitted with hydromechanical equipment, which is during the construction stage, of course, neither installed nor in operation. In this way, flood water from the channel could flow into the inundation only in the right bank, upstream the NPP Krško dam, and at the section where the embankments are not built yet. Analyses have shown that during high discharges the left retention would partially fill up also through the relief system being constructed as higher discharges would overflow the levee of the construction pit. As the construction of 2nd phase structures additionally reduced the spilling of water from the channel to the retention, at 100-year return period events the water levels of the Sava River in the area between the already built embankments would rise relative to the previous condition (up to 70 cm), while in a major part of the retention areas the water levels would decrease (up to 35 cm). Due to the influence of the construction pit and the disposal site with the excavated material, in this construction phase the water levels would still remain above the previous state only in the lower part of the right retention.

In stage 3 the middle third of the embankments is built. After the construction of the embankments throughout the length the outflow of water from the channel to floodplains is restricted to the section above the NPP Krško weir, the outflow openings in the built embankments (of a length of approx. 100 m) in the middle part, the inlet into the diversion channel, and the discharge over the relief system. In the latter, the spillway crest elevation of a fully open relief system was considered in the calculations, i.e. in the state where the concrete structure is built, while the hydromechanical installations are still lacking.

In this construction period, retention areas during high waters would be activated to a similar degree than upon the completion of the Brežice HPP, meaning that in the retentions lower discharges than prior to HPP construction would occur, and as a consequence also lower water levels in the most part of the retention areas. To relieve the lower part of the right retention and reduce the water mass spilling across the area at the construction pit, there are still two 100-m long openings in the middle part of the reservoir envisaged (Figure 9). The location of the opening on the left allows for as much outflow as possible (outer part of the curve) to the left retention, while the opening on the right allows for a more favourable flow field in the part between the construction pit and the motorway. The increased mass of the water current from the middle to the lower part in the right retention considerably weakens the transversal water current which is, due to the shape of the construction pit and the diversion channel, directed transversally, towards the motorway. The analysis of the velocity field of the final variant confirmed this effect; at the same time, local velocities (or erosion hazard) and local water levels along the motorway are not increased.

The final construction stage, which was critical mostly because of the potential locally increased velocities and thus erosion hazard, comprised the closing of openings in the embankments in the middle part, the closing of the diversion channel, and the redirection of the flow through the spillways of HPP Brežice. It was also necessary to determine the impact of redirecting the Sava River through HPP spillways on flood safety and the impact on the ongoing works at the reservoir (to estimate the possibility of damage) in the phase when the diversion channel is partially or completely backfilled.

Figure 10 shows the velocity fields in the case of still active 100-m outflow openings in the levees for the case with backfilled diversion channel (left) and the still open diversion channel (right). As evident, the lower part of the right retention between the HPP weir and the Ljubljana–Zagreb motorway was the most affected by erosive action due to maximum flow velocities in retention areas. The calculations have shown that erosion risk can be reduced if backfilling of the diversion channel starts at a later stage, to preserve its discharge capacity as long as possible. In the case of backfilling the diversion channel before completing the embankments the erosion processes would be strongest at downstream ends of the already finished embankments (openings in the middle part and before the inflow into the diversion channel). Water current velocities up to 3 m/s would occur, which can transport gravel and rubble up to a grain size of approx. 100 mm. By preserving the diversion channel open it was possible, due to higher discharge capacity of the lower part of the basin, to ensure lower water levels and velocities in the most critical sections.

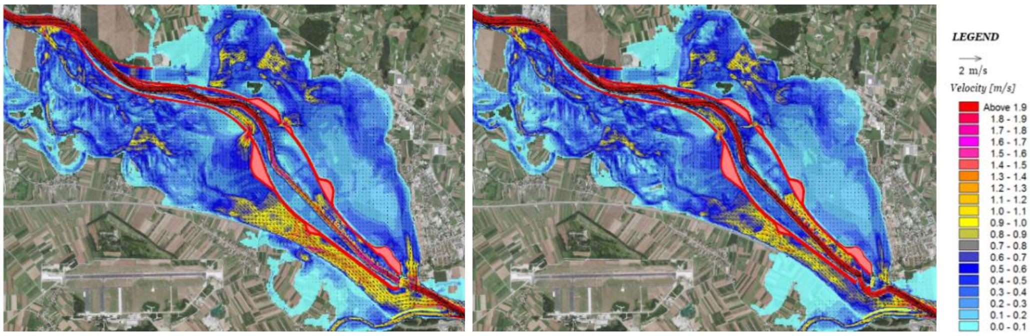

Fig. 10: Velocity field in the case of active 100-m outflow openings in the levees: (a) with backfilled diversion channel (left) or (b) still open diversion channel at the construction pit (right).

Here only some findings from the extensive set of calculations are presented, which show the diversity of the response of the water current to the developments in the floodplains. In the calculations the design engineer could evaluate the different ideas, concepts, scenarios, and thus appropriately designed the excavation of the construction pit and the diversion channel, the sequence of construction phases of embankments and levees and other planned works, and thus tried to minimise the impact on flood and erosion hazard. Despite trying to find the best possible construction sequence, analyses revealed that in the individual construction phases poorer runoff conditions in some areas are to be expected than those prior to the Brežice HPP construction or those upon the completion, as suggested by the calculations. As these areas are populated, and infrastructure facilities of national significance are at stake, the calculation results underlined the need for priority construction of flood levees and additional temporary measures to protect the areas and infrastructure that would be, during the construction, exposed to increased flood and erosion hazards (e.g. of a motorway section).

5. CONCLUSIONS

The appropriate siting of structures and planned developments, which have a significant impact on the runoff regime and can increase flood and erosion hazard for other users in space, needs to take into account both the impact of (stage-wise) construction on the aquatic environment and the impact of action of water on the structures and other works. When determining the acceptability of interventions, the emphasis is usually given to establishing the differences between the existing situation and the planned situation, i.e. the situation after the completion. As shown, during prolonged construction it is necessary to consider the impact of temporary structures, disposal sites, and the individual construction phases, i.e. in a situation when the planned intervention is still not operating as a functional unit.

Therefore, it is necessary to analyse any potential adverse effects of the changing (runoff) conditions on the relevant flood and erosion hazard of users of riparian and downstream space, as temporary conditions can negatively affect the spatial conditions even at high-waters with lower return periods. It was shown that the inclusion of hydraulic analysis into planning the stage-wise implementation is equally important as that in planning and optimising the final solutions of spatial developments. In the case of constructing structures and developments as part of HPP Brežice, the hydraulic calculations provided information about the appropriate planning of construction phases and identifying locations or dimensions of temporary structures and measures, as this provides an important retention area in the section between Krško and the state border and affects the runoff conditions in the border profile with the Republic of Croatia. Notably, NPP Krško is located in the impact area, where any deterioration of runoff and operational conditions is unacceptable, neither during the construction nor afterwards. By comparing intermediate situations and the results of the conditions prior to and upon completion of construction works it was necessary to determine and evaluate the potential deterioration in the individual phases of construction or changes in space, so that the HPP design engineer could predict different construction phases of the individual structures or propose and justify an additional set of (temporary) measures to remedy increased hazard and risk.

This paper also underlines that users of space and activities that take place therein must be made familiar with the processes and impacts of step-wise construction, particularly during prolonged construction. We also recommend that with extensive spatial developments, along longer river section and with larger impact areas, periodic calculations of runoff conditions are carried out. Changes in space have a dispersed character, so it is necessary to check whether any changes or land use affect runoff to a degree when the conditions for siting a structure are no longer met. As in the past the conditions during high-water events have demonstrated, even changes in overgrowth in floodplain areas can significantly affect flows and change the level of flood hazard [9]. Such additional risks should be reduced as much as possible with an appropriate zoning resolution.

SUMMARY

In the planning stage of the interventions in water space and riparian areas hydraulic model research of runoff regime is an established tool in the search of the final solution, which in addition to providing the functionality provides the preservation or mitigation of flood and erosion hazard. To support construction, stepwise planning of temporary structures and measures, etc., is crucial as well. The importance of analysing the runoff regime in a particular intermediate phase of the construction is mainly reflected in siting of an extensive and complex intervention, the construction of which takes place a long time, with changing environmental and hydraulic conditions. One should be aware that during the period of construction the temporary state in the area (particularly in an intermediate phase of construction) could have a significantly more adverse effect on the runoff regime (and consequently on adjacent activities and space users) than a final design state. Temporary flood hazard hydraulic analysis in the planning of construction phases is presented on the case of siting interventions according to the national spatial plan of HPP Brežice, to identify potential intermediate increase of hazard and risk, higher than that predicted for the HPP under full operation. Consequently, the planned construction process was adapted and optimized, which helped to reduce risks as well as costs.

Secretary of Dam Management Unit of Bengawan Solo RBO, INDONESIA

1. INTRODUCTION

Safety of dams can be successfully achieved through prudent implementation of solid dam safety program. As stipulated in the Ministerial of Public Works and Housing Regulation number No. 27/PRT/M/2015 concerning Dams (Regulation), the dam management in Indonesia carried out by River Basin Organization (RBO) through the Dam Management Unit (DMU). One of the tasks and functions of DMU is implementation of the dam safety program. To support the DMU in the implementation of the dam safety program, the national government prepared strategy and policy that can be applied by each DMU in the preparation and monitoring of the dam safety program in the basin. With the assistant of the World Bank in cooperation with Damwatch from New Zealand, the Maturity Matrices was introduced as a tool in measuring its performance or level of maturity of the dam safety in their jurisdictions through self-assessment.

Maturity matrix consists of the Master matrix (lists of dam safety program 'Components') on the second column and activity matrices on the third column. Master matrix consists of ten components with each have activities related to dam safety program. Maturity matrix is intended to assess the extent or the level of implementation of activities of dam safety program by the managers of the DMU.

The level of the implementation of dam safety program can be assessed with the maturity matrix is to know how far the program has been conducted by RBO in order to improve the implementation of the program of the dam safety. While the purpose of this assessment is the actualization of reliable dam safety management by RBO.

2. MATURITY MATRIX

2.1. Principle application of Maturity Matrix

The Maturity Matrices[1] are based on a system used to demonstrate the state of practice in an organization for performing an activity in a qualitative sense. The matrices focus on the operations of the DMU within the RBO and are targeted to the dam safety standards and guidelines in Indonesia. The primary benefit from using dam safety-related maturity matrices is the improved understanding of the effectiveness of the dam safety program across the whole range of dam safety activities. Maturity matrices are intended to reflect the most important components of the dam safety program and its activities as listed in Table 1.

Table 1. Program Components and Activities of Dam Safety Maturity Matrix

[1] *Dam for Development: Toward Enhancing Water Security in Indonesia, Maturity Matrices p. 21 (draft), The World Bank, 2017*

The matrix shows advancing maturity from a rudimentary or elementary level of practice through stages to advanced, expert or best practice.
Maturity matrix has 5 maturity level indicated with different colors. Description and typical characteristic of each proposed maturity level are shown in Table 2.

Table 2. Maturity Level Description and Typical Characteristic

	Maturity Level				
	Level 1 Needing Development	**Level 2** Elementary	**Level 3** Good Practice	**Level 4** Very Good Practice	**Level 5** Best Practice
Maturity Level Description	Lacks conformance to applicable guidelines, standards and best practice	Conforms to applicable guidelines, standards and best practice in some areas	Generally conforms to applicable guidelines, standards and best practice	High degree of conformance with applicable guidelines, standards and best practice with good understanding	High degree of understanding and conformance with applicable guidelines, standards and best practice. No significant opportunities for improvement

The 'Master Matrix' lists dam safety program 'Components' on the vertical axis as shown on Figure 1. Components describe the main activities of a dam safety program and align with ICOLD terminology and are common groupings of dam safety activities around the world.

Relationship between Master Matrix and Component-Matrices

2.2. Limitation of the Matrix

Based on the Regulation, dam construction and management should be implemented based on concepts of dam safety[2].The concept of dam safety shall comprise of 3 (three) pillars (Fig. 4), namely: a. structural safety; b. operation, maintenance and monitoring (surveillance); and c. emergency preparedness.

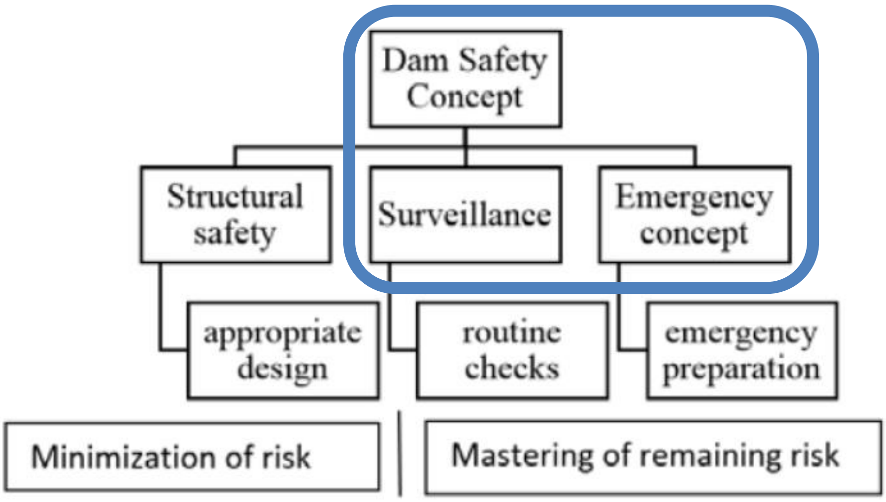

Fig. 4
Dam Safety Concept covered in Maturity Matrices

The maturity matrix primarily concerned with surveillance and emergency preparedness points of the dam safety concept. The discussion will be concentrated on the application of the matrix in Bengawan Solo RBO as the DMU showing the significant progress in the application of the maturity matrices in dam safety program.

3. ASSESSMENT

3.1. Result of self-assessment

Assessment of the performance of the DMU using the maturity matrices have been done with preparing the supporting data in accordance with the activities. The following self-assessment of on the DMU Bengawan Solo RBO which have been carried out, the assessment is using component matrices which

[2] *Article 3, The Ministerial Regulation Number 27/PRT//M/2015 Concerning Dam, Ministry of Public Works and Housing, The Republic of Indonesia, 2015*

are summaries into master matrix and plotted in polar graph to show the result of maturity level of dam safety implementation in Bengawan Solo RBO as shown on Fig. 5, then plotted into polar graph (Fig.6).

Components of the Maturity Matrix		Maturity Level				
		Level 1 Needing Development	Level 2 Elementary	Level 3 Good Practice	Level 4 Very Good Practice	Level 5 Best Practices
1	Governance	1	2	3	4	5
2	Information Management	1	2	3	4	5

Fig. 5
Results of the assessment of the DMU Bengawan Solo RBO

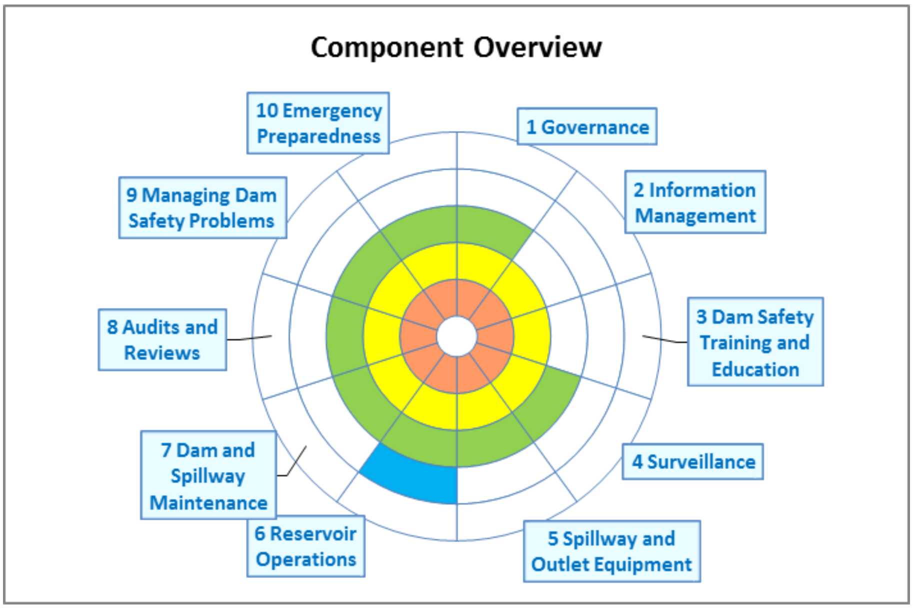

Fig. 6
Polar graph of the assessment result

Evaluation notes that support justification of scoring used in assessment of each components and its activities are as follows:

1. Component 1, Governance with its activities of: Regulation; Delegated Roles and Responsibilities; Internal & External Communications; and Resourcing;
   The score is: at good practice (level 3), in general they comply above activities by having Ministerial Regulation and guidelines for managing their dams and already disseminated to all staff concern; the river basin area divided into 3 areas namely: Upper Bengawan Solo sub basin covering 20 dams; Lower Bengawan Solo sub basin covering 3 dams; and Madiun sub basin covering 3 dams respectively. Each sub-basin headed by engineer as sub DMU they also have some competence engineer working at DMU; they have good communication mechanism in the internal DMU, with other unit within the RBOs and other agencies such as local and provincial agencies, ministry of Public Work and Housing; arrangement of resources starting from the personnel, equipment and budget allocation arranged annually.

2. Component 2, Information Management, with its activities of: Standards, Policies, Plans and Procedures; Physical Infrastructure; Operational; Studies, Reviews and Reports
   The score is: in the elementary level (level 2) since they have some standards, policies, plans and procedures related to the dam safety in DMU office; inventory of dam physical assets has just started, also existing/ recorded information, operational information and related study but not yet cataloging.

3. Component 3, Dam Safety Training and Education with its activities of: Dam Safety; Flow Control Equipment; Reservoir Operation; Incident and Emergency Preparedness; The score is: at the elementary level (level 2), they prepared just an early of training program which will be held regularly within the DMU with facilitator coming from RBO internally and also from the ministry to improve and refresh knowledge and skill of DMU personnel's. The training subject will include Dam Safety; Flow Control Equipment; Reservoir Operation; Incident and Emergency Preparedness. The training which has been run is mostly practical skill such as training for spillway and outlet operations.

4. Component 4, Surveillance, with its activities of: Surveillance Program; Inspections; Instrumentation and Data Management; Dam Safety Assessment; The score is: at good practice (level 3), DMU prepared standard operating procedures (SOP), annual surveillance program and disseminated to all staff member, including dam inspection program, visual dam inspection and its reservoir, instrumentation data record and management, as well as the dam performance with ultimately safety assessment of the dam. Daily reporting result dam according to SOP and rapid report via WhatsApp reporting.

5. Component 5, Spillway and Outlet equipment, with its activities of: Spillway and Outlet Equipment Program; Inspections and Maintenance; Testing; System Performance Assessment. The score is: at good practice (level 3).

All activities are arranged and in well-organized based on regular SOPs, there is continuous reporting on the observation and maintenance of spillway and outlets equipment. The purpose is to maintain the performance of the spillway and outlets equipment that will contribute to the safety of the dam and its reservoir. The works will include program implementation of the spillway and outlet equipment, examination and maintenance of spillway and outlet equipment to assess the condition and reliability also functional testing of spillway and outlet equipment.

6. Component 6, Reservoir Operation, with its activities of: Operation Protocols; Relationship with External Stakeholders; Debris Management
The score is: at a very good practice (level 4). The DMU of Bengawan Solo RBO has prepared the rule curve for reservoir operation purpose as a protocol and continuously recorded with a structured process as required in the SOP of dam operation. The annual operation plan is prepared based on rule curve and recommendation Basin Coordinating Team for the proposed water requirement from the users. The Debris management is done as part of maintenance works in accordance with SOP which has been made in order to improve the performance of the dam and its reservoir that secure on all the operating conditions.

7. Component 7, Dam and Spillway maintenance, with its activities of: Dam, Reservoir and Access maintenance; Spillway and Outlet Structure maintenance. The score is: at a good practice (level 3). UPB BBWS Bengawan Solo has arranged the operation pattern of reservoir and has been carried out recording with a structured process because it already has SOP of dam operation. Waste management is done in accordance with SOP that has been made the goal is to increase the implementation of maintenance of the structure of the civil society and construction related to the dam and its reservoir. Including structural maintenance or repairs, erosion protection, control vegetation and drainage maintenance (drainage surface and drainage relief internal). Including spillway and electrical outlets that shows the function of the safety of the dam also electrical components and mechanical.

8. Component 8, Review and Audit, with its activities of: Dam Safety Program Audit; Dam Safety Program Reviews; Dam Safety Reviews; Flow Control Equipment Reviews. The score is: at a good practice (level 3). The dam safety program is prepared annually. As a part of the SOP, the implementation and the program are regularly audited and reviewed by DMU manager. While the dam safety review including the flow control equipment being done in semiannual basis by the ministry and 5 years basis for the major inspection by the Dam Safety Commission, not all inspections have been implemented but have been included in the strategic plan related to the implementation of the major dam inspection.

9. Component 9, Managing Dam Safety Problems, with its activities of: Issue Management System; Managing Non-conformances; Managing Physical Infrastructure Issues; Managing Dam Safety Deficiencies
   The score is: at a good practice (level 3). Related to the dam safety management issues, periodical and special maintenance have been prepared annually, in addition, related to the problem of dam safety, routine visual inspection and monitoring of the safety parameters of the dam were conducted by DMU staff and implemented well. DMU has set up a reliable safety management of dam through inventory, categorization, priority setting, investigations, and asessment of the dam safey issues.

10. Component 10, Emergency Preparedness, with its activities of: Hazard and Consequence Identification; Owner Emergency Preparedness Plans; Relationship with Community and External Agencies: Tests and Exercises
   The score is: at a good practice (level 3), in relation to emergency preparedness, DMU of Bengawan Solo RBO has prepared an Emergency Action Plan though not yet for all dam, so that DMU of Bengawan Solo RBO may increase the awareness in identification of hazard and consequences potential failure of the dam and planning to respond to the incidents that may cause failure of the dam. This includes preparation of the plan for the state of emergency, build external relations and testing and training emergency situations including the simulation for the state of emergency in cooperation with the local government through Regional Disaster Management Authority.

3.2. Review and Discussion

The maturity matrices were launched in early 2017 and followed with two subsequent workshops in Batam (May 11-12, 2017) and in Semarang (July 17-20, 2017). The result of the self-assessment above showed the acceptance of DMU Bengawan Solo RBO to the maturity matrices is promising. The scoring of each activity with its line item descriptions require understanding the nature of the component, activity and also broader context of dam safety management as well as dam safety standards and guidelines. Fortunately the DMU of Bengawan Solo has sufficient competence human resources, so it is helpful in expediting the familiarity to the application of such maturity matrix for evaluating dam safety program.

Yet the objective of such assessment has to be achieved, in order to reach further achievement and to expedite the scoring supporting its assessment result with document as an evidence to facilitate scoring justification may also be necessary. The assessment result and its descriptions is a good start to demonstrate the anticipation of the DMU.

DMU as units that manage dams become vital objects on the application of self-assessment using dam safety program maturity matrix to see their own performance in running the program. Such assessment is conducted in accordance with of the dam safety management based on the applicable rules and procedures. However associated with workshop of maturity matrices in dam safety program, it is also important to refresh the understanding of participants in the dam safety management based on the applicable rules and procedures.

4. CONCLUSIONS AND RECOMMENDATIONS

4.1. Conclusions

- Dam safety maturity matrices has been understood and possible to be adopted for assessing the dam safety program run by DMU.
- Consistency in self-assessment has yet to be achieved, to expedite the proper assessment its need facilitator which on the other hand will also function in validation of the self-assessment capacity.
- The maturity matrix outcome also can be used as a guide to develop the current level to improve to the desired level depending the available resources within the DMU.
- Variability in DMU capacity may be consider when the tools will be nationally applied. Thus, workshop and training in the subject of maturity matrices in dam safety program and dam safety management should be regularly held.
- Skilled persons in Maturity Matrices application tour of duty has to be anticipate to maintain the capacity of DMU

4.2. Recommendations

- Workshop is very important to anticipate personnel tour of duty and also as a medium to exchange the understanding among DMU.
- The target level of maturity for each DMU shall not be same for all DMU, setting of the target level will be depending on their portfolio of dams.
- The Maturity Matrices could be expanded beyond RBO under the Ministry, such as water supply, hydro power and private dam owner with some modification.
- Dam Safety Maturity Matrices of dam safety program be included as part of annual and comprehensive safety review of all dams in Indonesia

1. INTRODUCTION

A large percentage of dams in operation today are more than 50 years old and as such the true condition of its structural integrity is not fully known. The deterioration of dams may result both from short and from long term effects. In most cases these effects may not be immediately noticed. To prevent sudden dam failure because of accumulated damages overtime, the timely identification of weak heterogeneous zones which may impair the dam's safety and operation is essential. Unfortunately, the conventional methods are tedious, time consuming, expensive and sometimes inefficient. To tackle these challenges, various numerical methods and inverse analysis has been proposed by the authors [1, 2, 3, 4, 5] considering the coupling effects on various phenomena present in the operational life cycle of the dam.

With the recent technological improvements in computational capabilities, waves have increasingly been applied to probe and obtain information on the structural integrity of mainly sub-surface structures. Information from the reflection, refraction and diffraction of these waves gives insight into possible anomalies which may negatively impact the structural stability and performance.

Quite many research projects have been carried out with regards to wave modeling underneath the earths' surface. There exist several code implementations ranging from simple to complex and using various numerical methods such as Finite Differences, Finite Elements, Ray theory, Integral solution, etc. The finite difference method is a common method used for solving the wave equation in geophysics and oil exploration as can be seen in works by [6, 7] and [8].

Based on the successful application of Full Waveform Inversion (FWI) in geotechnical exploration and non-destructive testing (NDT), especially with subsurface structures [9, 10, 11, 12, 13, 14, 15, 16], our method aims to extends this application to the identification of damaged regions in dams.

2. THEORY

Seismic waves are generally classified into surface waves and body waves. The surface waves as the name implies, generally travel on the while the body waves on the other hand travel through the inner parts of the earth or structure. Seismic inversion can be categorized into seismic reflection and seismic tomography. In seismic reflection the inversion of reflected waves usually gives information on geometry while refracted waves (seismic refraction) give information on elastic parameters. Seismic tomography application on the other hand, employs the inversion of transmitted, reflected and refracted signals from seismic observations to determine the distribution of material properties in a structure. Seismic tomography methods include travel time inversion (kinematic imaging) and Full Waveform Inversion (dynamic imagining).

Full waveform inversion (FWI), initially proposed by [17, 18] and further developed in the last decades, is regarded as the modern seismic imaging technique which utilizes a comprehensive representation of the interaction between wave physics and subsurface properties. It offers unique advantages in terms of generality, fidelity, complexity and robustness and is hence capable of imaging arbitrarily heterogeneous compression and shear-wave velocity profiles of the subsurface constituents [9]. The quality and efficiency of the inversion is sensitive to the initial model, acquisition setup, and the formulation of the inverse procedure (inversion parameters, domain, method, etc.).

To maintain numerical stability and efficiently use computational resources in simulating wave propagation in unbounded media, it is necessary to truncate the numerical domain. Several absorbing boundary conditions (ABC) has been proposed, however most of these ABC become unstable when considering heterogeneous materials in addition to other limitations. The perfectly matching layer (PML) proposed by [19] is used in this paper.

3. MATHEMATICAL MODEL

3.1. FORWARD MODEL

The elastic wave equation is solved numerically for the displacements **u**, stresses τ, density and Lamé parameters (λ and μ) using the finite difference method. The wave equation is discretized in time and space with each of the parameters placed on a staggered grid [20, 21]. The 2D elastic wave equation employed for the forward modeling is the stress-displacement formulation (τ- **u**) in Eq. [1]. The V_p and V_s velocities can be calculated from Eq. [2].

$$\rho \frac{\partial^2 \boldsymbol{u}_i}{\partial t^2} - \frac{\partial \tau_{ij}}{\partial x_j} = f_i$$
$$\tau_{ij} - C_{ijkl}\epsilon_{ij} = T_{ij} \qquad [1]$$
$$\epsilon_{kl} = \frac{1/2\,(\partial \boldsymbol{u}_i)}{\partial x_j} + \frac{1/2\,(\partial \boldsymbol{u}_j)}{\partial x_i}$$

$$With$$
$$\boldsymbol{u}_{t=0} = \bar{\boldsymbol{u}}_0 \; on \; \Omega$$
$$\frac{\partial \boldsymbol{u}_{(t=0)}}{\partial t} = \bar{\boldsymbol{v}}_0 \; on \; \Omega$$
$$\boldsymbol{u} = \boldsymbol{u}_1 \, on \; \Gamma_1$$
$$\frac{\partial C_{ijkl}\,\epsilon_{kl}}{\partial x} = \bar{(t)} \; on \; \Gamma_2$$
$$V_p = \frac{\sqrt{(\lambda + 2\mu)}}{\rho}; \qquad V_s = \sqrt{\mu/\rho} \qquad [2]$$

where:
- u_i is the particle displacement
- $\tau_{ij} = \lambda\theta\delta_{ij} + 2\,\mu\epsilon_{ij}$ are stress tensor components
- $C_{ijkl} = \delta_{ij}\delta_{kl}\lambda + (\delta_{ik}\delta_{jl} + \delta_{il}\delta_{jk})\mu$ is the stiffness tensor
- ϵ_{ij} is the strain tensor
- ρ is the density of the medium
- f_i, T_{ij} are volume and surface source terms
- λ and μ are the Lamés' parameters
- V_p and V_s are the primary and secondary wave velocity

According to [22, 23], the stability of the staggered grid code is guaranteed when λ, μ and ρ are averaged harmonically and arithmetically. The accuracy of the finite difference (FD) operator used to approximate the spatial derivatives is dependent on the order of the FD operator (i.e. truncation error of the Taylor series expansion). Reflection of the wavefield at the boundaries are prevented by using a PML to damp out the wavefield at the boundaries. Furthermore, it is necessary to satisfy spatial and temporal sampling conditions [24] for the wavefield to prevent numerical artifacts and instabilities during the finite difference simulation.

3.2. INVERSE ANALYSIS

The relationship between the experimental/field data and model can initially be expressed as:

$$F(\boldsymbol{m}) = \boldsymbol{u}^{\boldsymbol{exp}} \quad [5]$$

Where F is the forward operator, mapping the material properties/damage parameters **m** (i.e. $\lambda,\ \mu$ and ρ) to the measured signals. As the solution of Eq. [5] may not exist as the measured data $\boldsymbol{u}^{\boldsymbol{exp}}$ are not in the range of F, we follow a least-square solution approach in Eq. [6]. Thus, the main concept behind the inverse analysis is to minimize the data residuals $\delta\boldsymbol{u}$ or misfit between experimental or field data $\boldsymbol{u}^{\boldsymbol{exp}}$ and the simulated data from our forward model $\boldsymbol{u}^{mod}$. The objective function $C_f\ (\boldsymbol{m})$ which is to be minimized is the residual elastic energy in the residuals. That is the L2-norm of the error between the model response and the field or experimental data.

$$C_f\ (\boldsymbol{m})\ =\ 0.5\left||\boldsymbol{u}_m^{mod} - \boldsymbol{u}^{exp}|\right|_{L2} \quad [6]$$

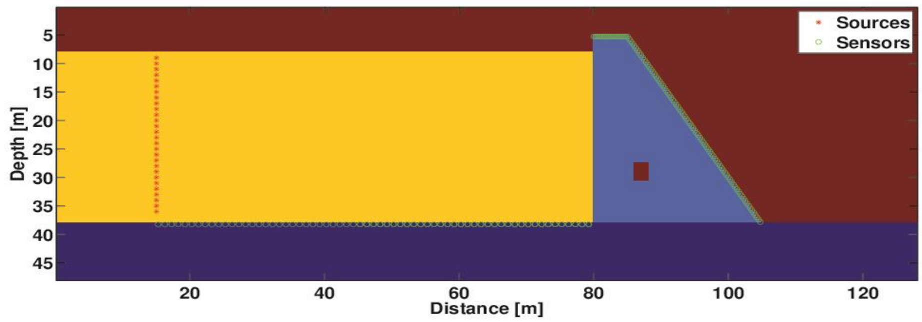
Various strategies are available for inverse analysis, these include both direct and random-search strategies such as Newton methods (Gauss-Newton, Full Newton, etc), Conjugate Gradient, Nelder-Mead simplex methods, Particle Swarm Optimization, Simulated Annealing, Genetic Algorithm and Regularizing Iterative Methods by [25].

4. NUMERICAL SIMULATION AND DISCUSSION

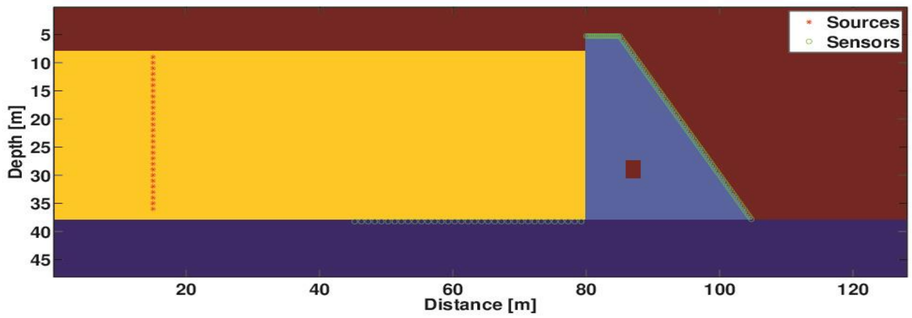
The numerical simulation is carried out for a dam (true model) with material properties defined in terms of seismic velocities summarized in Table 1 and obtainable in Fig. 2. To ascertain the effect of acquisition geometry on quality of results, the sources-sensors setups in Fig. 1 are used to acquire all the waveform data necessary for carrying on the inversion. The dam true model consists of anomalies both in the dam structure and in the foundation. The anomalies represent weaknesses in various regions and of varying magnitudes. In the dam structure, the topmost anomaly represents a 20% reduction in the parameter values (V_p, V_s, ρ), the second 10% and the third (i.e. crack zone) has a 30% reduction. All the anomalies in the foundation have an 70% reduction in the material parameter values.

Table 1
Dam material properties for true model

	V_p	V_s	ρ
Dam body	3500	2200	2000
Dam tunnel	0	0	1.25
Dam foundation	4500	2700	2550
Water	1500	0	1000
Air/Vacuum	0	0	1.25



(a) Setup 1

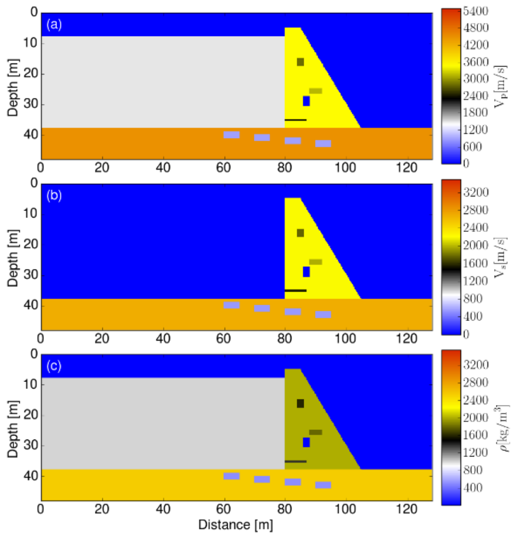


(b) Setup 2

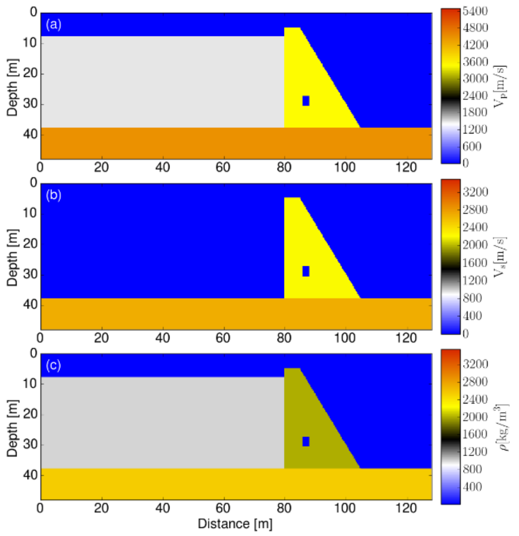
Fig. 1 Acquisition setup showing distribution of sources and sensors in the domain.

The computational domain has a height of 48m and length of 128m, and it comprises of the dam structure 28m high with a crest and base width of 4.5m and 19m respectively. A 30m by 80m water reservoir, a 10m deep foundation and the surrounding air is also considered. A 2D finite difference scheme on a staggered grid is used to solve the elastic wave equation. The computational domain is truncated using a 2.5m (i.e. 10 grid points) thick Convolutional-PML (C-PML) at both sides and at the bottom of the domain.

Owing to the high number of the systems' global degrees of freedom (i.e. identifying 3 parameters for each node in a domain with 512x192 = 98,304 nodes), an inverse analysis using methods such as particle swarm optimization (PSO) for anomaly identification, as used in [4, 5] would increase the complexity of the problem. Gradient and Newton methods involving the computation of the gradient and an approximation of the inverse Hessian operator have been successfully applied by [26, 27, 28]. Thus, motivating the application of the quasi-Newton limited memory Broyden-Fletcher-Goldfarb-Shanno (l-BFGS) method in this paper. The required model parameter gradient calculation is done using the adjoint state method as employed in [29]. Since the FWI is sensitive to the initial model, to enable convergence to the global minima, an initial model which contains the long wavelength part of the model to be resolved is required. Unlike in geophysical exploration, a priori information on the dam material parameters can often be gotten since most of these structures are man-made. Thus, the material properties at construction can be used as an upper bound as done in this case.



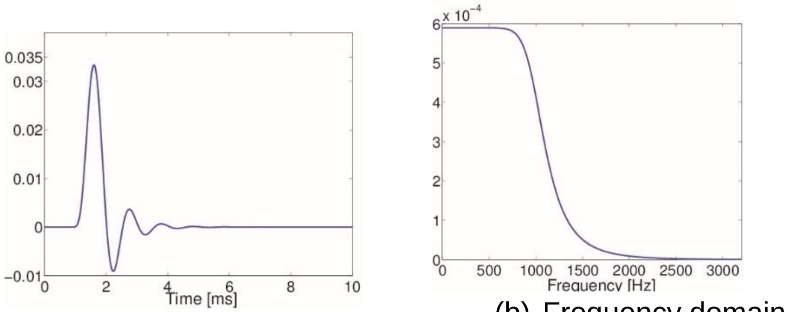
(a) True model



(b) Initial model

Fig. 2 Distribution of seismic velocities (V_p , V_s)and density in the air, water, foundation and dam structure (true and initial model)

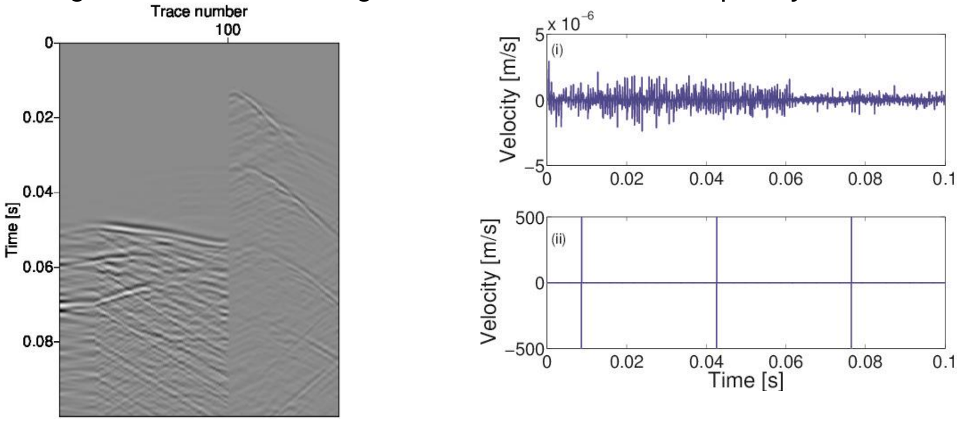
A closer look at Fig. 2 shows that the true model in (a) and the initial model in (b) differ only by the inclusion of regions of degraded material properties in the true model. Therefore, the 'as-built' material properties of the dam are taken as the starting model. To probe the dam material, spike wavelets are sequentially emitted from each of the sources (e.g. air guns). Here, a low-pass filtered spike with upper corner frequency of 1kHz is applied as shown in Fig. 3. For each excitation shot the source wavelet propagates for a duration of 0:1s and the time interval (*dt*) used for the analysis is $3x10^{-5}$s which satisfies the Courant-Friedrichs-Lewy criterion for stability.



(a) Time domain

(b) Frequency domain

Fig. 3 Source wavelet signal in time domain and frequency domain

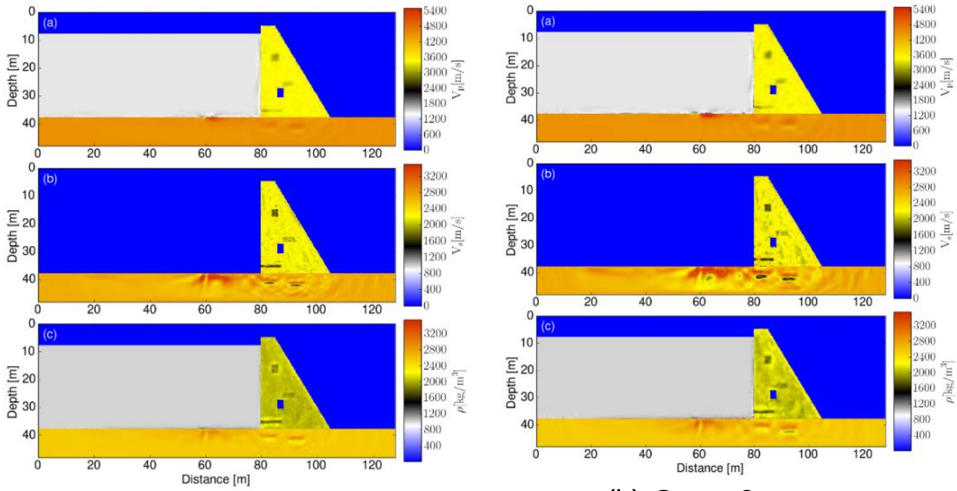


(a) seismogram for shot 14

(b) seismogram for selected traces

Fig. 4 Sensor response due to propagated waves in medium. (a) Seismogram of all 165 sensor response (b)(i) Response of selected traces.

Dam response recorded by the receivers/sensors due to waves propagating in the medium is obtained in Fig. 4. These synthetically generated seismograms would serve as field data for the inverse analysis (i.e. full waveform inversion). Originally proposed by [30], the FWI is carried out in multiple frequency stages. The inversion is done starting from lower frequencies to higher frequencies (i.e. 0:5-1kHz) to alleviate the non-linearity of the problem. These lower frequencies are less prone to grid dispersion and can identify high velocity regions. The output of low frequency inversion is used as a starting model for higher frequency inversion. Therefore, with each increasing stage of inversion (i.e. increase in frequency), the location/boundaries between different velocity regions becomes more clearly delineated and the quality of the inversion results improves. Inversion results obtained in Fig. 5 shows a good resolution of damages in the dam structure. Anomalies in the dam foundation were not properly resolved, however, from a comparison of the inverted models (i.e. V_p, V_s, ρ) the V_s model can resolve most of the anomalies/damage zones in the dam structure and parts of the foundation. Although less sensors are used in setup 2, better resolution of the damaged regions in addition to more numerical artefacts can be observed.



(a) Setup 1 (b) Setup 2

Fig. 5 FWI model comparison for acquisition setup 1 and 2.

5. CONCLUSIONS

Although the Full Waveform Inversion (FWI) has mainly been applied to subsurface exploration of material properties in practice, results obtained in this paper has shown its applicability for non-destructive tests (NDT) of super-structures. The FWI formulation used in our investigation is capable of effectively identifying and quantifying regions of weaknesses (i.e. heterogeneity) in both the dam structure and its foundation. The quality of the inversion is dependent on the initial model, the acquisition geometry and noise level in the measurement data.

1. INTRODUCTION

In rehabilitation of hydraulic structures, there are many chances to meet the need of concrete pouring into the water body. The study of underwater concrete technology has been conducted since the early age of concrete development. Some underwater concrete technologies have been developed, i.e. bucket, grouted-intruded aggregate, grouting and tremie[1]. These construction methods were the efforts the engineers ever made to reduce the serious segregation and loss of cement caused by the scouring of concrete during construction and hardening process, so as to avoid the deterioration of concrete quality and affect the water environment. In the late 1970s, a new type underwater concrete, named

Non-Dispersible Underwater Concrete was first realized by the development of cellulose ethers in Germany. Non-Dispersible Underwater Concrete technology has been employed in other countries in Europe, Japan and USA soon. This technology was adopted in the projects of Access bridge of Kansai International Airport, Akashi strait bridge, Rehabilitation of Copenhagen Port, Breakwater along west coast in Scotland and so on. In 1993, the publish of a Chinese translation of "Design and construction guideline to Non-Dispersible Underwater Concrete" by Research Center of Coastal Developing Technology in Japan, has a positive role in promoting underwater concrete technology in China [2]. Now, polymer flocculants with long polymer chain structures are widely used in Non-Dispersible Underwater Concrete. The cement particles absorbed by active functional groups on long carbon chains can be bridged to form stable floc structures. At the same time, the hydrogen bonds between the hydroxyl on the functional group in flocculant and water molecules will form to increase the affinity of water molecules. The long molecular chains of flocculants attract each other and the mesh structures form by these chains. Particles of cement are covered by the meshes and difficult to be dispersed by the washing of external water molecules. However, flocculant will affect the workability of concrete mixture, and also cannot totally avoid the washing effect of water on concrete mixture. The price of non-dispersible underwater concrete is relatively high. In early 2010s， an innovative technology for underwater concrete has been developed and authorized patent in China. It was named Self-Protected Underwater Concrete (SPUC) [3] later.

2. WORKING PRINCIPLE AND IMPLEMENTATION OF SPUC

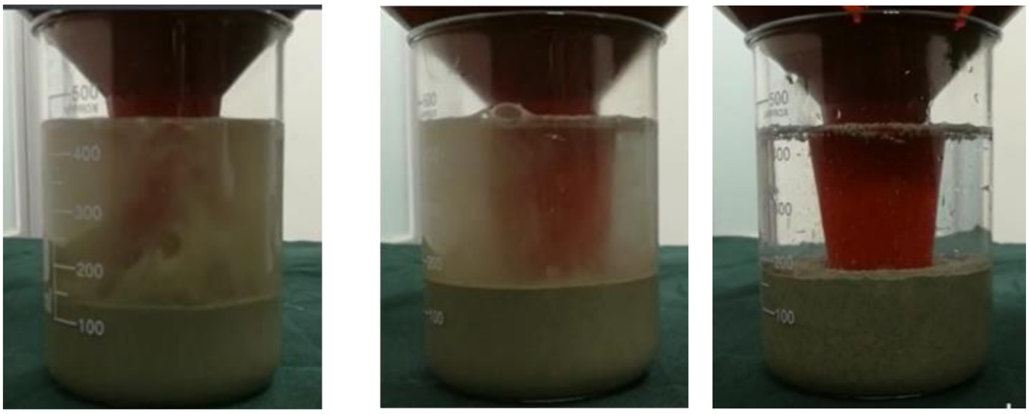
2.1. WORKING PRINCIPLE

The working principle of SPUC is different from that of Non-Dispersible Underwater Concrete. A soluble polymer, called Underwater Protective Agents (UPA) will be poured into the water body prior to the pouring of underwater concrete. Then the water body will be transformed into a solution of UPA, usually the concentration of UPA will be about 100 ppm. The structures of UPA molecules chains will prevent the dispensation of cement particles into the water body, so as to avoid segregation. The employment of self-compacting concrete makes the vibration-free cast of concrete.

2.2. DEMO COMPARISON BETWEEN DIFFERENT TECHNOLOGY

To demonstrate the difference among ordinary concrete, non-dispersible underwater concrete and SPUC，a demo test was conducted, as shown in Fig. 1. In the demo test, three type of fresh self-compacting mortar were poured via a funnel into the water in the beakers directly. The water-cement ratio and mix are almost identity, while only the flocculant added in non-dispersible mortar. The mortar in case (a) and case (c) are same, but UPA added prior to the pouring of mortar in case (c).

The demo shows that the water in case (c) remain very lucid. Much less cement in the water in case (b) than case (a). It is clear that the performance of SPU mortar is better than that of non-dispersible mortar, and the performance of the later is better than that of ordinary mortar.



(a) ordinary mortar (b) non-dispersible mortar (c) SPU mortar

Fig. 1
Demo of three technologies

2.3. IMPLEMENTATION PROCEDURE OF SPUC

The usage of UPA will simplify the construction of underwater concrete. When SPUC employed, the UPA will be poured into the water body where the concrete is poured later. Then SPUC can be vibration-free casted. The construction procedure is shown in Fig. 2.

UPA should be diluted to about 1% before casted into the water to form a 100 ppm UPA solution. After a certain amount of UPA is casted, concrete will be poured at the vicinity of casting point of UPA. At the same time, UPA casting-speed will be control with the speed of concrete pouring. The process will not stop until all workspace filled with SPUC.

3. IN-SITU TEST OF SPUC

3.1 TANJIANG BRIDGE IN-SITU TEST OF SPUC

To validate the SPUC technology, an in-situ test was conducted in Tanjiang bridge, Guangdong Province, China. A pit was digged and paved with plastic sheet with color bands, as shown in Fig. 3. Then water filled and UPA was poured into the water. Concrete had been poured until the pit filled with SPUC.

After concrete harden, the difference of elevation between the cast point and 5 m away is only 60 mm. The average compress strength of drill cores is 36.8 MPa, where design compress strength is only 25 MPa. The bottom concrete of the piers in this huge bridge was decided to pour by using SPUC technology.

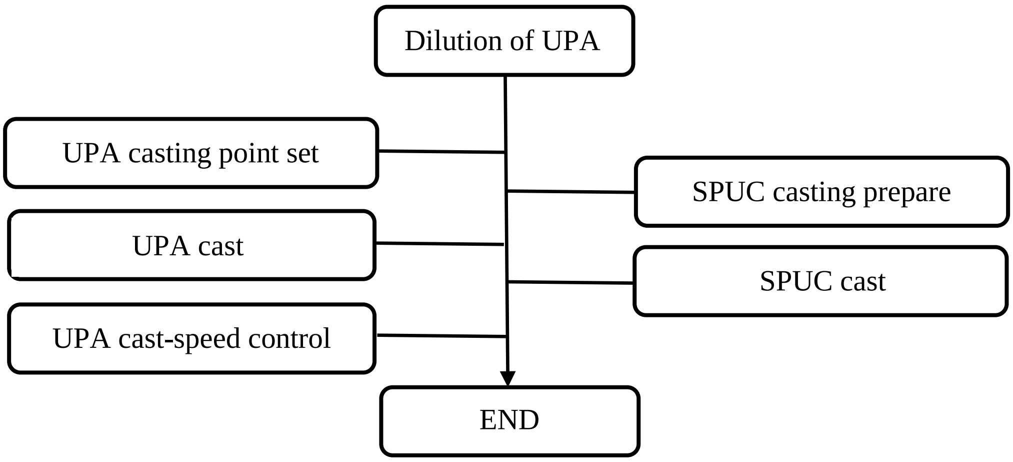


Fig. 2
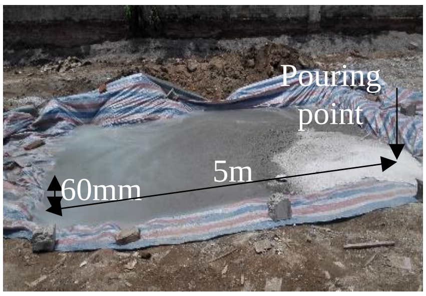
Flowchart of SPUC casting

(a) commencement of pouring

(b) process of pouring



(c) pouring finished

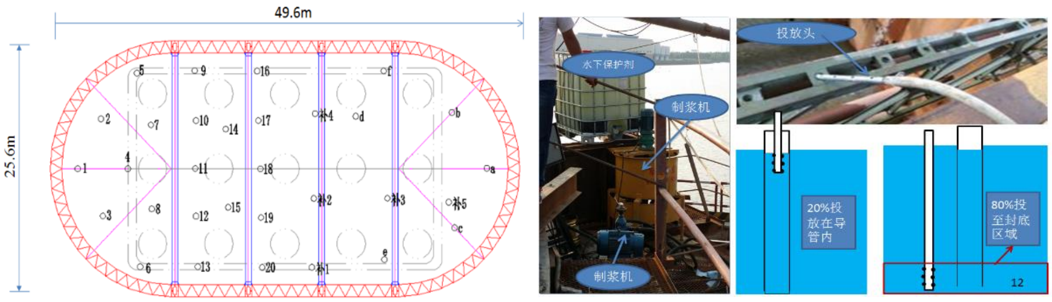
(d) drill cores after harden

Fig. 3
In-situ test of SPUC in Tanjiang bridge

4. ENGINEERING PROJECTS EMPLOYING SPUC

4.1 CONSTRUCTION OF SPUC IN BOTTOM OF PILES IN TANJIANG BRIDGE

The depth of the water is about 10 -15 m. The thickness of bottom concrete is 3.5 m. Area of concrete pouring is about 1000 m^2, as shown in Fig. 4(a). The small circle with numbers denotes position of 31 designed trimies with a diameter of 300 mm. But only 24 trimies were used since the fluidity of SPUC is better than expected. 80% of consumed UPA was casted into the bottom water in workspace via tremies before concrete pouring started. Then 20% remained UPA was casted into a tremie and an insulate ball with a plug device are installed at the opening of the tremie. Concrete poured into water via the tremie after the insulate ball plugged. The end of the tremie was kept embedded into the concrete about 500 mm depth. The distance between tremies is about 8 m. The slope of concrete surface was about 1:20 – 1:30 during whole pouring process surveyed by measure ropes.



(a) Layout of SPUC construction (b) Dilution and casting of UPA

Fig. 4

Layout and casting of UPA in SPUC construction in Tanjiang bridge

The whole process of SPUC construction lasted about 36 h smoothly. The total amount of SPUC poured is 2223 m^3. The average compress strength of drill cores is about 40 MPa, higher than design value of 25 MPa. The construction of SPUC in Tanjiang bridge was very successful.

4.2 SPUC IN REHABILITATION OF WANYAO DAM

Wanyao reservoir is a Large (Grade II) reservoir with irrigation, water supply, hydropower and flood control functions, which located in Jiangshan city, Zejiang Province, China [4]. The main dam of Wanyao reservoir is a Roller-Compacted Concrete gravity dam with a height of 79 m. The length of dam crest is 390 m. The whole dam is divided into 11 blocks, where Block 5 is spillway block and others are non-overflow blocks. During the poor construction quality, the dam has to be rehabilitated due to severe seepage problem. An impervious concrete face shall be installed at the upstream face of the dam. In design phase, the reservoir level is designed to be controlled at the Elevation 158.24. The contractor suggested that the reservoir level shall be lower more 10 m. Then, the layout of rehabilitation is shown in Fig. 5. The shadow part will be poured by SPUC.

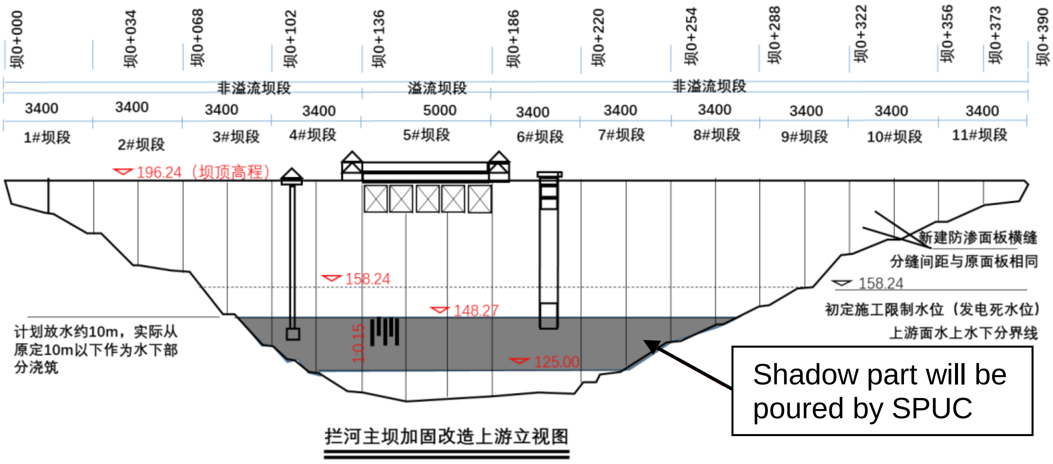


Fig. 5
Layout of rehabiliation by SPUC of Wanyao dam

Two mix of SPUC are suggested, listed in Table 1.

Table 1
Mix suggested

No.	1	2
Requirement	C25W8F100	C25W8F100
Cement, kg/m^3	407	407
Fly Ash, kg/m^3	128	128
Water, kg/m^3	172	172
Sand, kg/m^3	812	812
Coarse Aggregate, kg/m^3	827	827
Superplasticizer, kg/m^3	6.5	9.0
Slump, mm	450	750
Slump Flow, mm	260	280
V-Funnel, s	3.5	1.38
Air Content, %	4.4	4.4

SPUC will be mixed at the mixer plant at the dam crest and casted via a funnel fixed at the crest and a tremie into the workspace underwater. UPA will be diluted and casted into the water prior to the pouring of concrete same as other projects. The photo of the dam and the cast plan is shown in Fig. 6. The width of each block is 34 m and divided into 2 sub-block. 5 casting point will be set for each sub-block since the distance between two casting points is designed as 5 m.

Construction of SPUC will start in the spring of 2018.

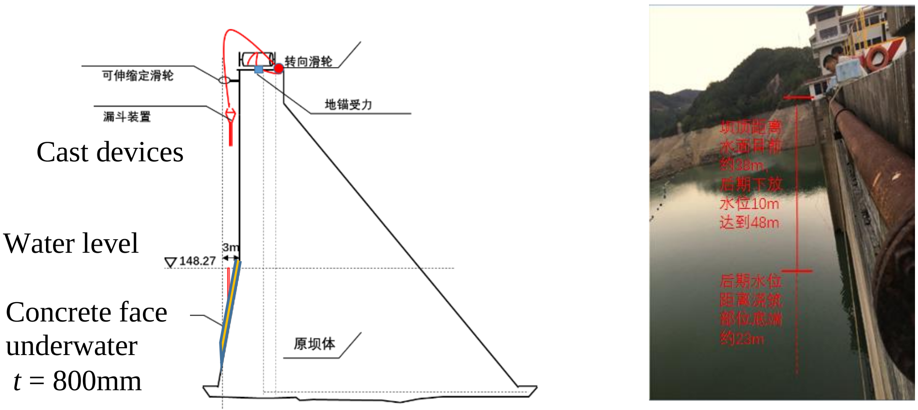

Fig. 6
Casting plan of SPUC and photo of Wanyao dam

SUMMARY

An innovative underwater concrete, named Self-Protected Underwater Concrete technology, is introduced in this paper. SPUC can be used in the case of Non-dispersive underwater concrete employed. SPUC based on the utilization of UPA. Successes of some SPUC engineering projects demonstrates that this technology has a great potential in the underwater concrete field.

1. INTRODUCTION

Large dams are civil engineering structures of great importance and present a high potential risk, given their relevant contribution to populations and the costly damage that would result from a collapse situation. Therefore, in the scope of dam safety control, knowledge regarding the dynamic behavior of dams must be continuously updated and improved, relying on the combined use of advanced vibrations monitoring systems and accurate numerical models of dam-reservoir-foundation (DRF) systems (Fig. 1) [1,2,3]. Regarding the monitoring systems, it is important to use quality equipment for measurement, transmission and storage of the recorded data, as well as the appropriate computer software to collect and process said data, and hence analyze/manage the obtained results, with the latter representing a major issue when intending to implement such a system. As for numerical modelling, this is an area that still presents important challenges due to the complexity of DRF systems, namely considering the effects of the water level variations, the dynamic reservoir-dam interaction and the reservoir hydrodynamic behavior, the support conditions, among others.

* *Vibrations dans les grands barrages. Auscultation et modélisation*

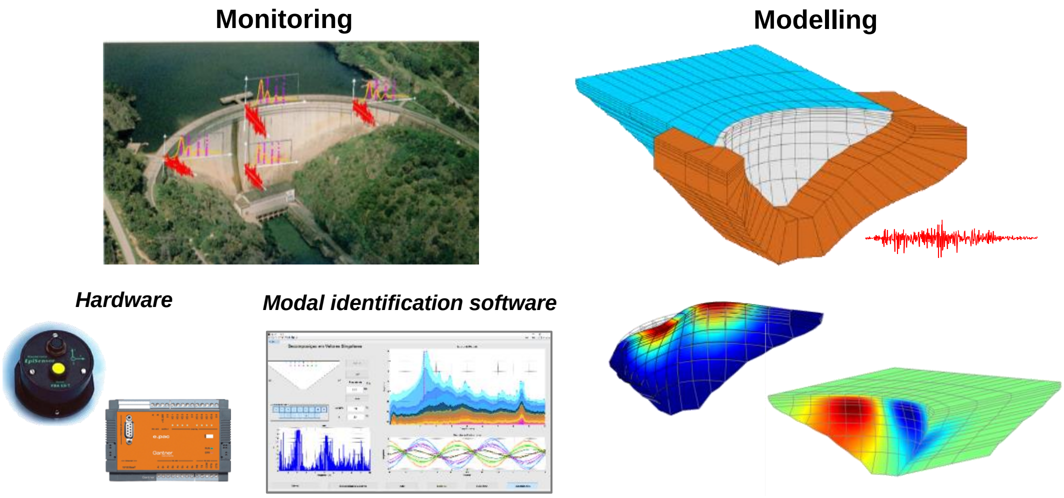

Fig. 1
Monitoring and modelling the dynamic behavior of large arch dams.

2. MONITORING THE DYNAMIC BEHAVIOR OF LARGE DAMS

For large concrete dams, the installation of systems for continuous vibrations monitoring aims to measure and analyze acceleration records in several points in the dam and in the foundation, for different ambient/operational excitation and earthquakes of different magnitudes, based on the latest data acquisition technologies. The data measurements should be performed in as many points as possible, in order to obtain reliable modal identification results. Nonetheless, the efficiency and accuracy of these monitoring systems also depend heavily on the use of sophisticated software for analysis and management of the collected data.

Therefore, it is of the utmost importance to develop and include computational tools, adapted to each dam, for automatic and/or interactive analysis [1,2], aiming to: a) identify the dam's main modal parameters (natural frequencies, mode shapes and modal damping), based on frequency domain and/or time domain modal identification methods [4], and study their evolution over time, considering the water level and seasonal thermal variations, or to detect possible structural changes due to deterioration processes [5]; b) measure the dam dynamic response for different reservoir levels, enabling to evaluate the amplification of the accelerations recorded in the foundation and in the dam [6], as well as to study the influence of the dam-reservoir interaction. Furthermore, the developed software should enable the comparison between the monitored dam dynamic response and its dynamic behavior as predicted with the numerical programs: this is of great value to validate and calibrate the numerical models, which are used to simulate the dynamic behavior of DRF systems and to carry out seismic safety verifications.

3. CABRIL DAM. MONITORING SYSTEM: HARDWARE AND SOFTWARE

Cabril dam was built in 1950's and is the highest Portuguese arch dam (Fig. 2). Located in the Zêzere River, this is a 132 m high double curvature arch dam with crest altitude of 297 m. The arch is 290 m long at the top, and the central cantilever has a maximum width of 19 m at the base and a minimum width of 4.5 m below the crest. In this dam, a significant horizontal cracking phenomena occurred near the crest (at a height of 280-290 m) during the first filling of the reservoir. Also, a concrete swelling process has been detected in recent years.

In the framework of LNEC research activities regarding monitoring and modelling the dynamic behavior of dams, a pioneer project was initiated in 2002 [1] to install a dynamic monitoring system in Cabril dam, which is in operation since 2008 (Fig.2). The outlined configuration for this system was based on experience gathered in LNEC over the years, from both monitoring data and numerical results [2,3,5,6,7]. The goal was to implement a system with a high dynamic range, capable of a continuous accurate measurement of the dam's response for several dynamic excitations: ambient/operation excitations or earthquakes of various magnitudes. This system was designed to measure accelerations in the upper zone of the dam and near the base, at a sampling rate of 1000 Hz and considering time periods of one hour, and it includes 16 uniaxial and 3 triaxial accelerometers.

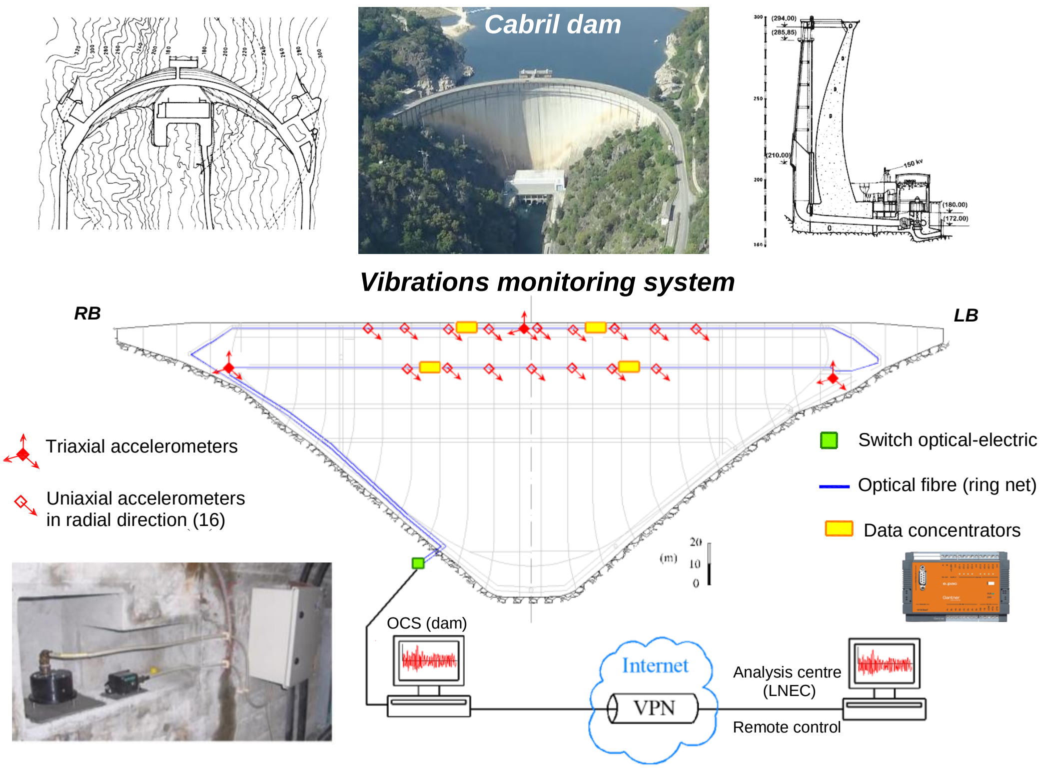

Fig. 3
Cabril dam. Plan and central cantilever (with intake tower) and vibrations monitoring system - schematic representation and main hardware components.

The uniaxial accelerometers (prepared to measure vibrations in a radial direction) are distributed in the upper part of the dam by two galleries, above and below the cracked zone. As for the triaxial accelerometers, one is located in the central cantilever (upper gallery), while the other two are installed near the insertion of the dam base, in both banks. The accelerometers are connected to a modular system composed by acquisition/digitalization units, which in turn are controlled by 4 data concentrators that receive the recorded data. This data is sent through an optical fiber local network (intranet) to a computer in the observation and control station (OCS), located at the dam power station. In total 25 accelerograms are recorded and stored every hour, continuously. The storage and management of the collected data is carried out at the server located in the OCS using appropriate software developed in LNEC. Regarding the remote control of the system, it is important to refer that the server can be accessed via internet from LNEC by computer or even by smartphone, using suitable software, which is of great relevance given that it allows to control and analyze such important data from a distance.

As previously mentioned, the hardware for measuring accelerations and the corresponding data acquisition software must be complemented with suitable software for automatic analysis and management of the collected data, to ensure the efficiency of the dynamic monitoring system and hence accurate results. For the case of Cabril dam, two programs were developed using MATLAB: *Modal_ID_auto2.0* and *Modal_ID2.0* (Fig. 4). Modal identification is performed using a frequency domain method [4], Frequency Domain Decomposition (FDD), including three variants, namely: a) by implementing a Random Decrement technique (FDD(RD)); b) using a Singular Value Decomposition (FDD-SVD); and d) considering the combined use of the previous techniques (FDD(RD)-SV).

As the name indicates, *Modal_ID_auto2.0* is a software that carries out automatic continuous data analysis based on specific outputs defined in advance (e.g. the modal identification technique or the measuring points to analyze). Besides the analysis and management of the data, it automatically generates and sends (via e-mail) files with a synthesis of the obtained results, to be analyzed by the engineers and technicians. Given its continuous analysis of the acceleration records, the results allow to study the evolution of the modal parameters over the year, taking into account water level and thermal variations.

On the other hand, *Modal_ID2.0* is an interactive program that performs the modal identification of the main modal parameters for a certain data file, which is associated to the hour-day-year input chosen by the user. Its interactive feature enables to carefully observe the records and modal identification outputs for a certain water level, and it facilitates the comparison with numerical results. In terms of the results obtained from the collected data, both programs present as outputs: a) the acceleration records for each installed accelerometer and the corresponding amplitude spectrum; b) the medium spectrum, as obtained by applying modal identification techniques; and c) the natural frequencies, which correspond to the main spectral peaks, and the respective vibration modes, including 3D mode shapes and harmonic waves representing the oscillatory movements in each measuring point, all associated to the measured water level.
