Dear colleagues,

It is with great respect and appreciation that we present the proceedings of the 13th International Conference on Structural Health Monitoring of Intelligent Infrastructure (SHMII-13), organized under the auspices of the Society for Civil Structural Health Monitoring (SCSHM, formerly ISHMII). This conference served as a dynamic forum for scientists, engineers, industry leaders, researchers, public sector experts, infrastructure owners, and representatives of technical associations from around the world to engage in meaningful exchange and collaboration.

Hosted by Graz University of Technology in Austria, the five-day event brought together a vibrant international community to share recent advances in the field of structural health monitoring (SHM). More than 200 contributions were presented across over 30 sessions, highlighting cutting-edge developments in smart sensing technologies, sensor networks, data processing and management, diagnostics and prognostics, and life-cycle performance evaluation. The scope of discussions spanned a wide range of civil infrastructure, including bridges, dams, tunnels, retaining walls, road and rail networks, high-rise buildings, and more.

These proceedings contain the extended abstracts and full papers presented at the conference. We sincerely thank all authors for their valuable contributions and the scientific committee for their commitment to a thorough and thoughtful double-review process.

We also extend our heartfelt gratitude to everyone who contributed to the successful organization of SHMII-13. This includes the local organizing team, student volunteers, technical staff, supporting institutions, and sponsors, whose dedication, professionalism, and hard work were essential to making this event a success. Their behind-the-scenes efforts ensured a smooth and enriching experience for all participants.

We hope these proceedings will serve as a lasting resource and inspiration for future research, innovation, and international collaboration in the field of SHM.

With kind regards,

Werner Lienhart & Markus Krüger

Chairs of the SHMII-13 Conference

# Table of Contents

<b>Keynotes</b>	<b>1</b>
Digitalizing Infrastructure: Advancing Structural Health Monitoring for Smarter Asset Management	2
SHM for bridges – the work flow	3
Bridge in service structural monitoring: the SCSHM benchmark	4
Distributed fiber optic sensing in civil structural health monitoring at the next level – Realization of a comprehensive sensing network along the Brenner Base Tunnel	5
Distributed fiber optic sensing in civil structural health monitoring at the next level – Realization of a comprehensive sensing network along the Brenner Base Tunnel	6
Stevenson Creek Experimental Dam Monitoring Centenary: Overview and Perspectives of Strain Sensing and Strain-Based Monitoring of Civil Structures	10
The Power of Optical and SAR Imaging for Remote Monitoring of Land and Infrastructure	11
<b>Session 1: Field Applications of SHM to extend the Lifespan of Railway Bridges</b>	<b>12</b>
Monitoring of fatigue crack propagation by means of distributed fiber optic sensing	13
Updating prediction of fatigue reliability index of railway bridges using structural monitoring data and updated load histories	23
Monitoring of wind induced vibration on a tied-arch railway bridge	31
Acoustic emission monitoring of fatigue cracks for railway steel bridge inspection	36
<b>Session 2: Geophysical Monitoring of Infrastructure</b>	<b>42</b>
Rail track subsurface imaging from train vibrations recorded at dark fiber networks	43
Monitoring of Concrete Infrastructure with Active Ultrasound Coda Wave Interferometry	45
Finite element mesh construction for seismic analysis using drone imagery	52
A review of methods and challenges for monitoring of differential settlement in railway transition zones	57
<b>Session 3: SHM in the frame of a Digital Twin in Civil Engineering</b>	<b>67</b>
Advanced Structural Health Monitoring and Predictive Maintenance of the Parchi Viaduct Using Distributed Fiber Optic Sensors and Digital Twin Technology	68
A digital twin based integrated sustainability and quality assurance concept for subway constructions	78
Evolving reliability-based condition indicators for structural health monitoring into a digital twin of a cable-stayed bridge	80
<b>Session 4: Structural Health Monitoring of Intelligent Civil Infrastructure using Fibre Optic Sensing</b>	<b>91</b>
Advancements in Distributed Fiber-Optic Sensing: Comparing Brillouin and Rayleigh Technologies for Geotechnical and Structural Monitoring	92
Hybrid monitoring systems: synergising distributed fibre optic sensing with spot measurements	99
Water distribution pipeline anomaly detection using distributed acoustic sensing (DAS)	108
Integrating Distributed Acoustic Sensing for Damage Detection in Old Pre-Stressed Concrete Girders: Preliminary Experimental Results	118
Structural performance monitoring for concrete girder bridges with distributed fiber optic sensors	124
AI-Driven Smart-Liner System with DFOS for Digital Twin-Based Real-Time Monitoring of Oil and Gas Infrastructure	132
Middle range, rapid strain sensing based on PNC-OFDR and its application to bridge monitoring	140

Advanced Structural Monitoring and Predictive Maintenance for Railway Bridges Using Distributed Fiber-Optic Sensors	144
Structural health monitoring in underground mining using fiber-optic sensing and 3D laser scanning for digital twin development	151
Fibradike sensor: validation through full-scale field testing	160
Identification and quantification of concrete cracks using various distributed fiber optic sensing techniques	167
DFOS-Based Monitoring of Prestressed Concrete Bridge Girders	170
Proposed approach for direct rail state monitoring with distributed acoustic sensing DAS	178
Monitoring Timber Structures with Fiber Optic Sensors: State of the Art and Application to a Timber Beam	188
Pi-bracket fatigue sensor for crack detection monitoring near stiffeners in bridge girders	194
<b>Session 5: Implementing Structural Monitoring in Daily Practice: Challenges and Solutions</b>	<b>202</b>
Monitoring of civil engineering structures - current and future use cases	203
A Structural Health Monitoring Framework For Intelligent and Sustainable Infrastructure: A Conceptual Perspective	209
Best Practices for Data Acquisition System Design: Practical Wisdom for Engineers and Practitioners	217
From Insight to Action: Deploying SHM for a suspension bridge	223
Use of Monitoring for Highway Bridges on Federal Highways in Germany – Current Status and Future Development	230
Study on the suitable sensor locations for tilt monitoring of power transmission tower	237
On potentials and challenges of physics-informed structural health monitoring for civil engineering structures	245
Retrofitting load measurement devices on existing anchored structures	252
Reliability Assessment of Structural Health Monitoring Systems using Model – Assisted Probability of Detection and Bayesian Model Updating	259
Advanced Monitoring Systems for Infrastructures: Integrating 6D Sensors and Low-Cost High-Precision GNSS	267
<b>Session 6: Engineering Applications of Artificial Intelligence for SHM</b>	<b>276</b>
Structural damage detection, localization, and quantification for high-rise buildings under earthquake excitations based on machine learning and sub-structuring approach	277
Machine Learning-Based Data Interpretation and Visualization for Tunnel Monitoring: A Case Study of Changshui Airport Tunnel	284
Developing physics-informed neural networks for structural parameters identification of beam with moving loads	295
Structural Health Monitoring of a suspended steel infrastructure: A statistical approach	304
Is it possible that AI can help us detect all damage in structural assets? A discussion on the scope of applicability of DL methods for diagnosis of the construction asset's technical condition	311
<b>Session 7: Computer Vision-based SHM</b>	<b>314</b>
Perspectives on vision-based bridge vibrational monitoring by drones	315
Universal unsupervised image segmentation model of multi-type component and damage for vision-based autonomous UAV inspection of bridges	322
Large-Scale Structural Anomaly Detection During Seismic Events Using Optical Flow and Transfer Learning from Video Data	329
Development of a Wireless Stereo Vision System for 3D Displacement Online Long-Term Monitoring of Tall Structures	332
Overview and Challenges of Computer Vision-Based Visual Inspection for the Assessment of Bridge Defects	336
Integrating Mixed Reality Technology, Deep Learning and Domain Knowledge for bridge inspection	345
3D projection of AI-derived concrete cracks on a Hydro Dam outlet tower	355

Computer vision-based recognition of random traffic flow for live load performance analysis of existing bridges	357
A novel approach to bridge repair using photogrammetry and additive manufacturing	359
Machine Vision-Based Super-Resolution Reconstruction for High-Precision Displacement Monitoring of Hydraulic Structures	363

## **Session 8: Advanced Geospatial and Engineering Surveying Solutions for Infrastructure Health Monitoring** **373**

Monitoring Slow and Dynamic Deformations of High-Rise Buildings Using Low-Cost GNSS Receivers	374
Potential of profile laser scanning (PLS) for the application in load tests	383
Advanced Infrastructure Health Monitoring with Multi-Sensor Systems and Geospatial Technologies	391
LiDAR for vibration monitoring of infrastructure: stretching limits by spatio-temporal time domain frequency analysis	399
Application of LiDAR technology in geodetic monitoring of reclaimed landfills	403

## **Session 9: International SHM Standards and Guidelines** **410**

Global Perspectives on Structural Monitoring in Civil Engineering	411
Structural health monitoring guidelines for road bridges in Germany	420
Structural Health Monitoring in the Italian Guidelines for Bridges	428
ANYTWIN - Characterization and standardization of monitoring data	431
Inspection as a basis for structural health monitoring	441

## **Session 10: Advanced Filtering in Structural Dynamics** **449**

Dynamic Monitoring using Hidden Markov Regression Model for Predicting Remaining Useful Life	450
Identification of Damping Coefficients of Multi-degree of Freedom System	457
Integrated Motion Measurement – a Tool for Structural Health Monitoring?	463
Solving structural dynamics with uncertainty quantification via evidential neural operators	473
Nonparametric identification of structural nonlinear behavior based on extended Kalman particle filter and Chebyshev polynomial model	479

## **Session 11: Fibre Optic Sensing in Field Applications** **487**

Insights into Rail Track Buckling from Distributed Fibre Optic Sensing Data	488
Distributed Acoustic Sensing for Civil and Geotechnical Infrastructure Monitoring Applications	496
DFOS solutions covering full monitoring needs of an enlarged concrete deck viaduct	501
Experimental study on two tunnel micro-leakage monitoring methods based on distributed fiber optic sensing technology	508

## **Session 12: Point Cloud Data Applications to evaluate Structural Conditions and Performances** **514**

A PC based FE model as an innovative learning tool in structural mechanics	515
RTK-Enabled UAV for Structural Health Monitoring Without GCPs	518
Advanced and Efficient Monorail Facility Inspections Using Optical Measurement Technologies, Including Laser and Imaging	520
Application Method of SfM/MVS Technique Combined with Point Cloud Data for Inspection of Steel Bridges	529
Re-meshing Method for Finite Element Model Updating based on Extracting Structural Anomalous Information from Point Cloud Data	538
Synthetic environment for close-range photogrammetry-based surface friction assessment of road infrastructures	540
Developing a Deep Learning-Based Method to Segment Bridge Members by using 2D Cross Sectional Point Clouds	550
A 3D Virtual Assembly Method for Cable-Stayed Bridge Closure Using Laser Scanning	558

Short- and long-term monitoring of bridges using terrestrial laser scanning data	562
--	-----

### **Session 13: Non-destructive Test Methods used for Inspection and Damage Assessment of Concrete Structures** **568**

External Magnetization based Elasto-Magnetic Sensing Technique for Tension Monitoring of Aged PSC Structures	569
Development of SFCW Radar System for Concrete Structure Inspection	571
A Novel System Identification-Based Method for Rebar Radius Estimation in Radar SAR-Based Non-Destructive Testing	577
Non-contact non-destructive monitoring of concrete structures using pulsed Laser and microphones	581

### **Session 14: Smart Sensing and Artificial Intelligence for Advanced Civil Infrastructure Monitoring and Management** **588**

AI-Powered vehicle classification for scalable infrastructure monitoring	589
Structural condition monitoring through information transferring with dimensional expansion	595
Unsupervised Anomaly Detection for Structural Health Monitoring: A Vibration-Based Approach Using Isolation Forest	597
Deep generative models to mitigate data scarcity in bridge structural health monitoring	604
Smart adaptive triggering strategy for edge intelligence enabled energy-efficient sensing	609

### **Session 15: Fibre Optic Sensing for Damage Detection at Bridge Structures** **617**

Post-tensioned wire breaks detection method using distributed acoustic sensing in bridges & viaducts	618
Detection of steel fractures in existing prestressed bridges with DFOS	628
Distributed fiber optic sensing of bridges with stress corrosion cracking	631
Lifetime elongation of existing prestressed bridges with a lack of structural integrity using DFOS	641
Concrete signature in long-term Distributed Fiber Optic Strain Sensing: Challenges and opportunities for Structural Health Monitoring	644

### **Session 16: Smart Integrated Sensors and Wireless Sensors (IoT)** **651**

Integrated Sensor Technology for Basalt-Reinforced Segmental Lining Elements	652
Wind Input and Acceleration & Displacement Outputs Monitoring System for High-Guyed Masts in ROSEHIPS Project	661
Wireless Multisensor Monitoring of Engineering Structures	664
Practical approach to calibrating wireless sensors for use in structural health monitoring in an outdoor environment	672
eNodes: GNSS Time-Synchronised Wireless Acceleration Measurement Nodes capable of operating indoors	682

### **Session 17: Smart Sensing Enhanced Resilient Civil Infrastructures** **685**

Study on the Propagation Law of Magnetic Induction Signals for Wireless Communication in Underground Structures	686
Smart Pavement Subsurface Monitoring with Distributed Embedded Passive RF Sensor Network	690
A Wireless Passive RFID Patch Antenna Strain Sensor	693
25-year Field Monitoring of the Tsing Ma Suspension Bridge in Hong Kong	697

### **Session 18: FBG and DFOS Applications for Infrastructure and Environmental Monitoring** **699**

Towards Accurate Road Health Monitoring: A Damage Detection System Using FBG Sensors	700
Etched fiber bragg grating sensor-based groundwater salinity monitoring for seawater intrusion	709
Geo-hazard DFOS Monitoring and its Applications	713
Structural Behaviors of Prestressed Double-T Slab under Loadings with Seasonal Effects	718
Vibration Analysis of Ship Hulls using Fiber Bragg Grating	722

<b>Session 19: Risk Assessment and Monitoring of Civil Structures</b>	<b>729</b>
Structural monitoring of Zeeland Bridge - improved structural identification by combining a modular model updating framework with a mobile measurement setup during load tests	730
Scotiabank Saddledome Roof Monitoring Program	737
Long-term monitoring and data processing of a continuous prestressed concrete bridge	745
Smart Structural Health Monitoring with Acoustic Emission	755
The Collapse of the Carola Bridge – Forensic Engineering and Palliative Monitoring	762
<b>Session 20: Wind-Loaded Structures and Monitoring under Environmental Conditions</b>	<b>768</b>
Understanding the Dynamic Behavior of Large Sign Structures Under Wind Loading	769
6-Component Operational Modal Analysis of wind turbines for damage detection	772
Estimation of Wind Turbine Foundation Settlement and Error Modeling Using High-Resolution Dual-Orbit Satellite Data	776
Distributed fibre optic sensing of decommissioned wind turbine blades under bending	786
Prediction of urban wind speed during tropical cyclones using a novel deep learning-based spatiotemporal model	792
<b>Session 21: Intelligent Sensing and Safety Assessment of Bridge Cluster Service Performance</b>	<b>799</b>
Graph network representation and intelligent evaluation for service performance of bridge clusters	800
Lightweight vision fundamental model-based structural surface crack segmentation using model distillation	803
Spatial-Temporal Graph Model for Environmental Temperature and Traffic Flow Prediction of City Regions	811
Ultimate flexural strength analysis of serving concrete main girders considering bridge deck pavement	817
<b>Session 22: Structural Health Monitoring of Transport Infrastructures using Drive-by Monitoring</b>	<b>822</b>
Data-Driven Monitoring Solutions for Concrete Structures: Long-Term Insights with CorroDec2G Sensors	823
Numerical dataset for benchmarking of drive-by bridge monitoring methods	831
Indirect footbridge damage classification using explainable deep learning: A field-testing study	834
Drive-by bridge modal identification under multi-source excitations	839
Field test on tunnel indirect damage identification from moving train response	842
<b>Session 23: Population Based Structural Health Monitoring (PBSHM)</b>	<b>848</b>
A methodology for data collection and aggregation in population-based structural health monitoring ecosystems	849
Towards a plug and play population-based structural health monitoring aggregation pipeline design for resource constrained systems	856
Advancing PEAR: Development of a Bridge Benchmark Datasets for PBSHM Research	864
A Transfer Learning approach for damage identification in operational viaducts	873
The future of conservation: Citizen Science models for the Photomonitoring of cultural heritage	882
Correlation of natural frequencies of bridges that are under similar environmental conditions	891
A Novel AI-Wavelet Based Framework for Benchmark Data Analysis in Structural Health Monitoring	898
<b>Session 24: Advancements in Vibration-Based Bridge Health Monitoring</b>	<b>905</b>
Preliminary results from a field application of dynamic monitoring on three spans of a railway bridge	906
A damage screening method of the concrete slab focusing on correlation of mode shapes	914
Feasibility of micro-motion from SAR imagery for vibration-based SHM	920
Setting an optimal threshold for novelty detection in data-driven Structural Health Monitoring	928
A Comprehensive Approach for Vision-Based Dynamic Monitoring of Structures and Infrastructure	936
Model Updating and Damage Detection for Bridge Integrity Management	944

On a data compression technique for acceleration signals from a railway bridge	951
--	-----

## **Session 25: Materials-Based Monitoring and Structural Health Assessment 960**

Intelligent Imaging: Transforming Concrete Health Assessment with AI	961
Monitoring of Non-Linearities in Fatigue Degradation of Metallic Materials Using Techniques beyond Stress and Strain	971
Towards structural health monitoring of clay-printed structures	979
Icelandic turf houses: A one-year monitoring overview	987
Gas permeability under varying laboratory conditions	995
Detailed material testing of adobe structures to complete a comprehensive SHM approach that includes laser scanning and ambient vibration studies	1000
Redundant Monitoring Strategies for Structural and Geohazard Assessment Using Wireless Tiltmeters and LiDAR on Linked Highway Bridges in Colombia	1008

## **Session 26: Bridge Model Calibration and Validation Using Structural Health Monitoring Data 1016**

Optimizing Bridge Recalculation: Uncertainty in SHM-Based Recalculation of Prestressed Concrete Bridges	1017
Hangar Stressing on the 6th Street Viaduct Replacement, Los Angeles, CA	1026
SHM Application in Development of New Live Load Distribution Factors for Timber Bridges	1032
Full-Scale Bridge Testing: Lessons from the Demolition of the Steinavötn Bridge	1041
Advancing high-fidelity Digital Twin Technology for Structural Health Monitoring	1049
Advancing High Fidelity Finite Element Model Updating Using Cooperative Game Theory: A Novel Framework for Structural Optimization	1057
Efficacy of decoupling techniques to extract the static strain response from the dynamic response of a bridge under a moving vehicle using low pass filter	1064
Laboratory Testing of Old Bridge Girders: Preliminary Results	1073
Investigation of the causes of the unusual gap between the bridge and abutment using long-term monitoring	1077
Monitoring the dynamic sensitivity of the Solkan footbridge to user-induced excitation	1083

## **Session 27: Monitoring applications using InSAR 1088**

InSAR as a Component of Geotechnical Monitoring During Subway Construction in Prague	1089
Utilizing PSDefoPAT™ to analyze surface deformation of embankment dams	1094
Exploring InSAR Capabilities for Bridge structural health monitoring using TerraSAR-X and Sentinel-1 Data	1101
Satellite-based InSAR for monitoring and safeguarding high-voltage power pylons amid the energy transition	1108
Remote Sensing for Stability Assessment of River Bridges: Case Study of the Red River Bridge in Winnipeg, Canada	1112
Potential of InSAR for Structural Health Monitoring of Flood Protection Systems	1120
ISABEL (Integrated SATellite and ground-based monitoring for Bridge HHealth Lifetime assessment)	1130
SGAM – Smart Geotechnical Asset Management: Enhancing predictive maintenance with data-driven insights and Earth Observation technologies	1140

## **Session 28: Smart Embedded Sensors and Non-destructive Test Methods for Quality Control 1143**

An EMI-based approach for Structural Health Monitoring of a Space Reinforced Concrete Frame Structure	1144
Tactile Pressure Sensors to analyse Anchor Wall Behaviour in mid-scale Experiments	1151
Long term monitoring of the Balladelaan bridge using Smart Aggregates	1158
Structural Health Monitoring of Composite Plate using Piezoelectric Transducer	1165

<b>Session 29: Hazard, Disaster and Damage Detection for Infrastructure</b>	<b>1168</b>
Study on Methods for Identifying and Evaluating Damage to Cross-Sea Bridges Subjected to Ship Collisions	1169
An automatic system for the rapid post-earthquake safety assessment of bridges	1176
Bridge superstructure vibrational analysis as means to detect scour in a medium span bridge	1183
2D sonar techniques for monitoring the canal bed morphology of entrances to navigation locks	1189
<b>Session 30: SHM of Tendons and Pipelines</b>	<b>1199</b>
On-Line Health Monitoring of Underground Pipelines by Source Localization of Leak Damages	1200
Effects of grout-strand interface modelling on the degradation of external grouted post-tensioning tendons	1203
Autonomous peak-picking procedure for tension force estimation in cables and external post-tensioning tendons	1210
Field monitoring and mitigation for high-mode vortex-induced vibrations of cables in cable-stayed bridges	1218
Field Application of TFC-based Electromagnetic Sensors for Monitoring Cross-sectional Loss in Tendons of Bridges	1225
<b>Session 31: System-level SHM and Emerging Technologies</b>	<b>1230</b>
Exploration of edge computing for monitoring a four-story building frame model	1231
On the use of 6C seismic station for bending-to-shear and torsional building response assessment	1239
Integration of Seismic Interferometry and System Identification Techniques for Real-Time Structural Health Monitoring: Automated Detection of Shear-Wave Velocity Changes Using Skyscraper Data for Validation	1241
Experimental assessment of GNSS-smartphone performance in monitoring dynamic motion	1247
Identification of Structural Dynamic Loads- From Physical Methods to Physics Informed Deep Learning Paradigm	1255
<b>Session 32: The SCSHM Benchmark bridge: first studies and results</b>	<b>1258</b>
Multi-purpose bridge strain data fusion for BWIM and structural monitoring	1259
Vehicle Speed estimation using convoluted reciprocity for bridge structural monitoring	1261
Physics-Informed Surrogate Modeling of the SCSHM Benchmark	1267
Vibrational analysis of the benchmark data set	1270
<b>Session 33: SHM of Tall and Historic Buildings</b>	<b>1275</b>
Study of Semi-Rigid Joints Effect on Global Stiffness of Space Steel Structure Based on Monitoring Data	1276
Sustaining vertical giants: Autonomous monitoring solutions for the construction and lifecycle of tall buildings	1282
Multi-scale digital twin for a high-rise structure combining ANN and monitoring data	1286
Assessment method for torsional performance of high-rise buildings based on period ratio	1294
<b>Session 34: Implementation and Digitalization in SHM</b>	<b>1301</b>
Digitalization of existing measurement equipment as a valid basis for monitoring and structural behaviour	1302
Increasing the value of bridge SHM data by leveraging network-level open data	1308
A comprehensive workflow for digitizing and determining condition indicators for bridge and building construction	1318
Principles and Case Study of IMSGeo: Automatic Displacement Monitoring System for Construction Sites	1326

# **Digitalizing Infrastructure:**

## **Advancing Structural Health Monitoring for Smarter Asset Management**

Sylvia Keßler<sup>1</sup>

<sup>1</sup>Helmut Schmidt University/University of the Federal Armed Forces, Hamburg, Germany  
email: sylvia.kessler@hsu-hh.de

### **ABSTRACT:**

Our transportation infrastructure faces increasing demands, driven by larger and heavier trucks that place growing stress on bridges with ever-higher frequency. At the same time, much of this infrastructure is aging, with many structures having reached or exceeded their intended service lives and operating near their capacity limits. Addressing these challenges requires innovative tools and approaches to monitor, evaluate, and maintain infrastructure assets effectively.

Structural Health Monitoring (SHM) offers a transformative solution by enabling continuous, sensor-based condition assessment. SHM systems can track changes in structural behavior, detect damages, and provide valuable data for condition evaluation and prediction. However, to fully realize the potential of SHM, the integration of sensor data into a seamless digital process chain—built on Building Information Modeling (BIM)—is essential. This linkage ensures that data is not only collected but also analyzed and utilized in a way that is directly connected to the structure's digital twin.

Within the DTEC-SHM project, we equipped two bridges with over 400 sensors to enable comprehensive monitoring. These included conventional sensors for measuring accelerations, inclinations, and temperatures, as well as weather stations for capturing environmental conditions. Additionally, innovative sensors were deployed for durability monitoring and axle load measurement through Bridge Weigh-In-Motion (B-WIM) technology. To complement the sensor network, a detailed finite element (FE) model was developed and calibrated using monitoring data and load testing results, enabling a deeper understanding of the bridges' structural behavior.

Now, we focus on advancing SHM applications by developing a predictive maintenance management system based on Key Performance Indicators (KPIs). This will allow for proactive and efficient maintenance planning. Furthermore, the digital twin of bridges will be refined and tested to enhance its integration with SHM systems. In addition, by prioritizing the preservation of infrastructure over new construction, the project promotes significantly more sustainable practices in infrastructure management.

For asset owners, SHM provides critical insights into the health of their structures, enabling informed decision-making to prioritize repairs, optimize maintenance schedules, and allocate resources efficiently. By leveraging SHM and digital twin technologies, asset owners can transition from reactive to predictive maintenance, enhance safety, and ensure the long-term sustainability of infrastructure. This keynote will explore these innovations, emphasizing what asset owners need to harness the full potential of SHM in addressing today's infrastructure challenges. In addition, the keynote provides an overview about the datasets collected through the DTEC-SHM project, which we are committed to sharing with the broader research and engineering community to foster collaboration and innovation.

## SHM for bridges – the work flow

Christian Sodeikat <sup>1</sup>

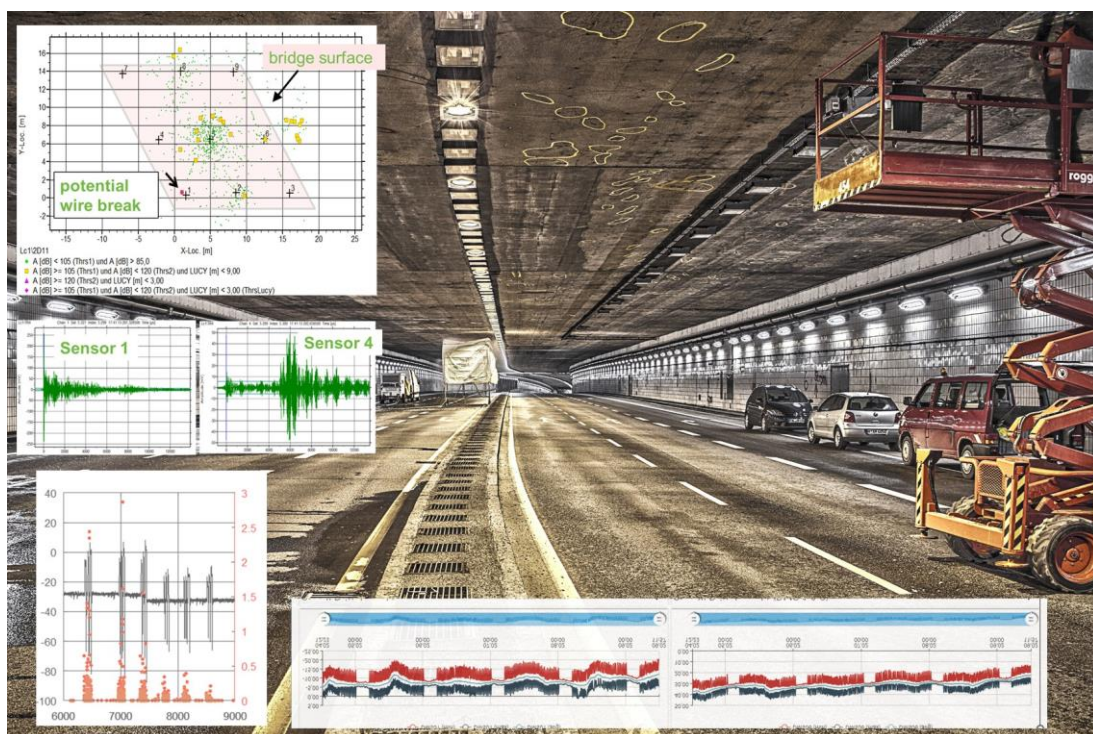

<sup>1</sup> Ingenieurbüro Schiessl Gehlen Sodeikat GmbH, Munich, Germany  
email: sodeikat@ib-schiessl.de

### ABSTRACT:

Numerous bridges in Germany and worldwide are subject to high stress from increased heavy traffic and their advanced age. Due to advanced damage and unfavourable construction methods, many bridges can no longer be repaired at a reasonable cost and must be replaced with new structures. However, to maintain traffic flow, they often need to remain in operation for years and be monitored in real-time for deterioration to ensure safe continued use. Complex measurement systems are now available for this purpose, capable of detecting various structural conditions, such as strain, or events, such as acoustic emissions from wire breaks of the prestressed reinforcement.

The planning of a monitoring system should proceed in a stage manner. The first step involves identifying the structural weaknesses and potential damage mechanisms of the structure, such as wire breaks, crack formation of the cross-section or reinforcement corrosion etc. Based on this, the structural responses resulting from the damage mechanisms are determined. In the final planning step, the measurement systems suitable for measuring the structural responses are selected.

This keynote presents the workflow for planning a monitoring system and provides examples of the implementation, visualization and evaluation of various measurement systems and measurement data in a common monitoring system.

## Bridge in service structural monitoring: the SCSHM benchmark

Maria Pina Limongelli<sup>1</sup>

<sup>1</sup> Politecnico di Milano, Italy

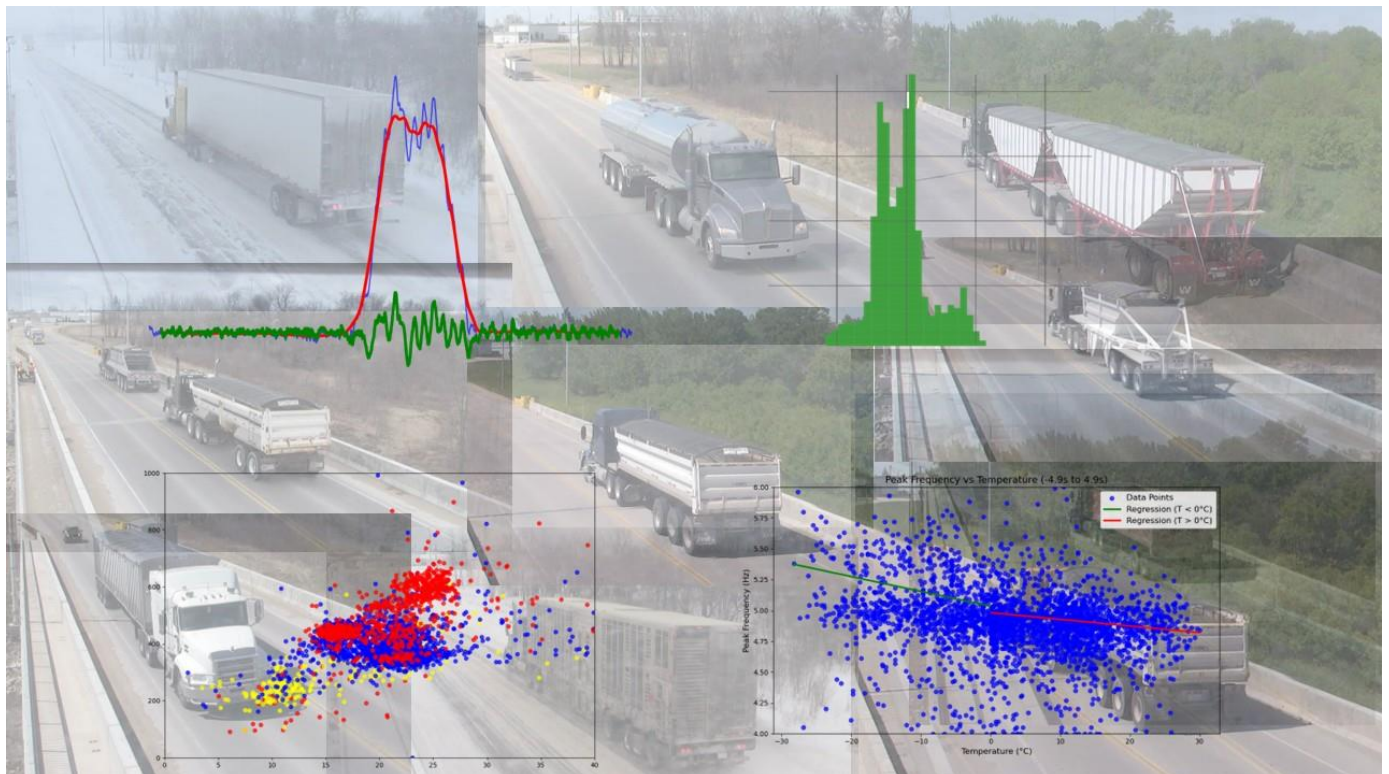

email: mariagiuseppina.limongelli@polimi.it

### ABSTRACT:

In 2023, the Data-Enhanced Infrastructures Management Committee of the Society of Civil Structural Health Monitoring (SCSHM) launched a benchmark study on in-service structural monitoring of bridges. A comprehensive dataset, developed in collaboration with the University of Manitoba, was made available to the engineering community to promote the validation and comparison of methods for structural performance evaluation.

The benchmark structure is a span of a multi-supported bridge with a total length of 291 meters. A monitoring system was installed on the structure and operated for approximately nine months. The instrumentation included strain gauges and thermocouples to record strain measurements and air/structure temperatures beneath the deck.

This presentation outlines the details of the structure, the objectives of the study, the dataset shared with the engineering community, and reports some initial applications that leverage the dataset to validate in-service monitoring approaches.

## Distributed fiber optic sensing in civil structural health monitoring at the next level – Realization of a comprehensive sensing network along the Brenner Base Tunnel

Christoph Monsberger <sup>1</sup>

<sup>1</sup>ACI Monitoring GmbH, Merangasse 73/3, 8010 Graz, Austria, Europe

### ABSTRACT:

The Brenner Base Tunnel (BBT) is one of the key civil infrastructure projects currently under construction world-wide and will be the longest underground railway connection globally with a total length of about 64 km once completed. Its service lifetime of 200 years implies essential requirements on the tunnel design, with focus on reducing risks and enabling optimized maintenance works based on appropriate monitoring. The tunnel owner BBT SE has therefore initiated an enhanced distributed fiber optic sensing (DFOS) network inside concrete tunnel lining segments for structural monitoring without human access. This contribution introduces the designed DFOS network, consisting of more than 35 km sensing cable along numerous tunnel cross-sections, spread over more than 30 km tunnel drive and two different construction lots.

**ABSTRACT:** The Brenner Base Tunnel (BBT) is one of the key infrastructure projects currently under construction and will be one of the longest underground railway connection with a total length of approximately 64 km once completed. Its service life of 200 years implies essential requirements on the tunnel design. One important focus is to increase the availability of the tunnel, e.g. by enabling optimized maintenance work based on appropriate monitoring. The tunnel owner BBT SE has therefore initiated an enhanced Distributed Fiber Optic Sensing (DFOS) network inside the segmental lining for structural health monitoring without human access. The technology has significantly evolved in recent years to monitor large scale infrastructure, especially for in-situ tunnel monitoring as the distributed sensing feature can provide a complete picture of the strain distribution without blind spots. This contribution introduces the designed DFOS network, consisting of more than 35 km sensing cable along numerous tunnel cross-sections, spread over more than 30 km tunnel drive and two different construction lots. The monitoring data is autonomously evaluated and transferred to the online dashboard in real time. Analysis of the strain distribution provides fundamental information about the actual loading state of the segmental lining. The results together with experiences gained from practical implementations demonstrate the technology's high potential for innovative civil structural health monitoring.

**KEY WORDS:** Distributed fiber optic sensing; segmental tunnel lining; structural integrity monitoring; deformation behavior; strain distribution

## 1 PROJECT CHARACTERISTICS AND MONITORING OBJECTIVES

The Brenner Base Tunnel (BBT), a flat rail link with high transport capacity, will connect the Tulfes portal (near Innsbruck, Austria) with the Franzensfeste portal (Italy) over a total length of approximately 64 km in the near future. The cross-alpine rail link is a key project of the 9,121 km long TEN-T Scan-Med (Scandinavian-Mediterranean) corridor and cuts the alpine crest in the base, with high overburdens of up to 1,720 m. It consists of two single-track railroad tunnels with a diameter of 8.1 m, spaced 70 m apart and accompanied by a continuous exploratory tunnel running 12 m below in-between (Figure 1). The exploratory tunnel improves the geological forecast for the rail tunnels, which are partially being advanced by tunnel boring machines afterwards.

Availability plays a decisive role for key infrastructures such as long cross-alpine rail tunnels. The tunnel design includes increased partial safety factors and concrete cover to reach a 200-year service life. Maintenance should be possible without interruption of the operation as far as technically feasible. Tunnel equipment has therefore been shifted to accessible areas or high-maintenance installation areas became accessible by horizontal shafts from the accompanying exploration tunnel.

In addition, the BBT-SE has incorporated an enhanced strategy for structural health monitoring (SHM) during construction and operation using Distributed Fiber Optic Sensing (DFOS). The technology is beneficial compared to conventional techniques as the fiber optic sensing cable can be directly embedded inside the structure to enable distributed strain (and temperature) assessment along hundreds of sensing points. The measurement results can be well compared to

traditionally used vibrating wire sensors [1], but also allow an overall assessment of the strain and temperature without blind spots. The sensing unit itself may be placed even kilometers away from the measurement location, even outside of the tunnel and monitoring is possible without any interference with construction works or later operation. The sensor's durability and insensitivity against electromagnetic interferences are essential with respect to the use in rail operation.

Figure 1. Schematic representation of the typical tunnel cross-sections at Brenner Base Tunnel project (based on [2])

The DFOS implementation at the BBT focusses on structural health monitoring of the segmental lining, with the aim of optimizing maintenance works by monitoring during operation [3].

Machine-driven tunnel structures within the BBT are constructed efficiently as single shells. Various monitoring approaches have been initiated during construction including chord length measurements, geodetic displacement readings of discrete targets using total stations, laser scanning and fiber optic sensors in defined cross-sections. While the first three are used for accompanying the construction process. The DFOS measurement ring is installed only at structural cross sections of interest like the intersection of rail tunnel and cross-passage as well as in fault zones. The deep-lying machine-driven tunnel and the high stiffness of the segmental lining require a load monitoring with high accuracy. The DFOS strain sensing feature is deployed to analyze the loading condition at dedicated locations inside the segmental lining. Hence, decisions can be made based on these results by choosing the appropriate pre-designed supporting measure for the openings of the cross passages. Additionally, supporting measures like secondary linings are placed according to the load bearing capacity of the existing lining.

The DFOS approach is therefore designed to pursue three primary monitoring objectives:

- 1) **Construction phase monitoring:** Verification of segmental ring openings and cross-passage advancements.
- 2) **Load-bearing assessment:** Ensuring compliance with structural safety requirements.
- 3) **Operational Structural Health Monitoring:** Enabling long-term monitoring without interrupting rail operations.

## 2 DFOS DESIGN AND MONITORING NETWORK

The instrumentation of concrete tunnel lining segments can be performed outside of the tunnel apart from excavation. This procedure is advantageous in terms of installation as the sensing cables can be reliably attached without time-consuming and cost-intensive inferences with the excavation works, which have not to be interrupted due to the sensor installation.

For more information about the implemented DFOS sensing cables for strain and temperature monitoring as well as the sensor installation inside the individual tunnel lining segments, reference is given to [4].

Inside the tunnel, the fiber optic monitoring segments are built as a normal ring without restrictions after the excavation has been performed. Once the ring is set, the connection boxes for each segment can be opened and the individual segments can be connected to establish a continuous monitoring loop. Supply cables are used to connect the fiber optic sensing cables inside the ring to the reading unit, which is placed in a measurement equipment box approx. 150 m to 200 m behind the monitoring cross-section (see Figure 2). This location is advantageous as the space along the TBM's back-up system is limited and the reading unit shall be as accessible as possible during monitoring for potential maintenance. The equipment

box itself is waterproof and does not only contain the reading unit, but also an uninterruptible power supply and an industrial PC with stable internet connection for reliable data transfer. The fiber optic installation works can be usually performed in about 90 to 120 minutes once the ring is constructed. Monitoring is started immediately after the installation, with the monitored segmental lining ring inside the shield, before the TBM continues its further excavation work.

Figure 2. Schematic representation of tunnel installation (based on [5])

The DFOS system's long-term performance and its suitability must be well considered within the network design to provide reliable monitoring over decades. Each individual monitoring cross-section is therefore not only linked to their equipment box behind the TBM, but also connected to a continuous network, which allows monitoring of numerous cross-sections using only one reading unit per tube (Figure 3, top). The so-called active monitoring zone during construction can therefore include up to 7 cross-sections in the actual configuration, excluding additional cross-sections in geological interference zones, where the reading unit is placed in the central equipment box. After the excavation works are completed, the overall system will be adapted for operational monitoring. The DFOS equipment boxes and corresponding connecting cables will be re-located to the maintenance cross-passages (cf. Figure 3, bottom), from where measurements can be performed without interruption during rail operation by accessing from the exploratory tunnel.

## 3 DFOS DESIGN AND MONITORING NETWORK

The installed fiber optic sensing network has been interrogated using the fTB 5020 from fibris Terre Systems GmbH (Germany). Based on the Brillouin Optical Frequency Domain Analysis (BOFDA) technique, this sensing unit enables distributed measurements up to 25 kilometers within several minutes per monitoring channel, a standard spatial resolution of 0.5 m and a strain repeatability of about 2–10  $\mu\text{m/m}$  depending on the sensing fiber [6]. The interrogation unit is placed inside the DFOS equipment boxes, where the raw data is collected and transferred to external databases via FTP gateway.

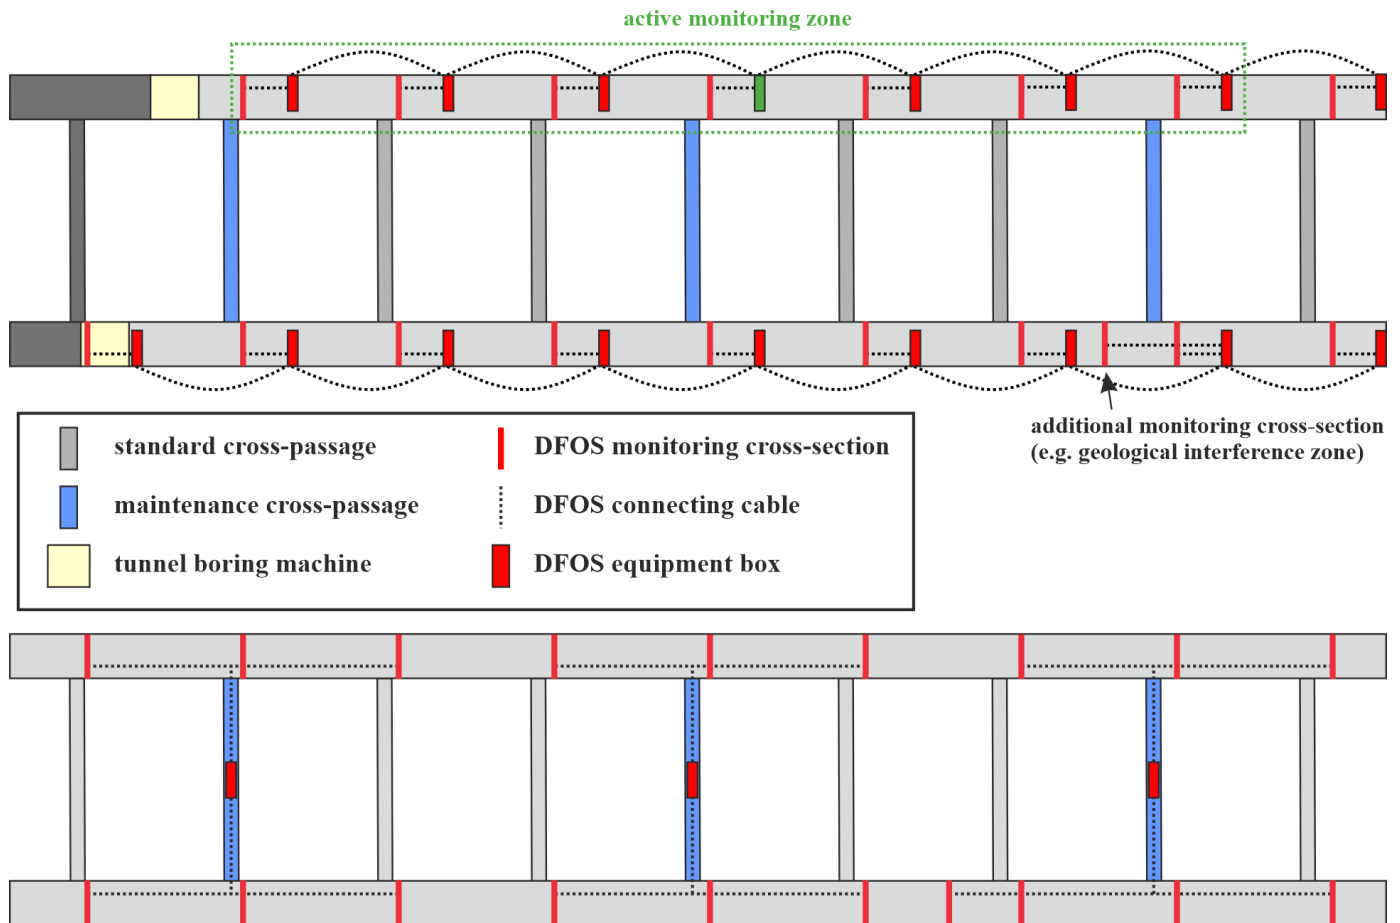

Figure 3. Schematic representation of overall monitoring setup during construction (top) and operation (bottom) [4]

The quality of the conversion from the raw measurement quantity (cf. Brillouin frequency shift) to strain (and temperature) depends on reliability of the sensor characteristics curve, usually not specified by manufacturers in detail. Using standard coefficients might however results in errors of up to several percent, cf. [7] or [8]. Therefore, each sensing cable production batch was calibrated at the unique calibration facilities at Graz University of Technology [9] to derive individual coefficients for cables installed at BBT.

Each DFOS monitoring ring delivers high-resolution strain measurements at three circumferential locations within each tunnel segment (beginning, middle and end), enabling the assessment of its circumferential total strain distribution at different locations within one monitoring ring. In addition to structural related strains, the recorded information along the individual layers includes also creepage, shrinkage and temperature-related strains. Furthermore, stress profiles are calculated from the derived strain profiles at the inner and outer layer based on the experimentally determined stress-strain behavior of the concrete [10]. This enables the integration of the circumferential normal force and bending moment distribution, which are finally compared to the internal forces of the segmental lining design to assess the rock loading conditions.

The monitoring workflow was validated by comparative DFOS measurements from loading tests of real-scale segmental

loading tests [11]. These experimental studies, performed under well-documented loading conditions, depict high correlation between calculated internal forces derived from DFOS measurements and analytical models utilizing traditional load cell data.

#### 4 CONCLUSIONS

The integration of DFOS technology at the BBT demonstrates that distributed fiber optic sensors have significantly developed within recent years and have reached the next level for civil structural health monitoring. Their capability to monitor fully distributed strain and temperature profiles with high measurement repeatability and resolution in real-time, without disrupting tunnel operation, qualify them as an ideal solution for long-term monitoring of relative deformations.

Known practical limitations can be overcome by suitable monitoring design and appropriate installation techniques, which also represent the DFOS technology path from fundamental research into innovative practice. It should be however highlighted that the quality of the monitoring approach is essentially related to its design and installation. It is therefore strongly recommended to include the monitoring design as early as possible into the project planning process, to use suitable, high-quality fiber optic components (i.e. interrogation unit and sensing cable) and to fit the sensor

installation to the construction process and reduce any interruption on-site to a minimum.

The tunnel construction lots at the BBT project were already being tendered with enhanced fiber optic monitoring solutions, aiming to provide an overall assessment of the structural behavior. This especially beneficial with respect to long-term monitoring since arising changes in the structural performance can be detected at an early stage to plan and design predictive maintenance works in due time during the operational lifetime. The DFOS system is designed to provide measurements without any interference with the regular railway operation from the maintenance cross-passages, which can be accessed from the exploratory tunnel. This fact combined with the fiber optic's insensitivity against electromagnetic interferences are essential for reliable sensing over decades.

## DISCLAIMER

This contribution is submitted as an **extended abstract** for the 13th International Conference on Structural Health Monitoring of Intelligent Infrastructure and presents an enhanced project review of the DFOS monitoring system realized at the Brenner Base Tunnel. Figures, texts and contents are therefore already partly or fully published elsewhere.

# Stevenson Creek Experimental Dam Monitoring Centenary: Overview and Perspectives of Strain Sensing and Strain-Based Monitoring of Civil Structures

Branco Glisic<sup>1</sup>

<sup>1</sup> Princeton University, Department of Civil and Environmental Engineering, USA  
email: bglisic@princeton.edu

## ABSTRACT:

The year 2025 marks the centenary of Stevenson Creek Experimental Dam tests. While the sensors were used in monitoring real civil structures under the test loading since the 19th century, these early sensors measured external changes in the structures, mostly deflections, and relied on direct human access to sensors to read the measurements. To the best of the author's knowledge, the first practical sensor to measure internal changes in civil structures with indirect remote reading capability was strain sensor, and the first such sensor was based on vibrating wire (VW) principle, invented in Germany in 1919.

The Stevenson Creek Experimental Dam Project motivated American scientists to develop, in 1924, a resistive strain sensor consisting of a stack of carbon discs. Several such sensors were embedded in the dam, and the scientists performed reading of the sensors remotely, using wired connections. This 100-year anniversary represents the moment for reflection on advancements in the development of strain sensors for applications in civil structures, and the impact that strain-based monitoring has in the field of structural health monitoring.

The aim of this presentation is to summarize the progress in strain sensing technologies over the last hundred years, overview the techniques for detection of unusual structural behaviors that various strain sensor types enabled, and present perspectives on the future developments related to strain-based monitoring.

# The Power of Optical and SAR Imaging for Remote Monitoring of Land and Infrastructure

## ABSTRACT:

The growing availability of high-resolution multi-frequency imagery from satellite, aerial, and ground-based platforms is revolutionizing the monitoring of geohazards, land deformation, and the structural health of critical infrastructure.

State-of-the-art image processing techniques—including Synthetic Aperture Radar Interferometry (InSAR), Digital Image Correlation (DIC), Speckle Tracking, Change Detection, and Structure-from-Motion (SfM) photogrammetry—enable the extraction of surface displacements and structural changes with unprecedented spatial density, precision, and temporal resolution. These fully remote and non-invasive methodologies support the systematic observation of large-scale areas, offering significant benefits for continuous and pervasive monitoring. Their integration into operational workflows enhances the ability to assess risks, improve infrastructure resilience, and inform data-driven decision-making processes in both natural and built environments.

# Field Applications of SHM to extend the Lifespan of Railway Bridges

# Monitoring of fatigue crack propagation by means of distributed fiber optic sensing

**ABSTRACT:** Distributed Fiber Optic Sensing (DFOS) is an innovative technique for Structural Health Monitoring (SHM). Taking advantage of the fact that DFOS can conveniently measure mechanical strain continuously along an optical fiber, it is increasingly used in monitoring of concrete bridges and tunnels. However, DFOS still needs research in new application areas, such as monitoring of steel bridges. In the present study, DFOS is used to investigate the potential to monitor fatigue crack initiation and propagation by experiments. In a full-scale test, a steel railway bridge was dynamically excited into resonance, generating fatigue-effective vibration amplitudes. The fiber was glued to the flange of the main beam in several loops to cover a larger area for crack detection. The measured strain signal was compared with results obtained from Finite Element Method (FEM) simulations supported by data acquired from conventional strain gauges and extensometers. The strain measurement with DFOS showed excellent agreement with the simulated strain. In this context, additional information about crack initiation, propagation, opening and length can be obtained indirectly from the DFOS measurement. However, when the crack is crossing the fiber, nonlinear effects come into play. To consider the nonlinear effects, a hysteresis model taking steel-fiber interaction into account was applied. The results of the study are presented and the applicability and potential of DFOS for fatigue crack monitoring in railway bridges is discussed.

**KEYWORDS:** Distributed Fiber Optic Sensing; Structural Health Monitoring; Crack propagation; Steel railway bridge; Finite Element Method; Dynamic excitation.

## 1 INTRODUCTION

Structural health monitoring of fatigue cracks in steel bridges aims to detect and evaluate cracks as early as possible before they can cause serious consequences. The current well-established method for detecting and monitoring fatigue cracks is visual inspection, which does not necessarily imply crack detection due to its inherent limitations [1]. Conventional extensometers, vibrating wire sensors, or strain gauges are well suited for monitoring only a small area of a component. This is suitable for monitoring of known cracks, but not for detecting new cracks [2].

To overcome the drawbacks of these methods, various sensors and monitoring techniques have been proposed. For example, a soft elastomeric capacitor that monitors a particular area of interest [3], coating sensors that use the change in potential difference [4], or the strain-based method employs fiber optic sensors [5].

When it comes to crack monitoring along bridges, the ability to simultaneously measure strain along a fiber, is the main advantage of the DFOS technique over other sensors that utilize different measurement principles [2].

The measurement principle of distributed fiber optic sensing is based on the backscattering of light sent through an optical fiber. Changes in temperature and mechanical strain lead to changes in the characteristics of the backscattered light, which are evaluated by reflectometer [1], [2], [6]. Rayleigh, Raman, and Brillouin scattering are commonly studied and mentioned in the scientific literature as types of scattering, where Rayleigh type achieves much higher spatial resolution and it is preferred for crack monitoring and micro-damage detection [1].

Spatial resolution is one of the most important factors in DFOS measurement. It can be thought of as the fiber being divided into small virtual gauges. The distance between the two closest gauges is also known as the “gauge pitch” (the term “gauge pitch” is used interchangeably in the literature). In this study, the finest available spatial resolution of 0.65 mm can be used with up to 20 m long fibers [7]. The spatial resolution decreases with increasing fiber length or sampling frequency. Small gauge pitches should be preferred in regions with large strain gradients, such as around cracks [1]. However, if the strains or strain gradients are too high and exceed the technical capabilities of the interrogator, the measurement software will replace unreliable values with not a number (NaN) value, also known as dropouts. Dropouts can also occur in the area of small bending radius, poor terminations, at the fiber splices, or due to high frequency effects during vibration [1].

The DFOS technique has found application in broad range of industries. One example can be taken from the structural health monitoring of a prestressed concrete highway bridge in Austria [8]. The authors took advantage of this DFOS technique to monitor mechanical strains and temperatures of approximately 2×30 m long bridge sections during the construction process. Within the observed time period, several cracks resulting from concrete shrinkage were detected. DFOS also allowed to observe the cracks closing while prestressing.

To the best knowledge of the authors, it is identified that the investigation of the crack propagation in a steel bridge under cyclic loading by means of DFOS remains unexplored. The present contribution wants to explore this possible new application and wishes to close this knowledge gap.

## 2 MATERIALS AND METHOS

The bridge investigated in this study was a steel railroad bridge built in 1953 and decommissioned in 2022. The single-span girder bridge with a length of 21.5 m and a width of about 2.2 m (after cutting the sidewalks) was transported as a whole, with crossties and rails, to the test site of the Austrian Federal Railways (ÖBB) in St. Pölten, see Figure 1, where it was subjected to an experimental campaign.

Figure 1: Pinkabach Bridge without sidewalks at the ÖBB test site.

### 2.1 Loading and investigated areas of the Pinkabach Bridge

Six concrete blocks, each weighing 11 tons, were placed on top of the rails to ensure that the minimum and maximum peaks of the imposed harmonic loading were always in tension. Harmonic excitation near to the bridge's natural frequency was applied using a large hydraulic exciter, the Mobile Seismic Simulator (MoSeS), provided by Austrian Institute of Technology (AIT). The amplitude of the imposed harmonic loading was intended to be on the same level as the maximum amplitude of a passing train.

Two critical areas (details) of the bridge were considered in this investigation. These were located on the lower right and left flanges near the transverse plane of symmetry of the bridge, see Figure 2. The right and left locations of interest are further referred to as Q3R and Q3L, respectively.

In order to initiate a fatigue crack at these locations, a notch was made on each side by an angle cutter near the gusset plates of the girders, which were used to attach the transverse and diagonal struts inside the bridge. At the Q3R location, the notch was 150 mm away from the symmetry plane; at the Q3L location, the notch was 360 mm from the transverse symmetry plane. Both notches were about 30 mm long and 3 mm wide.

### 2.2 Conventional measurement techniques

The experimental methods relevant to this study consisted of conventional strain gauge and extensometer measurements, positioned as shown in Figure 3. The latter allowed the measurement of crack openings, while the strain gauges provided information on the strain response of the structure due to the harmonic excitation. The strain oscillations were recalculated to stresses and the cyclic stress levels were evaluated using the rainflow counting algorithm. These results served as: i) an input for fracture mechanics calculations and ii) comparative values for the innovative DFOS application.

The strain gauges for ferritic steel 1-LY41-6/120 (HBK GmbH, Germany) were attached to the underside of the flanges directly below their webs, 800 mm from the transverse plane of symmetry, see DMS positions in Figure 2. Two extensometers K-WA-U020W (HBK GmbH, Germany) were installed at the tips of the notches on the left and right sides of the bridge. It should be noted that the mounting points of the extensometers were 40 mm away from the notch tip (80 mm from each mounting point), as indicated by the two crosses in Figure 3.

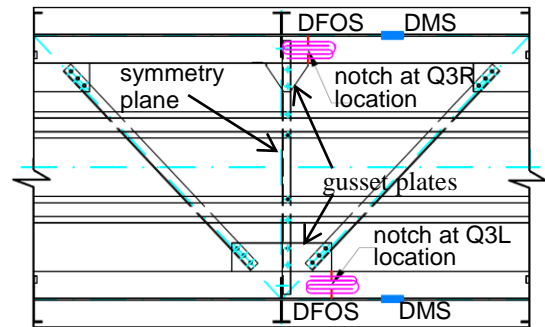

Figure 2: Top view of the central area of the Pinkabach Bridge plan showing the arrangement of the strain gauges, DMS (marked by blue rectangles), and DFOS fibers (pink loops) near the gusset plates.

Figure 3: Detailed scheme of the conventional measurement instruments installed near the center of the girder. Source: TU Graz, Hottinger Brüel & Kjaer GmbH.

### 2.3 DFOS measurement technique

Two polyimide optic fibers (Polytec GmbH, Germany) were glued (Loctite EA 3430, Henkel AG, Germany) at the Q3R and Q3L locations in front of the cut notches where crack initiation and propagation were expected. The fibers were laid in multiple loops on the underlying flange and are referred to as fiber sections 1 to 5, numbered ascending from the flange edge. Due to the minimum allowable bend radius of the fiber, the order of the acquired signal by ODISI 6000 interrogator (Luna Innovations Inc., USA), differs from the section numbering and corresponds to the winding of the loops that as illustrated in Figure 4. An example of the received signal from the five sections and their numbering is shown in Figure 5.

### 2.4 Linear FEM modeling of the DFOS measurements

The arrangement of the notched flange with a crack and an optical fiber was represented as a finite element method (FEM) model. The Ansys Mechanical Solver (Ansys Inc., USA) was used together with APDL coding to perform linear elastic calculations. In order to facilitate the manipulation and parameterization of the model and to speed up the calculations, a 2D FEM model was used to carry out the main numerical

simulations. Since the Q3R and Q3L locations are at very similar positions with respect to the length of the bridge, the 2D FEM model with the same geometry was used for both Q3R and Q3L locations.

Figure 4: Schematic representation of the half-flange with the fiber winding layout in relation to the fiber section numbering.

The dash-dotted and the continuous lines represent the web and the edge of the flange, respectively. The arrows indicate the uniaxial tensile stress state.

One of the most important parameters investigated in this study is the crack width, also referred to as the crack opening. Because the crack opens in the longitudinal direction of the flange ( $y$ -direction as shown in Figure 4), the contribution of the web to the girder stiffness was investigated as it is expected to have the most influence affecting the results of the 2D FEM model. In this context, the crack openings of the 2D model were compared with the 3D FEM model of the main longitudinal girder of the Pinkabach Bridge. The motivation was to investigate the effect of the absence of the web and the upper (compressed) flange on the stiffness of the 2D FEM model. This is described in more detail in Section 2.7.

### 2.5 Linear 2D FEM model of cracked flange and DFOS optical fibers

The geometry of the flange was modeled as a rectangle 400 mm wide, corresponding to the width of the flange, and 600 mm long, which is long enough to have a uniform stress state at its ends. The shape of the notch does not affect the calculated crack widths. Therefore, it was not accounted for in the present study and only the material discontinuity was considered, i.e., the nodes on the axis of symmetry located at the position of the crack were allowed to move freely. The fibers were modeled as beams with a thickness of 0.5642 mm at each position, taken from [2].

The flange mesh was generated with 8-node quadrilateral PLANE183 elements using plane stresses with a thickness

option [9] corresponding to the flange thickness. A mapped mesh with an element size of 5 mm and 1 mm in the longitudinal and transverse directions, respectively, was applied to the flange. The optical fibers were meshed using a three-node BEAM189 element with quadratic shape functions [9]. The length of the beam elements was 5 mm, and the position of the nodes coincided with the nodes of the flange. COMBIN14 elements [9] were used as spring elements connecting the coincident nodes of the flange and optical fibers and representing the glue between these two components. The COMBIN14 elements were used for nodes that were more than 5 mm away from the axis of symmetry.

The boundary conditions for the optical fibers were as follows: the nodes of the fibers lying on the axis of symmetry were constrained in their longitudinal displacement as well as in their total rotation. On the other side of the flange, the last nodes of the beam elements were coupled in all directions to their corresponding elements of the flange. The nodes of the flange that were on the axis of symmetry were constrained in the longitudinal direction, where there was also a fixed material on the other side. There was no constraint for the nodes in the cracked area, i.e. the crack length is controlled by the constraining the displacements of the nodes in the  $y$ -direction. One node on the symmetry axis, located in the center of the flange, was also constrained in transverse direction. The tensile load was applied in the form of pressure on the shorter edge opposite to the axis of symmetry. The geometry, mesh and boundary conditions are shown in Figure 6.

The material properties of the components were linear elastic. For the steel flange, standard elastic properties were used with a modulus of elasticity of 210 GPa and a Poisson's ratio of 0.3. The glass fiber was assigned a modulus of elasticity of 30 MPa and a Poisson's ratio of 0.3 [2]. The elastic modulus of the glue was initially unknown and it was subject of the investigation. After the investigation, a modulus of elasticity of 900 kPa was assumed.

### 2.6 Linear 3D FEM model of the main girder

The 3D FEM model simulates a crack in the flange of one of the main girders of the Pinkabach Bridge. The girder length, web height, web thickness, flange thickness, flange width of the girder amount to 21500 mm, 1875 mm, 14 mm, 30 mm, 400 mm, respectively.

Figure 5: An example of the acquired strain signal along the fiber at a specific time instance. The plateaus of the received signal correspond to the straight fiber sections shown in Figure 4.

Figure 6: The 2D FEM model of the cracked flange. The dashed line corresponds to the transverse axis of symmetry; the blue rectangles represent finite elements; the red rectangles mark the area of higher web stiffness; the yellow vertical lines mark the optical fibers. The blue rectangles on the symmetry axis indicate the boundary condition for the displacement. The orange rectangles applied to each fiber ending on the axis of symmetry are rotational constraints, while the green triangles correspond to coupled nodes between the fiber and the flange. Red arrows indicate the direction of the applied stress.

The flanges as well as the web were meshed by SHELL281 elements with quadratic base functions [9]. Around the notch, the mesh was finer than in the rest of the girder and its properties are the same in terms of element type and element size. Outside of the fine area, a coarse mesh was used. As for the web, elements with a length of 697 mm and a width of 127 mm were used. For the coarse part of the flange, the elements were 697 mm long and 200 mm wide. Mapped mesh with quadrilaterals was used on most of the girder geometry, as shown in Figure 7.

The boundary condition of the 3D FEM model was analogous to a simple supported girder, corresponding to suppression of longitudinal, and vertical displacements of the nodes at the short edge of the lower flange (with crack) on one side and the suppression of vertical displacements along the edge of the other side, see Figure 7. In addition, one node in the middle of the edge of the bottom flange at the end is constrained in transverse direction.

The loading of the numerical 3D FEM model was carried out by a single point force in the middle of the upper flange. The elastic material properties of all parts used in the 3D FEM model were the same as in the 2D model.

Figure 7: The 3D FEM model of the Pinkabach Bridge main girder with cracked flange and DFOS fibers. The displacement boundary condition, and the point load are marked by blue triangles and red arrow, respectively. The detail of the fine-mesh area with crack and DFOS fibers (yellow lines) is shown in the lower left.

## 2.7 Comparison of the linear 2D and 3D FEM models: web stiffening factor

The crack openings of the 2D FEM model were compared with those of the 3D model in order to investigate the influence of the absence of the web in the 2D model. This absence was manifested by a higher crack opening of the 2D model, indicating a lower stiffness of the 2D model. As a remedy, a strip of higher stiffness than the surrounding steel was inserted to the 2D FEM model. This strip is 14 mm wide and is located in the middle of the flange, geometrically corresponding to the footprint of the web, see the red area in Figure 6. The modulus of elasticity of the strip was expressed as a multiplication factor to the surrounding steel with a modulus of elasticity of 210 GPa. Depending on the crack length, higher elastic moduli were assigned to the strip in order to match the crack openings of the 3D and 2D models. The multiple of the higher steel elastic modulus of the strip is referred to as the web stiffening factor in this document.

The procedure for finding the web stiffening factor was as follows:

- Find the single point load of the 3D model (red arrow in Figure 7) that yields the same stress of 50 MPa in the homogeneous stress field in the vicinity of the notch (with crack length = 0) of the 2D and 3D models.
- After harmonizing the homogeneous stress fields in the vicinity of the notch and finding the point load of the 3D model, the distance between the two corner nodes at the very end of the notch was measured. This "notch opening" was compared to the 3D and 2D models.
- The strip stiffness of the 2D model (red area in Figure 6), which caused the same "notch opening" in the 2D and 3D models, was expressed as a multiple of the steel stiffness of 210 GPa. In this way, the web stiffening factor was obtained.
- The crack length behind the notch tip was increased by a certain increment, and the step iii) was repeated.

The web stiffening factors were obtained for crack lengths from 0 mm up to 160 mm by means of repeating steps iii) and iv). The increments for crack lengths from 0 mm to 140 mm were 20 mm, and for crack lengths from 140 mm to 160 mm

were 10 mm. The web stiffening factors as a function of crack length are plotted in Figure 8.

Figure 8: Web stiffening factors as a function of the crack length. Web stiffening factors are the multiples of the flange steel elastic modulus assigned to the strip in the 2D model.

### 2.8 Modeling the glue between the flange and optic fibers

The glue bonds the DFOS optical fiber with the underlying steel flange, see Figure 9 a). In the linear FEM models, this bond was modeled by linear springs characterized by their stiffness, see Figure 9 b). The springs connect coincident nodes of the flange and the fiber. The springs were active in the y-direction, the longitudinal axis of the flange. In the FEM models, the first spring was located 5 mm away from the symmetry axis. The next springs connected the flange and fibers from this point to the end of the fiber where the flange and fiber nodes were coupled, see Figure 6.

The stiffness of the glue was investigated based on experience from previous work [2] and the current DFOS measurement. Softer springs (i.e., softer glue) produced flatter strain peaks when the crack was close to the fiber. Increasing the stiffness caused the calculated strain response curve to become narrower, see Figure 9 c). The calculated strain response from the 2D model was compared to the measured DFOS signal. A glue stiffness of 900 kPa gave satisfactory agreement between the calculated and measured strain shapes and was used in further calculations.

Figure 9: Detailed sketch of a) cross-section of the bond between fiber, glue, and the flange, b) glue being represented as linear springs connected to coincident nodes (zero glue thickness). c) strain response corresponding to soft glue (dashed curve) and hard glue (orange curve).

### 2.9 Nonlinear hysteresis model for determining crack width

The linear FEM model, simulating the strain distribution from the glass fiber to the underlying object, is able to reproduce the

measured values up to the crack formation. However, as it will be shown in the result section, once the crack reaches the fiber, there is no longer sufficient agreement and the strain from the linear FEM model deviates more and more from the measured values as the crack increases in size. This is due to nonlinearities in the fiber and the glue that occur at very high strains and can no longer be represented by the linear model.

Although this phenomenon is known from earlier studies, as explained in [2], the physical background has not yet been clarified in detail. The most likely explanation is a permanent mutual displacement between fiber and base material in the glue layer (sliding), which occurs after exceeding the mutual friction, or plastic deformation of the optical fiber. A mechanical model based on this hypothesis had already been developed by the AIT research group and proved to be very effective. It allowed the strain behavior to be simulated with a high degree of accuracy under various loading and unloading scenarios and crack widths of up to 2.8 mm.

An overall model of the optical fiber structure and the glue was adopted from [2], with the parameters being slightly adjusted to the actual fiber used. This model makes it possible to calculate the interaction of these elements and also to calculate non-measurable strain signal during high-frequency excitation with large crack widths (high amplitudes) using FE methods. The hysteresis model consists of a combination of linear and nonlinear spring and beam elements. The fiber structure, including the connecting elements, is shown in Figure 10 a) and b). The glue (3) is modeled as a linear spring, while the coating (2) and the fiber (1) are defined as 1D beam elements. The crucial connection between the fiber and the coating is modeled by nonlinear springs (4). This is an elasto-plastic spring element whose force  $F$  increases linearly with the deformation  $V$  and the stiffness  $k_{int}$  up to the limit force  $F_S$ . After the limit force  $F_S$  is exceeded, slippage  $V_{SL}$  occurs as a permanent displacement of the fiber optic cable (1) relative to the coating (2), see Figure 10 c).

The model was implemented in the FE program Ansys, whereby, in contrast to the linear model, only a 20 cm long section around the crack and only one fiber at a time is considered separately. The aim of this investigation is to interpret the measurement signal and to draw conclusions about the crack width. During the interpretation, it can be determined whether the crack is currently closing or opening or whether a larger crack has occurred previously. It is not necessary to apply the nonlinear model to recalculate the crack width if a complete, continuous measurement signal is available, as the crack width can be calculated by integrating the signal over the fiber length. Since it is known that transient or permanent dropouts can occur at higher amplitudes and higher excitation frequencies, this step is important to significantly increase the accuracy of the crack width determination.

In the present case of the linear model described in Section 2.8, a fiber without a coating was used, which theoretically results in differences to the model shown in Figure 10, as the comparison with the simplified model in Figure 9 shows. However, since comparable nonlinear effects occurred in the measurement data despite the absence of the fiber coating, the model described in [2] was also applied here and showed good results.

Figure 10: Schematic drawing of a) cross section and b) side view of the nonlinear model used to estimate the crack width; c) the material model prescribed to the springs where slippage is initiated when the force  $F$  exceeds the limit force  $F_s$ .

This is also due to the fact that the model parameters were not determined individually, but were found empirically from the measurement data by model fitting as an overall model. These determined characteristic values in Table 1 thus do not represent any physical material parameters, but the overall structure including the glue. These characteristic values determined in this way are not transferable to other fiber applications, even with the same fiber, without slight adjustment.

Table 1: Input parameters for the nonlinear FE analysis.

element size	glue (spring)	coating (beam)	interaction (spring)	glass fiber (beam)
2 mm	$K = 10^6 \text{ N/m}^2$	$A = 10^{-4} \text{ m}^2$ $E = 30 \text{ MPa}$	$K = 7 \cdot 10^6 \text{ N/m}^2$ $F_s = 0.35 \text{ N/m}$	$A = 10^{-5} \text{ m}^2$ $E = 30 \text{ MPa}$

### 3 RESULTS

#### 3.1 Crack width vs. crack length under unit load

One of the main results of this study is the relationship between crack width and crack length. Since the problem is modeled with linear elasticity, it is reasonable to do this for a unit load. The calculations were carried out using the 2D model.

The crack widths were obtained for the following locations: at the notch tip ( $x = 30 \text{ mm}$ ), at the fiber locations, at the location of the crack tip, and the notch tip ( $x = 30 \text{ mm}$ ), but 40 mm above the axis of transverse symmetry of the 2D model ( $y = 40 \text{ mm}$ ). This location corresponds to the extensometer mounting points. The crack widths were determined for crack lengths from 0 mm to 160 mm with 5 mm increments. For each calculation, the appropriate web stiffening factor was taken into account. The results are shown in Figure 11. It is noteworthy, that the extensometer reading is non-zero even for zero crack length, which is caused by the elasticity of the steel between the extensometer mounting points.

#### 3.2 Comparison of crack growth and fracture mechanics

As part of the test evaluation, a fracture mechanics analysis of the fatigue tests on the Pinkabach Bridge was carried out by the scientific partner, the Institute of Steel Structures of the Technical University Graz (TU Graz), which also included the evolution of the crack length over the number of cycles for the two locations Q3L and Q3R shown in Figure 12. This fracture mechanics analysis is compared to the crack width vs. crack length relationship derived from the 2D FEM model in the previous Section 3.1, shown in Figure 11.

In order to perform this comparison, the number of cycles was determined at each measurement time instance. At this particular measurement time instance, the crack length was

determined using Figure 11 and the extensometer reading. This crack length and number of load cycles were entered into the fracture mechanics diagrams in Figure 12.

Comparison with the fracture mechanics analysis "best fit" (green curve) shows reasonable agreement, although it is not perfect. The numerical results tend to be slightly higher than the fracture mechanics results for short crack lengths. For long crack lengths, however, the numerical results are slightly lower than the fracture mechanics results. There are uncertainties in both, the fracture mechanics analysis and the numerical analysis, and it is expected that there will be differences. For example, a complete 3D model of the main girder including the gusset plates, and the influence of the bracing would allow a more accurate analysis. However, the method is considered to be adequate for estimating the crack length for practical construction purposes based on simple extensometer readings.

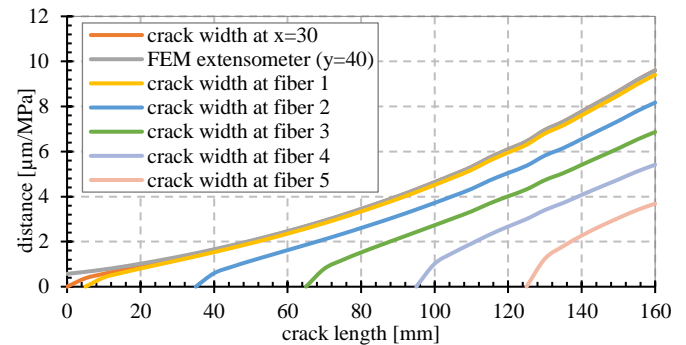

Figure 11: Crack width as a function of crack length; FEM extensometer corresponds to the displacement reading at the location of the extensometer attachment, i.e.: at the notch tip ( $x = 30 \text{ mm}$  from the flange edge) and  $y = 40 \text{ mm}$  above the axis of transverse symmetry of the 2D model.

#### 3.3 Comparison of the linear 2D FEM model with the DFOS measurement at the Q3R and Q3L locations

The strains calculated by the 2D FEM model, to which the conventional experiments provided input, are compared in side-by-side plots with the DFOS strain signal at multiple time instances throughout the experimental campaign. The results from the 2D FEM model at a time instance were obtained in 3 steps. First, the loading stress was determined as the difference between the minimum and maximum amplitude readings from respective strain gauge at the corresponding time instance, multiplied by the modulus of elasticity of 210 GPa. Second, the crack length was extracted from Figure 11 (FEM extensometer), by knowing the displacement reading of the extensometer divided by the loading stress derived from the

strain gauge reading for the corresponding time instance. Third, the applied stress and crack length were used as input for the FEM simulations.

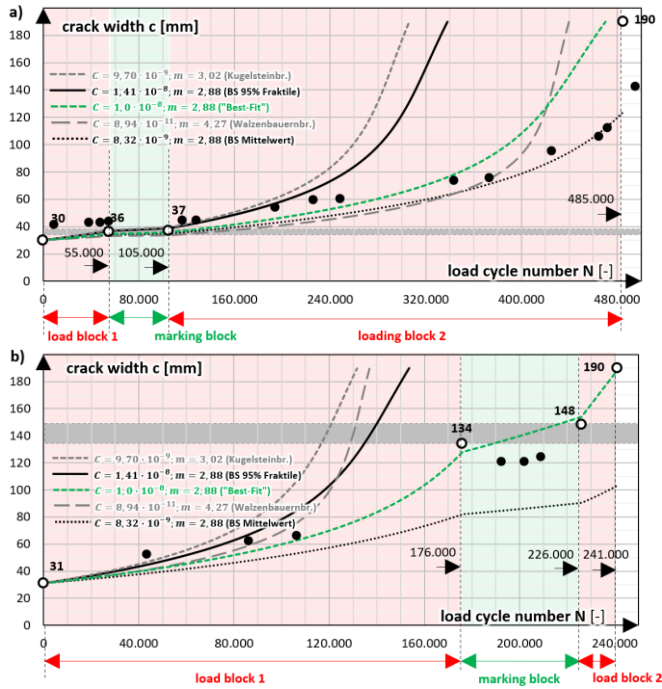

Figure 12: Fatigue calculations provided by TU Graz showing the crack length as a function of the number of load cycles for the two locations: a) Q3R and b) Q3L; the solid black circles show the results derived from the linear elastic FEM model; the monotonically rising curves correspond to different fatigue models. Credit: TU Graz.

The measured DFOS signal used for comparison with the numerical simulations was obtained by subtracting the minimum DFOS signal (red graph in Figure 13) from the consecutive maximum DFOS (green graph in Figure 13) signal for the corresponding time in order to account for the mean strain value (blue graph in Figure 13). In this way, the difference between the numerical and measured signals is “tared”, and they can be directly compared. The elevated strain values reminiscent of plateaus in this blue graph correspond to individual fiber sections. The order of the fiber sections is the same as shown in the Figure 4 and Figure 5.

An example of a typical comparison of the measured and simulated strain signals at fiber section 5 is shown in Figure 14, where the signals are almost identical. It was observed that when the fiber is far away from the crack tip, the measured and simulated signals are in good agreement.

The measured DFOS signal indicates that the cracks were already present near the fiber section 1 already on the first day of measurements at both Q3R and Q3L locations. At this time, it can be seen that the simulated and measured signal amplitudes do not match each other, see Figure 15. This suggests that a nonlinear effect is at play, which may be caused by the interaction between the optic fiber, coating, glue, and the flange due to excessive strain loading. This effect is even more pronounced as the crack propagates further behind the fiber, resulting in an “inversion” of the signal and an increasing number of dropouts, as shown in Figure 16.

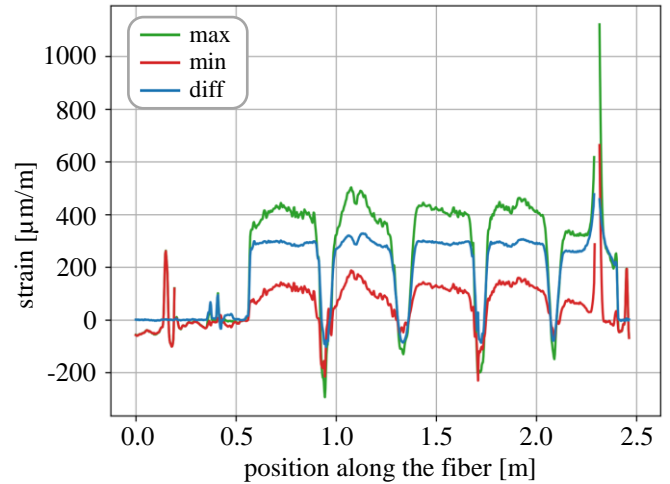

Figure 13: Subtraction of the minimum (red) and maximum (green) DFOS signal from May 9, 2023, at 10:52 to obtain the mean (blue), which was compared to the output from the numerical simulations; Q3R location.

Figure 15: The crack tip near fiber section 1 causing nonlinear effect resulting in smaller strain peaks, first day of measurement at Q3R location.

Figure 16: An “inversion” of the measured DFOS signal showing dropouts due to the wide crack opening inducing excessive strain. Third day of measurements at the Q3R location of fiber section 1.

### 3.4 Crack widths determined by the nonlinear model

The crack widths for the Q3L and Q3R locations were determined using the nonlinear FE hysteresis model. The following paragraphs describe the procedure at the Q3L location for fiber section 1. Here, two points in time were selected where the crack had already grown considerably, both on May 12, 2023, one at about 06:45 and one at about 10:30.

The best results were obtained in the earliest measurement because the crack widths were still not very large. The times of the maximum (load), minimum (unload) and constant load (resting state) of a cycle is considered in each loading case. At 06:41, the cyclic loading was stopped for a short time, which led to a brief complete reappearance of the DFOS strain signal. At this point, the permanent crack under constant load became very well measurable. The corresponding signal is shown in purple continuous line in Figure 17. The unloading curve (gray continuous line) is also clearly visible and shows only a few interruptions. It can be seen here that the measured values in the crack area are even slightly negative, while the areas where the load is applied remain virtually unchanged. This can be well modeled by means of the hysteresis model. It should be noted that as the crack width increases, so does the number of dropouts in the data. The loading curve (red) is only partially visible and must be reconstructed to determine the underlying area corresponding to the crack width. This is done by the accompanying FE analysis, which is shown in the Figure 17 as a dash-dotted line in the respective colors. Since the parameters of the FE model were optimized once for all processes, each recalculation only searches for the crack width that best matches the measurement data.

The crack widths,  $w$ , in Figure 17, indicate the crack opening at each loading phase. If  $w_{max}$  is given, it means that at an earlier point in time a larger crack caused a change in the fiber. This can be beneficial if there was no measurement at that point in time or if the signal was too disturbed to measure. In this case, the amplitudes of the crack widths are compared and validated with the results of the displacement sensors in combination with the relationship between crack length and width in Figure 11 derived from the linear 2D FEM model.

They result from the differences in crack width during loading (red) and unloading (gray) and thus correspond to the change in crack width during harmonic loading. The crack width at rest (purple) should be exactly between the two values for a symmetrical load amplitude. This also makes it possible to calculate the static crack opening without harmonic excitation. The crack opening under constant load at the fiber section 1 after crack crossing is therefore 0.205 mm and the amplitude of the crack opening under cyclic loading is 0.22 mm.

The same procedure was carried out for the later measurement at 10:28, see Figure 18, whereby the crack is considerably more developed. In this case, no DFOS strain signal could be measured in the loading phase. The strain data for unloading and constant load phases was very fragmented, but could be reconstructed by numerical simulation. The resemblance to the existing data is not as good as in the previous example, which indicates that there are more extensive nonlinearities that cannot be simulated by the model that is used. Therefore, it is expected that the evaluation of the crack widths will be less accurate in this case. Despite the absence of a loading phase, the crack width could be estimated from the difference between the unloading and the constant loading phases.

## 4 DISCUSSION

### 4.1 Influence of gage pitch on dropouts

Three gage pitches (0.65 mm, 1.3 mm, and 2.6 mm) were used during the DFOS experimental campaign in order to investigate their suitability for monitoring of crack propagation under harmonic loading. Although it is recommended to use the shortest gage pitches for regions with high strain gradients [1], in this case the signal acquired with the 0.65 mm gage pitch contained the most dropouts and noise. The larger the crack opening, the more pronounced this effect was. Therefore, it was not suitable for further processing and the two longer gage pitches were preferred for evaluation as the acquired signal

contained fewer dropouts, with 2.6 mm gage pitch having the fewest.

It is recognized that the situation can be remedied by using optical fibers with higher sensitivity. In [1], the authors monitored cracks in a concrete beam using four different optical fibers and gage pitch of 0.65 mm. The results emphasized the need for careful selection of optical fibers that are better suited for measuring high gradients, if case that the crack location and crack opening are to be reliably quantified.

— 2023-05-12 10:28,  $w = 0.33$  mm,  $w_{max} = 0.4$  mm

Figure 18: Matched strain signal of DFOS (“continuous lines”) and the nonlinear FEM model (dash-dotted line) for fiber section 1; measurement location Q3L at 10:28; unloading curves are red, constant loading in gray.

#### 4.2 Fiber layout – loop length and minimum fiber radius

In order to maintain the minimum fiber radius that can cause additional signal dropouts the optic fiber was laid in the following order of fiber section 1, 3, 5, 2, and 4. The lower the number, the closer the fiber section is to the flange edge and the notch. Although the length of the straight part of each fiber section was sufficient to capture the uniaxial stress state, it would be preferable to make these straight sections even longer, so there are no sudden signal drops as it can be seen, for example, on the right hand side of the blue line in Figure 14.

#### 4.3 Limitation of the linear FEM models

Although the handling of the 2D FEM model was significantly easier than the full-scale 3D FEM model of the main girder, significant amount of was required to correctly create the 2D FEM model. As a side effect, the contribution of the web to the stiffness of the flange in the presence of a crack was investigated. Interestingly, the web stiffening factor as a function of crack length is not monotonic. For crack lengths from 0 to 20 mm (and in the presence of the notch), the web stiffening effect slightly decreases, but from 20 mm to 150 mm, the web contributes to the overall stiffness by a factor 2.5 to 4.5, respectively.

It would be also of interest to investigate, how incorporating more construction details, e.g. constraining lateral movement of the main girder, modeling the gusset plates, or using

displacement loading, would manifest itself on the web stiffening factor as well as on the overall results. However, it is anticipated that these effects are rather small and would not significantly change the results.

#### 4.4 Validation and limitation of the nonlinear model

This study shows that the nonlinear hysteresis model is able to reproduce the measured DFOS strain signal for smaller crack widths where the interaction between the optical fiber and the flange is governed by nonlinear behavior. However, for larger crack widths, it remains subject to certain inaccuracy. The deviations increase with crack growth, indicating additional nonlinearities not represented in the model. It is therefore important to consider the expected crack widths of interest when selecting fibers. A thicker coating would smear the strain peaks around cracks over the longer part of the fiber core, resulting in lower peak values and thus preventing highly nonlinear effects from occurring.

The resulting crack widths for the two locations, the considered time instances, and the optical fibers were compiled and validated. The validation was done by comparing the crack width and crack length relationship developed from the extensometers and the linear FEM model in Figure 11 in Section 3.2. The results are summarized in Table 2 for measurement location Q3L and fiber sections 1 to 4.

For the considered time instances and the location Q3L, almost complete measured values are only available for the measurement time around 06:30. Therefore, the first validation was carried out at location Q3L for May 12, 2023, at 06:28, see third and sixth row in Table 2. The maximum deviations for this time instance are only 0.03 mm. This result is consistent with the previous findings on the accuracy of crack width measurements using DFOS in [2]. The comparison at 10:28 for the same location and measurement day shows significantly larger deviations of up to 0.09 mm.

Table 2: Comparison of the crack widths from the linear and nonlinear FEM models at Q3L location on May 12, 2023

		linear model + extensometer [mm]			
date	time (UTC)	fiber sec. 1	fiber sec. 2	fiber sec. 3	fiber sec. 4
12.05.2023	06:28	0.19	0.15	0.12	0.05
12.05.2023	10:28	0.35	0.30	0.24	0.17
		nonlinear model + DFOS [mm]			
12.05.2023	06:28	0.22	0.15	0.12	0.08
12.05.2023	10:28	0.35	0.21	0.21	0.11

#### 4.5 Practical applicability of the crack monitoring using DFOS

The DFOS measurement technique could be implemented in real-world scenarios analogous to the current study. The fiber can be placed in different shapes around critical details of new or existing bridges if the minimum bending radius requirement is met. Since the unit cost of a basic optical fiber is relatively low, two or more parallel fibers can be used to measure a quantity to increase redundancy in case of fiber damage.

If the structure is exposed to different temperatures, temperature compensation is required. In this case, it is recommended to install a fiber for temperature measurement next to the fiber for strain measurement. The temperature sensing fiber should be able to move freely so that it is not

affected by mechanical strain and can provide reliable temperature values.

One of the challenges is the risk of fiber damage during installation in the busy and harsh conditions of a construction site. To mitigate this risk, it is recommended to use a specialized company to install the fibers.

A notable practical example of the use of DFOS is on a concrete highway bridge near Aurachkirche, Austria, documented in [8]. In this pilot project, approximately 60 m of the Aurach Bridge is monitored in two 30 m long sections using 2.6 mm gage pitch. In each section, temperatures and strains were measured in the top and bottom slabs. During the observation period, several cracks were detected as a result of concrete shrinkage. The DFOS measurements also allowed to observe the crack closure due to prestressing. By integrating the area under the obtained strain signal, the crack widths were estimated, which were in line with the expectation for a prestressed concrete bridge. It was concluded that DFOS can be used to monitor important milestones in the construction process, including the development of cracks.

Another practical example is the recent installation of DFOS technology during the replacement of a railway bridge in Eschenau, Upper Austria. In this project, optical fibers will monitor temperature and strain throughout the construction process and future service life, enabling the detection of potential crack development. These examples demonstrate the growing adoption of DFOS in structural health monitoring projects and highlight the suitability of this technique for integration into routine bridge maintenance.

## 5 CONCLUSIONS

Based on the current study, the following conclusions are drawn: The FEM simulations fed with strain gauge and extensometer data can provide good qualitative and quantitative agreement with the measured DFOS strain signal. The simulated strain signal from the linear elastic FEM model agrees well with the measured DFOS strain signal in cases where linear elasticity governs the interaction between the optical fiber and the underlying steel flange. Once the crack is close enough to the fiber, the nonlinear effect comes into play and the nonlinear model must be used to reproduce the measured DFOS strain signal. In these cases, the nonlinear model can also be used to estimate the crack opening, see Section 2.9.

With increasing crack opening, the high strain in the optical fiber causes signal dropouts. This is usually the case when the crack has propagated well beyond the fiber.

The crack propagation can be clearly seen in the cyclic loading test using DFOS. First, the nonlinear effects come into play, which can be accompanied by some dropouts. Then, in the next phase, the peak of the measured strain signal changes to a trough so that it is "inverted" with respect to the previous state, see Figure 16.

The further away the fiber section is from the crack tip, the better the agreement between the measured and simulated strain signals was obtained. Typically, the best agreement between simulated and measured strain was observed for fiber section 5.

The DFOS have proven to be very good at determining steel strain up to crack initiation, crack detection, and crack widths

up to 0.2 mm. Beyond that, the measured strain signal become more incomplete and the signal reconstruction is subject to increasing inaccuracy. This is exacerbated by dynamic excitation, which disturbs the strain signal. If large crack widths are still of interest, it is advisable to use coated fibers for such measurements, which reduces the peak strains. If the information on whether and where a crack has occurred is sufficient, simple and inexpensive commercially available fibers, such as those used in the Pinkabach Bridge tests, can provide adequate information. When more precise evaluations were required, it became apparent that the fiber had to be selected precisely according to the expected crack widths. Overall, the DFOS technique was found to be suitable for crack detection and crack propagation monitoring.

## ACKNOWLEDGMENTS

The work presented here was carried out as part of the FFG COMET research project 'Railways for Future: Resilient Digital Railway Systems to enhance performance' (in short: Rail4Future) 882504, which was led by the Austrian Federal Railways ÖBB-Infrastruktur AG. The authors would also like to thank Alfred Lechner and Stefan Wittmann for their support with the measurements and the partners involved in the project for their excellent cooperation.

**ABSTRACT:** The assessment of fatigue consumption and the remaining lifetime of structural components is affected by considerable uncertainties on the side of the traffic loads, fatigue resistance and structural response. The purpose of the presented work was to develop methods for dealing with these uncertainties, as well as methods for improving the accuracy of assessment with the use of additional data.

Within the research project Assets4Rail, a structural monitoring system was installed on a railway bridge located on a local track in Austria. The system consisted of strain sensors, acceleration sensors and inclinometers. It was used to measure the bridge response during train passages with known axle loads in course of a test with controlled conditions. This data was used to calibrate the structural model and develop probabilistic methods for fatigue assessment. Influence lines at fatigue-critical locations were evaluated from measured bridge strain response including their uncertainty. Further uncertainties considered in the assessment include the load histories and the fatigue resistance.

The results showed the largest contribution by evaluation of model uncertainties from monitoring data. The effect of model updating was also considerable, but less significant. Further increase of estimation accuracy is achieved using section-specific traffic data. Whereas wayside monitoring data represent the reference scenario, the use of traffic management data provides a usable alternative.

**KEY WORDS:** fatigue; probabilistic; reliability; monitoring; updating.

## 1 INTRODUCTION

Railway bridges are often designed in steel. Their high ratio of traffic load to dead load as well as the high train axle forces makes them prone to fatigue issues. Many structures or components are reaching their planned lifetime. A survey conducted by the European project Sustainable Bridges, revealed that 75% of steel railway bridges are over 50 years old and almost 35% of them are over 100 years old [1]. Although fatigue damage is not among the leading causes of bridge collapses [2], it plays a role in maintenance of railway infrastructure. To optimize the investment planning for railway bridge maintenance and replacement, it is therefore advantageous to perform more accurate assessment of their expected remaining fatigue lifetime.

Several techniques to this end have already been developed and tested. The application of monitoring techniques to capture the real structural behavior has been implemented in many variants, usually evaluating the stress spectra from strain data acquired at fatigue-critical locations and consequent application of the Miner's rule to determine the damage accumulation [3]. The use of monitoring data leads often to lower stress ranges compared to results predicted by numerical models due to their inherent simplifications and their aspiration to ensure sufficient structural safety. Thus, SHM-based evaluations tend to predict a more extended fatigue lifetime. However, some application cases [4] show that it is not to be generalized as a rule.

Through a combination of monitoring data with calibrated FE-models, stress spectra can be evaluated also at unmeasured locations. This technique of virtual sensing has been validated

[5], [6] to obtain nominal stresses at railway bridges equipped with strain and acceleration sensors. The modelling can be further extended using the multiscale approach to also evaluate the local stresses – for example using a 3-scale concept encompassing the global scale, the structural member scale and the local scale [7].

Besides monitoring the structural response, the estimation of overpassing axle-load histories is the next important parameter in the fatigue accumulation assessment. While the train mixes defined in the Eurocode are suitable for design of new bridges, for the assessment of existing structures it is more expedient to use axle-load histories specific to the respective track location. The actual axle loads can be acquired for example using wayside monitoring systems applied on rails. However, the application of such systems is relatively new, so they provide data on the current state of traffic loading and axle-load histories prior to their installation remain unmeasured. During bridge lifetime, the axle-load histories may have changed significantly. Reconstruction of historic traffic loads provides a possible solution, as shown in a study for Norwegian railway bridges [8]. In here, it was identified that modern freight trains introduced after 1985 increased the fatigue damage accumulation rate significantly. Based on axle-load measurements in Dutch railway network, new fatigue load models for bridge assessment were proposed [9]. One of the load models addresses the period before 1970 and is based on limited available data and expert judgement. In another study [10], a simple approach was proposed, which considers development of total rail traffic volumes on national level, but neglects changes in train composition over time.

The evaluation of remaining fatigue lifetime is typically based on S-N curves as the definition of material resistance to fatigue loads. This approach features a fair amount of conservatism [11], which is understandable considering the significant variance of fatigue test results and the requirements of structural reliability, and it is necessary in semi-probabilistic assessment. However, the uncertainties can be modeled using a full-probabilistic approach by formulating the fatigue resistance as a random variable and evaluating probabilities of its exceedance. This type of evaluation results in estimating the reliability index and its development as the fatigue damage accumulates over time [12].

This work, which was done within the Shift2Rail project Assets4Rail [13], combines several abovementioned aspects, with the aim to highlight the joined effect of several methods. Three areas of more accurate fatigue assessment are addressed here: monitoring of structural response, track-specific axle-load histories, and probabilistic modelling of fatigue resistance. Moreover, the issue of track-specific axle-load histories is handled in different cases of data availability.

## 2 STRUCTURAL MONITORING AND MODEL CALIBRATION

### 2.1 Bridge description

The bridge is a semi-through type truss steel bridge (U-frame), which was constructed in the 1990's (Figure 1). It is a single span of 41.67 m length, which consists of 10 segments of equal length. The top chord has a rectangular cross-section, while the bottom chord is U-shaped. The diagonals have I-shaped cross section, except for the outer diagonals with rectangular cross-section. The truss members are constructed from welded steel plates and the truss members connect to each other with bolted plates.

Figure 1. Side view of the bridge.

The bridge carries a single unballasted railway track. The rails are placed on top of wooden sleepers carried by longitudinal beams, which are rigidly connected to transverse beams (Figure 2). The transverse beams connect to bottom chord of the truss. The connections are again executed using bolted plates. The bridge deck has two layers of diagonal bracing, stiffening the longitudinal beams under the sleepers, as well as bottom chords of the truss.

Figure 2. Structure of the bridge deck.

The bridge is located on a side track in Austrian railway network and experiences very low traffic volumes. This facilitated performing various tests and measurements on this bridge. For purposes of this study, a traffic constitution was assumed with properties that correspond to a main railway line, thus simulating high traffic volumes.

### 2.2 Measurement system

The bridge was equipped with 31 optical strain gauges. The sensor locations concentrated around truss-member connections between truss segments 4 and 5 (Figure 3), as well as connection between longitudinal and transverse beams at segment 8 and the transverse beam to truss chord connection (Figure 4). Since the fatigue evaluation was indented to be based on nominal stresses, the purpose of this monitoring system was to capture nominal stresses in structural members, which explains positioning the sensors at a little distance from the connection nodes and not directly on the fatigue hot spots.

Figure 3. Locations of fibre-optic strain sensors on truss members.

The sensors were located on several points of the same cross-section to increase accuracy of the measurement and also to capture secondary effects like transverse bending or warping of cross-sections. Additionally, acceleration sensors were placed on several locations across the bridge, as well as inclinometers and temperature sensors. However, they are not relevant for the purposes of the work presented here, therefore they will not be described here.

Table 1. Comparison of measured eigenfrequencies with predictions of the initial numerical model.

Parameter	Measured	FE-Model
$f_1$ , vertical bending	5.40 Hz	5.48 Hz
$f_2$ , upper chord 1 wave	9.99 Hz	10.22 Hz
$f_3$ , upper chord 1.5 waves	12.19 Hz	13.04 Hz

### 2.3 Model calibration

The numerical analysis was done using a shell model, which was constructed, meshed and calculated using FOSS (Free and Open Source Software) products. In particular the Pre- and Post-Processing platform SALOME [14] was used for the geometrical construction and meshing of the model, while the FEM-Solver CalculiX [15] was used for solving the meshed model. The model optimization of the FE-model was conducted using self-made algorithms in the Python programming language, utilizing optimization routines of the SciPy (Scientific Python) package.

The symmetry of the structure as well as the loading was used to reduce the model size and work with only half of the bridge and respective symmetry conditions (Figure 7, top). As the analysis will be done on the level of nominal stresses, a detailed modelling of the bolted connections was not necessary; the connections were modeled as rigidly connected plates (Figure 7, bottom).

Figure 7. Geometry of the FE-model (top) and a detail of its mesh (bottom).

Using modal analysis of the bridge structure, several eigenfrequencies and mode shapes were calculated; the first two of which are displayed in Figure 8.

Figure 8. Mode shapes of the FE-model:  $f_1=5.48$  Hz (left) and  $f_2=10.22$  Hz (right).

The model calibration was performed in three steps: 1. using measured strain responses during train passages, 2. using measured eigenfrequencies and mode shapes, 3. using both sets of measured data together. The updating was done twice, using two different objective functions: the squared differences approach (Eq.1) and the Gauss error function approach (Eq.2).

$$J_{sq} = \sum_{i=1}^m \left( \frac{z_n(i) - z_e(i)}{\sigma_e(i)} \right)^2 \quad (1)$$

$$J_{erf} = \sum_{i=1}^m \operatorname{erf} \left( w \cdot \frac{|z_n(i) - z_e(i)|}{\sigma_e(i) \sqrt{2}} \right) \quad (2)$$

The structural parameters that were subjected to updating are listed in Table 2. They comprise of relevant parameters affecting the global stiffness, stiffness of connections, as well as distribution of structural masses.

Table 2. Values of updating parameters.

Parameter	Initial value	Updated with $J_{sq}$	Updated with $J_{erf}$
Young's modulus [GPa]	210	220.5	205.8
Steel density [kg/m <sup>3</sup> ]	7850	8282	8282
Coef. for cross-girder connection stiffness	1	1.5	1.31
Coef. for main truss connection stiffness	1	1.5	0.683
Translation rail spring [MN/m]	0	0	0
Rotational bearing spring [MNm/m]	0	1000	0
Coef. for sidewalk mass	1	1.1	0.9
Cover plate mass coef.	1	1.1	0.9
Thickness of stiffener at cross-girder connection [mm]	17.5	20.2	19.2

The two updating algorithms suggested different solutions for the updating parameters. While the squared differences approach favored increase of both stiffness (global and connections) and masses, the updating approach of Gauss error function suggested in comparison lower connection stiffness and non-structural masses. The agreement of the updated parameters with their real values could not be checked due to significant effort that would be required for such testing. This would be also the usual case in any other real applications.

The updated models were subsequently used in evaluation of fatigue damage evaluation at selected fatigue-critical details. Five critical details were identified in total. The first three of them are displayed in Figure 9. Most critical was detail nr.3, which covers fatigue failure in the lateral direction in the stiffener plate at the toe weld. The upper fillet weld produced a

detail category of 36 N/mm<sup>2</sup> for a root crack at the weld, which ranked it as most fatigue-critical spot on the structure.

Figure 9. Three fatigue-critical details at the connection of cross-girder to bottom chord of the truss.

The differences in updated structural parameters resulted in influence lines of strain at fatigue-critical location as presented in Figure 10.

Figure 10. Influence lines of strain at five fatigue-critical details before updating (solid lines), after updating with... (dashed lines) and after updating with ... (dash-dotted lines).

### 3 TRAFFIC LOADS

To highlight the difference of traffic load assumptions in different cases of data availability, three cases were considered:

- No track-specific data available
- Traffic management data available for given section
- Wayside monitoring data available for given section

The first case represents the usual situation used in design of new bridges, where the train mix according to Eurocode is used. In the second case, the traffic management data provide basic information about train traffic specific to the track section. This information includes total train length, total train weight (estimated from wagon specifications), number of wagons and type of locomotive, and is listed for all train passages in a given time period. The third case represents the most accurate information: data from a wayside monitoring system, which provide axle forces and axle spacings of all train passages in a given time period.

Since the availability of wayside monitoring data is generally limited, it is expedient to have a methodology that can use traffic management data to generate track-specific estimation of traffic loads. Such a methodology was developed within the Assets4Rail project. Detailed description of the methodology

can be found in [16]; in this paper only a brief outline can be presented.

The procedure evaluates basic properties of trains from train management data and groups similar trains into clusters. For freight trains, the chosen basic properties were: unit mass of wagons [t/m], unit mass of locomotive(s) [t/m], and the number of carriages. Clustering algorithms were used to create train groups from available data, and then evaluate statistical properties of each group created. Figure 11 shows an example of evaluated train groups, represented by individual boxes. The placing and dimension of the displayed boxes correspond to the range  $\langle \pi - \sigma; \mu + \sigma \rangle$  of the three parameters annotated on the respective axes. The number in center of each box indicated the cluster size, i.e. number of train passages that were grouped in the respective cluster.

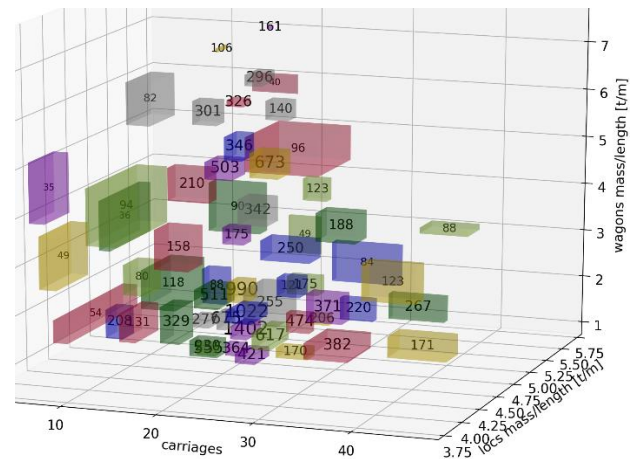

Figure 11. Clustered train management data of freight trains.

In the next step, a representative axle sequence was generated for each cluster. A database of wagon properties and a train model generation algorithm developed within the Assets4Rail project was used to this end. This algorithm requires deterministic values of basic train properties (number of carriages, etc.) as input: one set of values for each cluster. From the statistical evaluation of train data within each cluster, different quantiles can be chosen to represent each cluster. In order to compare the differences, the quantiles of 25%, 50%, 75% and 95% were used in further evaluations.

Schemes of generated axle sequences for 10 selected clusters of freight trains is partly shown in Figure 12; they consist of a sequence of arrows, height of which is proportional to the axle force magnitude. Loading situation of individual wagons (empty / full) is considered.

Figure 12. Partial schemes of freight train axle-sequences generated for selected train clusters.

In each train scheme, a locomotive with 6 axles is visible on the left side; the axle-force arrows display a force of 220 kN. The empty wagons can be recognized by the very small axle-forces shown at the wheel positions, which correspond to forces of less than 100 kN. The wagons feature different lengths (15 – 25 m) and axle configurations, which were chosen from catalogues of existing wagon stock.

Comparison of the track-specific train properties with the fatigue load model of the Eurocode showed some differences presented in Figure 13. The unit mass of the trains was considerably lower compared to the Eurocode standard traffic mix, while the number of axles was slightly higher in the freight trains. The shown results refer to one of the locations within Austrian railway network that was analyzed.

Figure 13. Cumulative Density Functions of the unit train mass (left) and number of axles (right) for trains generated from train management data compared to Eurocode.

In order to compare the differences between different axle-load sequences, their effect on the fatigue damage accumulation on different systems was analyzed. For this purpose, the midspan bending moment in simply-supported single-span bridges was used, simulating fatigue critical details governed by longitudinal stresses at such location. The span length was varied between 4 and 60 m. Eight traffic load mixes were analyzed: three Eurocode traffic mixes (light, standard, heavy), four traffic mixes generated the train management data using 25%, 50%, 75%, 95% quantiles of basic train properties for each cluster (TRGEN: \_q25, \_q50, \_q75, \_q95), and finally axle-sequences as measured by a wayside monitoring system. The fatigue damage accumulation evaluated using the wayside monitoring data was used as reference ( $d_{ref}$ ), since it represents the most accurate result. To eliminate the influence of total traffic volume, all traffic mixes were normalized the total traffic volume of 25 Mt/year. Figure 14 shows a comparison of the evaluated fatigue damages in relation to the reference (wayside monitoring data).

This comparison shows that the Eurocode standard traffic mix produced a fatigue damage that exceeds the reference by 50% - 160%, depending on the span length. The dependance of this exceedance on the span length could be caused by the way the Eurocode models were calibrated, and may vary for bridges with different static systems.

Using the train management data, this conservatism would be reduced to 35% - 105% exceedance.

Figure 14. Fatigue damage accumulation evaluated for different normalized traffic mixes relative to  $d_{ref}$ .

#### 4 FATIGUE RELIABILITY EVALUATION

A full-probabilistic approach was chosen to evaluate the reliability index of fatigue damage occurrence. This included probabilistic modelling of structural properties, traffic load actions, as well as the fatigue resistance. The distributions of many of the probabilistic variables were adopted based on the recommendations of the probabilistic model code [17]. The limit state function was defined according Eq. 3, where  $D_{cr}$  is the accumulated fatigue damage at the failure (defined as a probabilistic variable) and  $D_{year}$  is the fatigue damage accumulation within one year (also a probabilistic variable).

$$G(t) = D_{cr} - D_{year} \cdot t \quad (3)$$

The failure probability and the reliability index are then evaluated using Eq. 4 and 5, respectively.

$$P_f(t) = P[T \leq t] = P[G(t) < 0] \quad (4)$$

$$\beta = -\Phi^{-1}(P_f) \quad (5)$$

Figure 15 shows  $D_{year}$  for the detail Nr. 3, compared between different models. The blue curve represents the case without using any monitoring data (no prior information) and results into the highest estimates of damage accumulation. If the model uncertainty can be estimated from the monitoring data, it can substantially reduce the total uncertainties. In here, the model uncertainty was determined from the uncertainty of influence lines evaluated from the measurements with the test train and the resulting distribution of damage accumulation (the orange curve) shows a significant reduction as result. The influence lines still correspond to the initial model, i.e. without updating.

After the model updating, the evaluated damage accumulation shows further reduction, as it can be observed from the green curve obtained using updating with the squared differences approach (Eq.1), and red curve obtained using updating with the Gauss error function approach (Eq.2).

Figure 15. Distribution of the yearly fatigue damage accumulation on detail 3 using different numerical models.

The Figure 16 shows the reliability index evaluated at different points in time, comparing the same evaluation cases as in Figure 15: blue curve – without monitoring, orange curve – model uncertainty from monitoring but no updating, green and red curves – with additional model-updating step. The minimum required value of the reliability index is specified to be in range 1.5 – 3.8, depending on the accessibility of the detail and other factors. This range is displayed as a grey area. The failure probabilities related to reliability indices of  $\beta=1.5$  and  $\beta=3.8$  are  $P_f=0.067$  and  $P_f=7.23 \cdot 10^{-5}$ , respectively.

Whereas without monitoring data, the reliability index would reach after 100 years the value of  $\beta=2.1$  ( $P_f=0.018$ ), the inclusion of monitoring data combined with model updating could increase the reliability index value up to  $\beta=4.35$  ( $P_f=6.8 \cdot 10^{-6}$ ) in this particular case.

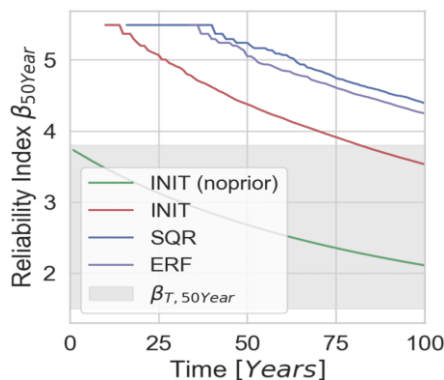

Figure 16. Development of the reliability index for detail 3 over time: comparison of different models.

## 5 CONCLUSIONS

The presented work summarizes the uncertainty parameters affecting fatigue damage evaluations and shows a way of dealing with them in a full-probabilistic analysis. The traffic loads can be updated using section-specific data, preferably wayside monitoring data that provide measured axle-load sequences. Alternatively, train management data can also be used to derive alternative, section-specific axle-sequences for fatigue evaluations. Since they rely on less accurate data regarding train masses compared to wayside monitoring, they tend to provide more conservative results. The use of train management data could be regarded as intermediate step between wayside monitoring (which is the reference) and the use of Eurocode fatigue load models.

Probabilistic fatigue evaluations have shown that updating of the uncertainty of influence lines using monitoring data contributed significantly to improving the result accuracy, as compared to the case with no prior information, in which model uncertainties according to recommendations of the probabilistic model code were used.

The updating of the numerical model provided a further increase of estimated reliability indices, at a cost of significant computational effort required to perform the model updating.

The results presented in this use case cannot be generalized. The increase of reliability index due to more accurate models of traffic loads and the numerical model of the bridge depend on many factors that are specific to the respective track section, the bridge structure and the monitoring system applied.

The purpose of this work was rather to present an approach that encompasses dealing with uncertainties on the side of traffic loads as well as of the structural response, and joins them together with probabilistic definition of fatigue resistance in a full-probabilistic evaluation of the fatigue reliability index.

The application of the presented methods could be recommended especially for cases where larger discrepancies between the original fatigue assessment assumptions and the reality are suspected. This may apply to bridges on track sections with much lower (or much higher) portion of freight traffic, or sections where freight trains operate with a significant number of empty wagons. Further, bridges with larger modelling uncertainties may profit from the use of monitoring data, for example short bridges (due to uncertain track interaction) or bridges that were calculated using models with significant simplifications, especially simplifications of member connections.

**ABSTRACT:** The ÖBB Rheinbrücke, situated in the vicinity of Lustenau, represents a novel approach to steel-concrete composite arch structure engineering, boasting a span of 102 meters. The primary supporting structure is a tied-arch comprising 12 round steel hangers, each with a diameter of 100 mm, situated on either side of the bridge. The maximum length of the hangers is 18.9 meters. In arch bridges of this type with steel hangers, wind-induced vibrations in the hangers can result in high-frequency, high-amplitude fluctuations in stress levels, particularly in the hangers and their connections. This can be problematic from the perspective of fatigue, particularly given that the hanger connections often have notch-sensitive details. Following the completion of the bridge, comprehensive monitoring was conducted in accordance with the original plan. This was done with the objective of acquiring data regarding the vibrations experienced by the hangers and the subsequent damage to the material. This data was then used to determine whether vibration-reducing measures were necessary. During the course of monitoring and subsequent evaluation, it was observed that wind-induced vibrations in the hangers could result in the occurrence of fatigue-relevant stress ranges. This article serves to emphasise the importance of structural health monitoring in confirming the efficacy of vibration reduction measures, which have the potential to extend the service life of railway bridges.

**KEY WORDS:** monitoring; wind-induced vibrations; fatigue.

### 1 INTRODUCTION

Railway bridges, integral to transportation networks, are subjected to diverse and dynamic loading conditions, necessitating diligent monitoring and maintenance strategies to guarantee their continued safety and operational efficiency. Specifically, the application of SHM to railway bridges enables the early detection of potential damage or deterioration, thereby averting catastrophic failures and extending the lifespan of these critical infrastructures. The implementation of SHM systems typically involves the deployment of various sensors, data acquisition systems, and communication networks to continuously monitor key structural parameters such as strain, displacement, acceleration, and temperature [1]. By analyzing the data acquired from these sensors, engineers can identify anomalies or deviations from baseline behavior, which may indicate the presence of damage or deterioration [2]. The integration of advanced data analytics, significantly augments the capabilities of SHM systems, enabling the detection of nuanced changes in structural behavior that might elude traditional inspection methodologies. These analytical techniques can discern patterns and trends in the data, thereby providing valuable insights into the underlying mechanisms driving structural degradation. [3]. In light of these considerations, this paper delves into the practical application of SHM in assisting the decision to apply correction measurements, with a particular focus on the ÖBB Rheinbrücke near Lustenau. the ÖBB Rheinbrücke is single-track and electrified. It is a total of 276.5 m long and 7.95 m wide and consists of a 102 m wide tied arch bridge over the Rhine as well as four trough bridges over the western foreland and two trough bridges over the eastern foreland (Figure 1).

Figure 1. ÖBB Rheinbrücke

The entire bridge has a continuous ballast bed. The tied arch bridge has two parabolic arches made of reinforced concrete, which are clamped in steel sleeves on the end cross girders. The bridge structure has twelve round steel hangers with a diameter of 100 mm on each side of the bridge. The maximum hanger length is 18.9 m. The connection of the hanger trapeziums to the connecting plate and the connecting plate to the upper flange of the longitudinal beam are designed as welded seams (Figure 2).

Wind-induced vibrations in these hangers can lead to high-frequency, high-amplitude stress fluctuations, particularly in the hangers and their connections, posing a significant fatigue risk. The susceptibility to fatigue is exacerbated by the presence of notch-sensitive details in the hanger connections, rendering them vulnerable to crack initiation and propagation under cyclic loading conditions [4]. Great attention was already paid to this issue during the planning phase of the bridge built in 2011. However, in order to gain experience of the phenomenon of hanger vibrations for this and future bridges, the hangers

were initially designed without vibration-reducing measures. nevertheless, precautions were taken for the later installation of measures to reduce vibrations.

Figure 2. Detail of the hanger connection

Two wind related physical phenomena, vortex-induced transverse vibrations and rain-wind-induced vibrations, can appear during the structure's service life. Those characteristics of those phenomena are briefly described below.

- **Vortex-Induced Vibrations:** These vibrations are caused by vortices detaching alternately from each side of the hanger. The frequency of this oscillating force is related to the Strouhal number, approximately 0.2 for cylinders. According to [5], the critical wind speed for the respective mode shape is calculated using equation (1)

$$v_{crit,i} = \frac{f_i D}{St} \quad (1)$$

Where  $D$  is the hanger diameter,  $f_i$  is the natural frequency of the respective mode shape and  $St$  is the Strouhal number.

- **Rain-Wind-Induced Vibrations:** These vibrations occur during simultaneous rain and wind events. They are characterized by low frequency and high amplitude, potentially leading to high stress amplitudes. According to [5], [6] the critical wind speed for this type of excitation can be calculated using equation (2).

$$v_{crit,i} = 73.5 \cdot D \cdot f_0 \cdot \left(\frac{f_i}{f_0}\right)^{0.6} \quad (2)$$

where  $D$  is the hanger diameter,  $f_0$  is the reference frequency and  $f_i$  the natural frequency for the respective mode shape

Empirical studies [7],[8],[9] indicate these vibrations are most likely in light to moderate rain and wind speeds between 4 and 20 m/s.

## 2 MONITORING SYSTEM AND DATA EVALUATION

After the construction of the bridge, an extensive measurement program was started as planned. The monitoring system deployed on the ÖBB Rheinbrücke comprised an array of sensors strategically positioned to capture the dynamic response of the hangers. In the preliminary stage of the program, two cables of varying lengths were subjected to monitoring. H6, the longest cable on the bridge, measures 19 meters, while H4 measures 14 meters. The most critical

element in terms of fatigue failure was used as the reference point for calculating the stresses. In the present case of the Rheinbrücke, they are the connections between the connecting plates of the hanger and the upper flange of the longitudinal girder (Figure. 2) which present a notch type of 45 N/mm(2) ([10], Table 8.5, Design Detail 1). Strain gauges were affixed to these hanger connection plates to measure stress variations, while accelerometers were installed to capture vibrational frequencies and amplitudes on the hangers. In addition, temperature sensors were integrated into the system to account for thermal effects on the structural behavior of the bridge. The acquired data was transmitted in real-time to a central data acquisition system, where it underwent processing, analysis, and storage. Table 1 and Figure 3 show the number and location of the installed sensors.

Table 1. Sensors at the Rheinbrücke

	Ref.in Figure 3	Number of Sensors
Acceleration	AS	8
Displacement	Weg	2
Temperature (Component)	TEMP	4
Linear strain gauges	DMS-L	35
Rosette strain gauges	DMS-R	10
Wind speed		1
Wind direction		1
Rain intensity		1
Air temperature		1

In order to keep the amount of data reasonably limited, the strain values are recorded in a triggered manner; the recordings are started at accelerations greater than  $0.4 \text{ m/s}^2$  at the hangers. The weather data and temperature, on the other hand, are recorded continuously.

Figure 3. Position of the installed sensors

During the almost ten-year monitoring period (April 2013 to the end of 2022) on the Rhine bridge, numerous events with vortex-induced transverse vibrations and rain-wind-induced

vibrations were recorded. To evaluate the recorded data, the critical wind speeds were calculated using formula (1) for vortex-induced vibration and formula (2) for rain-wind-induced vibration. The calculated speeds were useful for the analysis and classification of the different events.

To assess the effects of the wind induced vibrations on the fatigue resistance of the structure, the cut-off limit for the fatigue strength was calculated according to [10], resulting in a value of 15.8 N/mm<sup>2</sup>. This implies that every stress range above this limit is relevant for the fatigue resistance, and must be considered for the damage accumulation. The process of damage accumulation is an important aspect of fatigue analysis as it is used to predict the remaining service life of a component or structure. The Palmgren-Miner rule [11,12] has been used to calculate the amount of damage produced by a given loading history by summing the damage caused by each loading cycle.

The following sections describe one event of each type, providing a better insight into the effects of these events on the structure.

### 2.1 Vortex induced vibrations

Table 2 shows the calculated frequencies for the monitored hangers.

Table 2. Natural frequencies

Hanger Mode Shape	H4 f[Hz]	H6 f[Hz]
1	4.0	3.5
2	8.7	7.4
3	14.5	11.9

The measurements carried out show that the critical wind speed calculated for the 3rd natural frequency wind speed  $v_{crit,3} = 6$  m/s caused the hanger H6 to oscillate over longer periods of time with stress oscillation amplitudes above the fatigue strength threshold value, as the stress history plot in figure 4 shows. During the duration of the event, the condition for vortex-induced vibration excitation was fulfilled by a constant wind speed around the calculated critical speed for a long period of time (over two hours in this event).

Figure 4. Stresses caused by a vortex-induced vibration event

Figure 4 shows that the stresses measured on cable H6 are much higher than those measured on cable H4. The stresses on cable H4 are irrelevant for fatigue damage. Figure 5 clearly shows that the measured frequencies are close to the calculated third natural frequency. This indicates that higher natural modes than the first must be considered when evaluating fatigue damage.

Figure 5. Frequency of the vortex-induced vibration

### 2.2 Rain-wind induced vibration

To detect and characterize event of this type, a criterion based on the calculated critical speed (table 2) for the first natural frequency and the presence of persistent precipitation has been applied. A typical stress history for this type of events is presented in figure 6.

Figure 6. Stress history over a rain-wind induced vibration event

During the duration of this event, the wind speed was only occasionally in the range of the calculated critical wind speed  $v_{crit,1} = 15.7$  m/s, the damaging vibrations nevertheless occurred for a longer period of time. It should be also noted that it rained unusually heavily (over 50 mm/h) shortly before the build-up. Generally, from the recorded rain-wind-induced events, it can be inferred that the stress range of hanger H6 is significantly higher than in events in which vibrations are caused solely by vortex-excited transverse vibrations.

## 3 FATIGUE DAMAGE AND LIFE CYCLE

During the entire bridge monitoring period, regular calculations of the remaining service life of the critical weld seam between the connecting plate and the top chord of the longitudinal girder were carried out on the basis of the Palmgren-Miner rule. In order to be able to make a statement as to whether the observed stresses could become a problem for the hanger connections over the years, the stress range collective recorded during the measurement period was extrapolated to a service life of 100 years in this work. For this purpose, it is assumed that exactly the same stresses occur during the extrapolation period as during the period in which the monitoring was carried out. Under this assumption, the collective stress range measured can simply be multiplied by a corresponding factor and thus a forecast for the theoretical service life can be created using the Palmgren-Miner hypothesis. No distinction was made between individual vibration types in these forecasts; all vibration sources such as

rain-wind-induced vibrations and vortex-induced transverse vibrations, as well as train passages, are therefore included here. The data are added together to obtain a statistically sound statement about the remaining service life of the monitored hangers. It should be noted at this point that only heavy freight trains can cause stress oscillation amplitudes relevant to fatigue, and that these do not significantly reduce the remaining service life, due to their low frequency. The history of the theoretical residual service life is shown in Table 3

Table 3. Progress of theoretical service life (years)

Hanger	Marz 2018	July 2019	June 2020	June 2021	June 2022	Nov. 2022
H4	465	269	394	475	573	626
H6	42	40	21	18	22	23
H7	207	360	265	353	461	518

The remaining service life forecasts show that the influence of wind induced vibrations, on the hanger H6 is remarkable, while the influence on the shorter hanger (H4) plays a subordinate role with regard to the planned service life.

#### 4 VIBRATION-REDUCING MEASURES

Following the results of the monitoring campaign, it was decided to install a system to reduce the effects of vibration on the Rheinbrücke. Interconnecting adjacent cables using cross-ties is a method that has been experimentally tested on numerous suspension bridges [13], which simply and effectively mitigates the effects of wind-induced vibrations. In addition, this vibration reducing measure was already proposed during the planning phase in case of need. It consists of connecting the bridge hangers with small-diameter cables. In this way, the vibration energy is distributed over several hangers with different natural frequencies. In this manner, unexcited hangers act as dampers [13,14].

Figure 7. Vibration reducing cable

In May 2017 such measure was implemented by installing a 3 mm cable connecting hanger H7 and hanger H8 (Figure 7). After installation, H7, which has the same length as H6, was also monitored to evaluate the effectiveness of the procedure. As can be seen in figures 3 and 4, the amplitude of the measured stresses is significant reduced when compared with those in

hanger H6. Using this method, it is possible to improve the issue of fatigue damage in the structure, as can be seen from the calculation of the theoretical service life in Table 3. In the summer of 2021, the measure was installed on the remaining bridge cables. The data presented in Table 3 unequivocally reveals a trend change in the theoretical service life of cable H6 since the installation of the connecting cable. This finding is confirmed by calculations for the subsequent years, thereby underscoring the beneficial effect of this measure.

#### 5 CONCLUSION

This article presents the effects of vortex-excited transverse vibrations and rain-wind-induced vibrations on the ÖBB Rheinbrücke near Lustenau. Data collected during a long and extensive monitoring campaign on the bridge were used for this purpose.

The following conclusions can be drawn from the analyzed data:

- Wind-induced events cause fatigue-relevant stresses that are dependent on the weather conditions
- The effects of vortex-induced and rain-wind-induced events on the fatigue strength are much more pronounced for the hangers with greater length.
- The damaging effect of such events can be effectively reduced by installing cables joining adjacent hangers. The theoretical service life increases progressively, which confirms the positive effect of the measure against fatigue failure.

These findings underscore the critical importance of considering wind-induced vibrations in the design and maintenance of arch bridges, especially those with slender steel hangers. The implementation of a structural health monitoring system proved invaluable in detecting and quantifying these vibrations, allowing for timely intervention and mitigation strategies. The SHM system enabled the detection of wind-induced vibrations in the hangers, which could have led to fatigue damage and premature failure, thus contributing to the mitigation of potential risks.

# Acoustic emission monitoring of fatigue cracks for railway steel bridge inspection

Prokofyev, M.<sup>1</sup>, Marihart, H.<sup>1</sup>, Lackner, G.<sup>1</sup>

<sup>1</sup>TÜV AUSTRIA GMBH, Deutschstraße 10, 1230 Vienna, Austria

email: mikhail.prokofyev@tuv.at, heribert.marhart@tuv.at, gerald.lackner@tuv.at

**ABSTRACT:** Railway steel bridges are often affected by material fatigue, i.e. crack formation and crack growth at areas of high stress concentrations under millions of load cycles due to the traffic load. To support the continued safe operation of these structures a flexible and robust system solution for structural health monitoring is needed. It provides the responsible bridge inspector with useful information regarding the current condition and the future development of the monitored area. This offers the infrastructure operator an opportunity for optimised planning of inspection intervals and maintenance measures and helps to extend the service life of these structures. For this purpose, the RISE system was developed by TÜV AUSTRIA in close cooperation with the Austrian Federal Railways ÖBB. The RISE system monitors fatigue cracks and/or highly stressed areas using acoustic emission (AE). The system records the AE response from the monitored area while the material is stressed by the usual day-to-day railway operations. The analysis of the change of this material response over the monitoring period is used to predict the future development of the crack. In this paper the application of the RISE system for bridge inspection is presented for steel bridges in the railway network of ÖBB. The system solution is presented as a whole, from the installation on-site until the evaluation of the monitoring data and the obtained results supporting the responsible bridge inspectors.

**KEY WORDS:** SHMII-13; acoustic emission, fatigue cracks, steel bridges.

## 1 INTRODUCTION

Steel bridges are often affected by fatigue cracks due to cyclical loading caused by trains passing over them. Bridges at the end of their service life inevitably develop such cracks. The ÖBB team takes care of the maintenance of the bridges in its railway network and thus ensures the safety of the day-to-day train traffic. ÖBB employees inspect the bridges at regular intervals and assess their condition.

ÖBB was looking for a way to find a tool for these bridge inspectors to give them a way to monitor fatigue cracks and detect cracks at locations where cracks are suspected. In addition, this tool should be able to predict the future development of the condition of the monitored component when cracks already present, to help with a more precise planning for inspections intervals and repair measures. As part of the Rail4Future program co-financed by the Austrian Research Promotion Agency, the monitoring of cracks using acoustic emission (AE) was selected as the method. TÜV AUSTRIA and ÖBB have been cooperating for years in the implementation of acoustic emission as a monitoring tool for railway steel bridges. As part of this cooperation, a stand-alone solution, RISE (**R**emote **I**nspection **S**ystem **E**dge), has been developed. A monitoring solution for the detection and monitoring of fatigue cracks on railway steel bridges.

RISE offers monitoring as a service for railway infrastructure operators, from setting up the monitoring, recording the data to generating the report. In addition, a prediction on the future development of the crack is also provided.

This method is known as the failure forecast method (FFM). A method that is utilizing the near constant measurement data

stream from the device to predict the time until the maximum utilization of the monitored component is reached.

The RISE device was developed with the focus point to be a reliable and easy to install acoustic emission monitoring system. RISE is specifically designed for monitoring due to its compact design, low power consumption and simple installation.

## 2 OVERVIEW OF MONITORING SYSTEM

### 2.1 Technical overview

RISE by TÜV AUSTRIA is an acoustic emission system designed for detection and continuous monitoring of fatigue cracks. RISE consists of a hardware component, the RISE-Core, which is installed on site and a server infrastructure for data evaluation and monitoring result presentation on an online dashboard. The data from the RISE-Core is sent to this data platform via a mobile network and an encrypted connection. The data stream is processed on the server. The results are displayed on a graphical online interface, the RISE dashboard, where they are accessible by the customer.

The RISE-Core is installed at the position where a crack is suspected, or an already existing crack needs to be monitored. The system has four acoustic emission channels. The connected piezoelectric sensors detect the mechanical waves generated by the growth of cracks inside the material. Acoustic emission occurs when the defects in the material are excited by a load. The propagation of the defect is accompanied by the release of energy in form of an elastic wave. Acoustic emission is therefore a passive non-destructive method. In the case of railway steel bridges, the load needed for activation of cracks is the passage of trains over the bridge from the usual daily

traffic. Monitoring with the system therefore provides information about the acoustic emission material response to the currently operational load.

The preprocessing of the signals in the form of extraction of basic acoustic emission parameters takes place on site. The system is designed so that the power can be provided via a small off-grid solar system. A mobile network connection is required to outsource the needed computing power to a server. It is possible to use several RISE-Cores on one bridge. For every monitoring position one RISE system is required.

## 2.2 Theory of operation

Every time a train passes over the steel bridge, the material is stressed. This can cause fatigue crack growth to occur at locations with high stress concentrations due to periodic overloading of the material. The crack growth is accompanied by a stress reconfiguration and a sudden release of energy in form of elastic waves in the material. The mechanical waves propagate in the material and can be converted into an electrical signal utilizing the piezoelectric sensors. This signal is digitalized and the acoustic emission parameters that are relevant for further evaluation are extracted from it. The system therefore is recording the AE material response to the operational load.

As first processing of data on the server, located events are calculated. This method deals with combining the signal information from the whole sensor array and not an individual sensor only and providing the information about the point of origin of the mechanical wave. To indicate an acoustic emission event as a located event, several sensors must be excited by the mechanical wave and the strength of the electrical signal generated by the piezoelectrical element must exceed a specified threshold (in mV). In addition, the time difference on arrival at the different sensors must not exceed a certain specified value (1st-Hit Discrimination Time). This time value is related to the distance between the sensors and the time it takes for the mechanical wave to travel this distance at a defined speed of sound. The calculation of the wave's point of origin is calculated from the time differences of the individual signals, the speed of sound and the position of the sensors. The detection of the events relevant for further evaluation is carried out by 3 measuring sensors, which surround the crack or the monitored area in a triangular configuration.

So-called guard sensors are used to ensure that no noise from outside the monitored area interferes with the measurement. These are placed around the measuring array consisting of the three measuring sensors. Incoming waves that are first detected by one of the four guard sensors are not used to calculate the material response, as the system recognizes that the mechanical wave originated outside the monitored area of interest.

RISE provides a statement about the further development of the crack after a given measurement time. This method is known as the failure forecast method. The information helps the infrastructure operator to plan the inspection intervals and repair measures for ageing bridges. The method is based on rate-based structural health monitoring and requires near-continuous measuring data [1].

Many load-controlled processes, such as fatigue crack growth, show positive feedback. Crack growth accelerates as the degree of degradation progresses. The closer the system

gets to the point where it has exhausted its capacity to withstand the load, the higher the rate at which the degradation progresses.

This point in time is therefore the time when the maximum utilization of the monitored component is reached. The advantage of this method is that it is not the crack growth per se that is monitored, e.g. the crack length, but the change in a measured value that is symptomatic for the degradation (see Figure 1).

Figure 1 Illustration of the acoustic emission material response with the progression of a fatigue crack growth due to the cyclic loading of trains passing over the bridge.

In the case of acoustic emission monitoring, this value can be the energy of the acoustic emission signals, localized events, or hits detected from the monitored area.

Crack growth generates a mechanical wave that propagates through the material by releasing elastic energy stored in the crack tip. These mechanical waves can be converted into an electrical signal using piezoelectric sensors, which is then digitized and made available for further evaluation. The advantage of FFM over conventional methods for assessing degradation is that it does not require any detailed information about material properties and crack geometry. Only the material response to the operational conditions over time provides the data required to make a statement about future development.

Fukuzono [2] and Voight [3][4] were able to show in their works that there is a correlation for many degradation processes that can be expressed in Equation 1:

$$\frac{d^2\Omega}{dt^2} = A \left( \frac{d\Omega}{dt} \right)^\alpha \quad (1)$$

$\Omega$  is the measured variable associated with the degradation. In the case of monitoring fatigue cracks on steel bridges, the variable is the accumulated acoustic emission response of the material (see Figure 1). The two constants  $A$  and  $\alpha$  are empirical parameters that are dependent on the process under consideration. The equation can be integrated in the range from  $t$  to time  $t_f$  (time of maximum utilization of the component) with  $\alpha > 1$  (Equation 2):

$$\left( 1 / \frac{d\Omega}{dt} \right)^{\alpha-1} \approx (\alpha - 1) A (t_f - t) \quad (2)$$

The equation can be further simplified for the case that  $\alpha \approx 2$ , which is the case for fatigue crack growth [1]. This can be

verified from the measurement data by plotting the logarithm of the first and second time derivatives of  $\Omega$  and finding  $\alpha$  from the calculated slope.

So obtained equation shows a linear correlation (Equation 3).

$$\frac{1}{\Omega} \approx A(t_f - t) \quad (3)$$

As the rate of change of the material response is very high at the point in time at which the maximum material utilization of the monitored component is reached, a statement can be made from the monitoring data about this point in time. For this purpose, the inverse rate of the material response is plotted against time. The calculated linear regression line intersects the time axis at the point where the inverse rate of change of the material response approaches zero (see Figure 2).

Based on the remaining time until the maximum utilisation of the component is reached, a traffic light rating system is set up and the operator is given a recommendation on how to proceed. If the time until maximum utilisation is reached is longer than the time window of a regular periodic inspection, further monitoring is only necessary within the designated time (green area). If the time interval is shorter than the time window of a periodic inspection, a permanent monitoring is recommended (yellow area). If the time to maximum utilisation of the component is very short, not only a further inspection is required, but also safety measures are appropriate (red area).

The failure forecast method is shown to be tolerant for random variable amplitude loading that is statistically stationary as it is the case for train passages that have a variety of train mass [7]. A significant change in the exploitation of the bridge would require a new monitoring of the material response due to drastically changed traffic loads.

Figure 2 Illustration of application of the failure forecast method on continuous monitoring data. The linear regression line is intersecting the time axis at the time point of maximum utilization of useful life of the monitored component.

### 3 FIELD APPLICATIONS

#### 3.1 Bridge with fatigue cracks in the area of the transverse stiffener to the main girder web plate

During the regular inspection of this bridge, cracks were discovered in the area of the main girder web plates. In the first on-site analysis, these cracks could be identified as fatigue

cracks [5]. The cracks were limited to the connection detail of the transverse stiffeners welded to the main girder web plate.

Figure 3 Monitored position with the suspected crack at the welded connection of the transverse stiffener to the main girder web plate

A concept of measures was developed to carry out an objective assessment of the cracks on the main girder based on calculations and measurements and to make a statement about the future development. In the subsequent measurements, TÜV AUSTRIA was called in to help assess reinforcement measures by means of acoustic emission measurements at the crack positions [5]. Around 14% of the 140 identical elements were affected by the cracks. During this initial AE measurements, also at some reference points with no reinforcement installed, a new crack indication was detected. It was decided to do a further AE-monitoring using the RISE system at this position of interest (see Figure 3) and to assess the possible future development of the crack. The aim was to test the RISE as a tool for detecting cracks in the early stages and to use the measurement results of the monitoring to predict the future development of the cracks.

The measuring equipment required for the monitoring was installed while the bridge was in operation, so the train traffic was not affected. The piezoelectric sensors (VS150-RSC from Vallen, peak frequency at 150 kHz, integrated preamplifier with gain of 34 dB) were installed as shown in Figure 5. Three sensors were installed near the crack position. These sensors record the mechanical waves coming from the crack. To improve the coupling of the sensors to the surface, they were mounted with a coupling agent. In addition, the paint layer was removed off at the sensor positions. The sensors were attached to the surface using magnet holders. The connection to the sensors was made via BNC-cables (1.5 m). The RISE-Core measuring system was also attached near the measuring position using a magnetic holder. Four guard sensors were installed around the measurement position to shield the measurement setup from interfering noise from sources other than the crack position. These were positioned to suit the installation location in such a way that possible interference signals were first detected by the guard sensors and thus filtered in the signal processing. As a 230V connection was available near the bridge, the measuring system was connected to this. This was the only cable that had to be laid out to the measuring position.

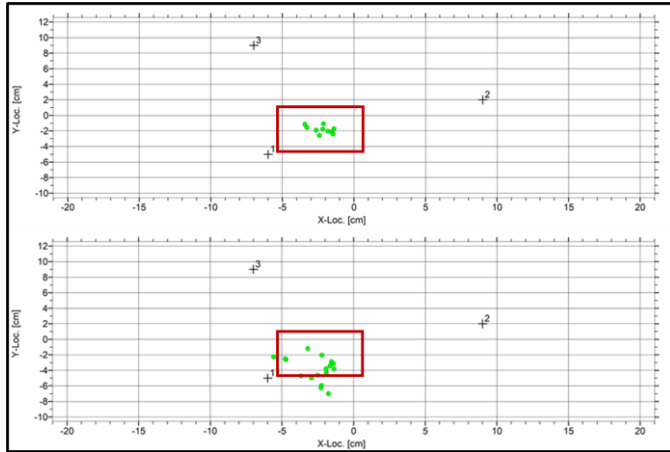

Figure 4 Top - Location map of events from pencil lead breaks at the position of the suspect crack. Bottom – Location map of events acquired after one train passage over the bridge in the position of the crack indication localized with pencil lead break test.

The functionality of the installation of the measuring device (RISE-Core) and the sensors for condition monitoring could be checked using user friendly installation software known as "Client Setup Mode". This software solution offers a supporting function for checking the functionality of the measuring chain, coupling verification of the sensors and localization in accordance with the EN 17391:2022-06 standard. Verification is carried out using a pencil lead break (0.5mm/ 2H, in accordance with ASTM E976). A simple and reproducible event with energy in the order of magnitude of crack growth events. To check the function and the correctness of the set parameters, pencil lead breaks were carried out in the area of the suspected crack (Figure 4).

Figure 5 AE sensor arrangement at the monitored position with suspected crack. Sensor 2, not in the picture, is positioned behind the connection detail in the distance of 12 cm from the suspected crack.

This area is also where the crack growth events are to be expected. The Figure 4 shows in the bottom map the localized events after a train passing over the bridge. The entire

installation and inspection of the measurement setup can be carried out by a trained technician within one hour. The measurement period was 6 months.

During this time, the passages of the individual trains and the resulting AE material response were recorded.

### 3.2 Monitoring at five representative points on a riveted steel bridge

This case involves a riveted steel bridge built in 1936, which was found to be in good condition during a visual inspection by the ÖBB bridge inspectors. The bridge was to be given a new corrosion protection. As this is a cost-intensive maintenance measure for the infrastructure operator, the ÖBB wanted to help with additional useful information to support the final evaluation of the condition of the bridge through the responsible bridge inspectors.

With the help of the bridge inspectors, five neuralgic areas on the bridge were selected. These points were selected from the experience of the technicians responsible for the inspection as the components most affected by cracks and can thus be used to assess the general condition of the bridge. This field example deals with the measurement of the first selected area, a transverse stiffener in the area of the fixed bearing of the bridge. This case is an example for monitoring of a hot spot. A larger area is monitored than in the case of already known cracks. Here too, the 3 measuring sensors (see Figure 6) detect the incoming mechanical waves in a triangular arrangement, which are triggered in the material by the load of the trains crossing over the bridge.

Figure 6 AE sensor arrangement at the monitored position for hot spot monitoring at the area of the riveted connection element of the transvers stiffener to the main girder.

The material response is evaluated for crack growth and provides information about the condition of the material in the monitored area. As commercially available magnetic sensor mounts are too large for the distance between the individual rivets, in-house developed sensor mounts are used for the riveted bridges. In addition, 4 guard sensors were applied around the triangular configuration of the measuring sensors in order to exclude spurious noise outside the measuring arrangement.

Figure 7 Modular PV-solution for RISE.

As there was no power supply on site at this bridge, a modular PV system was installed (see Figure 7) to supply the RISE device with power.

RISE requires less than 10 W of power when all sensor channels are fully utilized. The entire equipment could be transported to the site by three men.

#### 4 RESULTS

The material response was recorded by the RISE system during the monitoring process. The results of the cumulative plot of the AE material response can be seen in the Figure 8. At first glance, different trends in the material response can be recognised in the progression of the individual curves. The curve with the most pronounced progressive course is the Pinkabach bridge. A bridge that was completely dismantled in a single piece by ÖBB and equipped in the workshop with a shaker. It was subjected to a fatigue test [41]. As part of the Rail4Future project, TÜV AUSTRIA, in cooperation with ÖBB, carried out an acoustic emission measurement on the main girder bottom flange during the fatigue test, where an artificial crack was introduced and the AE material response during fatigue crack growth was observed.

Figure 8 Comparison of AE material response of the different bridges. Monitoring time is normalized. Red: fatigue test on the Pinkabach bridge with artificial introduced crack. Yellow: monitoring of a bridge at crack position. Green: representative hot spot on a bridge with no known crack indications.

The crack had grown after its initiation at the notch near to the edge of the bottom flange in transversal direction almost till to the web plate at the centre of the girder.

The material response shows a progressive growth, which is a well-known trend in the acoustic emission for sever degradation. In comparison to the Pinkabach bridge, both the trends of the crack affected bridge and the riveted bridge show a linear progression. The slope of the cumulative AE response is significantly more pronounced on the crack affected bridge where crack monitoring was performed than on the riveted bridge.

The application of the FFM like in the Figure 9 delivered the prediction of time of maximum utilization of the monitored components for the two bridges. In the case of the crack monitoring, for example, it was possible to conclude that further monitoring should be carried out at the next scheduled inspection interval. The riveted bridge showed that the remaining time until maximum utilisation of the first monitored position is so far in the future that a new investment in a new corrosion protection will be reasonable, when the other positions will show a similar result. Other positions on this bridge are still being monitored in order to make a general statement about the overall condition of the bridge. The results are made available to the customer on an online dashboard using a traffic light system. This allows the customer to track the status of their monitored bridges and components.

Figure 9 Failure forecast method applied on the monitoring data. Areas for the traffic light result grading system are marked.

#### 5 SUMMERY

The system solution RISE by TÜV AUSTRIA was presented as an acoustic emission monitoring tool for railway steel bridges. The acoustic emission monitoring system is able to detect and monitor cracks. Based on the failure forecast method, a statement can be made about the condition of the monitored component and after several months of measurement a further prognosis when the maximum utilization of the component is reached.

Two field examples were used to demonstrate how RISE could support the ÖBB bridge inspectors. A field case for identification of a suspected crack at the monitored component of interest was shown. After the detection of the crack a forecast for remaining time, until the maximum utilization time of the component, was done. In the second case a hot spot monitoring

was shown. Where the component was monitored to make sure that it was in good condition and no crack activity was present.

The system helps the infrastructure operators and bridge inspectors to plan maintenance intervals, repairs and new reinvestments measures for ageing bridges. This saves the infrastructure operator costs and reduces the man-hours required for monitoring. The examples showed that the system can be installed easily and in a short time. The monitoring does not require any major interventions and the installation can often be carried out while the bridge is in operation. The results and recommendations for the customer can be made available via an online dashboard using an easy-to-understand traffic light system.

In addition to the numerous monitoring projects already carried out on railway steel bridges, further bridge monitoring projects are planned with the help of which RISE can be established as an indispensable tool in bridge inspection and a helpful addition to the classic periodic inspections.

<sup>2</sup>ÖBB-Infrastruktur AG, Lassallestraße 5, 1020 Wien, Austria

email: michael.behm@geodata.com, michael.brauner@oebb.at

**ABSTRACT:** We demonstrate the practical feasibility of assessing geotechnical parameters of rail infrastructure based on ‘dark fiber’ distributed acoustic sensing (DAS) recordings using trains as sources. A workflow to image the shallow (3 m – 20 m depth) subsurface in terms of shear wave velocity has been established. The shear wave velocity distribution is obtained from inversion of seismic surface waves excited by the trains and recorded on the fiber optic cables, and is used as a proxy for the geotechnical strength (e.g., shear modulus). Our results allow for the interpretation of potential geologic hazards and other features relevant for assessing the geotechnical integrity of rail infrastructure. This approach does not require dedicated field measurements or interruption of the train schedule, and therefore represents a cost-effective and robust method for different application scenarios.

**KEY WORDS:** DAS, hazard, infrastructure, rail, near-surface geophysics

## 1 INTRODUCTION

Shallow geologic hazards such as washouts, karstification, liquefaction, or mass movements pose risks to rail infrastructure and operations. Additionally, the stability of artificial rail embankments may be affected by poor consolidation or external influences such as extreme weather events or neo-tectonic activity. While the conventional near-surface geophysical toolbox provides a range of suitable investigation methodologies, their application to rail networks is challenged by the train operation schedule and the potentially large spatial extent.

In recent years, Distributed Acoustic Sensing (DAS) performed on existing fiberoptic cable infrastructure (‘dark fiber’) has become a widely used approach for seismic subsurface imaging and monitoring (Li et al, 2022). As many rail tracks are equipped with fiber optics for telecommunication purposes, and trains are sources of abundant seismic energy, the method is potentially well suited for seismic subsurface imaging below rail tracks (Hernandez et al., 2023; Fuchs et al, 2018).

We present a case study from Austria (Europe), where DAS registrations of commuter trains along a 6.5 km long rail track section were used to image the shallow subsurface. A workflow comprising data selection, seismic interferometry, and advanced MASW (multi-channel analyses of surface waves) techniques resulted in almost continuous coverage of the shear wave velocity ( $V_s$ ) in the depth interval ~3 m - ~20 m. The results were validated against conventional MASW data and existing geologic/geotechnical information.

## 2 METHOD

DAS measurements provide strain or strain rate variations along a fiberoptic cable with potentially high resolution and accuracy. Dynamic strain variations are an expression of dynamic medium deformations, and therefore DAS data can be considered as first-order proxies to seismic wavefields. Seismic processing techniques can be used to model and characterize the subsurface in terms of shear wave velocity ( $V_s$ ) distribution which is indicative of geotechnical properties (e.g., shear modulus). Our workflow starts with geometrical calibration of the DAS recordings and selection of recording periods which

include trains. In a next step, the seismic interferometry method (e.g., Wapenaar et al., 2010, and references therein) is applied to reconstruct surface Rayleigh waves propagating in-between individual DAS channels and is used to synthesize virtual shot gathers for each channel. Those shot gathers are subjected to a proprietary MASW workflow (Xia et al., 1999) with emphasis on improving the S/N (signal-to-noise) ratio and taking advantage of the dense spatial sampling capabilities of DAS (Guan et al., 2024). The final output is a continuous 2D-model of the shear wave velocity distribution  $V_s$  below the rail tracks.

## 3 DATA, PROCESSING, AND RESULTS

The used fiber optic cable is installed in a hard-plastic protective tubing which runs inside a large concrete duct, therefore poor ground coupling is to be expected. Several loops and partial re-routing of the cable required careful geometrical calibration. A Febus A1 interrogator (Febus, 2025) was used for the measurement. Aiming for compromise between resolution and S/N ratio, the gauge length and channel spacing were chosen as 2 m and 0.8 m, respectively, such that finally 8,751 channels were recorded along the 6.5 km long section. The total recording length cumulates to ~7 h, during which time 29 commuter trains were registered with a temporal sampling rate of 2 ms, resulting in a data volume of ca. 370 GB. The trains are short (3 – 6 carriages) and operate with low speed (~70 km/h). From the continuous recordings, we only use short time windows around the train arrivals which contribute to ca. 5% of the entire data set.

The MASW workflow aims at deriving  $V_s$ -depth profiles at a nominal spacing of 5 m which are interpolated into continuous 2D models (Fig 1). The average frequency range for the retrieved surface waves is ~7 Hz - ~16 Hz. Due to partially insufficient fiber-ground coupling and re-routing, 70% of the section could be imaged continuously (Fig. 1). The resulting  $V_s$ -models were verified against conventional active source MASW profiles, geological and borehole information, and CPT logs. Overall, those different methods support the results obtained from the seismic imaging workflow.

The results allow for the interpretation of weakened embankment zones and shallow potential geologic hazards. A suspected small-scale mass movement is indicated by

Figure 1: Concept and result of the seismic processing workflow applied to DAS-data. Passing trains excite seismic surface waves (green wiggles), which are recorded at existing fiberoptic telecommunication cables (yellow line). The recorded seismic waves are inverted for the shear-wave (S-wave) velocity structure below the fiberoptic cable. Zones of low S-wave velocity (pale/purple colors) are interpreted for reduced shear strength and thus reduced geotechnical integrity (e.g., weakened embankments). Velocity variations at larger depths are indicative of lithological inhomogeneities.

significantly decreased velocities, and a known large-scale fault zone with the potential for neo-tectonic reactivation correlates with low velocities at larger depths.

#### 4 CONCLUSIONS

We have developed an efficient and robust workflow for imaging potential geologic hazards along rail tracks from seismic waves excited by trains and recorded on existing fiber infrastructure. This approach does not require dedicated field measurements or interruption of the train schedule. It can be used for large-scale mapping of entire rail networks as well as for time-lapse monitoring of selected and potentially hazardous sections. The methodology might also be applied to roads using vehicle noise as seismic sources.

**ABSTRACT:** Coda Wave Interferometry has been used in Geophysics to detect weak changes in scattering media. Past research in Structural Health Monitoring has shown that this methodology can be applied to concrete structures to detect material changes by calculation of relative velocity changes. Successive measurements with embedded ultrasonic transducers provide a repeatable signal for reliable long-term monitoring of concrete. To research the application in real-world structures, we have embedded ultrasonic transducers in a bridge in Ulm and a Metro station in Munich, Germany. This study gives an overview of the monitoring of these two structures. The results show the potential and challenges of the method. Data evaluation can be largely automated to gain insights into material changes and other influences on the structure, such as traffic-induced load and temperature variations. The experiments demonstrate the ease of installation, longevity of the sensor installation, and sensitivity of the measurement technique, but highlight problems with the application, especially if electromagnetic noise affects data quality. As no confirmed substantial damage was recorded during the monitoring period on both structures, we evaluate load tests to investigate the effect of static load on the structures and the coda monitoring results. The experiments show that the influence of load can be detected, even if the temperature influence is not removed from the data. This indicates that online damage detection with coda monitoring is possible, but further research on damage detection in real-world structures has to be conducted to confirm laboratory findings.

**KEY WORDS:** Active Ultrasound Measurements, Coda Wave Monitoring, Embedded Transducers

## 1 INTRODUCTION

Coda Waves – multiply scattered late-arriving seismic waves – have been studied in seismology for decades. Beginning with Keiiti Aki's work in 1969 [1], where he developed a method to determine the seismic moment of earthquakes from coda waves the analysis of these waves has since evolved as a valuable tool for understanding subsurface properties. In *Coda Wave Interferometry* (CWI), the medium acts as an interferometer, combining the scattered waves originating at a source at the receiver [2]. This enables the detection of small velocity variations in a material volume with a limited number of sources and receivers. These changes are often not detected by analyzing the direct wave. Applications of CWI include the detection of stress, temperature, and damage-related material alterations across multiple scales.

The heterogeneous composition of concrete allows the application of CWI in infrastructure as most structures are composed of concrete. Planès and Larose [3] have summarized the applications of CWI in concrete, including sensitivity to thermal fluctuations and stress-induced changes via the acoustic-elastic effect. Their following work has also shown the potential of localizing change with a sensor network [4], highlighting the potential of CWI for monitoring changes in large concrete structures. Their sensitivity-kernel-based approach leverages the spatial sensitivity of coda wave measurements, which allows analysis of different volumes of material with a limited number of measurements and sensors.

These advancements and the necessity of constant coupling for long-term monitoring have initiated the design of special

embedded piezoelectric transducers [5]. To further investigate the potential of concrete damage assessment by coda waves on the micro and macro scale, a DFG funded research group (FOR 2825) has combined modelling, simulations, laboratory experiments, and applications of CWI in large structures [6] using these transducers.

This publication intends to give an overview of two monitored structures, the applied technology, and key findings with their implications for future wider application of CWI-Monitoring to ensure early damage detection in infrastructure and support authorities and infrastructure owners in the process of long-term maintenance and infrastructure planning. The monitoring of large structures poses unique challenges as influences of temperature, traffic-induced load, and other external factors are detected with CWI. These factors must be taken into account to isolate indicators of material degradation. In this context, we will present results from monitoring a road bridge in the city of Ulm and a subway station in Munich. At both structures, retrofitted transducers have been used to monitor material degradation and environmental influences for several years. Therefore, they are representative specimens for analyzing the potential of CWI monitoring.

## 2 METHODOLOGY

### 2.1 Active Ultrasonic Measurements and Coda Wave Interferometry

For active CWI measurements in concrete, ultrasonic waveforms are consecutively recorded as time series  $u_1(t)$  and  $u_2(t)$ . When a pulse is emitted at the source, elastic waves travel through the medium and are scattered at inhomogeneities (e.g.

grains) or reflected at boundaries (e.g. concrete-air boundary). Therefore, when recording several milliseconds of signal after emission of the pulse, a waveform consisting of the direct wave travelling between source and receiver and later arriving scattered and reflected coda waves is recorded (for a sample waveform, see section 2.4, Figure 3). Changes in the medium (e.g. cracks) change the wave propagation and therefore the recorded waveforms. To detect such waveform changes, the basic measure for signal comparison is the *correlation coefficient* ( $-1 \leq CC \leq 1$ ), calculating a measure of signal similarity on a time window  $[t1, t2]$ . A decrease of CC indicates a change in wave propagation but is not linked to a specific physical property of the material.

Changes in the material affecting the bulk or shear modulus, directly influence the propagation velocity of P- and S-waves respectively. Therefore, CWI evaluates velocity changes, by analyzing phase shifts in the signals. The standard method for this analysis is the stretching technique [7], where the first signal is time-stretched to align with the second. The following equation describes the calculation of a velocity change using the stretching technique [3]:

$$\begin{aligned} & \operatorname{argmax}(CC(\varepsilon)) \\ &= \frac{\int_{t_1}^{t_2} u_1[t(1 + \varepsilon)]u_2[t]dt}{\sqrt{\int_{t_1}^{t_2} u_1^2[t(1 + \varepsilon)]dt \int_{t_1}^{t_2} u_2^2[t]dt}} \end{aligned} \quad (1a)$$

$$\varepsilon = -\frac{dv}{v} \quad (1b)$$

By varying the stretching factor  $\varepsilon$ , the correlation coefficient in equation (1a) is maximized. The maximizing stretching factor corresponds to the relative velocity change (equation 1b) between the recording of  $u_1$  and  $u_2$ . To analyze spatially localized changes, CC and  $\varepsilon$  can be evaluated on different time windows  $[t1, t2]$ , which corresponds to different sensitivities described by sensitivity kernels (see [8]).

For CWI in monitoring a reference needs to be chosen to determine the baseline. After choosing the baseline, all material changes altering wave propagation in a structure can be tracked by repeated ultrasonic recordings given source and receiver position and coupling do not change. In practice, several different approaches for choosing the reference exist, depending on the magnitude of change and the minimum threshold of CC that allows a reliable analysis of velocity change. If the medium is influenced by non-permanent environmental changes, the reference can be kept fixed, (fixed-reference technique), making a comparison to the baseline timestamp straightforward. Other methods change the reference constantly, e.g. the stepwise reference method [9] or a rolling reference method [10]. The velocity change can be referenced to the baseline as well, but the correlation coefficient is not referenced to the baseline anymore. The rolling reference method is especially advantageous in practical monitoring scenarios, as the reference lag can be adjusted based on external influences such as temperature or known stress variations, thereby improving the robustness of the velocity change estimation over time.

## 2.2 Sensors and Sensor Installation

Figure 1. ACS S0807 (red square) prepared for retrofit with a grouting cap, prepared for the desired installation depth (left) and attached to the rebar before concreting (right).

For long-term monitoring of real structures, it is essential to ensure constant coupling. Therefore, cylindrical piezoelectric P-wave transducers (type: S0807, dimensions: length 72mm, diameter 20mm) described in [5] and developed in cooperation with Acoustic Control Systems (ACS) are designed to be embedded in concrete, either attached to the reinforcement before concreting or retrofitted in an existing structure (Figure 1). In retrofit applications, the structure is evaluated with Ground Penetrating Radar (GPR) before drilling to avoid damage to rebars and tendons. The sensors are then placed within the borehole and regouted using reusable grouting caps.

These transducers can function both as sources and receivers, converting electrical signals into mechanical vibrations (elastic waves) and vice versa. In a sensor network, a typical configuration involves a source transducer emitting waves with one or several transducers acting as receivers (pitch-catch configuration). These roles can be interchanged, so source transducers can become receivers. With a bandwidth between 50 and 100 kHz, the transducers combine the possibility of analyzing direct waves for a large transducer distance with the high-frequency scattering properties required for CWI. Therefore, they are well suited for long-term structural health monitoring of concrete structures.

## 2.3 Measurement Devices

For monitoring with CWI, a custom measurement device was developed, as described in [11]. The device (Figure 2) is based on a Raspberry Pi and is capable of measuring one sensor combination every 5-10 seconds. The core component, the Raspberry Pi serves as the control unit, addressing the measurement PCBs, data storage, and transmission.

The system includes a power and pulse board that can send a 300Vpp double rectangular pulse to up to 75 multiplexed channels. The signal is then digitized and saved on the Raspberry Pi. The modular design of the measurement board allows the addition of temperature and humidity sensors to track environmental parameters.

The measurement device has shown that it can produce good data quality compared to a commercial system based on a NI-DAQ Mx and Keithley Multiplexer as described in [12]. The major advantage of the commercial system is the measurement

repetition rate. Therefore, it is used in experiments where fast dynamic changes in the medium require quick data collection.

Figure 2. W-Box, custom made CWI Measurement device based on a Raspberry Pi.

#### 2.4 Ultrasonic Measurements – Direct Wave and Coda

Figure 3. Two ultrasonic signals were recorded at a bridge in Ulm, Germany comparing the commercial US data acquisition device and the self-made W-Box. (a) The direct wave and (b) an excerpt of the coda.

Figure 3 shows two signals recorded with the W-box and the commercial data acquisition system in November 2021 and December 2021. In the direct wave (a), small amplitude differences are visible, primarily due to the different resolutions of the systems (14-bit vs. 16-bit). Despite this, the waveforms align closely. This supports the use of the slower W-box for long-term monitoring, supplemented by the faster commercial system when higher temporal resolution is required.

Figure 3 (b) shows an excerpt of the coda. A small shift can be detect, caused by temperature variations. During the time between the two displayed measurements, the temperature at the bridge decreased by approximately 3.5 degrees. This shows the sensitivity of the coda. The influence of temperature on the ultrasonic velocity measured by CWI has been researched, e.g. in [13] and quantified at around 0.03-0.06 percent per Kelvin,

which varies depending on the investigated structure. The onset of coda waves is a gradual transition. Even after the first arrival in figure 3, high energy reflections are recorded until 1.5 ms. Nevertheless, at this time the recordings do already include scattered coda waves. Therefore, the evaluation window for CWI has to be chosen individually for every source receiver pair after analysis of the wave recording.

### 3 MONITORED STRUCTURES

In the past years, we have instrumented two structures with the embedded ultrasonic transducers and recorded data with the W-Box. The recorded signals are directly uploaded to a database, where the signals can be analyzed (e.g. CC analysis) or requested for further evaluation through a MySQL API in Python.

#### 3.1 Gänstorbrücke Ulm

Figure 4. Sensor installation at 'Gänstorbrücke', Ulm. 20 sensors are installed in an array in the centre of the bridge (marked with red dots).

In 2020, 24 Ultrasonic transducers were embedded in the 'Gänstorbrücke' bridge in Ulm to monitor damage to the structure under constant traffic between the cities of Ulm and Neu-Ulm, Germany. The sensors were installed in the abutment and the center of the bridge (Figure 4). The bridge, designed by Ulrich Finsterwalder, is a 96m prestressed concrete structure, composed of two parallel partial structures with two slabs per partial structure. Of the 24 sensors, 20 were installed in the centre of the bridge in a single slab. Prior to the installation of the CWI monitoring system, the bridge was instrumented with a commercial monitoring system including acoustic emission, strain sensors, and temperature sensors in 2018 [14], after significant damage was detected to ensure safe operation until demolition and reconstruction in 2025.

To further evaluate CWI monitoring capabilities, in 2021, a static load experiment was conducted using a 15t and a 32t

truck to evaluate the behaviour of the bridge under a substantial load and the influence on coda waves. The monitoring system remained operational from 2020 until February of 2025 to test the longevity of the sensors as well as the signal quality. Over the five years of monitoring, no additional permanent damage was recorded on the bridge by the commercial monitoring system, confirming the stability of the bridge and the reliability of the monitoring systems.

### 3.2 Metro Station Scheidplatz Munich

Figure 5. Sensor installation at ‘Scheidplatz’, Munich.

The ‘Scheidplatz’ metro station in Munich, Germany opened in 1972, just before the Munich 1974 Summer Olympics. On the surface of the metro construction, several tramways and bus stops are located. As a result, the ceiling structure is subject to constantly varying loads due to public transport activity. To monitor the crack behaviour and load variations caused by passing and stopping tramways, 15 sensors were embedded in the ceiling in 2022 (Figure 5).

The brittle outer layer of the ceiling made overhead regrouting difficult. As a result, two sensors have bad coupling to the structure, leading to reduced signal quality. Nevertheless, they are still operational. Therefore, surface inspection is advised before retrofitting sensors, to devise the suitable regrouting technique. Besides the monitoring aspect, the installation was a pilot run for the W-Box and the installation procedure in an environment with significant electromagnetic noise.

Figure 6. Temperature (top) and CWI velocity change at Gänstorbrücke for the first half of 2024. The color of the scatters represents the correlation coefficient.

## 4 MONITORING RESULTS

### 4.1 Gänstorbrücke Ulm

Since its installation in 2020, the monitoring system has remained operational with only a few periods of downtime caused by instrument failures and network problems. Neither the coda monitoring system nor the commercial acoustic emission monitoring system recorded significant new damage during this period. This shows that the measures taken to preserve the bridge until reconstruction were sufficient.

The data quality throughout the entire monitoring period is consistently good. A minimal number of measurements were influenced by electromagnetic noise, which can be eliminated by frequency analysis. Without any new damage in the monitored area, we cannot make conclusions about the ability to distinguish damage from environmental influences in a real-world monitoring setup, however.

Nevertheless, the dataset provides valuable insights to assess the requirements for a real-world monitoring setup. Especially temperature changes cause strong signal decorrelation. Figure 6 shows the temperature and the relative velocity change of a representative transducer pair for the first half of 2024. During this time the temperature ranges from  $-10^{\circ}\text{C}$  to nearly  $30^{\circ}\text{C}$ . The velocity change was calculated on the first three milliseconds of the signal, thus investigating both, the direct wave and the coda, using the fixed reference method. Figure 6 shows a clear correlation of temperature and velocity change, particularly visible in the trough in January 2024. The relation between temperature and velocity change is linear, as shown in [15]. For ‘Gänstorbrücke’ we estimate a change of  $-0.025$  percent per Kelvin.

The color scale in Figure 6 indicates the correlation coefficient. When CC remains high, the results of the fixed reference CWI can be interpreted reliably. This is only valid for small temperature variations ( $\pm 10^\circ\text{C}$ ). In summer, the correlation coefficient decreases significantly, causing outliers and jumps in the results, which cannot be physically interpreted due to the strong decorrelation.

To improve the robustness for a long-term analysis, one could shift to the stepwise or rolling reference CWI. However, preliminary analyses of the ‘Gänstorbrücke’ dataset have shown that this does not significantly improve the interpretation of the long-term trends. Furthermore, these methods require more computational power and time. Given the focus on detecting short-term permanent change (i.e. damage) we propose to analyse the data in short rolling time windows while tracking the temperature to define a corridor of expected velocity change induced by temperature. To this purpose, a linear regression model is trained using temperature measurements and corresponding calculated velocity changes. This model allows the prediction of temperature induced ‘normal’ velocity changes. Based on the root mean square error (RMSE) of this model, a corridor can be defined indicating the velocity change attributed to temperature change with a certainty of 95%. This corridor can serve as a threshold for outlier detection and enable the automatic detection of no temperature induced changes.

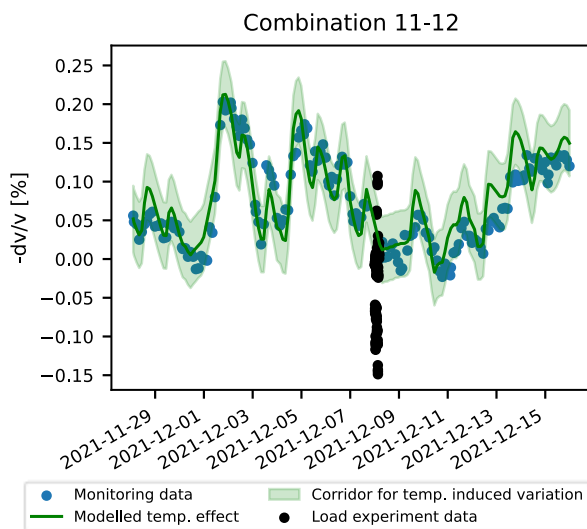

Figure 7. CWI velocity change in December of 2021. The temperature effect on the velocity change is modeled and a corridor of expected temperature induced velocity change is calculated. The data from the load experiment is highlighted in black.

Figure 7 shows this method for a three-week period in December of 2021, the time of the static load test. As the load test represents the largest known mechanical disturbance to the structure during the monitoring period, it serves as the best representation of damage-induced changes. A detailed analysis of the load test can be found in [15]. One can see that the linear model of temperature-induced velocity change fits well for the analyzed period. Using the fixed reference approach, CC

remains above 0.65 throughout the analysed subset. The temperature changes in these weeks were below  $\pm 10^\circ\text{C}$ . The permanent monitoring data is represented with blue scatters and the load test data is highlighted using black scatters.

One can see in Figure 7, that the velocity change induced by load is of the same magnitude as the change induced by temperature. Nevertheless, as the temperature model gives a corridor of expected change, the outliers can be detected. Combination 11-12 is a sensor combination with a minimum distance to the nearest loading point of 10 meters. Importantly, as during the load test, the bridge was not loaded all the time, the datapoints at unloaded measurements are within the temperature corridor. For sensor combinations located closer to the load application points, stronger deviations were observed (see [15]).

With the results of the load experiments, we show that for permanent monitoring a windowed approach can be beneficial for damage detection. Although no new damage was detected, the results show the capabilities of monitoring using CWI and embedded sensors. Key conclusions of this long-term experiment are:

- Data quality remains consistent with embedded transducers, although temperature variations have a big influence on the signals.
- The fixed reference method cannot be applied over long periods, even if no damage has been recorded.
- The load-induced perturbations can be detected within the temperature trend, even if they are of similar magnitude.
- A short window, fixed reference approach enables fast automated data analysis, and potentially allows for edge computing on site, while allowing for the detection of perturbations in the temperature trend.

#### 4.2 Metro Station Scheidplatz Munich

Since the sensor installation in 2022, signals have been continuously recorded at 10-minute intervals at ‘Scheidplatz’. This cycle reveals results indicating general increasing and decreasing trends in relative velocity change, which are attributed to temperature variations inside the concrete ceiling.

From February 24th to March 13th, 2023, the measurement frequency was increased to one measurement per minute to determine whether it was possible to study the structural behaviour following a transient load. In this case, the transient load was induced by tramways stopping directly above the sensor array. The total load of these tramways varies depending on the vehicle type, ranging from 560 kN to 722 kN, distributed over three or four axles. The results of March 18<sup>th</sup> are displayed in Figure 8.

During this period, the overall change in  $dv/v$  was approximately 0.20%, primarily attributed to temperature variations. Additionally, multiple frequent relative velocity drops of approximately 0.02% were observed, which generally recovered to their original values within 10 to 15 minutes.

These relative velocity drops were caused by the transient loads exerted by the passing tramways. Tramway operations conclude at approximately 1:15 AM; however, some relative velocity drops were detected even after this time. This is likely due to tramways passing through the station without stopping as they transit to the depot.

Figure 8. Relative velocity change. Velocity drops visible after the tramway stops above the sensor array.

This confirms that both stopping and passing tramways induce velocity drops in the structure. Previous experiments with CWI in 4-point bending tests [16, 17] have shown that velocity changes are predominantly negative. While we expect an increase in velocity in the pressure zone due to an increase in bulk modulus, the tension zone is dominant, especially in cracked specimens, causing a velocity drop with increasing load. As the installed structure is already cracked, the opening of cracks with load contributes to the velocity decrease. The observed velocity drops are reminiscent of the time-dependent nature of rock healing [18], and similar applications to assessing damage in concrete materials through slow dynamics [19]. To examine potential long-term variations in the relaxation processes of the structure, high-temporal-resolution measurements were repeated a year and a half later. This test was conducted from October 18th to November 7th, 2024, this time, the signal quality was significantly degraded. Additionally, we conducted controlled experiments by positioning a tramway stationary above the sensor array and regulating the passage of tramways to analyse their impact on the recorded signals.

Upon reviewing the data, it was evident that, starting in September 2024, electromagnetic noise levels had abruptly increased. This increase did not coincide with maintenance work on the electrical network, making the source of the noise not identifiable. Since then, data quality has deteriorated considerably, as illustrated in Figure 9, to the point where the recovery curves can no longer be extracted as in previous periods.

Various low-quality data rejection strategies were implemented based on waveform characteristics such as amplitude, duration, and signal-to-noise ratio (SNR). However, while these strategies were successful in filtering out the low-quality data, the remaining usable waveforms were insufficient for a detailed

slow dynamics analysis. Alternative approaches involving frequency filtering were explored, but in this case, the frequency bandwidths of the ultrasonic signals and the electromagnetic noise overlapped, rendering this method ineffective. The measurement device was inspected, confirming that it was not the source of the recorded noise. While poor sensor coupling or cable damage has not yet been ruled out, further investigation is necessary to determine the exact cause of the signal degradation. To prevent similar interference in future implementations of this method, it is recommended to monitor and mitigate potential sources of electromagnetic noise, such as maintenance work on nearby electrical networks, and to establish shielding or filtering techniques that preserve signal integrity.

Figure 9. Representative pre-processed waveforms with good quality (Top) and low quality likely due to electrical noise (Bottom).

## 5 CONCLUSION AND OUTLOOK

The presented CWI monitoring experiments show the potential and challenges of application in real world structures.

**Installation:** Embedding sensors either in existing structures or previously to casting the concrete is an easy way to ensure coupling and longevity.

**Data quality:** The measurement devices and cables must be tailored to the monitoring situation. In high electromagnetic noise locations like metro stations, data quality can suffer. An increased measurement repetition rate, or on-site rejection of ‘bad’ measurements can improve the data quality, but better shielding of cables and the measurement device can avoid data quality problems and ensure a seamless dataset.

**Data evaluation:** Temperature influences the data evaluation strategy. The influence depends on the individual structure and the location of the monitoring system. If long-term monitoring is the goal of the installation, temperature must be monitored. To display long-term trends, advanced methods like the stepwise method must be applied, but its benefits have to be evaluated individually. If the data is only evaluated on shorter time windows, the fixed reference method suffices, and corridors can be defined allowing automated outlier detection. This accelerates the calculation of results, enabling data analysis on-site, with online and automated monitoring results.

**Detection of changes not induced by temperature:** The target of CWI monitoring is the detection of irreversible change. Previous research has shown that CWI analysis can detect e.g. cracking [16] or alkali silica reaction [20], and can potentially monitor all material altering damage processes in concrete. In this study, we have shown the influence of traffic and load, which must be accounted for to distinguish between reversible changes and material degradation. Combining traffic/load monitoring with CWI could improve damage detection reliability. Furthermore, the analysis of recovery curves after repeated loading, as explored in the ‘Scheidplatz’ experiment, suggests the potential for damage state assessment. This aspect requires further controlled laboratory research.

The presented experiments and the datasets offer a strong foundation for further research. In February of 2025, shortly before the decommissioning of the ‘Gänstorbrücke’, a tendon was deliberately cut, and the effects of its destruction were monitored closely with CWI. This dataset provides the opportunity to further determine the detection and localization capabilities of CWI in real-world structures. Additionally, monitoring continues at ‘Scheidplatz’, where further experiments targeting damage assessment under repeated controlled loading can be conducted once electromagnetic noise issues are resolved. The continuous monitoring gives the opportunity to confirm laboratory experiments showing the potential of damage detection using CWI [4, 16, 20].

## ACKNOWLEDGMENTS

The Authors would like to thank the cities of Ulm and Neu-Ulm for their support in monitoring the ‘Gänstorbrücke’, as well as the Stadtwerke München, for giving us access and support in monitoring the ‘Scheidplatz’ subway station.

## FUNDING

The authors would like to thank the DFG for funding DFG FOR 2825 CoDA and the German Federal Highway and Transport Research Institute (BASt) for funding the instrumentation of the ‘Gänstorbrücke’ (Project 89.0345/2022).

**ABSTRACT:** Computational meshes serving as input to wave simulations are often crafted manually and bear a significant cost to construct. The aim of this work is to minimize that overhead and apply it to structures lacking models and meshes, particularly in earthquake-prone regions, to image and monitor their structural health in response to ground movement. To address this challenge, we have developed a workflow to facilitate the creation of 3D finite element meshes, starting with 2D photos acquired by an inexpensive consumer-level unmanned aerial system (i.e., a drone). After photo acquisition, the process proceeds by utilizing computer graphics and vision software to transform these photos into a 3D surface composed of triangles. Surface meshes are generally sufficient products for other workflows that likewise create 3D assets via reconstruction methods (e.g., for topographic mapping, archiving, and entertainment). However, to simulate waves through complex structures with high fidelity, we employ a spectral element wave solver, which requires a 3D volume composed of hexahedra. The steps from a 3D triangular surface to a 3D hexahedral volume include enclosing the surface, conditioning, and remeshing it with appropriate element geometry. We apply a first version of this workflow to the Contra (Verzasca) dam in Switzerland, from which we discuss key stages, challenges, and learnings in developing the pipeline – showcasing elastic wave simulation through the constructed mesh.

**KEY WORDS:** Photogrammetry; UAS; UAV; Gridding; Meshing; Numerical modelling; Geophysics; Seismology.

## 1 INTRODUCTION

Seismological research focused on understanding the behavior of complex media and structures to ground motion requires the use of computational meshes, which permit the physical world to be discretized in order to numerically solve the wave equation. These meshes must be constructed in a way that not only honors structural topography and field parameters, but also maintains efficiency, preserves the physics, and upholds numerical stability requirements dictated by grid size, frequency, and velocity parameters [1,2]. When no compatible computational mesh or model exists for the object or area of interest, a mesh must then be constructed from scratch. This is an arduous task for geoscientists, being a bottleneck for those wishing to focus their attention on imaging the Earth and likewise on deriving insights from the non-destructive testing of engineering structures and their responses to earthquakes.

A proposed solution to this challenge is a workflow that incorporates the use of unmanned aerial vehicles (i.e., UAVs, unmanned aerial systems (UASs), or drones) along with computer vision and graphics software to process the imagery and generate meshes for wave propagation and seismic research problems. Significant advances in hardware (e.g., digital cameras, GPS, drone portability, etc.) have opened the door to more flexibly capture thousands of images without resorting to expensive equipment, non-trivial calibration methods, and the use of priors (e.g., camera settings, motion, etc.) [3-6]. This lower barrier to entry has furthermore been complemented by improvements in key computer vision algorithms (namely, Structure-from-Motion and Multi-View Stereo) which now make it practical to reconstruct 3D surface models from these thousands of images using a high-end laptop or modest workstation [7].

We develop a first iteration of this workflow and apply it to the Contra dam located in the Verzasca valley in southern Switzerland, whose results we present. This structure and its surroundings have no known mesh, making it an ideal candidate to qualify whether it is possible to generate a useable mesh with minimal effort via these off-the-shelf and improved technologies.

## 2 WORKFLOW AND RESULTS

### 2.1 Methodology

The workflow to generate a computational-ready mesh for input into a spectral element wave solver, as applied to the Contra dam, is as follows:

- 1) identifying the object or area of interest
- 2) survey design
- 3) photo acquisition
- 4) color calibration
- 5) surface model generation
- 6) surface model enclosing
- 7) conditioning and layer additions
- 8) hexahedral remeshing
- 9) populating field parameters

We now proceed in the following paragraphs to describe these steps in further detail.

#### 2.1.1.a Identifying the object or area of interest

The Contra dam is selected as a test candidate, given the fact that it lies within a seismically active region and lacks a mesh for itself and its surrounding environment. Located near the city of Locarno, it is embedded in somewhat steep mountain flanks with outcropping metamorphic synfolds [8,9]. At the time of acquisition, the dam was undergoing maintenance with the

reservoir (Lago di Vogorno) drained to allow for an acquisition of not only the dam, but also the lakebed topography leading into the dam. The field site is presented in Figure 1.

Figure 1. (top left) Location of the Contra dam zoomed out and in respect to the city of Locarno to its southwest. The light teal line represents 5 km. Lime lines are mapped faults. (top right) A zoomed view of the area, as taken from swisstopo, with the dam near the center and the reservoir Lago di Vogorno behind. The lime polyline to the right of the dam is the edge of a mapped fault. (bottom left) A terrain map of the field site. (bottom right) A reconstructed orthophoto overlay revealing the drained lakebed.

#### 2.1.1.b Survey design

Data are collected with significant overlap among the photos such that common features could be identified. We achieve this by flying at different heights and by also adjusting the camera's angle. For the drone, we choose the DJI Mavic Air 2, retailing for under 1000 USD. With a field-of-view of 84° and given a fixed  $f/2.8$  aperture with equivalent focal length of 24mm, this brand of drone gives us the flexibility to acquire photos from seven meters or greater to achieve a reasonable depth of field, which is vital in the later step of identifying common features among the fore-, mid-, and backgrounds. In terms of acquisition paths, we opt for circular and linear hyperlapse defaults as found within the drone's support software. We do not use ground control points or calibration tables.

We additionally plan and coordinate with the dam operators and Locarno air traffic control prior to and during acquisition.

#### 2.1.1.c Photo acquisition

During a period of three hours, we pilot a Mavic Air 2 drone and use its camera to acquire 1143 images at 12 MP (4000 x 3000 MP). We select a shutter speed of 1/640 s and a 100 ISO

setting due to sunny conditions. A subset of the acquired photos is given in Figure 2.

Figure 2. Various photos of the dam and lakebed as taken from a drone.

#### 2.1.1.d Color calibration

Having acquired the photos on a sunny day over a few hours, we observe inconsistent lighting (Figure 2). As this may hinder mesh reconstruction [10], we apply basic post-photo processing to correct for various degrees of whiteness, brightness, and moving shadows.

#### 2.1.1.e Surface model generation

Multiple photogrammetry software options (WebODM, Meshroom, RealityCapture, and Metashape) are evaluated in terms of their speed, accuracy, ease-of-use, functionality, and of particular concern, ability to reconstruct 3D surface meshes with minimal topological issues (e.g., holes). RealityCapture (RC) and Metashape perform the best, with RC having the added benefit of being free. However, RC only runs on Windows and requires an Nvidia CUDA GPU. But due to clever memory management, RC does not require significant amounts of RAM. Metashape can run on Linux, Mac, and Windows, with RAM demands scaling with number of 2D photos. We move forward with a 3D surface mesh created in Metashape on a 16-core CPU/40-core GPU M3 Max MacBook Pro laptop with 64 GB of unified memory shared between the CPU and GPU. The photogrammetry process of importing photos, to feature matching, to image alignment, to the eventual mesh generation, decimation, and smoothing requires less than thirty minutes to complete.

#### 2.1.1.f Surface model enclosing

To perform 3D wave simulations using the spectral element method, we require a volumetric mesh and not a surface mesh. Our workflow uses a specific implementation of the spectral element method called Salvus [11], which requires a mesh either composed of hexahedra if solving 3D wave solutions or quadrilaterals for 2D problems. The reason for this is to exploit a fundamental benefit of using spectral element methods for wave propagation modelling: 2D quads or 3D hexes result in a diagonal mass matrix and thus trivialize inverting the mass matrix [11-13]. Given the 3D nature of our dam, we take the 3D triangular surface mesh from 2.1.1.e and extrude the mesh outwards and downward before sealing the base, thus creating

a watertight 3D surface mesh. This is accomplished using Blender, a free and open-source 3D computer graphics software package [14].

#### 2.1.1.g Conditioning and layer additions

Before converting the 3D enclosed surface mesh of triangles into a 3D volumetric mesh of hexes, we further correct for any additional topology issues using Blender's 3D sculpting tools and then remesh the surface into quads. Any unhandled spikes or non-physical geometries may result in bad elements (with small or negative Jacobians – i.e., squished elements) which would render subsequent wave simulations infeasible. And the reason for converting from triangles to quads is that the next step more robustly remeshes when given a quad surface. Once satisfied with the mesh, we add a water layer on top.

#### 2.1.1.h Hexahedral remeshing

The surface mesh is then transformed into a volumetric hexahedral mesh using Cubit, a meshing software tool developed to create tetrahedral and hexahedral meshes for finite element analysis and fluid dynamics [15]. To preserve the topography of the dam and the surface, we choose an element size of approximately 2.5 m x 2.5 m x 2.5 m. Based on results at this stage, an iterative process takes place by returning to 2.1.1.d to further improve the quality of this mesh. We accomplish this by conditioning the surface mesh in a manner that prevents Cubit from outputting volumetric meshes containing elements with a small Jacobian, as these elements are unphysical or dimensioned smaller than desired. A smaller element size dictates a decrease in timestep, which adversely increases simulation time and memory requirements. Results from steps 2.1.1.e to 2.1.1.h are presented in Figure 3.

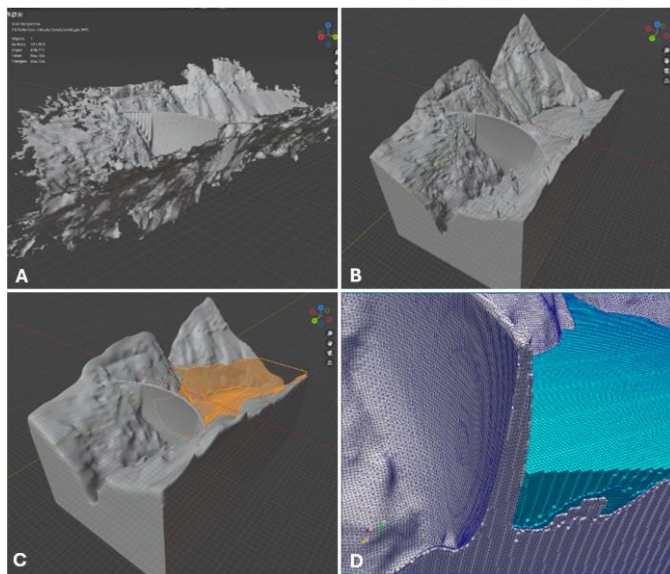

Figure 3. (A) displays the 3D surface mesh output as described in section 2.1.1e; (B) is the result of enclosing that surface mesh as detailed in section 2.1.1f; (C) shows a despiked and smoother version of (B) with the inclusion of a water layer in orange as noted in section 2.1.1.g; and (D) is an arbitrary slice through the hexahedral mesh, with bedrock and dam in gray and the water layer in blue as discussed in section 2.1.1h.

#### 2.1.1.i Population field and simulation parameters

To qualify the mesh, we must populate it with elastic field parameters. We use a homogeneous compressional velocity of 4800 m/s, shear velocity of 2800 m/s, and density of 2710 kg/m<sup>3</sup> for the basement bedrock and dam. The water layer is given a sonic velocity of 1500 m/s and density of 1000 kg/m<sup>3</sup>.

#### 2.2 Simulation

The prepared mesh can now be used as input to the wave solver. For illustrative purposes, we initiate a 130 Hz Ricker spherical explosive point source (i.e., the curl of displacement is zero in an elastic homogeneous model). Dirichlet boundary conditions are assigned to the water-air, dam-air, and basement-air interfaces, and absorbing boundaries are placed on the other outer faces. Snapshots in both 2D and 3D are showcased in Figure 4. The mesh thus succeeds in allowing a solution to the wave equation, thus validating the workflow for this use case.

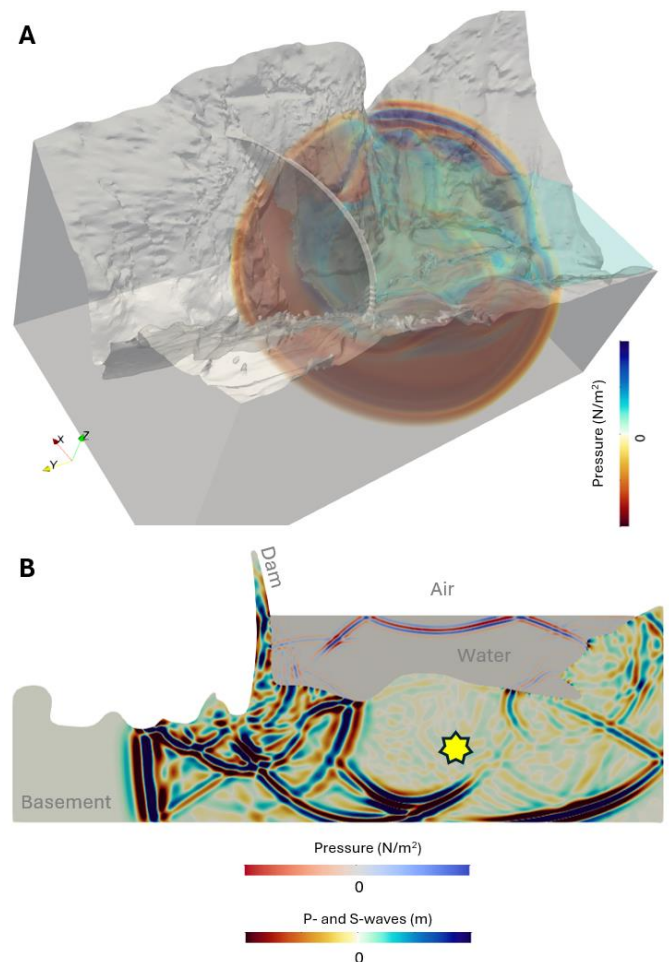

Figure 4. (A) shows a snapshot of an acoustic wavefield successfully propagating through the 3D mesh created from a drone photo acquisition. (B) is a slice through that 3D model at a later timestep to showcase various wave modes propagating through different media and structures in the model due to a point source activated at an earlier time at the location given by the yellow star. Waves within the water column are measured in pressure, whereas within the basement and dam they are given in terms of compressional and shear wave particle displacement.

### 3 DISCUSSION

#### 3.1 Alternative acquisition methods and inputs

Though the workflow emphasizes the use of drones to acquire photos as input, this is not a requirement. In fact, a LiDAR system, a phone camera, and other capture methods and tools could be employed – each with its own trade-offs [7]. We also consider the use of satellite imagery to construct a usable mesh. Unfortunately, it does not yield the necessary 3D detail or resolution to faithfully recover the dam and surrounding topography – which are paramount in ground motion studies [11,16,17]. Furthermore, satellite imagery is unable to capture complex 3D surface structures such as the dam's overhang. Figure 5 compares surface meshes created from various satellite sources to that generated from drone imagery.

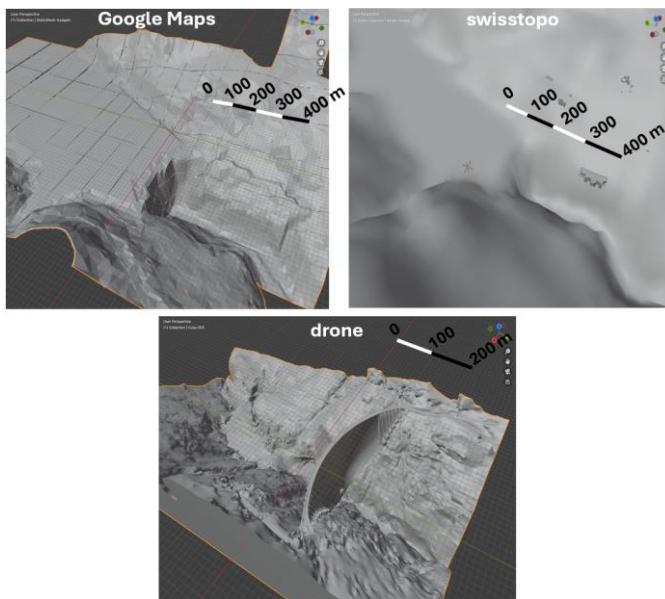

Figure 5. A comparison of different surface meshes created using satellite imagery input from Google Maps and swisstopo to that generated from drone imagery. There is added serendipity in having acquired the drone footage during dam maintenance. Meshes are displayed in perspective view.

#### 3.2 Seismic hazard and risk analysis

We now have a beneficial workflow that substantially reduces the burden of constructing meshes. This leaves us with ample time to prioritize our focus on other problems within seismology. One of these problems includes quantifying ground shaking and its impacts on the environment.

As an example, we may now compute ground acceleration in our model and hypothetically venture to assess the risk of structural failure. For this demonstration, we simulate two different rupture sites at the dam and note the acceleration values that the dam and the bedrock (basement) may experience, as given in Figure 6. Analyzing the wavefields further would allow one to compute peak ground acceleration (PGA) values as input to probabilistic hazard and risk calculations [18]. As can be observed, ground motion values are amplified and dampened by many factors, including the topography, orientation of the rupture mechanism, and the presence of air or water at an interface.

Figure 6. Magnitude of ground acceleration from two different sources, with snapshots taken near peak acceleration within the dam region for each scenario. Earthquake rupture location is indicated with a star, along with its orientation. The source at (A) is located farther from the dam and is underneath a water layer with smoother topography. (B)'s source lies closer to the dam below an air interface with rougher topography.

### 4 CONCLUSION

We provide a workflow outlining how images acquired from drones can be leveraged to create hexahedral meshes that may serve as input to wave simulations, successfully applying it to the Contra dam in Switzerland. The workflow has many steps, all of which may be readily accomplished by performing minor tweaks to off-the-shelf technologies. For situations where no computational mesh exists, acquiring the photos may take no more than a day or two – and in our case three hours. Given proficiency with the tools in the workflow, the simulation-ready mesh may be created in under a week, which marks a substantial improvement to the process of manually creating these meshes over the course of months. Nevertheless, some manual work is still required to make the mesh physics-ready – though this may be greatly reduced by spending more time upfront with the survey design to ensure the object of interest is properly photographed. Selecting photogrammetry software tools which are more robust to poorer acquisitions may further aid the process.

The way forward includes further workflow automation and determining how to more adaptively discretize the mesh such that we use fewer elements. Ideally, we envisage employing this methodology on structures lacking computer models, including historical structures in earthquake-prone regions. Up to this point, we have described a forward modelling process in response to a source. Naturally, using ambient or active vibrations to then invert for 3D elastic field parameters and possibly detect time-lapse changes at intermediate scales within such structures would be among the next steps to investigate.

**ABSTRACT:** Differential settlement in ballasted railway tracks, particularly in transition zones between two track forms, poses a critical challenge for railway infrastructure. Such settlement, often exacerbated by a stiffness gradient due to changes in track superstructure and substructure, typically causes a local dip in the longitudinal track level a few metres from the transition, leading to higher dynamic traffic loading and reduced passenger comfort. Regular monitoring of transition zones is essential for safe operations and cost-effective maintenance. This paper reviews methods for monitoring differential settlement in railway tracks. To measure the properties and loading of the superstructure, potential methods include fibre Bragg grating (FBG) sensors, point receptance measurements, track geometry (and track stiffness) recording cars, and wheel load impact detectors (WILD). Characterisation of the subgrade can be carried out via a multichannel analysis of surface waves (MASW), dynamic cone penetration tests (CPT), interferometric synthetic aperture radar (InSAR), frost sticks for temperature monitoring, and total stations. Lessons learned from an in-situ measurement involving an extensive FBG-based system deployed in northern Sweden to monitor a transition zone in harsh weather conditions are presented. Integrating a combination of monitoring methods with a simulation model to verify and support the accurate prediction of differential settlement is a useful approach to addressing challenges associated with track stiffness gradients and guiding the improvement of transition zone designs.

**KEY WORDS:** Differential settlement, railway transition zone, condition monitoring, fibre Bragg grating sensors

### 1 INTRODUCTION

In transition zones between two different railway track forms, there is a discontinuity in the track structure, resulting in a gradient in track stiffness. Examples include transitions between different superstructures, such as slab track to ballasted track, and/or between different substructures, such as an embankment to a bridge or tunnel structure. Differences in the cyclic loading and supporting substructure on either side of the transition may lead to differential settlement of the ballasted track and an irregularity in longitudinal rail level soon after construction due to densification of ballast and consolidation of the subgrade layers. This results in an amplification of dynamic traffic loading along the transition, contributing to the degradation process of the foundation and further deterioration of the vertical track geometry. Historically, the design of transition zones has aimed to minimise the difference in track stiffness between the ballasted track on the embankment and the engineering structure [1–4].

Some researchers argue that the main causes of track deterioration in transition zones are the non-uniform stiffness and damping between different layers of subgrade materials, which are impacted by variations in moisture and other geotechnical factors [5,6]. In a field test conducted in Sweden [7], it was observed that the displacement of sleeper ends varied significantly from one sleeper to the next due to differences in support conditions. This highlights the importance of ballast and subgrade conditions in a railway network.

Various transition zone designs have been implemented to mitigate variations in loading and support conditions. Many of these solutions aim to achieve a gradual and smoother variation in track stiffness from one track form to another. Some approaches are designed to enhance the support of the subgrade, such as transition wedges and approach slabs, while others focus on the superstructure, including the

implementation of track components such as wider sleepers, auxiliary rails, and elastic pads (including conventional rail pads with varying stiffness along the transition zone and/or under sleeper pads). A review of transition zone designs can be found in [5,6]. In parallel, advancements in real-time data acquisition, computational techniques, and the emergence of 'big data' approaches have enhanced the analysis and modelling of railway degradation, facilitating more comprehensive and precise evaluations [8].

Increasing frequency of traffic, higher axle loads and train speeds result in quicker deterioration of the infrastructure. Infrastructure managers need up-to-date information on both the current condition (diagnosis) and the expected future state (prognosis) of their assets to effectively plan maintenance and renewal efforts. Structural health monitoring (SHM) has emerged as a valuable tool for railway systems, enabling efficient asset management by providing real-time feedback on the condition of various components. By facilitating early damage detection, SHM enhances structural reliability and reduces life cycle costs. Condition-based maintenance means that system operators schedule maintenance based on the actual condition of the system and the anticipated deterioration rate. To achieve this, operators need to employ a monitoring strategy for recording the condition of their assets. The collected data can serve to develop or create regulations, such as acceptable condition thresholds [6], which are used to determine if maintenance should be performed.

### 2 LITERATURE REVIEW

Emerging sensing techniques, along with innovations in sensors and data analytics, present exciting opportunities in geotechnical, structural, and railway engineering to enhance the understanding of infrastructure performance during both construction and operation. A monitoring system could, and

perhaps should, be integrated into the construction package to facilitate long-term, proactive operational monitoring, thereby contributing to quality control, maintenance, resilience against hazards, and reuse. Such a system should include techniques capable of capturing a wide range of data, ranging from low sampling rate parameters such as temperature, humidity, moisture, settlement, and inclination to high sampling rate data including acceleration, noise, rotation, wind velocity, and more.

In railway engineering, monitoring techniques can be categorised into trackside monitoring of both geotechnical and structural elements, onboard monitoring, and inspection. Trackside monitoring involves the use of instrumentation in or adjacent to the track to monitor the track, vehicles passing by, or the interactions between them [9]. For the track, this includes observing the status of various track layers, their geometry, and how they evolve over time [10]. Examples include assessing the condition of ballast and subgrade using methods such as ground-penetrating radar (GPR) [11] and cone penetration tests (CPT) [12]. GPR uses electromagnetic waves to scan and map subsurface features within the railway industry, offering geospatial data on subsurface conditions [13]. To evaluate the stiffness and stratification of the layered substructure at a test site, a multi-channel analysis of surface waves (MASW) can be used [14]. Furthermore, fibre optic sensors can be embedded in the track bed to monitor settlement and detect early signs of degradation and potential landslides in the embankment [15,16]. Research has also been conducted on technologies capable of accurately monitoring the average settlement of railway lines over extensive areas using synthetic aperture radar (SAR) and interferometric SAR (InSAR) techniques [17].

On the other hand, onboard track monitoring and inspection are generally carried out using in-service vehicles, as their regular passing over longer sections of track allows for efficient monitoring of track status. Onboard component monitoring is carried out by instrumentation on vehicles, evaluating their condition over time. Dedicated vehicles are equipped with advanced equipment that enables in-depth inspections, which are vital for railway safety. However, these vehicles require special scheduling and trained personnel, limiting their usage [18]. Measurement units on these vehicles use technologies such as laser imaging, image processing, GPR, ultrasonic sensors, vibration sensors, high-precision accelerometers, and electromagnetic sensors.

Several in situ investigations utilising trackside monitoring have been conducted to assess the dynamic behaviour of railway track using instruments such as accelerometers, strain gauges, and displacement transducers. In [19], results were presented from an extensive monitoring campaign of transition zones (embankment to culvert) in the Netherlands. Vertical displacement at various depths of ballast and subgrade, axle load, and average track stiffness were measured using geophones, uniaxial accelerometers (within the ballast), triaxial accelerometers (within the soil below the track), strain gauges, and a high-speed camera. It was concluded that voided sleepers in the transition zone, due to long-term differential track settlement, were the main sources of large track displacements that caused increased impact loading and accelerated track degradation. Zuada Coelho et al. [12] used CPT and borehole data to consider stochastic variations in support conditions on

a network scale in the Netherlands when predicting track settlement using a two-dimensional model.

In [20], a track deflection and stiffness survey was carried out using micro-electro-mechanical-systems (MEMS) accelerometers. About 80 of these devices were placed on successive sleeper ends, primarily on the field side of the track, and then moved along the site during consecutive night-time possessions. This was done in two batches of 200 sleepers with an overlap of 50 sleepers, and measurements were repeated three months apart [21]. Additionally, a webcam mounted on a telescope was positioned at 6 m from the track to reduce the influence of ground vibration. It captured an image of the target, which was mounted on the sleeper for the measurement of peak-to-peak displacement. A key limitation of this method was that the video recording system could monitor the displacement of only one or two sleepers at a time.

Optical fibre sensors offer significant advantages over conventional and other smart sensors due to their high sensitivity, small size, and potential for short- and long-distance measurement. For example, Wang et al. [22] attached two FBG sensors on the rail web as a bi-directional device to measure longitudinal force in a high-speed railway line. Temperature compensation via calibration tests was conducted. Wheeler et al. [23,24] measured rail strains using Rayleigh backscattered, distributed optical fibre sensors. Their field test instrumentation included a 7.5 m long section of rail with nylon-coated single-mode fibres installed on the rail web at 20 mm and 155 mm from the bottom of the rail. The measured rail strains were used to determine shear forces, which, together with the known static wheel loads, were employed as part of the calibration to determine the rail seat loads for 14 consecutive sleepers as the train traversed the instrumented track. These data were then combined with measurements of dynamic rail displacement captured through high-speed imaging using digital image correlation (DIC) to process the rail seat load–deflection relationships for each sleeper.

On-board monitoring techniques have been investigated in research and used in infrastructure management [25]. This leads to better maintenance planning and reduces the delay between decision-making and the execution of maintenance actions. For example, in Finland, ballast degradation due to traffic and freeze-thaw cycles, leading to further particle breakage, settlement, or heaving, has been investigated using track geometry recording cars [26]. In Sweden, vertical track geometry degradation between 1999 and 2016 has been studied using regular monitoring by track geometry recording cars [27,28]. Furthermore, in Switzerland, an on-board monitoring policy is considered in infrastructure maintenance planning [29], and similarly in Australia [30].

This paper presents a review of methods and challenges associated with monitoring of differential settlement in railway transition zones. Specifically, it discusses the results and lessons learned from an extensive measurement campaign conducted under harsh conditions on a heavy haul line in northern Sweden. These measurements included both short-term dynamic and long-term static responses of the transition zone in different sleeper bays, using an FBG-based sensor setup and complementary measurements.

### 3 MONITORING AND MEASUREMENT METHODS

Monitoring in a railway transition zone may involve numerous sensor types and measurement techniques, such as seismic, electrical, electromagnetic, and resistivity methods in geophysics. Brief descriptions and definitions of some of these are presented below. In Section 4, the practical use of many of these techniques will be discussed with reference to the challenges encountered during an extensive field test recently carried out in a transition zone on Malmaban in northern Sweden.

#### 3.1 MASW

The Multi-channel Analysis of Surface Waves (MASW) method is a cost-effective and non-destructive geophysical technique used to evaluate subsurface conditions (and to determine the location of bedrock) by analysing the propagation of surface waves, particularly the dispersion of Rayleigh waves. It provides shear wave velocity profiles down to a depth of up to 20 m, which are used to obtain small-strain stiffness and damping properties of the soil [31].

In this specific field test, an excitation source, such as a sledgehammer, weight drop, or specialised loading device, generates surface waves. An array of geophones, typically ranging from 12 to 48, is placed in a straight line on the ground at regular intervals. These geophones detect and record the waveform and arrival time of the seismic waves. The Rayleigh waves exhibit dispersion, meaning their velocity changes with frequency due to variations in subsurface material properties. Lower-frequency waves penetrate deeper into the ground, while higher-frequency waves provide information about shallower layers [31]. Typically, earth models are formulated using CPT data to distinguish the number of soil layers and provide a reasonable estimation of soil density. Consequently, shear wave velocity is fitted to the data at smaller strains.

#### 3.2 CPT

The Cone Penetration Test (CPT) is a geotechnical investigation technique to provide a detailed soil profile by assessing the mechanical cone resistance of different layers of subgrade soils. The cone resistance is directly linked to the strength of the soils, and empirical relations are established to identify the soil type [32]. The data obtained from a CPT aids in designing track foundations, evaluating ballast and sub-ballast layers, and identifying soft soil layers that could lead to settlement or instability [32]. However, the density of data per square kilometre in railway infrastructure is generally relatively low due to the high cost of these boreholes [12].

The test is conducted by jacking or driving a steel cone into the ground at a controlled rate while continuously measuring cone resistance. Two primary types of CPT are used: Static Cone Penetration Testing (SCPT) and Dynamic Cone Penetration Testing (DCPT). In SCPT, the cone is jacked into the soil at 1 – 2 m intervals at a constant rate using a hydraulic system. This method records key parameters such as (1) cone resistance, which indicates soil strength, (2) sleeve friction, which helps to determine soil type, and (3) (excess) pore water pressure, which provides insights into soil drainage and consolidation behaviour. SCPT is frequently used in railway infrastructure to investigate embankment stability.

In DCPT, a steel cone is driven into the ground using a standardised weight dropped from a specified height. The number of weight drops required to penetrate a specific depth is recorded, providing an estimate of soil resistance and compaction quality. DCPT is widely utilised in ballast and subgrade assessment, as well as rapid evaluations of soil stability [32]. The data from CPT or MASW tests can be used to estimate dynamic subsoil stiffness and damping along the track using analytical approaches, such as the cone method from [33] and the analytical formulae in [34].

#### 3.3 GPR

Ground-Penetrating Radar (GPR) is a non-destructive electromagnetic geophysical technique used to investigate and analyse subsurface structures. These systems can be mounted on track geometry recording cars, enabling continuous data collection at operational train speeds. This allows infrastructure managers to efficiently assess large sections of the track network and make data-driven decisions for maintenance planning. GPR operates by emitting electromagnetic waves (EM) into the ground and measuring their reflections using a receiving antenna to identify issues such as ballast fouling, moisture intrusion, and subsurface voids, as these can be linked to changes in electrical impedance [13]. GPR functions within a finite frequency range where the velocity and attenuation of the EM wave are independent of frequency (typically 1 MHz – 1 GHz) [13].

The receiving antenna captures the reflected signals, and the system measures the time delay and amplitude of these reflections. This data is then processed and visualised in radargrams, in the form of black-and-white, or coloured, waves and patterns, each corresponding to the radar signals reflected by different underground materials. These radargrams enable engineers to analyse subsurface conditions, detect hidden defects, and determine the thickness of different layers. The frequency of the radar waves plays a critical role in determining both the resolution and depth of penetration. High-frequency waves, typically above 1 GHz, provide detailed images but can only penetrate shallow depths, making them ideal for inspecting ballast conditions. Lower-frequency waves, in the range of 100 – 500 MHz, penetrate deeper but offer lower resolution, making them more suitable for analysing subgrade and deeper structural layers. Water-saturated or clay-rich soils tend to absorb radar waves, limiting penetration, while dry, coarse materials like gravel or sand allow for better wave transmission [13].

#### 3.4 InSAR

Interferometric Synthetic Aperture Radar (InSAR) is a remote sensing technique that uses satellite-based radar imagery to measure ground surface deformation with millimetre-level precision. By analysing the phase differences between radar signals captured at different times, InSAR provides detailed information about land subsidence, uplift, and ground movement [32,35]. The precision of this technique is of the order of 3 – 5 mm.

#### 3.5 FREE AND FORCED VIBRATION

Point receptance analysis in railways is a testing technique used to assess the dynamic properties of track by measuring its response to applied forces. A sledgehammer with a steel tip, or

a falling weight of 8 kg, has been used in free vibration tests to generate an excitation impulse on the rail [36]. In a forced vibration test, a hydraulic actuator generates linear frequency sweeps with constant load amplitudes to stimulate various natural frequencies of a structure, such as a bridge [37]. The resulting accelerations are recorded using accelerometers or laser Doppler vibrometers at different positions, and the data is processed to compute Frequency Response Functions (FRFs). Measured FRFs can then be compared with corresponding calculated FRFs from a simulation model to identify the stiffness and damping of different parts of the structure [38].

### 3.6 PERMANENT DISPLACEMENT, SETTLEMENT

Various tools and instruments are available for measuring and monitoring settlement in track layers. These include the Multi-Depth Deflectometer (MDD), which is embedded in the track bed, uniaxial and triaxial accelerometers [39], settlement plates paired with total stations, vibrating wire-based measurement systems, liquid level sensors, inclinometers, Linear Variable Differential Transformers (LVDTs), Global Navigation Satellite Systems (GNSS), and FBG sensors.

The MDD is specifically designed to assess the mechanical response and deformation of soil layers. It is widely used at railway track sites to evaluate soil stiffness and condition. Primarily, the MDD serves as a reliable tool for accurately measuring the permanent deformation of different pavement layers. Additionally, it facilitates the calculation of the effective elastic moduli of multilayered pavement structures based on the collected data [40].

The LVDT is a displacement sensor used to detect linear movements in both the short and long term. It is commonly applied in railway infrastructure to monitor the displacement of components, such as sleepers, rails, bridges, and slabs [15].

A total station is an advanced electronic and optical instrument designed for precise measurement of angles, distances, and coordinates. In railway applications, it plays a crucial role in ensuring accurate track alignment, calculating gradients, and maintaining track conditions by detecting deviations and elevation changes [15].

The GNSS utilises satellite signals to determine the position of objects on Earth. It operates through a network of orbiting satellites that transmit signals to ground receivers, which process the timing and strength of these signals to compute position, altitude, and velocity. In railway systems, GNSS is used for continuous real-time monitoring of track settlement, enabling a better understanding of foundation changes at different stages and enhancing railway safety [41,42].

### 3.7 BALLAST INSPECTION

Ballast degradation occurs when fine materials or fouling agents accumulate in the spaces between ballast particles. This fouling can result from ballast fragmentation, contamination from external elements, or the infiltration of fines from the subgrade soil. Over time, as ballast continues to age, it becomes increasingly affected by fouling and degradation due to particle breakage and surface wear. These processes contribute to inadequate drainage, excessive settlement, track misalignment, and diminished lateral stability, all of which negatively impact railway track performance. In severe cases, excessive ballast degradation can lead to operational disruptions and safety risks [43]. Assessing ballast conditions typically involves visual

inspections, manual measurements, and field sampling, which is often followed by sieve analysis. Additionally, automated methods such as the Ballast Scanning Vehicle (BSV) have been introduced to enhance evaluation processes. The BSV is capable of capturing field ballast images, video footage, and 3D height maps from both plan and depth profile perspectives, enabling a thorough assessment of ballast conditions [44].

### 3.8 WILD

Wheel flats and other forms of wheel out-of-roundness can be detected through acoustic or visual inspections, or by measuring vertical wheel–rail contact forces using wheel impact load detectors (WILDs). These detectors help operators monitor force levels, enabling proactive maintenance to prevent excessive wheel out-of-roundness. Commercial WILD systems use various types of sensors, including strain gauge circuits, fibre optic technology for measurements of rail bending, and load cells for rail seat loads [45].

### 3.9 FROST DEPTH

Extreme weather conditions in northern European countries may lead to recurrent issues with freeze-thaw cycles and seasonal variations in track geometry. Frost depth can be measured using frost sticks [15].

### 3.10 TRACK GEOMETRY AND TRACK STIFFNESS RECORDING CAR

Track geometry recording cars are specialised rail vehicles equipped with advanced measurement systems such as laser profilometers, accelerometers, and ultrasonic sensors. Track geometry is evaluated based on band-pass filtered indicators, such as longitudinal level, horizontal alignment, cant, curvature, gauge, and twist. These indicators are assessed based on the specific wavelength intervals defined in EN13848-5, see Table 1 [46].

Table 1. Wavelength ranges according to EN 13848–5[46].

Longitudinal level	Wave type	Wavelength range (m)
D <sub>0</sub>	Short wave	1 – 3
D <sub>1</sub>	Mid wave	3 – 25
D <sub>2</sub>	Long wave	25 – 70

### 3.11 POINT MEASUREMENTS

Strain gauges (traditional or FBG-based), accelerometers, and contact pressure cells [39] are widely used in railway measurements to monitor track and vehicle dynamics, ensuring safety and performance. Strain gauges are installed on rails, sleepers, and train components to assess strain, stress, load distribution, and deformation under varying operational conditions.

## 4 CASE STUDY: THE GRANSJÖ TEST SITE

In 2022–2023, an extensive field measurement campaign was carried out in a transition zone at *Gransjö*, north of Boden, on the Swedish heavy haul line *Malmbanan* [15]. The transition zone was between a conventional ballasted track on embankment and a Moulded Modular Multi-Blocks (3MB) slab track. An FBG-based long-term monitoring arrangement, with a high temporal resolution, was used for both short-term and long-term condition monitoring of the operational railway track in the harsh conditions of northern Sweden. The test set-

up was limited to measuring the response in four selected sleeper bays.

Figure 1. An overview of the test site including a transition zone between ballasted track and 3MB slab track at Gransjö, north of Boden, Sweden.

#### 4.1 TEST SITE

Traffic on the line is dominated by iron ore freight trains with axle loads up to 32 tonnes, operating from the mines in Kiruna and Malmberget to the ports in Narvik and Luleå. The speed of the loaded heavy haul trains is 60 km/h. The line is also used by passenger trains at maximum speed 135 km/h and by other freight trains. The annual traffic load is of the order of 14 MGT (mega gross tonnes).

The track design includes 60 kg/m rails, rail fastenings with 10 mm rubber rail pads, and concrete sleepers designed for axle loads of 35 tonnes at a sleeper distance of 0.6 m. The 3MB track at Gransjö was constructed in September 11 – 15, 2022, as part of the Horizon 2020 Shift2Rail EU project In2Track3. [15]. It was decommissioned in August 2023, see Figure 1.

#### 4.2 GEOTECHNICAL SURVEY

Prior to the construction of the 3MB track, geotechnical tests in the form of CPT and MASW were conducted to determine the stiffness and stratification of the layered substructure. The results indicated that the subgrade at the site consists almost exclusively of moraine, mixed with large blocks of rock, with a maximum depth of 5 m to bedrock [47]. The embankment height varies between 2 and 2.5 m. Due to years of maintenance involving tamping and re-ballasting of the track, the thickness of the ballast layer (nominally 30 cm) has increased to 80 cm. This necessitated additional excavation depth to remove the ballast layer (and large blocks) during the construction of the 3MB slab system.

In the MASW survey [47], the dispersion of Rayleigh waves on the ground surface, acquired using vertical geophones, was used for the interpretation of small strain shear stiffness. See Figure 2 for an example of measured distribution of wave speed in a cross-section of the subgrade at the test site.

Track geometry was measured using a track geometry recording car. For reference, in another study conducted on Malmaban, track geometry car recordings from 1999 to 2016 were analysed to investigate rates of vertical track geometry degradation. This analysis indicated some correlation between track stiffness gradient and differential settlement, providing insights into how variations in substructure stiffness can lead to local track irregularities. As expected, it was concluded that the

settlement rate along Malmaban varies significantly depending on the local conditions and properties of the subgrade. For a poorly supported section of the track, the standard deviation of the longitudinal level (1 – 25 m), evaluated over a 50 m track segment, increases by approximately 1 mm per annum [27,28].

Track stiffness at rail level, measured using the same track geometry recording car before and after construction of the 3MB track, is presented in Figure 3. A large gradient in stiffness is observed at either end of the 48 m slab track. The mean value of the track stiffness is particularly low for the slab track due to the softer elastic pads and the poor compaction of the backfill material after the excavation carried out during construction.

Figure 2. An example of measured shear wave speed distribution of layered soil at the test site [47].

Figure 3. Track stiffness at rail level for ballasted track on embankment, two transition zones, and 48 m of slab track at Gransjö, measured by a track geometry recording car before and after construction. Blue vertical solid lines indicate the positions of two transitions (slab ends). Blue vertical dashed-dotted lines show the positions of instrumented sleepers 3, 5, 8, and 11, numbered from the slab.

#### 4.3 FROST DEPTH AND INSAR

The extreme weather conditions at the test site, with temperatures down to  $-40^{\circ}\text{C}$  during the winter and relatively warm summers, result in recurrent issues associated with freeze-thaw cycles and seasonal variations in track geometry.

The Swedish Transport Administration monitors frost depth using frost sticks, which record the temperature in the subgrade at various levels down to a depth of a few metres, thereby generating a temperature profile. The variation in frost depth over a period of eight months, recorded at a station near the test site, is shown in Figure 4. It is observed that prior to the end of October 2022, the ground was not frozen at all. By mid-December 2022, the ground had commenced freezing gradually down to a depth of 2 m. From mid-December 2022 until the beginning of May 2023 more than 2 m of the ground remained frozen.

Frost penetrating to a certain depth may induce the expansion of the subgrade, resulting in ground uplift. This phenomenon, known as frost heave, poses a significant issue on Malmbanan. To evaluate the average settlement at the test site, InSAR data was used, providing the average settlement over a specified surface area at various times. It was found that the average settlement at a track point near the test site is about 1 – 2 mm per year [31], see Figure 5.

Figure 4. Temperature profile of subgrade down to 2 m depth at a measurement station near the test site [15].

Figure 5. An example of InSAR long-term settlement measurements at a track point near the Gransjö site, covering the period from 2015 to 2021 [48]. Positive settlement numbers indicate downward permanent displacement.

#### 4.4 TRAFFIC LOAD

Information regarding traffic loading is crucial for evaluating railway infrastructure. In this campaign, data from a nearby wheel impact load detector was used to assess the range of mean wheel–rail contact forces for a specific train passage traversing the test site [15].

Additionally, to evaluate the influence of the stiffness gradient and to detect potential voids beneath sleepers, the wheel–rail contact force was measured within the transition zone. Temporary electrical strain gauges were used to measure the contact forces in sleeper bays 3, 5, and 8 from the transition. A Wheatstone bridge comprising two waterproof strain gauges,

each with a sensing area of 6 mm × 2.2 mm, was glued to the neutral axis of the rail within a specified span between two adjacent sleepers, oriented at  $\pm 45^\circ$  relative to the horizontal and vertical coordinate axes, see Figure 6. Shear deformations of the rail web were measured on two occasions, with a six-month interval.

It was concluded that the wheel–rail contact force in sleeper bay 3 was higher than in sleeper bays 5 and 8. The higher load could be attributed to vehicle dynamics when traversing the transition between two track forms with a stiffness gradient and potentially voided sleepers on the ballasted side. Consequently, the greater settlement of sleeper 3 could be a result of the higher loading. Additionally, it was observed that the wheels were generating forces, on average, about 5 kN higher in May 2023 than in October 2022 due to the evolving irregularities in the longitudinal level along the transition. The magnitude of forces derived from WILD data for the same train was consistent with the measured wheel–rail contact forces.

Figure 6. Full Wheatstone bridge mounted on the neutral axis of the rail web

#### 4.5 TRACK FORM DYNAMICS

Vertical point and cross receptances (frequency response functions) of both track forms were measured by exciting the rail using an instrumented impact hammer and recording the track response with accelerometers. The rail was excited either above a rail seat or at the centre of a sleeper bay. Apart from the hammer excitation, the track was in unloaded conditions. Accelerations were measured at locations sufficiently far from the transition to mitigate any boundary effects resulting from the change in track form.

For the ballasted track, see Figure 7, three resonance peaks can be observed in the measured receptance at 30, 290, and 950 Hz. The first peak corresponds to a vertical in-phase vibration of the rail and sleepers, characterised by high damping due to the propagation of waves in the ballast and subgrade. The second peak corresponds to an out-of-phase motion between the rail and sleepers, influenced by the flexibility of the rail pads. The third peak represents the pinned-pinned resonance mode, which is a vertical bending mode with a wavelength twice the sleeper span.

#### 4.6 SHORT-TERM TRACK RESPONSE

The instrumentation setup included sensors for measuring axial rail strains to assess rail bending moment and rail seat load, vertical sleeper displacement, and vertical acceleration at the sleeper ends. The setup consisted of four clusters placed in sections between two sleepers in sleeper bays 3, 5, 8, and 11, numbered from the transition. Each FBG-based cluster consisted of one accelerometer, one displacement transducer, and one strain array with four strain gauges. In total, 30 FBG sensors were installed. Aluminium covers and cable conduits

were added to protect the sensors and cables from mechanical damage and harsh weather conditions.

The interrogator was housed in a heated cabinet to maintain operational temperatures (0 – 60 °C) and positioned near a power source and data connection. Additional site equipment included a field computer, hard drive, junction box, temperature sensors, thermostat, fan, 4G antenna for backup, and a network switch. The interrogator continuously recorded sensors data at a 2 kHz sampling rate, distributing data via a network socket to a computer. A custom LabVIEW-based program, FemtoGateway, processed and stored the data locally before synchronising it with a server at Chalmers.

Figure 7. Magnitudes of measured rail receptances for the ballasted track. Vertical hammer excitation on the rail at midspan. Response measured on the rail at midspan (point receptance shown using a blue line) or on the rail at railseat (cross receptance shown using a red line).

Figure 8. Overview of the four clusters (C1 – C4), and strain sensor numbering for each cluster.

Figure 9. Detail of an instrumented sleeper equipped with a vertical base plate, an L-shaped mechanism, one accelerometer and one displacement transducer.

Axial rail strains were measured using strain gauges at the positions indicated in Figure 8. Based on the measured strains and assuming Euler-Bernoulli beam theory, examples of the evaluated time histories of rail bending moment above sleepers 5 and 11 for part of a loaded iron ore train are shown in Figure 10. Each peak corresponds to a passing axle. It is observed that the rail bending moment above sleeper 11 is higher than that above sleeper 5, indicating that sleeper 11 has softer support conditions. This was confirmed by comparing the corresponding measured sleeper displacements.

Based on the elongation of the displacement transducer, the vertical displacement of the sleeper was measured relative to a fixed anchor embedded deep into the ground (fixed reference), as indicated in Figure 9. Additionally, vertical accelerations were measured using six FBG-based accelerometers. Five of these were placed at the sleeper ends (3, 5, 8, 11, and 31), while one was positioned on the first block on the slab track side.

Figure 10. Rail bending moment above sleepers 5 and 11 along the transition.

#### 4.7 LONG-TERM TRACK SETTLEMENT

Permanent displacements of the track structure were determined by extracting the at-rest positions of the instrumented sleepers from intervals between train passages. The resulting long-term track settlements for sleepers 5 and 11, evaluated over a period of about 11 months, including one winter, are shown in Figure 10. It is observed that the initial settlement rate immediately after the installation of the slab track and transition zone was very high, but it slowed down after a few weeks of traffic. For sleeper 11, there was a reversal in the permanent displacement during the winter due to frost heave.

To verify the trend in measured permanent sleeper displacements, a sleeper level survey was conducted using a Trimble SX12 self-levelling, automatic-scanning total station with an active prism. The survey was carried out on six occasions over a period of ten months. Overall, the long-term sleeper displacement data aligned well with the total station survey results for the ballasted track until the end of December. Subsequently, the relative measurement from the FBG system, which was referenced to a ground anchor, indicated less upward movement of sleeper 5 due to frost heave compared to the total station survey results. This discrepancy may be due to the short (2 m) length of the anchor that did not extend below the frozen ground layers, see Figure 4. To obtain a fixed

reference, longer anchors extending beneath the frozen layers would have been necessary. For sleeper 11, the total station survey results were consistent with the relative track displacement measurements since the anchor length exceeded 4 m.

Figure 11. Evolution of permanent sleeper displacement (settlement) over time for sleepers 5 and 11. Sleeper 5 was tamped after 20 days of operation.

The Swedish Transport Administration utilises frost sticks to monitor frost depth. These instruments are capable of measuring temperature profiles to a depth of a few metres. Based on these measurements it was concluded that the ground remained unfrozen until late October, at which point it gradually froze to a depth of 2 m by mid-December. This depth was exceeded until early May 2023, cf. Figure 4. As air temperatures declined below  $-10^{\circ}\text{C}$  and frost depth exceeded 2 m, sleeper settlement at positions 5 and 11 ceased and initiated a reverse process. This indicated that frost heave was the probable cause of this uplift.

## 5 CONCLUSIONS AND LESSONS LEARNED

In this paper, various methods for measurement and monitoring of differential settlement in railway infrastructure have been reviewed. The case study presented, conducted in a transition zone between ballasted track and a short demonstrator section of 3MB slab track at Gransjö on Malmbanan, aimed to integrate existing data, such as geotechnical surveys and InSAR measurements, with observations from an extensive FBG-based instrumentation system that captured both short-term dynamic track responses and long-term static settlements (permanent displacements) of selected sleepers.

Given the sensor requirements, harsh weather conditions at the test site on Malmbanan, operational railway track with heavy haul train traffic, and budget constraints, FBG sensors were selected. This system reduced the installation time, which was critical due to the narrow installation window during the construction of the 3MB slab track. Another benefit was the simplified routing of optical cables, allowing the interrogator to be placed in a heated cabinet to maintain operational temperatures ( $0 - 60^{\circ}\text{C}$ ), as well as to be near the available power source and data connection provided by the track owner.

FBG-based sensors have a higher initial cost than traditional sensors but offer superior performance, including multiplexing capabilities, reduced installation complexity, and greater durability in harsh environments. Their high sensitivity and immunity to electromagnetic interference enhance reliability, making them a more efficient and sustainable choice for advanced monitoring applications despite the higher upfront investment.

The measured data have been used for a long-term assessment of the transition zone and the new slab track design, as well as for the calibration of track models for further simulation studies [38]. It was concluded that most implemented sensors performed reliably. The FBG-based strain gauges enabled the setup to successfully detect the type of vehicle, train speed, and the number of axles in each train. The spatial and temporal resolution of the observed rail curvature distribution were found to be sufficient for analysing rail bending moments.

A considerable variation in measured displacements between the selected adjacent sleepers in the transition zone was observed. These displacements depend on the initial and evolving support conditions of each sleeper and their distance from the transition. For example, sleeper number 3, located near the transition, became voided shortly after installation, while sleeper 8 appeared to be supported by a very stiff foundation, leading to minimal settlement. Good agreement was observed between the displacement data from the FBG sensors and the total station survey.

Unfortunately, the conditions and available time window during the construction of the transition zone and slab track at Gransjö were far from optimal. The excavated volume of ballast and subgrade was replaced with insufficiently compacted backfill material before the construction of the slab, leading to significant settlement of the slab track soon after installation. Due to the excessive settlement of the slab track, the fasteners on the slab side had to be adjusted to their desired height by sliding shims after 20 days of operation. At the same time, the first six sleepers on the ballasted side were tamped to restore the longitudinal level. Still, the substantial settlement of the slab track continued, albeit at a lower rate. This had a significant effect on the support conditions also for the sleepers near the transition, particularly indicated by the measured short-term displacements and settlement of sleeper 3.

The signal-to-noise ratio of the acceleration data was too low because the delivered accelerometers were designed to measure higher acceleration levels than anticipated, preventing the use of the acceleration data for reconstructing sleeper displacements [49]. This issue could not be resolved, as the sensors were deployed in clusters, and replacing them in the field was not feasible. To address this issue, it is recommended to implement more rigorous quality control tests prior to installation.

Furthermore, based on Euler-Bernoulli beam theory and the measured difference in rail bending moment across the width of the rail pad [23], the plan to evaluate time histories of rail seat loads failed due to inconsistent data from different strain gauges.

The test site was distant from the university, leading to high travel costs in the event that anomalies needed to be addressed during the measurement period. For example, the displacement sensors and anchor arrangements needed adjustments on a few occasions due to the unexpectedly high levels of settlement. The measurements were conducted during winter, with heavy snowfall and low temperatures, which further complicated access to the sensors and made the process more challenging.

Nevertheless, it is argued that the combination of the described FBG-based test set-up (improved with accelerometers with higher signal-to-noise ratio and more

consistent strain data) with existing geotechnical and traffic load data is a powerful approach that can be employed by infrastructure managers to justify, test, and evaluate transition zones and new track designs across their network.

This study has focused on the heavy haul track on Malmaban in northern Sweden, but insights discussed here are relevant to railways operating in other climates. Accurate monitoring of differential settlement in railway infrastructure is a common challenge worldwide, regardless of the type of loading and climate. It is argued that elements of the setup used here will assist infrastructure managers across the network in justifying, testing, and assessing new track designs.

## ACKNOWLEDGEMENTS

The current study is part of the ongoing activities in CHARMEC – Chalmers Railway Mechanics ([www.chalmers.se/charmec](http://www.chalmers.se/charmec)). Parts of the study have been funded from the European Union's Horizon 2020 research and innovation programme in the In2Track3 project under grant agreement 101012456, and the Europe's Rail Flagship Project IAM4RAIL – Holistic under grant agreement 101101966.

email: massimo.penasa@caemate.com, nils.weissenbach@caemate.com

**ABSTRACT:** Aging infrastructure poses significant challenges in ensuring safety, reliability, and long-term serviceability. The Parchi Viaduct, a 3-km multi-span structure on Milan's A51 Eastern Ring Road, experienced critical degradation in its Gerber saddles, necessitating temporary closure for safety assessments. In response, Milano Serravalle Milano Tangenziali S.p.A. and CAEmate S.R.L. deployed an advanced Structural Health Monitoring (SHM) system, integrating distributed fiber optic sensing (DOFS) and a physics-informed digital twin (PINN) to enable real-time load-bearing capacity evaluation and predictive maintenance. This paper presents the implementation of the WeStatiX SHM platform, utilizing DOFS to capture strain, temperature, and vibration data while dynamically updating a finite element model (FEM) through inverse analysis and multi-objective optimization. By continuously refining modal parameters such as natural frequencies, mode shapes, and damping ratios, the system enables early detection of structural anomalies and degradation trends.

The validated digital twin successfully predicted real-world structural behavior, confirming residual load-bearing capacity despite saddle deterioration and supporting the safe reopening of the viaduct under real-time monitoring per Italian NTC standards. Load test results and FEM simulations demonstrated excellent agreement, with taller piers exhibiting ~20% greater deflection, emphasizing pier height's impact on load distribution and deformation patterns. These findings enhance predictive maintenance planning, improve stress redistribution modeling, and contribute to prolonging the structural lifespan of aging infrastructure assets.

**KEY WORDS:** Structural Health Monitoring (SHM); Digital Twin; Distributed Fiber Optic Sensors (DOFS); Finite Element Modeling (FEM); Predictive Maintenance; Artificial Intelligence (AI); Operational Modal Analysis (OMA); Physics-Informed Neural Networks (PINN); Machine learning (ML)

## 1 INTRODUCTION

The Milano Serravalle Milano Tangenziali S.p.A. manages a motorway network with over 400 bridges and viaducts, requiring regular structural assessment to comply with national safety regulations. Increasing traffic loads, environmental exposure, and material aging necessitated the implementation of an advanced Structural Health Monitoring (SHM) system for real-time diagnostics and predictive maintenance.

Following the Ponti Guidelines, the SHM deployment prioritizes viaducts with high traffic volumes, complex configurations, or significant material degradation. The strategy captures structural responses under traffic-induced loading, providing quantitative safety assessments. The network includes various bridge types, many built in the 1960s and expanded in the 1990s, making SHM essential for early damage detection, optimized maintenance, and long-term serviceability.

This paper presents the Milano Serravalle SHM initiative, detailing sensor deployment, real-time data processing, and AI-driven digital twin modeling for viaduct safety assessment and predictive maintenance.

## 2 SYSTEM ARCHITECTURE

### 2.1 Structural Health Monitoring Framework

The SHM system deployed on the Milano Serravalle motorway network provides real-time structural diagnostics by continuously measuring key mechanical and dynamic parameters. It integrates threshold-based evaluation with a data-driven digital twin, ensuring a comprehensive and adaptive approach to infrastructure monitoring.

### 2.2 Threshold-Based Evaluation Approach

Conventional SHM relies on predefined safety thresholds derived from design standards, material properties, and historical data to detect deviations from expected behavior. While effective for early anomaly detection, this method is limited by uncertainties in aging structures, undocumented modifications, and hidden defects such as microcracks and corrosion. To address these gaps, advanced sensor-driven modeling techniques complement threshold-based assessments.

### 2.3 Model-Driven Digital Twin Approach

To overcome static threshold limitations, the SHM system employs a model-driven digital twin that continuously refines structural models using real-time sensor data. A finite element model (FEM) serves as the foundation, integrating as-built documentation, material properties, and initial boundary conditions. However, continuous refinement is essential to align the model with actual structural behavior.

Real-time sensor data from distributed fiber optic sensors (DOFS), MEMS-based accelerometers, and inclinometers is processed in the SHM cloud platform, where inverse modeling techniques, including physics-informed neural networks (PINNs), adjust structural parameters dynamically. This

feedback loop enhances damage detection, predictive maintenance, and risk assessment.

Modal and frequency analysis further refine the model by tracking changes in natural frequencies, mode shapes, and damping ratios, key indicators of stiffness loss, fatigue, or settlement issues. This enables early intervention and cost-effective maintenance planning.

#### 2.4 Multi-Sensor Data Acquisition System

The SHM system relies on a multi-sensor network to capture the structure's response under various conditions. Triaxial MEMS accelerometers facilitate Operational Modal Analysis (OMA) for detecting stiffness reductions. Inclinometers and displacement transducers measure rotations and deflections at critical structural interfaces, identifying foundation movements and misalignment.

DOFS technology provides continuous strain, temperature, and stress distribution data, crucial for detecting localized stress

Figure 2. Logical scheme of the system architecture implemented by Milano Serravalle.

concentrations and thermal expansion effects contributing to material fatigue.

All sensor data is synchronized via satellite-linked data acquisition units (UCLs) and transmitted through fiber optic networks to the SHM cloud platform, ensuring precise temporal alignment for real-time analysis.

### 3 DISCRETE SENSORS

The structural health monitoring (SHM) system deployed across the Milano Serravalle motorway network incorporates a comprehensive array of discrete sensors, each carefully selected to measure critical structural and environmental parameters. The placement and configuration of these sensors were strategically determined based on the structural scheme, constraint conditions, and anticipated mechanical behavior of each viaduct. This systematic deployment ensures that all relevant dynamic, thermal, and displacement-related phenomena are captured with high accuracy and precision.

#### 3.1 Sensor Types and Technical Specifications

A range of high-precision sensors was employed to monitor key structural response parameters, including vibrations, rotations, displacements, and temperature variations. The primary sensor types used in the monitoring network include:

- **Triaxial MEMS-Based Accelerometers:** These sensors are used for capturing dynamic structural response by

measuring accelerations in three orthogonal directions. The accelerometers deployed in this system have a measurement range of  $\pm 2$  g, with a frequency response spanning from 0 Hz to 500 Hz and a spectral noise level of  $\pm 22.5 \mu\text{g}/\sqrt{\text{Hz}}$ , ensuring high-resolution vibration monitoring. Their role is particularly critical for Operational Modal Analysis (OMA), which enables real-time identification of stiffness variations and localized damage detection.

- **Biaxial MEMS Inclinometers:** The inclinometers are installed to measure angular rotations at key structural joints and supports. These sensors feature a measurement range of  $\pm 15^\circ$  with an angular resolution of  $0.001^\circ$ , enabling precise detection of structural tilting, pier settlements, and deformation trends over time.
- **Potentiometric Displacement Transducers:** To monitor relative displacements between structural components, potentiometric displacement transducers were installed at expansion joints and pier connections. These devices have a measurement range of 0–150 mm, with a precision of 0.05 mm, allowing for accurate tracking of longitudinal and transverse displacement variations.
- **High-Sensitivity Thermometers:** Thermal effects play a significant role in structural deformation and stress redistribution, particularly in reinforced and prestressed concrete structures. Thermometers were deployed across critical structural sections, enabling the continuous monitoring of temperature variations. This data is essential for compensating thermal expansion effects in stress analysis and predicting long-term material fatigue due to cyclic temperature fluctuations.

#### 3.2 Sensor Placement Strategy

The placement of sensors was carefully optimized to ensure maximum coverage of structural behavior while minimizing redundancy. In general, accelerometers and inclinometers were mounted along the lateral edges of the bridge decks, with installations concentrated at on-axis sections and quarter-span positions. These locations were selected to provide a detailed characterization of modal behavior, resonance effects, and dynamic loading conditions.

To capture pier behavior and bridge support movements, inclinometers and displacement transducers were positioned at the tops of piers and at expansion joints, where rotational deformations and relative displacements are most pronounced. This setup allows for early detection of differential settlements, support degradation, and abnormal structural movements that could indicate potential failure mechanisms.

Thermometers were distributed across key structural regions, including deck intrados, piers, and expansion joints, ensuring comprehensive thermal profiling. This placement allows for accurate correlation of temperature-induced stresses with real-time displacement and strain measurements.

#### 3.3 Data Acquisition and Synchronization

All sensors were hardwired to a high-speed data transmission network, ensuring continuous and reliable data flow to the central processing platform. The monitoring system employs a satellite-synchronized local control unit (UCL), which manages data acquisition, synchronization, and pre-processing before transmitting the information to the SHM cloud platform.

The optical fiber transmission BUS provides a secure and interference-free data link, enabling real-time sensor readings to be collected, processed, and stored in a structured database. The synchronized nature of this setup ensures that all measurements are precisely time-aligned, allowing for accurate modal and frequency analysis of the structures.

Once collected, the sensor data is integrated with the digital twin platform, where it undergoes automated noise filtering, anomaly detection, and inverse modeling-based calibration. This process allows engineers to rapidly detect deviations from expected structural behavior and implement predictive maintenance strategies.

### 3.4 Role of Discrete Sensors in the Digital Twin Model

The real-time measurements from discrete sensors serve as the foundation for updating and refining the digital twin model. By continuously integrating modal data from accelerometers, rotational data from inclinometers, and displacement readings from transducers, the FEM-based digital twin can iteratively adjust its parameters to match actual structural behavior.

The long-term tracking of temperature variations and displacement trends further enhances the predictive capabilities of the model, allowing for proactive intervention before critical failure conditions arise. As a result, the combination of discrete sensor data and AI-driven model updating enables a high-fidelity representation of viaduct performance, significantly improving the reliability of maintenance planning and infrastructure resilience.

Figure 3. Discrete sensors used: displacement transducers (top), biaxial inclinometer (bottom left), triaxial accelerometer and biaxial inclinometer (bottom right).

## 4 THE “VIADOTTO DEI PARCHI” AND THE DISTRIBUTED FIBER OPTIC SENSORS (DOFS)

### 4.1 Structural Characteristics of the Viadotto dei Parchi

The Viadotto dei Parchi is a critical viaduct on Milan’s A51 Eastern Ring Road. Originally designed by engineer Silvano Zorzi in 1970, the structure features a continuous deck plate integrated with the piers, forming spans of 24 meters. Its design includes a zero-moment point positioned 7 meters from the pier axis, materialized through a Gerber-type saddle system that ensures efficient load redistribution and structural continuity.

The viaduct consists of two parallel structures, each supporting a separate motorway carriageway, with a center-to-center distance of approximately 29 to 30 meters. Extending nearly 3,000 meters in total length, it is one of the longest and most strategically significant bridges within the Milan motorway network.

### 4.2 Structural Expansion and Modification

In 1992, the viaduct underwent a major expansion to accommodate increased traffic demand, adding a third lane to the Eastern Ring Road. The available space between the two existing viaducts allowed for the construction of two additional structures, effectively increasing capacity while maintaining overall structural integrity. However, this intervention introduced engineering challenges, including increased dynamic loads, differential settlements, and stress redistribution between the old and new structures.

Due to the viaduct’s scale and the number of spans, an advanced monitoring system was required to assess its real-time structural performance, particularly in response to dynamic traffic loading, thermal variations, and long-term material degradation. This necessity led to the deployment of a Distributed Fiber Optic Sensor (DOFS) network, providing high-resolution continuous monitoring across the entire structure.

Figure 4. “Viadotto dei Parchi” after the widening in the early 1990s.

### 4.3 Advantages of Distributed Fiber Optic Sensors Over Discrete Fiber Sensors

The DOFS system implemented on the Viadotto dei Parchi represents a significant advancement over traditional discrete fiber optic sensors, such as Fiber Bragg Gratings (FBG). FBG sensors operate through spectroscopic techniques that measure strain at discrete points along the fiber. While useful in localized assessments, they present several limitations, including restricted spatial resolution, installation complexity, and fragility.

FBG sensors are typically deployed in limited chains, resulting in spatial gaps in the monitoring data and reduced effectiveness in capturing localized stress concentrations or progressive deformation. Their fabrication process modifies the fiber optic core, making them prone to breakage, and installation requires precise alignment with specialized equipment, increasing deployment costs and long-term maintenance efforts.

DOFS technology overcomes these limitations by using a continuous optical fiber embedded into the structure with mortar or adhesive compounds. This approach enables uninterrupted, high-resolution measurements of strain, temperature, and mechanical deformation along the entire monitored length. The method ensures superior durability, simplified installation, and greater resistance to environmental degradation, making it a more reliable solution for long-term structural health monitoring.

#### 4.4 Measurement Principles and Data Acquisition in DOFS Systems

DOFS measurements rely on light scattering phenomena that occur within the optical fiber when subjected to external loads. The Brillouin Scattering Effect, a nonlinear optical phenomenon, forms the foundation of the measurement system. By analyzing the Brillouin frequency shift, the system determines absolute strain and temperature variations with high precision.

The system achieves a strain resolution in the micro-epsilon range, allowing the detection of extremely subtle structural deformations. The spatial resolution is adjustable, ranging from a few meters to a few centimeters, depending on the interrogation time and system configuration. Temperature effects are automatically compensated through a dual-wavelength technique, ensuring that strain measurements remain unaffected by thermal fluctuations. A secondary optical fiber within the same system provides independent temperature readings, allowing precise differentiation between temperature-induced expansion and load-induced deformation.

In addition to static strain and temperature measurements, DOFS systems capture real-time structural vibrations, enabling the identification of natural frequencies, mode shapes, and transient dynamic events. Unlike traditional accelerometers, which have bandwidth limitations, DOFS technology measures broad-spectrum vibrational activity with unmatched sensitivity, further enhancing the accuracy of structural assessments.

#### 4.5 Deployment of DOFS on the Viadotto dei Parchi

The DOFS network was installed to maximize monitoring effectiveness across critical structural components. Optical fibers were embedded along both the intrados and extrados of the deck, covering longitudinal stress paths to ensure comprehensive strain tracking. Their positioning was optimized based on FEM simulations, allowing accurate assessment of curvature, bending moments, and stress redistribution.

By integrating DOFS with the digital twin model, the monitoring system provides real-time structural assessments. This integration enables the early detection of microcracking and stress concentrations before they evolve into critical failures. Additionally, long-term deformations associated with creep, shrinkage, and fatigue effects can be tracked, ensuring that maintenance strategies are data-driven and proactive. The continuous monitoring and validation of FEM predictions ensure that theoretical models remain aligned with real structural behavior.

The sensors used in this project were developed as a patented technology by a spin-off company of the Polytechnic of Milan, further enhancing the resolution, reliability, and predictive

capabilities of SHM methodologies employed on the Viadotto dei Parchi.

#### 4.6 Impact of DOFS-Based Monitoring on Structural Management

The implementation of DOFS-based SHM on the Viadotto dei Parchi has significantly improved structural assessment methodologies. The ability to obtain continuous, high-resolution strain and temperature data across the entire viaduct allows for more effective maintenance planning and risk mitigation.

Real-time monitoring enables early detection of evolving structural anomalies, allowing timely intervention before critical damage occurs. By tracking long-term performance trends, engineers can optimize reinforcement and retrofitting strategies, extending the viaduct's service life while reducing maintenance costs. Furthermore, the integration of DOFS technology with digital twin modeling minimizes reliance on costly manual inspections, enhancing efficiency in infrastructure management while ensuring compliance with safety regulations.

Figure 5. Cross section of DOFS fiber arrangement.

#### 4.7 DOFS Findings

The Viadotto dei Parchi serves as a pioneering case study in the application of distributed fiber optic sensing for SHM. The successful deployment of DOFS technology has demonstrated its superiority over traditional discrete sensor networks, providing unmatched measurement resolution, real-time diagnostics, and enhanced predictive maintenance capabilities. The combination of DOFS with AI-enhanced digital twin modeling establishes a comprehensive framework for long-term structural health assessment. By continuously integrating high-fidelity monitoring data into predictive maintenance strategies, this approach sets a new benchmark for SHM in large-scale civil infrastructure applications. Future implementations of similar systems across other critical viaducts will further refine predictive models and improve infrastructure resilience.

## 5 FINITE ELEMENT MODELING AND DIGITAL TWIN TECHNOLOGY

Figure 6. Comparison between real structure and Digital Twin.

### 5.1 The Role of Digital Twins in Structural Health Monitoring

The integration of digital twin technology within the Milano Serravalle motorway network represents a paradigm shift in structural health monitoring (SHM), enabling a continuous, bidirectional exchange of information between the physical structure and its virtual counterpart. These simulation-based digital twins leverage high-fidelity finite element models (FEMs) to replicate the mechanical, thermal, and dynamic behavior of infrastructure assets, allowing engineers to conduct real-time diagnostics, predictive maintenance, and performance optimization.

The development of digital twins follows a phased modeling approach, in which each structural component is incrementally integrated into the model, mirroring the actual construction sequence of the viaduct. This approach ensures that time-dependent effects, such as viscosity (creep), concrete shrinkage, and load redistribution, are accurately accounted for. By incorporating historical construction data, including post-tensioning phases and material aging effects, the digital twin provides a high-fidelity representation of the viaduct's evolving mechanical properties over its operational lifespan.

The thermomechanical behavior of the structure is also explicitly modeled, allowing for the simulation of temperature-induced stresses, expansion effects, and seasonal thermal cycles. This is particularly relevant for large-scale viaducts, where differential thermal expansion between spans can lead to progressive degradation and altered load paths over time.

### 5.2 Finite Element Model Development for the Parchi Viaduct

A comprehensive FEM was developed for the Parchi Viaduct, following standard structural simulation methodologies used in the design and assessment of large-scale infrastructure assets. The model accurately represents the structural geometry, material properties, and support conditions of the viaduct, ensuring that its simulated response aligns with real-world structural behavior.

Figure 7. Parchi Viaduct and its Digital Twin (side view).

The deck, piers, and foundations were modeled using 20-node brick finite elements with quadratic shape functions, which provide a high degree of accuracy in stress and strain calculations. The DYWIDAG bars and post-tensioning tendons were modeled as axially loaded structural elements, ensuring a realistic representation of prestress-induced force distributions.

Figure 8. Parchi Viaduct and its Digital Twin (bottom view).

Given the variable pier heights of the viaduct, multiple models were generated to account for differential stiffness effects associated with varying substructure configurations. The selected pier heights of 7.5 m, 12.5 m, and 17.5 m reflect the actual structural conditions encountered during field inspections. These variations were included in the FEM to ensure accurate modeling of load redistribution effects and differential settlements.

### 5.3 Interaction Between Spans and Load Redistribution Effects

One of the key challenges in modeling the Parchi Viaduct was accurately simulating the interaction between successive spans. The viaduct's Gerber saddle system introduces complex load redistribution mechanisms, requiring nonlinear contact elements to properly model stiffness discontinuities and stress transfer zones.

The interaction between successive spans was simulated using contact elements with linear elastic behavior, which were constrained to react only in compression. This approach captures the realistic load transfer behavior between deck segments, allowing for accurate assessment of bending moments and shear forces (Figure 9).

The original deck structure incorporated a system of longitudinal

and transverse post-tensioning bars, while the widened deck sections utilized 12 additional longitudinal cables, each containing 19 strands of 0.6-inch steel tendons. The interaction between these newly introduced elements and the existing structural components was modeled using tensioned beam-type elements, accurately representing the anchoring effects and prestress redistribution mechanisms (Figure 10).

Figure 9. Model of three adjacent spans of the Parchi Viaduct.

Figure 10. Modelling of the bars and longitudinal tendons within the original and widened deck.

Figure 11. Anchor detail used in the joint area.

#### 5.4 Calibration of the Digital Twin Using SHM Data

To ensure that the finite element model remains an accurate representation of the actual viaduct, the WeStatiX SHM platform employs AI-driven inverse modeling techniques for continuous model updating. The calibration process follows a multi-step approach:

- 1) Initial FEM Validation
  - The FEM is initially validated against historical design calculations and load test results from the viaduct's original construction phase.
- 2) Integration of Real-Time SHM Data
  - Sensor data from DOFS, MEMS accelerometers, and displacement transducers is used to update strain fields, displacement trends, and modal parameters in the model.
- 3) Iterative Model Refinement via AI Optimization
  - A multi-objective optimization framework iteratively refines material properties, boundary conditions, and stiffness coefficients, ensuring alignment with measured structural response data.
  - Physics-informed neural networks (PINNs) are employed to enhance the accuracy of model predictions, particularly in identifying early-stage stiffness degradation.
- 4) Utilization Factor Computation and Structural Safety Assessment
  - The stress state of individual structural components is computed through numerical integration of the finite element stress field.
  - The exploitation coefficient of materials (concrete, reinforcement bars, prestressing cables) is evaluated to ensure compliance with design safety margins and regulatory requirements (Figure 9).

#### 5.5 Structural Joint Modeling and Connection Reinforcement

The integration of widened structural segments introduced new connection challenges, requiring specialized modeling techniques to assess joint behavior and stress redistribution. In the transition zones between the original deck and the expanded deck, beam-type elements were used to model anchor

connections, ensuring that the prestress force transfer was accurately simulated (Figure 12).

Figure 12. Modelling of the anchors used in the joint area.

Additionally, the joints were analyzed under both static and dynamic loading conditions, allowing for detailed assessment of fatigue-induced stress cycles. By incorporating nonlinear contact constraints, the model was able to replicate realistic load transfer mechanisms, ensuring that joint regions remained within safe stress limits under operational loads.

#### 5.6 Structural Monitoring and Digital Twin Utilization for Predictive Maintenance

The calibrated digital twin model serves as a decision-support tool for predictive maintenance, enabling engineers to:

- Simulate various loading conditions and forecast long-term degradation trends.
- Identify structural weaknesses by detecting deviations in modal properties.
- Optimize maintenance schedules by predicting the remaining fatigue life of critical components.
- Ensure regulatory compliance by continuously monitoring stress utilization factors.

By integrating real-time SHM data with FEM simulations, the digital twin enables a data-driven approach to infrastructure management, reducing reliance on reactive maintenance strategies and minimizing the risk of unexpected structural failures.

### 6 POST-PROCESSING OF MEASUREMENTS AND DIGITAL TWIN CALIBRATION

#### 6.1 Dynamic Adaptation of the Digital Twin to Measured Data

A fundamental feature of the digital twin framework employed in the Milano Serravalle motorway network is its ability to dynamically update its properties based on the real-time behavior of the structure. Unlike static numerical models, which rely solely on design assumptions and material properties, the digital twin is designed to minimize discrepancies between theoretical simulations and measured structural response data. This ensures that the computed stress states, deformation patterns, and modal properties of the viaducts reflect their actual in-service conditions rather than idealized design scenarios.

The primary objective of the digital twin calibration process is to ensure that the numerical model accurately represents the structure's response across its entire load history. By continuously refining key structural parameters, the system enhances predictive accuracy and enables early detection of damage mechanisms. Through an automated and iterative

inverse analysis (back-analysis) framework, the digital twin minimizes deviations between sensor-acquired data and finite element simulations, allowing for high-fidelity structural assessments.

### 6.2 Inverse Analysis and Model Calibration Techniques

The real-time calibration of the digital twin is achieved using advanced inverse modeling techniques, which allow for the automated identification and refinement of uncertain structural parameters. The WeStatiX SHM platform implements an iterative multi-objective optimization framework, leveraging surrogate models trained on thousands of numerical simulations to efficiently estimate unknown properties.

The parameters subject to calibration include both linear and nonlinear material characteristics, whose variation over time may indicate the onset of damage or degradation. Some key parameters continuously updated in the digital twin include:

- Elastic and nonlinear material properties (stiffness variations due to progressive damage).
- Time-dependent effects such as creep, shrinkage, and corrosion-related stiffness reductions.
- Boundary conditions and joint behavior changes caused by foundation settlements or bearing degradation.
- Temperature-dependent stress redistributions due to seasonal thermal cycles.

Through inverse analysis, these parameters are iteratively adjusted until the numerical model converges with real-world sensor measurements, ensuring that structural assessments remain highly accurate and reliable (Figure 13)

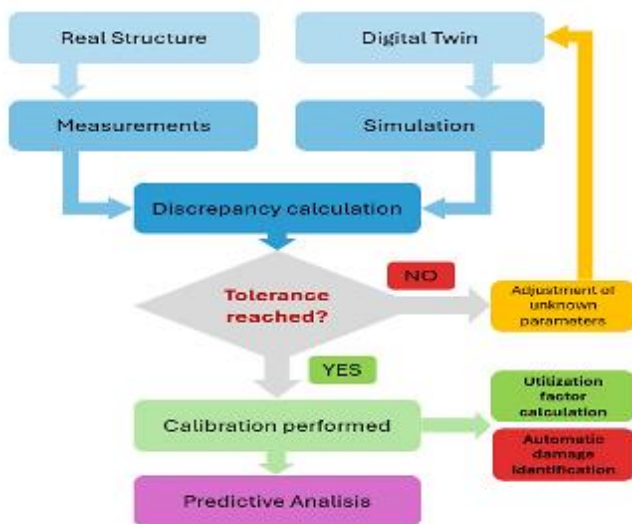

Figure 13. Calibration through inverse analysis.

### 6.3 Operational Modal Analysis (OMA) for Dynamic Parameter Identification

A key component of digital twin calibration is the identification of the structure's dynamic properties through Operational Modal Analysis (OMA). Unlike traditional modal testing, which requires artificial excitation sources such as shakers or impact hammers, OMA leverages the ambient vibrations naturally

present in the structure, such as those induced by wind, traffic loads, and micro-seismic activity.

By processing acceleration data from MEMS-based sensors placed along the viaduct deck and piers, the system is able to accurately determine the structure's modal frequencies, mode shapes, and damping ratios (Figure 14). This enables continuous tracking of structural stiffness variations, which are critical for detecting:

- Local reductions in stiffness caused by fatigue, cracking, or reinforcement deterioration.
- Progressive changes in modal parameters indicative of structural aging.
- Sudden shifts in dynamic response due to damage events such as bearing failures or impact loads.

Figure 14. Inverse analysis calibration.

The digital twin is continuously updated to minimize discrepancies between FEM-based modal predictions and OMA-extracted parameters, ensuring real-time identification of structural changes. This approach allows for the detection of subtle stiffness reductions before they become critical, enabling early intervention strategies.

### 6.4 Distinguishing Thermal, Transient, and Permanent Deformation Components

One of the key challenges in long-term structural monitoring is the ability to differentiate between transient deformations (due to environmental conditions) and permanent structural changes (indicative of damage evolution). The WeStatiX SHM platform employs an automated algorithmic framework to process rotation, displacement, and strain data, allowing it to reconstruct the full deformation state of the viaduct. The system applies multi-stage filtering and correlation techniques to distinguish between:

- Thermal deformations, caused by seasonal and diurnal temperature fluctuations.
- Transient load-induced deformations, resulting from traffic loads and dynamic excitation.
- Permanent deformation trends, which may indicate creep effects, prestress losses, or progressive material fatigue.

Unlike traditional calibration approaches that simply enforce measurement-matching, the WeStatiX SHM methodology does not impose measured data onto the numerical model directly. Instead, it utilizes a cause-and-effect framework, ensuring that the structural behavior is characterized over time, across its entire operational lifespan.

### 6.5 Multi-Timescale Calibration Strategies

To provide a comprehensive assessment of structural performance, the digital twin employs two interrelated

calibration procedures, tailored to identify different categories of structural changes:

#### 1) Long-Term Calibration

This process is designed to track slow-evolving structural characteristics, such as material degradation, creep progression, and corrosion effects.

Using longitudinal datasets spanning months to years, the calibration process refines the governing material laws, ensuring that the digital twin reflects the actual deterioration mechanisms influencing the structure (Figure 15).

Figure 15. Modal shape identification.

#### 2) Short-Term Calibration

This process is focused on detecting rapid changes in structural behavior, such as those caused by thermal fluctuations, sudden damage events, or traffic-induced loading variations.

It enables precise assessment of thermomechanical material properties, as well as the quantification of elastic and plastic deformations caused by transient loads.

Both calibration processes work in tandem, allowing the system to accurately separate transient anomalies from permanent structural changes while ensuring that the digital twin remains an accurate and reliable decision-support tool.

### 6.6 Digital Twin Utilization for Predictive Maintenance and Decision Support

The continuously calibrated digital twin provides a quantitative basis for structural decision-making, allowing engineers to:

- Predict the remaining service life of critical components based on degradation trends.
- Assess real-time stress utilization factors to ensure that safety margins are maintained.
- Optimize maintenance schedules based on accurate forecasts of fatigue life and prestress losses.
- Trigger automated damage alerts, allowing for targeted inspections and cost-effective interventions.
- Through automated calibration, inverse modeling, and real-time FEM updating, the digital twin enables a fully predictive maintenance approach, shifting away from traditional schedule-based inspections toward data-driven infrastructure management.

The post-processing and calibration methodologies implemented in the WeStatix SHM platform represent a state-of-the-art approach to real-time structural assessment. By leveraging inverse analysis, OMA-based modal tracking, and AI-driven

optimization techniques, the system ensures that the digital twin remains dynamically synchronized with real-world structural behavior.

This multi-layered calibration framework provides a powerful tool for early damage detection, predictive maintenance, and infrastructure resilience assessment, setting a new benchmark for SHM in large-scale civil infrastructure applications.

## 7 VALIDATION RESULTS AND PREDICTIVE ANALYSIS

### 7.1 Load Testing and Digital Twin Validation

To ensure the accuracy and reliability of the digital twin model, validation was conducted by simulating controlled load tests, comparing the numerical results with real-world structural behavior observed during field testing. For the Parchi Viaduct, these load tests took place in May 2021, during which multiple spans of the viaduct were subjected to static loading using a maximum of six fully loaded trucks, each weighing approximately 30–32 tons. The arrangement of the vehicles on the deck, as illustrated in Figure 16, was designed to produce representative loading conditions for evaluating the structural response.

Figure 16. Truck loading configuration.

During the tests, topographic survey methods were used to measure deck displacements and assess deformation trends under loading conditions. The digital twin model, previously described, was utilized to numerically simulate the load tests, integrating precise vehicle positions, tire contact pressures, and asphalt-layer load distribution effects in accordance with regulatory standards. These elements were accurately modeled to ensure a realistic representation of stress propagation through the bridge deck and substructure (Figures 17, 18, 19).

Figure 17. Parchi Digital Twin load configuration (side view).

Figure 18. Parchi Digital Twin load configuration (top view).

Figure 19. Utilization factor visualization of Parchi Twin.

## 7.2 Pier Height Influence on Structural Response

The simulation model was further refined by incorporating variations in pier heights, introducing additional pier elevations of 15 m and 9 m, corresponding to different spans of the viaduct. The results demonstrated a significant correlation between pier height and deflection response, with taller piers exhibiting approximately 20% greater maximum deflection under the same applied loads (Figure 20). This effect highlights the importance of accounting for pier stiffness variations in structural assessment and maintenance planning, as local stiffness differences can influence global load redistribution patterns.

Figure 20. Pier height load test correlation of Parchi Twin.

Comparisons between measured displacements from the load tests and simulated results from the digital twin showed excellent agreement, with negligible discrepancies in both maximum deflection values and the overall deformation trends (Figure 20). These results confirm the high fidelity of the digital twin model and its ability to accurately capture real-world structural behavior under operational conditions.

## 7.3 Distributed Fiber Optic Sensor Data Analysis

In addition to traditional displacement monitoring, the distributed fiber optic sensing (DOFS) system installed on the Parchi Viaduct provided continuous real-time strain measurements, enabling both dynamic characterization and modal parameter identification for each individual span. The DOFS system measures strain rate values, defined as the derivative of strain over time.

This data is automatically processed by the SHM platform to extract modal characteristics, including natural frequencies and damping ratios (Figure 21).

Figure 21. Natural frequency identification.

Continuous strain measurements allow for full-field reconstruction of structural deformation.

Any anomalous strain distributions or unexpected deformation patterns are automatically flagged, triggering maintenance alerts before failure conditions develop.

For other viaducts within the highway network, similar modal parameter identification and deformation reconstructions were performed using accelerometer and inclinometer data, combined with temperature compensation models. An example of this modal analysis workflow is shown in Figure 22, where deformation trends were reconstructed based on correlated inclinometrics and temperature data.

Figure 22. Deformation reconstruction using inclinometric data.

## 7.4 Interactive Visualization and Digital Twin Integration

One of the key features of the WeStatix SHM platform is the integration of digital twins within an interactive geospatial interface, providing real-time access to structural health data for all monitored viaducts in the motorway network. Through an interactive map interface, engineers can:

- Select specific viaducts and bridge structures to access real-time monitoring data.
- Perform virtual inspections through 3D visualization of the digital twin model.
- Review sensor data trends, including modal parameters, stress distributions, and temperature variations (Figure 23).

This user-friendly visualization system ensures that structural assessment personnel can efficiently analyze infrastructure health indicators, facilitating rapid response to emerging issues while streamlining the decision-making process for maintenance planning.

Figure 23. Interactive map.

### 7.5 AI-Based Predictive Maintenance and Self-Learning Algorithms

A distinguishing feature of the WeStatiX SHM platform is its advanced predictive analysis capabilities, which leverage physics-informed artificial intelligence to anticipate future structural behavior based on:

- Historical SHM data trends
- Machine learning-trained degradation models
- Structural simulations under progressive load scenarios

By continuously assimilating real-world monitoring data, the digital twin functions as a self-learning system, progressively improving its predictive accuracy (Figure 24). This automated learning process enhances the platform's ability to:

- Predict structural degradation trends and forecast the remaining service life of individual bridge components.
- Simulate long-term performance under variable load conditions, identifying potential failure scenarios before they occur.
- Optimize maintenance scheduling, ensuring that interventions are proactively planned based on data-driven insights rather than reactive repairs.

Figure 24. Monitoring and prediction dashboard.

The WeStatiX SHM system integrates a suite of real-time dashboards, enabling infrastructure managers to analyze monitoring data and numerical simulation outputs simultaneously. These dashboards display key structural health indicators, including:

- Current stress states and utilization factors
- Real-time displacement and deformation trends
- Predicted deterioration pathways based on historical load conditions

By integrating AI-driven forecasting with SHM diagnostics, the platform provides unprecedented decision-making capabilities, supporting a predictive maintenance strategy that optimizes

resource allocation, minimizes intervention costs, and ensures long-term infrastructure resilience.

## 8 CONCLUSIONS

The AI-enhanced digital twin framework implemented for the Pavia Viaduct has demonstrated the effectiveness of real-time SHM in large-scale infrastructure monitoring. By integrating DOFS, OMA, and PINN-based inverse modeling, the WeStatiX SHM platform accurately captures structural behavior, detects damage progression, and optimizes predictive maintenance.

Load test comparisons validated the high accuracy of the digital twin, with minimal discrepancies in displacement predictions. The observed 20% increase in deflection for taller piers underscores the need to incorporate pier height variations in FEM-based assessments. Real-time monitoring has provided crucial insights into stress redistribution, long-term deformation, and material degradation, enabling early anomaly detection.

Beyond reactive damage identification, self-learning AI algorithms support long-term deterioration forecasting and data-driven maintenance planning. Interactive visualization tools further enhance usability, enabling real-time virtual inspections and safety assessments.

This study establishes a scalable SHM methodology for infrastructure asset management, lifecycle extension, and cost-effective maintenance. Future work will refine AI-driven anomaly detection, expand digital twin applications, and integrate multi-hazard risk assessments, advancing proactive structural assessment and predictive maintenance strategies.

**ABSTRACT:** In regard to subway structures, non-destructive testing and structural health monitoring techniques are beneficial for construction and operation, which require an integrated quality control and sustainability concept. Such an integrated concept is presented, focusing on two main tasks. Inspection during construction will lead to a better quality of the components and structures. Proper data can be integrated into a building information model (BIM). The conceptual design should, however, anticipate later impacts and possible deteriorations at critical parts. The building information model could then be continued (updated) in the form of structural health monitoring (SHM) to make (visual) maintenance of subway structures more efficient, resulting in fewer disruptions (fewer closures, less downtime) and lower costs. It can also contain sensors at non-visible or non-assessable locations. Recording impacts on the structure (e.g. loads, vibrations, chlorides) enables a digital model as a so-called digital twin and the calculation of the remaining service life. Such a concept is presented for a new subway station in Munich.

**KEY WORDS:** Digital model; BIM; Subway station; Monitoring.

## 1 MOTIVATION

In order to minimize the carbon footprint of constructions over their life cycle, it is necessary to maximize their service life. In addition, operational disruptions or breakdowns must be kept to a minimum in terms of number and duration to avoid "switching effects" to private transport. Up to now, quality control during construction has mainly been carried out visually. Conformity with the approved and released execution documents is examined, representative random samples of the building materials to be installed are taken, and compatibility with subsequent components and equipment elements is checked. However, as soon as a component or construction section has been concreted, quality control is essentially only carried out on the surfaces (e.g. gravel pockets, cracks, etc.).

During the operation of the construction, inspection of infrastructure in Germany is carried out based on the German standard DIN 1076, establishing an inspection cycle of 6 years for so-called "major structural inspections" (German: Hauptprüfung). So-called "minor inspections" (German: Nebenprüfung) with a reduced scope must be carried out every adjacent 3<sup>rd</sup> year.

## 2 STRATEGY FOR NOVEL QUALITY INSURANCE

### 2.1 New constructions

A customized selection and combination of BIM (Building Information Modelling), non-destructive testing (NDT) inspection techniques, and monitoring procedures can improve quality assurance during the construction phase and make condition monitoring and maintenance easier and more competent during operation. The first step would be categorizing all structural components with regard to their importance for stability, traffic safety, and durability. This can be done based on a Building Information Modeling (BIM)

approach. The BIM model can be the basis for a digital model (sometimes referred to as a *Digital Twin*) containing physical or chemical material parameters for each structural component. To derive the resistivities of the materials, the monitoring of exogenous impacts can lead to a better understanding of material degradation. Proper monitoring techniques have the capability to measure such impacts as well as physicochemical conditions of the material in near real-time to update the digital model. Such a model is often called *Digital Shadow*, which always represents the actual state of the construction.

### 2.2 Existing structures

Such implementations are most efficient if they are implemented during the construction of the structure. However, there is also considerable potential for such a monitoring approach to increase resilience, durability, and, therefore, sustainability of existing structures from the perspective of retrofitting during operation. Such techniques can be combined with conventional visual inspection during certain intervals (as mentioned above), but can contribute information from the interior of the structures and from structural parts that are inaccessible.

Figure 1. BIM model of a new subway station.

## 3 COMBINED APPROACH

To exemplify the above-given strategy, a novel monitoring concept is illustrated for a new subway station to be built (see

a BIM model in Fig. 1). Assuming that the station has a total length of 400 m, such an underground structure is typically built in the so-called “cut-and-cover” technique (“Deckelbauweise” or “Schlitzwand-Deckel”, see the example in Fig. 2). The outer walls are first inserted into the ground as diaphragm walls. The reinforced concrete cover is then produced in a shallow cover construction pit. Under the protection of the already constructed diaphragm walls and the tunnel cover, the ground is excavated up to the lower edge of the floor slab. The floor slab, the inner shell, the mezzanine floors, and the platforms are then constructed from bottom to top using solid construction methods. This construction process considerably limits the traffic restrictions caused by the construction work as well as the dirt and noise emissions. The subway station significantly impacts the groundwater, which is why all external components must be designed as watertight concrete structures and complex culvert structures are required.

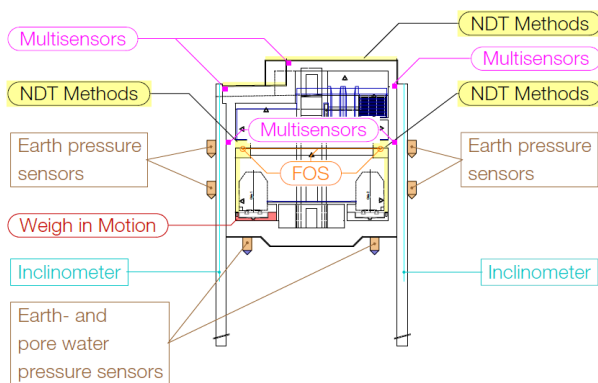

Figure 2. Cross-section of the BIM model in Fig. 1 of the subway station.

Fig. 2 provides, in addition, some elements of an integrated quality control concept, which is divided into measures for quality assurance during the construction phase and for structural maintenance during operation. Non-destructive testing methods such as endoscopy, ultrasound, radar, electromagnetic induction, etc., are primarily used. These are mainly operated right after the production of concrete components that are important, for example, in terms of structural design or for the tightness of the building. This is intended to rule out damage that is not visible on the surface, such as cavities, etc. Continuous monitoring methods such as fiber optic measuring methods are used in the construction phase, for example, for concrete parts with architecturally high-quality surface design to control the development of hydration heat and thus the early forced stresses in order to control the post-treatment and thus limit the formation of cracks.

Sensor systems and monitoring methods are also very important for repetitive structural testing and for structural maintenance during operation. For this reason, a new subway station can be equipped with a series of measuring devices for continuous monitoring of the structure: Earth pressure and pore water pressure sensors to record the load conditions, inclinometers to measure the structural deformations, multi-sensors, particularly in the area of component or structural joints, to detect the penetration of moisture and possible corrosion activity [1] (Fig. 3), fibre optic measuring systems to observe the stress conditions and possible load redistributions

in the load-bearing components [2] and, last but not least, so-called “weigh in motion” systems for vibration measurements in the track bed. For more information on sensing systems for structural health monitoring it is to be referred to the literature [3].

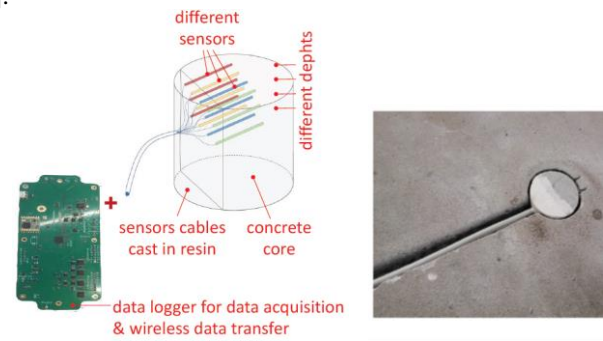

Figure 3. Multi-sensor system for corrosion monitoring [1] including different sensor modalities (left) and embedded into a concrete structure via a borehole (right).

#### 4 CONCLUSIONS

Quality assurance for subway stations, as presented here, essentially consists of a combination of a digital model with modern measurement methods. This makes it possible to improve the quality achievable during the construction of the structure and to maintain the structure's condition at a high-quality level for a long time during operation. The structure's service life can be significantly extended, and the probability of occurrence and extent of operational disruptions minimized, as was shown earlier for wind turbines [4].

It is certainly true that the development of a digital twin and the installation and operation of inspection and continuous monitoring procedures are associated with costs. However, these costs are very low in relation to the structure's life cycle and the considerable monetary and environmental benefits associated with extending the service life.

#### ACKNOWLEDGMENTS

The authors recognize the support from several companies providing information on sensors and measurement equipment, including Duramon, Switzerland, namely Dr. Seguí Femenias. The help of all WTM Engineers Munich team members, including Helmut Heiserer, Benedikt Maier, Taha Mohiuddin, Andrea Paci and Stefanie Setzer, is gratefully acknowledged by the authors.

**ABSTRACT:** In Germany, the bad condition of many older bridges and changes in the code provisions often result in deficits after assessment and recalculation. In case the necessary structural safety is not provided, structural health monitoring can be employed to gain knowledge about the time variant actions, the progression of structural damage and the overall condition of structures. To allow for effective use of the usually dense monitoring raw data, the derivation of condition indicators is key, since they indicate a need for action for the owners and the engineers. At the same time, real-time data as well as comprehensive condition indicators are key elements for creating a Digital Twin of a structure, as a Digital Twin requires a bidirectional flow of data, which affects the physical entity of the twin. In this paper, a method for deriving condition indicators from monitoring data is described which was developed for a large cable-stayed bridge, the Köhlbrand Bridge in Hamburg, Germany. The method allows for the calculation of a reliability index as a time variant condition indicator based on dynamic monitoring data, which is then implemented into a Digital Twin of the structure.

**KEY WORDS:** SHM, reliability, condition indicators, condition monitoring, digital twin, bridges.

## 1 INTRODUCTION

Due to the poor condition of many older bridges and changes in the regulations, there are often deficits in the recalculation of existing bridges according to the German recalculation guidelines (NRR) [1]. If the required structural safety cannot be verified using standardized load models and modified resistance models in accordance with the various NRR standards, structural measurements can be carried out for a limited period or as continuous structural health monitoring (SHM) to gain knowledge about actions that vary over time. This makes it possible, for example, to derive object-specific traffic load models by using complex algorithms and models to infer the traffic volume and traffic composition based on structural measurements [2]-[4]. In the case of time variant physical state variables, an approach can be to reduce these to extreme values in defined time intervals and describing the frequency of their occurrence using approximation functions [5],[6]. These approximation functions allow for a prediction of which extreme values of the state variable will occur in the future [7] and what reliability against structural failure will result from this [8]. It is important here that sufficiently long measurement periods are available for such an investigation [9] and that the long-term stability of the measurement system is guaranteed for the measurement period [10].

The general aim of SHM is to assess the condition or performance of the structure. The key to this is the derivation of condition indicators for the structure which can relate, for example, to the state of preservation, safety or maintenance [11] and indicate to operators and engineers any need for action. Key figures relating to structural safety can be determined using a component-based or system-based approach [12]. In the simplest case, for example, a physical state variable of an individual component is compared with a corresponding threshold value to determine a degree of

utilization. However, since these utilization rates are based on different actions, materials and failure modes with different variability, a utilization rate does not allow any conclusions to be drawn about the existing risk and, strictly speaking, only enables a binary assessment of the risk (exceedance or no exceedance). In this article, a procedure is therefore explained and implemented using the example of the Köhlbrand Bridge in Hamburg, which allows a reliability index to be derived from the dynamic monitoring ring data as a time-varying condition indicator in relation to a buckling monitoring. As part of the smartBRIDGE Hamburg project, the condition indicator was integrated into a digital twin of the structure, which contains a total of over 40 different condition indicators.

Figure 1. Köhlbrand Bridge Hamburg (source: HPA-archive Martin Elsen).

Since the buckling verification in this example is to be classified as a decisive structural check, this safety index does not refer to the system reliability but is determined for the

critical components of the structure. The structure and the problem are explained in more detail in the following chapter.

## 2 PROBLEM DESCRIPTION AND MEASUREMENT MEASURES

### 2.1 Problem Description

As one of Hamburg's most important traffic arteries, the Köhlbrand Bridge has been crossing the Köhlbrand between the Elbe island of Wilhelmsburg and Waltersdorf since 1974. The middle section, the river bridge, is a two-legged cable-stayed bridge with individual spans of 97.5 m, 325 m and 97.5 m (Fig. 1). The superstructure is designed as a single-cell steel box girder with an orthotropic deck [13].

In the course of a recalculation of the current bridge carried out in 2016 in accordance with levels 1 and 3 of the German recalculation guideline [1], the verification against buckling of the web and base plates in the pylon area for the required target load level (i. e. LM1 according to the German bridge code DIN-FB 101) could not be provided [14],[15]. The buckling verifications were carried out using the so-called reduced stress method in accordance with the German code for steel bridges DIN-FB 103 [16]. Due to the normal force distribution in the stiffening girder, the pylon area represents the decisive area for the buckling checks, with the checks being exceeded by up to 30 %. As part of level 3 of the recalculation guideline [17], cable force measurements were carried out to determine the stresses from permanent actions, which resulted in slightly lower longitudinal compressive stresses. However, the buckling check could not be provided here either using the reduced stress method. The degrees of utilization resulting from the calculation according to level 3 are shown in Fig. 2.

The iterative verification using the method of effective widths according to DIN FB 103 [16] Chapter III-4 also led to an intolerable exceedance. As a result, a distance requirement

of 50 m for trucks was added to the existing truck overtaking ban as a compensatory measure in accordance with the 1st amendment to the recalculation guideline [17] in order to reduce the traffic loads on the outer lanes and to be able to apply the reduced BK60 load model in accordance with the older traffic load code DIN 1072 (1967) [18]. However, this measure leads to considerable disturbance of regional and national traffic in Hamburg.

To be able to lift the distance requirement in the medium term, early monitoring measures were commissioned by the Hamburg Port Authority AöR (HPA) as part of the smartBRIDGE Hamburg project [19], the piloting of a digital twin of the Köhlbrand Bridge. These include strain measurements in the web and floor plates in the area at risk of buckling, as well as acceleration measurements on some of the harp cables to assess the risk of buckling. To assess the risk of buckling, the long-term buckling monitoring data from a 12-month period from July 2019 to June 2020 was evaluated as a first step. The data evaluation has recently been extended to December 2024. The aim of the monitoring is to determine whether there is a risk of buckling for the superstructure in the current load situation with the distance requirement and whether there are sufficient load-bearing reserves to lift the distance requirement. Probabilistic evaluation concepts of different levels of complexity were developed for this purpose. In the following, a simplified evaluation concept for the detection of buckling risk is described and applied to the long-term data of the buckling monitoring to derive a suitable condition indicator for assessing the risk of buckling.

### 2.2 SHM Measures

As the buckling of the web and floor plates could not be verified analytically, even with the aid of cable force measurements, MKP GmbH and WTM Engineers GmbH developed a measurement concept for a continuous structural monitoring. Variable actions in the superstructure were to be recorded via strain measurements on the superstructure and converted into acting stresses. In addition to the strain measurements, sensors for measuring the temperature of the structure, meteorological data (air temperature, radiation, humidity, wind direction and wind speed) and accelerations on the superstructure were provided. In conjunction with a Weigh-in-motion system installed on the structure, the additional sensors record the external effects on the bridge structure almost completely and should, for example, make it possible to assign the measured stress components in the web and floor plates to the different traffic load components. In addition, acceleration sensors (y- and z-axis) were permanently installed on 22 harp cables, which corresponds to a quarter of all cables on the current bridge. These sensors enable, among other things, the continuous determination of the cable forces,

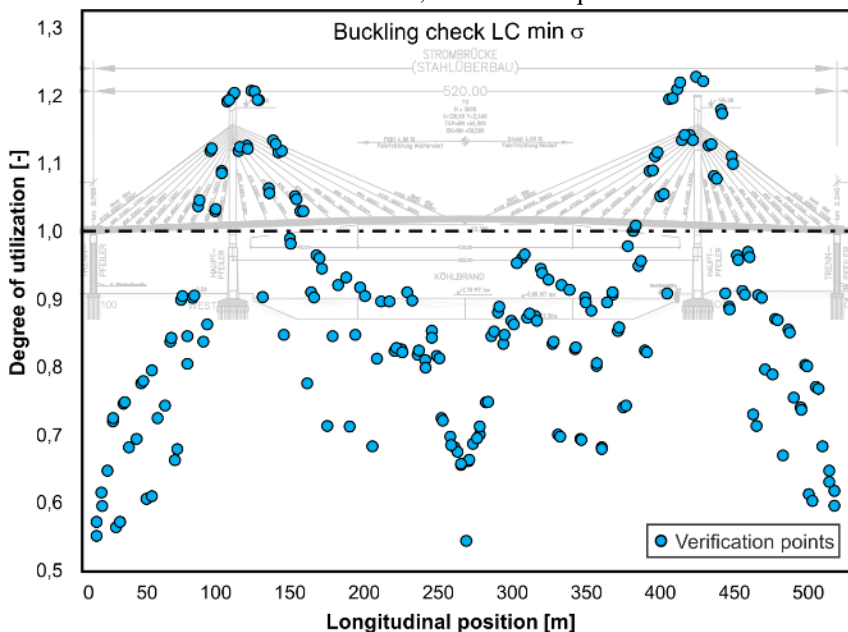

Figure 2. Utilization of buckling verification after recalculation level 3 (taken from [15])

Figure 3. Position of the measuring cross-sections in longitudinal direction  
(source: MKP GmbH)

on which the stresses due to dead load of the superstructure depend on to a large extent.

The strain measurements were carried out in a total of seven measurement cross-sections along the longitudinal axis of the current bridge (Fig. 3).

A distinction is made between two types of measuring cross-section: Measuring cross-section ST1 (Fig. 4a) comprises nine Y-rosette strain gauges (arrangement of the measuring elements  $0^\circ/45^\circ/90^\circ$ ) on the web, bottom and top plates, through which three independent directions of strain are recorded to determine the main stress states. Measuring cross-section ST2 (Fig. 4b) is a reduced measuring cross-section and comprises four T-rosette type sensors in the corners of the box girder. These record two directions of strain (arrangement of the measuring grids  $0^\circ/90^\circ$ ) to accurately determine the strain

distribution in the horizontal and vertical directions, considering transverse strain influences, but without the possibility of determining the main stress directions. The details of the strain sensor arrangement of the ST1 and ST2 measuring cross-sections are shown in Figures 4c and 4d. The strain sensors of the monitoring system measure at a frequency of 100 Hz, whereby the minimum (min), maximum (max) and average values (avg) of the strains and stresses of 5-minute intervals are stored and evaluated.

The sensor system is very extensive with a total of 94 strain sensors in the superstructure, 44 acceleration

sensors on the cables, nine acceleration sensors on the superstructure, 20 temperature sensors and eight additional meteorological sensors. The scope of the measurements can also be explained by the continued use of the measuring system as part of the smartBRIDGE Hamburg project [19], in which additional condition indicators were developed and monitored. In addition, the aim was to check whether the Finite Element (FE) hybrid model of the structure provides accurate strain states under a defined load, which requires an accurate measurement of the strain distribution over the entire cross-section height.

### 2.3 Load Tests

Defined load tests and model calibrations are required to verify the plausibility of the stress values measured on the structure and to be able to relate them to the stress values calculated using normative load models. For this reason, the sensor system installed in June 2019 was tested as part of extensive load tests during a full closure of the structure in July 2019. The structure was driven over with four concrete pump vehicles with a total weight of around 180 tons in different formations (Fig. 5a). In addition, measurements were carried out on cables under ambient and harmonic excitation with installed and removed dampers to determine the damping parameters. The evaluation of the load tests generally showed very good agreement between the measured longitudinal stresses and the stresses of the FE models [20]. The influence line of a real crossing and the influence line of an FE beam and shell model are compared as an example in Fig. 5b. The FE shell model shows almost complete agreement with the measured longitudinal stresses, while the beam model slightly underestimates the stresses. This is to be expected as longitudinal stress concentrates in the corner areas of the box girder, an effect which is not captured by a beam model. The functionality and accuracy of the monitoring system could thus be confirmed by the field test and the FE model.

## 3 EVALUATION METHODOLOGY

### 3.1 Semi-probabilistic evaluation concept

The developed concept for the monitoring-based buckling analysis is shown in Fig. 6. The concept is focused on the metrological determination of the acting stresses, whereby the resistance side of the buckling analysis is not directly included in the consideration (Section 3.2). The following two methods are available as examples for determining the design stresses from variable effects: Direct measurement of the steel stresses in the buckling field (method (a)) and indirect measurement by determining the external actions (method (b)).

Direct measurement according to method (a) requires strain measurement on the cross-section using strain gages at the relevant points. The existing stresses from dead loads can be

determined by cable force measurements or taken from the recalculation. The extreme values of stresses from a relatively short measurement period (e.g. one year) can be converted into design values of the acting stresses by a statistical evaluation of the variable stresses. On the resistance side, the permissible stresses according to DIN FB 103 [16] are applied. The target values for reliability can be taken from EC0 [21].

In the indirect measurement according to method (b), the main effects on the current bridge are recorded and characteristic values for the respective actions are derived. These can in turn be applied to the structural FE model to determine the characteristic stresses in the buckling areas. The design value of the compressive stress can then be determined conventionally using the design partial safety factors and combination coefficients of German bridge codes. Alternatively, the combination coefficients can be derived individually based on the data from the long-term monitoring.

In this article, the design stresses are determined based on method (a), as this method does not require a distinction between different types of action, but only a distribution function for the measured extreme values is derived.

### 3.2 Determination of target reliability

The total design resistance stresses in the ultimate limit state (ULS) are determined in accordance with the recalculation of the bridge [14],[15] based on the concept of reduced stresses in accordance with DIN-FB 103. The design resistance of the variable compressive stresses in the longitudinal direction  $\sigma_{Q,Rd}$  results from the difference of the total design resistance according to DIN FB 103  $\sigma_{Rd,DIN-FB}$  minus the design value of the permanent actions  $\sigma_{g,Ed}$ . For the area of the base plate, the design resistance of the variable compressive stresses results according to Eq. (1).

$$\sigma_{Q,Rd} = \sigma_{Rd,DIN-FB} - \sigma_{g,Ed} = -113 \text{ N/mm}^2 \quad (1)$$

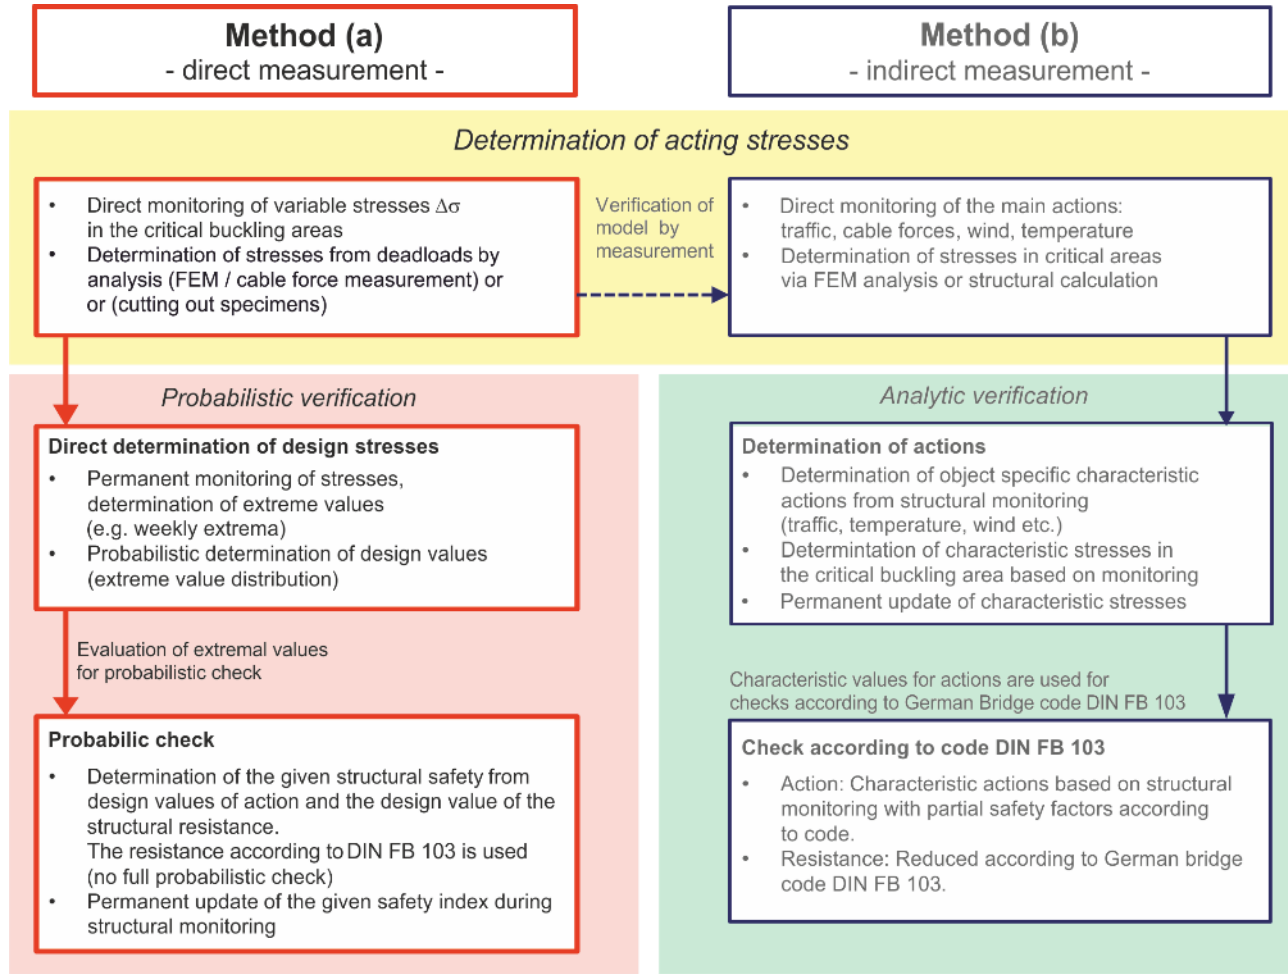

Figure 6. Concept for compensating for safety deficits through SHM (source: WTM Engineers)

For the area of the web plates, the design resistance of the variable compressive stresses at the point of intersection with the base plate are given by Eq. (2).

$$\sigma_{Q,Rd} = \sigma_{Rd,DIN-FB} - \sigma_{g,Ed} = -123 \text{ N/mm}^2 \quad (2)$$

Since the resistance side is not considered further when determining the design values of the action or when calculating the existing reliability, the target value of the reliability index for the actions  $E_d$  is determined with  $\beta_E = \alpha_E \cdot \beta$  (EC0 [21], Eq. C.6a), with  $\alpha_E = -0.7$  and  $\beta = 3.8$  according to EC0, Table C.2 [21].

For the case of normally distributed basic variables of the actions, Eq. (3) applies to the determination of the measurement value  $E_d$ .

$$E_d = m_E + \alpha_E \cdot \beta \cdot \sigma_E \quad (3)$$

Here,  $m_E$  is the mean value of the actions with the standard deviation  $\sigma_E$ . The target value of the reliability index  $\beta$  thus refers to both permanent and variable loads. However, the evaluation concept presented here is based on the stresses from dead loads determined in the recalculation and only the design value of the variable stress is determined probabilistically from monitoring data. For this purpose, it should first be checked under which boundary conditions a separate consideration of

permanent and variable actions is on the safe side. Permanent and variable loads can be divided on the safe side according to Eq. (4).

$$E_{g,d} + E_{Q,d} = m_g + m_Q + \alpha_E \beta \sqrt{\sigma_g^2 + \sigma_Q^2} < m_g + m_Q + \alpha_E \cdot \beta (\sigma_g + \sigma_Q) \quad (4)$$

Due to the fact that the permanent actions are determined with  $E_{g,d} = \gamma_g \cdot m_g$  and  $\gamma_g = 1.35$ , Eq. (4) can be transformed into Eq. (5).

$$E_{Q,d} < m_g \left[ \alpha_E \cdot \beta \cdot \frac{\sigma_g}{m_g} + 1,0 - \gamma_g \right] + [m_Q + \alpha_E \cdot \beta \cdot \sigma_Q] < m_Q + \alpha_E \cdot \beta \cdot \sigma_Q \quad (5)$$

The estimate at the end of Eq. (5) is valid for the conditions  $V_g = \sigma_g/m_g < 0.132$ ,  $\gamma_g = 1.35$  and  $\beta_E = \alpha_E \cdot \beta = 2.66$ . In the event that the aforementioned boundary conditions apply, the design value of the variable actions  $E_{Q,d}$  can therefore be determined on the safe side with the target safety index  $\beta_E = \alpha_E \cdot \beta$ . These are generally complied with for normal bridge structures, as the coefficient of variation  $V_g$  for dead loads should be well below 10 %. As a cable-stayed bridge is a structure with a complex interaction between cable forces and stiffening girders, further investigations were carried out as part of the buckling monitoring to determine the variability of the self-weight stresses using Monte Carlo simulations. The previous consideration still only applies to the case of normally

distributed variables, whereas the measured minimum values of the stresses are to be described here by an extreme value distribution of type I (Gumbel-distribution). However, as this provides values that are on the safe side compared to a normal distribution, the design value of the variable actions  $E_{Q,d}$  with the target safety index  $\beta_E = \alpha_E \cdot \beta$  is determined on the basis of an extreme value distribution in the simplified procedure presented here.

### 3.3 Determining the rated values from measurement data

To determine the parameters of the extreme value distribution, the selected reference period must be chosen in such a way that the structure experiences a load series that recurs as evenly as possible during this period. In the case of an hourly evaluation, strong stress differences arise between day and night hours, as well as in the case of a daily evaluation between working days and weekends. This results in unfavorable standard deviations of the extreme values. A comparatively uniform exposure is obtained if a weekly evaluation is selected as the reference period [4],[22].

For a continuous monitoring period of one year, 52 weekly extreme values are available for determining the parameters of the distribution function. The standard deviation  $\sigma_x$  and the mean value  $m_x$  can be estimated from the available weekly extreme values, e.g. using the method of moments or the maximum likelihood method. The density and distribution function of the extreme value distribution type I (Gumbel distribution) for minimal values are given in Eqs. (6) and (7) [23].

Density function for minimum values:

$$f(x) = a \cdot \exp[a(x - u) - \exp[a(x - u)]] \quad (6)$$

Distribution function for minimum values:

$$F(x) = 1 - \exp[-\exp[a(x - u)]] \quad (7)$$

Using eqs. (8), (9) the parameters  $a$  and  $u$  of the distribution function can be determined.

$$a = \frac{\pi}{\sigma_x \cdot \sqrt{6}} \quad (8)$$

$$u = m_x + \frac{0,577216}{a} \quad (9)$$

A special characteristic of the extreme value distribution type I is that the standard deviation of the distribution function does not change when the reference period is altered. Accordingly, the extreme value distribution for a selected reference period results from the shift of the extreme value distribution along the horizontal axis by converting the expected values (Fig. 7). The initial reference period of one week can thus be adapted to the corresponding target period for the measurement.

The reference period can be converted by calculating the corresponding fractile value. The associated exceedance

probability  $q$  is calculated for maximum values according to Eq. (10) [24].

$$q = 1 - \frac{1}{n_a \cdot a} \quad (10)$$

where

$n_a$  values per year depending on the reference period of the extreme values (here  $n_a = 52$ )

$a$  Return period or assessment period in years

Next, Eq. (10) must be adjusted for minimum values according to Eq. (11):

$$q = \frac{1}{n_a \cdot a} \quad (11)$$

The calculation of fractile values of an extreme value distribution type I is carried out for minimum values according to Eq. (12).

$$F^{-1}(x) = u + \frac{1}{a} \ln(-\ln[1 - q]) \quad (12)$$

where

$q$  undercut probability

The characteristic value of the effect  $E_k$  for a reference period of 50 years is obtained as a 2% fractile value of the expected value of the annual extreme value distribution (with  $q = 1/(1 \cdot 50) = 0.02$ ) or as a 0.038% fractile value of the expected value of the weekly extreme value distribution (with  $q = 1/(52 \cdot 50) = 3.8 \cdot 10^{-4}$ ). The reference period for which the characteristic value of the action is to be determined cannot be clearly determined. While according to EC1 [25] the characteristic values for some types of action refer to a reference period of 50 years (e.g. wind or temperature), a return period of 1000 years is specified for the LM1 load model according to EC1-2. In [26] examples are given according to which reference periods between 50 and 1000 years were applied for characteristic traffic loads. Since no normative partial safety factor for variable loads is applied in the present evaluation, the choice of the reference period is of secondary importance, since the target value of the reliability for different reference periods according to EC0 [21], Eq. C.3 is to be

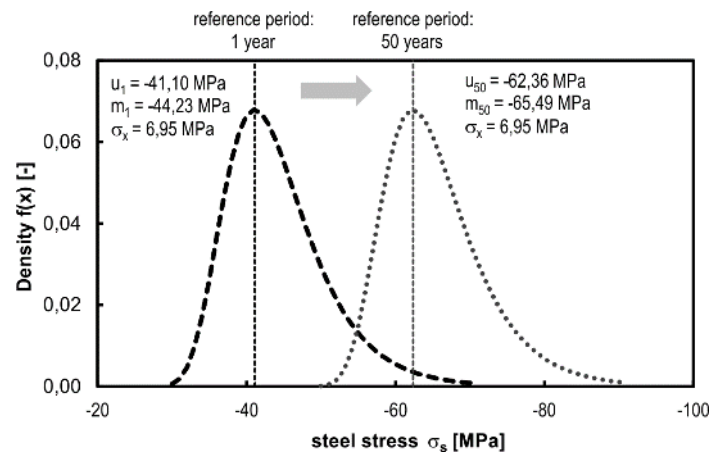

Figure 7. Exemplary conversion of the extreme value distributions for two reference periods (source: WTM Engineers)

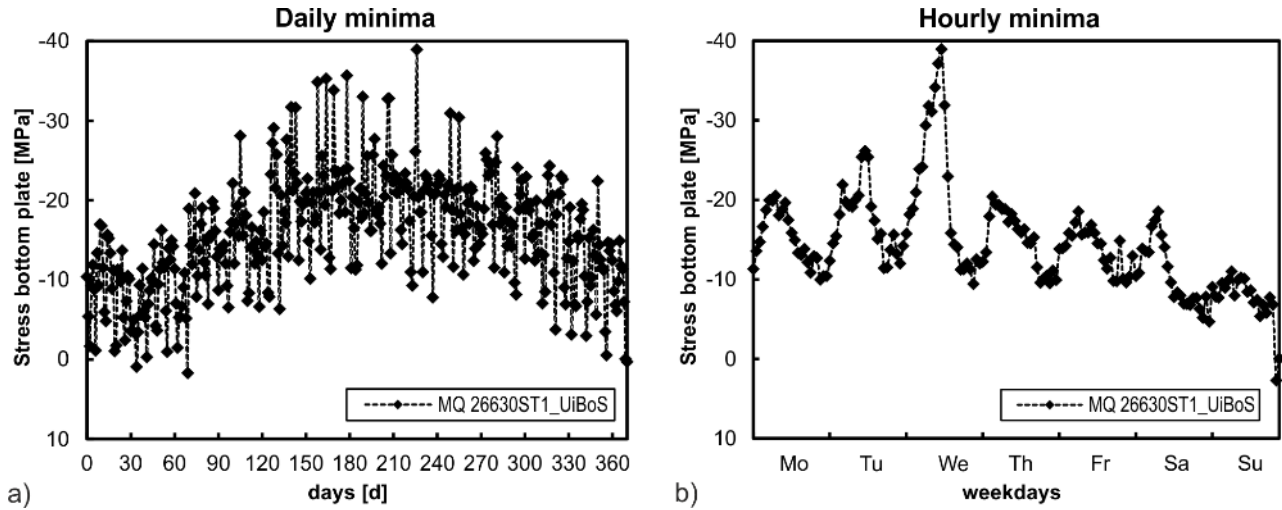

Figure 8. a) Daily minima of the measurement period; b) Hourly minima of a week in February 2020 (source: WTM Engineers)

converted in such a way that the same design values result for all reference periods.

It is important to note here that the weighting factors specified in the standards  $\alpha_R = 0.8$  and  $\alpha_E = -0.7$  only apply to a reference period of 50 years and may therefore only be applied to the value  $\beta_{50}$  (see also DIN 1055-100 [27], Eq. B.7).

The  $\beta_{50}$  index can be converted to other reference periods by applying the weighting factors for maximum values according to Eq. (13) (corresponding to EC0, Eq. C.3).

$$\Phi(\beta_n) = [\Phi(\beta_1)]^n = [\Phi(\beta_{50})]^{n/50} \quad (13)$$

Here,  $\Phi(\beta)$  is the cumulative distribution function of the standardized normal distribution. Eq. (14) applies for minimum values with  $\beta < 0$ .

$$\begin{aligned} \Phi(\beta_n) &= 1 - [1 - \Phi(\beta_1)]^n \\ &= 1 - [1 - \Phi(\beta_{50})]^{n/50} \end{aligned} \quad (14)$$

To determine the design value of the action  $E_d$ , the fractile value of the action associated with the reference period  $n$  must be determined with the undercut probability  $q = \Phi(\beta_{E,n})$  based on the characteristic value  $E_k$  determined according to Eq. (12).

The safety index for actions  $\beta_{E,50}$  is 2.66 for a reference period of 50 years, which corresponds to an undercut probability of  $q = \Phi(-2.66) = 0.4\%$ .

#### 4 VERIFICATION OF BUCKLING RISK

##### 4.1 Evaluation of long-term data

The statistical evaluation of the variable stresses from the long-term monitoring is only shown here for the critical base plate of the measurement cross-section 26630 in the pylon area (see Fig. 3). The daily minima measured on the south side of the base plate during the measurement period are shown in Fig. 8a. The seasonal influence of the compressive stresses, which increase towards winter, can be clearly seen. The diurnal influences of temperature and traffic can also be seen in the hourly minima of a February week shown in Fig. 8b.

Figures 9a and 9b show the weekly minima of two measuring points each in the base plate and in the web in measuring cross-section 26630 over the measuring period. In addition to a greater variance, the measured values of the base plate on the

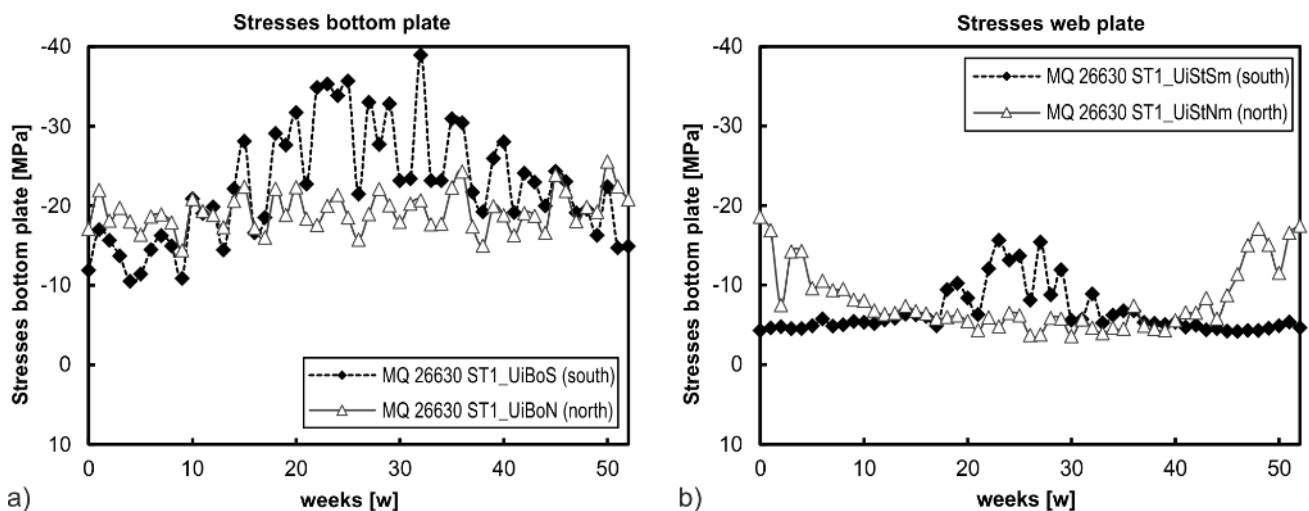

Figure 9. Weekly minima of the measuring points a) 26330 ST1\_UiBoS (south side); b) 26330 ST1\_UiBoN (north side) (source: WTM Engineers)

south side (Fig. 9a) show a clear influence of the seasonal temperature profile compared to the same measuring point on the north side. Analyses of the different types of actions have shown that influences from direct sunlight are much more pronounced at this measuring point, which explains the stronger basic variance. In addition, there likely is a local temperature-related constraint that does not exist in this form on the north side. Similar effects are visible for the evaluation of the web stresses, whereby these are due to the influence of direct solar radiation (Fig. 9b). A more detailed investigation was carried out, which, however, is not the subject of this paper.

The distribution of the weekly extreme values of the two measuring points in the relevant measuring cross-section 26630 is shown in Fig. 10. The parameters of the extreme value distribution (type I)  $m_x$  (expected value) and  $\sigma_x$  (standard deviation) as well as the minimum compressive stress  $\sigma_{s,min}$  recorded at the measuring point during the measuring period are each shown in the diagram. It can be seen that the Gumbel distribution represents a very good approximation of the actual distribution of the weekly extreme values at the measuring points investigated.

However, it is also clear that the distribution functions differ significantly with regard to the standard deviations. The critical stresses occur at the measuring point MQ 26630 ST1\_UiBoS (Fig. 10a)) on the south side of the superstructure. The parameters of the distribution functions determined for the individual measuring points are the basis for the design stresses determined in the following.

#### 4.2 Determination of the design values

Based on the weekly extreme values recorded during the measurement period and presented in the previous section, the design values of the action were determined with an extreme value distribution of type I according to the calculation steps explained in Section 3. Table 1 summarizes the target reliabilities  $\beta_t$  and  $\beta_{E,t}$ , the weighting factors  $\alpha_E$ , characteristic values of the actions  $E_k$  and the design values  $E_d$  for different

reference periods. The partial safety factors  $\gamma_Q$  result from the ratio of the design value  $E_d$  to the characteristic action  $E_k$ .

Table 1. Comparison of target reliability and characteristic expected values for different reference periods

Reference period t	1 year	50 years	100 years	200 years	1000 years
Target reliability $\beta_t$	4,68	3,80	3,62	3,44	2,98
Target reliability $\beta_{E,t}$	-3,78	-2,66	-2,42	-2,16	-1,44
Weighting factor $\alpha_E = \beta_{E,t} / \beta_t$	-0,81	-0,70	-0,67	-0,63	-0,48
Expected value $E_{k,t} = u(t)$ [MPa]	-41,27	-63,18	-67,05	-70,92	-79,91
Design value $E_d$	-94,2				
Partial safety factor $\gamma_Q = E_d/E_k$	2,28	1,49	1,40	1,33	1,18

The calculation of the design value of the stress is carried out below as an example for a reference period of 200 years. The parameters  $a$  and the model value  $u$  result in

$$a = \pi / (7.182 \cdot \sqrt{6}) = 0.179$$

and

$$u = 22.47 + 0.577216 / 0.179 = 19.25 \text{ MPa}$$

for the weekly extreme value distribution (initial values cf. Fig. 10a). The fractile value for determining the characteristic value  $E_k$  for a reference period of 200 years is

$$q = 1 / (52 \cdot 200) = 9.615 \text{E-}5.$$

The characteristic expected value is therefore

$$E_{k,200} = 19.25 + 1 / 0.179 \cdot \text{LN}[\text{LN}(1 - 9.615 \text{E-}5)] = 70.92 \text{ MPa}.$$

The fractile value of the target reliability for the ULS for a reference period of 200 years is

Figure 10. Distribution of the weekly extreme values in the base plate of measurement cross-section 26630 for a) the south side; b) the north side (source: WTM Engineers)

$$P_f = \Phi(\beta_{E,200}) = 1 - [1 - \Phi(-0.7 \cdot 3.8)]^{200/50} = 1.539E-2$$

(here the reliability index for a reference period of 50 years is the starting point). This corresponds to a safety index of

$$\beta_{E,200} = \Phi^{-1}(1.539E-2) = -2.16.$$

The design value thus results in

$$E_d = -70.92 + 1 - 0.179 \cdot \text{LN}[\text{LN}(1 - 1.539E-2)] = 94.2 \text{ MPa}.$$

Based on this evaluation, it can be determined that the safety against buckling can also be provided for the safety level applicable to new structures with a significant safety margin. The ratio of permissible compressive stress to design compressive stress ( $\eta = \sigma_{Q,Rd} / \sigma_{Q,Ed}$ ) is  $\eta = 113/94.2 = 1.20$ .

#### 4.3 Additional stress due to lifting of the distance requirement

The calculations to date reflect the state of traffic under the distance requirement in force during the measurement period. However, one aim of the permanent monitoring was to lift the current distance requirement in the event that sufficient safety reserves arise with regard to the buckling proof. One question to be clarified is the extent to which the stresses are likely to increase as a result of the removal of the distance requirement. According to Table A1-3 of the NRR [17], the traffic compensation measures of a truck overtaking ban and a truck distance requirement of 50 m correspond to a reduction of the target load level from LM1 to BK60.

In simplified terms, the load can increase from load model BK60 to LM1 if the spacing requirement is lifted. A comparison of the UDL loads distributed over a large area of the load models BK60 and LM1 results in a potential increase of  $q_{LM1}/q_{BK60} = 1.18$  if the traffic mix is largely maintained when the distance requirement is lifted.

According to the recalculation of the Köhlbrand Bridge [15], the share of traffic loads in the variable loads is approx. 50 %. This means that an increase in the traffic load by 18 % results in an increase in the variable loads by a total of around 9 %. Even if the distance requirement is lifted, the buckling check is not expected to fall below the safety requirements for new structures. In any case, permanent monitoring would be continued if the distance requirement is lifted in order to be able to assess the actual effects on buckling safety.

#### 4.4 Dynamic monitoring of reliability

To enable dynamic monitoring of reliability as a condition indicator, the existing safety index can be calculated for a reference period of 50 years to assess the buckling safety with

$$\begin{aligned} \beta_{E,50,prov} &= \Phi^{-1}(F(\sigma_{Q,Rd})) \\ &= \Phi^{-1}(1 - \exp[-\exp(0.179 \cdot (-113 + 63,18))]) = -3.64 \\ (\text{with } \sigma_{Q,Rd} &= 113 \text{ MPa}). \end{aligned}$$

In continuous long-term monitoring, the existing safety index  $\beta_{E,50,prov}$  can be updated weekly in this way. This is shown as an example in Fig. 11. From the 25th week of long-term

monitoring, the database for calculating the existing reliability  $\beta_{E,50,prov}$  is expanded and updated by one value every week. In this way,  $\beta_{E,50,prov}$  approaches the final value of -3.64 after one year of monitoring. If the distance requirement is lifted, the effects on buckling safety can be assessed immediately after a few weeks using this diagram. The advantage of this reliability-based parameter is that it reflects the cumulative load history and exceptional load events can be directly classified here. In addition, lower reliability requirements can be defined as threshold values for existing structures with a short remaining service life. The advantage of this parameter is also that, unlike a degree of utilization, its threshold values are independent of the kind of verification to be performed (and therefore do not have to be scaled) and the procedure shown here is therefore transferable to other types of verification.

#### 4.5 Integration into the digital twin of the Köhlbrand Bridge

The condition indicator described above was used as part of a higher-level project to develop a digital twin of the Köhlbrand Bridge [19] and integrated directly into the system. The system is based on a BIM model of the current bridge and the ramp structures and combines the available information from structure books, the German digital structures database (SIB), information from structure diagnostics and the structure monitoring within one system. Instead of operating separate data silos, all available key information on the condition of the structure is combined in one system. A major advantage is that it is much easier to recognize correlations between different sources of information. For example, information on structural damage is displayed directly in the 3D model (Fig. 12).

The taxonomy of the BIM model is based on the component groups according to the German taxonomy code ASB-ING. For the “Strombrücke” substructure of the Köhlbrand Bridge, a condition indicator was developed for each component group, which summarizes all available information on the component group into a condition group. A procedure was developed to combine the condition scores from the structural inspections with the information from structural monitoring to form a condition score [28]. Fig. 13a shows the condition indicator “superstructure” (steel box girder). The overall condition of the

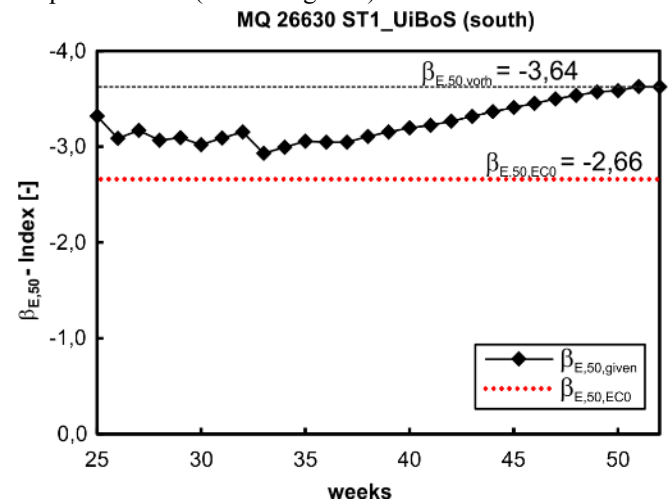

Figure 11. Dynamic development of existing reliability from long-term monitoring (source: WTM Engineers)

Figure 12. Visualization of structural damage information  
(source: MKP GmbH)

superstructure results from the PCI (Partial Condition Indicator) of the structural inspection and the PCI of the measurement-based calculations. With the PCIs “buckling safety” and “fatigue safety of transverse frame”, the CI includes the monitoring of two potential damage scenarios that were classified as critical for the structure based on sensitivity analyses.

The buckling safety is assessed by the previously described probabilistic evaluation of the strains measured at the areas at risk of buckling (Fig. 13b). The calculation of the existing safety index for buckling failure on the basis of structural measurements is explained in Section 4. The reliability index (here  $\beta_E$ -index, related to the action side) is permanently determined from the existing measurement data, which in turn is converted into a condition rating as explained in [28],[29]. In the visualization, the changes in the condition scores are shown in order to illustrate the effect of the damage scenario under consideration on the overall structure. In addition, a time diagram with the development of the reliability index over time

is shown to illustrate the development of the condition over time and, if necessary, for an initial plausibility check.

## 5 SUMMARY AND OUTLOOK

In this paper, long-term buckling monitoring data from a twelve-month period from July 2019 to June 2020 was evaluated to derive a reliability-based condition indicator for assessing the risk of buckling of the Köhlbrand Bridge superstructure. The aim was to use probabilistic methods to determine whether there is a risk of buckling for the superstructure in the current load situation with a distance requirement in place and whether there are sufficient load reserves to lift the distance requirement.

The statistical evaluation of the weekly extreme values showed that the critical stress values occur on the south side in the pylon area of the superstructure. As expected, the distribution of the measured values could be approximated very well by a type I extreme value distribution. Based on the distribution function, the design values of the variable actions were determined and compared with the structural resistances. This data was used to derive a time-variable reliability index as a condition indicator, which places exceptional load events in the context of the load history and whose threshold values can be defined independently of the verification to be performed. In this example, there were sufficient reserves to lift the distance requirement. Continuous monitoring will nevertheless be continued, also in order to be able to assess the actual effects on safety against buckling if the distance requirement is lifted. In a further step, the condition indicator described in this article was implemented with other condition indicators as part of the smartBRIDGE Hamburg project in a digital twin of the Köhlbrand Bridge. By combining and aggregating all available information on the condition of the structure into a condition score, operators and structural engineers can immediately identify any need for action on the structure.

**ABSTRACT:** We report on recent developments in distributed fiber-optic strain and temperature sensing (DTSS) technologies. In recent years, both Brillouin- and Rayleigh-based fiber-optic sensing systems have found an increasing number of applications measuring static and dynamic displacement and deformation events in geotechnical and structural health monitoring. The focus of this contribution is on Brillouin-based DTSS systems, for which we present recent advancements in spatial resolution and signal-to-noise ratio under harsh real-world conditions. The state-of-the-art Brillouin DTSS technology is considered also in relation to Rayleigh-based technologies like c-OFDR and DAS systems that also play an increasing role in geotechnical and structural monitoring, in order to illuminate the technology-specific strengths and challenges within the DFOS family. Recent insights from industrial projects and research activities in embankment monitoring are presented.

**KEY WORDS:** Distributed Fiber Optic Sensing, Structural Health Monitoring, geotechnical monitoring, Brillouin DTSS, BOFDA, embankment monitoring, crack detection

## 1 INTRODUCTION

Fiber-optic sensing is applied in many different domains of structural and geotechnical surveillance. Among the various technologies available, Brillouin-based Distributed Temperature and Strain Sensing (DTSS) offers particular advantages in that it addresses the analysis of physical parameters with measurement performance that meets engineering requirements particularly well. These performances, in particular the spatial resolution, accuracy and measurement range, integration time, long-term reliability continue to evolve thanks to a continuous development effort from the scientific and industrial community. The type of optical sensing fibers and deployed sensors in general, as well as the installation procedures and the management techniques for sophisticated measurement data sets must also be continuously adapted to the demanding needs of continuously more complex projects and the new technological possibilities that become available.

In this study, an overview of the most widely used distributed fibre-optic sensing technologies is presented, with a comparison of these technologies according to their key advantages.

In particular, we demonstrate the latest developments achieved by the Brillouin Optical Frequency Domain Analysis (BOFDA) technology, in terms of enhanced spatial resolution and deployability on various types of sensing fibers.

These performances make it possible to achieve measurement results with previously unattained quality and flexibility. This is demonstrated by the application of crack detection on dike covers presented in this article.

## 2 DISTRIBUTED FIBER OPTIC SENSING TECHNIQUES FOR STRUCTURAL AND GEOTECHNICAL MONITORING

Monitoring of buildings, transport infrastructure and the geotechnical and hydrogeological natural environment using distributed fiber optic sensors is becoming widespread.

The availability of a range of complementary measurement techniques on the market to suit the specific requirements of diverse applications and environments has enabled DFOS to be used on a large scale and for a variety of different Structural Health Monitoring (SHM) and geotechnical monitoring projects [1]. Even more importantly, a new generation of interdisciplinary engineers is arising and tackling large-scale and complex DFOS-based projects mastering dedicated instrument and sensors integration procedures as well as data management models complying with the spatially distributed nature of the DFOS, also deploying artificial intelligence and digital twins [2].

Complementary DFOS measurement techniques can be applied alternatively or jointly in structural monitoring campaigns [3, 4]. Different sensing technologies have advantages and disadvantages in terms of sensitivity to specific physical quantities, spatial distribution, temporal response, stability, field applicability, and financial cost.

The most relevant DFOS technique of interest for structural and geotechnical monitoring are shortly presented here after.

### 2.1 High-spatial resolution coherent Optical Frequency Domain Reflectometry (c-OFDR)

In the case of structures of limited dimensions (typically smaller than 100 m), monitoring with coherent Optical Frequency Domain Reflectometry (c-OFDR) [5, 6] is often the preferred choice.

The c-OFDR technology measures the distributed profile of the intensity of Rayleigh backscattering. This backscattering profile constitutes a unique fingerprint of the microscopic distribution of the scattering centers along the optical fiber, and is assumed to be stable over time – with limitations due to ageing, water intrusion, radioactive impact, etc. With its sub-centimeter spatial resolution and microstrain accuracy over tens of meters, c-OFDR is well suited for precise monitoring in SHM applications, achieving high acquisition rates (up to few hundreds of Hz for small objects under test), allowing for dynamic measurements. Commercial instruments are, on the other hand, limited in monitoring large structures and for long-term measurement campaigns. Even if rectification of the decorrelation of measurements in the long-term have been demonstrated in post-processing of acquired data [7, 8], the technique is mostly deployed in laboratory environments or for short, discrete measurement campaigns.

For the structural and geotechnical monitoring of larger objects, long spatial range DFOS techniques such as Distributed Temperature and Strain Sensing (DTSS) based on Brillouin analysis, and Distributed Acoustic Sensing (DAS) based on the dynamic analysis of Rayleigh scattering are widely preferred.

## 2.2 Dynamic measurements by Distributed Acoustic Sensing (DAS)

Distributed acoustic sensing (DAS), also referred to as phase sensitive optical time-domain reflectometry ( $\Phi$ -OTDR), is a fiber optic sensing technology also relying on Rayleigh backscattering and is sensitive to strain and temperature perturbations in the fiber [9, 10]. By injecting pulses of coherent laser light into an optical fiber, an optical phase change is recorded, resulting from the backscattered light between two sections of fiber. DAS broadband capability at frequencies of several kHz and its high sensitivity in the picostrain range makes it ideally to be deployed in application fields such as geophysics (seismology, oil and gas, geothermal energy), electricity distribution, and perimeter monitoring. On the other hand, its inadequate performance to detect strain changes at low frequencies implies that its deployment is rare in long-term quasi-static geotechnical applications, where changes occur in time scales ranging from seconds (e.g. by pile loading tests) to years (e.g. for monitoring tunnel convergence, subsidence in transport infrastructure, landslides). One of the rare deployment examples of low-frequency DAS to characterize the movement of slow-moving shallow landslides is recurrently cited in literature [11].

On the other hand, DAS finds possible deployment opportunities in SHM, for example for monitoring the dynamic response of built structures such as bridges [4]. Namely the combination of DAS with long-term stable DFOS techniques, such as Distributed Temperature and Strain Sensing (DTSS) based on Brillouin Optical Time/Frequency Domain Analysis (BOTDA / BOFDA), comes with several advantages. Both the Brillouin and Rayleigh backscatter are sensitive to strain and temperature changes, but complementary spectral information can be gained. DAS is mainly sensitive to strain changes caused by acoustic signals or vibration along the fiber with acquisition rates up to several kHz. This allows insights on the vibration behavior of the bridge. Brillouin sensing, in contrast, offers

highly stable and reliable measuring of long-term evolutions of strain and temperature.

## 2.3 Long-term stable DTSS by Brillouin Optical Time/Frequency Domain Analysis (BOTDA / BOFDA)

Brillouin scattering allows for measurement of the absolute material density state of an optical fiber, thereby providing strain and temperature profiles over more than 50 km, with a spatial resolution down to 50 cm. These performance figures make distributed Brillouin sensing highly suitable for monitoring large structures [12, 13, 14].

The basic principle of all distributed sensing principles based on Brillouin scattering is to spatially resolve the nonlinear Brillouin interaction along an optical fiber in order to retrieve the locally characteristic Brillouin frequency shift, which in turn is (over most of the strain and temperature ranges that are relevant for geotechnical monitoring) linearly connected with the fiber's density. The Brillouin frequency shift can be retrieved from the Brillouin backscattering in a reflectometric set-up, which requires access to only one end of the sensing fiber; such configurations are denoted by the letter "R" in the common acronyms (BOTDR/BOFDR). The signal quality of distributed Brillouin sensing can be highly improved by analyzing the resonance frequency between two counterpropagating optical signals injected from both ends of the sensing fiber. Such configurations bear the letter "A" at the end of the specifying acronyms (BOTDA/BOFDA). Whether the spatially resolved profile of the Brillouin frequency shift is recorded in the time domain or the frequency domain, is denoted by the letters "T" and "F" (BOTDA/R, BOFDA/R).

Due to its primarily measured material parameter being the intrinsic density of the optical fiber, the BOTDA/BOFDA technology is specifically long-term stable and free from the requirement of on-site sensor calibration both at the initial baseline measurements and during long-term operation. With the calibration parameters known for the fiber-optic sensing cables in use (to be acquired from one-time laboratory tests), the Brillouin frequency shift from each measurement iteration can be converted into absolute values for temperature and strain, with no drift being caused by aging, fatigue, or changes in the optical properties of the cables and connectors. Therefore, the technique is especially suitable for geotechnical and structural monitoring over a time horizon even of many years.

For reliable and stable measurements, the behavior of the bonding between the fiber-optic strain sensing cable and the surrounding structure under test must be considered. This is a key point when defining the integration procedures of the sensors in the host structure. On concrete structure the sensor can be embedded with high during the construction process, e.g. close to reinforcement elements (re-bars, pre-stained tendons), or applied on surface by retrofitting (by continuous gluing or using discrete fixation anchors). In the case of geotechnical monitoring this can be optimized, for example by burring the sensing cables in compacted soil or more efficiently in combination of smart geocomposites [15].

Often it is necessary to compensate the effect of temperature on the strain measurement (since Brillouin, as well as Rayleigh sensing show strain-temperature cross-sensitiveness). In order

to separate strain and temperature, the use of dedicated (loose-tube) fiber-optic temperature sensing cables, in which the fiber is mechanically decoupled, in parallel to a tight-buffered strain sensing cable is often the preferred monitoring configuration.

#### 2.4 Cracks, voids, debonding detection by Distributed Temperature Sensing (DTS)

Distributed Temperature Sensing (DTS) using Raman (and also Brillouin and Rayleigh) scattering is widely used in geotechnical and structural monitoring. It ensures accurate deformation measurements by compensating for thermal effects, tracks exothermic reactions in concrete curing, and detects fluid seepage in dams, pipelines, and tailings storage [16]. It has also been shown how DTS can be effectively applied to detect the presence of subsurface defects (voids) in concrete-filled structures [17]. The DTS methodology combined with heat conduction modeling, and inverse analysis has been applied to measure the geometry of foundation piles and to calculate their bearing capacity [18]. Recent studies demonstrate how Brillouin-based DTS can be used for non-intrusive detection of desiccation cracks in dikes. This application is discussed in a later section of this work.

#### 2.5 Key takeaways

- DTS & Brillouin-based DTSS offer the best long-term stability, making them ideal for infrastructure monitoring over decades.
- DAS is highly reliable for dynamic applications, such as seismic, traffic monitoring, vibrational mode analysis.
- c-OFDR provides high precision, but is more sensitive to environmental factors over time.

### 3 PERFORMANCE PARAMETERS AND PRACTICAL IMPLICATIONS OF BOFDA MEASUREMENTS

Specifically for the Brillouin Optical Frequency Domain Analysis (BOFDA), the technology on which the focus of this work lies, we would like to go into deeper detail on two performance aspects for practical distributed measurements in optical fibers.

#### 3.1 Performing DFOS measurements in multi-mode optical fibers using Brillouin sensing system:

It is commonly accepted that for each of the different DFOS technologies, the respective optimum fiber type shall be used in order to gain optimum performance. In Raman DTS systems, these will be multi-mode optical fibers due to their ability to handle high optical power levels (even though dedicated single-mode Raman DTS systems exist, minimizing modal dispersion to achieve higher distance ranges). In contrast, for Brillouin DTSS, literature clearly states that the use of single-mode optical fibers is mandatory. The reason here is that, in multi-mode optical fibers, the excitation of the Brillouin interaction needs to be achieved for each optical mode separately, which makes the backscattering intensity (or the Brillouin gain) highly sensitive to the arbitrary modal distribution of the involved optical signals [19]. While earlier works had shown that a strict limitation to exciting the fundamental mode only

when injecting the optical signals into the fiber under test [20], such an approach has not found its way into practice, with the consequence of a clear directive to practical users of Brillouin DTSS to exclusively use single-mode optical fibers as sensors.

However, in many real-world application scenarios, the user might not have the choice of the fiber type – be it due to previously installed fiber-optic cables that comprise multi-mode fibers for whatever reason, or due to imperfect project design or any other cause. Therefore, Brillouin DTSS measurements in multi-mode fibers have been frequently reported, and the results show that they are indeed suitable for quantitatively meaningful strain and temperature sensing. One of such application scenarios is reported in a later section of this work.

In general, the design variety of multi-mode optical fibers contains specifications on the core diameter (typically 50  $\mu\text{m}$  and 62.5  $\mu\text{m}$ ), and the refractive index profile between core and cladding being a gradient or a step-function profile.

On order to give a generic orientation for Brillouin DTSS performance in a common-type multi-mode optical fiber, we present laboratory measurements from a step-index 50/125  $\mu\text{m}$  (core/cladding diameters) step-indexed optical fiber of 445 m length. The measurements are performed using a BOFDA system on an optical fiber loop with the multi-mode optical fiber under test connected in series with a standard single-mode optical fiber (ITU-T G.652) of 120 m length for reference.

Figure 1. Brillouin gain spectra from one BOFDA measurement on a multi-mode and a single-mode optical fiber

Figure 2. Full BOFDA measurement result: Intensity of Brillouin interaction (color map); local Brillouin frequency shift (black trace)

The measurement results (figures 1, 2) show that the characteristics of Brillouin sensing for a specific fiber type, specifically the characteristic parameters of the Brillouin gain spectrum, indeed differ between the multi-mode optical fiber under test and the reference single-mode fiber:

1. Brillouin frequency shift: While single-mode fibers have a characteristic Brillouin frequency shift (at room temperature and under strain-free conditions) at values between 10.6 GHz and 10.9 GHz, the multi-mode fiber shows a considerably

lower Brillouin frequency shift at 10.31 GHz. This is a quantitative difference, but does not at all compromise the performance of Brillouin sensing, because the observed frequency lies well within the scan range of commercial interrogator units.

2. Brillouin linewidth: The full width at half its maximum of the Lorentzian-shaped Brillouin gain spectrum is observed as 36 MHz for the multi-mode fiber and 25 MHz for the single-mode fiber. Again, this is merely a quantitative characterization and does not imply a significant degradation of the measurement quality.

3. Brillouin gain: The amplitude of the Brillouin gain spectrum of the multi-mode fiber is observed to be 3 dB (half intensity) below the reference single-mode fiber. The direct consequence of this discrepancy is a loss of 3 dB in signal-to-noise ratio between the two fiber types, confirming that single-mode optical fibers are better suited for distributed Brillouin sensing. However, considering the very clear implication of single-mode fibers being the obligatory choice, this 3 dB difference is considerably small. All in all it can be stated that multi-mode optical fibers can in fact be used for distributed Brillouin sensing.

### 3.2 The spatial resolution of BOTDA and BOFDA systems

The spatial resolution is one of the central performance figures of any DFOS system. In general, the following definition has been widely accepted throughout the industry [21]:

*The spatial resolution is specified for a fiber by the minimum distance between two step transitions of the fiber's strain / temperature condition. It is directly related to the pulse length of the measuring instrument.*

For general time-domain DFOS systems, the relation between the pulse length  $\Delta t_p$  and the spatial resolution  $\delta z$  is

$$\delta z = \frac{1}{2} \frac{c_0}{n} \Delta t_p$$

with  $c_0$  being the vacuum light speed and  $n$  the group refractive index of the optical fiber. A rectangular pulse of 10 ns length thus allows a spatial resolution of 1 m.

When considering incoherent frequency-domain systems, such as BOFDA, the pulse length is not directly determinable because no physical pulses are used. In BOFDA, a series of sinusoidally modulated signals is injected into the optical fiber as the pump light; the received signal (the Stokes wave, upon which the sinusoidal modulation is transferred) is analyzed by gain and phase, which – over the full series of different modulation frequencies – results in the complex transfer function, that, eventually, can be converted into the pulse response (and thereby the equivalent time-domain signal of a BOTDA system) by means of an inverse Fourier transform. Whereas in a time-domain system, the spatial resolution is directly related to the pulse width, in a frequency-domain system it is related to the width of the virtual pulse after the inverse Fourier transform, and therefore, in its origin,

determined by the bandwidth (or range of the frequency scan) of the sinusoidal intensity modulation.

The equivalent relation found in literature implies that a bandwidth of 100 MHz results in a spatial resolution of 1 m. We hereby state that this appears to be not consistent with the theory behind nor with experimental results. The key to this discrepancy between commonly accepted literature and everyday observation is that these literature sources neglect the complex nature of the retrieved transfer function. The true assumption there is that the number of scanned frequencies of the transfer function within the given bandwidth equals the number of points along the equivalent time axis for the relation 100 MHz bandwidth  $\Leftrightarrow$  1 m spatial resolution.

However, every frequency point of the complex transfer function comprises two values in the complex domain (gain and phase, or real and imaginary part, respectively). Conservation of information energy results in the fact that this doubles the number of points along the time axis (and thus the equivalent spatial axis), and results in a spatial resolution twice as narrow as the above cited literature implies. The relation for incoherent frequency-domain systems, specifically BOFDA, becomes

$$\delta z = \frac{1}{4} \frac{c_0}{n} \frac{1}{\Delta f_m}$$

in which  $\Delta f_m$  is the bandwidth of the sinusoidal intensity modulation.

Figure 3. Virtual pulse in the time / spatial domain from a BOFDA acquisition scan

Figure 4. Discrete strain event of 0.5 m along an optical fiber, measurement result from BOFDA ( $\Delta f_m = 101.76$  MHz)

For future developments, this means that a native spatial resolution (virtual pulse width) of 0.25 m is achievable by increasing the bandwidth of the intensity modulation to 200 MHz, which is subject to current research by the authors.

#### 4 APPLICATION CASE: UNINTRUSIVE CRACK DETECTION ON DIKE COVERS BASED ON DTS

In the Netherlands, levees also referred to as ‘dikes’ are built from locally obtained materials like sand, clay, and peat, with peat and clay as the most common and abundant materials. They are used as they are the least permeable and most cohesive, thus most mechanically stable and erosion resistant. The outer portions of dikes tend to be made of grass covered hard clay, while the inner portions may be made of sand or peat for easier drainage and flexibility. Nonetheless, these materials respond differently to prolonged drought conditions. Under prolonged periods of dry weather, clay and peat dominated soils tend to develop desiccation cracks in the outer parts and thus the evaporating of moisture tends to increase their dimensions in time. Peat for example, is also a very organic and porous soil which shrinks massively during drought periods which also causes mechanical fracturing of the outer covers of dikes. These processes can seriously compromise the dike’s ability during a sudden storm as faster infiltration will saturate the dike core faster which in combination with a high-water level may result in a slope stability failure and consequently an eventual dike breach.

Currently, the detection of desiccation cracks over dikes involves is done mostly by visual inspection and only prior and during drought periods which normally occur during the spring and summer [22]. These inspections, often result in subjective conclusions and their spatial density and frequency are significantly low with respect to their natural occurrence [22]. Some attempts have been made to increase efficiency in their detection by developing artificial intelligence methods which combine visual inspection and satellite data in machine learning algorithms to analyze dike sections susceptible to cracking and predict them based on exogenous variables [23]. Such methods are useful, but they still depend on extensive human-supplied datasets, which can be inaccurate and relatively small.

For the present study, the main hypothesis is that a DTS fiber-optic (FO) cable-based sensor can be used to differentiate ‘healthy’ dike cover area from a similar area with desiccation cracks, without requiring the sensing cable to be buried in the ground. It is expected that the thermal response along the FO cable must differ significantly among the two types of surfaces given that the thermal emission and absorption will be highly influenced by the difference in thermal capacity and thermal conductivity. FO cables have been already widely used in geohydrological research [7] such as temperature monitoring for abnormal seepage water flow detection and soil moisture content measurement [26, 27]. It is important to note that by making the system as less intrusive as possible, the collected thermal signal is highly influenced by a larger number of external environmental heat sources such as solar radiation (absorption and reflection) wind thermal advection, convection and dispersion, grass moisture content, evapotranspiration, ground heat flux cycle and cable material emissivity among the most important. All these processes and their influence in the thermal response recorded by the sensor have been studied in detail via finite element model and can be found in [24].

To test the main hypothesis, setup under real scale and representative environmental conditions was built at ‘Flood Proof Holland’; a Dutch real scale dike and flood defense testing facility operated by Delft University of Technology among other local governmental and private partners.

The setup consisted in the installation of a multi sensor thermal monitoring system over a pre-existing desiccation peat-based crack found on one of the lab dikes. The cracked area thermal emission was monitored during a period of 20 days and 20 nights with a frequency of 15 minutes. The crack was monitored simultaneously with a Thermal Forward-looking infrared Remote sensor Camara (TRC), a conventional pc webcam and a DTS based FO sensor (See Figure 5).

Figure 5. Dike Crack Monitoring setup at FPH, The Netherlands.

The TRC recorded 16-bit (uint16) thermal images of the crack throughout the measurement period (See figure 6). Each image had a thermal resolution of  $256 \times 320$  thermal pixels and an intensity range spanning from 0 to  $2^{16}-1$ . Its calibration was performed using the recorded air temperature in the climatological Rotterdam Airport from the KNMI (Royal Dutch Metrological Institute), located approximately 5 km from FPH.

Figure 6. Thermal image of crack with chosen TRC areas for pixel averaging and point DTS fiber cable measurement locations for time series retrieval.

The TRC was mounted just on top of the crack at an elevation of 2.6 m. This made possible to cover an approximate area of 2 m by 1.80 m wide. Over the same surface, the FO multimode

cable was laid and anchored to the ground in linear transects orthogonally directed with respect to the main axis of the crack. The DTS system consisted on a BOFDA interrogator manufactured by fibrisTerre Systems GmbH type fTB 2505 [28] and a fiber-optic cable of 3 mm of external diameter (including Kevlar isolation, armoring and polystyrene jacket) with a multi-mode optical fiber as the sensing elements.

Each transect was approximately 4.5 m in length spaced every 0.5 m as shown in Figure 1. The first part of the study consisted in analyzing and post-processing time series extracted only from the TRC images by choosing representative areas inside them and averaging their temperature values per area from the thermal pixels. The time series are presented in Figure 7. Each area represented different elements (see Figure 2) to be analyzed such as a bare grass covered area (TRC-GRS), a cracked area (TRC-CRK) and the environmental air temperature (KNMI).

Figure 7. Time series generated from averaging thermal pixel on each image at different locations.

From Figure 7, it can already be observed that there is almost no delay among the three different time series given the chosen recording frequency (15 minutes). However, in terms of amplitude of the signal it can be observed that the TRC-GRS is greater most of the time with respect to the TRC-CRK which implies that the cracked areas have less capacity of storing the heat and may also release the stored one in a faster way, especially for the hotter days at the end of the monitored period. In addition, it can also be observed that both type of dike surfaces is always warmer when comparing them to the nocturnal environmental temperature during the last days which also can be explained by the stored heat during the day. So, from this preliminary analysis, it was concluded that the best way to characterize the thermal response of each of the surfaces while reflecting both emission and storage of heat, was by estimating the maximum daily amplitude on each of the surfaces. To validate this, the time series analysis of specific points over the grass before and after the crack (See figure 6) and the temperature in the segment of FO exactly over the crack were analyzed as well.

Figure 8. Thermal image of cracks with chosen areas for pixel averaging and DTS fiber cable approximate locations for time series retrieval.

It is important to note that the cable's exposure to the environment affects its temperature readings. The estimated temperature from the TRC-GRS will differ from the DTS-GRS due to the thermal properties and emissivity of the cable jacket material, which absorbs and releases heat at a different rate compared to the grass surface. This is why in the Figure 4, it can be observed that the amplitude values is greater for the cable in cracked zones which contradicts what was observed with the TRC in Figure 7. This is due to the effect of the very different thermal properties of the cable with respect to the grass and crack cover when directly exposed to the solar radiation and environment moisture. Nonetheless while inverse, the relation holds trough out the whole-time span of the experiment which means that it can still be used for crack detection despite of presenting the opposite thermal behavior of the actual soil medium.

Now based on these conclusions, a way of reflecting the difference in thermal properties at each location (cracked and healthy), is proposed based on the estimation of the maximum daily amplitude value ( $A_{max}$ ) from each thermal signal withdrawn from the DTS. To do that, we propose to plot the cracked and non-cracked  $A_{max}$  ratio between DTS and KNMI versus the same  $A_{max}$  from KNMI as shown in Figure 9.

Figure 9. Amplitude ratios of DTS over KNMI plotted against maximum daily amplitude from KNMI. Left plot corresponds from cable over crack. Right plot comes from cable where no crack is present (see Figure 6).

From this last figure, the results indicate that indeed, in locations where a crack is present, the ratio of heat amplitude at a point with a crack compared to a point without one is typically greater than 1 due to the influence of the thermal properties of the cable. In contrast, at locations where no crack exists at the midpoint, this ratio is consistently less than 1. This suggests that areas with cracks tend to release heat more quickly and cool to lower temperatures at night compared to areas where the grass remains unfractured. We have also confirmed these findings through a finite element model study. Based on all the observations reported earlier, this study concludes that a DTS FO based sensor can be used to effectively detect cracks using daily cycle measurements taken at three points along a cable sensor. This conclusion relies on the physical principle that the recorded internal temperature of the cable tends to be higher in cracked surfaces during daytime and colder during nighttime with respect to the cable reading over grass. This behavior is inverse to the one observed by monitoring the temperature with TRC which reflect the actual thermal emission from the grassed surface without any interference.

## 5 CONCLUSIONS

This study highlights the effectiveness and evolving capabilities of distributed fiber-optic sensing technologies for structural and geotechnical monitoring. Among these, Brillouin-based systems, particularly BOFDA, demonstrate specifically long-term measurement stability, making them well-suited for complex infrastructure applications. The successful use of DTS for non-intrusive crack detection on dike covers further underlines the potential of fiber-optic sensors in surface-level diagnostics without the need for invasive installation. By leveraging the thermal response differences across varied surface conditions, DTS proves to be a powerful tool for environmental and structural assessments. The findings presented herein lend further support to the ongoing integration of DFOS in contemporary monitoring strategies, a process that is set to be further accelerated by the ongoing advancement of sensing technologies (instrumental performance, sensors quality), integration procedures, and complex data interpretation methodologies.

**ABSTRACT:** The diagnosis and maintenance of both new and ageing infrastructure are among the main challenges facing the civil engineering and geotechnical industries today. The effectiveness of monitoring systems depends on several factors, including the choice of measurement techniques. Conventional point-based methods (e.g., vibrating wire sensors, electrical strain gauges, or accelerometers) are inherently limited by their locality, as they cannot directly capture what occurs between discrete measurement points. In contrast, distributed fibre optic sensing (DFOS) introduces new capabilities for structural condition assessment by enabling continuous measurement of various physical quantities along the entire length of the sensor. This eliminates the risk of missing localized extreme events or damages, such as cracks, leakages, or stress concentrations. However, the widespread adoption of DFOS is hindered by the high costs of optical interrogators, which often restrict its use to periodic measurements rather than fully automated monitoring. A practical solution to this challenge is the synergistic combination of point-based and distributed technologies within hybrid monitoring systems. Such systems leverage the strengths of both approaches, offering a more comprehensive understanding of structural behavior. This paper explores the concept of hybrid systems, illustrating their potential and real-world applications through selected case studies.

**KEY WORDS:** hybrid system, DFOS, distributed sensing, optical sensors, bridges.

### 1 INTRODUCTION

Diagnostics and maintenance in an appropriate technical condition of existing, ageing infrastructure (including bridges, tunnels, pipelines and other safety-critical facilities) is one of the key challenges currently faced by both Polish and global civil engineering. Today, experts conducting periodic inspections have significantly broader responsibilities than in the past [1], along with an increased scope of accountability for the decisions they make. Therefore, the decision-making process [2] related to the operational safety of structures, particularly those with large spans [3] or unconventional structural solutions, should be supported by objective, effective, and cost-efficient diagnostic methods. As a result, integrated structural health monitoring (SHM) systems [4] are increasingly being used, enabling the measurement of selected physical and mechanical parameters of structures during their normal operation.

Beyond the growing awareness within the engineering community, the development of monitoring systems is also, unfortunately, driven by the recurring occurrence of structural failures and collapses [5][6]. These incidents often stem from errors made during the design, construction, and maintenance of bridge structures. From a statistical standpoint, it is impossible to completely eliminate such errors. However, it is essential to take measures aimed at minimising the risk of structural failures. SHM systems contribute to this objective by providing early warnings of potential hazards, detecting trends that enable forecasting of structural behaviour over time, and supplying objective data for the calibration of theoretical and numerical models.

The effectiveness of monitoring systems, however, depends on numerous factors, including the choice of measurement

techniques, data acquisition methods, installation quality, selection of measurement locations, accuracy of applied data processing algorithms, thermal compensation, and the adopted diagnostic procedures. Developing an effective system requires interdisciplinary knowledge that often extends beyond the expertise of civil engineers and even mechanical specialists. Another challenge is the wide range of measurement techniques available on the market, each with its own advantages and limitations. There is no universal solution. Monitoring systems should therefore be designed individually, tailored to the specific characteristics and operational conditions of a given structure.

Analysing the rapidly evolving market for structural diagnostics and monitoring, certain trends shaping the general approach to monitoring systems design can be observed. One of the most promising directions is the development of hybrid monitoring systems, which aim to synergistically combine selected measurement techniques to optimise the information obtained about the structural safety while simultaneously reducing overall system costs. The following sections of this article explain the concept of hybrid systems and present their operational principles using the selected case studies, with the main focus on bridge structures.

### 2 SPOT MEASUREMENTS CONTINUOUS IN TIME

The fundamental requirement for implementing an early warning system is to carry out measurements automatically and continuously over time. The vast majority of such systems are built using spot sensors, installed at selected locations within the structure – Fig. 1.

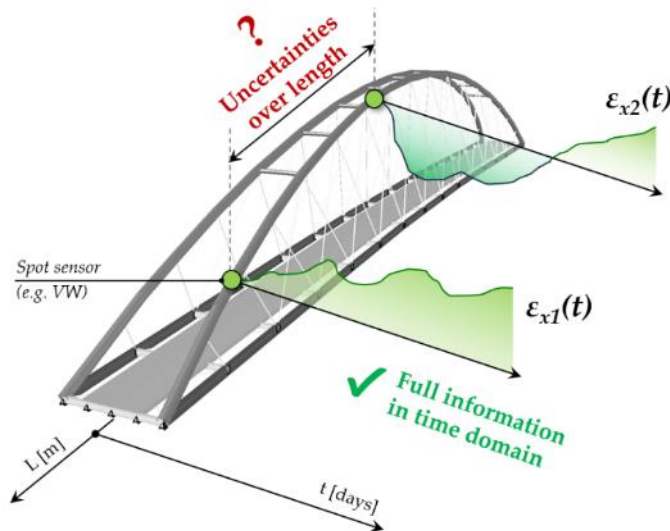

Figure 1. The scheme of the monitoring based on automatic spot sensors, performing continuous measurements over time at selected locations of the structure.

Thanks to their long-term stability, high accuracy, and resistance to environmental conditions, vibrating wire gauges [7] have found widespread use in such systems. The most commonly measured physical quantities are strains [8], based on which local stress in the monitored material can be estimated. Nowadays, all vibrating wire gauges are equipped with integrated thermistors, allowing for appropriate corrections to the measured strain values due to temperature changes over time, as well as enabling an assessment of the global structural performance due to the thermal loading [9]. This approach allows for the analysis of time-dependent phenomena, including trend identification, forecasting the behaviour of the structure, and identifying potential threats that become apparent in changes in locally measured parameters.

Depending on the design of the vibrating wire gauge, in addition to strains, it is possible to measure other physical quantities such as stress, displacements, rotations or forces. Other spot measurement technologies are also used, such as piezoelectric accelerometers for vibration monitoring, MEMS inclinometers for measuring rotations, inductive sensors, and many others. A typical scheme of a spot-based monitoring system for a bridge structure is shown in Figure 2.

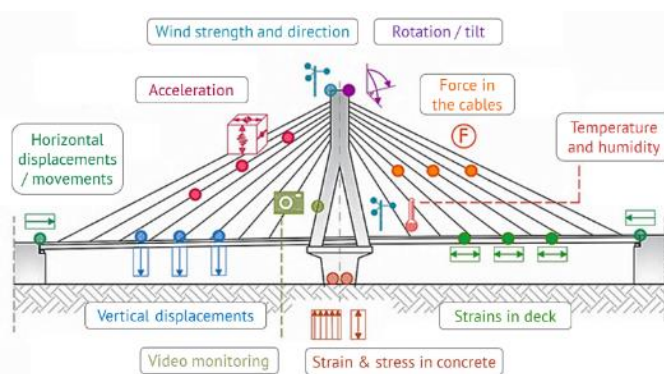

Figure 2. A typical monitoring system for a bridge structure designed with spot gauges.

The gauges are connected to local dataloggers that send measurement data to a remote server, where further analysis and interpretation are carried out. The cost of such loggers is typically negligible in the context of the entire investment. However, despite the many advantages of this approach, it also has several limitations. First, measurements are only taken at selected spots. Aside from the need to choose optimal measurement locations, which is often not a trivial task, there is a lack of information during operation about what is happening with the structure between the measurement points. In other words, this system does not allow for the direct detection of local threats, such as cracks, damage, or stress concentrations. Furthermore, the unit cost of a single gauge is relatively high due to the justified necessity of using high-quality sensors. Another issue is often the need to install long and complex cable routes, as each sensor must be connected to the logger using dedicated signal cables.

### 3 DISTRIBUTED FIBRE OPTIC SENSING (MEASUREMENTS CONTINUOUS OVER LENGTH)

Distributed fibre optic sensing (DFOS) [10] features a number of advantages such as high accuracy, measurement stability over time, and immunity to electromagnetic interference. However, its primary characteristic and advantage, distinguishing it from traditional discrete methods, is the ability to perform measurements of strain, temperature, displacement, and vibration not only at selected points of the structure but along its entire length (Fig. 3), ranging from a few centimetres to several hundred kilometres. Therefore, the analysis of the structure's performance can be carried out not only in the time domain  $\epsilon(t)$  but also in the length domain  $\epsilon(l)$ , providing entirely new insights and diagnostic possibilities.

Figure 3. The scheme of the monitoring based on fibre optic sensors (DFOS), performing continuous measurements along the entire length of the structure.

Thanks to the use of linear sensors, there is no need to select optimal locations for measurement locations, the number of which is often limited by budget constraints. DFOS sensors are installed along the entire length of the monitored elements or entire structures [11], such as bridges [12][13], roads [14], tunnels [15], railways [16][17], collectors and pipelines [18], or linear concrete elements like girders [19]. A significant

consequence of performing geometrically continuous measurements is the ability to directly detect local damage or threats, such as concrete cracking [20][21], local stress concentrations, sinkholes, leaks, and others. As a result, the effectiveness of the measurement system in early risk identification is very high – there is no possibility of missing extreme values of the measured physical quantities. This is one of the main reasons for the dynamic growth and development of DFOS technology in construction and civil engineering, which translates into a noticeable increase in its practical applications. Figure 4 shows selected examples of implementations within Polish bridges only [22, 23, 24, 25, 26, 27]. The full list of bridges and various types of structures is much longer.

Figure 4. Example bridge structures in Poland equipped with distributed fibre optic sensing DFOS systems.

It is worth emphasising that depending on the type of chosen interrogator (optical datalogger), sensors, and installation approaches, the DFOS technique allows for the measurement of various physical quantities. The most commonly measured parameters include mechanical-thermal strains [28], but also shape changes (displacements) [29][30] and vibrations. Interestingly, there is the possibility of connecting the same sensors to different optical interrogators for simultaneous measurements of various quantities, such as strain and temperature. It should also be noted that, although the DFOS technique can represent a breakthrough in monitoring and diagnosing structures, there is no one universal solution for optimal sensor and interrogator properties. In other words, a wide range of optical fibres, cables, and sensors is available

on the market [31][32][33], each characterised by its own advantages and limitations. When selecting a specific sensor, attention should be given to aspects such as:

- size and shape of the cross-section (round, rectangular),
- internal construction (layered, monolithic),
- core material parameters such as elasticity modulus or maximum elongation,
- type of outer surface (smooth, ribbed, with a braid),
- mechanical, chemical, and environmental resistance,
- minimum bending radius.

It is important to emphasise that both the parameters of the interrogators and sensors should be selected individually based on the needs of a given project. For example, in the case of embedding sensors in concrete, round cross-sections and an external braid to improve adhesion are preferred. On the other hand, for gluing to flat surfaces, a flat rectangular cross-section without a braid is better. Sensors are a key component of the entire system. Once integrated into the monitored structure, they should provide reliable information about its performance throughout the entire service life. In telecommunications applications, optical fibres are used with various protective coatings, as well as layered cables, where the fibre is protected by additional protective layers. However, these layers usually do not adequately transmit strain to the sensing fibre inside the cable, creating the risk of data misinterpretation [20]. Therefore, in engineering applications, sensors designed as composite elements with fibres fully integrated with the single-material core during production are more often applied. Fig. 5 shows the family of various monolithic sensors. The EpsilonSensor has a low modulus of elasticity (3 GPa), making it particularly sensitive to detecting cracks in concrete. The EpsilonRebar, with a modulus of 50 GPa, can, in addition to its sensing function, also serve as reinforcement with parameters similar to typical GFRP (glass fibre reinforced polymer) bars. The EpsilonFlat is suitable for bonding to the surface of structures, while the EpsilonGraph is ideal for projects where rapidly changing temperature is a key parameter.

Figure 5. Typical monolithic sensors for mechanical-thermal strains [courtesy of SHM System / Nerve-Sensors].

There is no doubt that a well-designed DFOS system can provide unique information, allowing reliable inferences about the technical condition of a structure. However, a key limitation of this technology in practice, slowing down its widespread

adoption, is the high cost of optical interrogators. Therefore, a common practice is to use a single device for periodic readings from sensors installed on multiple structures. Of course, the cost efficiency of the system will also depend on the scale of the investment and the responsibility (failure consequences) of the monitored structure.

While DFOS measurements are most commonly performed periodically today, it is worth noting the rapid development of optical equipment. In recent years, new devices have appeared on the market, and existing ones have been improved in terms of selected parameters, such as spatial resolution or maximum measurement range. The high cost is partly due to the patents in place, which, in some cases, will expire in a few to several years. Therefore, it is expected that the cost of such devices will decrease in the future, while their diagnostic capabilities will increase. Creating intelligent infrastructure today, equipped with relatively not expensive DFOS sensors, will not only allow precise periodic measurements but also prepare for the use of future, yet unknown capabilities.

It is also worth noting that DFOS sensors are, at the same time, signal cables (transmitting information from thousands of measurement points directly to the interrogator). In spot measurements, a signal cable must be routed (and secured) from each sensor to the local datalogger, which in many cases can be problematic. This applies especially to structures such as bridges, large-scale buildings (halls and stadiums), and linear infrastructure such as pipelines, collectors, or railways. A comparison in cross-section volume of 20 typical signal cables with a single optical fibre is shown in Figure 6.

Figure 6. Comparison of 20 typical signal cables with a single optical fibre, capable of handling tens of thousands of measurement points.

#### 4 HYBRID SYSTEMS

To summarise the above considerations, it should be stated that the primary limitation of classical spot techniques is their locality, while the limitation of DFOS methods is their periodicity (resulting from economic, rather than technical, factors). Therefore, a natural consequence of attempting to solve this problem is the synergistic combination of spot technology with geometrically continuous sensing through the design of a hybrid system – Figure 7. In this approach, automatic spot measurements (continuous in time) are supported by periodic DFOS measurements (continuous in length) to optimise the obtained information, while maintaining

economic feasibility. Hybrid systems have the following advantages:

- low cost of distributed fibre optic sensors,
- possibility of limiting the number of relatively expensive spot gauges and cabling,
- no need to purchase expensive DFOS interrogators,
- ability to install distributed sensors during the construction phase, with measurements taken at later times (a “time-delayed investment”),
- increased system reliability through comparative analysis of data from at least two independent measurement techniques,
- direct detection of local damage, cracks, or stress concentrations (using DFOS sensors),
- possibility of analysing and identifying long-term trends in the operation of the structure (forecasting with spot gauges).

Figure 7. Concept of a hybrid system providing information about the technical condition of the structure both as a function of time and as a function of length.

Hybrid systems are not just a theoretical concept, but an increasingly common solution used in practice. According to the authors, it is one of the main directions that the structural health monitoring market will follow in the coming years. The further part of this article discusses the examples of the use of a hybrid approach for the diagnostics of one of the polish bridge and gas pipeline.

#### 5 EXAMPLE APPLICATION – THE CONCRETE BRIDGE IN NOWE MIĘSTO LUBAWSKIE

The analysed system concerns the road bridge over the Wel River, which is the longest and most technologically complex structure on the Polish national road DK15. This five-span bridge, with a total length exceeding 267 m, was built as part of the bypass around the city “Nowe Miasto Lubawskie”. The load-bearing structure of the bridge is a prestressed concrete box girder (Figure 8) with a structural height of 3.5 m. The installation of the box girder system using longitudinal launching technology was divided into 9 segments, each of which was cast in two stages. Due to certain concerns regarding the durability of the structure, it was decided to equip the existing bridge with a hybrid monitoring system, consisting of: 1) distributed fibre optic sensors for strain measurements and crack detection, and 2) automatic vibrating wire gauges for strain and temperature measurements continuous in time.

Figure 8. General view of the analysed bridge from the outside (top) and inside of the prestressed box (bottom).

Distributed strain sensors (EpsilonSensors) with an external braid were installed in four measurement lines (A, B, C, D) along the entire length of the bridge, achieving a total of 1040 meters of sensing path. Assuming a spatial resolution of the interrogator used at 5 mm, this results in a total of 208,000 measurement locations within a single session. Installing such a large number of spot gauges with cabling would be impossible both technically and economically. The sensors were installed inside the prestressed box in near-to-surface grooves using a dedicated mortar. Additionally, 4 sections were installed on the side wall of the box along the prestressing cables, with a total length of 44 m, by gluing the sensors without external braid directly to the surface (Figure 9).

Figure 9. Installation of the EpsilonSensors with braid in near-to-surface grooves (top) and without braid directly on the concrete surface (bottom).

For the automatic measurements, spot strain gauges in the form of vibrating wire transducers were chosen, installed in 3 cross-sections, with 4 gauges in each section. This resulted in a total of 12 measurement locations, additionally equipped with reference thermistors – Figure 10.

Figure 10. Example view of vibrating wire strain gauge (Geokon 4000) during installation.

The location of all the sensors (both spot gauges and distibued EpsilonSensors) within the hybrid system in question is shown in Figure 10.

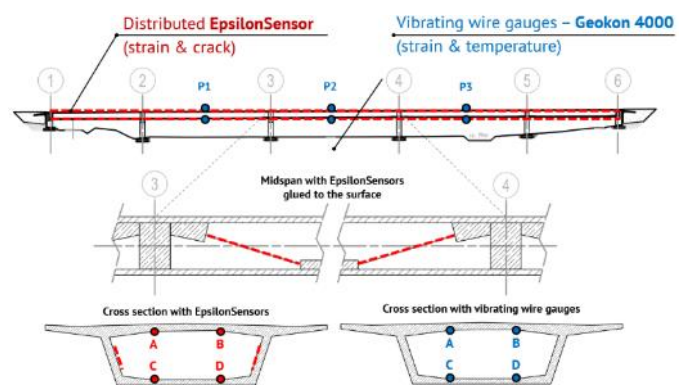

Figure 11. Location of distributed sensors (red) and vibrating wire gauges (blue) within the considered hybrid system.

An example of the strain and temperature plot as a function of time for a selected spot gauge is presented in Figure 12. The period under consideration is the first year of system operation, from July 2023 to July 2024. The obtained results indicate a complete dependency of strain on temperature changes on an annual basis, without any visible alarming trends. The graph shows three vertical blue lines marking the moments of periodic DFOS measurement sessions (S00, S01, and S02). The S00 session was the reference state (zero reading) for both independent techniques to enable their direct comparison.

On the other hand, the profile of the measured strains along the entire length of the central span (60 m) obtained during the periodic, but distributed measurements is presented in Figure 13. The DFOS-based strains profiles exhibit a smooth course, without distinct local extremes characteristic of cracking. Based on the measurements, no open cracks were found along the entire length of the bridge, which is a crucial piece of information for assessing the durability of the analysed structure. Local fluctuations are related to the typical behaviour of concrete as a heterogeneous material. During the first measurement session (S01), a temperature drop of approximately 30°C was recorded in reference to zero reading, which caused the bridge length to decrease due to thermal contraction (negative strain values). Measurements in session S02 were taken under similar thermal conditions to session S00, so the measured strain profile is close to the zero axis.

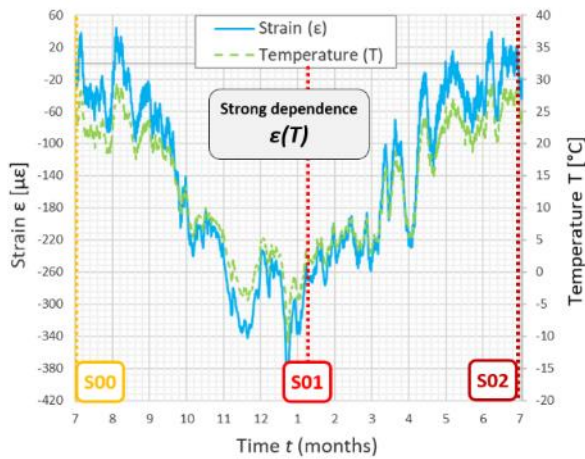

Figure 12. Example strain changes versus temperature changes over time at selected location.

Figure 13. Example strain distribution along the central span in subsequent measurement sessions.

The data from the first year of system operation indicate the normal behaviour of the bridge (in accordance with theoretical predictions) under varying thermal conditions. No hazardous trends were identified through continuous measurements, nor were any local damages detected by distributed sensing.

## 6 EXAMPLE APPLICATION - PIPELINE

The second example concerns the high-pressure pipeline monitored with a hybrid approach. The general concept of the system is visualised in Figure 14. The installation included 12 vibrating wire strain transducers (Geokon 4150) arranged within four cross-sections (Figure 15). On the other hand, the entire 180 m long segment of the pipeline was equipped with distributed strain sensors (EpsilonRebas) and distributed shape sensors (3DSensors).

There were two types of installation approaches. The first one (and more challenging) included the gluing the strain sensors directly to the pipeline surface (Figure 16). On the other hand, both strain and displacements sensors were embedded in surrounding ground (Figure 17), which is relatively simple procedure. The goal of that was to analyse the quality and possible correlation of the data obtained with these two methods and thus to optimise the future installations.

Figure 14. Visualisation of the hybrid monitoring system for the analysed gas pipeline segment

Figure 15. Vibrating wire gauges and their initial check during installation on the pipeline section.

Figure 16. Distributed strain sensors (EpsilonRebars) during the installation (just before gluing) directly on the pipeline.

Figure 17. Distributed displacement sensors (3DSensors) during the installation within the surrounding ground.

Figure 18 shows the analysed segment of the pipeline equipped with all the sensors in the final installation stage, right before backfilling the entire section with soil.

Figure 18. The view of the monitored section during final stage of installation (just before its backfilling with the soil).

The example data provided by the system in the first year of its operation are discussed hereafter. Figure 19 shows the relationship between strain and thermal changes measured by one of the spot gauges at a selected location. As with the previously presented bridge, the data indicate the normal, cyclic behaviour of the pipeline with no alarming trends. There is a full correlation between these two quantities, indicating that other potentially hazardous mechanical actions (e.g. mass movements, settlements, or sinkholes) are not present.

Figure 19. Example strain changes versus temperature changes over time at selected location.

Despite the importance of the above findings, it is not possible to determine the extreme strain (and stress) values or directly answer the question regarding the pipeline's state between measurement locations based on spot gauges. Since no significant deformations were identified throughout the entire year of operation, the results from the pressure test conducted before the pipeline was put into service were selected to demonstrate the capabilities of distributed measurements.

Figure 20 presents the influence of spiral welds, resulting in local distortions in strain profiles. These welds cause both tensile and compressive strains. In the theoretical analysis of a continuous pipeline section under the pressure test, only tensile strains are expected. A similar effect, but much stronger, was observed at the pipeline bends, as shown in Figure 21. Such effects are not always considered in engineering analysis during the design stage, nor are they detectable by conventional spot techniques. This is why the DFOS approach enhances the understanding of the structural performance of pipelines,

enabling better (safer) designs in future applications, as well as effective monitoring for optimised maintenance.

The last, but not least, example of DFOS data shows strain distributions at the beginning of the analysed section (Figure 22). Based on this, it is possible to estimate the length of the transition zone along which the friction between the pipeline and surrounding ground is mobilised. After this length, the mean strains in the pipeline section oscillate around zero due to full constraint.

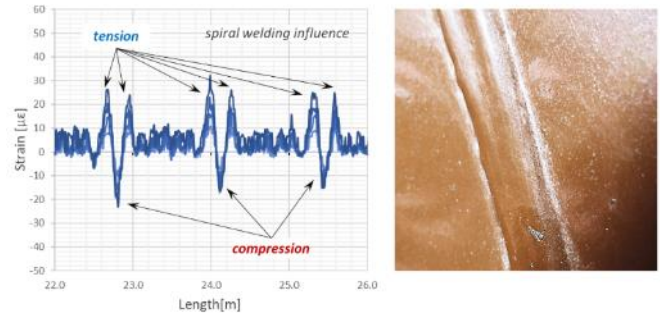

Figure 20. Distributed strain sensing results: the local influence of spiral weld along the length

Figure 21. Distributed strain sensing results: the local influence of the turn (curve) along the length

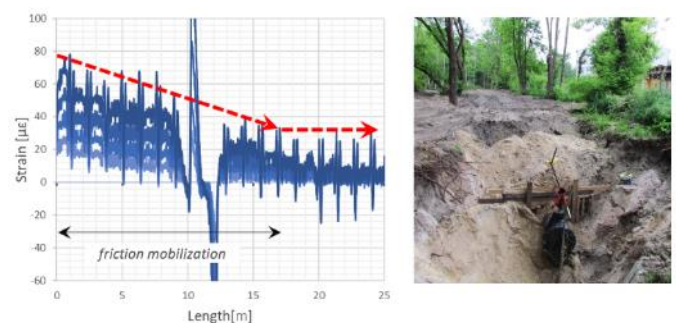

Figure 22. Distributed strain sensing results: the estimation of friction mobilisation at the beginning of the section

An important feature and, at the same time, an advantage of DFOS technology is its capability to measure various physical quantities using exactly the same sensors connected to different optical interrogators. In the present project, EpsilonRebars provided mechanical strain data, as shown above, but also enabled distributed temperature sensing (DTS) with a Raman-based interrogator. Example temperature profiles measured over three consecutive months along the entire length of the

monitored pipeline section are presented in Figure 23, alongside results from reference spot thermistors. The data comparison shows very good agreement, demonstrating the required accuracy of DFOS technology in practical field applications.

Figure 23. Example temperature distributions along the pipeline in three subsequent months versus results from reference spot thermistors (R1, R2, R3 and R4).

The temperature can be averaged over the entire length and presented in the time domain to observe changes on an annual basis and identify possible trends. Such data are presented in Figure 24 for three EpsilonRebars glued directly to the pipeline surface. The colours in the last three months correspond to the colours in the temperature distributions in Figure 24.

Figure 24. Mean temperature values from three EpsilonRebars in subsequent months over the entire year.

## 7 SUMMARY

The article discusses the concept and an example implementation of a hybrid monitoring system on a bridge and a gas pipeline. Thanks to the adopted approach, it was possible to obtain extensive information about the technical condition of these structures while maintaining economic feasibility.

In the first year of the systems' operation, the full correlation between strain and temperature over time was identified using automatic spot measurements. No concerning trends in the structures' performance (e.g., a monotonic increase in strains unrelated to temperature changes) were observed.

Meanwhile, periodic, geometrically continuous DFOS measurements enabled a detailed analysis in the length domain. In the case of the prestressed bridge structure, they confirmed that it remained in an uncracked state along its entire length - crucial information for assessing technical condition and structural safety. For the pipeline, DFOS provided deep

insights into the local influence of welds and geometrical bends on strain distribution, an aspect that could not be captured by other spot sensing technologies.

The technical effectiveness and economic benefits of hybrid monitoring systems, along with lessons learned from previous applications, suggest that this approach will be increasingly adopted in the structural health monitoring market in the near future, particularly within safety-critical infrastructure.

## ACKNOWLEDGMENTS

The research on monolithic sensors design was funded by European Funds through the National Centre for Research and Development under the Intelligent Development Operational Program 2014–2020, as part of the following projects:

- “Innovative Fibre Optic Sensor for Measuring Strain and Temperature” (POIR.01.01.01-00-1154/19),
- “Development of the new fibre optic sensor allowing for the determination of the vertical and horizontal displacements of the studied objects at the distances of up to 120 km” (POIR. 01.01.01-00-0550/15)

These projects were implemented by SHM System (Kraków, Poland, [www.shmsystem.pl](http://www.shmsystem.pl) (accessed on 10 March 2025), [www.nerve-sensors.com](http://www.nerve-sensors.com) (accessed on 10 March 2025)).

**ABSTRACT:** Leak detection for water pipelines, and anomaly detection more broadly, is vital to ensuring reliable access to drinking water. Monitoring transmission and distribution pipelines supports proactive fault detection to reduce water loss amid deteriorating infrastructure and depleting water resources. Distributed acoustic sensing (DAS) in the form of phase-sensitive optical time-domain reflectometry ( $\phi$ -OTDR) can quantify vibrations and sound along fiber optic cables over long distances with high spatial resolution and frequency. In this study, DAS was deployed on a new fiber optic cable-instrumented pipeline to investigate DAS sensitivity to pipe water leakage noise. A reproducible workflow for system deployment and signal processing aimed at pipe water leak detection in field conditions is presented. The influence of fiber optic cable type (tight-buffered vs. loose tube) and installation condition (pipe-mounted vs. trench-lain) on DAS sensitivity was assessed during pipe water filling and simulated leakage. Findings demonstrate relatively high sensitivity to water leak noise detection when DAS is deployed on fiber optic cables near the pipeline. This informs best practices for data-driven pipeline monitoring by presenting a reproducible procedure to operationalize water pipeline leak detection using DAS.

**KEY WORDS:** Water pipeline leak detection; Distributed fiber optic sensing (DFOS); Distributed acoustic sensing (DAS).

### 1 INTRODUCTION

Water leak detection on transmission and distribution pipeline networks is critical to reduce water loss. Growing challenges, such as deteriorating infrastructure and depleting water resources, highlight the need for resilient water infrastructure to ensure reliable access to drinking water. Proactive monitoring plays an important role in helping track down unaccounted non-revenue water losses across geographically distributed pipeline systems. Monitoring also helps water supply agencies effectively predict life expectancy and plan maintenance and rehabilitation of lifeline pipelines. Furthermore, water infrastructure monitoring in low-resource environments is vital for resilient asset management in vulnerable communities.

Conventional methods for pipeline water leak detection are often limited in their balance of scale or spatial resolution. Satellite sensing with synthetic aperture radar (SAR) as well as unmanned aerial vehicle (UAV) sensing with multi-spectral or thermal imaging can detect elevated levels of underground soil moisture caused by leaking water. These offer regional-scale monitoring, but at relatively low spatial resolution. Various pipe-mounted or in-pipe point sensors can detect leakage-related water pressure drops or acoustic emissions, but their scale and spatial resolution is dependent on sensor density (which scales poorly due to high installation and maintenance costs). Ground penetrating radar (GPR) to detect subsurface moisture and listening sticks to listen for water leakage noise can offer pipe segment scale and spatial resolution, but their large-scale deployment is constrained by slow manual labor. In short, conventional methods balance between scale and spatial resolution due to technical constraints. As a result, they typically need to be deployed in parallel to attempt comprehensive monitoring of entire pipeline networks.

However, regional-scale sensing with meter-level spatial resolution is in fact achievable with Distributed Fiber Optic Sensing (DFOS). This family of technologies is at the forefront of large-scale infrastructure performance monitoring of strain, temperature, vibrations, and sound along fiber optic cables over long distances at a high spatial resolution with high measurement frequencies [1]. Distributed acoustic sensing (DAS) in the form of phase-sensitive optical time-domain reflectometry ( $\phi$ -OTDR) has proven uniquely suitable for vibration and sound monitoring of linear civil infrastructure such as offshore wind turbines [2][3], roadways [4], boreholes [5], and pipelines [6][7]. Furthermore, DAS has proven an effective tool even in noisy acoustic environments [8].

Previous work has investigated ground movement-induced pipeline deformation, a common cause of pipe water leakage, in both laboratory and field conditions using Distributed Strain and Temperature Sensing (DSTS) [9][10][11]. This study builds on this work to develop robust methods to directly investigate pipe water leakage by characterizing the distributed acoustic signal of typical and atypical pipeline activities. DAS was deployed on a new 120 m (394 ft) segment of 15.3 cm (6-inch) Earthquake Resistant Ductile Iron Pipe (ERDIP) in a residential neighborhood within the Hayward Fault Zone in Berkeley, California. This new pipeline replaced the old existing pipe which had previously experienced multiple main breaks and major leakage events.

Operationalizing DAS involves implementing an interpretable and reproducible workflow for system deployment and signal processing. Data gathering should be grounded in domain knowledge encompassing real world conditions and decisions and adaptable to past, present, and future data. Data processing should support: 1) predictable outputs withstanding scrutiny from reality checks; 2) computationally efficient use of data storage and processing resources; 3) stability under perturbations in input data and data

gathering and processing judgement calls [12]. In this context, this study presents a reproducible workflow for DAS system deployment and signal processing aimed at pipe water leak detection in field conditions.

## 2 DAS METHOD

Distributed Fiber Optic Sensing (DFOS) quantifies backscattered light in optical fibers to quantify strain, temperature, or vibrations and sound. DFOS involves a sensing device (optical interrogator) connected to one end of a long linear sensor (fiber optic cable). The interrogator sends pulses of light through the optical fiber core of the cable. As these light pulses travel through the core, they interact with imperfections in the silica glass material and are backscattered. Light is backscattered in three typical mechanisms: Raman, Brillouin, and Rayleigh scattering. These mechanisms are sensitive to changes in temperature, strain, or vibrations/sound along the fiber. Rayleigh backscattered light is detected by the interrogator and processed with optical interferometry for distributed acoustic sensing (DAS) [1]. Specifically, phase-sensitive optical time-domain reflectometry ( $\phi$ -OTDR) uses the phase change  $\Delta\phi$  of coherent Rayleigh backscattering to quantify vibrations and sound as dynamic strain  $\varepsilon$  given a known operational wavelength  $\lambda$ , fiber refractive index  $n$ , gauge length  $G$ , and photoelastic scaling factor  $\xi$  [8].

$$\varepsilon = \frac{\lambda}{4\pi n G \xi} \Delta\phi \quad (1)$$

### 2.1 System selection

A DAS system includes a sensing device (optical interrogator) and sensor (fiber optic cable). Optical interrogator hardware and data acquisition parameter selection must ensure adequate sensing range, sampling frequency, spatial resolution, and sampling interval to capture the signal of interest. The sensing range must be sufficiently long to capture measurements along the entire sensing fiber. Sampling frequency should ensure sufficient temporal resolution to capture signals of interest at frequencies below the Nyquist frequency. For context, the Nyquist frequency is the highest frequency that can be accurately measured in a discrete signal and is typically defined as half the sampling frequency. In short, sampling frequency should be greater than double the expected frequency of the signal of interest. Spatial resolution (gauge length) [13] and sampling interval (gauge pitch or channel spacing) [14] depend on optoelectronic hardware component capabilities. In short, spatial resolution and sampling interval should be sufficiently low to capture localized signals along the fiber. Generally, data acquisition parameters are limited by hardware limitations and data processing constraints.

In this study, data acquisition parameters were set to a sampling frequency up to 100 kHz, a minimum spatial resolution of 2 m, and a minimum sampling interval of 1 m for 690 m total sensing fiber length using an OptaSense ODH4 DAS interrogator unit. Note, the 100 kHz raw ping rate was decimated down to 25 kHz during data acquisition and down to 5 kHz during data processing for reasons explained later.

Fiber optic cable selection must ensure proper protection of the optical fiber core and adequate coupling between the core and the external environment. Protecting the optical fiber core from moisture, chemicals and physical damage in the external

environment is necessary to ensure fiber survival. This protection is achieved through various layers separating the central core from the outer cable jacket. Two typical protection designs are tight-buffered (Figure 1) and loose-tube (Figure 2). Tight-buffered cables tightly envelop the optical fiber with a plastic buffer to protect from moisture, steel reinforcement wires to protect from physical damage, and a plastic outer jacket to serve as a fluid barrier. Loose-tube cables loosely suspend the optical fiber with gel-filled tube to protect from excessive tension or bending, surrounded by aramid yarn and a plastic outer jacket to protect from fluid moisture.

Figure 1. Tight-buffered fiber optic cable

Figure 2. Loose-tube fiber optic cable

In terms of DFOS performance, the tight layer boundaries of tight-buffered cables provide a high degree of strain transfer from the outside environment to the fiber optical core. This enables high acoustic signal transmission from outside the cable to the fiber core. On the other hand, the gel-suspension layer boundary in loose-tube cables results in a significantly lower degree of strain transfer from the outside environment to the fiber optical core. This results in lower acoustic signal sensitivity from outside the cable to the fiber core.

In terms of durability and long-term environmental longevity, tight-buffered cables are more rugged and flexible during handling and installation but less resistant to extreme environmental conditions. On the other hand, loose-tube cables are more fragile during installation, but more resistant to hard environments with significant moisture and temperature changes. As a result, tight-buffered cables are typically used for DFOS applications or short-distance telecommunications, while loose-tube cables are used for long-distance telecommunications. Accordingly, tight-buffered cables are often more expensive due to lower niche demand, while loose-tube cables are more affordable given the high demand during mass deployment in global telecommunications networks.

In this study, tight-buffered cables and loose-tube fiber optic cables were both used to compare their DAS sensitivity to

pipeline water leakage noise. Tight-buffered cables were sourced from NZ Sensing (NZS-DSS-C02). Loose-tube cables were sourced from Belden (FSSC002N0).

## 2.2 System deployment

DAS system sensitivity is influenced by the ability of the signal of interest to reach the fiber optic cable. The closer the cable sensor is to the signal source, the better the dynamic strain transfer-related acoustic signal transmission between the cable outer jacket and the fiber core, the better the DAS sensitivity.

If it is possible to install fiber optic cables designated for DAS directly on the monitored structure, they should be positioned as close as possible to the expected signal source location. Structure-mounted (or even structure-embedded) fiber optic cables intuitively offer the best DAS sensitivity. Installing both tight-buffered and loose-tube fiber optic cables supports DSTS (tight-buffered cables with high strain transfer for strain sensing vs. loose-tube cables with low strain transfer for temperature sensing). In the case of DAS, installing both enables a robust comparison between the two. However, deploying structure-mounted fiber optic cables has financial and logistical challenges due to the material and labor cost associated with custom installations.

Instead, existing buried fiber optic cables can be used. Conveniently, these existing cables are widespread under city streets in urban areas with fiber optic internet and telecommunications networks. This provides a cost-effective opportunity to deploy DAS on “dark” (currently unused) fibers in these existing cables without having to install new cables. However, deploying dark fiber DAS on existing telecommunications cables has two significant challenges: 1) existing cables may not be close to the monitored structure and 2) existing cables typically have a loose-tube (either gel-filled or air-filled) internal structure. This results in typically lower dark fiber DAS sensitivity using these types of existing cables.

In short, structure-mounted fiber optic cables offer superior DAS sensitivity but require resources to deploy, while existing buried fiber optic cables offer a convenient low-cost sensor but have lower DAS sensitivity. Using dark (unused) telecom fibers offer unique opportunities for widespread urban DAS activity monitoring. However, quantifying dark fiber DAS sensitivity to pipe water leakage remains a technical challenge.

In this study, both characteristic cable configurations were simulated to investigate their influence on DAS sensitivity to pipeline water leakage noise. Four sensing cable type and location configurations were deployed: 1) pipe-mounted tight-buffered; 2) pipe-mounted loose-tube; 3) trench-lain loose-tube; 4) trench-lain tight-buffered (Figure 3). Pipe-mounted cables were epoxied along the top of the pipe directly to the external pipe wall (Figure 4). A generic field-grade epoxy (toughened methacrylate adhesive system) was used to securely attach the fiber optic cables to the outer surface of the top of the pipe. Cables were aligned and epoxied straight along each approximately 6 m (20 ft) pipe segment. A small loop of slack cable was left at each joint between pipe segments to accommodate the discontinuity in the pipeline surface. Overall, the pipe-mounted cable installation process had a productivity of about 30 minutes per pipe segment. This time was primarily spent on placing and smoothing out the epoxy along the cables.

Trench-lain cables were aligned parallel to the pipeline and laid out on the bottom of the excavated pipe trench (Figure 5).

This process was relatively fast and did not require any specialized tools. Reasonable effort was taken to ensure the cables were aligned straight along the pipeline with an approximately 5 cm offset from the side of the pipe.

Figure 3. Fiber optic-instrumented pipeline

Figure 4. Pipe-mounted fiber optic cable installation

Regarding fiber protection, no additional protection measures were taken. This was to simulate a simple direct-

burial fiber cable installation process. After fiber optic cables were epoxied to the pipeline and lain in the trench, the entire trench was backfilled with coarse sand. The backfill material (Class I backfill) is a typical crushed stone manufactured aggregate used in pipeline construction in the region. The trench backfill material was poured into the trench and was not compacted. A final thin layer of pavement subbase layer of coarse aggregate was placed on top of the trench backfill. This pavement subbase was compacted at the ground surface.

Figure 5. Trench-lain fiber optic cable installation

These four combinations were compared to investigate the influence of fiber-environment coupling conditions. Pipe-mounted cables were expected to exhibit higher DAS sensitivity to signals originating from the pipeline than trench-lain cables. Tight-buffered cables were expected to exhibit lower noise levels with a higher signal-to-noise (SNR) ratio than loose-tube cables with higher noise and lower SNR.

DAS measurements were performed during pipeline commissioning in which this 120-meter pipeline section was connected to the wider water distribution pipeline network. After the two ends of this pipeline was physically connected to the network with valves, the commissioning process involved 1) filling the empty pipe with water and 2) high flow flushing water through the pipe to flush out random debris.

During both tasks, a valve was opened at the downhill end of the pipe to allow water from the pressurized network to flow into the pipe, and a second valve at the uphill end of the pipe was open to air pressure. This water then flowed up into the pipe and filled the pipe with a velocity of approximately 0.7 m/s (2.3 ft/s). This filling process took approximately 180 seconds to fill 120 m of pipe. This meant that once the water level inside the pipeline reached the uphill valve, water would flow out to the ground surface. In the case of the second task, the high flow flushing process resulted in water violently

erupting into the air (Figure 6). These conditions uniquely resembled a violent pipeline break and high flow pipe water leakage. This presented an opportunity to quantify DAS signal characteristics during simulated pipe water leakage.

Figure 6. Simulated leakage at uphill end pipe valve

### 2.3 Signal processing

Analysis of  $\phi$ -OTDR DAS data started with downsampling the raw measured phase shift data to reduce dataset size while preserving key signal characteristics. The 100 kHz interrogator ping rate was decimated down to 25 kHz during data acquisition and down to 5 kHz during data processing to reduce computational costs and facilitate data handling. Data acquisition decimation was performed by a proprietary OptaSense algorithm inside the ODH4 operating software. Data processing decimation was performed by filtering (order 8 Chebyshev type I zero-phase anti-aliasing digital filter) and downsampling the signal. This effective sampling rate of 5 kHz with a Nyquist frequency of 2.5 kHz was sufficiently high to capture the relatively acoustic signal of pipeline water flow.

Next, phase change  $\Delta\phi$  was related to dynamic strain  $\varepsilon$  as presented earlier (Equation 1). Next, frequency band extraction (FBE) was used to inspect the acoustic signal energy content at a specific frequency band appropriate for pipe water leakage noise. Given the dynamic strain spatial timeseries  $x_{ch}(t)$  across time  $t$  for each channel location  $ch$ , each timeseries is divided into time frames and windowed with a periodic Hann window applied to each frame  $w(t)$ , and detrended by subtracting the mean value within the time frame  $\mu_{ch}$ .

$$\tilde{x}_{ch}(t) = (x_{ch}(t) - \mu_{ch}) \cdot w(t) \quad (2)$$

Detrending helps remove low-frequency signal drift, while windowing helps reduce spectral leakage in the signal [12][15]. A Fast Fourier Transform (FFT) is then then applied to the detrended and windowed signal.

$$X_{ch}(f) = FFT(\tilde{x}_{ch}(t)) \quad (3)$$

Next, the power spectrum for each channel is estimated on the FFT and scaled based on the FFT size  $N_{FFT} = 256$ , sampling frequency  $f_s$ , and energy correction factor  $C_w = \sqrt{8/3}$  for Hann window coherency gain.

$$P_{ch}(f) = \frac{2}{N_{FFT} \cdot f_s} \cdot |X_{ch}(f)|^2 \cdot C_w \quad (4)$$

Afterwards, the frequency band extracted (FBE) power for each channel is extracted by averaging the power across the number of frequency bins  $N_f$  within the target frequency band from  $f_{min}$  to  $f_{max}$ .

$$FBE_{ch} = \frac{1}{N_f} \sum_{f_{min}}^{f_{max}} P_{ch}(f) \quad (5)$$

Finally, the mean FBE power in the frequency band is expressed on a logarithmic scale as decibels (dB).

$$FBE_{ch}^{dB} = 10 \log_{10} FBE_{ch} \quad (6)$$

Given the initial input strain spatial time series in units of microstrain  $\mu\epsilon$ , the units of FBE power are  $dB(\mu\epsilon^2/Hz)$ . The FBE power spatiotemporal trend was visualized along the entire fiber length using a waterfall plot format of space (y axis) vs. time (x axis) vs. FBE power (pixel color). This full fiber signal encompassed multiple pipe-sensing strands on the pipe or in the trench separated by intermediate fiber sections which were spliced together at pull boxes at either end of the pipeline. By inspection, the start/end points of each relevant sensing strand were indexed, and the dataset was partitioned by strand. FBE power was compared between the four combinations of cable type and installation location to assess acoustic signal quality and identify channels with signals of interest.

These signals of interest were then evaluated using channel-specific spectrograms and magnitude spectra. Spectrograms visualize signal power spectral density (PSD) across frequencies and time. The spectrogram is computed using the short-time Fourier transform (STFT) with a Hann window  $N_{window} = 2048$ , overlap of 50%, and FFT size  $N_{FFT} = 1024$ .

$$S(t, f) = STFT(\tilde{x}_{ch}(t)) \quad (7)$$

PSD is then computed on the STFT across frequency and time and reported as decibels (dB/Hz).

$$PSD(t, f) = 10 \log_{10}(|S(t, f)|^2) \quad (8)$$

The magnitude spectrum visualizes signal magnitude  $M$  at various frequencies. The magnitude spectrum in decibels (dB) is computed on the FFT across the total signal frequency range.

$$M = 20 \log_{10}|X_{ch}(f)| \quad (9)$$

To compare different characteristic signals of interest, signal-to-noise (SNR) ratio was computed using root-mean-square amplitude of the signal  $A_{signal}$  and “noise” (absence of signal of interest)  $A_{noise}$  strain timeseries using the expressed as decibels (dB).

$$SNR = 20 \log_{10} \left( \frac{A_{signal}}{A_{noise}} \right) \quad (10)$$

### 3 DAS RESULTS

DAS measurements were performed continuously during a 1-hour pipeline commissioning procedure to capture acoustic signals during three characteristic processes (Figure 7):

- 1) water flow as the pipe is filled with water
- 2) pressure transient-related resonance vibrations
- 3) simulated leakage

First, time-domain signals during both characteristic processes were explored by visualizing FBE power across time and space. Waterfall plots of FBE power were created using DAS measurements from all signal channels along the 120-meter pipeline. Furthermore, to facilitate comparing DAS sensitivity between the four cable deployment configurations, signals from each were plotted in four stacked subplots.

Second, frequency-domain signals were investigated at the simulated leakage location at the uphill end valve. DAS measurements from channel 120 (location 120 meters) were selected for this purpose. Acoustic signal frequency content over time was explored with spectrograms. Signal baselines were assessed with time-independent magnitude spectra and quantified with signal-to-noise (SNR) ratio to compare between the four sensing cable configurations. Note, SNR was computed using the same strain amplitude signals used to compute the magnitude spectrum of the “signal” and “noise” spectrum. In full transparency, SNR was computed for the full pipe signal relative to the empty pipe noise (water flow detection), resonance signal relative to the no resonance noise (pressure transient detection), leaking pipe signal relative to the full pipe noise (leakage detection).

Ultimately, the objective of this proof-of-concept experimental setup was to explore DAS signals from fiber optic cables along a water distribution pipe in the context of local installation methods and environmental conditions.

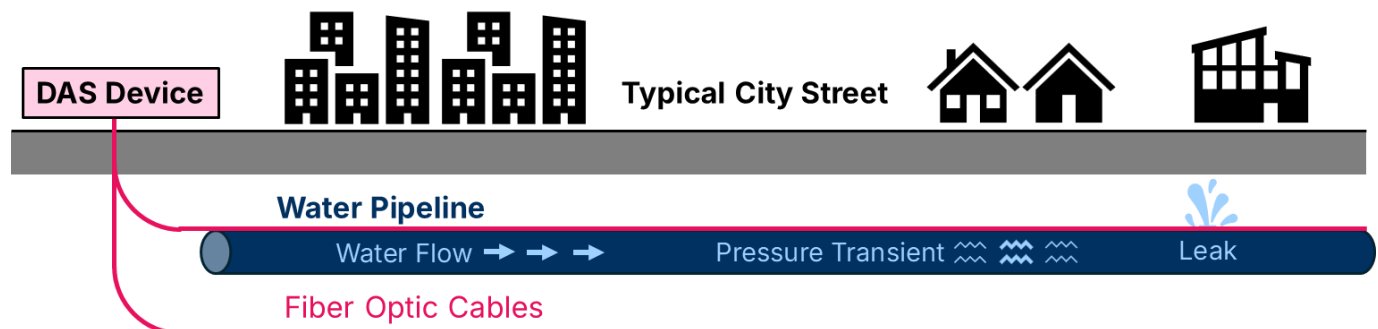

Figure 7. DAS for water pipeline monitoring

### 3.1 Water flow detection

DAS sensitivity to water flow inside the pipe during water filling was investigated. Water flowed into the empty pipe from the downhill end valve. The uphill end valve was open to air pressure. This resulted in a rising water level inside the inclined pipe (Figure 8). As the water level advanced up pipe, water flow and sloshing emitted vibrations and sound. This characteristic acoustic signal was detected and tracked across time along the pipeline. The spatiotemporal trend of 10 to 100 Hz frequency band extracted (FBE) reveals the advancing water level from the downhill end (location 0 m) to the uphill end (location approx. 120 m) (Figure 9). Signal visibility is best on tight-buffered cable on pipe, and progressively worse for other sensing configurations.

Figure 8. Pipe water flow condition

Figure 9. 10 to 100 Hz FBE power during pipe water filling

Spectrograms of frequency-domain signals at the uphill pipe end (location 120 m) reveal a characteristic jump in PSD at 0 to 400 Hz frequencies as the water level passes (Figure 10). This PSD signal is similarly visible on all sensing configurations. Differences in magnitude spectra before and after water level arrival highlight the relatively high SNR between the empty pipe noise floor and the water-filled pipe signal on all sensing configurations (Figure 11).

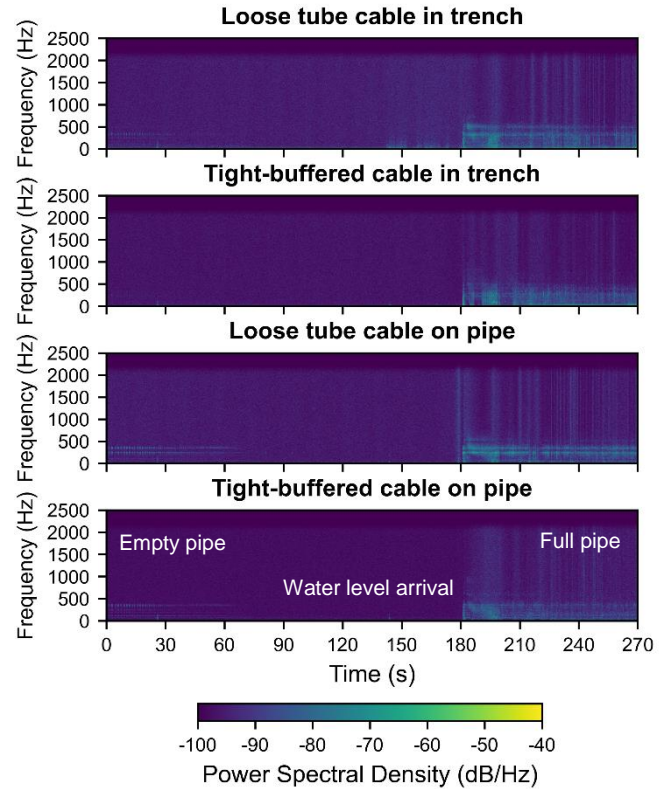

Figure 10. Spectrogram during passing water level

Figure 11. Magnitude spectra during passing water level

In short, DAS detected pipe water flow on all four sensing cable configurations. FBE Power signal is most visible on tight-buffered cable on pipe. Nonetheless, frequency-domain signal was relatively similar on all four sensing cable configurations.

### 3.2 Pressure transient detection

DAS sensitivity to pipe water pressure transients was assessed. After the pipe was filled and the simulated leakage experiment was finished, the final steps of the pipeline commissioning procedure were performed. During this time, a water pressure transient was detected (Figure 12). FBE power from 2 to 20 Hz reveals a 10 second period of elevated acoustic signal along the entire pipeline (Figure 13). The resonant acoustic signal grows, stabilizes, and then disappears. It is most visible on the tight-buffered cable on the pipe, with progressively lower visibility on the other cable configurations.

Figure 12. Pipe water pressure transient condition

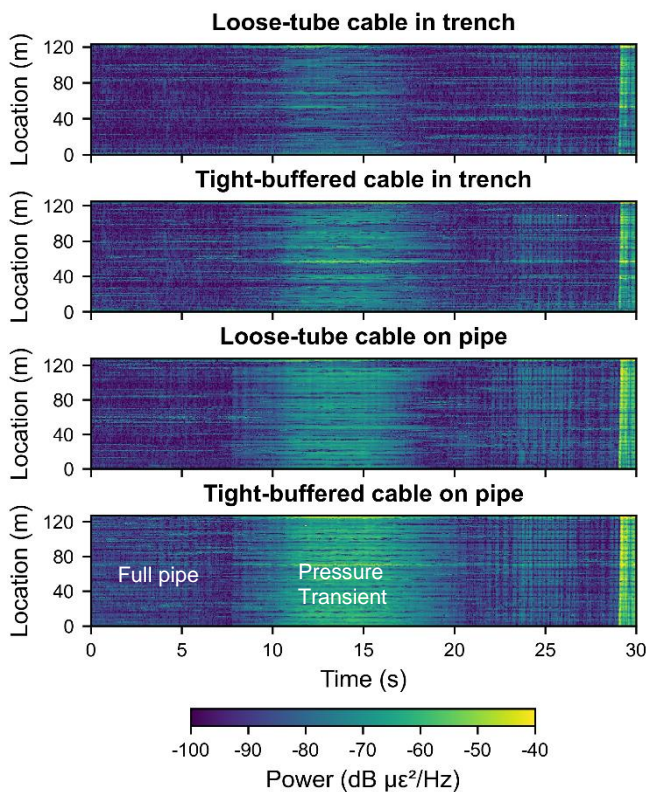

Figure 13. 2 to 20 Hz FBE power during pressure transient

Spectrograms at the uphill pipe end (location 120 m) reveal elevated PSD at low 0 to 20 Hz frequencies (Figure 14). PSD levels at higher frequencies remain relatively low and do not display a matching trend between the different sensing cables configurations. However, magnitude spectra reveal a much clearer difference between signals during the resonant pressure transient and the signal before without acoustic resonance (Figure 15). Both tight-buffered cables and the loose-tube cable on the pipe exhibited less noisy magnitude spectra and a higher SNR than the loose-tube cable in the trench.

Figure 14. Spectrogram during pressure transient

Figure 15. Magnitude spectra during pressure transient

In short, DAS detected a pipe water pressure transient on all four sensing configurations, albeit with lower SNR on loose-tube cable in the trench.

### 3.3 Leakage detection

DAS sensitivity to pipe water leakage noise was evaluated. After the pipe was filled with water, water inflow increased by further opening the downhill end valve. This ensured water would escape from the open valve at the uphill pipe end to simulate high-flow leakage (Figure 16). Simulated leakage was maintained for 6 to 7 minutes until the downhill valve was closed. Water rushing through and exiting the pipe generated vibrations and sound. FBE power from 10 to 100 Hz highlights the start and end of the heavy water flow along the entire pipeline (Figure 17). FBE power was similarly visible on all four sensing configurations. As expected, the maximum acoustic signal was measured at the simulated leakage location.

Figure 16. Pipe water leakage condition

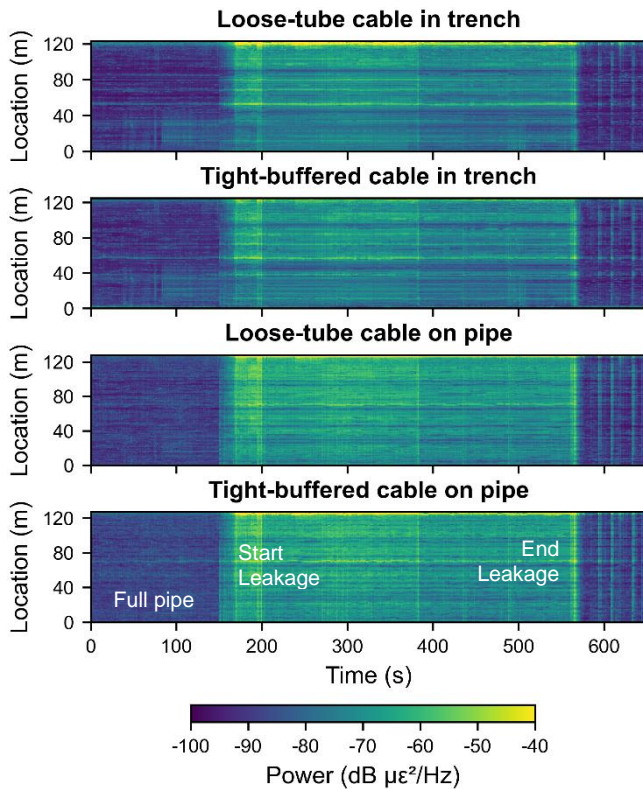

Figure 17. 10 to 100 Hz FBE power during simulated leakage

Spectrograms of frequency-domain signals at the simulated leakage location (location 120 m) display a striking jump in PSD at 0 to 400 Hz, and elevated PSD at 400 to 1000 Hz during simulated leakage (Figure 18) on all sensing cable configurations. Differences in magnitude spectra for signals from the full pipe and leaking pipe suggest a reasonably high SNR between the leaking pipe signal against the full pipe baseline (Figure 19).

Figure 18. Spectrogram of channel at simulated leak

Figure 19. Magnitude spectra of channel at simulated leak

In short, DAS detected pipe water leakage on all four sensing configurations, with similar sensitivity on all four sensing cable configurations.

To summarize, each of the three pipe signal states: 1) pipe water flow, 2) pressure transient-induced resonance, and 3) simulated leakage exhibited unique DAS data characteristics in terms of FBE power, spectrogram power spectral density, and magnitude spectrum trends.

Pipe-mounted cables exhibited a higher degree of FBE power sensitivity than trench-lain cables. Tight-buffered cables generally exhibited a higher degree of FBE power sensitivity than loose-tube cables. At the channel near the simulated leakage location, all sensing configurations exhibited relatively high frequency-domain signal visibility. Notably, trench-lain fibers turned out more sensitive than expected. Their high signal sensitivity was possible because they were located very close to the pipeline. This suggests that trench-lain fiber optic cables can offer sufficient DAS sensitivity to detect pipeline signals if the cables are located close to the pipeline.

#### 4 DISCUSSION

Deploying DAS for water pipeline leakage monitoring presents a trade-off between DAS signal sensitivity and fiber optic cable deployment feasibility and cost (Figure 20).

Figure 20. Qualitative comparison of DAS sensitivity to pipeline signals vs. fiber optic cable deployment cost

Mounting fiber optic sensing cables directly to the pipe offers superior DAS sensitivity. This is because pipeline acoustic signals can transmit directly to the fiber. However, this approach requires significant manual labor and installation logistics coordination. In short, it is a high-cost high reward approach appropriate for high resource deployment conditions such as new installations or retrofits for lifeline pipelines.

On the other hand, laying fiber optic sensing cables in the trench along the pipeline offers relatively lower DAS sensitivity. This is because pipeline acoustic signals need to travel through the trench backfill soil to reach the fiber. However, this approach requires less manual labor and is faster than attaching cables to the pipe. With reasonable DAS sensitivity, this medium cost approach may be a more feasible alternative for low resource deployment conditions. Nonetheless, both methods require resources and coordination to deploy sensing cables during pipeline construction excavations. They are therefore only usable if a DAS deployment is planned before pipeline construction activities.

Long term monitoring and maintenance are also a challenge. Although sensing cables typically have a long lifespan, when deployed in a pipeline alignment, they may be accidentally

damaged during pipeline maintenance operations. Installing DAS interrogators in the field may be cost prohibitive given the need for power supply, climate control, and theft-prevention. From a scaling perspective, deploying sensing cables inside the pipeline alignment as done in this study can be difficult. Accordingly, it works best for critical pipelines with committed stakeholders in a supportive regulatory environment.

Alternatively, dark fiber DAS using existing buried telecommunications fiber optic cables is incredibly convenient with zero physical deployment installation and negligible maintenance costs. In this approach, a DAS interrogator is safely connected to an existing telecommunications cable network that runs from a datacenter through the pipeline network of interest. From a scaling perspective, a standardized dark fiber DAS method for detecting water pipeline leakage would offer a truly low cost and large-scale solution. However, this approach typically has lower DAS sensitivity given that existing cables may be far away from the monitored pipeline and may have poor acoustic signal coupling with subsurface soil. Therefore, further research is needed to better understand and improve dark fiber DAS sensitivity to pipe water leakage.

#### 5 CONCLUSIONS

This study presents a reproducible workflow for DAS system deployment and signal processing for water pipeline leak detection in field conditions. The experimental configuration involved fiber optic sensing cables deployed directly in the pipeline alignment during construction. Both tight-buffered and loose-tube cables were installed on the pipe and in the trench. All four sensing cable configurations exhibited relatively high DAS sensitivity (high SNR) to pipeline acoustic signals during pipe water filling and simulated leakage. These results approximate a potential upper-bound for DAS sensitivity to water pipeline leak detection for each of the sensing cable configurations.

In contrast to other past work which simulated pipeline leakage in fully controlled laboratory conditions, this study consciously pursued the complete opposite approach to embrace the potentially high levels of uncertainty associated with deploying fiber optic cables and DAS in the field. In this context, we acknowledge this study is limited to a single location with a single pipeline and a single simulated leakage signal source. The presented optimistic results of high SNR for all sensing cable configurations near the simulated leakage may be due to supportive experimental conditions. Intuitively, all four deployed sensing cables were on or very close to the pipe, so they detected pipeline acoustic signals reasonably well. Had the sensing cables been further away, their DAS sensitivity to pipeline signals would likely have been reduced.

Further work will investigate DAS sensitivity for water pipeline leakage detection with sensing cable configurations where fiber-optic cables are further away from the pipeline of interest. This will help demonstrate the workflow is applicable to dark fiber conditions where DAS is deployed on existing buried telecommunications cables which may be not close to the monitored pipeline. Furthermore, additional testing in locations with different subsurface conditions (soil type, temperature, moisture), with various pipe materials and leakage mechanisms is needed to develop a comprehensive dataset of pipe water leakage noise signals. This will support a robust and

adaptable workflow for dark fiber DAS to operationalize water pipeline leakage detection. This standardization effort can be scaled up with engagement from public agency stakeholders and regulators to ultimately transform the state of practice for water pipeline monitoring.

To summarize the main contributions of this work:

1. Developed reproducible framework for DAS system deployment and signal processing for water distribution pipeline monitoring.
2. Characterized influence of fiber optic cable type (tight-buffered vs. loose-tube) and installation location (on pipe vs. along pipe in trench) on DAS sensitivity to pipeline acoustic signals.
3. Explored time-domain and frequency-domain content of acoustic signals relevant to pipeline anomaly and leakage detection.

**ABSTRACT:** In this study, we investigate the load-bearing capacity of pre-stressed concrete girders under various damage levels. We employed Distributed Acoustic Sensing (DAS) technology to monitor and quantify changes in the girder response as damage levels were incrementally introduced. This approach enabled the real-time measurement of dynamic behavior over the entire length of the girder, allowing for a detailed characterization of damage-induced structural changes. To complement the DAS-based approach, we also applied classical acceleration-based damage detection techniques. By integrating these methods, we aimed to cross-validate the results and provide a more comprehensive understanding of damage progression and its impact on structural performance.

The experimental campaign, conducted in Ljubljana, ZAG, involved full-scale testing of pre-stressed concrete girders subjected to controlled damage scenarios. This setup ensured a realistic assessment of the girders' residual capacity and failure mechanisms. The paper presents preliminary results from this experimental study, emphasizing the capability of DAS measurements to detect and characterize damage, while also comparing its performance against traditional methods. By combining advanced sensing technologies with established techniques, this research highlights the potential of DAS as a transformative tool in structural health monitoring.

**KEY WORDS:** Distributed Acoustic Sensing; Distributed Fiber Optic Sensing; Structural Health Monitoring; Frequency Analysis; Load Test; Infrastructure Monitoring; Bridge Monitoring.

## 1 INTRODUCTION

Structural Health Monitoring (SHM) of civil structures is gaining more and more significance in the recent years, especially in the case of bridges, since many of them are coming to the end of their design life time or even have to be replaced earlier due to increased loads on the structure. Current incidents such as the collapse of the Carola Bridge in Dresden, Germany draw international attention to the importance of infrastructure monitoring.

In order to gain more knowledge on the structural response due to increasing loads and damages, laboratory load tests on a bridge girder were carried out. The bridge girder stems from a bridge partly collapsed due to flooding in summer 2024. More detailed information about the tested bridge beam and the test procedure can be derived from [1]. The aim of the controlled load tests was to determine the structural behavior and perform measurements at all damage states in order to get a better understanding for condition assessment. This can be done using different measurement techniques, which can be broadly categorized in point-wise and distributed sensors. Suitable point-wise sensors are e.g. accelerometers, but also static or dynamic Robotic Total Station (RTS) measurements [2][3] can deliver valuable results. The drawback of these point-wise techniques is that they require several sensors in order to monitor the structure, and all of them need to be mounted in appropriate positions to obtain meaningful results. Distributed Fiber Optic Sensing (DFOS) functions as a distributed sensor, where one fiber can precisely sense information along its entire

length. Different DFOS techniques can provide insights on the frequency behavior of the structure, but also on the bending due to the applied force. Furthermore, cracks appearing in the structure can be detected. The fiber can be glued on the structure, but also embedded directly inside the structure if it is newly constructed. The application of DFOS for bridge monitoring is currently becoming of more interest [4].

All of the mentioned measurement techniques were applied at the conducted laboratory tests. However, this paper focuses on the results and comparison of Distributed Acoustic Sensing (DAS) and accelerometers.

## 2 BRIDGE MONITORING WITH DFOS

The general principle of DFOS is light coupled into a glass fiber, which gets scattered at natural impurities at every point inside the fiber. A part of the light gets backscattered to the interrogation unit, where different information, especially temperature ( $T$ ), strain ( $\epsilon$ ) or strain rates ( $\epsilon/t$ ), can be derived depending on the measured backscatter effect (see Figure 1). As the light propagates through the fiber, information is sensed along the entire length of the fiber, which can amount up to several tens of kilometers. Significant advantages of DFOS are immunity to electromagnetic interferences and only the small and lightweight fiber being needed on-site, a passive element which requires no power supply.

Since this paper focuses on Distributed Acoustic Sensing (DAS) only, the following paragraph will describe the working principle in more detail.

Pulsed light is coupled into the fiber with high frequency, whereby the maximum sampling frequency  $f_{max}$  is dependent on the fiber length  $L$  by

$$f_{max} = \frac{c}{2nL} \quad (1)$$

in order to avoid overlapping pulses in the fiber.

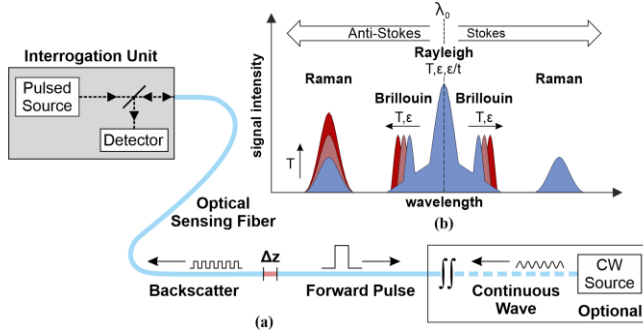

Figure 1. (a) Schematic representation of the operating principle of distributed fiber optic sensing techniques and (b) different backscatter effects, based on [5].

DAS interrogation units only detect and measure Rayleigh backscatter, which has the highest intensity [6]. Rayleigh backscatter is affected by strain and temperature changes, which in turn cause differences in the optical path length. The optical path length is determined from the differential phase between two scatter points [7]. Since the measurand is the optical phase change within a certain distance (the gauge length), the output consists of relative measurements describing the behavior of strain within a certain period of time, resulting in strain rate measurements. The gauge length is typically on the order of several meters and defines the spatial resolution of the measurement. Compared to other DFOS techniques, DAS provides lower spatial resolution, but much higher temporal resolution reaching up to several kHz, making it suitable for dynamic measurements.

The seamless high frequency measurements can provide valuable information about the structural integrity of a bridge by deploying only one fiber to the structure. By numerically integrating the derived strain rate measurements to strain, additional information about the strain distribution along the structure can be gained.

### 3 LOAD TESTS

#### 3.1 Setup

The structure under test is a prestressed girder with a deck plate and has a length of about 10 m. It was placed in the laboratory of the Slovenian National Building and Civil Engineering Institute (ZAG) underneath a hydraulic actuator able to apply vertical load. More information about the placement of the girder on the testing facility can be found in [1]. Several sensors were mounted on the structure. The location of the sensors discussed in this paper can be seen in Figure 2, but also other sensors such as tilt sensors, RTS and camera have been used.

Figure 2. Schematic representation of tested structure with mounted sensors.

As also shown in Figure 3, the fiber was mounted on the upper and lower part of the girder along its entire length. A second fiber was glued in order to be able to perform simultaneous measurements with different DFOS techniques, which are not subject of this present paper. For the DAS measurements, the inner fiber was used.

Figure 3. Glued fibers on the bridge girder placed in the laboratory.

The measurement settings for DAS and accelerometers were as stated in Table 1.

Table 1. Measurement settings.

	DAS	Accelerometers
Sampling frequency	5000 Hz	200 Hz
Measurement channels	25	3
Measurand	$\mu\text{m}/\text{m}/\text{s}$	$\text{m}/\text{s}^2$

#### 3.2 Test procedure

The test procedure consisted of 10 load phases with 2 cycles each, increasing the maximum load with every phase. For the first three phases, the applied load was increased stepwise with a waiting time of 2 minutes after every load increment, while for the latter phases a constant linear load increase was applied. The loading speed was 1 kN/s, and the same procedure was applied for both loading and unloading. The load cycles are shown in Figure 4. Note that the pause between the load phases 3 and 4 is not shown correctly in the plot, since there was an overnight pause in between.

In between the phases, ambient vibration tests were performed. These aimed to stimulate the girder in a way so the eigenfrequencies could be detected. The stimulation was performed by a human jumping on the girder in order to induce an impulse. After phase 5, shaker tests were performed by placing a vertical shaker on the beam, stimulating it with different singular frequencies as well as with a frequency sweep.

Figure 4. Performed load cycles.

### 3.3 Eigenfrequencies

The eigenfrequencies can be determined from the ambient vibration tests and provide significant information about the structural integrity, since a change in the eigenfrequency indicates structural damage. Figure 5 shows the ambient vertical vibration of the girder after phase 2, measured with the accelerometers at 3 discrete positions on the beam bottom.

Figure 5. Accelerometer measurements of ambient vibration, 3 positions on the bottom.

DAS measurements can be obtained along the entire fiber. The occurring strain rates caused by the excitation of the girder can be seen in Figure 6, whereby the y-axis shows the distance along the fiber, and the x-axis depicts the change over time.

Figure 6. DAS waterfall plot of ambient vibration.

From the DAS waterfall plot, a location on the fiber close to the accelerometer can be selected. For comparison, a location at the bottom center and also in the upper center was chosen. Note

that the spatial resolution of the DAS amounts to 0.8 m. When compared with the accelerometers, it is noticeable that the measurements look very comparable with the single impacts being clearly differentiable in both (Figure 7). For better comparison, the DAS measurements have been down sampled to the same sampling frequency as the accelerometers (200 Hz). What stands out in the DAS measurement is the significant difference between the upper and lower part of the beam, with the lower section showing considerably more movement than the upper section. This indicates a high vertical position of the neutral axis. As the measured vibrations on the upper and lower fiber are in phase (see Figure 8.), the neutral axis must be located above the upper fiber.

Figure 7. DAS measurements of ambient vibration, top and bottom center.

Figure 8. Measurements of upper and lower fiber are in phase for measurement of ambient vibration.

In order to determine the eigenfrequencies appearing through the excitation, a Short Time Fourier Transform (STFT) with a window length of 4 s was computed both for the accelerometers and DAS measurements. For the accelerometer mounted at the bottom center of the girder, the resulting amplitudes of each window are shown in Figure 9. The appearing main frequency amounts to 14.75 Hz. The same procedure was applied to the DAS measurements. Again, a bottom center position on the fiber, as well as a top center position were chosen for comparison. For both positions, the same eigenfrequency of 14.75 Hz was observed (Figure 10), which is in agreement with the accelerometer measurements shown in Figure 9.

Figure 9. Eigenfrequency of the beam after loading phase 2, bottom center accelerometer.

However, the measured amplitudes at the bottom and top part vary significantly, with the bottom part responding about 5 times stronger than the top part (note the different scaling in Figure 10). This again implies a high vertical position of the zero line of the beam.

Figure 10. Eigenfrequency of the beam after loading phase 2, bottom and top center measured with DAS.

One of the main advantages of Distributed Fiber Optic Sensing is the seamless measurement along the entire fiber. The frequency and amplitude can be obtained at any point and give a more complete picture of the overall structural behavior. Therefore, a frequency analysis was carried out for every point along the fiber. The eigenfrequency of 14.75 Hz remained constant along the entire girder, but the amplitude varies strongly as it can be seen in Figure 11.

Figure 11. Amplitude curve for eigenfrequency of 14.75 Hz along the top and bottom part of the beam.

Note that the different dimension of the amplitudes compared to Figure 10 stems from the FFT being computed over the entire event, instead of 4 s windows. Again, it can be observed that the bottom part of the beam shows stronger reaction, and also the middle part of the beam shows increasing amplitudes for both the upper and lower side.

The eigenfrequencies have been determined for every ambient vibration event, which was carried out after each load phase. With increasing damage, the measured eigenfrequencies decrease significantly. The first cracks appeared in load phase 2. Table 2 shows the results for both DAS and accelerometers, which are in complete agreement for every measurement. Note that due to the window size of 4 s, the frequency resolution only amounts 0.25 Hz.

Table 2. Comparison of eigenfrequencies for DAS and accelerometers, ambient vibration at different damage states.

Impulse Excitation	After load phase	$f_{Acc.}$ [Hz]	$f_{DAS}$ [Hz]
1	Phase 2	14.75	14.75
2	Phase 3	14.25	14.25
3	Phase 4	14.25	14.25
4	Phase 6	13.75	13.75
5	Phase 7	12.50	12.50
6	Phase 8	10.50	10.50
7	Phase 9	10.00	10.00

### 3.4 Shaker Tests

In addition to the ambient vibration tests, experiments with a shaker were carried out. The shaker weighs approx. 100 kg and can oscillate vertically. Different singular frequencies and amplitudes can be set, and also frequency or amplitude sweeps can be performed. The shaker was placed as close to the middle of the girder as possible (Figure 12).

Figure 12. Placement of the vertical shaker on the girder.

First, a frequency sweep from 2-100 Hz was carried out. After that, the shaker was operated with different constant frequencies but increasing amplitude. An overview of the test procedure is shown in Figure 13. The different amplitude sweeps can be clearly seen in the DAS raw data. A STFT shows in more detail the appearing frequencies and amplitudes. The frequency sweep ( $t=100-350$  s) is visible well, with higher amplitudes appearing when the shaker frequency matches the eigenfrequency. Also, the second harmonics can be detected.

Figure 13. Overview shaker tests - raw data and STFT.

After that, the STFT with a window size of 2 seconds clearly shows the amplitude sweeps ( $t=500-1500$  s) at different constant frequencies. A strong structural response can be detected when the input frequency amounts to the eigenfrequency or the latter is a harmonic of the stimulating frequency. This can be seen in the first ( $t=500-600$  s) and third ( $t=840-1000$  s) sweep, where the input frequency is 7.1 Hz and 14.2 Hz. Furthermore, a detailed look is taken at the excitation close to the eigenfrequency. Note that the eigenfrequency already decreased to 14.25 Hz, since the shaker tests were carried out after phase 5 (compare Table 2).

Taking a closer look at sweep 3, where the girder was stimulated with the eigenfrequency, also the harmonics can clearly be detected. This can be seen at the bottom position as well as at the upper position (Figure 14). The most dominant is the third harmonic at 42.6 Hz.

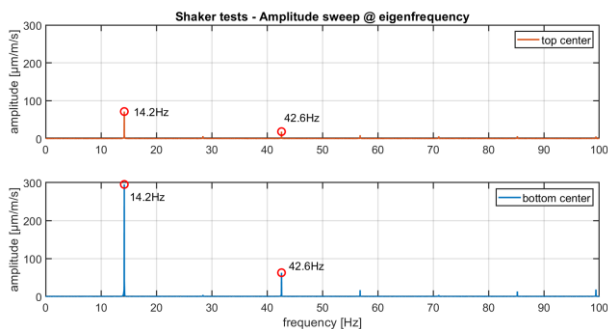

Figure 14. FFT at top and bottom center position.

### 3.5 Load Capacity

In addition to a frequency analysis, DFOS measurements can also serve to determine the applied strain on the structure. Typically, static DFOS measurements such as Optical Frequency Domain Reflectometry (OFDR) or Brillouin backscattering are used to measure absolute strain. These systems usually provide a better spatial resolution, but a poor sampling rate, if at all capable of performing dynamic measurements.

By numerically integrating the measured strain rates over time, the appearing strain can be calculated from the DAS

measurements. For this purpose, a known starting value (initial strain) is needed. In case of the load tests, this was accomplished by starting the measurement before any load is applied, thereby minimizing the induced integration error. However, this is based on the assumption that the fiber does not experience any permanent strain from the previous load cycles. Figure 15 shows a waterfall plot of the appearing strain along the entire fiber. The load increments can be seen as progressively increasing elongation of the fiber over time, as well as a clear difference between the upper and lower part of the beam.

Figure 15. Waterfall plot of induced strain along the fiber, load phase 2.

Taking a closer look at the top and bottom center position of the girder, the load increments and pause time in between are visible (Figure 16), as well as the significant difference in strain between the upper and lower part. Note that the outlier in the load strain profile ( $t=750-900$  s) derives from a failure of the hydraulic actuator.

Figure 16. Increasing strain at top and bottom center, phase 2.

Figure 17 shows the strain distribution along the fiber for load phase 4, cycle 2. At this phase, there was no load incrementation followed by a waiting period, but a linear increase of the load until the maximum load. The applied load is approximately one third higher than in phase 2 (see Figure 4), which results in significantly higher strain. Figure 17 shows the loading as well as the unloading of the element.

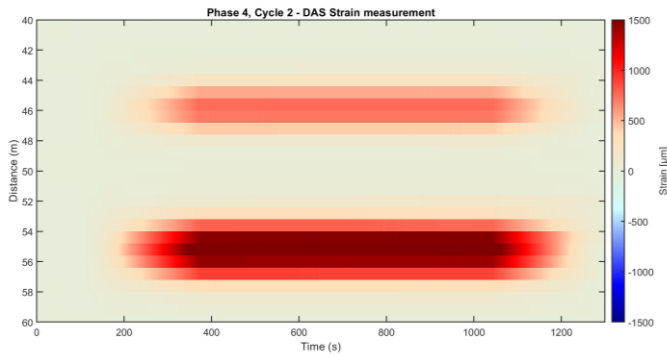

Figure 17. Waterfall plot of strain distribution, phase 4, cycle 2.

Of particular interest is the strain distribution, which appears very concentrated in the center of the girder, where the force is applied (Figure 18, right).

Also, a more detailed look can be taken at the strain distribution on the bottom and top center of the girder (Figure 18, left). The lower part experiences significantly higher strain, amounting more than twice as much as the upper part. It should also be noted that with increasing force the ratio of the measured strain between the lower and upper part increases, which implies an upwards moving neutral axis with increasing load.

Figure 18. Load phase 4. Left: Measured strain at top and bottom center. Right: Strain distribution along the fiber at maximum load.

#### 4 SUMMARY AND CONCLUSION

The loading tests have shown that Distributed Fiber Optic Sensing is a suitable measurement technique to determine the structural integrity of girders or bridges. While delivering comparable results to other sensing techniques, it can provide significant advantages compared to pointwise sensors. A frequency analysis can be performed seamlessly along the entire fiber, whereby the high sampling rates can determine any changes in the eigenfrequencies. In addition to the high frequency strain rate measurements, the occurring strain at the structure can also be determined. The obtained results can provide valuable insights about the damage state of the structure. All this information can be sensed with only one fiber mounted to the structure, whereby after the initial installation no further direct interaction with the structure is necessary.

Further work will include a deeper look on detecting the tearing of tension cables, as well as a more detailed look on damage assessment using mode shapes.

#### ACKNOWLEDGMENTS

We want to acknowledge the collaboration with the Slovenian National Building and Civil Engineering Institute (ZAG), which carried out the load tests at their laboratory and gave us the opportunity to install our sensors and carry out the measurements.

**ABSTRACT:** The alarming frequency of bridge collapses in recent years underscores the critical need for advanced monitoring strategies tailored to existing infrastructure. Many concrete bridges, built decades ago, now face increasing traffic demands and environmental stressors that threaten their structural integrity.

This study investigates the use of distributed fiber optic sensors (DFOSs) with high spatial resolution (independent strain measurements every 2.6 mm) during static load tests to assess the structural performance of concrete girder bridges. The goal is to gain a deeper understanding of their condition using data-driven approaches. The fiber optic technology provides detailed strain profile information that gives insights into global bridge behavior, such as stress distributions, support conditions and static responses. It also allows the detection of cracks along the fiber path and other localized effects that may remain undetected without a calibrated numerical model.

This method of structural performance monitoring is applied to a prestressed concrete bridge in Switzerland. Static load tests have been performed on a full-scale bridge in Switzerland and the resulting distributed strain datasets allow the accurate understanding of bridge behavior, including deflection extrapolation and crack detection. The results underline the potential of DFOS to develop novel data-driven solutions for extending the service life of structures.

**KEY WORDS:** Distributed fiber optic sensors, Structural identification, Structural performance monitoring, Structural health monitoring, Load testing, Concrete bridge.

## 1 INTRODUCTION

Across the globe, bridge networks are experiencing a rapid deterioration amid rising traffic demands and environmental effects, posing significant challenges to infrastructure safety and management. Budgetary constraints and the potential socioeconomic disruptions from closures or failures, such as the catastrophic collapse of the Morandi Bridge in Genoa [Calvi et al., 2019], highlight the critical need for accurate structural safety assessments to optimize resource allocation and ensure public safety.

Traditional engineering approaches, created for the design of new structures, are not adapted to existing bridges, where material degradation and unforeseen modifications obscure true conditions. Compounding this issue, visual inspections suffer from subjectivity and an inability to detect hidden flaws, driving the need for more reliable, data-driven solutions [1]. To address these shortcomings, researchers have developed advanced monitoring methodologies that harness field measurements to either pinpoint damage or deepen understanding of structural behavior [2]. Structural performance monitoring (SPM), in particular, seeks to uncover hidden reserves of load-bearing capacity by leveraging precise measurements from real-world conditions [3]. The effectiveness of such frameworks hinges on the choice of monitoring technology. Since the 1950s, strain gauges have been a cornerstone of structural assessment, valued for their affordability and durability [4]. However, their discrete spatial sampling limits their ability to capture the full spectrum of a bridge response, especially in aging concrete structures prone to localized deterioration.

The introduction of fiber optic sensors (FOS) has marked a pivotal advancement, enabling distributed strain monitoring over extended distances with high spatial resolution [5]. More recently, distributed fiber optic sensors (DFOS) have pushed this boundary further, achieving gauge pitches as fine as 1.3–2.6 mm through breakthroughs in optical technology. This development, depicted in Figure 1, facilitates precise detection of local strain anomalies, such as impacts of concrete cracks, by analyzing time- and frequency-domain signals, far exceeding the capabilities of traditional sensors [6].

Figure 1. Comparison between distributed fiber optic sensors and conventional strain gauge for concrete-structure monitoring.

Despite these advances, notable gaps remain in the literature. Most research focuses on long-term structural health monitoring (SHM) to track trends over time [7], while the potential of DFOS for SPM, evaluating immediate responses under specific loads, remains largely untapped.

This study explores the transformative potential of DFOS in concrete bridge monitoring, with a focus on the role of signal processing in unlocking comprehensive structural understanding. Using datasets collected during static load tests on a full-scale prestressed concrete bridge, the approach demonstrates how DFOS-derived strain profiles provide a dual lens, detecting local effects like cracks and elucidating global responses like girder interactions and boundary effects. The primary objective of this study is to show the result of application a novel SPM methodology that integrates DFOS technology with static load testing to provide detailed evaluations of both local and global structural behaviors [8].

This approach is applied to an existing prestressed concrete bridge, Ferpècle bridge in Switzerland. This methodology illustrates the substantial benefits of DFOS and signal processing in providing a holistic understanding in enhancing safety, optimizing maintenance strategies, and extending the service life of critical infrastructure.

## 2 BRIDGE BEHAVIOURS IDENTIFICATION – 6 STEPS METHODOLOGY

Evaluating the structural integrity of existing bridges, especially those with complex geometries, demands detailed knowledge of their characteristics and construction history, yet such information is frequently incomplete or absent for older structures. This section outlines a new methodology [8] that utilizes static load test data to generate new insights, enhancing the accuracy of structural assessments. The methodology, illustrated in Figure 2, centers on SPM of girder bridges using DFOS.

Figure 2. Overview of the methodology for the examination of existing girder concrete bridges with DFOS.

Step 1 involves selecting monitoring systems and load test configurations to acquire informative datasets. Multiple DFOS, coupled with a high-resolution data acquisition system, capture strain responses with fine spatial detail during controlled static load tests. Supplementary sensors, such as linear variable

differential transformers (LVDTs), may be incorporated to augment data richness. Step 2 entails analyzing and refining the collected data. At each measurement point, the most probable value is extracted and anomalies are filtered to ensure only reliable, representative data proceed to analysis. In Step 3, the consistency of strain data is validated against expected values derived from the bridge structural properties and the load test configurations. Step 4 examines the strain distribution to determine the bridge's static behavior, revealing global structural patterns and localized effects, such as concrete cracks (via strain peaks) and the impact of secondary elements on main girder deformations.

Step 5 extrapolates stress distributions among girders, support conditions, and bridge deflection from the strain data, yielding refined insights into structural behavior for improved assessments. Step 6 addresses structural safety through standard verifications, though these lie beyond this study's scope; further details are available in [9]. This model-free approach systematically converts raw data into actionable knowledge, facilitating a comprehensive understanding of three-dimensional bridge behavior.

## 3 STRUCTURAL PERFORMANCE MONITORING WITH DISTRIBUTED FIBER OPTIC SENSORS

### 3.1 Bridge presentation

Located in Les Haudères in the Swiss Alps (canton of Wallis) at an altitude of 1450 meters, the Ferpècle Bridge is a prestressed reinforced concrete structure erected in 1958. Designed with a single 35-meter span, the bridge originally consisted of two girders, each 1.5 meters high, arranged in a slender TT cross-section and is one of the first prestressed bridges in the country (Figure 3). In 2023, a structural intervention expanded the deck width from 5.3 meters to 7.9 meters using ultra-high-performance fiber-reinforced cementitious composite (UHPFRC). This intervention employed a cantilevered UHPFRC slab with varying thickness, rigidly linking the superstructure to the abutments and converting the bridge into a semi-integral static system (Figure 4) [9].

Figure 3. Photograph and cross-section scheme before intervention.

Figure 4. Photograph and cross section scheme after intervention.

This structural modification, accomplished by establishing a monolithic connection between the superstructure and abutments, redistributes bending moments, removes expansion joints and increases support capacity. As a result, the bridge benefits from significantly enhanced rigidity, bending capacity, and shear strength, while the low permeability of UHPFRC improves its long-term durability.

Materially, the bridge was initially built with C30/37 concrete, now reassessed as C40/50 to account for strength increases over time [10]. The reinforcing steel has a characteristic tensile yield stress of  $f_{yk}=345$  MPa, and the prestressed bars feature a strength of  $f_{pd}=840$  MPa. The UHPFRC, categorized as type UB, meets Swiss standards with a tensile strength of  $f_{Utd}=6.9$  MPa [11].

### 3.2 Distributed fiber optic monitoring campaign

Comprehensive monitoring campaigns were conducted in 2023 and 2024, following the intervention on the Ferpècle Bridge to evaluate its structural behavior and mechanical properties. During the deck widening from 5.3 to 7.9 meters, scaffolding facilitated the installation of distributed fiber optic sensors (DFOS) along the full 35-meter span of both prestressed concrete girders. Grooves 6 mm deep were cut into the external web of each girder, 0.5 meters from the girder bottom. DFOS cables (SMARTeC-DiTeSt SMARTProfile Sensor [12]) were affixed with glue and protected by aluminum plates to shield against environmental exposure, as illustrated in Figure 5. This figure also depicts the fiber optic positioning process and a schematization of the SMARTeC sensor, which incorporates two fibers for detecting temperature variations and two for measuring strain, both monolithic sensors with standard acrylate coating, further shielded by UHPFRC cantilevers. The installation presented challenges, requiring a scaffolding to groove the concrete and the careful gluing of fiber optic cables to avoid sensor slip. Uniform glue distribution was critical to ensure consistent response in the concrete-glue-coating-sensor system. The upstream girder is designated Channel 1 (CH1) and the downstream girder Channel 2 (CH2). Strain data were recorded using a LUNA ODiSI 6100 system [13] at a 2.6 mm resolution, yielding approximately 12,000 data points per

girder, at a 5 Hz sampling rate. Five static load tests were performed using one or two three-axle trucks, each weighing 26.4 tons (axle loads: 8.9 tons, 10.4 tons, 7.1 tons; transverse axle spacing: 2.0 meters). These configurations, detailed in Figure 4, included single-truck midspan loading (LT1 and LT2), dual-truck side-by-side placement at midspan (LT5) and longitudinal alignment along one girder (LT1 and LT2) to maximize the effects in one-quarter span.

Figure 5: SMARTeC fiber optic installation

Six linear variable differential transformers (LVDTs) were installed vertically beneath the girders at midspan, near abutments and quarter-span positions, recording deflection at 10 Hz to complement DFOS datasets.

A similar monitoring campaign was conducted in 2024, differing only in the repositioning of the two LVDTs from near the abutments to the transverse beam at quarter-span locations and an increase in truck load to approximately 28 tons.

For both campaigns, temperature compensation was deemed unnecessary due to the short data collection period (approximately 30 minutes) and cloudy sky conditions. These conditions did not result in temperature changes significant enough to alter the structural response compared to the calibration baseline. This assumption is validated by the strain and LVDT signals in the time domain, as shown in Figure 9, where signals start at zero when no truck is on the bridge and return to zero after the truck leaves, indicating no effects necessitating temperature compensation.

Figure 6. Sensor configuration. (Up) Elevation view; (Down) Plan view.

Figure 7. Sensor configuration. (Up) Cross section in one quarter-span for the load configuration LT3; (Down) Photo of the bridge with sensor locations.

Figure 8. Static load tests with either one truck (LT1 and LT2) or two trucks (LT3, LT4 and LT5).

Each test produced two strain vectors per girder ( $N \times T$  dimensions, where  $N \approx 12,000$  points and  $T$  denotes time steps), totaling ten vectors across the campaign. LVDTs yielded six deflection vectors per test ( $1 \times T$  dimensions), totaling 30 vectors.

### 3.3 Application of the methodology for LT3

The methodology of Section 2 is applied considering the strain measurements by the DFOS for CH2 during LT3 from the monitoring campaign of 2024.

As a first step, the raw DFOS and LVDT data are processed to extract reliable structural response measurements. Consistent strain and deflection values are determined by averaging measurements taken while the trucks remain stationary (Figure 9), filtering out anomalies. For CH2, the most probable strain value at a midspan DFOS point is  $20 \mu\epsilon$  while for LVDT4 (one quarter span of CH2), the deflection is 2.32 mm. Post-selection, DFOS datasets are reduced from  $N \times T$  to  $N \times 1$  vectors ( $N \approx 12,000$ ), and LVDT datasets from  $1 \times T$  to  $1 \times 1$ , streamlining subsequent analysis. Figure 10 illustrates the reconstructed signal for LT3 in CH2.

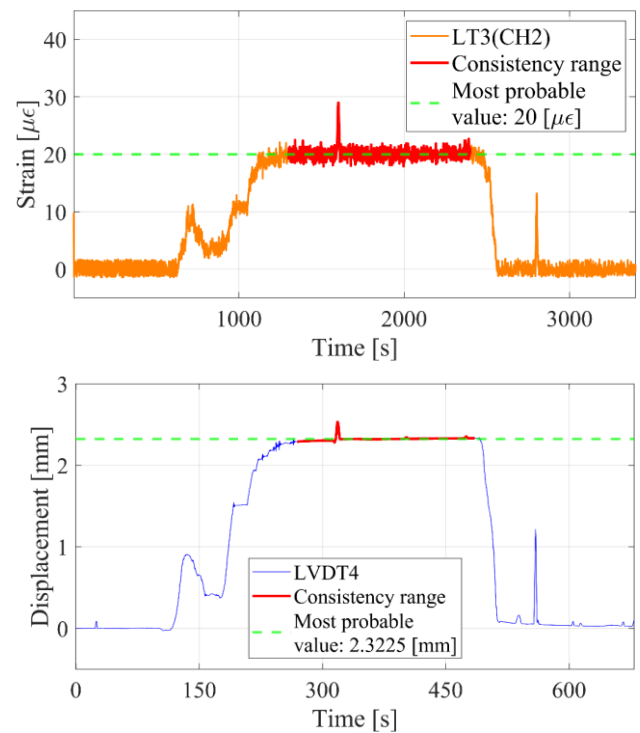

Figure 9. Signal selection. (Up) Strain value at a specific DFOS measurement of CH2 under LT3; (Down) Deflection value for LVDT4 under LT3.

The reliability of LT3 strain data is validated by confirming their consistency with expected structural behavior. The strain distribution for LT3, as shown in Figure 10, aligns fully with the load configuration and the fixed-fixed static scheme. Strain data exhibit negative values near the abutments, positive values at midspan, and zero values near the transverse beams at the one-quarter and three-quarter span positions, following the expected bending-moment diagram. Notably, the strain on the left side of the diagram is higher at the one-quarter span than at

the three-quarter span, which is entirely consistent since the load is applied at the one-quarter span.

Figure 10. Reconstructed strain signal with the selected value at every DFOS measurement location of CH2 under LT3.

Beyond the noise range (approximately  $\pm 5 \mu\epsilon$ ), strain peaks are observed on the left side and near midspan on the right side, represented by red dots in Figure 11.

Figure 11. Peaks characterization for LT3 data in CH2.

These peaks are localized using the prominence technique [14], which identifies significant strain values by measuring how much they stand out from their surroundings. The strain peaks are detected in the negative strain zone when the strain is negative (at the initial and end sides of the bridge) and in the positive strain zone when the strain is positive (at the middle of the bridge), reflecting the expected strain distribution. This method ensures that only relevant peaks, corresponding to structural responses rather than noise, are detected. Furthermore, as depicted in Figure 12, these peaks persist throughout the monitoring period when the truck is stationary, confirming their consistency rather than indicating transient anomalies. They likely indicate concrete cracks or stress concentrations, which, for this case study, cannot be confirmed through visual inspection or unmanned aerial vehicle (UAV) photogrammetry due to the protective steel plates covering the fiber optic locations. Since the available data do not allow differentiation between cracks and stress concentrations, all strain peaks are conservatively treated as cracks. The relative crack opening (positive strain) and relative crack closing (negative strain) are evaluated by integrating the strain over the effective influence length of the crack.

Figure 12. Consistency of DFOS measurements at peak A location in time.

Figure 13 presents histograms of relative crack opening and closing, clearly showing that the magnitudes are very low and do not pose structural concerns. The term ‘relative’ is used because the DFOS signal captures only the strain induced by the load test, not pre-existing crack widths. The width of pre-existing cracks and the causes of these strain peaks will be investigated in future monitoring campaigns. Additionally, some data are absent on the right side of the signal, but given the high spatial resolution (2.6 mm gauge pitch), the dataset remains sufficiently consistent for analysis.

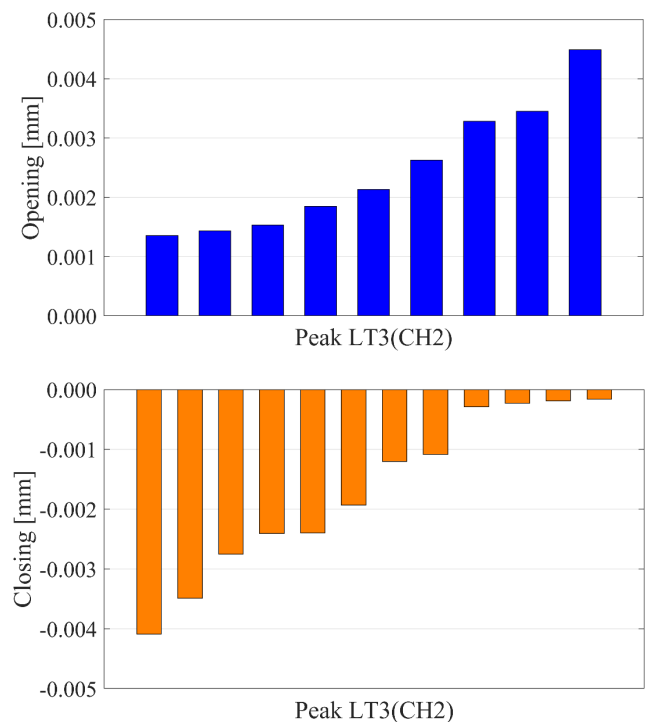

Figure 13: Crack width variation for LT3 in CH2. (Up) Relative crack opening; (Down) Relative crack closing.

The analysis of DFOS data highlights the localized impacts on strain distribution at the interfaces between the main girders and secondary beams, significantly shaped by the specific load configurations applied. The strain distribution across CH1 and CH2 displays distinct localized effects near the crossbeam edges. The LT3 load configuration induces a noticeable strain

reduction near the junctions with secondary beams, as evident in Figure 14.

Figure 14. Strain measurements along the main girders for LT3 data of 2024.

This phenomenon stems from the transverse positioning of the axial load and the three-dimensional interactions between the main girders and secondary beams.

At this stage, the structural performance can be assessed using three key parameters:

- transverse load distribution between the main girder, quantifying the traffic load carried by each girder;
- boundary conditions;
- deflection of the main girders.

The transverse load distribution is evaluated by analyzing the strain ratio from DFOS datasets for the two main girders. This approach captures the influence of structural characteristics and load configurations while ensuring robustness by minimizing the impact of localized anomalies through reliance on spatially continuous strain data.

To illustrate the effectiveness of DFOS measurements, five monitoring scenarios are examined, each using different methods to calculate load distribution coefficients derived from sensor data:

- Scenario 1 uses strain data from the DFOS, focusing on the ratio between CH1 and CH2 measurements;
- Scenario 2 employs values calculated from equilibrium equations based on classical beam theory (De Saint-Venant), typically used in bridge assessments without monitoring data;
- Scenario 3 relies on discrete strain measurements at midspan, simulating a conventional strain gauge at that location;
- Scenario 4 combines discrete strain measurements at midspan and quarter-span strain data;
- Scenario 5 integrates discrete strain measurements at midspan and near-support measurements.

Results for load distribution coefficients ( $\epsilon_{CH2}/\epsilon_{CH1}$ ) for LT3 are presented in Figure 15. The strain ratios using DFOS display a near-Gaussian distribution. For Scenario 1, the strain ratio is thus taken as the mean value of this distribution. When calculated using only discrete measurements (Scenarios 3 to 5), the results are substantially affected by local phenomena linked to boundary effects and strain variability at critical sections. Moreover, employing classical pre-design approaches based on equilibrium equations (Scenario 2), the strain ratio obtained

differs significantly from the measured DFOS strain ratio, indicating that load distribution between girders is more balanced than suggested by conservative design assumptions.

Figure 15. Transversal load distribution evaluation.

These scenarios result in inaccurate bending moment evaluations, as shown in Figure 16, potentially overestimating or underestimating safety.

Figure 16. Bending moment comparison. (Up) Maximum bending moment in CH2; (Down) Minimum bending moment in CH2.

Once the load distribution is established, the characterization of boundary conditions becomes essential. These are evaluated by comparing DFOS strain profiles with theoretical distributions for simply supported and fixed-fixed configurations (Figure 17). From the graph, the theoretical fixed-fixed model closely aligns with the observed data (negative strains at supports, positive at midspan), confirming the post-intervention static scheme. Minor discrepancies, due to uncertainties in elastic modulus ( $E$ ), stiffnesses of abutments, and load distribution coefficients, do not compromise this conclusion, confirming the structural modification's effectiveness.

Figure 17. Boundary-condition valuation in CH2 under LT3.

Subsequently, bridge deflection is derived from DFOS datasets via double integration of the strain profile, following the methodology outlined in [8]. This process relies on load distribution data, boundary conditions, and structural rigidity. Since the latter cannot be directly measured from DFOS datasets, it is approximated between 33 GPa (C30/37) and 42 GPa (C80/95). Simulations with different rigidity values enable defining an envelope of possible bridge deflections, with the best fit, calibrated across all five load tests, determined by aligning rigidity with LVDT measurements, as shown in Figure 18.

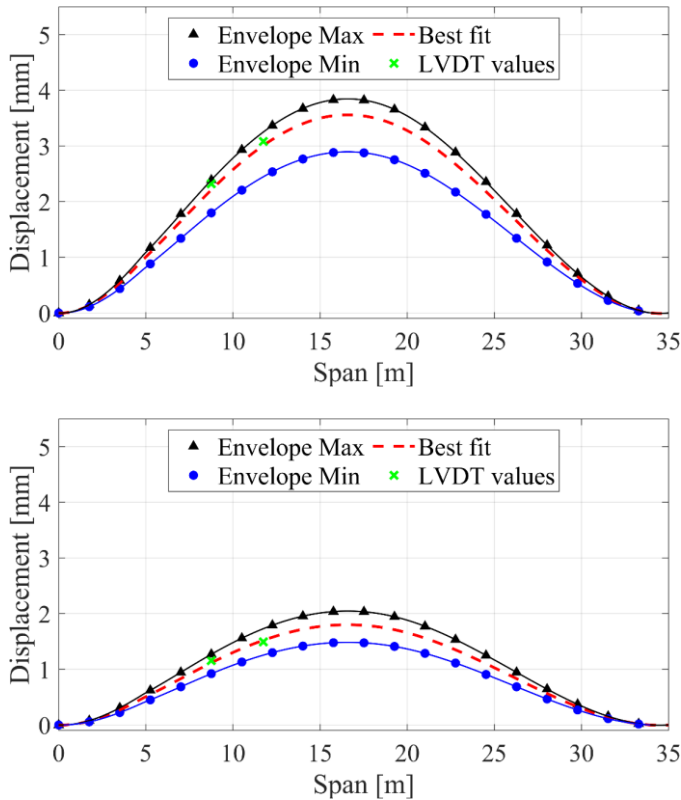

Figure 18. Comparison DFOS displacement predictions vs LVDT measurements under LT3. (Up) Comparison in CH2; (Down) Comparison in CH1.

The mean discrepancy between best-fit predictions and LVDT measurements, considering all load tests (LT1 to LT5) for both

channels (CH1 and CH2), is 0.065 mm. This compares favorably to the 0.101 mm mean absolute difference reported in [8] using 2023 datasets, possibly due to greater uncertainty in LVDT positioning in 2023 compared to 2024. The small differences between these predictions demonstrate that DFOS-based deflection estimates can closely match actual measurements when rigidity is calibrated.

Furthermore, the impact of discrete strain measurements and conservative pre-design assumptions on displacement prediction is evaluated. Table 1 presents the maximum, minimum and mean absolute relative displacement differences between DFOS and LVDT measurements for Scenarios 1 to 5. The maximum difference increases significantly from Scenario 1 (0.162 mm) to others: 405% (0.818 mm) in Scenario 2, 253% (0.571 mm) in Scenario 3, 1909% (3.252 mm) in Scenario 4, and 264% (0.590 mm) in Scenario 5. The minimum difference varies slightly, from 0.00018 mm in Scenario 4 to 0.020 mm in Scenario 3. The mean difference rises by 362% (0.299 mm) in Scenario 2, 267% (0.238 mm) in Scenario 3, 1141% (0.803 mm) in Scenario 4, and 183% (0.183 mm) in Scenario 5 relative to Scenario 1 (0.065 mm).

Table 1. Maximum, minimum, and mean absolute relative displacement values between DFOS and LVDT measurements for Scenarios 1 to 5.

	Max discrepancy [mm]	Min discrepancy [mm]	Mean discrepancy [mm]
Scenario 1	0.162	0.013	0.065
Scenario 2	0.818	0.002	0.299
Scenario 3	0.571	0.020	0.238
Scenario 4	3.252	0.0018	0.803
Scenario 5	0.590	0.005	0.183

These findings indicate that Scenarios 2 to 5 yield mean displacement estimation errors ranging from 0.2 mm to 0.8 mm, whereas Scenario 1 has a mean error around 0.065 mm, establishing it as a reliable tool for displacement monitoring. It demonstrates that load-distribution estimations using only discrete strain measurement may be inaccurate and lead to significant discrepancies in the expected bridge deflection.

#### 4 CONCLUSIONS

This study investigates the DFOS-based methodology from [8], originally developed for 2023 datasets, to analyze the 2024 Ferpècle Bridge datasets. By evaluating strain data across both channels under various static load configurations, the approach demonstrates its ability to capture local phenomena (e.g., cracks, secondary beam effects) and global responses (e.g., boundary conditions, load distribution, displacement estimates) with exceptional accuracy and precision. Compared to traditional discrete strain sensors, DFOS offers significant advantages, yielding the following insights:

- **High-resolution monitoring.** DFOS enables spatially continuous strain measurements with millimeter-scale precision, accurately determining load distribution coefficients, bending moment diagrams, and displacement estimates with ~0.1 mm accuracy, surpassing the capabilities of discrete sensors.

- **Longitudinal (1D) crack detection.** The methodology reliably identifies cracks and stress concentrations but faces challenges in classification due to limited data on pre-existing micro-crack distributions (sometimes difficult to detect due to their size and locations) and its linear sensing configuration, which restricts bi-dimensional (2D) strain mapping.
- **Consistency across years.** The 2024 results align closely with 2023 findings, confirming the methodology's reliability, high accuracy, and precision, while indicating no significant structural changes in the bridge.
- **Future directions.** Further research should investigate temperature effects under ambient daily and seasonal loads, integrate visual inspection or UAV photogrammetry alongside 2D strain mapping to enable proper crack characterization and develop a calibrated finite element model (FEM) to support long-term SHM.

This high-resolution DFOS methodology provides detailed insights into structural behavior, enabling precise safety assessments and informed decision-making for sustainable bridge maintenance and management.

## ACKNOWLEDGMENTS

The authors are thankful to the Structural Engineering Platform (GIS) from École Polytechnique Fédérale de Lausanne (EPFL) and Prof. Eugen Brühwiler for supporting the data collection process. The authors are also thankful to the DMTE – Service de la mobilité from the Wallis Canton for supporting the monitoring campaign.

**ABSTRACT:** This study presents an innovative AI-powered smart-liner system designed to enhance the safety and efficiency of oil and gas transportation and storage infrastructure. By integrating polymer composite liners with distributed fiber optic sensors (DFOS), the system enables continuous monitoring of mechanical deformations and damage formation, providing real-time insights into the infrastructure's condition throughout its lifespan. Finite element analysis (FEA) is employed to simulate the mechanical responses of the smart-liner-protected specimen over time. Machine learning (ML) algorithms are applied to analyze images generated from collected DFOS data, enabling the identification and assessment of risk variations across different locations and time steps. This approach demonstrates the high accuracy and effectiveness of ML in automatically detecting deformations and crack formation under buckling loading conditions. The methods enable comprehensive structural health monitoring, allowing for precise localization, visualization, and quantification of mechanical changes and damage within the infrastructure. With the above approaches, the smart-liner system facilitates continuous data collection across the entire protected surface, supporting the development of a dynamic digital twin model that evolves alongside the infrastructure. The findings provide critical insights for the oil and gas industry, offering an advanced and efficient solution for monitoring and mitigating risks associated with transportation and storage infrastructure.

**KEY WORDS:** Distributed fiber optic sensors; Structural health monitoring; Finite element analysis; Machine learning.

## 1 INTRODUCTION

As the traditionally most energy-consuming industry in the United States [1], the oil and gas industry relies on an extensive network of pipelines, storage tanks, and processing facilities to transport and store hydrocarbons. The infrastructure network is crucial for maintaining the stability and efficiency of the energy supply chain, ensuring that the country can meet its growing energy demands and support rapid economic growth. However, pipeline infrastructure is subjected to various mechanical, environmental, and operational stresses that can lead to material degradation, structural deformations, and eventual failures. Such failures pose significant risks, including environmental pollution, financial losses, and safety hazards for personnel and surrounding communities. A notable example of oil and gas infrastructure failure is the Deepwater Horizon oil spill in the Gulf of Mexico, which occurred in 2010. This disaster is one of the largest and most devastating oil spills in history. The primary cause was the failure of the cement and shoe track barriers, allowing the uncontrolled surge of high-pressure hydrocarbons to escape from the wellbore, travel up the riser, and ignite the oil spillage [2]. Additionally, the San Bruno pipeline explosion occurred in the same year due to the fracture in the welded seam, resulting in the eight deaths [3]. These catastrophic events show significant needs for protecting and monitoring the health conditions of the oil and gas infrastructure.

Ensuring the mechanical resilience of infrastructure is crucial. One way to protect the oil and gas infrastructure is by implementing a polymer composite liner, which is made of fiber fabric and polymer composite. It serves as an additional protective layer, protecting metallic pipelines and storage tanks

from mechanical stress, corrosion, and environmental degradation [4], [5]. Polymer composite liners provide significant advantages, including high strength-to-weight ratios, corrosion resistance, and enhanced durability [6]. The liners are engineered to withstand extreme environmental conditions, making them ideal for high-risk applications such as oil and gas transportation and storage. However, despite these benefits, the liner-protected infrastructure still faces structural challenges. One critical issue is mechanical deformation, which can occur due to factors such as thermal expansion, pressure fluctuations, external impacts, and ground movement. Over time, these deformations may lead to localized buckle or collapse, ultimately compromising the structural integrity [7]. Traditional monitoring techniques, such as periodic visual inspections and ultrasonic testing, are often insufficient in detecting infrastructure early-stage damage, as many deformations occur beneath the surface or in hard-to-reach areas. Additionally, the liner is always installed on the interior surface of infrastructure, making the inspection and maintenance even more difficult. To address these limitations, a practical and efficient structural health monitoring (SHM) system is necessary to ensure prolonged service of liner-protected oil and gas infrastructure.

Distributed fiber optic sensor (DFOS) is widely used in monitoring structural health, for its ability of continuous measurement along the fiber length [8]. DFOS operates by transmitting light pulses through optical fibers and analyzing the backscattered signals to measure strain and temperature along the fiber length. This capability is particularly important for large-scale infrastructure, where traditional sensors are impractical or insufficient. Besides, DFOS has advantages in

small size, lightweight, water resistance, and suitable for harsh working environments such as extreme weather conditions and seismic-prone regions, making it applicable and reliable in the oil and gas industry [9]–[11]. Zhang et al. [12] attached DFOS on the exterior surface of the pipeline to monitor its compressive and tensile strain distribution. Inaudi and Glisic [13] monitored the conditions of gas pipelines with DFOS for two years. The measured strain and temperature results showed high accuracy. The installation method of both DFOS and liner involves attaching them to the interior surface of the target object. Therefore, the integration of DFOS and polymer composite liner is worth exploring, as it has the potential for simultaneous structural protection and real-time SHM. The DFOS-embedded liner system becomes “smart”, which facilitates continuously track of strain variations, and provides early warnings before critical failure occurs. For example, with the continuous measurement and sensitivity properties of DFOS, it is widely applied to detect cracks in concrete structures [14]. Thus, it also has the potential to detect cracks in liners for the development of a comprehensive SHM for oil and gas infrastructure. This integration marks a significant advancement in SHM, enabling a proactive approach to oil and gas infrastructure maintenance.

With the development of smart sensor and AI technology, digital twin becomes an emerging technology in civil and infrastructure applications. DFOS is a critical component in a digital twin model, for its capacity of collecting and updating real-time data [15]. Digital twin model acts as a dynamic, real-time, virtual representation of physical structures. It continuously evolves based on data and simulators for real-time monitoring purpose [16]. Although DFOS provides real-time strain monitoring data, the digital twin model has limitations in presenting the structural shape, for example, the deformation information. To address this issue, finite element analysis (FEA) is an alternative solution, for its capacity in simulating structural mechanical responses efficiently. As the infrastructure is monitored using DFOS, real-time strain data can be correlated to FEA simulation results to find the corresponding deformation information, which supports the development of the digital twin model. The correlation approach requires a high-efficiency method to satisfy the requirement of real-time monitoring purpose. Hence, the AI-driven machine learning (ML) based method is proposed to automatically identify the most accurately correlated pairs. Then the structural deformation is reconstructed and provided to establish an efficient, real-time digital twin model in a rapid response time. Additionally, minor damages are found in the polymer composite liners of oil and gas pipelines [17]. The early detection and maintenance are vital for structural safety. By integrating DFOS with FEA and AI-driven correlation methods, an efficient and real-time digital twin model can be developed to enhance structural health monitoring. This approach not only improves real-time visualization of structural behavior but also facilitates early damage detection, ultimately contributing to the safety and longevity of critical oil and gas infrastructure.

In this paper, we develop a smart-liner system with DFOS to protect and real-time monitor the strain responses of oil and gas infrastructure. FEA and AI-driven approaches are paired with the smart sensor data to identify the digital twin-based real-time

SHM function. Section 2 introduces the experimental design, including the materials used to prepare the test sample and experimental instrumentation. Section 3 provides the method of DFOS strain field generation and interpolation function for damage identification and localization. Furthermore, the steps for the digital twin model establishment are introduced, including developing the finite element model for experimental validation and conducting AI-driven strain field correlation between DFOS and FEA results. Section 4 presents the strain field comparison results. Meanwhile, the minor damages in the test sample are identified and localized. Afterward, the best correlated strain fields are fed back to FEA for the development of the digital twin model. This study aims to investigate the feasibility of a smart-liner system with DFOS in real-time structural health monitoring of oil and gas infrastructure, and the accuracy of the digital twin model in representing the structural information. By inducing the buckling load, the study has the potential to provide valuable insights into damage identification, localization, and prevention, contributing to the enhanced safety and reliability of oil and gas infrastructure.

## 2 EXPERIMENTAL DESIGN

### 2.1 Materials

The materials prepared to develop the smart-liner protected metallic substrate, including metallic substrate, polymer composite liner, DFOS, and adhesive layer. A 152.4 mm × 304.8 mm (W × L) steel plate is used as a substrate, which represents the metallic pipes and vessels that store and transport oil and gas. A commercial Starline® 2000 polymer composite liner made of woven fabric and polyurethane/polyethylene coating serves as a protective layer for the metallic substrate. The installation of DFOS is a critical step in sample preparation. One Luna high-definition DFOS is first firmly attached to the surface of the liner with a thin coating of 3M DP460 epoxy adhesive. After the adhesive is consolidated, the DFOS-installed liner is then securely attached to a metallic substrate through a 1 mm thick epoxy resin adhesive layer, which simulates the liner rehabilitation for oil and gas pipelines. The prepared sample is placed at room temperature for 24 hours to ensure it is fully cured. The installation of DFOS does not require specialized tools or expert personnel, making it suitable for practical field applications where ease of deployment is essential.

The schematic of a smart-liner protected metallic substrate sample is shown in Figure 1. The sample contains three layers: polymer composite liner, adhesive layer, and metallic substrate. The DFOS is embedded into the interface between the liner and adhesive layer. The thicknesses of each layer from top to bottom are 1.94 mm, 1 mm, and 0.81 mm, respectively. The DFOS, though delicate and easily fractured, is flexible which allows for embedding in a semi-circular style for turning installation direction. It is equipped with a thin, sensitive optic fiber inside, and protected by a multi-layer coating. The DFOS used in this study relies on Rayleigh scattering of light. When a laser pulse travels through the fiber, a small portion of the light is scattered in all directions due to its natural inhomogeneities [18]. External loads, such as mechanical stress, thermal expansion, or vibrations, induce strain in the fiber, causing measurable changes in the backscattered Rayleigh signal. By analyzing these changes, the system can detect variations in

strain along the length of the fiber. We install a 5 m fiber length long DFOS, covering the strain measurement area in a zig-zag pattern.

Figure 1. Schematic of a smart-liner protected metallic substrate.

## 2.2 Experimental instrumentation

To introduce the buckling damage on the smart-liner protected metallic substrate, it is placed in an MTS Criterion® Electromechanical Test Systems, which has a force capacity up to 600 kN. As shown in Figure 2, the sample is clamped on the two edges along the longitudinal direction and subjected to an eccentric buckling load, simulating real-world complex structural deformation. The two clamped sections have same dimension with 25.4 mm × 30 mm (W × L). The loading machine is controlled by a constant displacement rate of 0.2 mm/min, with a total vertical displacement of 5 mm. Luna optical distributed sensor interrogator (ODiSI) 6100 is used for strain data collection from DFOS. When backscattered light interferes with the reference signal in the interrogator, it generates an interference pattern containing phase and amplitude information, which correlates with strain variations along the fiber. By applying a fast Fourier transform, the system extracts high-resolution, spatially continuous strain data. This processed data is used to generate a high-resolution strain profile along the fiber length, providing a real-time, visually accessible strain plot on the ODiSI control platform.

Figure 2. The smart-liner protected metallic substrate sample clamped in loading machine.

## 3 RESEARCH METHODOLOGY

### 3.1 DFOS strain field generation

The measurement performance of DFOS is highly reliant on its settings, including measurement rate and gauge pitch. If the measurement rate is too high, the generated strain data not only occupies excessive storage and computational resources but also contains unnecessary noise. Previous DFOS applications in engineering practices used measurement rates ranging from 5 to 50 Hz [19]–[21]. In this study, the measurement rate is set to 10 Hz to balance the measurement accuracy and efficiency. Gauge pitch, also called spatial resolution, refers to the distance between each measurement point along the optic fiber. The measurement area in our case is relatively small, as shown in Figure 2. A large gauge pitch, for example, 5.2 mm [22], is inapplicable. Since this is a laboratory experiment conducted with a short DFOS length, the highest available spatial resolution of 0.65 mm is selected to achieve a dense strain measurement [23].

The illustration of the smart-liner system with DFOS is shown in Figure 3. The DFOS is attached to the polymer composite liner surface in a zig-zag pattern, forming 14 distinct measurement lines with a uniform spacing of 10 mm. L1 represents the first line, and L14 is the last line close to the clamped edge, which is subjected to the largest buckling deformation. The blue stars represent the measurement point along the fiber. As discussed earlier, the distance between two contiguous measurement points equals the gauge pitch of 0.65 mm. DFOS covers an area of 130 mm × 200 mm, for strain monitoring purpose.

The generation of the DFOS strain field contains the conversion of the one-dimensional strain data to the two-dimensional strain field, through the X-Y coordinate system, as shown in Figure 3. For example, to map the strain data point on L1 into the strain field, the Y-coordinate is fixed along the line, and the X-coordinate is uniformly increasing at the rate of gauge pitch. In this approach, the DFOS strain field is generated, enabling visualization representation of strain distribution for smart-liner system.

Figure 3. Schematic illustration of the smart-liner system with DFOS.

### 3.2 Damage identification and localization

To promote the application of DFOS for real-time monitoring of large oil and gas infrastructures, automated damage identification and localization are essential. When the DFOS

passes through a crack, a significant increase in strain rate is always detected, making it applicable to identify the presence and location of cracks [24]. To achieve the identification, obtaining strain values on a finer grid is the prerequisite. Bilinear interpolation and triangle-based interpolation are two widely employed planar interpolation algorithms for estimating unknown data based on known data in two-dimensional plane [25]. This study applies bilinear interpolation to estimate the strain on a finer grid, because DFOS has a fixed gauge pitch, the collected strain is uniformly distributed. Bilinear interpolation is a method that uses repeated linear interpolation to interpolate functions of two variables, which typically used on regular grids. Equation (1) illustrates how this method estimates the value for a target point using four neighboring lattice points.

$$f(x, y) \approx w_{11}f(Q_{11}) + w_{12}f(Q_{12}) + w_{21}f(Q_{21}) + w_{22}f(Q_{22}) \quad (1)$$

where  $(x_1, y_1)$ ,  $(x_2, y_2)$ ,  $(x_1, y_2)$ ,  $(x_2, y_1)$  are the coordinates of the four neighboring lattice points  $Q_{11}$ ,  $Q_{12}$ ,  $Q_{21}$ ,  $Q_{22}$ . The weights  $w$  are listed as follows:

$$\begin{aligned} w_{11} &= \frac{(x_2 - x)(y_2 - y)}{(x_2 - x_1)(y_2 - y_1)} \\ w_{12} &= \frac{(x_2 - x)(y - y_1)}{(x_2 - x_1)(y_2 - y_1)} \\ w_{21} &= \frac{(x - x_1)(y_2 - y)}{(x_2 - x_1)(y_2 - y_1)} \\ w_{22} &= \frac{(x - x_1)(y - y_1)}{(x_2 - x_1)(y_2 - y_1)} \end{aligned}$$

The gradient calculation formula, shown in Equation (2), represents the slope limit as the distance between two neighboring lattice points  $d$  approaches zero. A denser grid provides a gradient closer to the true value but increases computational costs. Based on a convergency study, we determine to interpolate strain value on  $0.1 \text{ mm} \times 0.1 \text{ mm}$  grid, as further reducing the grid size has little impact on the gradient.

$$\text{gradient} = \lim_{d \rightarrow 0} \frac{f(x + d) - f(x)}{d} \quad (2)$$

### 3.3 Establishment of digital twin model

This study aims to develop a smart-liner system with DFOS to enable digital twin-based real-time monitoring of oil and gas infrastructure. Once the smart-liner system with DFOS collects the real-time, accurate strain results, we establish a digital twin model for virtual and real-time representation. To build the virtual model, we create a three-dimensional finite element model to replicate the experimental testing on smart-liner protected metallic substrate. Section 3.3.1 presents the detailed design, including geometry, interfacial contact, and mesh information, to construct the finite element model to simulate the smart-liner protected metallic substrate under the eccentric buckling load. Section 3.3.2 shows the AI-driven method to correlate the DFOS-measured strain field and FEA-predicted strain field. This method facilitates deformation reconstruction and the digital twin model establishment to visualize buckling deformed smart-liner system in the real-time.

#### 3.3.1 Finite element model design

FEA is carried out to simulate the smart-liner protected metallic substrate under the buckling load, correlate strain results with the experimental study, and generate deformation information to establish the digital twin model. FEA is a powerful computational tool that enables accurate prediction of structural behavior under various loading conditions, which is widely applied in the oil and gas transportation and storage infrastructure [26]. By simulating experimental scenarios, it reduces the need for costly physical samples, saving both time and resources. Abaqus/CAE 2024 is employed to generate and analyze the finite element model in this study. The finite element model has same geometry and material settings as the test sample with three layers: metallic layer, the adhesive layer, and liner layer. To generate the mesh for this thin and multi-layer object, the widely-used C3D8R (8-node linear brick element with reduced integration) element is not the best choice. Instead, we select the C3D8S (8-node linear brick element with improved surface stress visualization) element for discretization, because of its advantage in estimating surface strain [27]. The mesh size of this model is 2.5 mm uniformly. The material properties of each layer are presented in Table 1. The metallic substrate is made of high-ductility steel and simulated using a bilinear model with strain hardening. The adhesive layer and polymer composite line have significantly lower stiffness compared to the metallic substrate. Thus, elastic models are applied in the analysis.

Table 1. Material properties in finite element model.

Layer	Material property
Metallic substrate	Young's modulus = 210 GPa
	Poisson's ratio = 0.3
	Yield strength = 500 MPa
	Ultimate strength = 635 MPa
Adhesive layer	Ultimate strain = 0.2
	Young's modulus = 1 GPa
Polymer composite liner	Poisson's ratio = 0.3
	Young's modulus = 400 MPa
	Poisson's ratio = 0.4

Figure 4 exhibits the finite element model of the smart-liner protected metallic substrate. The bottom edge areas are constrained to move and rotate, identical to the bottom clamped area in the experiment. The top edge is also constrained to rotation but allowed for a vertical displacement of 5 mm, accurately replicating the experimental buckling load setup. The interfacial contact between two interfaces is simplified as tied, given the careful curing procedures, to simulate a perfectly bonded condition.

Figure 4. Finite element model of smart-liner protected metallic substrate.

Performing a buckling analysis in Abaqus involves two steps: linear eigenvalue analysis, and nonlinear Riks analysis. The linear eigenvalue analysis is the first step, which estimates the critical buckling load and corresponding mode shape. This method assumes small deformations and linear material behavior, making it computationally efficient. While this method is useful for obtaining a quick estimate of the buckling load, it does not account for geometric imperfections, material nonlinearities, or post-buckling behavior, which may lead to inaccurate predictions. Therefore, we also conduct nonlinear Riks analysis that accounts for geometric and material nonlinearities, as well as initial imperfections. The geometric and material nonlinearities are enabled by changing the setting and inputting material nonlinear properties. The first three mode shapes from linear eigenvalue analysis serve as the initial imperfections. The magnitudes of the first, second, and third buckling mode shapes are set as 1.00%, 0.50%, and 0.25% of the plate thickness, respectively [28]. The predicted strain distribution is compared with the DFOS strain field result for validation purpose, and then correlated with the DFOS strain field to generate corresponding deformation distribution to establish the digital twin model.

### 3.3.2 AI-driven strain field correlation

It is common for the strain data from experiments and simulations to exhibit slight differences, because of the discreteness of the experiment. To fill this gap, this research implements a strain field correlation method based on the convolution neural network (CNN) to find the most similar pair between DFOS and FEA results. Figure 5 illustrates the basic process of strain field correlation. The inputs are strain field images generated from DFOS and FEA, from which CNN can be used to extract the abstract features. Then, the cosine similarity between the extracted features of the DFOS and FEA data is compared. Through iterating over the entire FEA database, the best matching pair is found. In order to enhance the feature-extracting capability of CNN, the pre-trained ResNet18 model is used to process the input images. ResNet is a classic CNN that has shown extraordinary feature extraction ability in engineering fields [29], [30]. We employ ResNet18, one of the smallest models of ResNet, to process images, and its output feature maps are flattened to a one-dimensional vector for comparison. The best matching pair will be fed back

into FEA for deformation generation and digital twin model establishment.

Figure 5. The workflow of strain field correlation.

## 4 RESULTS AND DISCUSSION

### 4.1 Strain field comparison between experiment and FEA

The one-dimensional DFOS data collected on the interface between the adhesive layer and polymer composite liner is converted to a two-dimensional strain field for visualization and comparison, following the methodology introduced in Section 3.3.2. The strain results with the increasing vertical displacement levels are shown in Figure 6. The positive strain in the middle of the right edge is represented in yellow, indicating the tensile strain. The negative strain at the corners of the right edges is represented in dark blue showing the compressive strain. The strain fields show an approximately symmetric pattern with respect to the central transverse line. As the test sample is subjected to an eccentric load and clamped at the corners of the left edges symmetrically, resulting in a symmetric strain distribution. The slight asymmetry can be attributed to the instrumental limitations such as the minor drifts.

Additionally, the strain distribution contours on the interface between the adhesive layer and liner are obtained from FEA results, as shown in Figure 6. To facilitate the comparison, the strain fields from DFOS and FEA are extracted at the same displacement level and share the same colormap. Due to the advantage of numerical analysis is free of external disturbances, the comparison results show that FEA has a symmetric strain distribution, which is highly similar to the results from DFOS. For further validation, we apply pixel-based comparison to quantify the similarity between DFOS and FEA results, by using the parameters including structural similarity index measure (SSIM) and mean absolute percentage error (MAPE). Table 2 presents the strain field comparison results. The SSIM results for the three cases are approximately around 0.9, indicating the results from DFOS and FEA have high similarities. MAPE results provide the relative error percentage between DFOS and FEA results, which demonstrate that the difference is less than 0.60%. Overall, the strain comparison demonstrates that the FEA results have good agreement with the DFOS results, validating the accuracy of the finite element model. Building on this, FEA can help DFOS expand the capacity from strain monitoring to mechanical performance monitoring, reconstruct the structural deformation, and facilitate the establishment of the digital twin model.

Figure 6. Strain distribution fields with increasing vertical displacements collected from DFOS (left), and FEA (right).

Table 2. Strain field comparison results.

Displacement level	SSIM	MAPE
1 mm	0.91	0.56%
3 mm	0.91	0.22%
5 mm	0.89	0.60%

#### 4.2 Identification and localization of potential damages in adhesive layer

The identification of potential damages is important, as they often correspond to the areas where failure initiates. The damages on the adhesive layer are hard to detect visually so a non-destructive monitoring method is necessary. As introduced in Section 3.2, the DFOS strain rate has a significant increase when it passes a crack. By converting the location of the strain rate surge into two-dimensional coordinates, we can localize the damage in the structure, which enables real-time structural damage monitoring. After processing the strain data from DFOS using interpolation and gradient calculation, we can visualize the region where the strain rate increases rapidly. Figure 7 shows the plot of strain gradient distribution. We set the strain gradient limit of damage as 200, any region with a strain gradient greater than 200 is highlighted in red circles. The results show that damages commonly occur close to the edge, near the highest strain region. It is also observed that, although the strain field distribution has a symmetric pattern, the potential damage has not. Therefore, the identification and localization of damage becomes more significant, as they are unpredictable. This method leverages the continuous measurement capacity of DFOS, enabling the detection and mapping of the potential damage. It enhances the efficiency of real-time structural damage monitoring, can be employed to identify potential damages in liner-rehabilitated oil and gas infrastructure, and extends the structural service life.

Figure 7. The location of potential damages in adhesive layer.

#### 4.3 Strain correlation and digital-twin model establishment of buckled liner-protected metallic substrate

Although DFOS and FEA results demonstrated a good agreement, the strain field correlation is required for an accurate representation of deformation reconstruction. In terms of the strain field correlation methods as introduced in Section 3.3.2, the DFOS strain fields at 1 mm, 3 mm, and 5 mm displacement levels are inputted into the AI-driven strain correlation model and set as ground truth. FEA strain fields are organized as a database, which includes all FEA strain fields at every 0.01 mm displacement. By extracting the features from DFOS strain fields and iteratively comparing the cosine similarities of the FEA strain field database, the most similar pairs are found. Table 3 shows the strain correlation results. We compare the corresponding displacements of the correlated strain field pairs. It can be seen that the correlation results have some differences, but the difference is not significant, remaining within an acceptable millimeter-level range for practical applications in the oil and gas industry.

Based on strain correlation results, we reconstruct the deformation and establish the digital twin model of the buckled liner-protected metallic substrate, as illustrated in Figure 8. The digital twin model presents the key deformation characteristics and provides a predictive framework for real-time monitoring. The comparison and correlation between the experimental and numerical strain fields verify the effectiveness of the digital twin model. The digital twin framework enables continuous tracking of deformation states, which is crucial for real-time SHM, enabling dynamic, real-time, virtual representation of the liner-protected metallic substrate. This study highlights the potential of a smart-liner system with DFOS in combination with a digital twin model for structural integrity assessment. The findings support the feasibility of using digital twin models for predictive maintenance and damage prevention in oil and gas infrastructure. Although the implementation of the digital twin model faces challenges, such as high initial investment and potential incompatibility, experimental investigation demonstrates its capability for real-time monitoring of liner-protected substrate conditions, with the potential to prevent even greater financial losses resulting from pipe failure. Additionally, the installation of CIPP liners is a mature and

widely adopted practice. The integration method developed in this study also confirms the durability of DFOS under buckling conditions. Therefore, the implementation of the smart-liner system is both feasible and promising for practical applications.

Table 3. Strain field correlation results.

Displacement level	Correlated displacement	Difference
1 mm	0.81 mm	-0.19 mm
3 mm	3.38 mm	+0.38 mm
5 mm	4.75 mm	-0.25 mm

Figure 8. Digital twin model of buckled liner-protected metallic substrate with increasing deformation.

## 5 CONCLUSION

In this paper, we establish a digital twin-based real-time monitoring system for oil and gas infrastructure by integrating smart sensor technology, finite element analysis, and deep learning algorithms. Through the embedment of the distributed fiber optic sensor into the polymer composite liner, this study validates the feasibility and accuracy of the smart-liner system in real-time monitoring of the strain fields, without compensating the protective capability of the liner. Enhanced by finite element analysis, the smart-liner system achieves the capability from strain monitoring to structural mechanical performance monitoring. Further improved with a deep learning-based approach, the digital-twin model is generated for visualization of a three-dimensional smart-liner protected substrate with accurate deformation representation. In addition to the external visualization, some flaws inside of the structure, such as cracks, are detected through the smart-liner system, showing the robust health monitoring capabilities. Several summarized conclusions are listed as follows:

- The durability of DFOS under large deformation is promising. Under an extreme buckling scenario, as shown in this study, the DFOS can constantly

provide accurate and continuous data, and facilitate strain field monitoring for oil and gas infrastructure.

- The finite element analysis results are of high accuracy, with a lowest SSIM of 0.89, and highest MAPE of 0.60% compared to experimental results. This validates the reliability of developed finite element model in predicting structural behavior, supporting its use in generating digital twin model.
- The smart-liner system has the capacity to identify and localize minor cracks in the adhesive layer with high efficiency, realizing early maintenance and rehabilitation.
- The AI-driven strain correlation analysis establishes a foundation for developing the digital twin model. This model provides a real-time, three-dimensional representation of the structural physical conditions, enabling accurate structural health monitoring for oil and gas infrastructure.

In summary, this study proposes a framework for establishing the digital twin model for real-time structural health monitoring of oil and gas infrastructure. This study has limitations in assessing the proposed framework on the smart-liner protected metallic substrate. Scaling this study to large and complex oil and gas transportation and storage infrastructure networks introduces challenges such as data management, sensor deployment, and integration with existing large-scale infrastructure. With the advancement of high-performance computing technologies, data analytics is becoming increasingly capable of handling the vast amount of information generated by distributed sensing systems. Distributed sensing technologies have already been applied in large-scale structures such as bridges, railways, and pipelines [31], [32], demonstrating their feasibility and robustness in extensive monitoring applications. Furthermore, the widespread application of polymer composite liners in the oil and gas industry supports the practical applicability of scaling up the developed smart-liner system for structural health monitoring across extensive networks of pipelines and storage facilities. Future work will be expanded to the long-term durability test, aiming to investigate the long-term performance of smart-liner system and digital-twin models.

**ABSTRACT:** Distributed fiber optic sensing is a suitable method for long-term, wide-area monitoring of civil engineering structures such as the ground, tunnels, dams, and bridges. In recent years, distributed strain sensing technologies such as distributed acoustic sensing (DAS) and optical frequency domain reflectometry (OFDR), which can realize real-time monitoring, have made remarkable progress. In particular, OFDR, which performs strain sensing with high spatial resolution, can quantitatively evaluate the strain distribution of civil engineering structures with an accuracy comparable to conventional strain gauges. This method has been limited in its application to structural health monitoring due to its short measurement range. However, by extending the sensing distance, it is evolving into a practical technology for on-site testing. This paper introduces middle-range, rapid strain sensing based on Phase-noise-compensated OFDR (PNC-OFDR) and its application to bridge monitoring. Optical fiber sensors were installed on bridge girders, and the change in strain distribution when the moving load was applied by vehicles was measured using the PNC-OFDR sensing system.

**KEY WORDS:** PNC-OFDR; bridge monitoring; strain; dynamic strain.

## 1 INTRODUCTION

Distributed optical fiber sensing, in which an optical fiber is installed as a sensor on a target object to measure strain and temperature distribution, is actively applied for long-term, wide-range monitoring of civil engineering structures such as the ground, tunnels, dams, and bridges. For example, ground anchors embedded with optical fiber sensors are installed on on-site slopes, and landslide monitoring is performed by the tension measurement using optical fiber sensors [1]. This monitoring has been carried out over several years, and the measurement data acquired over a certain period are compared quantitatively. The long-term feasibility of the distributed strain sensing using Rayleigh backscattered light spectrum, which is a high-precision measurement technique, was reported. In addition, seafloor fiber optic cables and terrestrial fiber networks (dark fiber) over tens of kilometers are used as sensing fiber to monitor seismic activity [2] and traffic flow [3].

In terms of sensing technology, with the advent of wavelength tunable coherent OTDR [4] and DAS based on phase-OTDR [5] that detect Rayleigh backscattered light with high intensity, high-precision strain sensing on the order of  $1\mu\epsilon$  and real-time monitoring over the entire length can be performed at the construction site [6]. Currently, distributed fiber optical sensing is utilized to evaluate construction quality and manage safety in the construction field. Strain and temperature distribution data are converted into physical quantities such as displacement and tension force, and construction management based on the sensing data is carried out. For a detailed analysis of the data, it is important to verify that the strain measured by the distributed fiber optical sensing matches the value indicated by a conventional electrical strain gauge. In regard to bridge monitoring, bridge structure shows a variety of responses, from

slowly changing static strain to dynamic strain caused by traffic loads. However, few methods can evaluate strain distribution statically and dynamically with a gauge length of a few centimeters, similar to that of a strain gauge. A comparison table of DFOS spatial resolution and sample rate is shown in Figure 1. Brillouin-based sensing technology BOTDR and Rayleigh-based sensing technology TW-COTDR, which have been widely used for structural health monitoring, have a spatial resolution of about 1m or 10cm and are suitable for static sensing. Phase OTDR, one type of DAS, is utilized as a dynamic sensing method to capture vibration distributions with a spatial resolution of several meters. OFDR is both a static and dynamic sensing method [7, 8, 9] with spatial resolution close to that of a strain gauge. Despite its excellent sensing performance, OFDR has been restricted to applications in structural health monitoring due to the sensing distance limited by the temporal coherence of a laser source. Since the sensing

Figure 1. Performance comparison of distributed strain sensing technology.

distance is generally less than 100 m, OFDR has been widely used for laboratory use in civil engineering. On the other hand, in the field of telecommunications, a PNC (phase noise compensation) algorithm for demodulating the coherence of a laser source has already been verified, and PNC-OFDR, which implements the PNC algorithm in OFDR, has succeeded in measuring with a spatial resolution of 5 cm over a distance of 40 km [10]. However, this PNC-OFDR has not been confirmed for strain and temperature measurements performed in structural health monitoring. The authors expected that PNC-OFDR would be a practical strain sensing technology for on-site structural health monitoring and developed a distributed strain analyzer based on PNC-OFDR (Figure 2). This paper describes an overview of the PNC-OFDR based strain measurement system and reports its application to static and dynamic strain measurements on an actual bridge.

Figure 2. PNC-OFDR based distributed strain analyzer and a laptop PC for data processing.

## 2 PNC-OFDR BASED STRAIN SENSING SYSTEM

### 2.1 Rapid sensing with a fast wavelength-swept laser source

OFDR, known as a high-precision strain measurement method, incorporates a wavelength-tunable laser source with excellent coherence. Most of these tunable laser sources sweep the output wavelength slowly by motor drive and are used for the static strain analyzer that samples data over several seconds. Recently, Anritsu released a new high-speed wavelength swept light Source [11]. This laser realizes both high-speed wavelength-sweeping using a MEMS (Micro-Electro-Mechanical System) scanning mirror and high coherence, contributing to middle-range fiber sensing. Especially, sweep repetition frequency, which corresponds to the time interval in strain sensing, reaches 150 Hz. According to the Nyquist theorem, the maximum observable frequency is 75 Hz, making it possible to measure dynamic strain caused by traffic vibrations. Besides, another feature of this system is the short data acquisition time. Acquisition time per one shot is 2 msec. This property is similar to taking photographs that are resistant to subject blur using a high-speed camera and is believed to be suitable for stable static and vibration (dynamic strain) monitoring of infrastructure structures that are subjected to live loads. Figure 3 shows about data sampling when measuring static and dynamic strain with this system. The laser wavelength is swept periodically with a 15 nm width, and dynamic sensing can be performed by arbitrarily setting the time interval in synchronization with the sweep period. It is also possible to perform long-term static strain sensing, such as creep monitoring.

### 2.2 Extending the sensing distance by the PNC algorithm

In distributed strain sensing using Rayleigh scattered light, reference and measurement data are obtained, and the relative strain variation is output. Strain is calculated from the spectral correlation to each segment, corresponding to the distributed fiber optic sensor gauge. Figure 4 shows a schematic diagram of OFDR-based distributed strain sensing. The data for the entire length of the optical fiber is converted into spectral data

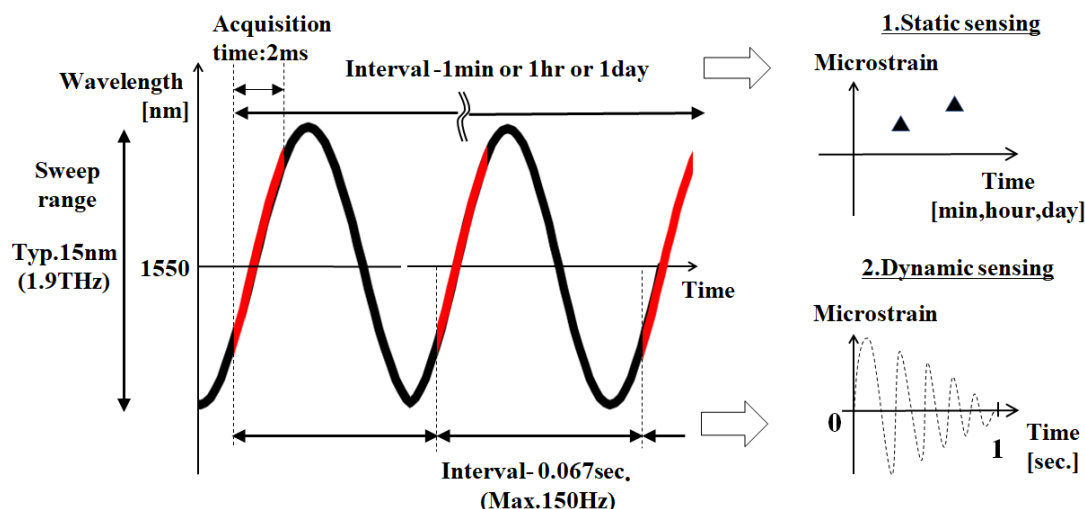

Figure 3. Static and dynamic strain sensing using with a fast wavelength-swept laser source.

Figure 4. Schematic diagram of OFDR-based distributed strain sensing.

for each gauge, and strain is calculated by multiplying the strain coefficient by the spectral shift frequency that shows the cross-correlation peak. Since this measurement method utilizes the repeatability of the spectrum, it is particularly important to perform a linear wavelength sweep to reproduce the spectrum. To achieve high spectral correlation, wavelength sweep correction is performed, which resamples the raw data based on clock timing with a constant wavelength interval. While this wavelength sweep correction works well up to the coherence length of the source, further correction algorithms are required to go beyond the distance limit of the source. The analyzer implements a PNC algorithm to extend the sensing distance to 1,000 m [12], over 70 times the coherence length of the swept laser. Table.1 shows the measurement specifications of the PNC-OFDR based strain sensing system.

Table.1 Specifications of PNC-OFDR based strain sensing system.

Sensing distance [m]	1000
Acquisition time [ms/shot]	2
Max. sampling rate [Hz]	150
Strain resolution [ $\mu\epsilon$ ]	1
Spatial resolution [cm]	0.5~10

### 3 APPLICATION TO BRIDGE MONITORING

By applying this sensing technology to bridge monitoring, it is expected to capture the distribution of static strain changes used to evaluate seasonal variations, as well as the dynamic strain response subject to moving vehicles. In addition to identifying stress variations that indicate structural strength and the location of damage, it may be possible to obtain information useful for the maintenance and management of civil engineering structures, such as estimating traffic loads. In this study, we report the results of measuring the strain distribution when vehicles are stopped and passing through an existing bridge with optical fiber sensors installed on the bottom of the bridge girder. The applicability of PNC-OFDR sensing system to bridge maintenance was verified.

#### 3.1 Bridge monitoring methods

These tests were conducted on the prestressed concrete bridge of the Atami Beach Line (Figure5.). Figure 6. shows the layout of the optical fiber sensors and strain gauges installed on the bottom of the girder. 0.9 mm tight-buffered single-mode fiber

was used as the optical fiber sensor, and it was firmly bonded with epoxy glue to the concrete surface on the bottom of the girder closest to the mountain side.

First, a load test was conducted in which a vehicle was placed at the center of the bridge span to measure the static strain. Three vehicles with different weights were used for quantitative static strain evaluation. Then, as a dynamic load test, a 20-ton truck runs at a speed of 60 km/h on the road close to the mountain side. The strain distribution was output with a sampling interval of 5 cm and a spatial resolution of 10 cm. In the dynamic loading test, the sampling rate was set to 5 Hz.

Figure 5. PC bridge of the Atami Beach Line (Testing site).

Figure 6. Location of the strain gauges and installed fiber sensors during the load test.

### 3.2 Results

Figure 7 shows the strain distribution on the bottom of the girder when cars were placed at the center position between P2 and P3. The results of the strain gauges measured at the same time were also plotted. The downward direction on a vertical axis represents tensile strain value. Tensile strain due to deflection at the bottom of the girder can be seen. The strain increases in proportion to the vehicle weight, and the strain gauge and DFOS values match well. The relationship between the strain at the center of the span and the vehicle weight is shown in Figure 8. This linear correlation indicates the elastic response of the bridge girder. These results suggest that DFOS could be used to detect overloaded vehicles that cause damage to road bridges.

Figure 7. Strain distribution in static loading tests.

Figure 8. Relationship between strain at the center of span and vehicle weight.

Figure 9. shows the dynamic strain distribution when a 20-ton truck was running as a dynamic loading test. The strain distribution according to the vehicle position can be confirmed. At a speed of 60 km/h, it takes about 1.6 seconds to pass through the 26.9 m span. Strain distribution changes over a period of 1.6 seconds, and the dynamic strain caused by the vehicle movement is accurately captured by the PNC-OFDR based strain sensing system. Strain values at the center of the span observed in the static and dynamic loading tests were nearly equal, suggesting the possibility of dynamic weight monitoring such as the bridge weigh in motion.

Figure 9. Dynamic strain distribution during vehicle movement with 5Hz sampling.

### 4 CONCLUSION

We investigated a PNC-OFDR based strain sensing system equipped with a high-speed wavelength-swept laser source and its application to bridge monitoring. This system can obtain static and dynamic strain distribution with the same accuracy as a strain gauge. Currently, the sensing distance of this system has been extended to 1000m.

We will continue to develop PNC-OFDR so that it will become a sensing technology necessary for quantitative evaluation of civil engineering structures, such as bridges.

**ABSTRACT:** This submission presents a structural monitoring solution for railway bridges and viaducts that leverages distributed fibre optic sensors (distributed temperature and strain sensing, DTSS, and distributed acoustic sensing, DAS) to capture both long-term static trends and dynamic behaviour under train loads. The long-term monitoring uses hourly DTSS strain measurements, accounting for day/night and seasonal variations, while the dynamic monitoring system records real-time strain and vibration data during train passages. By integrating these measurements with structural calculation services, the system can detect anomalies (e.g., stiffness changes, potential cracking) and inform predictive maintenance. Lastly, the results are displayed via a digital twin, providing an intuitive, web-based platform for analysing historical data and forecasting future conditions.

**KEY WORDS:** Distributed acoustic sensors, Distributed temperature and strain sensors, Structural health monitoring, Railway bridges.

## 1 INTRODUCTION

The increasing demand for reliable and efficient monitoring of critical infrastructure has driven the development and deployment of advanced sensing technologies. Among these, distributed fibre optic sensing (DFOS) has emerged as a powerful tool, offering continuous, real-time measurements over long distances with high spatial resolution [1]. Distributed temperature sensing systems (DTSS) and distributed acoustic sensing (DAS) have demonstrated significant potential in a wide range of civil engineering applications [2], [3], [4]. State-of-the-art implementations of DFOS include structural and crack monitoring, geotechnical engineering (such as landslide detection and tunnelling construction and integrity monitoring), the surveillance of buried infrastructure, and transportation infrastructure monitoring (including railways and bridges) [2]. Within this broad landscape, DAS and DTSS have been successfully applied to railway bridge monitoring, enabling early detection of structural degradation, train-induced vibrations, temperature variations, and other anomalies that could compromise safety or performance [5], [6], [7]. These implementations establish DFOS as a multi-scale monitoring solution capable of addressing both immediate safety concerns (through real-time anomaly detection) and long-term preservation needs (via historical trend analysis), while overcoming traditional limitations of discrete sensor systems through its distributed, high-resolution measurement capabilities.

In this paper, we present the results obtained from monitoring a 471-meter-long concrete viaduct used by high-speed trains. The system integrates three main units: a sensing unit, a computing unit, and an information analysis unit. The sensing unit consists of two distributed fibre optic sensors that simultaneously monitor the structure by interrogating optical fibres embedded along the structure. These sensors include a distributed acoustic sensor (DAS) and a distributed strain and temperature sensor (DTSS). The computing unit processes the

measurements acquired by these sensors to calculate various structural parameters under both static and dynamic conditions. Static structural parameters are derived from measurements obtained when the viaduct is at rest, while dynamic structural parameters are obtained from measurements obtained during and after a train passage. The following static parameters are calculated: vertical displacement of the deck and displacement of the piers. Also, the calculated dynamic parameters include deck dynamic properties, vertical acceleration of the deck, bending rotation of the deck, fatigue caused at longitudinal and transverse reinforcement of the deck, and dynamic displacement of the piers. The analysis unit analyses the results to determine whether the obtained structural parameters fall within a normal range or exhibit any anomalies compared to historical data and theoretical modelling.

The structural monitoring system provides operators with two key functionalities based on temporal scope: (1) current state assessment, enabling remote evaluation of real-time structural health through comprehensive indicators and immediate risk alerts, which reduces inspection needs and optimizes maintenance responses; and (2) future state prediction, using advanced analytics to forecast structural evolution and assess capacity for future operational scenarios, thereby improving maintenance planning and infrastructure adaptability. This dual approach transforms traditional reactive maintenance into a proactive, data-driven strategy while enhancing both safety and resource efficiency.

## 2 METHODS

### *Distributed fibre optic sensors*

#### 2.1.1 Distributed Temperature and Strain Sensing (DTSS)

The DTSS system employs Brillouin backscattering in optical fibres to provide continuous, high-resolution measurements of strain and temperature along the entire bridge structure. By analysing spectral shifts in the Brillouin backscattered light, DTSS achieves a spatial resolution of 0.5–1 m with strain accuracy of  $\pm 10 \mu\epsilon$  and temperature precision of  $\pm 0.5^\circ\text{C}$  [8], [9], [10]. In this application, DTSS monitors long-term deformations and detects gradual anomalies such as settlement or bearing degradation. Its absolute strain measurement capability and high spatial resolution make it particularly suited for structural health monitoring. The optical fibre is interrogated by a UTS-FB1000 DTSS system from Uptech Sensing [11]. It is configured with 20 Hz sampling rate, a spatial resolution of 1 m, and a spatial sampling interval of 1 m, covering the full 470 m of the viaduct.

#### 2.1.2 Distributed acoustic sensor (DAS)

The DAS system utilises phase-sensitive optical time-domain reflectometry ( $\phi$ -OTDR) to detect dynamic strain variations along the optical fibre [1], [12]. Sensitive to vibrations up to several kHz, DAS captures high-frequency events including train-induced vibrations, impact loads, and sudden structural changes. In this implementation, DAS provides real-time monitoring of dynamic responses during train crossings, enabling the identification of transient phenomena. The system's dense spatial sampling allows for localised event detection across the entire bridge span. The optical fibre is interrogated by a UTS-AS1000 DAS system from Uptech Sensing [13]. It is configured with 1kHz sampling rate, a pulse width of 50 ns, a gauge length of 5 m and a spatial sampling interval of 5 m.

#### 2.1.3 Limitations and Complementarity

While DTSS excels in static or quasi-static monitoring, its sampling rate (typically  $< 100$  Hz) [14] limits dynamic response characterisation. This limitation can be mitigated by integrating complementary information from DTSS, which provides accurate temperature measurements. By combining data from both sensors, it is possible to decouple temperature effects from true mechanical responses, enhancing the reliability of dynamic strain interpretation. Their integration in this study creates a synergistic monitoring framework: DTSS establishes baseline structural behaviour and detects slow-evolving damage, while DAS identifies transient events and verifies dynamic performance. This dual-sensor approach overcomes individual limitations, providing comprehensive structural assessment across all relevant timescales, from gradual deterioration to instantaneous dynamic loading.

### *Optical fibre cable installation on the structure*

The monitoring system integrates DTSS and DAS interrogators within Span 1 at the viaduct's northbound section. A single optical fibre, epoxy-bonded to the structure, completes two full

round trips (totalling  $\sim 2.5$  km) following a systematic path: starting from the interrogators, it sequentially traverses the upper right (UR), upper left (UL), lower left (LL) and lower right (LR) surfaces. Strategic fibre loops are incorporated at deck cross-sections to capture transverse structural responses, while vertical runs instrument the piers, descending one side and ascending the opposite. This configuration achieves four complete viaduct passes, enabling comprehensive 3D monitoring through: (1) longitudinal strain profiling along all critical surfaces, (2) transverse deformation assessment via deck loops, and (3) pier behaviour characterization. Figures 1 and 2 detail the installation geometry and pier instrumentation respectively.

Figure 1: Optical fibre installation on a viaduct deck. Four optical fibre segments (blue lines) are installed, one on each side, as well as on the top and bottom of the deck. Additionally, loops of fibre are placed across the transverse section of the deck.

Figure 2: Optical fibre installation on the piers (orange line).

### *Data acquisition and processing architecture*

The monitoring system utilizes both sensors in a coordinated manner to capture complementary structural responses. The DTSS sensor operates in a dual-mode configuration, performing periodic static measurements at fixed intervals to monitor long-term deformations and thermal effects, then automatically switching to dynamic-measurements mode. Simultaneously, the DAS sensor provides continuous, real-time vibration monitoring with millisecond temporal resolution, ensuring comprehensive detection of all dynamic events.

The software architecture employs modular microservices for all computational operations (characterization, alarm detection, and predictive analytics), executed through orchestrated workflows. Local processing units on the viaduct handle real-time structural characterization and immediate

alarm detection, reducing data transmission volumes via 4G VPN by preprocessing sensor outputs. Cloud-based Azure services perform historical data analysis and predictive modelling, supported by: (1) a NoSQL database storing processed results in JSON format, (2) blob storage for raw sensor data archiving, and (3) a web-accessible frontend for operator interaction. Orchestrators in both environments manage service dependencies and execution sequences, ensuring proper data flow between services where outputs become subsequent inputs. This hybrid architecture optimizes bandwidth usage while maintaining complete data traceability for verification and system upgrades throughout the infrastructure's lifecycle. The data handling pipeline scheme is shown on Figure 3.

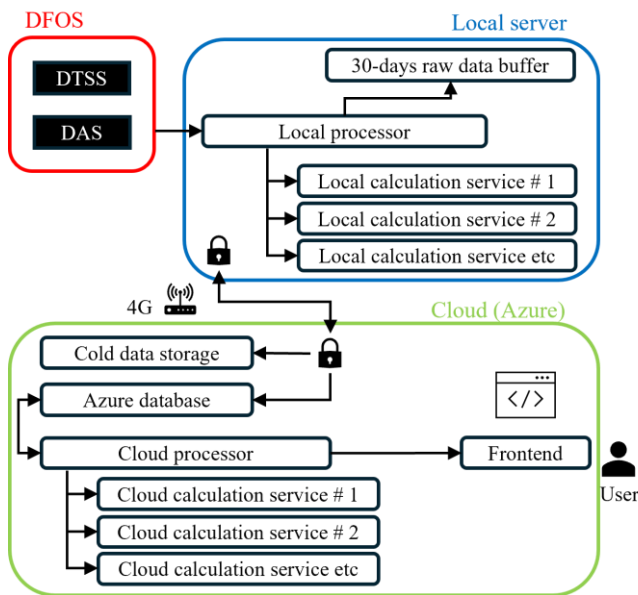

Figure 3: Data handling pipeline.

Given the dual-mode sensing architecture, accurate time synchronization is essential to correlate static (DTSS) and dynamic (DAS) measurements for event-based diagnostics and digital twin integration. Both systems independently generate data streams with embedded timestamps. To align these streams, the local processing unit performs time correlation by matching temporal features, such as strain peaks, slope reversals, or train-induced vibration signatures, across both modalities.

Time references are maintained through a hybrid synchronization approach: GPS-disciplined oscillators provide high-precision absolute timing, while NTP (Network Time Protocol) ensures fallback synchronization across distributed edge nodes and cloud-based analytics. This architecture enables sub-millisecond temporal alignment between DTSS and DAS outputs, ensuring that combined measurements reflect coherent physical events and supporting reliable fusion of static and dynamic data streams in the digital twin environment.

### 3 STRUCTURAL MEASURANTS AT VIADUCTS

#### *Static measurements*

At 30-minute intervals (or at a user-defined sampling rate), the system captures a ‘snapshot’ of the current deformed shape of the monitored deck and piers. Each measurement is checked to ensure displacements remain within predefined thresholds while also detecting: (1) substructure settlements, (2) bearing lockups (in instrumented piers), and (3) excessive deck deformations. This automated process enables real-time structural integrity assessment and early anomaly detection.

#### 3.1.1 Deck’s vertical displacement

The calculation is based on the execution of four fundamental steps: (1) computation of the strains measured at the four corners of the section; (2) fitting of the curvature plane passing through these four points using a least-squares adjustment; (3) application of the generalised Mohr’s theorem in three-dimensional space to determine rotations and deflections at all points [15]; and (4) enforcement of boundary conditions at the initial point to derive displacements and rotations at any location along the deck. This systematic approach ensures accurate structural deformation analysis while accounting for geometric constraints.

Figure 4 shows the viaduct and its spans (grey background scheme) along with the static vertical displacement at all spatial locations for a specific datetime (black line). Also, historical data from 18 months (orange line indicating the historical average, while the shaded area represents the standard deviation) is shown. Analysis of the historical data reveals that each span experiences a distinct vertical displacement.

Figure 4: Deck’s static vertical displacement.

#### *Dynamic measurements*

#### 3.2.1 Dynamic properties

This constitutes an essential service as it provides the foundation for detecting structural changes through dynamic behaviour analysis. Using the DAS measurements, the system continuously calculates the viaduct’s dynamic characteristics, specifically determining for each of the first N vibration modes: (1) the natural frequency, (2) the vibrational mode shape (structural deformation pattern), and (3) the damping ratio. Using the Stochastic Subspace Identification-Covariance method (SSI-Cov) reliable operational modal analysis under ambient vibrations is performed [16]. This calculation forms the critical baseline for structural health monitoring by quantifying the bridge’s dynamic fingerprint and enabling subsequent detection of behavioural deviations that may indicate damage or degradation.

### 3.2.1.a Calculation method

The vibration characterization process involves three key stages: (1) The SSI-Cov algorithm computes vibration poles (mode shapes, natural frequencies, and damping ratios) across multiple solution orders, generating both physical and spurious results. (2) A pole stabilization stage filters non-physical poles by eliminating those with inconsistent dynamic properties (e.g., negative damping) or insufficient consensus across solution orders. (3) A final pole clustering stage, using HDBSCAN's density-based algorithm [17], groups duplicate poles from different orders while automatically determining the optimal number of clusters based on modal similarity in multidimensional space.

This robust three-stage process ensures only validated, unique vibration modes are returned, with the clustering step providing additional quality control by rejecting any remaining outliers. Figure 5 and Figure 6 shows the results of stages (1) and (3), respectively, demonstrating the algorithm's capability to distinguish physical vibration modes from computational artifacts. The implemented filtering and clustering successfully identify 20 meaningful vibration modes. Each identified vibration mode is associated to a specific mode shape which enables structural engineers to do a comprehensive analysis of the algorithm result.

Figure 5: Vibration modes calculation at stage (1), SSI-Cov method result.

Figure 6: Identified vibration modes at stage (3) after filtering and clustering. Each mode is numbered and represented by a distinct coloured line.

### 3.2.1.b Dynamic behaviour change detection

This service identifies structural degradation by monitoring changes in dynamic characteristics (natural frequencies, damping ratios, and vibration modes) across multiple monitoring events, while accounting for temperature effects measured by DTSS. Using HDBSCAN clustering, it groups historically observed frequencies based on their associated mode shapes rather than simple frequency proximity. For each cluster, the algorithm: (1) quantifies temperature's influence on frequency variations, and (2) compares current frequencies against their temperature-adjusted historical interquartile ranges. When frequencies deviate beyond expected thermal-effect boundaries, the system triggers alarms indicating

potential stiffness reduction (e.g., from cracking). This dual analysis of vibrational patterns and thermal compensation ensures reliable damage detection while preventing false alarms from normal temperature-induced variations.

### 3.2.2 Dynamic vertical displacement and bending rotation

#### 3.2.2.a Calculation method

The dynamic analysis is initiated automatically upon detection of train passage across the structure, employing the same method used for static displacement calculations. The system acquires displacement and rotation data at each timestep, with sampling frequencies ranging from 50 Hz to 1000 Hz depending on whether DTSS or DAS sensors are utilised. For each monitored cross-section, temporal evolution analysis of the deformation data provides dynamic curvatures, dynamic rotations, instantaneous dynamic deflections, velocities (first derivatives), and accelerations (second derivatives). This methodology enables comprehensive characterisation of the structure's dynamic response under live loading conditions, while maintaining consistency with the static analysis framework through shared computational architecture.

#### 3.2.2.b Regulatory compliance and operational limits

These parameters are strictly regulated by railway standards as they critically impact both passenger comfort and operational safety. UIC guidelines establish specific limits for dynamic structural responses, including [18]: (1) maximum permissible passenger-perceived accelerations during bridge crossings, and (2) dynamic deflection thresholds expressed as a percentage of span length - with stricter limits applying to higher train speeds. The standards define "good comfort" levels when dynamic displacements remain below these velocity-dependent thresholds. Additionally, the regulations mandate compliance with complementary safety-related limits governing structural vibrations and deformations, ensuring simultaneous satisfaction of both comfort criteria and essential safety requirements throughout the infrastructure's operational life. These parameters are used together with the historical behaviour of structural parameters to define alarms and behavioural changes.

#### 3.2.2.b.1 Vertical dynamic displacement

Figure 7: Deck's dynamic vertical displacement.

Figure 7 illustrates the viaduct and its piers (grey background scheme) together with the vertical dynamic displacement of the deck induced by a train passage for all spatial locations of the viaduct (grey line). Additionally, statistical values derived from

18 months of operational data are presented. The blue and green lines indicate the maximum and minimum average displacement values, respectively, while the shaded areas represent the corresponding standard deviations for positive (blue) and negative (green) displacement values. This visualization enables direct comparison between instantaneous structural response and long-term performance trends, facilitating the identification of anomalous behaviour or progressive stiffness degradation. The historical displacement monitoring results demonstrate two key structural behaviours: spans in direct contact with the ground (Spans 1 and 11) exhibit significantly reduced displacement amplitudes (0.2-0.4 mm) due to enhanced restraint from soil-structure interaction, while all spans show consistent asymmetric response with positive displacements (+0.8 mm peak) being approximately 30% smaller than negative displacements (-1.2 mm peak). Also, the results indicate that vertical displacement is maximum at midspans and minimum at the piers, being consistent with expected behaviour for this type of structure.

### 3.2.2.b.2 Vertical dynamic acceleration

Deflection calculation throughout curvature integration allows the derivation of vertical accelerations of the deck, enabling to check safety and comfortability on the train. Figure 8 illustrates the vertical dynamic acceleration of the deck induced by a train passage for all spatial locations of the viaduct (grey line), together with its historical values. The blue and green lines indicate the maximum and minimum average acceleration values, respectively, while the shaded areas represent the corresponding standard deviations for positive (blue) and negative (green) acceleration values. Similar to the previous case, the historical acceleration data reveals consistent spatial trends across the viaduct: Spans 1 and 11, which interface with the ground, exhibit lower peak accelerations compared to intermediate spans. Also, the maximum acceleration occurs at the centre of the spans and minimum at the piers.

Figure 8: Deck's dynamic vertical acceleration.

### 3.2.2.b.3 Bending rotation

Curvature integration enhances the calculation of the induced rotations of pot bearings. Figure 9 illustrates the bending rotation induced by a train passage for all spatial locations of the viaduct (grey line), together with its historical values. The blue and green lines indicate the maximum and minimum average bending values, respectively, while the shaded areas

represent the corresponding standard deviations for positive (blue) and negative (green) bending values. The historical data analysis reveals distinct rotational pattern along the viaduct, with maximum rotation occurring near the piers and minimum rotation at midspan locations. This behaviour is consistent with expected structural mechanics for simply supported spans.

Figure 9: Deck's dynamic bending rotation.

### 3.2.2.b.4 Pier's dynamic displacement

The monitoring system extends its dynamic characterization methodology to instrumented piers, employing an analogous analytical process to that implemented for the deck structure. Figure 10 shows one of the piers (grey background scheme) together with its vertical dynamic displacement after a passing train (black lines), together with its statistical values. The blue and green lines indicate the maximum and minimum average height values, respectively, while the shaded areas represent the corresponding standard deviations for positive (blue) and negative (green) height values. Historical monitoring data reveals a distinct asymmetry in displacement variability, with negative displacements exhibiting greater variance than positive displacements.

Figure 10: Pier's dynamic displacement.

### 3.2.3 Fatigue check of reinforcement

A major concern in railway bridges is degradation due to material fatigue, especially of steel reinforcement and prestressing [19]. Dynamic measure of the induced strain both along the deck and at specific cross sections allows to compute stress variations and fatigue cycles induced both at longitudinal prestress and transverse reinforcement [20].

### 3.2.3.a Calculation method

Building on the dynamic strains and curvatures obtained from the previous calculation service, this module determines strain distributions across any point of the cross-section. Through extrapolation, it specifically evaluates strain conditions at reinforcement locations (which are typically more eccentric than measurement points). This enables the analysis of stress variations in both longitudinal and transverse reinforcement during each train passage.

### 3.2.3.b Fatigue analysis

This service analyses DTSS-measured stress data from train crossing events to quantify fatigue life consumption. The algorithm: (1) performs rainflow cycle counting to identify stress ranges and mean stresses, (2) optionally converts to equivalent alternating stress (per Eurocode EN 1992-1-1 guidelines for reinforcement/prestressing steel [21]), (3) compares results against material S-N curves to determine allowable cycles, and (4) applies Miner's rule for cumulative damage assessment [22]. Separate analyses are conducted for transverse reinforcement (from transverse fibre loops data) and longitudinal prestressing steel (from longitudinal deck fibres), with material-specific fatigue limits applied in each case.

### 3.2.3.c Results

Figure 11 illustrates the transverse stress distribution in the internal reinforcement (Fi) of the upper slab at section L/4 of Span 1 under different train loading scenarios. The stress profiles are evaluated for both minimum and maximum train load cases. The colour legend distinguishes the results: Min Fi is represented in green, Max Fi in gray, the average minimum stress in red, and the average maximum stress in orange. This figure highlights how internal forces respond to varying operational loads, providing insights into the structural performance of the interior reinforcement.

Figure 12 presents the transverse stress distribution in the superior reinforcement (Fs) of the upper slab at the same section under identical loading conditions. The color coding for Fs is as follows: minimum Fs is shown in red, maximum Fs in gray, the average minimum stress in green, and the average maximum stress in blue. By comparing these results with Figure 11, the figure reveals differences in stress behavior between internal and superior reinforcement layers, aiding in the assessment of load distribution and reinforcement efficiency in the slab structure.

Both figures collectively enhance the understanding of stress variations under different train loads, supporting the evaluation of structural integrity and design optimization.

Figure 11: Deck's transverse internal reinforcement.

Figure 12: Deck's transverse superior reinforcement.

## 4 CONCLUSION

This study demonstrates the successful implementation of a dual-mode DFOS monitoring system integrating DTSS and DAS technologies for comprehensive railway bridge assessment. The system provides: (1) synchronized static-dynamic measurements (static deformations via DTSS, vibrations up to 1 kHz via DAS), (2) historical trend analysis revealing temperature-compensated structural evolution, and (3) event-based diagnostics (train responses). Results validate the approach's capability to detect stiffness changes, bearing anomalies, and fatigue-critical stress variations. The DTSS-DAS synergy establishes a new paradigm for infrastructure monitoring, combining kilometre-scale coverage with meter-resolution measurements for lifecycle management.

In addressing practical deployment aspects, the survivability of optical fibers in harsh environments, particularly under sustained dynamic loads, was considered. While tight-buffered cables were selected to minimize micro-bending losses, ongoing vibration exposure may still induce attenuation changes. Future deployments could integrate real-time loss monitoring and fiber routing strategies (e.g., loose-tube or armored cable designs) to improve durability.

Although this study focused on a 471-meter concrete viaduct, the proposed dual-mode system is adaptable to a broad range of bridge typologies, including steel truss, cable-stayed, and segmental concrete structures. For longer spans, signal processing techniques (e.g., dynamic range scaling, adaptive windowing) and distributed computing architectures can be extended to preserve performance without compromising spatial or temporal resolution.

Overall, the dual-mode DFOS platform, enhanced by edge computing, time-synchronized sensing, and AI-driven analytics, offers a robust and scalable solution for intelligent bridge monitoring across diverse operational and structural contexts.

## ACKNOWLEDGMENTS

The author would like to acknowledge ADIF for lending the monitored viaduct for this project.

## FUNDING

This work has been partially funded from the following projects: PTQ2021-011958 Torres Quevedo Grant from Ministerio de Ciencia, Innovación y Universidades, Government of Spain, 0011-1408-2023-000026 Doctorados Industriales of 2023 from Government of Navarra and CPP

03/2021 “Soluciones tecnológicas para mantenimiento predictivo de Puentes y Viaductos” from CDTI and ADIF.

**ABSTRACT:** This study aims to evaluate the use of distributed fiber-optic strain and temperature sensing for structural health monitoring in underground mining drifts and chambers including 3D mobile laser scanning. This method seeks to create a digital twin to improve safety and efficiency through better digital planning. Temperature and deformation data from distributed fiber-optic sensing (DFOS) cables will serve as boundary conditions of the combined ventilation and geomechanical models of the drift and chambers. Initially, a 60-meter-long drift will be monitored using fiber-optic cables. Next, deformations of a flexible arch support, induced by hydraulic cylinders, will be observed. A hydraulic cylinder will then apply load orthogonally to the rock. Fiber-optic cables will be inserted and cemented into the rock, along rock bolts, and in boreholes around each bolt to measure deformations from rock bolt pull-out tests. Preliminary examinations identified the best adhesive bonding method for DFOS cables, considering the specific ambient conditions. A 3D point cloud will be used to plan and validate the cable installation. The meshed 3D cloud will serve as the foundation for the combined ventilation and geomechanical models, creating a virtual reality-capable digital twin enhanced with live DFOS measurements.

**KEY WORDS:** fiber-optic sensing, 3D point cloud, digital twin, underground mining

## 1 INTRODUCTION

In the recent years, digital twins have increasingly been investigated within the realms of tunnel construction [1] and mining [2], [3] with promising results. All digital twins must be provided with real data to capture and model reality as closely as possible (e.g. [1], [3], [4]). Depending on the particular use of the digital twin, various types of datasets and sensors are used including 3D laser scanners, environmental data such as temperature and humidity [1] and information on geology and rock deformation [3] to name only a few. Since the beginning of modern fiber-optic development in the 1960s, distributed fiber-optic sensing (DFOS) has found a wide range of applications ranging from infrastructure health monitoring [5], [6], river dikes [7], volcano monitoring [8] and tunnel monitoring as well as underground mine monitoring [9], [10]. In the context of the latter, the DFOS technique enables the detection of small temperature and strain changes and their resulting deformations [9], [10]. In the realm of DFOS based measurement principles, the Brillouin optical frequency domain analysis (BOFDA) technique [11] allows for distributed measurements along several kilometers with a spatial resolution below 1-meter [7] and has been successfully used for structural health monitoring [5], river dike monitoring [7] and tunnel inspection [9].

In this paper, the BOFDA based fiber-optic solution provided by fibrisTerre Systems GmbH (Germany) is used. The mine used for installation of the fiber-optic cables and for

construction of the underground lab is the research and education mine “Forschungs- und Lehrbergwerk (FLB) Reiche Zeche” at TU Bergakademie Freiberg (TUBAF) in Germany. The fiber-optic cables will be installed in a 60 m long drift and additionally in four chambers for experimental setups. Both the main drift and the chambers form part of the FLB mine and are referred to underground lab in the following. The first part of the installation of the fiber-optic cables is scheduled to be completed by September 2025.

The strain and temperature measurements will be used as boundary conditions for geomechanical and ventilation models, which will be coupled including a geometrical and geological model of the underground lab. The creation of an artificial intelligence (AI)-supported coupled model will enable real-time visualization of changes in physical parameters in the coupled geomechanical and ventilation model, which will ultimately lead to development of a digital twin. For a more detailed overview about the individual models see [12]. To our knowledge, fiber-optic sensing data was not yet used for providing temperature and strain measurements as boundary conditions for creating a digital twin in an underground mine. Therefore, the overall aim of the collaborative research project “MODEL coupling in the context of a VIRTUAL underground lab and its development process” (MOVIE) is to develop a digital twin of the underground lab provided with fiber-optic sensing-based temperature and strain data, which will ultimately be visualized using a Meta Quest 3 mixed-reality headset (see Figure 1).

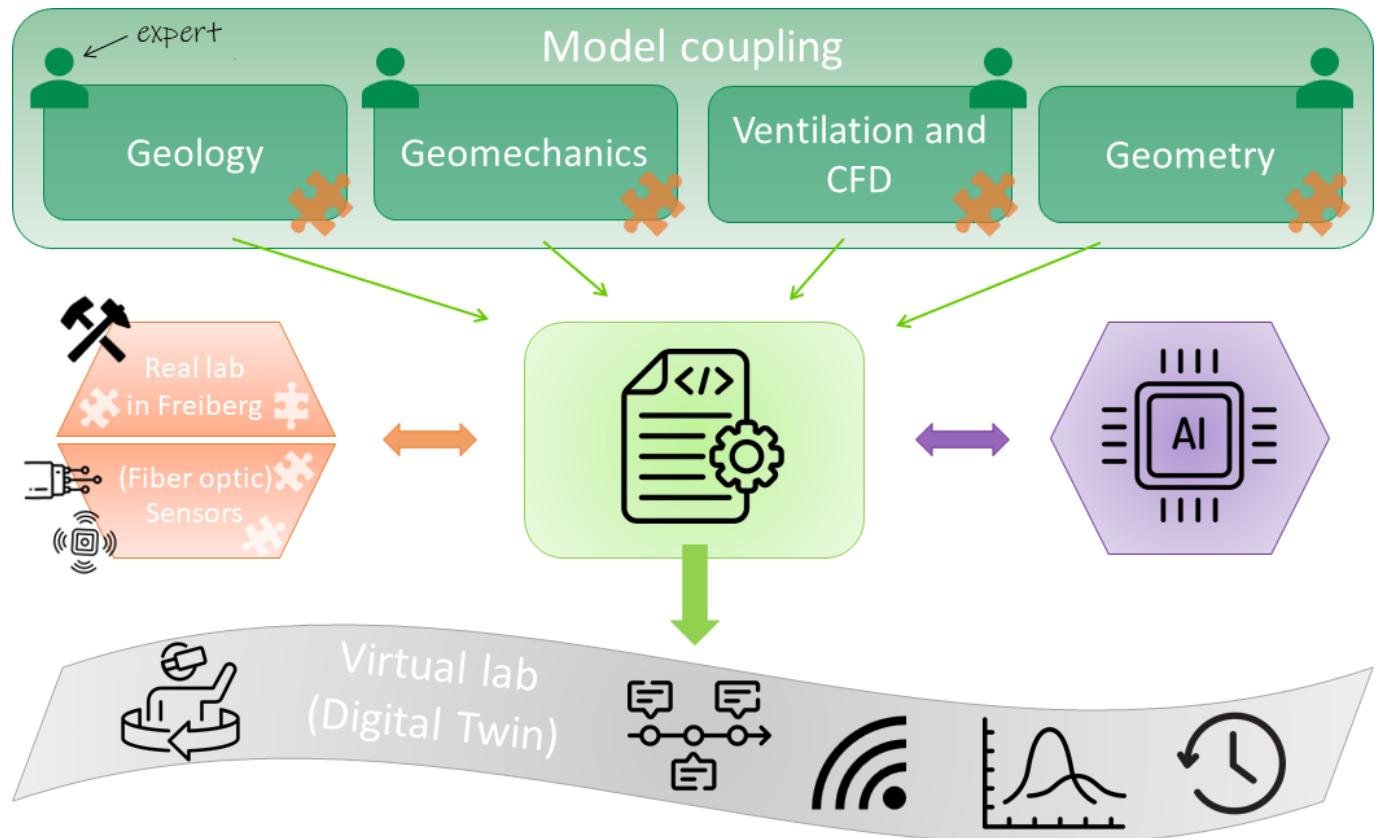

Figure 1 MOVIE project overview. Special emphasis in this paper is on fiber-optic sensing and laser scanning (Geometry).

The MOVIE project includes partners at five different departments at the Clausthal University of Technology (TUC) and one department at the TU Bergakademie Freiberg (TUBAF). Additionally, one external industry partner is included, fibrisTerre Systems GmbH (fibrisTerre). The project is led by the Chair of Geomatics for Underground Systems within the Institute of Geotechnology and Mineral Resources (IGMR) at the TUC. Despite the MOVIE project covering various aspects of geomechanical and ventilation modeling and AI application, this paper focuses on the installation of the fiber-optic cables, supported by a 3D point cloud acquired with a Zoller+Fröhlich (Z+F) FlexScan 22 mobile mapping SLAM platform. Additionally, the meshed surface of the underground lab, i.e., the geometrical model, generated from the 3D point cloud is of concern in this paper.

## 2 MATERIALS AND METHODS

### 2.1 The underground lab

Geologically, the FLB mine consists of ortho- and paragneisses and is veined with silver/lead/zinc mineralization. From the first discovery of silver-rich ores in 1168, active mining was maintained until 1969 with a focus on lead and zinc in the last exploitation stage [13]. Currently, the mine hosts more than 30 national and international collaborative research projects conducted in the underground space. The decision to plan the underground lab here is based on this particular part of the mine being relatively isolated from the other mine workings and experiments. The area of the underground lab can only be accessed via two raises from a lower level, however, only one

of the raises has a mine ladder, while the other access is intended for material transport via winches. This isolated location allows the conditions to be well controlled, particularly in terms of temperature and ventilation. The underground lab (see Figure 5) consists of a 60 m long main drift and four chambers with variable roof heights ranging between 2.75 and 4.9 m.

### 2.2 3D point cloud acquisition and data processing

Two 3D point clouds of the underground lab were acquired in two different field campaigns using a Z+F FlexScan 22 mobile mapping SLAM platform (Figure 2). The first point cloud was acquired in March 2024 containing a total of 368,291,128 points (~9.75 GB in e57-format). The second point cloud was acquired in May 2024 containing a total of 621,441,614 points (~16.5 GB in e57-format). The Z+F FlexScan 22 system incorporates a Z+F IMAGER 5016a laser scanner mounted on a backpack, merging the high spatial resolution of a stationary laser scanner with the versatility of a mobile platform. This technology is based on the simultaneous localization and mapping (SLAM) approach, which enables to create a map of the environment while data capturing [14].

The acquired 3D point clouds were processed using the software Z+F Lasercontrol 10.0.7.1. including loop closure, intensity based filtering and manual cleaning of noisy data points. Additionally, the 3D point clouds were aligned and registered using the open-source software packages CloudCompare 2.13.2. In the next processing stage, the resulting aligned and registered 3D point cloud was meshed based on a Poisson-Surface reconstruction approach using the

open-source software package MeshLab 2023.12 to generate triangular meshes with variable spatial resolutions. The generated mesh, i.e., the geometrical model, serves as the input to the geomechanical and ventilation models created by the project partners at TUC. Additionally, the geometrical model was visualized using the software package LiquidEarth One provided and developed by Terranigma Solutions GmbH. This software package was specifically designed for the visualization of geologic models in virtual reality including the use of a Meta Quest 3 VR headset and serves as the target software for visualization of the digital twin to be developed in the MOVIE project.

Figure 2 Z+F FlexScan22 mobile mapping SLAM platform.

### 2.3 Gluing experiments on fiber-optic cables using epoxy resin glue and injection mortar

The use of the fiber-optic cable type Fibrasens DSS-S and the fiber-optic cable type Solifos BRUsens DFOS B-DTS 2SMF was decided due to their specific design to perform strain and temperature measurements, respectively. Additionally, the cables have an overall good flexibility and proved to be reliable in former projects of fibrisTerre.

Especially for fiber-optic strain measurements, optimal bonding conditions to the object to be measured have to be ensured. Typically, DFOS cables for strain and temperature measurements are installed on pre-existing structures, e.g. in geotextiles [7], along rock bolts [10] or on reinforcement grids [9]. However, in the underground lab, none of these structures are present and installation along, e.g., rock bolts would result in a spatial discretization of the deformation measurement to the span interval between the rock bolts, e.g., [10]. Therefore, gluing experiments using the Fibrasens DSS-S strain cable were conducted on-site in the underground lab and under room temperature conditions in the Geomatics Indoor Lab at the IGMR using hand specimens taken from the underground lab to identify the optimal adhesive bonding method. Based on experiences of fibrisTerre, the epoxy resin glue Sikadur 31+ from Sika and the injection mortar FIS VS Low Speed 300 T from Fischer were tested. The Sikadur 31+ consists of two components that must be mixed in an external container before application. One container of the epoxy glue, containing a total of 1.2 kg, was used for the test. The epoxy glue is a moisture-tolerant adhesive designed to bond a variety of different

materials including concrete, natural stone, ceramics etc. and is used for repairs, joint fillings and crack sealing. According to the manufacturer information [15] the Sikadur 31+ has a compressive strength of ~50 MPa and a tensile strength of ~6 MPa after 3 days curing time at +10°C. The shear strength is reported as ~16 MPa. In contrast, the FIS VS Low Speed 300 T is delivered in a cartridge press containing 490 g of two components that are instantly mixed in the press upon handling. This injection mortar has approved use in water-filled drill holes and is used for fixations in cracked and non-cracked concrete as well as masonry. Due to its preferred use with anchors in drill holes, the strength metrics of the FIS VS Low Speed 300 T depend on the diameter of the anchor/rod used and the composition of the concrete/masonry. Information on bonding strength metrics were taken from the manufacturer homepage [16]. According to manufacturer information, permissible tensile loads are in the order of 0.34 kN up to 3.43 kN and permissible shear loads are in the order of 0.26 kN to 3.28 kN for solid and perforated masonry. In normal concrete, values for permissible tension and shear loads ranging from 3.9 kN up to 121.2 kN are reported depending on the anchor/rod type used. The characteristics of the epoxy resin glue and the injection mortar were estimated to be suitable to securely bond the Fibrasens DSS-S cable with a weight of 9 kg/km to the gneiss host rock.

Handling and application were tested using both a cartridge press and a trowel. The behavior of both the epoxy glue and injection mortar under dry and wet surface conditions was tested. Before gluing a cable to the wall or the specimen, the surface was prepared using a scratch brush to remove loose particles and dust. For temporarily fixing the fiber-optic cable to the rock surface, two fabric tapes were tested. The first was a standard tape for domestic use, and the second was the natural rubber tape “Beton- und Mauerband Premium, 44 mm x 50m” specifically manufactured for use on poorly adhering surfaces such as walls and concrete [17].

### 2.4 The DFOS measurement system

The fiber-optic measurements presented in this paper are based on the DFOS principle, specifically using the BOFDA, which enables spatially resolved strain and temperature measurements along the profile of the fiber. The measurement hardware consists of an interrogation unit (model name: fTB 5020), a fiber-optic switch for channel extension (a total of 12 channels for this project), an industrial PC and an ethernet switch for internet connection (Figure 3). For data analysis, the software fTView will be used and the cloud platform fTScope for data storage (not shown in Figure 3).

The BOFDA measurement enables a range of spatial resolutions for temperature and strain measurements of 0.2 m to 2.5 m depending on the fiber length. The minimum resolvable event is >2 microstrain [ $\mu\epsilon$ ] and >0.1°C for temperature measurements. Total fiber lengths of up to 80 km are possible [18].

The BOFDA technique makes use of the so-called Brillouin frequency shift of the fiber, which in a first instance is dependent on the intrinsic properties of the fiber material itself. However, small changes in the local density also impact the Brillouin frequency shift, which are interpreted in terms of changes in temperature and strain [7].

The conversion from Brillouin frequency shift [GHz] to temperature and strain for each position along the fiber is performed using the following relationships:

$$f_B = f_{B0} + \varepsilon \cdot c_\varepsilon \quad (1)$$

$$f_B = f_{B0} + (T - T_0) \cdot c_T \quad (2)$$

where  $f_B$  is the measured Brillouin frequency shift [GHz],  $T$  is the temperature [°C] and  $\varepsilon$  is the applied strain in microstrain [ $\mu\varepsilon$ ]. The calibration parameters  $f_{B0}$ ,  $c_\varepsilon$  and  $c_T$  are dependent on the specific optical fiber and cable type used (strain or temperature cable).

To test the DFOS measurement configuration, an aluminum frame was installed in the Geomatics Indoor Lab at the IGMR, which will be equipped with clamping jaws and deflection rolls to enable test strain and temperature measurements using both cable types.

## 2.5 Fiber-optic cable installation configuration and experimental setup in the underground lab

On-site in the underground lab, the fiber-optic sensors will be installed along the main drift to obtain longitudinal temperature and strain along the entire drift. These sensors will be installed with the aim of providing continuous measurements throughout the MOVIE project period. In contrast to the strain cable, the temperature cable in the main drift is planned to be installed disconnected from the drift wall using clamps, as measurements of the temperature of the air inside the drift is of interest. The temperatures on the surface of the rock, where the fiber-optic strain sensing cable is installed, are assumed to be overall stable and in equilibrium with air temperatures, with no sudden variations to be expected. The temperature distribution retrieved from the fiber-optic temperature sensing cable will

therefore be suitable to temperature compensate the strain measurements along the drift, where the fiber-optic strain sensing cable is largely running in parallel to the temperature sensing cable. For the strain cable installations that are directed further into the gneiss body, being the rock bolt test installations, the temperature is assumed to be even more stable and constant over the cable length. The temperature impact on these strain measurements will therefore be neglected, and no temperature compensation is assumed to be necessary. To induce measurable deformation in the gneiss that is large enough to be used as boundary conditions for the geomechanical model, three test rigs will be installed in three of the four chambers to perform short-term push and pull experiments. In the first chamber, an arch support will be installed in such a way that a distance from direct contact with the rock is maintained, allowing exertion of pressure on specific points of the support structure. In the second chamber, a hydraulic cylinder will be installed, which enables to transfer a load orthogonally onto the rock.

For both chambers, stress and strain changes will be recorded with fiber-optic cables installed superficially either in the support structure of the arch or directly on the chamber wall surrounding the hydraulic cylinder.

In the third chamber, four separate configurations of 4 m long anchor boreholes surrounded by four 5 m long measurement boreholes are planned, resulting in a total of four anchor boreholes and 20 measurement boreholes to be drilled. The fiber-optic cables will be directly cemented into the rock along the rock bolts. For each of the four configurations separately, the rock bolt cemented in the anchor borehole will be pulled and deformations of the surrounding concrete and rock will be measured in the measurement boreholes along the cemented fiber-optic cables.

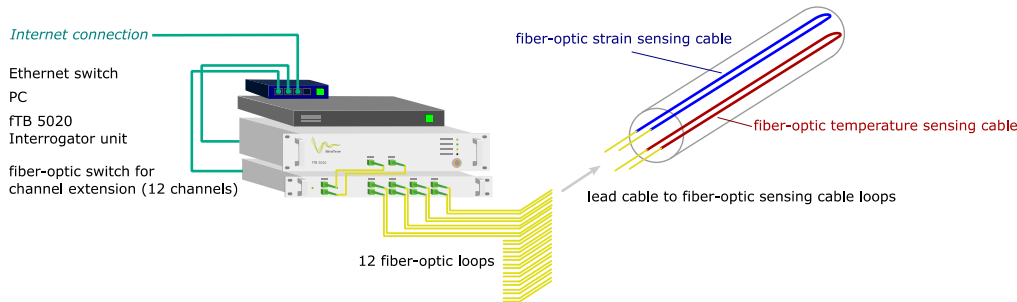

Figure 3 fibrisTerre measurement setup (principle).

Additional numerical simulations were conducted by the Geomechanics department at the TUC based on the rock elasticity modulus, the mechanical properties of the steel and the detection limit of the fibrisTerre interrogation unit of 2  $\mu\varepsilon$  to ensure optimal fiber-optic cable installation planning. The simulation parameters are based on the dimensions of the planned experiments. For the hydraulic cylinder in chamber 2, a steel plate with diameters of 0,30 m was modeled, which was placed on a rock cube 1.5 m in diameter with an assumed elastic modulus of 50 GPa. A maximum pressure of 182 MPa was exerted on the steel plate. The simulation results were used to identify the maximum radius in which a superficial strain change can still be measured if a load is transferred onto the

rock. Results showed a maximum radius of ~52 cm around the steel plate to be maintained for the cable installation (Figure 4). For the rock bolt pull out test in chamber 3, a borehole with a radius of 38 mm and a depth of 4 m was assumed, in which a rod with radius 25 mm and a length of 3975 mm is installed. The scenario was modeled under the assumption of inelastic grout and steel and a rock elasticity modulus of 50 GPa. The simulation results were used to identify the maximum distances between the anchor and measurement boreholes in which a strain change in the measurement borehole is expected to be still measurable. The results showed a maximum distance of ~36.2 cm to be maintained (Figure 4).

Figure 4 Geomechanical simulation results of (A) plate load test and (B) rock bolt pull out test. A strain cut off value of  $10^{-5}$  was used in both cases. To save computational effort and under the assumption of radial symmetry, only one fourth of the geometry was simulated.

The 3D point cloud acquired in May 2024 was used for fiber-optic cable installation planning for the main drift and the test rigs separately. The Trace Polyline tool available in the software package CloudCompare 2.13.2. was used to draw polylines in the 3D point cloud representing the fiber-optic cables to be installed. To estimate the overall lengths of the cables, the individual polylines were summed up in CloudCompare. Since the 3D point cloud only allows for estimating the lengths of cables installed superficially, the lengths of the cables needed for the rock bolts were added to the calculated superficial installation lengths.

All cables from the main drift installation and the test rigs will be installed in a loop configuration from and towards a fiber-optic cable termination box connected with the fibrisTerre measurement configuration, which both will be installed roughly opposite of chamber 2.

### 3 RESULTS

#### 3.1 Visualization of 3D point cloud and determination of fiber-optic cable positions and their lengths

The 3D point cloud acquired in May 2024 was scanned with an average spatial resolution, i.e., average point distance, of approximately 0.76 mm in roughly 29.5 minutes. Due to computational performance reasons, a subsampled version of the original 3D point cloud with a resolution of ~3.63 mm (22,378,105 points; ~417 MB in .e57-format) was used for planning the installation of the fiber-optic cables, which still captured enough details to ensure realistic positioning of the cables. Figure 5 shows the subsampled 3D point cloud of the underground lab, including its four chambers. Additionally, Figure 5 shows the meshed 3D point cloud visualized in the target software for the digital twin LiquidEarth One. Figure 6 presents views within the 3D point cloud, showing the polylines representing the positions of the fiber-optic cables for the main drift and exemplary for chambers 1 and 2. Based on a high resolution meshed version of chamber 2, a relatively flat

section extending across a large portion of the roof was identified, making it an ideal candidate for the installation of the hydraulic cylinder unit and the cables surrounding the terminating steel plate of the cylinder (see Figure 6C).

Table 1 Estimated lengths [in meters] of the Fibrasens strain cable and Solifos BRUsens temperature cable based on polylines drawn in the 3D point cloud

Position	Experiment setup	Cable type	Length [m]
Main drift	Continuous monitoring	Strain	138
Chamber 1	Arch support structure	Strain	29
Chamber 2	Hydraulic cylinder	Strain	35
Chamber 3	Rock bolt pull out	Strain	387
<b>SUM [m]</b>			<b>589</b>
Main drift	Continuous monitoring	Temperature	<b>138</b>

The lengths of the cables to be installed were determined in the 3D point cloud supported by the results of the geomechanical simulations. The overall length of the Fibrasens strain cable to be installed for the main drift and the test rigs was estimated to be roughly 600 m, while the overall length of the Solifos BRUsens temperature cable was estimated to be roughly 140 m. Table 1 presents the detailed estimated lengths for the strain cable along the main drift and the test rigs separately. Since temperature measurements are only performed along the main drift, the estimated length of the temperature cable is added at the bottom of Table 1.

Figure 5 (A) 3D point cloud of underground lab including main drift and four chambers (chambers numbered 1 to 3 are used for installation of the test rigs); (B) Meshed 3D point cloud visualized in software LiquidEarth One developed by Terranigma Solutions GmbH; (C) View inside the underground lab in LiquidEarth One using a Meta Quest 3 VR headset.

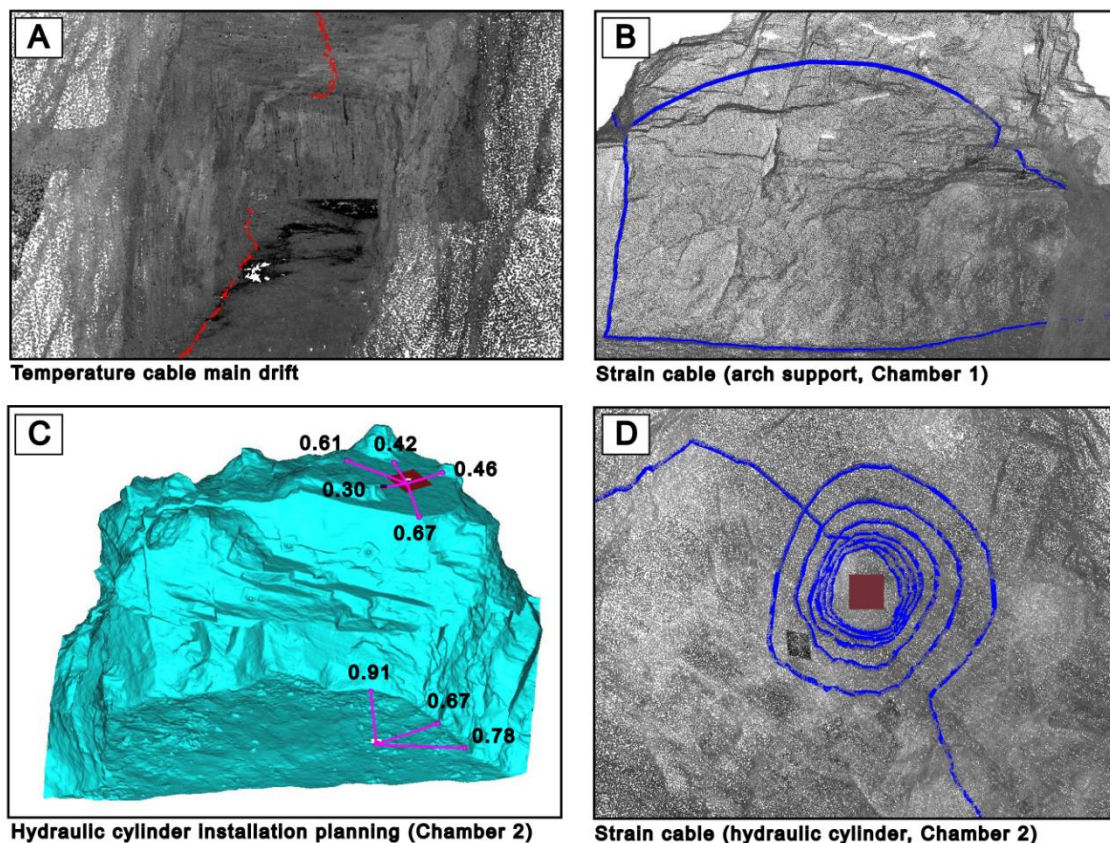

Figure 6: Views in the 3D point cloud (and mesh) showing the positions of the fiber-optic cables to be installed as polylines (A) BRUsens temperature cable in main drift, (B) Fibrasens strain cable in the arch support structure (Chamber 1), (C) Meshed 3D point cloud of Chamber 2 for estimation of distances (in meters) to the walls for installation planning of the hydraulic cylinder.

The terminating steel plate of the hydraulic cylinder is shown as a dark red square on the chamber roof (D) Fibrasens strain cable around the steel plate of the hydraulic cylinder (dark red) in Chamber 2 (view towards the chamber roof)

### 3.2 The gluing experiments

Several gluing tests were conducted to ensure optimal bonding between the Fibrasens strain cable and the drift wall (Figure 7). For temporarily fixing the cable to the rock surface, the tape for domestic-use did not provide sufficient adhesion for both dry and wet surfaces. However, the special wall and concrete tape adhered well to a dry surface. Under room temperature conditions in the Geomatics Indoor Lab at IGMR, the Sikadur 31+ epoxy resin glue achieved its maximum bonding strength one day after application, with no observable differences for wet and dry surfaces. After mixing, the epoxy resin glue remained usable for approximately 60-70 min, but became sticky (and therefore unworkable) after roughly 90 min. Once applied, the cables were securely fixed to a rock specimen in the Geomatics Indoor Lab or on-site on the drift wall and could not be removed by pulling on the cable. In contrast, the FIS VS Low Speed 300 T injection mortar reached maximum bonding strength after just 3.5-5 min. However, on damp surfaces, the cured mortar broke off with slight force. Application of both the glue and the mortar to a vertical wall and overhead was challenging, as a lot of material crumbled or fell off and did not adhere to the rock. The use of a cartridge press and a trowel partially solved this problem and proved to be the most effective method to best apply both the glue and the mortar to the rock.

## 4 DISCUSSION

### 4.1 3D mobile laser scanning and determination of fiber-optic cable positions/lengths

The Z+F FlexScan22 mobile backpack laser scanner solution proved capable of accurately capturing the complex wall geometry of the underground lab with a very high resolution of approximately 0.76 mm in about 29.5 min

acquisition time. Compared to a classical terrestrial laser scanning system, at least about eight different stationary scanner positions would have been necessary to capture the underground lab, resulting in a much longer data acquisition time. Despite the high data acquisition speed, a shortcoming of the mobile laser scanning system are omnipresent noise pixels in the drift, which requires greater (manual) cleaning efforts compared to data acquired with a stationary terrestrial laser scanner system. In contrast, the registration of independently acquired 3D point clouds is not necessary when using a mobile laser scanner system, which should result in an overall shorter time for data acquisition and processing using the Z+F FlexScan22 solution.

Using this approach made it possible to identify optimal positions for the fiber-optic cables and to estimate their required lengths in the 3D point cloud. Due to the high point density, it is not possible to click every successive point in the 3D point cloud as a vertex point of the polyline. This might lead to some of the distances between individual vertex points being shorter than in reality, since some of the line segments between individual vertex points might not follow the wall roughness, which might result in a slight underestimation of the cable lengths. Conversely, due to uncertainties in the distance measurements themselves stemming from intrinsic device errors and external factors such as dust particles and/or humidity, the points in the 3D point cloud are slightly spread, i.e., not exactly matching with their position on the wall. This might lead to greater roughness in the 3D point cloud compared to the drift wall, which could, in contrast, result in a slight overestimation of the cable lengths. However, for the practical installation of the cables on-site, the estimated positions and cable lengths will act as a guiding principle and do not need to be accurate on a centimeter-scale. Additionally, the practical installation of the cables requires consideration of the maximum allowed bending radii, which are 3.8 cm for the Fibrasens strain cable and 9.6 cm for the Solifos BRUsens temperature cable. Due to the large roughness of the drift walls, the bending radii might be exceeded in some places particularly for the strain cable.

### 4.2 The gluing experiments and fiber-optic cable installation configuration

The Geomatics Indoor Lab and on-site experiments presented in this paper showed that gluing the strain cable to the drift wall is a difficult task, since most of the glue and mortar crumbles or falls off especially when working on a perpendicular wall or overhead. Still, direct installation on the wall is necessary in this project, since there are no pre-existing structures present in the underground lab, which the cable can be installed at and direct installation on the wall allows to make full use of the system's spatial resolution. To overcome this issue, cutting a ~3-25 mm deep and ~4 mm wide slit in the drift wall is planned with the strain cables placed in. After its installation, the slit will be closed with the injection mortar due to its easier handling and the shorter setting time if compared to the epoxy resin glue. Before application of the mortar, the acquisition of another 3D point cloud is planned to document the position of the slit (and therefore the position of the fiber-optic cable).

The overhead installation of the cables might still be challenging, but could be successfully addressed with combined use of the cartridge press and trowel. If needed, “modeling” rough parts using the injection mortar is possible, which will ensure optimum bonding between the strain cables and the drift wall. Cable installation within the arch support structure and installation along the rock bolts for the rock bolt pull out test requires a different setup, which is in the planning phase at the time of writing this paper.

The current fiber-optic cable setup plans the installation of a termination box and the fibrisTerre measurement configuration in the underground laboratory. This results in the shortest possible spanned distances between the termination box and the individual test rigs (see Table 1). The same applies for the temperature and strain cables installed in the main drift for continuous measurements. Still, the planned setup in chamber 3 requires longer cable lengths if compared to the installations in chamber 1 and 2 due to cable installation along the 4 to 5 m long rock bolts. Additionally, each of the four configurations of anchor and measurement boreholes must be connected to the termination box separately, as the cable will most likely be destroyed after performing a pull out test. Besides pure cable installation with the help of a 3D point cloud, meshes were created for visualization purposes and a highly resolved mesh of chamber 2 was used for installation planning of the hydraulic cylinder. The mesh allowed to identify a region most suitable for installation of the terminating steel plate and to precisely determine the distances to the wall to ensure enough space for installation of the cylinder foot.

It is planned to prepare the cables based on the determined lengths in the Geomatics Indoor Lab at IGMR before installing them in the underground lab. This preparatory step might be beneficial, since the very sensitive splicing work should be kept away from the harsh and dark environment of an underground environment.

#### 4.3 Long-term stability of the BOFDA measurement system

Due to its primarily measured material parameter being the intrinsic density of the optical fiber, the BOFDA technology is specifically long-term stable and free from the requirement of on-site sensor calibration both at the initial baseline measurements and during long-term operation. With the above calibration parameters known for the fiber-optic sensing cables in use (to be acquired from one-time lab tests), the Brillouin frequency shift from each measurement iteration can be converted into absolute values for temperature and strain, with no drift being caused by aging, fatigue, or changes in the optical properties of the cables and connectors. Therefore, the technique is especially suitable for the monitoring of the underground structure over a time horizon of many years. More critical, however, will be the long-term behavior of the bonding between the fiber-optic strain sensing cable and the rock and grout structures under test.

#### 4.4 Preparation of data fusion and comparison to El Teniente mine (Chile)

A first attempt at fusing the fiber-optic position data, i.e., the polylines, with the BOFDA strain and temperature

measurements provided promising results via exporting the strain and temperature data from fTView and merging them with the exported fiber-optic position data from CloudCompare using a Python script. When merged, the strain and temperature data can be re-loaded into CloudCompare as scalar fields of the position data and can be visualized. The strain and temperature measurements will serve as the boundary conditions for a coupled geomechanical and ventilation model provided by our project partners. As a first step towards visualization, the meshed version of the acquired 3D point cloud, i.e., the geometrical model, was uploaded and visualized in the target software for our digital twin LiquidEarth One using a Meta Quest 3 VR headset. The final product, i.e., the digital twin, to be visualized in LiquidEarth One and using virtual reality will be a coupled geomechanical and ventilation model provided with measurements from the fiber-optic sensors as boundary conditions and speeded-up with AI to shorten processing times and to enable real-time user interaction. The planned AI based approach is currently developed at TUC and is based on the Equilibrium Neural Operator (EquiNO) for solving steady-state multiscale modeling problems [19]. The expected results of the MOVIE project might be transferable to active mining environments such as e.g. the El Teniente mine in Chile. In this mine, fiber-optic sensors were installed in the ventilation level of a 201 m long test field and measured deformations were interpreted in terms of mining activities conducted in the production level [10]. The results presented in this paper are expected to be transferable to mines in a hard rock setting, such as e.g., the El Teniente mine [cf. [20]]. Additionally, the use of a digital twin, as described in this paper, might simulate the impacts of mining activities in terms of geotechnical parameters and ventilation even before a particular mine is opened, thereby enhancing safety and efficiency. Due to the capability of the BOFDA technology to measure within a range of up to 80 km, the results of this project should also be scalable to large mining areas. However, challenges remain in installing and protecting fiber-optic strain sensing cables when considering the occurrence of (locally constrained) deformations in the macrostrain region, such as e.g., in coal mines [21]. With both metallic and non-metallic fiber-optic sensing cable designs being typically specified for operation up to 1% strain, other strategies than straight gluing and pre-strained anchoring will need to be considered.

Since this is an ongoing research project, future changes to the described configurations and workflows might apply. Nevertheless, the results presented show the great potential of using 3D mobile laser scanning data for installation planning of fiber-optic cables in the underground space.

## CONCLUSION

This paper presents the current state of the work done within the larger collaborative research project MOVIE with the aim of developing a digital twin of a 60 m long underground lab located in the FLB research mine in Freiberg (Germany) including real-time DFOS based temperature and strain measurements and visualization in VR. The installation planning of the fiber-optic cables was supported by SLAM based mobile laser scanning using a Z+F FlexScan 22

platform. The acquired 3D point cloud was successfully used to estimate the lengths of the fiber-optic strain and temperature cables to be installed for both a continuous measurement setup and additional temporary experimental setups. Additionally, a meshed version of the 3D point cloud, i.e., the geometrical model, was visualized in virtual reality using a Meta Quest 3 VR headset. Since no pre-existing structures are present in the underground lab, several gluing tests under dry and wet conditions using the epoxy resin glue Sikadur 31+ from Sika and the injection mortar FIS VS Low Speed 300 T from Fischer were conducted. Overall, the injection mortar outperformed the epoxy resin glue due to its shorter setting time and easier handling and application. Future steps in the project will include installation of the strain cables in a slit cut in the drift wall and subsequent gluing with the injection mortar, which will enable a safe installation of the cables. An additional 3D point cloud will be acquired to document the positions of the cables once installed. The results of the DFOS temperature and strain measurements will be used as boundary conditions for a coupled geomechanical and ventilation model, which is supported with an AI model to enable real-time visualization of changes in physical parameters.

## 5 ACKNOWLEDGMENTS

The project "Modellkopplung im Kontext eines Virtuellen Untertagelabors und dessen Entwicklungsprozess - MOVIE" is part of the research program "GEO:N - Geosciences for Sustainability" on the topic "Digital Geosystems: Virtual Methods and Digital Tools for Geoscientific Applications" funded by the German Federal Ministry of Research, Technology and Space (BMFTR). GEO:N is thus part of the BMFTR program "Research for Sustainable Development (FONA)". For the opportunity to realize this project, the consortium thanks the BMFTR and the project management organization.

**ABSTRACT:** Earthen geohydraulic structures, such as dams and river embankments, are vital for water resource management and flood control, especially as climate change and urbanization increase hydrological risks. Internal erosion, often triggered by seepage, remains a major failure mechanism and can cause sudden, catastrophic collapses. Traditional monitoring systems lack the spatial and temporal resolution needed for effective early detection. To address this gap, a novel Distributed Pressure Sensor (DPS) based on distributed fiber optic (DFO) technology has been developed by the University of Applied Sciences of Eastern Switzerland (OST). The DPS offers high spatial resolution and extended range, enabling precise measurement of distributed pore water pressure - key for early detection of internal erosion processes. Following successful laboratory validation, the DPS was deployed in a full-scale test embankment (84 m long, 39 m wide, 4 m high) at the AIPo Research and Technical Centre in Boretto, Italy. Preliminary results show that the DPS accurately captured pore pressure evolution, matching conventional piezometer readings while detecting localized variations and two-dimensional flow effects that point sensors could not resolve. These findings highlight the DPS system's strong potential for improving early warning capabilities in geohydraulic structure monitoring.

**KEY WORDS:** Dike Monitoring, Distributed Pressure Sensor, Distributed Fiber Optic technology.

### 1 INTRODUCTION

River dikes and earthen dams play a crucial role in water management, including energy production and flood risk protection. Following the catastrophic events in northern Italy of May 2023 [1] and the Rhone region of Switzerland in June 2024 [2], the need for enhanced protection and monitoring of such structures has become evident.

The primary failure mechanisms of these structures are overtopping and internal erosion [3]. Among them, internal erosion is often underestimated and typically not clearly detectable after failure [4].

Conventional monitoring systems, which rely mainly on point-based sensors, are limited in both spatial and temporal resolution. As a result, monitoring during flood events often still depends on visual inspections, sometimes involving hundreds of volunteers, which reflects an outdated approach [4].

In last decades, a promising monitoring alternative has emerged: the use of Distributed Fiber Optic (DFO) technology, which enables high-resolution measurements of temperature and deformation along the entire length of the installed sensing cable [5]-[6]. In this context, an innovative development within the DFO sensor family has been proposed by Höttges, et al. [7], who introduced a Distributed Pressure Sensor (DPS). This sensor is capable of measuring pore pressure with high sensitivity and accuracy, over distances of several kilometers. The DPS is designed to monitor seepage anomalies by directly measuring pore pressure within the structure, which can serve as an early indicator of internal erosion processes as pointed out by Fell, et al. [4].

The DPS has already been validated through extensive laboratory testing on model dikes (Höttges, et al. [7]; Höttges, et al. [8]). This paper presents a further step in the validation

process of this novel sensor by reporting preliminary results obtained under full-scale field conditions, using a dedicated full-scale test embankment constructed at the AIPo Research and Technical Centre. The objective is to assess both the installation process and the sensor's performance in a controlled field environment that closely replicates field operating conditions.

### 2 DISTRIBUTED PRESSURE SENSOR - DPS

The sensor was developed within the framework of the FIBRADIKE project [9], whose core objective was the development of a DPS based on DFO technology. The sensor, whose latest design has a diameter of 13 mm, consists of an optical fiber that is wound helically around a cylindrical, compressible central element (Figure 1). When the central element is subjected to hydrostatic pressure, it compresses, causing the helical fiber to deform accordingly. The hydrostatic pressure is then back calculated using a calibration coefficient ( $C_p$ ) that converts the measured radial strain of the fiber into corresponding pressure values. This coefficient is determined by laboratory testing under controlled pressure conditions. According to Höttges, et al. [8] the sensor can reach a sensitivity of 100 Pa and an accuracy of 15 % RD (relative deviation of reading) for a spatial resolution in the order of a few centimeters using the Rayleigh interrogation technique [10]. Additionally, the core of the central element is equipped with two single-mode fibers and two multi-mode fibers, loosely housed in a central tube (see Figure 1), which can be used for Distributed Temperature Sensing (DTS). This configuration enables simultaneous monitoring of pore pressure and temperature, enhancing the sensor's capability for detecting and characterizing seepage-related anomalies. Additionally, the inner part of the central element is filled with aramid yarns (see

Figure 1), which according to Höttes, et al. [8], can provide a tensile strength of up to 20 kN. This feature is particularly useful for installations requiring high tensile strength of the cable, such as pulling or trenching operations.

The sensor was developed and calibrated for pressures up to 200 kPa, specifically designed to operate within the typical pressure range found in river dikes. Although higher pressure ranges are possible, they were not tested in this study. The sensor demonstrates good repeatability and low hysteresis within the tested pressure range [7].

Figure 1. Design of the DPS, adapted from [7].

### 3 FULL-SCALE TEST EMBANKMENT

#### 3.1 Embankment design and construction

The test embankment is constructed at the AIPo Research and Technical Centre situated in the municipality of Boretto - Province of Reggio Emilia (RE - Italy). The test embankment has a length of 84 m, 39 m wide and 4 m high with a slope 1:2 [9], see Figure 2. The embankment is founded on 16 m thick clay layer and 16 m thick medium to coarse sand (aquifer), from which water is pumped to fill the reservoir.

Figure 2. Test embankment with the 4 different sections.

The test embankment was constructed using two different materials: a coarse soil typical of Swiss river dikes and a finer soil characteristic of the river dikes along the Po River plain. These two zones are referred to as Swiss (CH) and Italian (IT) sections, respectively. According to the Unified Soil Classification System (USCS), the IT-Material is classified as sandy clay (CM), while the CH-Material is classified as clayey sand (SC). The granulometric distribution of the two materials is shown in Figure 3. Based on in-situ permeability tests, the permeability  $k_m$  is approximately  $1 \cdot 10^{-5} \text{ m/s}$  for the CH and  $2 \cdot 10^{-7} \text{ m/s}$  for the IT-Material.

Two different sensor installation methods were also implemented, each applied to a different section. The first, referred to as "ex novo", simulates the sensor installation during the construction process. The second, referred to as "existing",

involves the installation of the sensors after the construction of the basin has been completed, using the Horizontal Directional Drilling (HDD) technique [11].

In total, four different zones were constructed, each representing a unique combination of material type and installation method (Figure 2). This paper focuses solely on the installation and results of the "ex novo" section.

The test embankment was constructed using the described two different materials, placed in 30 cm thick compacted layers. Each layer was compacted using a roller compactor (about 6 passes per layer) with the optimal water content determined in the laboratory. The Swiss section was additionally equipped with a gravel filter, designed to prevent toe erosion failure. To prevent localized seepage inhomogeneities, the transition zone between the two materials (Figure 2) was constructed by interlayering both material types.

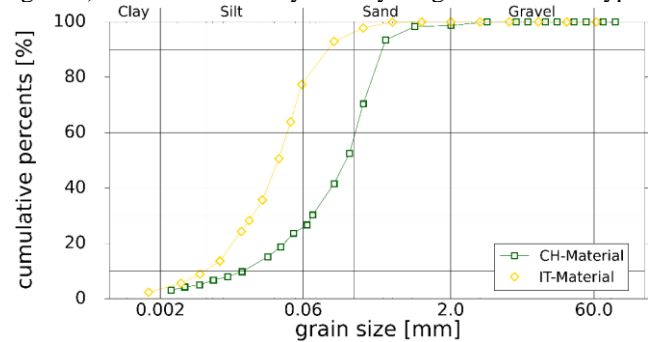

Figure 3. Granulometry of CH-material and IT-material.

#### 3.2 Experimental setup

The DPS sensor was installed in the "ex novo" section during construction, arranged in a mesh pattern at three different elevations ( $z$ ) from the bottom of the basin:  $z = 0.3 \text{ m}$  (Layer 01),  $z = 1.3 \text{ m}$  (Layer 02), and  $z = 2.3 \text{ m}$  (Layer 03). Figure 4 illustrates the DPS cable mesh installed in Layer 01, showing two main orientations: the longitudinal (L) direction (x-axis) and the transversal (T) direction (y-axis). The longitudinal direction is defined as parallel to the assumed river flow, while the transversal direction is parallel to the seepage flow within the dike. The DPS was installed in two different configurations: as a free cable, and within saturable tubes (black rectangles in Figure 4) equipped with porous stones. These tubes are designed to protect the DPS from earth pressure variations and to ensure that only hydrostatic pressure is measured in those sections.

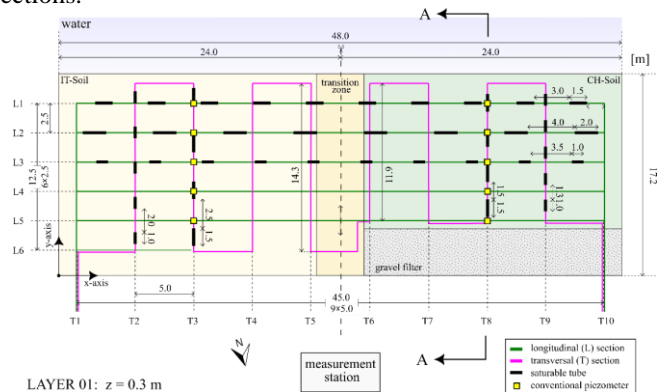

Figure 4. Mesh installation of the DPS in Layer 01 of the "ex novo" section.

To validate the DPS measurements, 10 conventional piezometers were installed in two main cross-sections (T3 and T8) of the “ex novo” section in Layer 01 (indicated by yellow square in Figure 4). The piezometers are of the vibrating wire (VW) type, with a measurement range of 0-170 kPa and an accuracy of  $\pm 0.4\%$  of full scale (FS). Figure 5 shows the installation layout of both the DPS sensors and the piezometers along the A-A cross-section indicated in Figure 2.

Figure 5. A-A cross section of the installation.

### 3.3 Testing procedure

The water level values recorded during the test are presented in Figure 6. Initially, the water level stood at 1 meter due to rainfall accumulation and was raised to 2.3 meters by pumping groundwater from the aquifer through an existing well (Phase 1: Filling – about 5 h). After reaching the target level, the basin was allowed to drain naturally for approximately one week (Phase 2: Self-Drain – about 165 h). This was followed by a controlled, three-stage emptying process designed to reduce the risk of instability associated with rapid drawdown (Phase 3: Emptying – about 70 h). The water level was monitored using a piezometer installed at the water-side toe of the test embankment.

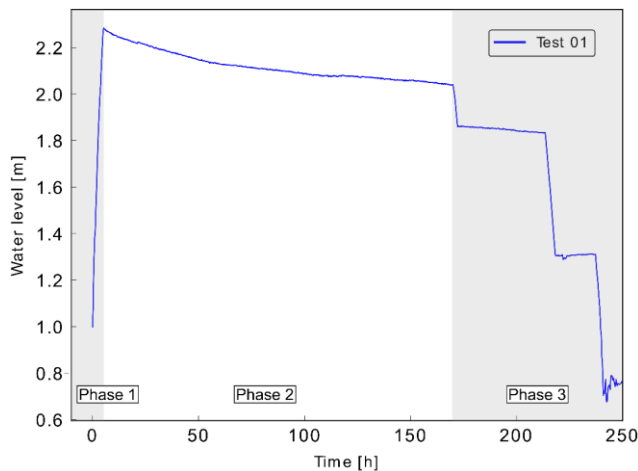

Figure 6. Water level inside the basin during the test.

The data from the DPS helical fiber were collected manually at approximately 30-minute intervals using a commercially available Rayleigh-based Optical Backscatter Reflectometer (OBR 4600, Luna Innovations [12]). Due to the manual acquisition process, measurements were limited to the initial filling Phase 1 and continued for approximately 12 hours of the Phase 2. The core temperature fiber was automatically interrogated using a Raman-based system (AP Sensing, DTS - N45 Series [13]), with an acquisition time of 4 minutes.

Conventional instruments recorded data automatically every 15 minutes. Temperature and piezometer measurements were recorded continuously until the end of the test, when the basin was fully emptied (after approximately 240 hours).

### 3.4 Data processing

The data obtained from the DPS were post-processed using a spatial sampling interval of 10 cm and a spatial resolution of 10 cm, with a reference that was updated after each measurement. This approach reduces noise that would otherwise accumulate if the initial measurement were used as a fixed reference throughout the test. The spectral shift values were then cumulatively summed after each iteration.

Subsequently, artificial peaks were removed using the “peak prominence” method available in Python [14], which identifies local maxima by comparing each value to its neighboring points. Detected peaks were then replaced with the median value of their surrounding neighbors. The resulting data were then smoothed using a Savitzky-Golay filter [15].

The filtered values obtained were then converted to pressure using the pressure coefficient  $C_p$  (described in section 2).

The raw data from the DTS system were not post-processed, as the results provided by the instrument were already corrected through automatic calibration in loop mode. A sampling interval of 1 meter, a spatial resolution of 0.5 meters, and a measurement time of 1 minute were used.

The piezometer data were not corrected, as both barometric and temperature corrections have minimal influence and were therefore neglected.

### 3.5 Preliminary Results

Figure 7 illustrates the pore pressure measured with piezometers in Layer 01 (Figure 4) for the two different materials at four time intervals: at the start of the test, and after 12, 24, and 60 hours (Figure 6). The corresponding water levels, shown in blue, are also reported in Figure 7, for these intervals.

Figure 7. Piezometer measurements for the two soil materials at four time intervals (0h, 12h, 24h and 60 h) in Layer 01.

Figure 8 presents the post-processed pressure variation measurements across all transversal sensor lines from T4 to T9 in Layer 01 (Figure 4) for five different time: 1.6 h, 3.1 h, 4.2 h, and 10.2 h. These results represent the distributed pressure data along the full fiber length (axial cable development), obtained from the DPS system after applying filtering and peak correction techniques, as described in section 3.4. The pressure variation is calculated cumulatively by changing the reference measurement taken from the beginning of the test when the water level in the tank was already 1 m high. The longitudinal segments of the transversal loop are referred to as the “wet

side” (WS) when the segment is on the water-facing side of the embankment, and the “dry side” (DS) when it is on the air-facing side; see Figure 4.

Figure 8. Pressure variation measured during the filling phase using the transversal DPS cables in Layer 01.

It should be noted that the data from lines T2 and T3 exhibited increased noise and irregularities, due to localized issues related to sensor splicer connections during the test. For this reason, these data were excluded from the results analysis.

Figure 9 (a) shows a comparison between the vibrating wire piezometer sensors (VWPS) and the transversal DPS cable measurements at T4 (see Figure 4), while Figure 9 (b) presents the same comparison at location T8. The analysis was conducted at T4, which is also situated within the IT-Material section. Both figures show the results for the same time intervals as shown in Figure 8.

Figure 9. Comparison between the DPS measurements and the vibrating wire piezometer sensors (VWPS) at different time intervals in the transversal direction: (a) T4 and (b) T8.

Figure 10 shows a colormap of Layer 01 based on the transversal DPS measurements presented in Figure 8. The colormap was generated using bicubic interpolation of the transversal DPS data, with additional measurement from T1 and T10, which were obtained from the longitudinal cable L1 (see Figure 4).

Figure 10. Distributed temperature results for transverse section of Layer 01 at (a) 1.5 h, (b) 3.1 h, (c) 4.2 h, 6.6 h, and (d) 10.2 h after the start of the test.

The absolute temperature distribution obtained by the core temperature fiber of the DPS cable is shown in Figure 11 at four time intervals: 1 hour, 12 hours, 24 hours, and 144 hours after the start of the test. Similar to Figure 10, the data are displayed as colormaps using bicubic interpolation, derived from both the longitudinal and transversal cable sections in Layer 01 (see Figure 4).

Figure 11. Distributed temperature results for Layer 01 at (a) 1 h, (b) 12 h, (c) 24 h, and (d) 144 h after the start of the test.

#### 4 DISCUSSION

The initial pore pressure measurements (Figure 7) confirmed that the sensors installed in Layer 01 were already below the seepage line prior to the test, consistent with the 1 m water level maintained due to prolonged rainfall.

The Swiss (CH) material, with its coarser granulometry and higher permeability, responded more rapidly to water level changes compared to the IT-Material, which had a finer particle distribution and lower permeability. This contrast is evident in both the vibrating wire piezometer sensor (VWPS) measurements (Figure 7) and the DPS readings (Figure 8 and Figure 9). In particular, the DPS captured a steeper and delayed pressure curve within the IT section, aligning with the expected slower hydraulic response. Additionally, a minor effect from the activation of the drainage filter in the Swiss section is observed, indicated by a slight decrease in pore pressure recorded by the piezometer and the DPS installed at that location.

A good agreement was observed between the VWPSs and the DPS measurements (Figure 9). However, in the central part of the transversal section, the DPS shows slightly higher pore pressure variations compared to the VWPS. When comparing the time intervals, it is evident that the DPS system responds more rapidly than the VWPS particularly during the first interval at 1.5 hours. The DPS captures changes in pore pressure almost instantaneously, whereas the VWPS exhibits a slightly delayed response due to its mechanical components and different response time [16, 17]

The effect of the saturable tube on the DPS cable is particularly noticeable in the CH-Material section, as shown in Figure 9 (b), where a region of constant pore pressure is observed at a distinct location.

Colormap visualization (Figure 10) clearly delineates the transition between the CH and IT materials, demonstrating the DPS's capability to resolve subtle spatial variations in pore pressure distribution. Moreover, the boundaries around sensor lines T1 to T10 exhibit signs of two-dimensional (2D) pore pressure effects within the plane of Layer 01, suggesting more complex flow dynamics in these regions that deviate from the assumed one-dimensional (1D) behavior.

Temperature measurements (Figure 11) remained stable during the first 24 hours. Since the DTS cables were installed below the initial seepage line (see Figure 7), no significant temperature changes were expected during the test period, which is consistent with what was observed. A slight temperature increase was detected only after approximately 144 hours, particularly in the CH section, which is consistent with the higher thermal conductivity expected in coarser soils.

Since the DPS data were collected within the first 17 hours - during which temperature variations were negligible - no temperature correction was applied to the pressure data.

Approximately one year after installation and following the test results presented, some localized disturbances or breaks in the sensor signal were observed. These problems were probably caused by small mammals such as mice or beavers - and were related to the reduced mechanical robustness of the earlier DPS cable design, which was installed in the "ex novo" section and featured a thinner outer protective layer. This vulnerability highlighted a practical limitation in field applications. In response, newer DPS cable designs were developed with an enhanced outer protective layer to improve durability and mitigate such risks, thereby increasing long-term reliability in real-world conditions.

## 5 CONCLUSION AND OUTLOOK

The application of a novel Distributed Pressure Sensor (DPS) system was evaluated through field testing on a full-scale test embankment at the Research and Technical Centre of the Agency for the Po River (AIPo) in Boretto, Italy. Preliminary results, supported by comparisons with traditional piezometer measurements, confirm that the DPS system can be effectively deployed as a distributed pore pressure sensor. In contrast to point-based sensors, the DPS system provides high spatial resolution data, enabling the detection of localized phenomena - such as preferential flow paths or, as observed in the test embankment, changes in permeability due to variations in soil materials or their properties - that may be overlooked by discrete sensors.

DPS systems offer significant advantages over traditional point-based instrumentation, particularly in terms of spatial resolution and potential cost efficiency. Although the initial cost of interrogation units is relatively high, the ability to continuously monitor pore pressure along the full length of the cable reduces the need for multiple point sensors. In terms of coverage efficiency, an approximate ratio of 1:10 can be considered - meaning that for every point sensor replaced, approximately 10 meters of DPS cable can be installed, providing continuous data across that distance. This estimate does not yet account for further cost savings from reduced installation time, simplified cabling, and fewer data loggers or interrogation devices.

Overall, DPS systems show strong potential to provide substantial technical and logistical benefits, especially in large-scale or long-term geotechnical and hydraulic monitoring applications. However, to further validate the long-term reliability of the DPS technology, future work should include extended monitoring campaigns to assess sensor drift, determine optimal calibration intervals, and develop standardized maintenance protocols. Although the DPS technology has not yet been extensively tested, several research projects are planned to explore its deployment in various environmental and structural settings, aiming to broaden its validation across different use cases, such as:

- Application of DPS for detecting and monitoring backward erosion piping within the framework of the LIFE SandBoil project [18];

- Implementation of the DPS system in a real river dike section of the Rhone dike in the Canton of Valais, (Switzerland) [9].
- Large-scale testing of DPS for dynamic wave measurement, expanding upon previous work introduced by Höttinger, et al. [19]

These developments are expected to contribute significantly to the broader adoption of distributed sensing technologies in hydraulic and geotechnical engineering.

## ACKNOWLEDGMENTS

The authors would like to thank the financial supporters of this project: the Swiss Federal Institute for the Environment (FOEN) and the Cantonal Service for Flood Protection of the 3<sup>rd</sup> Rhone.

Special thanks go to the team at the University of Applied Sciences in Rapperswil (OST), particularly Isabel Bohren for designing the test embankment and assisting with sensor installation, and Dr. Antonio Salazar for his help with data analysis and processing.

We are also grateful to the AIPo team - especially Agnese Bassi, Giuseppe Capuano and Luca Crose - for their support during the embankment construction and sensor installation. Thanks to Idrovie Ltd. construction company for their dedication during the work.

The authors also wish to thank SISGEO Ltd. for their support during the installation of the conventional monitoring system, especially Daniel Naterop and Vincenzo Caci.

We further acknowledge the geotechnical group at the University of Bologna, with thanks to Prof. Dr. Guido Gottardi, Dr. Michela Marchi, and Dr. Ilaria Bertolini for their support and expertise during the design of the embankment and the sensor installation. Appreciation is also extended to the geotechnical group at the University of Padova of Prof. Dr. Simonetta Cola, particularly Dr. Nicola Fabbian, for his assistance with the sensor installation and the design of the measuring system.

Finally, sincere thanks to Dr. Massimo Facchini for his assistance during the measurement campaign and his contribution to the design of the DFO measuring system.

**ABSTRACT:** Distributed fiber optic sensors (DFOS) are extensively used for concrete crack monitoring in recent years, especially in scientific-related applications and laboratory testing. These mainly focus on Rayleigh scattering due to its high spatial resolution and strain resolution, but with significant limitations in the sensing range. This contribution introduces an enhanced laboratory test series, in which five individual test specimens were equipped with multiple installation setups and tested under well-known conditions. The sensing network was interrogated using four different sensing units based on high-resolution Rayleigh as well as Brillouin scattering. The resulting strain sensing profiles do not only allow an identification of the crack location itself, but also a quantification of the crack width. It can be demonstrated that Brillouin sensors are definitely capable of capturing reliable crack widths over long distances, despite their limitation in the spatial resolution. The outcomes are significantly important in practice as civil infrastructures often require monitoring over several kilometers.

**KEY WORDS:** Distributed fiber optic sensing, crack sensing, concrete structures, structural integrity monitoring, laboratory testing

## 1 MONITORING OBJECTIVES & TEST SETUP

In recent years, the capabilities of distributed fiber optic sensors (DFOS) for monitoring concrete cracks are demonstrated in various scientific-related projects and laboratory testing, which commonly utilize Rayleigh scattering (e.g. [1] or [2]). This sensing technique can provide measurements with high spatial and strain resolution, but with significant restrictions in the sensing range. Brillouin sensing is capable of monitoring large-scale civil infrastructure as they can provide measurements over numerous kilometers, which however results in spatial limitations and therefore impedes the capabilities for strain-based crack monitoring.

This contribution analyzes the suitability of Brillouin interrogators for identifying and quantifying evolving cracks inside concrete. An enhanced laboratory test series including five individual test concrete specimens equipped with multiple installation setups was realized at Graz University of Technology (TU Graz, Laboratory for Structural Engineering). For applying the loading force during testing, one central reinforcement bar (diameter: 18 mm) was embedded in each concrete specimen (total length: 3000mm). Thin steel plates were attached to the formwork and cast into the concrete to weaken the cross-section at defined locations, which ensures a controlled cracking of the structure during loading. The five specimens vary depending on the number of crack locations, ranging from one to five defined cracks.

The testing specimens were equipped with twelve different layers of fiber optic sensing cables per specimen, including tight-buffered optical fibers [3] as well as prefabricated sensing cables from numerous manufacturers [4–6]. The sensors were either glued to the reinforcement, directly embedded inside the specimens in different arrangements or glued to the outer surface using different adhesive after concreting. Each

specimen was tested separately under controlled axial loading, where the rebar was fixed at the bottom and pulled apart at the top side (Figure 1) to initialize the crack opening along the specimen at the predefined locations.

Figure 1. Practical realization of laboratory test setup with one defined crack location.

Loading for all specimens was performed in two steps with 15 kN each up to the initial cracking, which was determined to be around 30 kN. Afterwards, the load was further increased in 10 kN steps up until the ultimate failure of the specimen at around 100 kN and beyond. By applying the mechanical crack initiation steel plates, it could be ensured that primary cracks only open at well defined locations.

The DFOS sensing network was interrogated by Brillouin interrogators from three different manufacturers utilizing the Brillouin Optical Time Domain Analysis (BOTDA) as well as the Brillouin Optical Frequency Domain Analysis (BOFDA) with a spatial resolution of 0.5 m at each load step. To verify the recorded Brillouin strain distributions, reference measurements were acquired using a high-resolution OBR from Luna Innovations Inc. (USA) based on the OFDR (Optical Frequency Domain Reflectometry). The load was kept constant for each load step to ensure identical loading conditions for all interrogators. Multiple distance transducers (DD-1) from HBM GmbH (Germany) were placed at the specimens' surface to measure the true crack width.

## 2 CRACK ANALYSIS & TESTING RESULTS

The aim of the five sample test series is to analyze crack patterns with different spacing and crack widths. The analysis presented in this extended abstract focus on the crack localization and width derivation, which is why only one specimen with one defined crack location is discussed. The resulting strain sensing profiles along a concrete-embedded sensing cable [4] for all different interrogators are depicted in 2. It must be noted that the data represents the raw measurement signal with a physical spatial resolution of 0.5 m, but with different spatial sampling and is not further processed or filtered. The high-resolution OFDR measurements (left) confirm the initial crack opening at the loading step of 30 kN, with a significant peak arising in the middle of the specimen

(position: 1.5 m) over an area of approx. 200 mm. The Brillouin sensing techniques are not capable to visualize the initial cracking with such high resolution due to their spatial limitations, although interrogator B-02 also indicates cracking already at 30 kN. The peak width and magnitude is continuously increasing with each subsequent load step up to the maximum load of 130 kN applied for the actual specimen. Even if the strain peak appears over a larger area, Brillouin interrogators B-02 and B-03 can represent the OFDR technique well for loads higher than 30 kN. The B-01 signal, however, only represents major strain events for the last three load steps.

The strain distribution for Brillouin sensors is usually derived by determining the mean Brillouin frequency for each position along the optical fiber using curve fitting methods (e.g. Lorentzian fitting). In order to optimize the strain sensing results for B-01, comprehensive data reprocessing has been performed by low-pass filtering of the full Brillouin spectrum before curve fitting. The resulting strain profiles depicted in Figure 3 demonstrate that the data can be significantly optimized to reproduce the strain peak due to the developing crack similar to other Brillouin interrogators.

The crack width derivation itself may be performed by numerical integration of the measured strain sensing values over the area of interest, i.e. the strain peak area. The integration length, or rather the start and end point of the crack induced area along the signal, can be practically determined by analyzing the strain gradient at each side of the peak. These points are identified as the locations, at which the strain variation does not exceed a certain threshold within a defined number of subsequent data points. For further information and details on the determination principle reference is given to [7].

The crack widths derived for all DFOS technologies and the reference distance transducer are listed in Table 1. The results of the Brillouin interrogators are in good agreement with those of the high-resolution OFDR, with maximum deviations lower

Figure 2. Strain profiles recorded by various DFOS interrogators during load test: Rayleigh OFDR and Brillouin B-01/B-02/B-03 (left to right).

than 0.1 mm at loads of up to 90 kN or rather a width of approx. 0.6 mm. Cracks in reinforced concrete structures are usually controlled under service in a range of 0.2 to 0.4 mm [8], which can be obviously determined for all sensors. The distance transducers mounted on the surface also confirm the absolute accuracy for load steps up to 90 kN. Higher loads indicate minimal local slippage between the sensing cable and the concrete or even the different sensing cable layers at the crack location, which is why the width derivation using numerical strain integration seems to be no longer applicable.

Figure 3. Strain sensing profiles of Brillouin interrogator B-01 before (left) and after spectrum filtering (right).

It must be noted that the quality of the crack width derivation is strongly related to the parameter settings for the integration length. These vary depending on not only the sensing technique but also the installation technique of the optical sensing cable. The dedicated test series is capable of providing an essential lookup table to appropriately perform the integration length determination for different configurations for future monitoring applications.

Table 1. Crack widths derived from various DFOS interrogators and measured by conventional distance transducers at different load levels.

load [kN]	crack width [mm]				
	DD-01	OFDR	B-01	B-02	B-03
15	0.00	0.00	0.05	0.00	0.00
30	0.28	0.22	0.20	0.18	0.00
40	0.38	0.30	0.27	0.25	0.26
50	0.39	0.35	0.30	0.30	0.32

130	1.57	2.68	2.85	2.79	2.87

### 3 CONCLUSIONS & OUTLOOK

This extended abstract discussed the suitability of numerous Brillouin interrogators for localizing concrete cracks and quantifying their corresponding width. An enhanced test series with five individual specimens equipped with multiple DFOS installation setups was realized to investigate crack opening under well-known laboratory conditions. The crack location along the resulting strain profiles could be well captured by all interrogation units and enabled the derivation of crack widths for different load levels using numerical integration. The derived values correspond well with reference measurements from the distance transducer mounted at the surface for all tested Brillouin interrogators, with maximum deviations of approx. 0.1 mm within the usual service range for reinforced concrete structures.

It could also be demonstrated that the original data processing might fade out local deficiencies like cracks in the strain sensing profiles. This limitation may be overcome in this specific case by applying appropriate filtering to the raw Brillouin spectrum data.

The presented research focused on the traditional strain-based data analysis. In addition, initial tests for crack width determination using a feature extractor based on a CNN (Convolutional Neural Network) autoencoder, which was applied to the raw Brillouin spectrum along the sensing network [9]. This artificial intelligence (AI) approach will be further investigated and optimized to provide more comprehensive methods for analyzing concrete cracks along civil infrastructure.

### ACKNOWLEDGMENTS

The laboratory test series and the monitoring program was carried out within the collective research project “AI FORschung” (Nr. 52106504) financed by the Austrian Research Promotion Agency (FFG), which is part of the EUREKA Clusters AI Call 2021.

**ABSTRACT:** Due to bridges' critical role in transportation networks, the assessment and maintenance of existing bridges have become a priority. Prestressed concrete bridges constitute a significant portion of Europe's transportation network, yet many no longer meet today's technical requirements. This is primarily due to two factors: (i) the unforeseen increase in heavy goods traffic, and (ii) insufficient experience with early reinforced and prestressed concrete construction methods, coupled with inadequate regulations, which resulted in design weaknesses and structural deficiencies. One critical failure mechanism, identified when recalculating existing bridges based on updated guidelines, is insufficient shear load-bearing capacity, which has prompted the premature demolition of numerous bridges. A thorough understanding and rigorous monitoring of shear behavior is essential since neglecting this problem could lead to notable consequences, especially for aging infrastructure. In this paper, a distributed fiber optic sensor (DFOS) based monitoring system, inspired by shear detection concepts, is tested. A decommissioned prestressed concrete bridge girder was equipped with a DFOS grid, allowing for detailed monitoring of crack width, location, and shape. Preliminary test results confirm the successful installation and early detection of cracks, highlighting the system's potential to identify microcrack formation, monitor crack growth, and support maintenance strategies.

**KEYWORDS:** Structural Health Monitoring; Distributed Fiber Optic Sensors; Microcracking; Crack Growths; Load Testing; Prestressed Concrete.

## 1 INTRODUCTION

Concrete serves as the cornerstone of contemporary infrastructure, valued for its adaptability, strength and longevity. Nonetheless, despite its formidable exterior, concrete exhibits inherent material characteristics that, if neglected, may result in structural failures. Among these, shear forces are a critical and complex failure mechanism, due to the brittle behavior. Improper management of shear stresses may lead to abrupt, severe cracking, endangering the service life and safety of infrastructures such as bridges. One of the reasons for this is that these aging bridges were originally designed for lower traffic loads, and this issue is intensified by the absence or insufficient shear reinforcement [1], [2]. Modern codes surpass traditional visual inspections in terms of objectivity, repeatability, and sensitivity, imposing higher safety margins, often revealing structural deficiencies when existing bridges are recalculated for shear strength.

Unlike flexural failures, which can be predicted with relative precision using established theoretical frameworks, shear-related issues lack a universally accepted conceptual model [1]. Ductile failure provides a clear warning signal, such as plastic deformation, while brittle failure occurs suddenly, offering minimal warnings. This distinction is crucial because, under shear forces, concrete exhibits rapid crack development without the gradual yielding seen in flexural failures. With the growing demands on bridge structures due to increasing traffic loads, particularly from heavy goods vehicles, the need for advanced monitoring and assessment techniques are expected

to intensify in the coming years [3]. Current methods for shear monitoring rely mostly on visual inspections, which are labor-intensive, subjective [4], and not effective when surface damages are not present in the structure.

As shear load-bearing behavior remains a challenging aspect of structural evaluation, innovative monitoring technologies such as distributed fiber optic sensors (DFOS) offer promising solutions to ensure the safety, durability, and sustainability of critical infrastructure. To improve the efficiency and precision of crack detection, integrating continuous strain monitoring systems like DFOS can provide real-time, comprehensive data on damage states [4]. DFOS can accurately measure small strain changes during the linear elastic state, an advantage that surpasses traditional visual inspections in terms of objectivity, repeatability, and sensitivity. Although the application of fiber optic sensing in construction is relatively recent, the technology is rapidly evolving and has shown potential in various infrastructure applications [5]–[8]. Low-cost optical fibers that serve as sensors can be retrofitted onto existing structures or embedded into new constructions, providing a convenient approach for distributed structural health monitoring.

Inspired by the shear monitoring concepts [2], [9]–[13], this paper presents an application of a DFOS grid for crack monitoring in a prestressed concrete girder. The aim is to further investigate the potential and to assess the effectiveness of surface-bonded DFOS for microcrack detection, formation, and the sensor placement for short-term monitoring. A two-dimensional DFOS grid was designed and applied to the surface of a prestressed concrete bridge girder, which was

subsequently tested under load. Following a brief state-of-the-art review in Chapter 2, the experimental setup and corresponding results are presented.

## 2 SHEAR BEHAVIOR AND DIAGNOSTICS

### 2.1 *Critical shear behavior*

Concrete bridges, especially those older than 30 years old, were designed under shear-reinforcement rules now known to be insufficient for modern traffic loads, and routinely exhibit calculated shear deficits, which raise significant concerns about their long-term structural performance [14]. The shear failure is governed by diagonal cracking: when inclined tensile stresses (highest near supports) exceed the concrete's tensile strength, a rapid chain of web-shear cracks propagates toward loading areas and supports, often with little warning [15], [16]. When a beam is subjected solely to pure bending, tensile stresses that exceed the concrete's tensile strength will cause vertical cracks to form and extend up to the neutral axis. However, when shear forces are present, they cause the flexural cracks to rotate, resulting in flexural-shear cracks, which are typical in slender reinforced concrete girders subjected to shear. In flanged girders, deep girders, and prestressed ones, the dominant shear failure mode is web-shear cracking. Cracks initiate at the beam's centroid where the principal elastic tensile stress exceeds the concrete strength, and then extend toward both the loading area and the supports [16].

Concrete shear resistance arises from aggregate interlock, dowel action of longitudinal bars, and, in deep members, arch action. Geometry (shear-span/depth ratio) and reinforcement ratios critically govern which mechanism dominates [15]. Moreover, large members display a pronounced size effect, failing more abruptly. Analytical frameworks, such as strut-and-tie models, compression field theory, and critical shear-crack theory, seek to capture these phenomena, but each has limitations when applied to prestressed girders, where axial compression and anchorage stresses further complicate shear behavior [1], [17]. This sudden and complicated failure mode underscores the need for continuous monitoring systems, such as DFOS grids, to detect microcrack initiation and propagation before diagonal crack development.

### 2.2 *Need for shear monitoring*

Following the bridge recalculation and assessment guideline (May 2011), Fischer et al. [18] performed the statical recalculation of 115 bridges' superstructure that required shear reinforcement, and 57% of them exhibited low shear capacity. Notably, it is the case that some of these structures do not display visible shear cracks. This highlights the need to implement a monitoring system that measures the development and long-term performance of these structures, to accurately estimate the remaining service life and ensure the safety of the infrastructure [2], [4], [16]. Critical shear behavior is primarily marked by the development of diagonal cracks, which present challenges in early detection. These cracks, which form at inclined angles relative to the beam's axis and do not align with the reinforcement, are inherently more unpredictable than flexural cracks. The heterogenous nature of concrete, diagonal cracks' orientation, and variable crack width introduce significant uncertainties in early crack detection and crack propagation [19], [20]. Consequently, effective shear

measurement systems are essential for reliable structural analysis and monitoring of shear failures [15].

Currently, shear monitoring predominantly relies on visual inspection of the concrete surfaces [4]. While this approach can reveal surface-level damages, it is labor-intensive and susceptible to human error, potentially leading to missed early signs of deterioration [4].

Developing a robust measurement concept for shear monitoring in real-world bridge applications is a challenging problem. While controlled laboratory conditions allow for predetermined critical sections and failure locations, practical implementations face challenges such as limited sensor measurement range, harsh environmental conditions, and economic constraints. These factors increase the risk of missing critical zones during monitoring. To overcome these challenges, there is a clear need for an innovative, autonomous, and robust measurement system, potentially leveraging advanced techniques like DFOS and digital image correlation (DIC), to accurately reflect the evolving structural state and enhance long-term infrastructure safety [4].

### 2.3 *Distributed fiber optic sensing (DFOS)*

Fiber optic measurement has evolved remarkably over the recent decades. Initially developed for telecommunications [21], its adoption in structural health monitoring (SHM) within the construction industry has surged, particularly for concrete structures [22]. They offer a unique advantage by providing continuous, high-resolution strain data over entire structural elements, an attribute that is very valuable for monitoring complex damage patterns associated with shear failure. Because of the relatively recent application of fiber optics in concrete construction, the field is developing dynamically in both research and industry [23].

Unlike conventional sensors, which provide data at discrete points, DFOS capture the full strain distribution along their length with high resolution, enabling the early detection of microcracks and the tracking of crack initiation, propagation, and width changes [24]. By continuously mapping strain across large areas, DFOS can reveal subtle changes in crack patterns that might otherwise remain undetected.

DFOS can be integrated into new structures during construction or retrofitted onto existing bridges. When embedded, they offer immediate insights into load-bearing behavior, prestressing levels, and deformation characteristics [25], [26]. Whether surface-bonded in retrofit scenarios or embedded during construction, DFOS provide real-time strain data to validate structural models and support continuous, long-term performance monitoring. In retrofit applications, bonding DFOS to the concrete surface also enables the direct identification of strain hotspots for targeted inspections. Advanced techniques even allow the derivation of 2D strain images from 1D strain curves, which can be used to get a direct understanding of the situation and stress/strain-state [27]. Given that diagonal cracking is a defining feature of shear failure, a complex and unpredictable 2D phenomenon, employing DFOS is a highly promising approach for SHM.

Because of their ability to monitor the crack pattern over large areas, several research groups [2], [9]–[13] have investigated the possibility of utilizing DFOS for creating a shear monitor concept. DFOS are arranged in a mesh-like manner and installed on the concrete surface to compute 2D strain

measurement in the critical shear force zone (as shown in Figure 1). A key advantage of DFOS over other measurement techniques, like DIC, is that they do not require a direct line of sight to the shear-affected area, allowing measurements to be carried out regardless of lighting conditions. By contrast, DIC's noise floor and measurement accuracy are highly sensitive to both the spatial resolution of the images and the size of the measurement field.

Figure 1. 2D sensor arrangement for shear monitoring

The skew angle of the cracks must be taken into account to evaluate the crack widths, since the traditional integration approach that is effective for bending cracks perpendicular to the sensor fails for skewed cracks. In [4], [28], the fundamental process of DFOS-based shear force measurement is explained. A method that incorporates the skew angle into the crack width calculation has been proposed and experimentally validated in [28]. The suitability of DFOS to be used for monitoring shear forces has been confirmed by both laboratory and practical applications. In existing structures, DFOS sensors are typically bonded to the concrete, as demonstrated by Rodriguez et al. [12], [27]. Additionally, Poldon et al. [10] successfully installed DFOS on both longitudinal and transverse reinforcement to track the development of shear and flexural cracks in reinforced concrete beams, a method further validated by practical case studies [9], [13].

Although the initial results are promising, they also highlight the need for further testing and research to rigorously validate the DFOS grid concept's reliability, not only in monitoring shear-induced cracking, but also for tracking the development and precise localization of general bending cracks, to fully determine its practical applicability in real bridge monitoring.

### 3 TEST AND MEASUREMENT CONCEPT

#### 3.1 Test specimen and test setup

For this experiment, a prestressed concrete girder from a decommissioned road bridge near Ljubljana, Slovenia, was selected for its representative characteristics and historical modifications. Spanning the Kamniška Bistrica River, the bridge measures 52.60 m in length and 8.2 m in width, with five spans ranging from 9 m to 13 m supported by thin wall intermediate supports (Figure 2). Notably, the bridge underwent widening in 1989 to accommodate pedestrians and cyclists by adding prefabricated prestressed reinforced concrete T-girders and an interconnected reinforced concrete slab. The girders and deck were designed with concrete grades MB40 and MB30, which correspond to Eurocode classes C30/37 and C20/25, respectively, in accordance with EN 206-1 and EN 1992-1-1. Prestressing cables with a strength of 1840/2090 MPa were used, while other types of

reinforcements, including smooth and ribbed rebars as well as mesh reinforcement, ranged from 240 MPa to 500 MPa.

Six girders were extracted from the structure for laboratory bending and shear tests (see Figure 2). To investigate the girder's behavior under a damaged state, it was deliberately damaged before testing by cutting one of three prestressing layers comprising of six tendons, thereby providing an opportunity to monitor the resulting changes in structural behavior using the DFOS grid.

Figure 2. Schematic bridge representation

#### 3.2 Sensor placement and experimental procedure

In the damaged girder, the DFOS grid (as shown in Figure 1) was applied to the web's concrete surface to capture continuous strain data. The DFOS grid consisted of two sensors, with lengths of 12 m and 13 m, respectively. The first sensor (DFOS 1) was arranged in both horizontal and vertical orientations: initially, it was installed horizontally in three parallel layers of 1.6 m segments with a 0.165 m spacing between layers to obtain distinct horizontal strain readings; subsequently, the remaining fiber was configured vertically into 0.33 m segments spaced 0.2 m apart. The second sensor (DFOS 2) was installed diagonally, with each diagonal segment measuring 0.52 m. Additionally, the intersection points of the sensors were aligned as closely as possible, ideally converging at a single point, to enhance data precision and ensure optimal strain transfer. This configuration formed a comprehensive sensing grid capable of capturing crack formation across sensor length, thereby providing a complete strain field of the targeted area. A schematic representation of the sensor layout and test setup is presented in Figure 3.

The fibers employed were single-mode (SM) fibers with a tight buffer made of Hytel and an overall diameter of 900  $\mu\text{m}$ . Measurements were carried out with an Optical Distributed Sensor Interrogator (ODiSI) 6100 series from LUNA Innovations. This technology leverages the principles of Rayleigh scattering and optical frequency domain reflectometry, providing high-resolution local strain data. The ODiSI was operated in full-optimization mode, delivering a spatial resolution of 0.65 mm and a per-channel measurement rate of 3.13 Hz.

Ensuring optimal bonding to the concrete surface is important for accurate strain measurements. Since the girder was prefabricated, it possessed a smooth finish that required only dust and debris removal. The installation process involved initially fixing the sensor pointwise at predetermined intervals with a fast-curing cyanoacrylate adhesive (CYN), followed by the application of a two-component injection mortar along its entire length. This high-viscosity mortar rapidly hardens and is

suitable for bonding sensors on vertical surfaces. At the intersection points, the sensors overlap three times, introducing bending and less reliable results. Figure 3 depicts the DFOS sensor grid configuration and its precise mounting locations on the prestressed concrete girder.

Figure 3. Test setup and cross-section representation (in cm)

Figure 4. Sensor bonding procedure on concrete

After applying the grid, the surface was painted to facilitate DIC measurements. However, the DIC evaluation is beyond the scope of this paper.

Figure 5. DFOS grid covered with DIC speckle pattern

The girder was simply supported on rollers and subjected to three-point bending. The loading test spanned two days and involved cyclic loading and sustained constant load conditions to replicate diverse operational states and observe the crack initiation and propagation phases. In the initial cutting stage, a hole of 10 cm in diameter was drilled to induce damage in the specimen (Figure 6). A full drill-through was performed to cut the bottom layer of tendons, thereby deliberately weakening the girder. This intervention was carried out at a location 70 cm from the loading point, providing a controlled site to monitor the ensuing changes in structural behavior using the DFOS grid.

Figure 6. Test initiation with the cutting procedure

## 4 PRELIMINARY RESULTS

### 4.1 Load-displacement behavior

Loading was applied under force control at a rate of 1 kN/s (phases P1 to P3), and then under displacement control at a rate of 0.1 mm/s (phases P4 to P6) with a maximum load of 428 kN. Figure 7 shows the load-displacement behavior, where the vertical displacement was measured with a displacement transducer located in the middle of the girder.

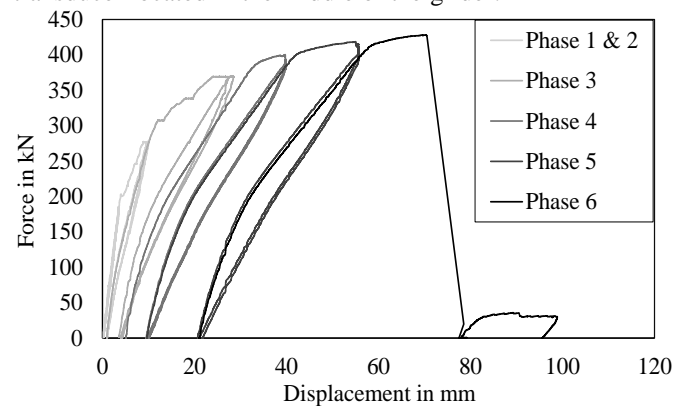

Figure 7. Force-displacement behavior of the girder

The load was gradually increased in six distinct phases, P1–P6, with each phase consisting of two loading–unloading cycles. After the second unloading cycle of each phase, the girder was put to rest for 20 minutes under ambient vibration conditions. Upon completing phase 3 on the first test day, the girder was brought to the phase 3 peak load (369 kN) and maintained at this constant level overnight. On the following day, the load was released (unloading phase) before initiating phase 4, creating three stages between phases 3 and 4: loading, constant force, and unloading.

The graph in Figure 7 illustrates a progressive stiffness reduction and the onset of plastic deformation with increasing load. In the early phases P1–P2, the steep force–displacement slope denotes the girder’s high initial stiffness, with visual crack initiation occurring during the first cycle of phase 2 (P2–C1) in the damaged zone. As loading advances into phases P3–P4, the slope diminishes, reflecting stiffness loss from crack propagation and the commencement of permanent deformations. In the final phases P5–P6, approaching the ultimate capacity of 428 kN, the response becomes distinctly nonlinear, marked by successive crack formation and partial yielding of the reinforcement.

In Figure 8 below, the crack patterns on the face of the girder opposite to where the DFOS grid was installed, overlaid with a

schematic representation of the sensor layout for comparison, are shown. At the peak load of phase 5, multiple cracks are visible, with crack openings marked directly on the concrete surface during the test. In the region corresponding to the DFOS grid, the first signs of cracking appeared as early as loading phase 3, indicating that the sensor network would have detected these strain concentrations in real time.

Figure 8. Crack pattern from the other side of the girder at load phase 5 (418 kN)

#### 4.2 Framework and labeling

The data from the DFOS grid was analyzed using the fosanalysis framework (available at <https://github.com/TUD-IMB/fosanalysis/>) developed at TU Dresden, which enables a streamlined workflow from data parsing and preprocessing to crack detection and crack width estimation [24]. This approach yielded excellent agreement between measured and calculated crack widths across different loading stages, indicating the robustness of both the DFOS system and the analysis framework [29].

The preprocessing procedure within the fosanalysis V0.4 framework involves a series of steps designed to enhance the quality and interpretability of the raw strain data obtained from DFOS. Initially, the so-called Strain Reading Anomalies (SRA) are removed using the Global Threshold Method (GTM), where a strain threshold of 300  $\mu\text{m/m}$  is applied to eliminate extreme or unphysical values. Following this, data recorded during phases of constant load are aggregated over time by computing the median value of several consecutive readings, thereby reducing short-term fluctuations and improving stability. Data dropouts, instances where sensor readings are missing or corrupted, are linearly interpolated. To further enhance the signal quality, a sliding mean filter with a window radius of 2 is applied, which smooths the strain profile by averaging adjacent values. A detailed explanation of each method and its implementation is provided in [30].

Figures 9 and 10 plot the peak strains recorded along the DFOS 1 and DFOS 2 sensors at the maximum load of each phase, confirming that a surface-bonded sensor grid, installed without surface grooving, can reliably capture strain evolution under short-term loading. On the horizontal axis of the graphs in figures 9 and 10, sensor lengths are shown; the vertical axis displays strain with maximum peaks of around 3500  $\mu\text{m/m}$  and 4000  $\mu\text{m/m}$ , respectively. High strain peaks started to appear during load phase 3, corresponding well with crack initiation marked with red in Figure 8. During phase 5 of the loading test, the highest strain peaks were recorded. It should be noted that some of the observed strain peaks are associated with sensor turns, and these locations must be carefully accounted for in the

analysis, not to be addressed as crack indicators. The true regions of interest are listed in Table 1 below.

Figure 9. Strain Profile from DFOS 1

An important aspect to be noted is the documentation of the sensor installation, including the exact lengths of sensor segments, starting positions of the grid, and loop configurations. Such detailed records are essential for distinguishing between strain peaks arising from actual structural behavior and those that may result from sensor turns or installation artifacts.

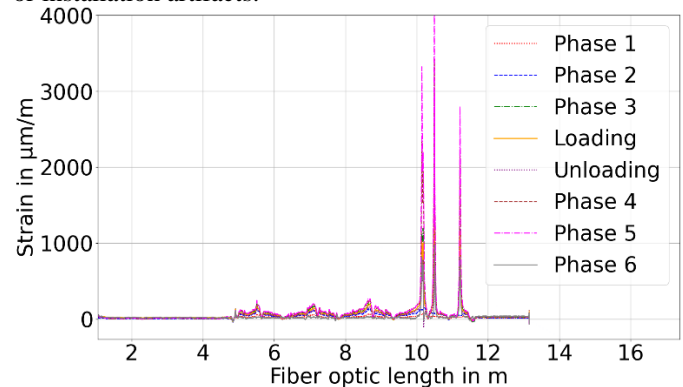

Figure 10. Strain profile from DFOS 2

By defining segments and specifying the length range of strain readings, the analysis was divided into horizontal and vertical components for DFOS 1 and diagonal components for DFOS 2. This allowed for accurate localization of areas of interest and targeted data cuts, thereby improving the reliability of crack detection and width estimation at different loading phases.

#### 4.3 Segment cuts and crack detection

Table 1 summarizes the segment crops analyzed for strain peak identification. For DFOS 1, three horizontal layers: bottom, middle, and top, were identified in the region surrounding the primary flexural crack at approximately 3.6 m, 4.0 m, and 7.0 m along the fiber, as confirmed by the crack pattern in Figure 8. Two vertical segments (segments 1 and 2) in DFOS 1 were also selected, with a prominent strain peak observed near the 8.0 m mark. Strain readings were measured in the sensor length between 5 to 12 m for DFOS 2. Within this range, inclined segments labeled 7, 8, and 9 exhibited significant strain peaks and were therefore selected for detailed analysis.

Table 1. Cropped region summary

Cropped Region	Sensor Length Range (m)
Bottom Crop (DFOS 1)	1.98-3.76
Middle Crop (DFOS 1)	3.86-5.56
Top Crop (DFOS 1)	5.64-7.28
Vertical 1 (DFOS 1)	7.42-7.77
Vertical 2 (DFOS 1)	7.79-8.145
Inclined 7 (DFOS 2)	9.335-9.855
Inclined 8 (DFOS 2)	10.075-10.595
Inclined 9 (DFOS 2)	10.865-11.3

By using DFOS, early-stage strain peaks can be identified, allowing for the detection and measurement of potential crack widths. As shown in Figure 11, during phase 3 of the test, the horizontal parts of the sensor exhibit strain peaks ranging from 80  $\mu\text{m/m}$  (top segment) to 300  $\mu\text{m/m}$  (bottom, vertical and inclined segment). These readings indicate a potential onset of crack formation, providing valuable insights into the early development of damage in the beam and allowing monitoring of the structures in the early stages. In the horizontal and inclined segment plots (a, c), the vertical axis denotes strain, while the horizontal axis indicates the sensors' relative positions. For the vertical segment plot (b), the axes are swapped.

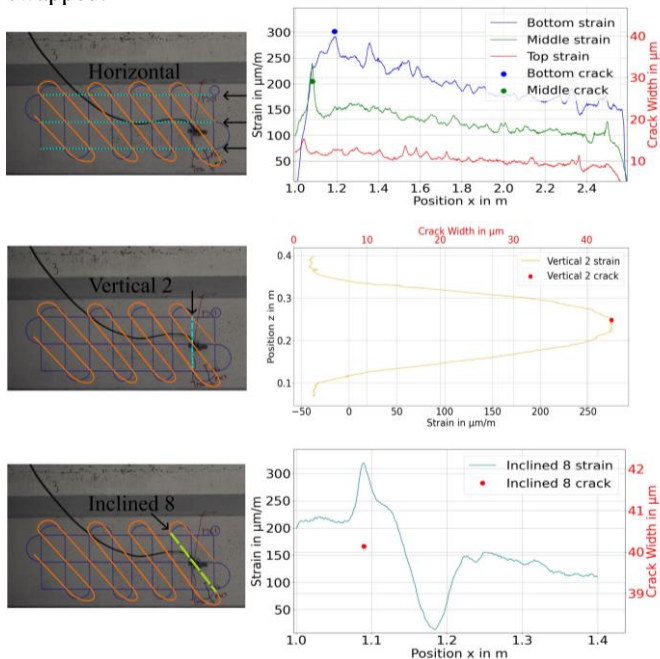

Figure 11. Early-stage DFOS strain profiles indicating incipient crack formation (a) Horizontal, (b) Vertical, and (c) Inclined segments

Building on these early observations, the evolution of strain profiles in three directions of the grid is analyzed. In Figure 12, the measured strain profiles of the horizontal segments of DFOS 1 (top, middle, and bottom) reveal a clear bending response. The readings are shown in temporal order, starting with loading up to phase 3, unloading part, and then loading in phase 5. The top segment exhibits strain peaks up to 2500  $\mu\text{m/m}$ , while the middle and bottom segments reached peaks up to 3500  $\mu\text{m/m}$ . Notably, prominent strain peaks at the

bottom correspond to the initial bending crack detected in Figure 11 (a), which becomes more pronounced as load levels increase and the crack propagates further into the beam cross-section.

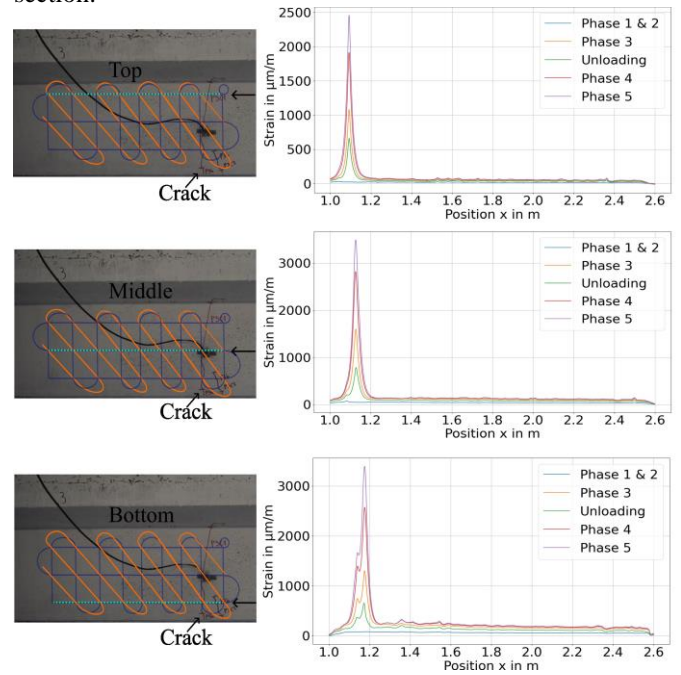

Figure 12 Horizontal strain profiles (a) Top, (b) Middle, and (c) Bottom for DFOS 1

Progressing from the top to the bottom segment, an increase in strain magnitudes can be observed, indicating the development of a crack near the left side of the sensor grid, in the region between 1.2 m to 1.4 m from the origin (check Figure 3). These peaks remain even after the unloading phase, marking a potential crack opening, which is also identified in the corresponding image of the girder. Even after the unloading phase, notable strain remains, indicating the presence of residual crack widths and partial permanent deformation in the beam. These peaks could also be detected by the diagonal and vertical segments, as will be seen in Figures 13 and 14 below.

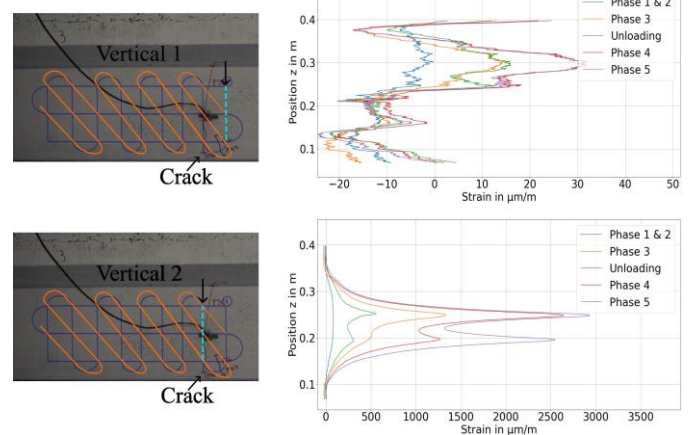

Figure 13. Vertical strain profiles (Vertical 1 and 2) from DFOS 1

The measured vertical strain profiles (Figure 13), under the same load steps, correspond well with the expected structural response of the beam. The vertical axis represents the sensor

location in the  $z$  direction (check Figure 3), while the horizontal axis shows strain in  $\mu\text{m/m}$ . Vertical segment 1, located along the left side of the beam, exhibits strain variations indicative of localized stress redistribution. In these regions, negative strains reflect compression, while positive strains indicate localized tensile effects. The strain readings in this segment, although only in a few  $\mu\text{m/m}$ , can suggest an interaction between bending and shear forces, likely influenced by crack propagation near the sensor grid.

The vertical segment 1 remains within  $\pm 30 \mu\text{m/m}$ , indicating a low-stress or compression zone near the neutral axis. As the load increases, the strain peaks in segment 2 become more noticeable (up to  $2500 \mu\text{m/m}$ ) in the region between 0.2 m to 0.3 m in  $z$  direction. This peak is also an indicator that a crack has been formed in this region, similar to the horizontal readings from the DFOS 1, which detected crack initiation from an early stage (Figure 11) and propagation in both directions.

Figure 14 presents the strain profiles measured along three diagonally oriented segments (labeled inclined 7, 8, and 9, check Table 1) under the same load steps as for DFOS 1. The horizontal axis denotes the relative sensor position in the  $x$  direction (origin at  $x = 0$ ), and the vertical axis shows strain measurement. In these diagonal segments, located within a region of potential crack formation, distinct differences in strain behavior were observed.

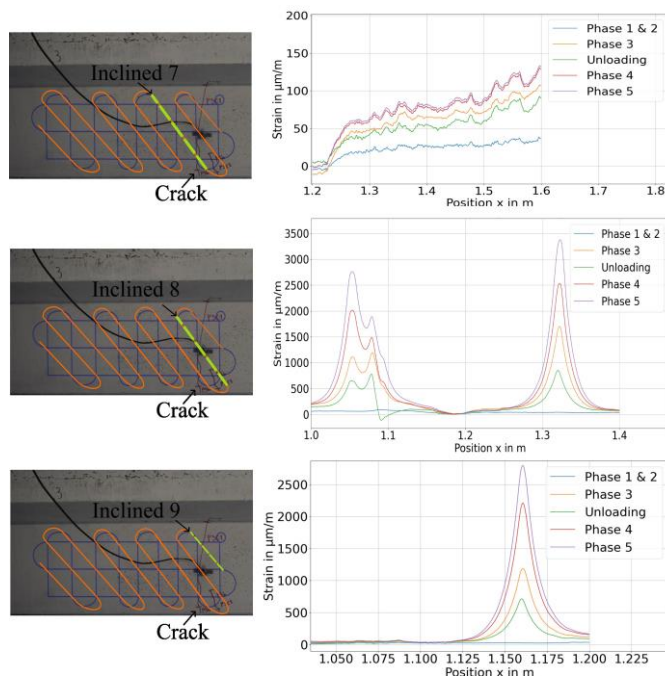

Figure 14 Strain profiles in diagonal segments 7-9 from DFOS  
2

Segment 7 displayed a steady increase in strain with loading but showed no pronounced peaks (up to  $120 \mu\text{m/m}$ ), suggesting that no major crack crossed this particular sensor path. In contrast, segments 8 and 9 exhibited prominent strain peaks under higher loads (between  $2500 \mu\text{m/m}$  to  $3500 \mu\text{m/m}$ ), especially segment 8, where two distinct peaks of  $2700 \mu\text{m/m}$  and  $3400 \mu\text{m/m}$  were observed. This suggests a concentration of cracking or stress in a relatively confined zone. The difference in peak heights for various load steps also

demonstrates how the crack opening widens under load and partially closes upon unloading.

The prominent peaks in each plot correspond to localized cracking, which was successfully detected and quantified by the DFOS grid. Furthermore, strain readings in vertical (vertical 2) and inclined sections (inclined 8) reveal the presence of two distinct strain peaks, which may be attributable to crack branching phenomena.

Despite initial expectations to capture diagonal cracking, such cracks were not observed within the grid region. However, the DFOS grid effectively captured and localized vertical cracks from early stages, confirming its potential as a robust tool for structural health monitoring (SHM). The experimental results indicate that for short-term measurements, good bonding between the optical fiber and the concrete surface can be achieved without the need to mill a groove. However, for long-term monitoring under varying environmental conditions, DFOS installation in grooves is recommended. Notably, as observed in the research [23], DFOS sensors installed without grooves can capture higher strain peaks.

Overall, the DFOS-based monitoring proved effective in capturing the strain behavior of the prestressed bridge beam. The results validate the early detection of cracks, well before they become visible to the human eye, similarly to previous research [24] and provide a detailed understanding of crack evolution under varying load conditions. The observed strain peaks could be partially validated through experimental visualization, as evidenced by the crack pattern visible on the opposite side of the beam. Early registration of cracks, especially shear cracks, can be critical, as the development of small shear cracks in large critical regions can, with increasing load, precipitate a sudden shear collapse of the entire reinforced concrete structure.

## 5 CONCLUSION

The experimental investigation demonstrates that the surface-bonded DFOS grid can be reliably installed without grooving and delivers effective short-term monitoring of prestressed concrete girders. Its high spatial resolution enabled the early detection of microcracks and captured the subsequent growth and spatial pattern of vertical cracks. Strategic sensor placement proved essential for localizing damage zones. These promising results lay the groundwork for advanced structural health monitoring of concrete bridges. Future work at the openLAB Research Bridge in Bautzen, Germany [26], will further validate and refine this DFOS-based monitoring concept.

## ACKNOWLEDGMENTS

The authors gratefully acknowledge the financial support provided by the German Federal Ministry for Digital and Transport (BMDV) through the research project ANYTWIN (Standardizing Monitoring-Based Safety Assessments of Bridges and the Integration into Digital Twins, funding reference: 01F2248B), funded within the mFUND innovation program.

The authors would like to express their gratitude to colleagues from Technische Universität Graz for their assistance during the installation and measurement of the DFOS grid. Special thanks are also due to colleagues at the Slovenian National

Building and Civil Engineering Institute (ZAG) for their expertise in conducting the experimental tests and coordinating critical aspects of the research. The authors acknowledge the financial support from the Slovenian Research and Innovation Agency: Research core funding No. P2-0273 and Infrastructure funding IO-0032.

**ABSTRACT:** Railways are one of the fundamental modes of transportation, dating back centuries. They allow for the movement of people and goods across hundreds and thousands of kilometres. Such a large system relies on precise timing and excellent organization. Any incident or failure can result in losses amounting to millions of euros and cause unacceptable delays. Monitoring the condition of the railway is necessary to ensure safety and system effectiveness, but it is challenging due to the long distances that need to be monitored. Conventional sensors can provide high-quality data, but they do not offer a complete picture of the railway's state, and local defects can be overlooked. A great solution for railway monitoring is DAS. A fibre optic sensor integrated with the structure can be used to obtain information about strain and vibration, with a fine resolution of even down to 1 metre, over tens of kilometres of track. Installing the sensor in the railway substructures can be challenging and exposes the sensor to potential damage. Another approach discussed in the article is to attach the sensor directly to the rail. Long sections of track can be covered with monitoring within a few hours using automated machine, enabling direct measurement of the rail's condition. This paper presents the results of such installation, showing the potential of synergizing monolithic distributed fibre optic sensors with DAS technology to increase the safety and reliability of rail transport.

**KEY WORDS:** rail, railway, DAS, strain-rate, monolithic sensors, dynamic measurement.

### 1 INTRODUCTION

Research presented in the paper is mostly driven by the goal of improvement of safety in railway transport. We live in the times when due to galloping climate changes, sustainable ways of transportation, like railways may be one of the key ways of slowing down the global temperature from increasing [1]. However, there are challenges that have to be overcome to increase sustainability level of rail transport. The development is eagerly promoted due to its considerably lower emission rates than other modes of transportation. However, greenhouse gas emission is not the only environmental threat coming from transport industry. Another factors worth consideration are noise pollution and direct threats to wild animals [1]. Rail tracks run through the whole countries and continents. Their paths all possible zones, cities, wildlands and rural areas. The span between the stations reaches tens of kilometres, which makes it extra-ordinarily difficult to control and limit threats. Additionally, railway structures are prone to experience local damages due to deterioration. During the operation time, railways are exposed to harsh weather conditions, rapid temperature changes, uneven substrate settlement and massive vertical loads of passing trains. Exposition to such conditions may cause change of the track geometry. Damaged tracks may influence not only comfort of the passengers but also their safety. In most extreme case the train may fall of the track. Such an accident may be a huge environmental or urban catastrophe. Fixing is difficult, slows down or even completely blocks other trains and causes large costs and labour consumption [2, 3].

Following risks may be significantly limited or even completely avoided by proper monitoring the railway. Effective solution for such an application is Distributed

Acoustic Sensing (DAS). The DAS technology is subpart of the Distributed Fibre Optic Sensing (DFOS). All the DFOS technologies utilise optical fibre as an array of sensors. Sensing device - optical interrogator - divides the fibre into set of aligned segments. As a result of the measurement, each segment (gauge) is represented as a discrete data point in result array. Value of each data point is a mean value of a measured physical quantity in all the points located in specific gauge [4, 5]. The DAS interrogators divide the fibre into dense set of overlapping channels (gauges) providing full continuity of the measurement along the fibre path. The distributed nature of this sensing technique allows continuous recording with multiscale grid of virtual unit gauges. Virtual placement of the gauges allows free manipulation on their arrangement without necessity of rearranging the setup. All the changes can be introduced by proper tuning of the interrogators [6,7]. Crucial part of system designing is proper placement and installation of the sensor. Industrial practice is to install the sensor in the trackside or to use already installed telecom cables [8, 9]. Installation of the sensors in the ballast layers of the railway may be challenging due to the complexity of the structure, traffic and law regulations. Moreover, such installation method requires placing additional cable duct which disturbs strain transfer mechanism. Another unfavorable phenomenon occurring in soil mechanic is non-elastic behavior of gravel ballast layers. Rocky, non-expansive soils as gravel used for sub-track construction do not transfer tensile forces. In such configuration only vibrations can be measured. More comprehensive solution is to attach the sensors directly to the track. This way system can measure direct strain of the element to give more information about the actual track condition [10]. Nevertheless, DAS interrogators have limited dynamic range.

Strong, high amplitude vibration may lead to saturation effect occurrence. This may lead to the substantial data loss [11]. Correct configuration of interrogator settings and adoption of sensor properties is crucial for proper operation of the measurement system. In this paper, authors propose the solution for direct rail track monitoring, allowing dynamic measurements of high-speed trains, passing with velocity of up to 250km/h, alongside with the long-term static strain measurements. The solution was tested during full-scale field experimental sessions, proving the feasibility and correctness of such an approach.

## 2 DISTRIBUTED ACOUSTIC SENSING PRINCIPLES

### 2.1 Rayleigh backscattering application in DAS

Rayleigh backscattering can be effectively used for precise strain and temperature measurements in both silica and polymer fibres. Two main approaches of Rayleigh phenomenon can be distinguished: Optical Time-Domain Reflectometry (OTDR) and Optical Frequency Domain Reflectometry (OFDR). OTDR-based measurements are usually much faster and can be performed on significantly longer sections of the fibre than OFDR [12]. DAS interrogators operate on OTDR combined with phase control coherency ( $\phi$ -COTDR) in order to deliver high-quality information about the rate of the strain change (strain-rate), along the fibre. Distribution of the reflected light intensity in the fibre for COTDR is random.

Regardless this randomness nature of the signal, it varies harmonically, as shown in Fig. 1. This way, with application of phase control approach, the phase information can be revealed. Whereas the phase angle is directly proportional to the strain change along the fibre axis [13], creating the opportunities for practical applications in civil engineering and geotechnics.

Figure 1. Intensity changes are irregular along distance but harmonic along phase shift axis [13].

### 2.2 Dynamic range of DAS interrogators

Dynamic range of acoustic sensing device (interrogator) is the magnitude of the strain change between two time samples that can be accurately unwrapped. Due to harmonic behavior of the intensity, only certain magnitude of strain change can be measured accurately. Because of that, DAS interrogators differentiate the strain in time domain in order to obtain strain-rate, using the following equation:

$$\frac{\mu\epsilon}{s} = \frac{\partial\mu\epsilon}{\partial t} \quad (1)$$

where  $\frac{\mu\epsilon}{s}$  is strain rate given in microstrains ( $\mu\epsilon$ ) per second and  $\frac{\partial\mu\epsilon}{\partial t}$  is a derivative of strain in time-domain.

Use of strain-rate allows to measure wider range of strain by measuring small changes and then stitching them together, by phase unwrapping in order to obtain whole picture, as shown in Fig. 2 [13].

Figure 2. Wrapped and unwrapped differential phase.

As the value of the strain change can be both positive and negative, the dynamic range of any DAS interrogator is limited between  $[-\pi; \pi]$ . Return signal is always within this range, even if the input strain in the time  $dt$  would move outside the limit [14].

Figure 3. Phase angle change in complex coordinate system.

The phase angle change between the two following samples should not exceed  $|\pi|$ . If so,  $\phi_{t2}$  is non-distinguishable from  $\phi_{t3}$ . The exceeding the limit due to the high vibration amplitude during recording is being called saturation effect. Dynamic range can be improved with higher sampling resolution or shorter gauge length. Due to higher sampling frequency, time distance  $dt$  is shortened, allowing to observe the events of higher dynamics (higher amplitude change in time). Shortening the gauge length limits the part of the fibre from which energy is being acquired (averaged) from.

Exact effect of the gauge length value can be observed in the relation between the angle phase shift and strain [15]:

$$d\phi = \frac{4\pi G \zeta}{\lambda} \epsilon \quad (2)$$

Where  $d\phi$  is a phase angle shift,  $G$  is gauge length,  $\zeta$  is opto-elastic scaling factor,  $\lambda$  is the operational optical wavelength in vacuum and  $\varepsilon$  is the strain. Based on the equation (2), we can conclude that the relation between gauge length and phase angle shift is linearly proportional.

### 3 PROPOSED APPROACH FOR DAS-BASED DIRECT RAIL TRACK STATE MONITORING

#### 3.1 System design

The system in question was deployed on a railway line in south-central Poland to monitor its technical condition and enable the maximum speed of trains to be increased to 250 km/h.

A key objective of the system was to enable multiple fibre optic measurement techniques using a single sensor, making it adaptable to various sensing methods beyond just DAS. This flexibility allows to use other interrogation schemes simultaneously (including for example Brillouin-based strain sensing DSS and Raman-based temperature sensing DTS). In the designed system, it was decided to install two sensors on the side surface of the rail web (Figure 4) in order to add Distributed Displacement Sensing (DSS) functionalities to the system. Knowing the spacing between the sensors, measuring strain distributions over the entire length and assuming relevant boundary conditions, both local curvatures and vertical displacements (shape changes) can be calculated.

Figure 4. Cross-section of rail with sensors' location.

The sensor integrated into the system is an adjusted version of the EpsilonFlat – the monolithic solution from Nerve-Sensors family. Unlike the standard EpsilonFlat, which utilises two sensing fibres, this modified version employs four fibres, as shown in Figure 5. Table 1 summarises selected mechanical properties of the sensor.

Figure 5. Cross-section of the sensor used in the system.

Table 1. Selected mechanical parameters of the EpsilonFlat

Parameter	Value
Strain range	±4%
Elastic modulus	3 GPa
Bending radius	100 mm

The monolithic core of the sensor, coupled with its flat cross-section, ensures the best possible strain transfer mechanism,

resulting in precise and high-quality readings [16]. Low elastic modulus of the sensor itself combined with the elastic glue causes minimal, negligible influence of the sensor on the mechanical parameters of the rail. This design effectively captures and transmits strains with minimal distortion, guaranteeing the accuracy and reliability required for monitoring the rail's performance over time.

Additional fibres within the sensor cross-section allowed for the world-unique approach in system configuration. This adjustment enhances the sensor's versatility, providing additional configuration possibilities to meet the unique challenges of the project. Sensors were delivered on site in 50 m long sections. Two fibres were spliced together creating one long loop to be measured with long-distance interrogators. However, two additional fibres allow for connection of high-spatial resolution interrogators to scan shorter sections with higher precision, if necessary (Figure 6). It shows, that various measurement devices do not have to compete with each other, but can be used synergistically to expand the diagnostic capabilities of the entire system. While maintaining high-resolution data acquisition capabilities, it is also possible to offer a cost-effective and versatile solution for large-scale monitoring applications.

Figure 6. Scheme of the measurement path.

The sensors were arranged in a 2 x 250-metre-long loop, featuring two continuous sensing paths and independent, shorter 50-metre-long sections. Every 50 metres, the sensor paths passed through connection wells, where the necessary connections were made – Figure 7.

Figure 7. Connections between segments of the sensors during installation and the view of the protective well.

This configuration ensured that the system maintained optimal functionality across the entire loop, allowing for continuous monitoring while facilitating easy maintenance and troubleshooting through strategically placed connection points. The segmentation of the fibres into shorter paths also enhanced the flexibility of the system, accommodating long-distance spans without compromising signal integrity or performance.

Chosen arrangement allowed simultaneous acquisition of dynamic and static measurement data.

### 3.2 Sensor installation

The installation of the sensor required initial pre-sanding of the rail's side, aimed at achieving proper grip. The goal was to exfoliate only a thin layer of loose corrosion, ensuring minimal impact on the rail's mechanical parameters. This effect was successfully achieved using a water under pressure, a method that provided the necessary surface preparation without compromising the rail's integrity. The selection of materials for the bonding process was critical to the success of the installation. High durability, a low elastic modulus, excellent corrosion resistance, and strong adhesion were essential to ensure the sensor's secure attachment. To meet these requirements, epoxy-based adhesives were employed for gluing the sensor to the rail. The selection of the glue was preceded by research into various solutions in the laboratory.

To guarantee precision and time effectiveness of the installation, a specialised piece of equipment was designed and developed specifically for this project (Figure 8). The cart system utilises electric motors and pneumatic glue dispensers to ensure an even and consistent application of adhesive. The electric motors power the movement of the carts, enabling precise control over the positioning and alignment during installation.

Figure 8. Semi-automatic rail cart used for sensors' effective installation along the rail.

This technology allows for a highly efficient, repeatable, and controlled gluing process, contributing to the overall success and reliability of the sensor installation. Before the final application within the operate railway line, the solution was tested on an experimental section of the rail (Figure 9) to better understand on-site challenges and minimise the risk of errors. The success of the installation in Poland allowed for the commercialisation of the cart in Germany and UK.

Figure 9. EpsilonFlats after test installation.

The combination of innovative installation technology, high-quality materials, and specially designed sensors resulted in a gluing speed of up to 120 metres per hour. This makes the approach an excellent solution for km-long sections, where conventional manual bonding is very difficult, if not impossible to achieve. In the current project, the total length of 2,200 metres of sensors was installed directly to the rail surface.

### 3.3 Spatial survey

Chosen configuration of the sensing path, despite of multiple benefits, is also connected with some challenges. Complicated layout requires the proper selection of the active sensing segments (excluding loops, patchcords and pigtails) within the whole optical path. DAS-based interrogators usually operate on spatial resolutions of not less than 1 m. In this scale, it is challenging to clearly distinguish the measurement part of the fibre from the connecting part.

The proposed solution to the problem was to use pigtails (connecting cables between the segments) with different fibre properties, causing the clear differences in the Brillouin signal. To make a detailed documentation of the sensing path, the hybrid Rayleigh & Brillouin interrogator Neubrex NBX-7031 (Figure 10) was used with its backscattering-based mode.

Figure 10. Neubrex NBX-7031 hybrid interrogator.

Brillouin backscattering allows direct fibre parameters identification without necessity of providing reference reading. The Brillouin shift, quantity linearly connected with absolute strain of the fibre [17], allows to clearly distinguish between the measurement sections glued to the rail and free connecting patchcords. – Figure 11.

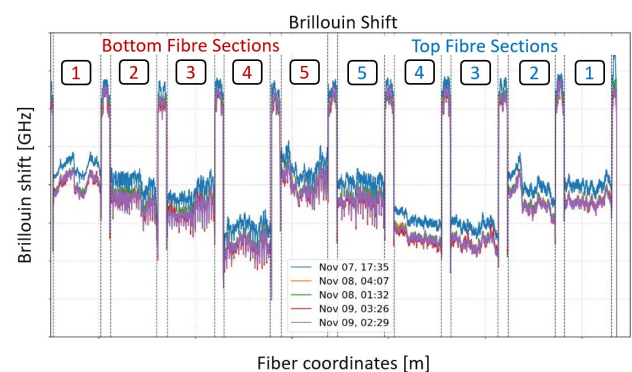

Figure 11. Brillouin Shift measurement results.

Brillouin survey provided very precise information about the exact length of the measurement path components. Proper tuning of the optical device reflection coefficient  $ROI=1.468$

with the coefficient used in DAS interrogator resulted in 1:1 translation of measurement path between the fibres. In the cases where standard methods for spatial surveying may be not efficient enough, shown approach is an ideal solution for self-survey of the sensor.

### 3.4 Used DAS interrogator and measurement settings

Observing a highly dynamic event, such as the high-speed passage of a train, demands both the highest possible sampling frequency and the shortest achievable gauge length. Achieving this balance is crucial for capturing rapid changes in strain distribution along the fibre optic sensor. There are multiple ways to enhance gauge length, both at the sensor and interrogator levels. For example, one approach involves implementing weak Fibre Bragg Gratings (weak-FBGs) along the entire fibre, which can improve spatial resolution and measurement precision. However, this method is often costly and not universally compatible with all interrogator devices, making it less practical for certain applications. Alternatively, gauge length optimisation can be achieved through advanced signal processing techniques and the use of appropriate interrogation technology.

In the project, the Febus A1 DAS interrogator (Figure 12) was deployed – a device that utilises Phase-Sensitive Coherent Optical Time-Domain Reflectometry ( $\phi$ -COTDR) to enhance reading quality. Unlike the classical DAS approach, where the injected light pulse is a simple impulse, the Febus A1 leverages optimised coding and signal processing algorithms to improve sensitivity and spatial resolution. This advanced approach ensures reliable interrogation over fibre optic paths exceeding 100 km, while mitigating the risks of signal fading and significant Signal-to-Noise Ratio (SNR) degradation.

Figure 12. FEBUS A1 interrogator.

A key advantage of  $\phi$ -COTDR in the Febus A1 is its ability to achieve a gauge length as short as 1 metre, a spatial resolution that is typically unattainable with standard interrogators. Conventional DAS systems often struggle to maintain short gauge lengths due to limitations in pulse-based interrogation methods, which can lead to reduced spatial resolution and increased noise. By employing optimized signal processing, the system effectively enhances precision without compromising signal integrity. This feature is particularly valuable for applications requiring highly localised strain and vibration measurements, such as high-speed train monitoring, where detecting rapid structural changes with fine spatial granularity is crucial. This makes the device a perfect choice for railway dynamic monitoring.

For the in-situ testing, it was decided to measure the dynamic passages of the trains using combination of the parameters summarised in the below table.

Table 2. Used DAS acquisition parameters.

Parameter	Value
Gauge length	2 m
Sampling frequency	40 kHz
Channel (gauge) spacing	20 cm

### 3.5 Methodology of the experiment

To evaluate the performance of the monitoring system in a real-world high-speed scenario, an experiment was conducted using a Pendolino ED250 train. The location of the measurement section was a long, mostly straight section of the railway track. During the experiment, multiple train passages were recorded under varying speeds to assess the system's capability in detecting and analysing strain signals associated with different train dynamics. To minimise the influence of temperature fluctuations on the readings and provide maximally stable conditions, all DAS measurements were conducted at night. The railway traffic was suspended for the duration of the experiment, ensuring an undisturbed testing environment. The measurement crew maintained constant communication with train operators to ensure that the train traveled at the predefined speeds. A total of four test runs were performed at velocities of 200, 220, 240, and 250 km/h within a single night. The time interval between consecutive passages was determined by the necessary stopping, reversing, and re-accelerating of the train to the target speed, with a minimum of 45 minutes between the runs. This ensured that the rails had sufficient time to fully stabilise after each passage, preventing residual strain effects from influencing subsequent measurements. As a reference technique, heavy-duty accelerometers with dynamic range of 50 G and frequency range from 5 to 2000 Hz were employed.

## 4 RESULTS AND PROCESSING

### 4.1 Raw data: strain-rates

The raw data recorded by the device is a strain-rate array (Figure 13) at discrete points located in the centers of predefined gauges. Each discrete value represents an average of the rate of strain change along the single gauge length. As the fibre is interrogated as whole, initial processing (or post-processing) has to be introduced in order to cut-out measurement sections from the entire path.

Figure 13. Example strain-rates recorded by the bottom sensor during train passage with 250 km/h speed.

A recorded image provides high-quality insights into dynamic processes existing in the railway structure during high-speed train passage. Three main zones of the signal may be distinguished. In the bow-zone, a para-seismic wave travelling through the rail may be observed. In the main part of the signal – the train-zone – signal is complex. Eight skew lines on the map represents the moments in time where the wheel bogies of the train were in specific locations along the rail. Number of the lines correspond with number of the bogies. Empty spaces between the lines represents the spans of every carriage between the subsequent bogies. Last zone of the signal is a zone of tail waves, the ones lasting in the structure for some time after the train passage [18]. Overall check at the signal allows to assume that used acquisition parameters, combined with dedicated monolithic-core of fibre optic sensors, resulted with non-saturated, high-quality signal, recorded in extraordinary proximity to the strong vibration source.

#### 4.2 Spectral analysis

Distributed Acoustic Sensing can be used as a network of virtual, unit-like channels, each functioning akin to a geophone, measuring strain or displacement at various points along the fibre-optic sensor. The system output can thus be understood as an array of time-series recorded by specific virtual gauges positioned along the fibre, capturing the strain dynamics of the monitored structure. Due to this nature of the signal, any method of classical digital signal processing is valid, allowing for a wide range of analytical techniques to be applied to the DAS data.

Figure 14. Spectrogram of the single time-series of strain-rate recorded in the middle of measurable section.

The example data presented in Fig. 14 clearly reflects the direct influence of train passage, with distinct frequency components corresponding to the mechanical events. Notably, the spectrogram reveals a predominant contribution from low-frequency waves. This phenomenon is likely linked, inter alia, to a rapid rise in temperature within the rail due to its loading by the passing train, coupled with a relatively slow heat dissipation rate from the rail. The thermal effects associated with the train passage thus become embedded in the strain measurements, manifesting as low-frequency trends.

Given the dynamic nature of the observed event, the authors opted to mitigate the influence of these thermal effects by applying a low-cut Butterworth filter of the third order. The chosen cut-off frequency of 5 Hz serves to effectively attenuate the low-frequency components, which are primarily attributable to temperature-induced strain. This filtering step not only reduces the trend-like behaviour often observed in the

integrated strain signal but also compensates for the confounding effects of temperature variations, enabling a clearer view of the mechanical strain caused by the train passage.

This approach illustrates how DAS measurements supported with proper sensors, can be refined to focus on the relevant mechanical signals, removing the thermal noise that may otherwise obscure the true nature of the event under study. While reference measurements using accelerometers were also employed, it is worth noting that these sensors primarily capture signals from 5 Hz and above, aligning with the chosen filtering approach but playing a less central role in addressing the low-frequency thermal effects observed in the strain data.

Deeper understanding of the signal can be achieved by application of the Frequency Band Energy (FBE) analysis. This approach allows for comparison between energy levels in specific frequency bands. The energy  $E$  of the discrete, finite-time signal, denoted as  $x$  is sum of the signal's absolute value square in proper time  $t$  boundaries (3).

$$E = \int_{t_1}^{t_2} |x(t)|^2 dt \quad (3)$$

Since the total energy remains conserved between the two domains, it is possible to analyse the distribution of the energy across different frequency components by examining the squared magnitudes of the Fourier coefficients. Hence, by summing the squared magnitudes of a specific portion of the Fast Fourier Transform (FFT) coefficients, denoted as  $X$ , one can determine the energy contained within a particular frequency  $f$  band [19] using equation (4).

$$FBE = \sum_{f_{min}}^{f_{max}} |X(f)|^2 \quad (4)$$

From the Distributed Acoustic Sensing (DAS) perspective, such a method provides the capability to monitor the occurrence of different frequencies along the entire fibre length and provide neat visualisation. This ability is particularly valuable for analysing dynamic changes in the recorded signal and distinguishing specific patterns based on their spectral characteristics. By integrating this approach with the Short-Time Fourier Transform (STFT), it becomes possible to not only categorise signals by their frequency components but also track their temporal evolution, offering deeper insight into underlying phenomena.

In the presented research, the authors conducted STFT analysis twice, utilising two distinct window lengths to maximise the level of detail in signal examination. The first calculation employed a longer window, consisting of 8129 samples – chosen as the eightfold multiple of 1024 – which was specifically applied to the first six bands corresponding to the lowest frequencies. This selection was made to enhance frequency resolution in the low-frequency domain, where finer spectral details are often crucial for accurate interpretation. For the remaining higher-frequency bands, a window of 1024 samples was determined to provide optimal results, balancing time and frequency resolution to ensure a comprehensive and precise analysis of the recorded signal.

Presented results of FBE were calculated from the signal after low-cut filtration introduced previously.

Figure 15. Comparison of energy levels within specific frequency bands.

When a train travels along the track, various phenomena generate acoustic noise in addition to mechanical changes. The primary sources of this noise include the train's machinery, braking system, and, most significantly, the interaction between the wheels and the rail. Most of these acoustic noises are concentrated at frequencies above 500 Hz [20].

However, noise-induced mechanical vibrations consist of low-amplitude waves with high attenuation, meaning they do not significantly affect the mechanical state of the rail. The authors empirically analysed the entire frequency spectrum and determined that the range of  $<0; 2.5>$  kHz is the most relevant, either due to its contribution to overall strain rates or the information it carries. The frequency bands for calculation were selected to maximise information and comparability while ensuring proper coverage within the chosen range. Since energy levels decrease across subsequent bands, the bands were gradually widened to maintain sufficient values for comparison.

The data exhibits a clear pattern, showing that the majority of the signal is concentrated in the low-frequency range, up to 50 Hz. Higher frequencies, up to 600 Hz, contain relatively low energy. A significant portion of the signal consists of acoustic noise. Above 600 Hz, the energy level progressively increases, peaking between 1.1 kHz and 1.5 kHz. In this range, a highly visible noise band appears, particularly around the third and fourth carriages. According to the technical documentation of the Pendolino ED250, this high-noise area corresponds to the placement of traction transformers within the train. These findings highlight the direct relationship between onboard equipment and noise influence on the measurements. Noise-carrying frequency bands in this case are clearly separated from the valuable parts of the signal. With this information, authors decided to apply additional Butterworth low-pass filter of the 3<sup>rd</sup> order, with cut-off frequency of 1 kHz.

Characteristics of the FBE maps allow assumption that wide frequency distribution is connected with wide frequency range of an event rather than with saturation effect occurrence.

#### 4.3 Spectral coherence check

To ensure high-quality measurements, the fibre signal must not be saturated. To verify that clipping due to exceeding the dynamic range does not occur, spectral coherence between collocated channels should be calculated. Authors estimated spectral coherence by the following equation:

$$\gamma^2(f) = \frac{|G_{xy}(f)|^2}{G_{xx}(f)G_{yy}(f)} \quad (5)$$

where  $G_{xy}(f)$  is the cross-spectral power density, and  $G_{xx}(f)$  and  $G_{yy}(f)$  are the spectral power densities of either signal. High coherence ( $\gamma^2 \approx 1$ ) signifies a strong correlation between DAS signals with synchronous recording, while low coherence suggests a weaker correlation or the possible presence of noise caused by signal clipping (saturation) [11].

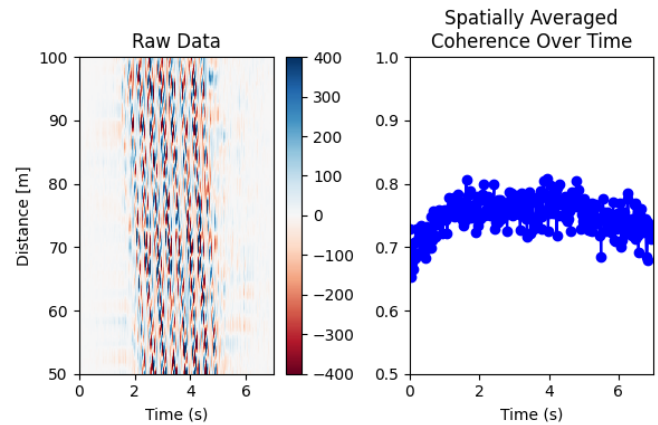

Figure 16. Side by side comparison of the raw strain rate (left) with the calculated signal spectral coherence (right).

Spectral coherence had been calculated between all the following DAS channels with window length of  $10^3$  samples and presented in Fig. 16. Values on the diagram represent spatial mean coherence from each set of windows. Results show high spectral coherence, mostly  $> 0.7$ . High magnitude of spectral coherence between adjacent channels indicates that signal has not been saturated.

#### 4.4 Strain-change and reference check

All DAS interrogators measure the strain change in time. If properly recorded, the strain-rate signal can be integrated over time to reconstruct the train change – a quantity that is more intuitive from engineering perspective and easier interpreted in comparison to direct strain rate signal. Moreover, when considering the Bernoulli hypothesis – which assumes that plane sections remain plane and perpendicular to the neutral axis after deformation – it follows that vertical displacements and longitudinal strains are intrinsically linked.

In the case of steel rails with expected very small displacements ( $< 1.5$  mm), this assumption is especially valid, also due to the high stiffness of the steel and its homogeneity. Consequently, accelerometer measurements, which capture vertical motion, can serve as a reliable reference for strain-based calculations. This interrelation reinforces the validity of using accelerometer data to compare with DAS measurements.

Accelerations  $a$  measured by accelerometers were integrated twice in time  $t$  to obtain vertical displacements in specific points.

$$d(t) = \iint a(t)dt \quad (6)$$

As the quantities to be compared are known to be proportional, but exact coefficient of proportion is unknown, only the tendencies were compared. For that sake, values have been normalised and presented in Figure 17.

Figure 17. Comparison of DAS-measured strains (blue) with displacements from accelerometers (orange).

The compared data clearly show the expected correlation. Since the sensor is positioned in the bottom zone of the rail, its strain behaviour reflects its location relative to the neutral axis of the rail. In a downward displacement of the rail, the bottom sensors experience positive strain (tension). Conversely, during upward displacement, the same sensors are compressed, resulting in negative strain.

## 5 CONCLUSION

The study briefly discussed in the article demonstrates a robust approach for direct rail state monitoring using Distributed Acoustic Sensing (DAS) and specially designed monolithic sensors. By directly attaching the sensors to the rail surface, the system is capable of simultaneously capturing both dynamic and static strain data over very long distances using various types of interrogators, including those with high spatial resolution. Experimental results from high-speed train passages validate that the measured strain signals align with classical beam theory: fibres located at the bottom of the rail exhibit positive (tensile) strain during downward displacement and negative (compressive) strain during upward displacement. Furthermore, advanced signal processing techniques, including spectral analysis and energy band evaluations, effectively isolated the mechanical strain effects from thermal influences, thereby ensuring reliable data assessment and interpretation. The innovative semi-automatic installation method significantly enhanced deployment speed and consistency, making the solution both scalable and cost-effective. Overall, the proposed DAS-based monitoring system offers a promising tool for real-time railway infrastructure assessment, leading to improved safety, optimised maintenance strategies, and enhanced operational reliability in rail transportation.

## ACKNOWLEDGMENTS

The research on sensor design was funded by European Funds through the National Centre for Research and Development under the Intelligent Development Operational Program 2014–2020, as part of the project “Innovative Fibre Optic Sensor for Measuring Strain and Temperature” (POIR.01.01.01-00-1154/19). **ABSTRACT:** Fiber optic sensors (FOS) offer compelling advantages for Structural Health Monitoring (SHM). However, their application in timber structures remains underexplored. This article reviews the state-of-the-art use of FOS in timber structures and presents an experimental study conducted at the Universitat Politècnica de València. A 3-meter-span timber beam was subjected to a four-point bending test and instrumented with long-gauge strain FOS. The measured strains were used to derive stresses, which were then compared to theoretical values. The results highlight the potential of FOS for accurate stress monitoring in timber elements and contribute valuable insights to the advancement of SHM in sustainable construction.

**KEYWORDS:** Timber structures; Historic structures; Fiber optic sensors; Strain monitoring; Stress.

## 1 INTRODUCTION

The built environment is responsible for approximately 39% of global energy-related CO<sub>2</sub> emissions, of which about 11% arises from embodied emissions—those generated during the production, transportation, and installation of building materials [1]. Shifting towards a Circular Economy model is increasingly recognized as essential to mitigate this impact. Among the strategies, the rehabilitation and reuse of existing structures plays a critical role. Among the different potential construction materials, timber stands out as a sustainable material due to its low carbon footprint, high recyclability, and significant cultural value, especially in heritage buildings (see e.g. Figure 1).

Figure 1. Timber beams at “Estació del Nord”, a train station in Valencia, Spain.

Structural Health Monitoring (SHM) is a key enabler of sustainable rehabilitation strategies. SHM techniques provide continuous insights into the condition of built structures, which helps to optimize maintenance, supports resource-efficient interventions, and extends service life. Within this context, fiber optic sensors (FOS) present compelling advantages over traditional electrical sensors, offering immunity to

electromagnetic interference, high sensitivity, and multiplexing capabilities [2]. Despite growing interest in sustainable rehabilitation methods, the application of FOS in timber structures remains limited and underexplored. Most existing SHM studies have focused on concrete and steel, with relatively few addressing timber. This research seeks to fill that gap by experimentally evaluating the performance of long-gauge FOS in monitoring strain and stress distributions in a timber beam subjected to bending. The main objective is to assess the feasibility and accuracy of using FOS for SHM in timber structures, particularly in heritage or rehabilitated buildings.

The paper is structured as follows: Section 2 briefly reviews the state of the art in fiber optic monitoring of timber structures. Section 3 describes the experimental setup and testing procedure. Section 4 presents the experiment results and Section 5 discusses the performance of FOS in timber. Finally, Section 6 summarizes the main findings and outlines directions for future research.

## 2 REVIEW OF THE CURRENT STATE OF THE ART

Early explorations of fiber optic sensing in timber structures began with Sargent (2009) [3], who used Fabry–Perot interferometric FOS to monitor temperature during the kiln drying of radiata pine boards, confirming the method’s accuracy but also highlighting sensor fragility under extreme conditions. Marsili et al. (2017) [4] applied Fiber Bragg Gratings (FBGs) to both small specimens and historic timber beams (before and after carrying out a strengthening operation), successfully measuring strain and damping, and demonstrating the potential of FBGs for both laboratory and field applications. Expanding on structural monitoring and reinforcement assessment, Li et al. (2018) [5] instrumented Chinese traditional timber structures, including mortise-tenon joints, using FBGs to effectively track beam deflections and column inclinations under load. Further advancing this line of research, Helmer-Smith et al. (2021) [6] tested a scaled timber Warren truss monitored with distributed fiber sensors (DFOS),

successfully capturing strains, and highlighting the capabilities of FOS in truss systems.

More recently, advanced applications have focused on distributed sensing and bond-slip monitoring. Ernewein and Woods (2023) [7] used DFOS to study glued-in steel rods within glulam elements during pull-out tests, capturing detailed strain distributions and bond-slip behavior that surpassed the resolution of traditional strain gauges. Extending DFOS application, Felicita et al. (2024) [8] instrumented timber foundation piles and monitored the stress distribution along their length, validating DFOS accuracy and showcasing its potential for buried timber elements.

### 3 EXPERIMENT DESIGN

#### 3.1 Loading Set-Up

To evaluate the capability of FOS in monitoring the behavior of timber beams under bending, a four-point bending test was conducted, as shown in Figure 2. A sawn timber beam, graded as C18 according to the Spanish code [9], was placed on two hinged supports to simulate a simply supported condition. The dimensions of the steel plates at the supports that were in direct contact with the timber beam were 180x180x40 mm. The load was applied using a hydraulic jack placed at the center of a rectangular steel spreader beam, which transferred the force to two loading points spaced 1 meter apart. Steel plates measuring 85 mm in width and 3 mm in thickness were placed on the top surface of the timber beam at these two points to facilitate uniform load application. The total length of the tested beam was 3400 mm, with a span of 3000 mm. The beam had a depth ( $h$ ) of 202 mm and a width ( $b$ ) of 75 mm.

#### 3.2 Equipment installed

The beam's vertical displacements were recorded using two linear variable differential transducers (LVDTs). Additionally, five long-gauge strain sensors were installed on the beam using brackets screwed into the timber. Table 1 provides the detailed positions of these sensors. The gauge length of the FOS was 500 mm. Figure 3 shows the position of the sensors installed for the test, both LVDTs and FOS. Figure 4 shows a detail of the elements used to distribute the load to the beam, while Figure 5 and Figure 6 provide a detailed view of the long-gauge sensors installed at sections S1 and S2.

Figure 2. Loading set-up. Position of the monitored cross sections.

Figure 3. Sensors installed in the tested beam.

Table 1. Specifications for the sensors installed.

Sensor ID	Measuring units	Related section	Position
LVDT-S2	mm	S2	Mid-span
LVDT-S1	mm	S1	1 m from mid-span
LGS2TF	microstrains	S2	27.88 mm from the beam's top face
LGS2BF	microstrains	S2	26.58 mm from the beam's bottom face
LGS2MID	microstrains	S2	57.54 mm from the beam's bottom face
LGS1TF	microstrains	S1	30.48 mm from the beam's top face
LGS1BF	microstrains	S1	30.05 mm from the beam's bottom face

Figure 4. Central segment of the tested beam showing the loading elements.

Figure 5. FOS installed in Section S2.

Figure 6. FOS installed in Section S1.

#### 4 RESULTS

This section presents the results obtained from monitoring the timber beam during the bending test. A step-loading protocol was employed, in which the load was incrementally increased to predefined thresholds and then held constant to allow for stabilization. Displacement control was displacement-driven, with a constant loading rate of 0.05 mm/s.

Figure 7 displays the force applied by the hydraulic jack over time, along with the displacements recorded by the LVDTs, plotted on a secondary vertical axis. The curves follow the same trend, showing that the displacements increase proportionally with the applied force. The number of steps in the displacement curves corresponds exactly to the loading steps of the applied force. The maximum recorded force was 11.19 kN, which resulted in LVDT displacements of 7.18 mm at Section S2

(LVDTs2) and 4.99 mm at Section S1 (LVDTs1).

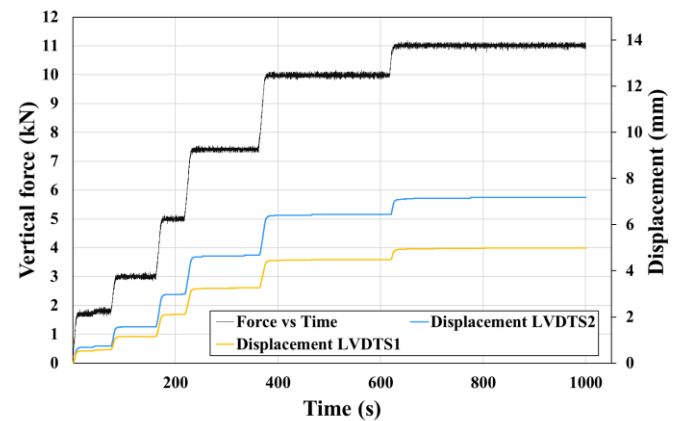

Figure 7. Force and LVDT displacements over time during the bending test.

Figure 8 and Figure 9 display the strain curves recorded by each long-gauge sensor throughout the test. Sensors installed below the geometric centroid of the beam cross section are expected to record tensile strains (negative values), while those positioned above the geometric centroid should register compressive strains (positive values). As expected, sensors LGS1TF and LGS2TF, both located above the geometric centroid, measured compressive strains and sensors LGS1BF, LGS2BF and LGS2MID measured tensile strains.

A comparison of the curves also shows that, as expected, the further a sensor is from the geometric centroid of the cross section, the greater the strain it experiences. Additionally, sensors positioned at the mid-span of the beam experienced higher strain levels than those located at Section S1, which is nearer to the support.

More specifically, the maximum recorded compressive strain at Section S2 was 590  $\mu\epsilon$ , while the maximum tensile strain reached 502  $\mu\epsilon$ . Sensor LGS2MID, located closer to the geometric centroid recorded a maximum strain of 277  $\mu\epsilon$ . LGS2BF recorded a strain 1.81 times greater than that of LGS2MID.

In contrast, the FOS located at Section S1 recorded significantly lower strain values, with a maximum compressive strain of 269  $\mu\epsilon$  and a maximum tensile strain of 155  $\mu\epsilon$ . This notable difference highlights the effect of the bending moment distribution along the beam. Since Section S2 is in the segment of the beam where the bending moment is at its maximum, higher strain values are expected and observed. Conversely, Section S1, being nearer to the supports where the bending moment is lower, experiences lower strain levels.

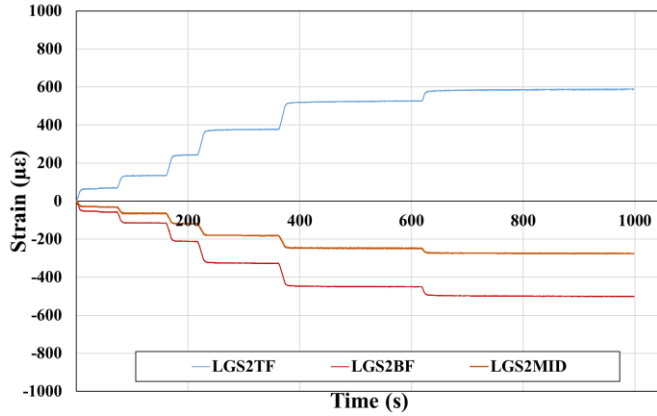

Figure 8. Strain curves for the long-gauge fiber optic sensors installed at S2.

## 5 DISCUSSION

### 5.1 Determination of the modulus of elasticity

To validate the use of fiber optic sensors (FOS) in this test, experimental stress values are compared to their theoretical counterparts.

Theoretical stresses are calculated using Equation 1, while experimental stresses are derived from Equation 2. In both equations,  $\sigma$  represents the tensile or compressive stress (in N/mm<sup>2</sup>). In Equation 1,  $M$  is the bending moment at the cross-section (N·mm),  $I$  is the moment of inertia of the cross-section (mm<sup>4</sup>), and  $y$  is the vertical distance (mm) from the location of the strain measurement to the geometric centroid of the cross-section. In Equation 2,  $\varepsilon$  is the strain measured by the FOS, and  $E_{m,g}$  is the timber modulus of elasticity (in N/mm<sup>2</sup>).

$$\sigma = \frac{M}{I} y \quad (1)$$

$$\sigma = \varepsilon E_{m,g} \quad (2)$$

The modulus of elasticity  $E_{m,g}$  can be obtained either from the Spanish code CTE-DB-SE-M, based on the timber strength

class, or measured experimentally according to UNE-EN 408:2011+A1 [10], using the expression shown in Equation 3:

$$E_{m,g} = \frac{3al^2 - 4a^3}{2bh^3 \left( 2 \frac{w_2 - w_1}{F_2 - F_1} - \frac{6a}{5Gbh} \right)} \quad (3)$$

The parameters in this equation are defined as follows:

- $a$ : the distance from a loading point to the nearest support (1 m in this test),
- $l$ : the span between supports (3 m),
- $b$  and  $h$ : the width and height of the timber beam, respectively (provided in Section 3),
- $F_2$  and  $F_1$ : two load values within a linear portion of the force–displacement curve (with a correlation coefficient  $\geq 0.99$ ),
- $w_2$  and  $w_1$ : the corresponding displacements for forces  $F_2$  and  $F_1$ ,
- $G$ : the transverse modulus of elasticity, taken from the code for class C18, with a value of 560 MPa.

Using the following values:

- $F_2 = 10990$  N,
- $F_1 = 3200$  N,
- $w_2 = 7.14$  mm,
- $w_1 = 1.66$  mm,

the calculated value of  $E_{m,g}$  is 14577 MPa.

### 5.2 Stresses at section S1

Experimental stresses calculated for section S1 were compared to their theoretical values, as shown in Figure 10. The difference between the experimental and theoretical value for LGS1TF accounts for 0.10 MPa, which is negligible. However, the difference for LGS1BF is 1.59 MPa. More specifically, theoretical calculations provided greater values of tension, but lower compression stress than those obtained from the monitored strains. The maximum theoretical stress values are 3.83 MPa (at the location of the top sensor) and 3.85 MPa (at the location of the bottom sensor), which suggest the exact same stress at the tensioned fibers and at the compressed fibers, and it is justified by the 0.31 mm difference at the installation position in relation to their respective extreme face (top face or bottom face of the beam). However, experimental results of maximum stresses for LGS1TF and LGS1BF locations are 3.93 MPa and 2.26 MPa respectively. These values denote a clear dominance of compression over tension along the length where the sensors are installed for section S1.

At this point it is worth noting that the calculations assumed several hypothesis. Stress calculated with Equation 1 assumes that the material is homogeneous and linear elastic. As it is known for timber, this constitutes a simplification, since it is a heterogeneous material, with varying properties in each direction. Local defects, such as the presence of knots, where the density of the timber grain is higher, and some variability in the direction of the timber fibers can also influence the behavior of the beam under loading, leading to differences between the compression and the tension stresses. Minor differences in the installation of the sensors to the beam can also lead to differences in the results, such as the distance from sensor LGS2TF's axis to the top face of the beam, which is 27.88 mm, while for LGS2BF is 23.54 mm. Accuracy during

the installation should be as precise as possible to reduce variability.

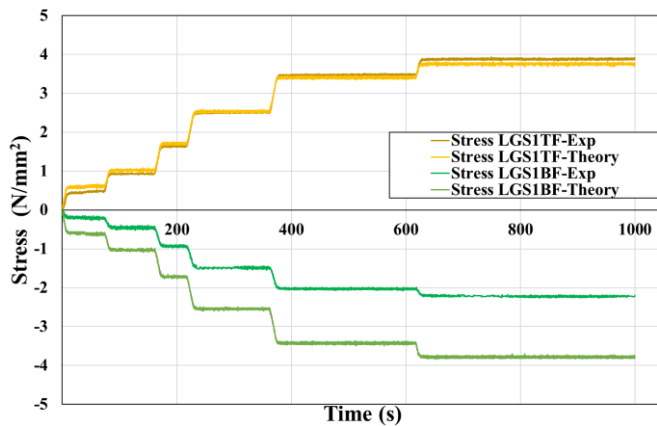

Figure 10. Theoretical stress versus experimental stresses at section S1.

### 5.3 Stresses at section S2

As shown in Figure 11, differences can be observed between the experimental and theoretical stress values for each long-gauge sensor installed at section S2. These differences are more evident when comparing the stress values at the final loading step (Step 6) of the test.

For sensor LGS2TF, located in the compression zone of the beam, the experimental stress at Step 6 is 0.68 MPa higher than the theoretical value, representing an 8% difference. In the tension zone, for sensor LGS2BF, the theoretical stress exceeds the experimental value by 1.07 MPa, resulting in a 12.75% difference. Similarly, for sensor LGS2MID (also in tension), the theoretical stress is 0.66 MPa greater than the experimental, corresponding to a 14.12% difference. These discrepancies highlight the complexity of comparing real-world measurements with simplified analytical predictions, particularly in anisotropic materials such as timber. In addition, comparing sensors LGS2MID and LGS2BF — both located in the tension zone but at different distances from the centroid — further illustrates the consistency of the results. The maximum recorded strain at LGS2MID was  $277 \mu\epsilon$ , while LGS2BF registered  $502 \mu\epsilon$ , yielding an experimental strain ratio of 1.81 as detailed in Section 4. Using Equation 1 and considering the sensors' relative positions and the maximum applied force of 11.19 kN, the corresponding theoretical stresses are 4.61 MPa for LGS2MID and 8.24 MPa for LGS2BF — a ratio of 1.79. This close agreement between theoretical and experimental ratios supports the validity of the strain measurements and suggests a good correlation between sensor position and measured mechanical response.

To provide a more comprehensive comparison, Table 2 presents the absolute values of experimental and theoretical stresses for loading steps 3 and 6, along with the corresponding percentage differences. All long-gauge sensors were installed within the region of constant bending moment, as defined by the four-point bending configuration, ensuring that there is no uncertainty regarding the bending moment acting on the segment of the beam being analyzed.

To ensure the accuracy of theoretical stress calculations, key geometric parameters were precisely measured. The vertical distances ( $y$ ) from each sensor to the beam's geometric centroid

were verified using a digital caliper, and the cross-sectional dimensions of the timber beam were also recorded with high precision. The modulus of elasticity, used to derive experimental stress values from strain measurements, was obtained through an independent experimental procedure following standard guidelines [10]. Therefore, it is not considered a source of significant error in the comparison.

The observed differences are more likely attributed to the natural anisotropy and heterogeneity of timber, including the presence of knots, cracks, grain deviations, or localized density variations. These factors can influence the mechanical response at specific cross-sectional locations and lead to deviations from the idealized behavior predicted by classical bending theory.

Table 2. Comparison of stresses at section S2 for loading steps 3 and 6.

	LGS2TF	LGS2BF	LGS2MID
Experimental stress at step 3 (MPa)	3.52	3.08	1.73
Theoretical stress at step 3 (MPa)	3.61	3.82	2.14
Difference (%)	2.49	19.37	19.15
Experimental stress at step 6 (MPa)	8.54	7.26	4.01
Theoretical stress at step 6 (MPa)	7.78	8.24	4.61
Difference (%)	8.90	11.92	13.99

Figure 11. Theoretical stress versus experimental stress at section S2.

## 6 CONCLUSIONS AND FUTURE RESEARCH

This study focused on monitoring key parameters of a classified timber beam subjected to a four-point bending test, enabling a comparison between stresses derived from strain measurements and theoretical values based on classical strength of materials principles. The following conclusions can be drawn:

- Fiber optic sensors (FOS) are effective tools for monitoring the strain behavior of timber structural elements. The results obtained during testing showed strong agreement with the expected behavior under a step-loading protocol. FOS provided high-resolution strain data, from which stress was reliably derived

using appropriate mechanical models and material properties. This capability highlights their value in structural health monitoring (SHM) applications.

- FOS have the potential to detect localized anomalies in material behavior. For example, sensor LGS1TF-Exp exhibited a 58.7% deviation from its theoretically derived stress value, a difference which cannot be overlooked. Possible explanations include the presence of defects—such as knots or abrupt grain deviations—that alter local strain behavior. Installation-related issues may also have contributed to the anomaly.
- Precision in FOS installation is critical. The accuracy of strain measurements is highly dependent on proper sensor alignment, bonding quality, and the technician's skill. Even with optimal procedures, a certain level of uncertainty is inevitable due to the high sensitivity of these sensors (on the order of  $2\ \mu\epsilon$ ), underscoring the importance of meticulous installation and calibration.
- Further research is needed to systematically explore the causes of large deviations between measured and theoretical stress values. The nearly 59% error observed at the location of sensor LG-S1-BF is too large to be attributed solely to timber's natural variability—such as knots, fiber misalignment, or moisture content—though these factors do influence strain-stress correlation. It is therefore likely that some form of installation or operational error occurred. Future work should include defect mapping, and improved sensor validation protocols to try to isolate and quantify these effects.

## ACKNOWLEDGEMENTS

This article is part of the grant PID2021-128152NB-I00 funded by MICIU/AEI/10.13039/501100011033 and by ERDF/EU. The authors also wish to acknowledge the support received through the predoctoral grant PRE2022-103404, funded by MICIU/AEI/10.13039/501100011033 and by FSE+ (European Social Fund Plus). This grant was awarded to the first author to support his doctoral research.

**ABSTRACT:** This study investigates an innovative pi-bracket sensor system integrating distributed fiber optic sensing with Brillouin Optical Time Domain Analysis to detect cracks in bridge girders near stiffeners. The system is designed to overcome challenges in crack detection at these critical locations. Experimental validation was conducted on a 3-meter steel beam featuring a welded stiffener positioned 25mm from a simulated crack. An aluminum pi-bracket served as a mounting device for the fiber optic sensor. Comparative analysis between experimental measurements and finite element simulations demonstrated the system's ability to detect crack openings as small as 0.2mm. Abaqus Finite Element Analysis predicted strain values of 145 $\mu\epsilon$ , while laboratory experiments recorded 129 $\mu\epsilon$ , a discrepancy of approximately 11%. Strain concentrations were localized to the regions where the pi-bracket was in direct contact with the beam. The strong correlation between computational models and empirical data substantiates the efficacy of the proposed sensing system. These findings highlight the system's potential for structural health monitoring of bridge infrastructure, particularly for detecting and quantifying cracks near stiffeners.

**KEY WORDS:** Structural health monitoring; Crack detection; Fiber optic sensing; Brillouin optical time domain analysis.

## 1 INTRODUCTION

Short and medium span bridges are critical components of national transportation networks, significantly contributing to economic activity. As these structures age, they become increasingly vulnerable to structural deficiencies such as reduced load-bearing capacity, accidental damage, material deterioration, fatigue cracking, and foundation problems. Of particular concern is the formation and propagation of cracks in steel bridge girders, which can severely compromise structural integrity [1, 2, 3].

Steel girders, typically constructed from web plates with welded flanges, are fundamental to bridge design, however, they are prone to cracking. These cracks often arise due to cyclic stresses caused by vehicular traffic and environmental factors. Early detection is critical to prevent unexpected service disruptions and mitigate associated economic losses [4, 5].

Advancements in distributed fiber optic sensing (FOS) systems have significantly enhanced the monitoring of bridge structures. However, a critical limitation of this technology is its inability to reliably detect cracks that form near stiffeners, components that are especially susceptible to crack initiation and propagation due to residual stresses, geometric discontinuities from welding, and stress concentrations arising from restricted deformation under repeated loading cycles [8]. Because the FOS is distributed, it is often left unattached in the vicinity of stiffeners, resulting in unmonitored zones extending 5-10 inches on either side of the stiffener, as illustrated in Figure 1. Furthermore, these unattached portions of the FOS lack the support and protection provided by the surrounding structure, rendering them more vulnerable to mechanical damage. These limitations raise concerns regarding the reliability of current monitoring systems in ensuring the structural integrity of steel bridges [1].

Figure 1. Steel girder with welded stiffener and DFOS in current monitoring system

This study seeks to address these challenges by evaluating a pi-bracket fatigue sensor integrated with FOS technology and Brillouin Optical Time Domain Analysis (BOTDA) for crack detection in steel girders. The pi-bracket serves as protective housing for the FOS, preventing mechanical damage while enabling crack detection near stiffeners. Conventional Structural Health Monitoring (SHM) practices often avoid attaching FOS near stiffeners due to fiber bending constraints, limited space, or risks of mechanical damage during installation.

This research aims to evaluate the pi-bracket sensor system's ability to accurately detect and monitor cracks in critical areas of a simulated bridge girder and compare its performance with

Finite Element Analysis (FEA) predictions. Ultimately, this study aims to advance the development of more reliable SHM systems, promoting enhanced safety, proactive maintenance, and extended service life for bridge structures.

## 2 METHODOLOGY AND EXPERIMENTAL SETUP

### 2.1 FEA Model

A three-dimensional finite element model was developed using ABAQUS to simulate the experimental setup (Figure 2). The model consisted of three main components: the steel girder, aluminum pi-bracket, and steel stiffener, all modeled as deformable planar shell elements with thicknesses corresponding to experimental dimensions (8.9mm for girder web, 15.7mm for girder flanges, and 3.175mm for pi-bracket). Two distinct material properties were incorporated: steel and aluminum. The simulation focused on the linear elastic behavior within the elastic region of the elastic-plastic relationship, defining only Young's modulus and Poisson's ratio for both materials. Aluminum was characterized by a Young's modulus of 69000 MPa and a Poisson's ratio of 0.33, while steel was defined by a Young's modulus of 210000 MPa and a Poisson's ratio of 0.3.

Figure 2. FEA model of the beam with the stiffener crack and pi-bracket.

The connections in the ABAQUS model between the FOS, pi-bracket, and beam were modeled as rigid interfaces using tie constraints. This modeling approach enforces identical displacements and rotations at the interface, effectively simulating a completely rigid bond between the connected components. Although this represents an idealized scenario, it is sufficient for the purposes of this study, which focuses on the ability to detect the initiation of cracks.

Regarding fiber rupture concerns, our detection system targets very small crack openings, significantly below thresholds that would risk fiber damage. Even in the unlikely event of rupture due to extreme crack propagation, the distributed nature of the FOS (with its dense sampling points) would instantly identify the failure location, enabling immediate inspector dispatch for visual assessment. This aligns with the research objective: developing a continuous monitoring system for early crack detection to support timely intervention and maintenance.

To simulate a simply supported 3-meter steel girder, appropriate boundary conditions were applied to each end of the beam. A pinned support at one end restricted U1, U2, U3, UR2, and UR3, while a roller support at the other end allowed axial displacement. The crack was explicitly defined as a stationary geometric discontinuity using a face partition at the

beam's midspan web location, extending 57mm vertically from the bottom edge of the web. The crack was defined as a contour integral, with the crack extension direction specified by selecting q-vectors. The singularity was modeled as a collapsed element side with a single node, with the mid side node parameter set to 0.3 to accurately capture the stress singularity.

The simulation employed displacement-controlled loading (crack opening 0.1mm and 0.2mm), with concentrated forces applied at the midspan of the beam. The applied displacement was defined as the relative movement between two nodes located at the same height as the pi-bracket, on either side of the crack. This approach does not imply that the entire crack opens uniformly by the prescribed amount. Instead, the displacement at the crack tip remains zero, while the maximum opening occurs at the bottom of the web, between the flanges. For example, when a 0.2 mm displacement is specified the actual opening at the crack tip is zero, and the opening at the bottom of the web is larger.

The model was primarily meshed using Quad 4-node shell elements (S4R), with Tri 3-node shell elements (S3) used in areas surrounding the crack. The S4R element is a general-purpose quadrilateral element suitable for large-strain analysis, featuring six degrees of freedom per node with bilinear interpolation.

This FEA model configuration enables accurate simulation of the beam's behavior under specified loading conditions, allowing detailed analysis of stress distributions and deformations, particularly in critical regions surrounding the crack and pi-bracket. The objective was to assess the pi-bracket sensor system's ability to detect strain changes resulting from crack formation, aligning with the study's focus on evaluating sensor performance for SHM applications.

### 2.2 Experimental Setup

The test configuration used a W250x67 (W10x45) structural steel beam in a simply supported arrangement spanning 3 meters to replicate typical in-service conditions (Figure 3). A controlled crack was introduced at midspan through precision machining, extending through the bottom flange and vertically 57 mm into the web from the beam's underside.

Figure 3. Beam - Section.

To simulate realistic bridge girder geometry, a transverse stiffener was welded to the beam 25 mm from the crack edge on one side. This asymmetric design was chosen to generate asymmetric stress distributions characteristic of operational bridge environments, and to allow a comparative assessment between stiffened and non-stiffened regions.

The pi-bracket assembly was installed at a vertical offset of 35 mm above the bottom flange's upper edge, with its central axis aligned to the stiffener position (Figure 4). This spatial

configuration was optimized to facilitate sensor routing while maintaining proximity to critical stress zones, enhancing detection sensitivity to crack-induced strain fields. The geometry of the stiffener, crack location, and pi-bracket placement were designed to emulate common failure scenarios observed in aging bridge infrastructure.

Figure 4. Pi-bracket geometry.

### 2.3 Instrumentation

The primary sensing technology used in this study was the DiTeSt SMARTape II fiber optic sensor, developed by Smartec. This high accuracy distributed strain sensor, comprising a single continuous optical fiber, was adhered to both sides of the beam using epoxy adhesive. On the front face, the sensor was routed over the simulated crack using the Pi-Bracket, which acted as a protective harness (Figure 5a). In contrast, on the rear face, the sensor was directly bonded to the surface of the beam, passing through the crack region (Figure 5b). Fiber continuity was ensured by routing it back at one end of the beam to transition from the front to the rear face.

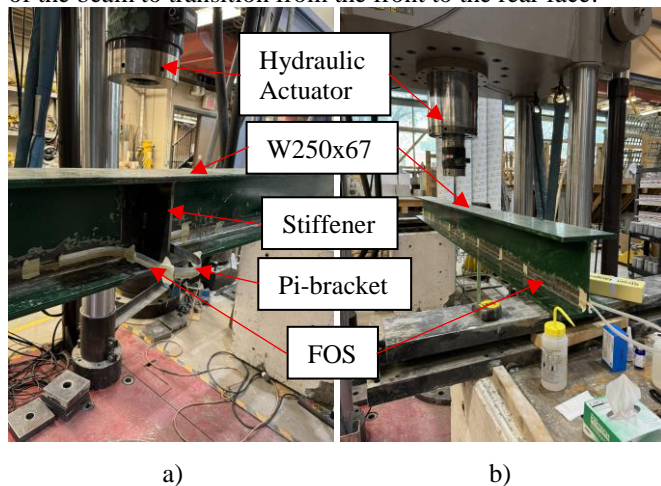

Figure 5. a) SMARTape on the front face; b) SMARTape on the rear face.

The termini of the SMARTape sensor were fusion spliced to extension fiber optic cables and connected to a Data Acquisition (DAQ) system, enabling real-time monitoring and data collection throughout the experiment. Various configurations of the Neubrescope NBX-6050 DAQ system were tested to identify optimal parameters prior to this experiment. The optimal configuration utilized a 5 cm sampling interval and a 10 cm spatial resolution. This system used

BOTDA technology to achieve high-resolution strain distribution measurements along the length of the FOS.

In the context of steel bridges, critical fatigue cracks are typically considered to be those with widths in the range of 0.1 mm to 0.3 mm, as cracks within this interval are generally regarded as significant for early intervention and maintenance [10]. According to the manufacturer's specifications, the DiTest SMARTape II fiber optic sensor can detect cracks as small as 0.2 mm, and we anticipated that the proposed pi-bracket system would achieve comparable performance. It is important to note that the objective of this study is to evaluate the ability of the pi-bracket sensor system to accurately detect and monitor the presence of cracks, rather than to quantify their exact widths. The primary goal is to determine whether the system can detect the initiation of a crack and enable the immediate intervention of an inspector for further evaluation. This approach supports proactive maintenance and timely intervention, which are critical for ensuring the safety and longevity of bridge infrastructure.

### 2.4 Fiber Optic Sensor Calibration

The initial strain measurements lacked sufficient resolution to clearly identify the positions of the beam and pi-bracket along the FOS, as shown in Figure 6.

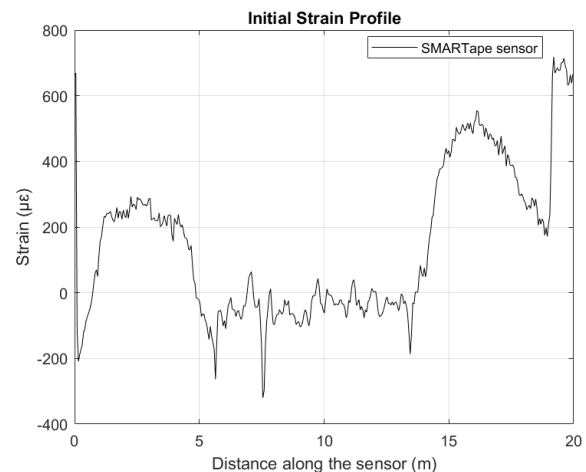

Figure 6. Initial calibration strain profile.

To address this limitation, a thermal localization method was used to enhance spatial resolution and accurately determine key positions. This involved applying localized heat to specific points on the beam, including both ends and the pi-bracket apex. The resulting strain response was recorded and compared to the initial unheated strain profile to isolate the thermal effect.

Thermal localization was employed to precisely determine the positions of the beam faces and the pi-bracket along the FOS strain profile (Figure 7). In the experimental setup, a single, continuous SMARTape sensor was routed from the front to the rear face of the beam, enabling comprehensive strain measurements across the entire structure. By applying thermal localization, the locations of key structural features, such as the front face, back face, and the pi-bracket, were accurately mapped onto the strain profile. Specifically, Sensor S1 corresponded to the portion attached to the front of the beam, spanning from 5.75 meters (A) to 9.35 meters (C) along the sensor length, with the pi-bracket located at 7.55 meters (B). Sensor S2 referred to the segment affixed to the rear of the

beam, extending from 10.25 meters (D) to 13.25 meters (E), with the crack opening situated at 11.75 meters.

Figure 7. Thermal localization of FOS segments.

Figure 8 provides a comprehensive schematic representation of the entire FOS configuration, illustrating the spatial relationships between the SMARTape II sensor and the pi-bracket.

Figure 8. Schematic diagram of fiber optic sensor.

## 2.5 Experimental Procedure

The experimental protocol was designed to rigorously assess the efficacy of the FOS and pi-bracket for crack detection and monitoring. This process involved a sequence of executed stages, beginning with initial configuration and calibration. The experimental apparatus, comprising the beam, pi-bracket with attached FOS and pi-gauge, was interfaced with the DAQ system. The Neubrescope NBX-6050 was adjusted to its optimal parameters, and the FOS was calibrated to ensure measurement accuracy.

According to the manufacturer's specifications, the DiTest SMARTape II fiber optic sensor can detect cracks as small as 0.2 mm [6]. We anticipated that the proposed pi-bracket system would achieve comparable performance. The static load experiment was conducted under controlled laboratory conditions at an ambient temperature of 19.8°C. The crack opening was controlled by a pi-gauge (PI-5-100, Tokyo Sokki Kenkyujo) with a resolution of 0.001 mm and an accuracy within  $\pm 1\%$  according to the manufacturer, which was installed at the same height as the pi-bracket to ensure precise crack width [9]. Strain data from the SMARTape sensor were collected for the no-crack condition (referred to as the “initial

crack”), as well as for crack opening widths of 0.1 mm and 0.2 mm, with baseline readings taken before load application.

A hydraulic actuator applied midspan loading to induce crack opening. The experiment used displacement control, pausing at a 0.1 mm crack width to record load and beam displacement data (Table 1). Strain measurements were taken at this point. The load was then increased to achieve a 0.2 mm crack width, where additional readings were obtained. Multiple measurements were taken and averaged to generate strain profiles for each crack opening width.

## 3 RESULTS AND DISCUSSION

### 3.1 FEA Results

The FEA model developed in Abaqus was used to simulate the experimental setup and to investigate the strain behavior of the pi-bracket sensor system under controlled crack opening conditions. This modeling enabled a detailed examination of strain patterns along the FOS.

Two distinct strain profiles were analyzed, as shown in Figure 9. The first strain profile (blue line in Figure 9) represents a scenario without the pi-bracket, reflecting current SHM practices where a continuous FOS is left unattached near stiffeners, resulting in an unmonitored zone of about 10 cm on each side due to installation constraints. This profile serves as a baseline for comparison, illustrating the strain distribution in the absence of the pi-bracket's influence.

The second profile (red line in Figure 9) incorporates the pi-bracket, capturing strain measurements continuously along the entire beam span, including the areas near stiffeners. The green vertical lines in Figure 9 identify the position of the pi-bracket along the strain profile, providing spatial reference points for interpreting the sensor configuration.

To match the DAQ averaging from the experiment, strain profiles were averaged between two points along the path.

Figure 9. FEA strain profiles for 0.2mm crack: Comparison of Beam with and without Pi-Bracket.

Figure 9 demonstrates that the pi-bracket allows for uninterrupted strain monitoring across the region near the stiffener and crack, effectively eliminating the unmonitored gaps seen in the baseline scenario. Specifically, the region between 1.3 m and 2.2 m along the sensor corresponds to the segment of the FOS routed through the pi-bracket for the second modeled scenario. In contrast, for the first scenario

without the pi-bracket, the strain profile is interrupted to reflect current practice where the FOS is left unattached to the surface near stiffeners and therefore does not register any strain in these regions.

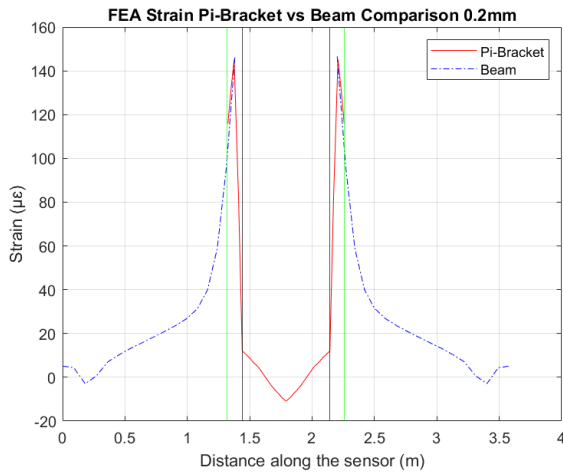

Figure 10. FEA strain profile of Pi-Bracket for 0.2mm crack: Identification of contact and non-contact Pi-Bracket regions.

Figure 10 further isolates the strain response of the pi-bracket section from the overall profile shown in Figure 9, again for a 0.2 mm crack opening. In this figure, black vertical lines indicate the portions of the pi-bracket that are not attached to the beam, while the areas marked by green vertical lines on either side represent the sections of the pi-bracket that are glued to the beam. This distinction is important for interpreting the strain distribution, as the attached and unattached regions of the pi-bracket exhibit different mechanical behaviors due to their interaction with the beam.

For further clarification, Figure 11 provides a schematic of the pi-bracket, highlighting the attached and unattached regions relative to the beam, which aids in interpreting the strain profiles in Figures 9 and 10.

Figure 11. Pi-bracket – part identification

These FEA results demonstrate the effectiveness of the pi-bracket in capturing and distributing strain from the crack region, allowing for continuous monitoring even near critical features such as stiffeners. This provides a valuable reference for comparison with the experimental data.

### 3.2 Experimental Results

The experimental phase of this investigation yielded extensive strain data collected by the SMARTape FOS system. These measurements provide valuable insights into the

performance of the pi-bracket sensor configuration under controlled crack propagation conditions. Figure 12 displays the averaged strain profiles derived from multiple measurements, showing the sensor's response to progressive crack opening widths of 0.1 mm and 0.2 mm, as well as the initial state with no crack for direct comparison before and after crack initiation. The green vertical lines in Figure 12 identify the strain segments S1 and S2: S1 corresponds to the front face of the beam, where the FOS is routed via the pi-bracket, and S2 corresponds to the back face of the beam, where the FOS is attached directly over the crack (since there was no stiffener on this side). This setup, with the stiffener welded to one side only, allows for a direct comparison of the strain profiles between both regions.

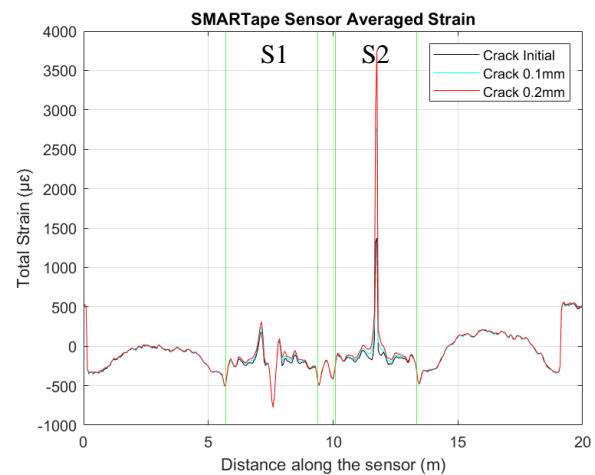

Figure 12. SMARTape averaged strain profiles.

Figure 13 presents the strain profiles obtained by subtracting the initial strain profile (no crack condition) from those measured at 0.1 mm and 0.2 mm crack openings. This approach isolates the strain response resulting specifically from crack widening, eliminating any residual or pre-existing strains within the FOS. The data indicates a significantly higher strain value (2382.1 µε) recorded by the sensor section S2, which was directly bonded over the crack, compared to the maximum strain recorded by sensor section S1, distributed over the pi-bracket (129.1 µε). All the results are summarized in Table1.

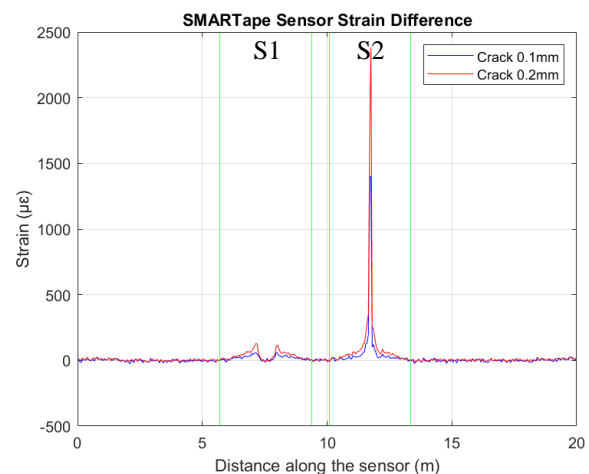

Figure 13. SMARTape strain profiles isolating crack-induced strain.

Table 1. Experiment and FEA Results.

Experiment						FEA Simulation		
Crack width [mm]	Load [kN]	Beam displacement [mm]	S1 Strain max. [ $\mu\epsilon$ ]	Strain Pi-Bracket Crown [ $\mu\epsilon$ ]	S2 Strain max. [ $\mu\epsilon$ ]	Strain Pi-Bracket Crown [ $\mu\epsilon$ ]	Strain Pi-Bracket max. [ $\mu\epsilon$ ]	Strain Beam no bracket max. [ $\mu\epsilon$ ]
0	0	0	0	0	0	0	0	0
0.1	15.9	-1.26	60.6	-8.3	1402.9	-5.4	72.95	73.7
0.2	31.9	-2.38	129.1	-11.04	2383.1	-10.8	145.14	146.6

Figure 14. Detailed strain profiles for Section S1.

Figure 14 presents a detailed analysis of the strain profiles for section S1, which includes the pi-bracket at its center. The green vertical lines indicate the position of the pi-bracket along the strain profiles. Although the data exhibits some residual noise, the overall trends in the strain profiles demonstrate the sensor's capacity to detect strain changes induced by crack opening, even when mediated by the pi-bracket. Potential sources of noise include environmental vibrations and temperature fluctuations. The data from S1 provides insights into how the pi-bracket influences strain distribution compared to the direct measurement at the crack location (S2).

### 3.3 Comparison

This section presents a comparative analysis of experimental results obtained from SMARTape sensor measurements and FEA predictions, evaluating the efficacy of the pi-bracket sensor system for crack detection near stiffeners. The comparison focuses on strain measurements at critical locations, specifically the pi-bracket and crack-adjacent regions (Figures 15, 16).

FEA simulations predicted a maximum strain of 145.1  $\mu\epsilon$  in the pi-bracket at the location of direct beam attachment for a 0.2 mm crack opening. Experimentally, the maximum strain recorded by sensor section S1, distributed over the pi-bracket, was 129.1  $\mu\epsilon$  for an equivalent crack opening (Figure 15). Again, the green vertical lines indicate the position of the pi-bracket along the strain profile. This

represents an approximate 11% discrepancy between the FEA prediction and the experimental measurement. The observed level of agreement suggests that the numerical model adequately predicts the strain behavior of the pi-bracket under the applied loading conditions.

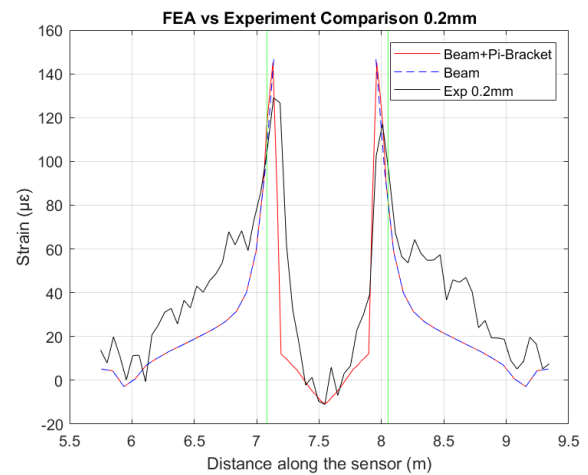

Figure 15. FEA vs Experiment comparison for 0.2mm crack.

Figure 16 presents the same strain results as Figure 15 but focuses exclusively on the strains within the pi-bracket for both the FEA simulations and laboratory experiment at a 0.2 mm crack opening.

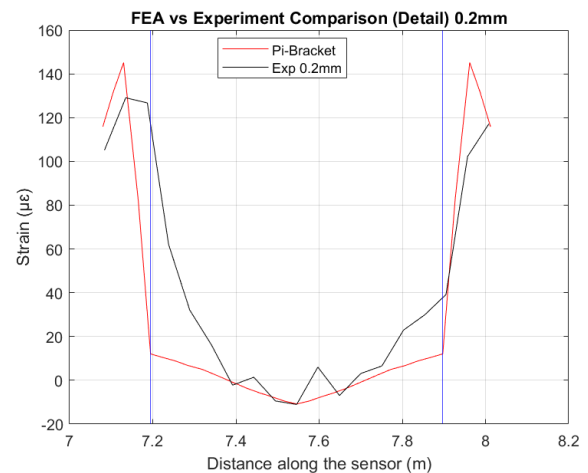

Figure 16. FEA vs Experiment comparison of Pi-Bracket for 0.2mm crack.

Figure 16 illustrates the separation of the unattached central region of the pi-bracket from the beam by blue vertical lines, distinguishing it from the attached areas on either side. The FEA predicted a maximum strain of  $-10.8 \mu\epsilon$  at the crack tip for a 0.2 mm crack opening. Experimentally, the SMARTape sensor section S1 recorded a strain of  $-11.04 \mu\epsilon$  at the pi-bracket crown (Figure 15), demonstrating close agreement with the FEA results.

Although the strain magnitudes at the pi-bracket crown were relatively small compared to those measured directly over the crack ( $2383.1 \mu\epsilon$ ), the SMARTape sensor affixed to the beam-bonded portions of the pi-bracket successfully detected the crack, registering strains of  $129.1 \mu\epsilon$  versus  $145.1 \mu\epsilon$  predicted by FEA. This 11% discrepancy validates the numerical model's capability to simulate the pi-bracket's behavior under crack propagation while highlighting the sensor system's sensitivity.

#### Key Findings:

**Validation of Computational Framework:** The strong correlation between experimental strain measurements ( $129 \mu\epsilon$ ) and FEA predictions ( $145 \mu\epsilon$ ) confirms the reliability of the numerical model in representing the pi-bracket response to crack-induced strain.

**Strain Gradient Localization:** Elevated strain values were predominantly localized at the crack interface, with sensor section S2 (directly over the crack) showing significantly higher strains than section S1 (pi-bracket region). This confirms the influence of geometric discontinuities on strain distribution.

**Detection Validation:** The pi-bracket sensor system demonstrated sufficient sensitivity to detect crack initiation, with strain magnitudes large enough to be readily observed.

**Pi-Bracket Efficacy:** The pi-bracket functions effectively as both a strain-transfer mechanism and a protective interface for the fiber optic sensor, supporting its potential integration into SHM systems.

The observed 11% difference between experimental and simulated strains can be attributed to simplifications in the FEA model, real-world experimental factors such as sensor performance and data acquisition variability, and mesh density limitations imposed by the software version used. Despite these factors, the overall agreement substantiates the pi-bracket sensor system's effectiveness for crack detection in bridge girders.

Despite these discrepancies, the overall agreement between the experimental results and FEA predictions validates the effectiveness of the pi-bracket sensor system for crack detection in bridge girders. The observed 11% discrepancy suggests that simulation captures experimental behavior with reasonable accuracy, as expected.

### 3.4 Advantages of the Pi-bracket Sensor System

The pi-bracket sensor system provides improved accuracy in detecting cracks near stiffeners, which are typically challenging to monitor. It functions as a protective harness, shielding the continuous FOS from mechanical damage, a common issue when sensors are left unattached around stiffeners due to bending limitations. This design enables uninterrupted and direct strain measurements along the entire length of the girder, including critical regions near stiffeners.

By integrating BOTDA technology, the system simplifies data acquisition and demonstrates strong alignment with FEA predictions. This combination offers a reliable and efficient approach for validating computational models and facilitating proactive bridge maintenance strategies.

### 3.5 Real-World Applicability, Limitations, and Capabilities

The findings of this study highlight the potential of the pi-bracket sensor system for practical application in bridge infrastructure, particularly for monitoring high-risk areas near stiffeners. The system is recommended for use in both new bridge construction and retrofitting existing structures to enable targeted monitoring of these critical regions. Its localized measurement capability allows for deployment in areas prone to cracking, while the pi-bracket serves as a protective harness for the FOS.

It should be emphasized, however, that the authors do not recommend the use of this system for monitoring existing cracks. Given the higher cost of FOS compared to conventional methods such as strain gauges, it is not cost-effective for short-term monitoring where the sensor would be installed, the crack repaired at some point, and then the sensor removed or replaced. Instead, this system is best suited for long-term, continuous monitoring, where the FOS is permanently attached to the surface of the girder. This makes it particularly advantageous for bridges that are approaching or have exceeded their intended service life, especially in cases where local authorities lack the financial resources for comprehensive retrofitting or replacement. In such scenarios, the pi-bracket sensor system provides a cost-effective solution for ongoing structural health monitoring, enabling proactive maintenance and extending the operational lifespan of critical infrastructure. Furthermore, the system is well-suited for deployment immediately following crack repair, to monitor the repaired region and prevent recurrence.

It is important to recognize that this system has certain limitations. The installation process can be complex, and environmental factors may influence performance. Additionally, the initial cost of implementation may exceed that of traditional methods, although the long-term benefits could outweigh these expenses. Furthermore, experimental validation was limited to a single beam, necessitating further testing on larger-scale structures to confirm its effectiveness.

Despite these constraints, the pi-bracket sensor system offers several advantages, including accurate crack detection, quantitative strain measurement, remote monitoring capabilities, and integration with FEA models. Its protective design enhances sensor durability and reliability. These attributes make it a valuable tool for improving crack detection in bridges, contributing to enhanced safety, reliability, and longevity of critical infrastructure.

While the initial cost of the pi-bracket FOS system may exceed that of traditional methods, its long-term benefits provide significant value. The system enables continuous, real-time monitoring of strain and crack development, allowing for early detection and timely maintenance interventions that enhance structural safety and reliability. This proactive approach helps extend the service life of

bridges by preventing severe damage and delaying costly retrofits or replacements. Additionally, continuous monitoring reduces the need for frequent manual inspections, lowering maintenance costs and minimizing traffic disruptions. The protective design of the pi-bracket also improves sensor longevity, reducing replacement frequency.

It is essential to emphasize that the primary objective of this study was not to investigate fracture mechanics or crack interaction phenomena but rather to evaluate the pi-bracket sensor system's ability to detect early-stage cracks. This capability facilitates preventative measures against potential structural failures in bridge infrastructure.

Given the limitations of existing inspection protocols [3, 7], which rely heavily on periodic manual assessments, this system offers a continuous real-time monitoring solution. It enables immediate crack detection and automated alert generation, allowing for timely deployment of inspectors for detailed visual examination and initiation of necessary repairs.

To address challenges associated with fatigue loading and environmental variations in real-world conditions, future implementations could incorporate frequent data acquisition (e.g., every five minutes). By subtracting consecutive strain measurements, the system could isolate strain changes attributable solely to crack formation while minimizing the influence of dynamic bridge responses or environmental factors. Further investigation is needed to validate this differential approach under complex loading scenarios. Additionally, research should explore the effects of temperature fluctuations and determine optimal averaging times to enhance accuracy and reliability.

### 3.6 Recommendations for Future Research

Future research should refine the FEA model with higher-resolution meshing to better match experimental results. The pi-bracket system also requires testing under dynamic and fatigue loading, ideally on full-scale bridges, to evaluate durability and real-world performance. Laboratory testing at a constant 19.8°C does not account for temperature variations; therefore, it is recommended to assess temperature effects to distinguish them from crack-induced strains. Additionally, future work should address detection threshold quantification and evaluate false-alarm rates. Developing standardized mounting protocols, including adhesive choice and bracket alignment, will improve field deployment consistency. Finally, cost-benefit analyses comparing system costs to savings from early crack detection are essential to support practical adoption.

## 4 CONCLUSIONS

This study demonstrates the efficacy of the pi-bracket sensor system as a viable method for crack detection near stiffeners in bridge girders, exhibiting reliable detection capabilities for crack opening widths of 0.2 mm. The FOS distributed over the Pi-bracket recorded a strain of 129  $\mu\epsilon$  at a 0.2 mm wide crack opening. Comparative analysis between FEA and laboratory experiments utilizing a FOS provided significant insights into the pi-bracket sensor's performance. The concordance between experimental

results and Abaqus simulations corroborates the system's effectiveness and reliability, illustrating the robustness of both the sensor and the modeling approach employed for design optimization.

The pi-bracket configuration successfully addresses the challenge of monitoring traditionally inaccessible areas near stiffeners, while the integration of BOTDA sensing facilitated reliable distributed measurements along the beam length. These findings indicate that the pi-bracket sensor system presents a promising and practical solution for SHM of bridge infrastructure, particularly in critical regions susceptible to fatigue cracking.

Future research directions may include comparative analysis of girder strain profiles under two loading conditions, first resulting in crack openings of 0.2 mm, versus the same load applied to an uncracked girder. The primary objective would be to isolate and quantify the strain variations attributable solely to crack formation. To achieve this, the strain profile of the uncracked girder to be subtracted from that of the cracked girder under identical loading conditions. This approach effectively eliminates the influence of the applied load, revealing the strain signature specific to the presence and severity of the crack.

## ACKNOWLEDGMENTS

The authors would like to express their sincere gratitude to Research Manitoba for providing the necessary funding to support this project. Additionally, we appreciate the administrative support provided by Charleen Choboter, whose assistance has been invaluable throughout the project's duration and beyond.

**ABSTRACT:** Monitoring represents an effective approach for addressing the diverse challenges associated with the maintenance of civil engineering structures. It contributes to improving both the availability and safety of these structures. By increasing the amount of information available about the structure, monitoring supports better-informed decisions regarding its preservation. Due to the complexity of monitoring applications, specific use cases are outlined. A key advantage of these use cases is that new technologies can be tested within well-defined and limited scopes. The use cases “monitoring of known, localized damage,” “monitoring of known deficits identified through reassessment or resulting from outdated design procedures” and “monitoring aimed at assessing traffic loads and their effects” currently account for the majority of implemented monitoring measures. Their practical implementation is demonstrated through case studies from the Brandenburg State Road Authority. Additional use cases, such as “monitoring to support structural inspections” - for example through the use of imaging techniques - and “monitoring of major structures,” such as large viaducts, are gaining importance, with initial practical examples already present in Europe. Future applications reveal potential for expanded use, particularly in the context of “monitoring to support predictive lifecycle management.” This will become increasingly important in the implementation of digital twins, as announced in the national BIM master plan. Furthermore the concept of a “Birth Certificate” is intended to establish a reference state of the structure prior to commissioning, which can then be used for comparison with future measurements over time. The integration and interaction of these individual use cases pave the way for the implementation of digital twins.

**KEY WORDS:** STRUCTURAL HEALTH MONITORING, USE CASES, BRIDGES, DIGITAL TWIN

### 1 INTRODUCTION

Currently, the maintenance management of civil engineering structures is characterized by a reactive approach, where interventions are only initiated once visible damage has occurred. The introduction of a predictive lifecycle management strategy offers considerable potential to fundamentally improve the reliability, resilience and long-term availability of infrastructure systems.

Today’s civil engineering structures are confronted with a growing set of challenges — including aging infrastructure, significant maintenance backlogs, rising traffic loads, and a shortage of qualified personnel to plan and carry out necessary maintenance activities.

These challenges are contrasted by advancements in the field of digitalization. Examples include planning with Building Information Modeling (BIM), data analysis using artificial intelligence (AI) methods, the implementation of digital twins, and the use of augmented or virtual reality (AR/VR) for periodic condition assessment as part of structural inspections. These technologies -including the use of monitoring systems as highlighted in this article - can contribute significantly to supporting the objectives of structural maintenance. By combining these various methods, a holistic evaluation of digitally available information becomes possible, paving the way for more efficient, proactive, and integrated infrastructure management.

### 2 CURRENT USE OF MONITORING ON FEDERAL HIGHWAYS

This article follows the definition of monitoring provided in the DBV (German Concrete and Construction Technology Association) guideline. According to this definition, monitoring describes the overall process of recording, analyzing, and evaluating structural responses and/or loads using a measurement system over a representative period of time (i.e., temporal development of the measured variable; continuous, periodic, or event-based measurements, either global or local) [1].

Monitoring is currently limited to addressing existing damages and deficits, as shown by a survey conducted by the German Federal Ministry for Digital and Transport (BMDV) among state road authorities and the Federal Highway Company. The survey, conducted in 2020, identified approximately 100 monitoring applications, which primarily involved bridges built between 1960 and 1980. The main reason for implementing monitoring was to capture structural responses, typically using deformation and temperature sensors [2].

There are several reasons why the use of monitoring on bridges along federal highways remains relatively limited. One major factor is the lack of specialized knowledge regarding the implementation of monitoring. This gap can be addressed through the development and application of standardized guidelines such as the DBV leaflet “Monitoring: Planning,

Contracting, and Operation,” the DGZfP (German Society for Non-Destructive Testing) leaflet B 09 “Continuous Monitoring of Structures,” and the pre-published report “Guidelines for Strategic Monitoring of Structures” [1; 3; 4].

Professional training, along with the involvement of engineering firms and specialist consultants for the various aspects of monitoring, can also provide valuable support. Another key barrier is the difficulty in demonstrating the economic benefit of monitoring. The methodology presented in the research project “Economic Analysis of Monitoring Measures” for evaluating the cost-effectiveness and added value of monitoring can help encourage broader adoption [5]. The high complexity of the topic - particularly regarding the planning, implementation, and evaluation of monitoring measures - is another limiting factor. In this regard, the use of defined application cases and the step-by-step introduction of new technologies within clearly defined and manageable scopes can provide effective support.

### 3 USE CASES MONITORING

The implementation of use cases is a strategy to increase the use of monitoring. Use cases can be derived from project objectives and represent processes for achieving those objectives [6]. The advantage of use cases is that the use of new technologies can be tested in defined and limited areas, allowing obstacles to be overcome. The monitoring use cases existing in the federal highway sector are shown in Figure 1.

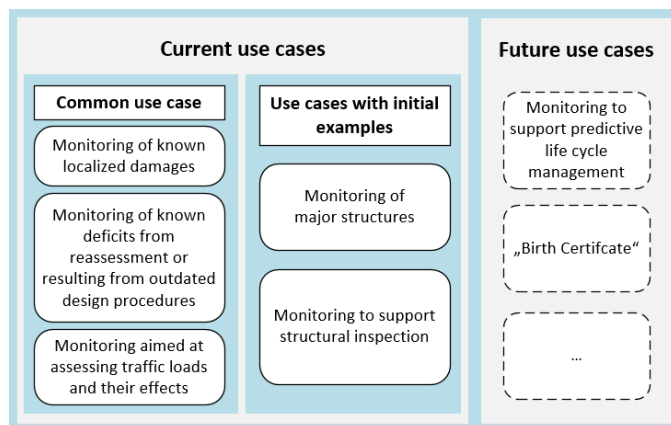

Figure 1. Monitoring use cases.

#### 3.1 Common use cases

The use cases of monitoring of known localized damages, of known deficits from reassessment or resulting from outdated design procedures and using monitoring to determine loads and loads effects representing the most common use cases in Germany. These use cases are employed to address specific questions regarding the civil engineering structures, their condition, and its development over time. Starting from known damages or deficits, a monitoring concept is developed that is tailored to the structure and the specific question at hand.

##### Monitoring of known localized damages:

In this case, a local monitoring system is typically deployed. This local monitoring provides a good opportunity for monitoring the progression of damage. By monitoring the local condition, an estimation of further local developments can be

made. This approach serves to extend the remaining service life and increase safety.

Figure 2. Bridge over the DB AG facilities along the B1 in Brandenburg an der Havel.

This use case is implemented on the bridge over the facilities of the Deutsche Bahn AG (DB AG) along the B1 in Brandenburg a der Havel (Figure 2). The structure was built in 1971 and is a single-span bridge with a span length of 47 meters. Separate, parallel superstructures carry the two traffic lanes. Their cross-sections are nearly identical and consist of two steel box girders and an orthotropic deck plate.

Numerous damages were identified on the structure during the structural inspection. These include, among others, cross-sectional reductions due to corrosion, fatigue cracks in the deck, and an abnormal positioning of the roller bearings. An object-specific damage analysis (OSA) demonstrated that the bearing positions are due to misalignment of the abutments caused by settlement. Geodetic measurements of the abutments showed that this process has not yet stabilized, indicating that further tilting is to be expected. Since the deformation capacity of the roller bearings is already highly stressed, permanent monitoring of the bearing movements is required.

Figure 3. Monitoring system on the bridge bearing.

This monitoring task is realized by installing inductive displacement transducers on each roller bearing (Figure 3) [9]. This allows for the monitoring of the remaining available bearing travel to ensure it is not exceeded. To identify long-

term trends, the measurement data from the temperature monitoring system of the superstructure are also used. Over the years, a nearly linear relationship between bearing movement and temperature has been observed (Figure 4). Changes in the regression relationship between temperature and bearing movement can serve as an indicator of a system change.

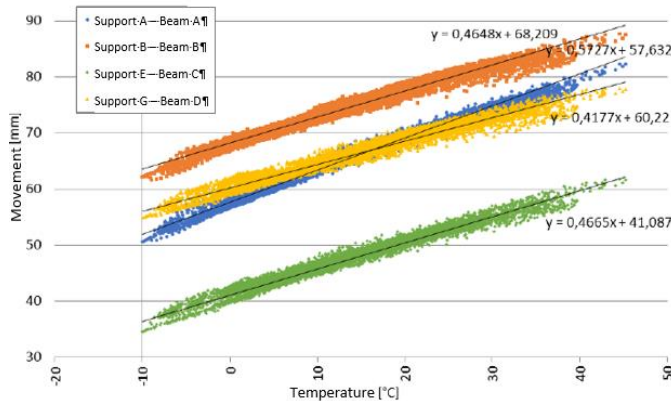

Figure 4. Evaluation of measurement data for one year.

#### Monitoring of known deficits from reassessment or resulting from outdated design procedures:

This use case is relevant when deficits in structures are identified during reassessment or when similar deficits are found in comparable constructions. Often, there are no visible damages yet, and the type or location of potential damage is unknown. Global monitoring enables the monitoring of the deficient structure. Global monitoring is designed to capture and evaluate global parameters of a structure that may indicate damage. A significant change in the global stiffness of the structure is generally required to enable precise system response measurements via global monitoring.

These parameters can be determined from the system response, for example, by measuring acceleration or deformation. The measurements serve to capture changes that develop in the structure over time. Provided the structure behaves in a ductile manner with failure warning signs, the basis for global monitoring of system reactions is that impacts and damages significantly affect the system stiffness, thereby having a direct influence on the load-bearing behavior of the structure. The various methods of global structural monitoring are based on the assumption that damages in the structure can be detected by changes in its global load-bearing behavior. Through measurements of these parameters and subsequent evaluation, conclusions can be drawn about the nature and location of the damage [10; 11].

Alternatively, global monitoring can be designed to detect the cause of the damage. For this, an acoustic emission monitoring system could be used, for example, to detect strand wire fractures in pre-stressed concrete structures [12] or fatigue crack formation in orthotropic deck slabs [13]. With a sufficiently large monitoring system, all areas where the deficit was identified can be monitored. The monitoring system detects and localizes any damage that occurs from the start of the monitoring.

The use of local monitoring can be applied, for example, in the case of fatigue in the coupling joint during recalculation deficits or shear force recalculation deficits, such as in the local

monitoring of shear areas to detect the formation of shear cracks.

Figure 5. Bridge over the Havel along the B96 in Fürstenberg/Havel.

The measure for the bridge over the Havel River along the B96 in Fürstenberg/Havel serves as an example of this use case (Figure 5). The structure was built in 1968 as a single-span pre-stressed concrete slab with a span of approximately 16 meters. Hennigsdorf pre-stressing steel was used, which is now classified as being at risk of stress corrosion cracking. As part of the object-specific investigations to verify the failure warning behavior, samples of the pre-stressing tendons were taken. Broken tendons were already identified during the sample extraction. Laboratory tests confirmed that the tendons did not meet the required fracture elongation or tensile strength. The fracture patterns show significant initial cracks due to stress corrosion cracking.

Due to the importance of the structure for traffic, closure to traffic is only permissible in extreme cases. Therefore, a monitoring system using acoustic emission was installed on-site. The measurement system consists of 12 acoustic emission sensors, each positioned outside the navigation channel of the Havel River. Since its commissioning, a total of 10 tendon fractures have been recorded at the structure by the end of 2022. Each tendon fracture triggered an event-based structural inspection.

#### Monitoring aimed at assessing traffic loads and their effects

The actions on the structure can include direct effects from external loads (e.g. dead loads, traffic loads, wind or snow loads) and indirect effects due to restrained deformations (thermal stresses) caused by climatic influences (temperature) or settlement differences.

Climatic influences such as humidity and temperature can be measured through weather stations. The impact of temperature on the structure is measured using temperature sensors within and on the structure. Determining the temperature plays an important role in compensating for the temperature effect on measurements. In certain use cases (e.g., monitoring of coupling joints), temperature is a significant influencing factor for the assessment. Traffic and the composition of traffic are also of great importance for capturing the relevant effects on bridge structures. The use of Bridge Weigh-in-Motion (B-WIM) systems can, for example, determine the actual current traffic loads [14].

Figure 6. Bridge over the Spree along the L35 in Fürstenwalde/Spree.

In the State Road Agency, a study was conducted to realistically capture object-specific target load levels. Monitoring systems were installed on individual structures to accurately record the respective boundary conditions [15]. One example is the bridge over the Spree River along the L35 in Fürstenwalde/Spree. The Spree crossing consists of a main bridge and a bridge over a side branch of the river (Archen arm) (Figure 6). The main bridge is a pre-stressed arch bridge with a span of 67 meters. The bridge over the Archen arm was constructed as a composite structure with a steel girder deck and concrete deck plate. It has individual spans of 25.5 meters, 28 meters, and 29 meters.

The determination of the target load level is relevant because there is a comparatively high traffic load and congestion due to junctions before and after the structure.

Figure 7. Measuring system on the bearing shelf/seat of the abutment.

To capture the effect, strain gauges were used, and temperature sensors were deployed to compensate for the measurement values' temperature influence. Temperature compensation in this use case is carried out in two steps: first, real-time compensation during measurement using a Wheatstone bridge; second, calibration of the recorded values by determining a baseline load level for a specific time series.

The measurement system was installed on the bearing shelf of the abutment (Measurement system on the bearing shelf/seat of the abutment, Figure 7). The verification of the measurement results was carried out through camera recordings of the ongoing traffic. The measurement took approximately two

years. As a result, it was demonstrated that the target load level BK30/30 can be justified for the structure. The subsequent recalculation revealed deficits in the fatigue performance. However, the available measurement data allows for the derivation of an object-specific fatigue load model to optimize the verification process. This step is still pending.

### 3.2 Use cases with initial practical examples

"Monitoring to support structural inspection" and "Monitoring of major structures" are use cases where initial implementations are present in practice, but further research and support for implementation are still necessary.

#### Monitoring to support the structural inspection:

As part of the structural inspection according to [8], monitoring can be used to provide supplementary information that cannot be obtained through conventional inspections. The use of monitoring is possible at various stages in the structural inspection process. One option is the use of instrumented components to assess the behavior. For example, instrumenting bridge deck expansion joints and measuring performance parameters offers the advantage that these components are repaired based on actual loading. Instrumented components provide information on existing damage to the relevant parts and, if necessary, allow the prediction of future developments [16]. By now this use case is not aligned with DIN 1076 and is currently under discussion in the relevant standardization committees.

An alternative is the use of image-based monitoring, where structural images are automatically captured, and the georeferenced 3D geometry of the structure is subsequently determined. This allows the identification of areas of the structure that should be further examined during the structural inspection.

The image data can also be used for AI-supported analysis to automate the detection of cracks, spalling, or changes [17; 18]. Extracting damage information and locations, such as cracks from the captured image datasets, parallels the system identification methods of sensor-based monitoring [19]. Parts of traditional hands-on inspections can be enhanced and improved through digital tools.

Alternatively, Virtual and Augmented Reality (VR/AR) can also be used in the context of structural inspections. In this case, image-based techniques are also applied, where image data is georeferenced and linked to an existing 3D model.

#### Monitoring of major structures:

Monitoring of major structures refers to structures whose failure would have a large impact on the transportation network. Examples of such structures include major viaducts or river crossings. For these structures, the use of monitoring can be a useful addition to ensuring availability, even when no damage or deficits are currently known. To implement this use case, identification of the relevant structures is necessary. Their significance can stem from traffic-related or structural reasons. Traffic-related reasons include the importance of the structure for network availability or high traffic volumes. Structural reasons arise from the size and location of the structure, considering any limited options for providing short-term replacement. For this use case, global monitoring is relevant. In contrast to the use case "Monitoring with known deficits," no

deficits need to be known in this case. This use case can apply to both new and existing structures.

Monitoring of major structures is more widespread abroad, as demonstrated by the monitoring of the Ponte da Lezíria bridge built in Portugal in 2007 [20]. The bridge was equipped with an extensive monitoring system to measure static and dynamic parameters. This system supports the structural inspections, and the asset owner has continuous access to an assessment of the structure's condition [20].

Similarly, at the bridge in the Digital Test Field Highway, the embedded sensors and the aggregation of the measured data provide the asset owner with continuous access to the current condition of the bridge, allowing for quick and effective decision-making when changes in the condition are detected [21]. The benefits of using preventive monitoring for bridges without existing damage have been demonstrated in [22].

### 3.3 Potential future use cases

The use case "Monitoring to support a Predictive Lifecycle Management" will gain significant importance in the context of implementing Digital Twins, which are announced in the BIM Master Plan [23]. Initial steps and ideas for implementing this use case were outlined in [19].

The potential of monitoring arises from the ability to monitor structures over long periods and detect changes. The potential lies in determining the structural condition and quantifying the reliability of the structure, characterizing the behavior of the structure with the goal of anomaly detection, and securing the remaining service life [19].

Monitoring data can provide information, for example, about damage mechanisms. This information can then serve as the basis for determining performance indicators in combination with other data. This approach aims to reduce uncertainties in the condition assessment and identify appropriate maintenance measures [19].

The use case "Birth Certificate" aims to establish a reference condition of the structure before commissioning, providing a basis for interpreting the impact of later changes and making statements about the expected behavior of the structural and equipment components. This reference condition can be compared with subsequent measurements, thus providing a decision-making foundation for determining the timing of necessary measures, such as permanent monitoring. For clarification the single measurement as mentioned above does not constitute monitoring in the classical sense, which generally implies continuous data acquisition.

The performance of a baseline measurement, including a proof load test, is mandatory in Switzerland, Italy, and France [24–26]. In [17], the performance of a baseline measurement at the Hochmosel Bridge is described. Here, in addition to vibration and strain measurements to determine the behavior of the bridge, imaging techniques were also used, among other things, to determine the 3D geometry.

## 4 INTEGRATION OF USE CASES

The interaction of the individual use cases can be envisioned through the implementation of Digital Twins. A Digital Twin can be understood as a digital representation of the real road infrastructure, which interacts with the real structure, records all properties throughout the entire lifecycle, and generates

information for decision support from the data [27]. Figure 8 provides a schematic representation of a bridge's digital twin, highlighting the various data sources and the role of monitoring within the system.

Figure 8. Monitoring as part of the digital twin according to [28].

Monitoring and the information and insights gained from it are essential foundations for the development and use of Digital Twins. The monitoring data provides insight into the current condition of the structure and serves as input data for determining future behavior. Therefore, the use of monitoring is fundamental to the processes of monitoring, analysis, prediction, and control that occur within the Digital Twin.

## 5 CONCLUSION

The use of monitoring on engineering structures of the federal highways is still not widely spread, but it is gaining in importance. Through the use cases, there is the opportunity to demonstrate the potential of monitoring and overcome barriers to its implementation. Currently, monitoring is of great importance in supporting the availability of engineering structures and, in particular, ensuring the remaining service life. A wealth of experience is already being gathered in these use cases today, which can be beneficial in the long term for the introduction of Digital Twins. Initial results, within the framework of Digital Shadows, can already demonstrate the potential on a smaller scale.

The benefits resulting from the application of monitoring measures can be quantified in monetary terms – for example, through savings on inspections, extended service life or early damage detection. In contrast, the benefits of the digital twin cannot yet be expressed in concrete figures, but they can be described qualitatively – such as improved decision-making, increased transparency regarding the structural condition and long-term potential for process optimization.

In conclusion, monitoring and the demonstrated use cases help bridge the gap between the physical structure and its digital representation.

**ABSTRACT:** This paper presents a vision for next-generation Artificial Intelligence (AI) based structural health monitoring (SHM) systems through the lens of DREAM-SHM: a framework comprising Dynamic, Real-time, Evaluative, Adaptive (AI-based), Modular, Self-diagnostic, Holistic, and Multi-sensory principles. The aim is to enable smart infrastructure that can sense, and evolve corresponding to structural behaviour, material degradation, environmental effects, and changing operational or economic constraints. The paper reviews current SHM technologies, highlighting the strengths and limitations of contact-based sensors, such as accelerometers, strain gauges, fibre optic sensors, and non-contact approaches including vision-based systems, infrared thermography, radar, and ultrasonic techniques. Emphasis is placed on their integration with wireless sensor networks, Internet of Things (IoT) platforms, and Artificial Intelligence (AI) for advanced data fusion, anomaly detection, and predictive analytics. The computational aspects underpinning SHM systems, such as cloud-edge processing, machine learning, and multi-modal sensor data integration, are described to enable timely and informed decision-making. In addition, the paper situates DREAM-SHM within the context of sustainability, demonstrating how adaptive and intelligent SHM systems support the goals of circular economy and net-zero carbon by prolonging asset life, reducing maintenance burdens, and improving environmental responsiveness. This work outlines a pathway toward structurally intelligent and resource-efficient infrastructure.

**KEYWORDS:** Structural Health Monitoring (SHM), Intelligent infrastructure, Sustainable infrastructure, Multi-modal sensing, Contact-based sensing, Non-contact sensing, Internet of Things (IoT).

## 1 INTRODUCTION

The infrastructure of the future should be smart, adaptive, and capable of responding to both operational and environmental challenges in real-time. As urbanisation continues to accelerate and infrastructure ages, ensuring safety, efficiency, and longevity of our built environment has never been more crucial. Traditional methods of structural inspection and maintenance, though important, are often time-consuming, costly, and prone to human error. The Structural Health Monitoring (SHM) paradigm offers an innovative solution to these challenges, enabling continuous, non-destructive assessment of structural integrity and performance [1-3]. SHM aims to detect and diagnose faults early, ensuring that any issues are addressed before they escalate into catastrophic failures. It involves assessing factors such as structural loads, damage status, defect localisation and quantification, growth rate estimation, future performance prediction, and remaining life estimation [1, 4, 5]. In an ideal SHM system, these evaluations are performed in real-time, providing global insights into the health of a structure as it operates [3].

At its core, SHM involves several essential components, including sensing, load identification, damage detection, damage characterisation, and future performance prediction [1, 6]. SHM systems incorporate continuous or periodic sensing and data collection, allowing for the real-time monitoring of structures under various operational and environmental loads. Sensors, whether passive or active [7], are integrated into the structure during manufacturing or retrofitted for ongoing monitoring. These sensors can be classified as contact-based (e.g., accelerometers, strain gauges, fibre optic sensors, Linear

Variable Differential Transformers (LVDT), and thermometers) or non-contact-based (e.g., vision-based systems, infrared thermography, and radar). Both types of sensors capture critical data about the structure's behaviour, environmental conditions, and operational status, transmitting this information to storage systems or cloud-based servers for analysis and decision-making [8, 9].

Contact-based sensors offer high accuracy but often require direct attachment to the structure, periodic maintenance, and replacement, resulting in increased operational costs. Moreover, critical measurement points may be difficult or impossible to access, leading to incomplete or inaccurate data [10, 11]. To address these challenges, non-contact sensors provide an alternative by enabling wide-area and mobile sensing. These sensors operate without requiring direct attachment to structures and are typically positioned at a distance. They capture optical images and videos using technologies such as digital cameras, high-speed cameras, and synthetic aperture radar from satellite sensors. Smartphone-based sensing technologies are also increasingly integrated into SHM systems, expanding their capabilities [9]. By utilising mobile platforms such as unmanned aerial vehicles (UAVs), automobiles, trains, and boats, fly-by, drive-by, tram-by, or sail-by monitoring systems can be deployed, enhancing spatial coverage and reducing data gaps. This more efficient approach enables broader monitoring capabilities across large infrastructure networks, offering a more comprehensive assessment of structural health over time.

As infrastructure becomes more interconnected and intelligent, the need for adaptive, dynamic systems that respond

in real time to changing conditions is greater than ever. This is where DREAM-SHM as a novel Structural Health Monitoring framework offers a transformative solution. By integrating contact-based and non-contact sensors, Internet of Things (IoT) platforms, and Artificial Intelligence (AI), DREAM-SHM enables structures to not only monitor their health but also adapt dynamically to both environmental and operational changes. The system continuously collects data from sensors and uses AI-driven algorithms to analyse this information, allowing the structure to respond in real time to conditions such as temperature fluctuations, humidity, material stress, and even operational demands. By optimising these factors, DREAM-SHM can maintain both the structural integrity of the building and the comfort of its occupants, while also reducing energy consumption and lowering carbon emissions. Moreover, this integration can help address issues such as overcrowding or traffic congestion by adjusting building operations based on real-time data.

This paper explores the concept of DREAM-SHM, detailing how its combination of advanced sensors, IoT networks, and AI technologies unlocks the next generation of intelligent infrastructure. It reviews the different sensor technologies used in SHM, both contact-based and non-contact, and presents a discussion of the computational aspects that enable DREAM-SHM to adapt to changing conditions. This paper explores the potential of these technologies to revolutionise infrastructure monitoring and maintenance, highlighting their ability to optimise not just structural health but also the environment within and around the infrastructure.

## 2 SENSOR TECHNOLOGIES FOR STRUCTURAL HEALTH MONITORING

SHM systems depend on sensor technologies to collect continuous or periodic data from infrastructures under operational and environmental conditions. These sensors are typically classified into contact-based and non-contact types, each with unique advantages and limitations [12]. A thorough understanding of both categories is essential for developing a more adaptive and intelligent SHM framework.

### 2.1 Contact-Based Sensors

Contact-based sensors are physically attached to the structure to capture direct measurements of parameters such as strain, stress, acceleration, displacement, and temperature. These sensors have traditionally formed the backbone of SHM systems, especially in critical and high-risk infrastructure.

#### 2.1.1 Strain Gauges

Strain gauges are widely used to measure strain resulting from applied loads. They are typically bonded to the surface of structural elements and detect minute changes in length as electrical resistance variations. Despite their accuracy, they are susceptible to environmental degradation and require careful installation and protection [13-15].

#### 2.1.2 Accelerometers

Accelerometers are essential in dynamic monitoring, capturing vibrations, modal properties, and transient responses during events such as traffic loading or seismic activity. They can be deployed in arrays across a structure to identify changes

in stiffness or detect anomalies associated with damage [10, 16-18].

#### 2.1.3 Fibre Optic Sensors

Fibre optic sensors, including Fibre Bragg Gratings (FBGs), are capable of long-range, high-resolution measurements of strain and temperature. Their immunity to electromagnetic interference and ability to multiplex multiple sensing points along a single fibre make them highly suitable for harsh environments and large-scale infrastructures [19-21].

#### 2.1.4 Linear Variable Differential Transformers (LVDTs)

LVDTs are used to measure displacement and deformation with high precision. These sensors are commonly applied in laboratory tests and long-term monitoring of joints, cracks, and bearing movements in bridges and buildings [22].

#### 2.1.5 Thermocouples and Thermistors

These sensors measure temperature variations, essential for understanding thermal loading effects on structural behaviour. They are often used in combination with other sensors to decouple environmental influences from structural responses.

#### 2.1.6 Limitations of contact-based sensors

Despite their reliability and accuracy, contact-based sensors have several drawbacks, such as installation and maintenance can be labour-intensive and costly. Sensor failure due to environmental exposure requires frequent inspection and replacement. Coverage is often limited to selected points, leading to sparse spatial resolution [23].

### 2.2 Non-Contact Sensors

Non-contact sensors offer remote sensing capabilities and are particularly valuable for large-scale structures where full-field contact-based monitoring is impractical [24]. These sensors can be deployed on stationary platforms or mobile carriers such as UAVs, vehicles, or boats to conduct “fly-by”, “drive-by”, or “sail-by” inspections.

#### 2.2.1 Vision-Based Methods

Vision-based SHM systems use digital or high-speed cameras to capture visual data from structures [25]. Techniques such as Digital Image Correlation (DIC) [26] and photogrammetry allow for the measurement of displacement, deformation, and surface cracking [27, 28]. These methods are enhanced through artificial intelligence (AI), particularly deep learning algorithms that automate defect detection and characterisation [29].

#### 2.2.2 Infrared Thermography (IRT)

IRT detects subsurface anomalies such as delamination and voids by capturing thermal patterns on a structure's surface. It is non-invasive and efficient for inspecting large areas. However, it is sensitive to environmental conditions and often requires post-processing with deep learning models to reduce false positives [30-38].

#### 2.2.3 Ultrasound-Based Techniques

Air-coupled ultrasound techniques use high-frequency waves to detect micro-cracks and internal flaws. These are particularly useful in metallic and composite materials where internal

defects may not be visible externally. Non-contact ultrasound methods allow remote application, reducing the need for physical access[24].

#### 2.2.4 Radar Vibration-Based Methods

Microwave and millimetre-wave radar systems can remotely monitor structural vibrations and dynamic responses with sub-millimetre accuracy. These non-contact methods are particularly effective for tall, slender, or otherwise inaccessible structures such as towers, bridges, and wind turbines. They offer robust performance in challenging environmental conditions, as they are less affected by lighting, fog, or moderate precipitation compared to optical techniques. Radar-based monitoring enables real-time displacement and modal analysis without requiring physical sensor installation on the structure[24].

#### 2.2.5 Magnetic-Based Techniques

Magnetic-based methods such as Magnetic Flux Leakage (MFL) and magnetostrictive sensors are used to detect stress concentrations, cracks, corrosion, and other anomalies in ferromagnetic materials. These techniques work by measuring disturbances in the magnetic field when it encounters defects or discontinuities within the material. They are particularly valuable for monitoring pipelines, prestressed cables, steel-reinforced concrete, and metallic bridge components, offering a non-destructive means of assessing structural integrity in inaccessible or high-risk environments [24].

#### 2.2.6 Wireless Sensor Networks (WSNs)

WSNs use embedded or surface-mounted sensors that wirelessly transmit structural data to remote data acquisition systems. This reduces installation complexity and allows for scalable deployment across large infrastructures. Integration with energy harvesting solutions enhances their long-term viability [24, 39].

#### 2.2.7 Hybrid and Mobile Monitoring Approaches

Combining multiple non-contact methods or integrating them with mobile platforms (e.g., UAVs or autonomous ground vehicles) provides comprehensive spatial and temporal data. These systems are especially useful for structures with limited accessibility or under high traffic loads [9].

#### 2.2.8 Advantages of Non-Contact Sensors

These sensors enable full-field and remote monitoring, reduce maintenance and installation costs, improve safety for inspectors and increase spatial coverage and flexibility.

#### 2.2.9 Challenges of Non-contact Sensors

Environmental conditions (e.g., lighting, humidity, wind) can affect the accuracy of these sensors. Data processing complexity increases with large-scale visual or radar datasets. These sensors are high dependent on robust algorithms for data interpretation.

### 2.3 Summary and Considerations

The combined application of contact and non-contact sensor technologies can provide complementary insights into structural integrity. While contact sensors offer high accuracy for localised measurements, non-contact sensors excel in wide-

area and remote assessments. The integration of AI and the Internet of Things (IoT) further enhances data acquisition, fusion, and interpretation capabilities [40, 41].

A future-forward SHM system, such as DREAM-SHM, should not only integrate these sensors intelligently but also enable self-reflection and prediction, adapting its sensing strategies based on structural performance, environmental changes, and user demands. This vision sets the stage for the next generation of intelligent, adaptive, and sustainable infrastructures.

## 3 DREAM-SHM: TOWARDS INTELLIGENT, AND ADAPTIVE STRUCTURES

The future of civil infrastructure depends on its capacity to sense, adapt, and evolve, and attributes central to the next generation of intelligent systems. In this context, this paper suggests the DREAM-SHM framework: a novel approach to Structural Health Monitoring that is Dynamic, Real-time, Evaluative, Adaptive (AI-based), Modular, Self-diagnostic, Holistic, and Multi-sensory (Figure 1).

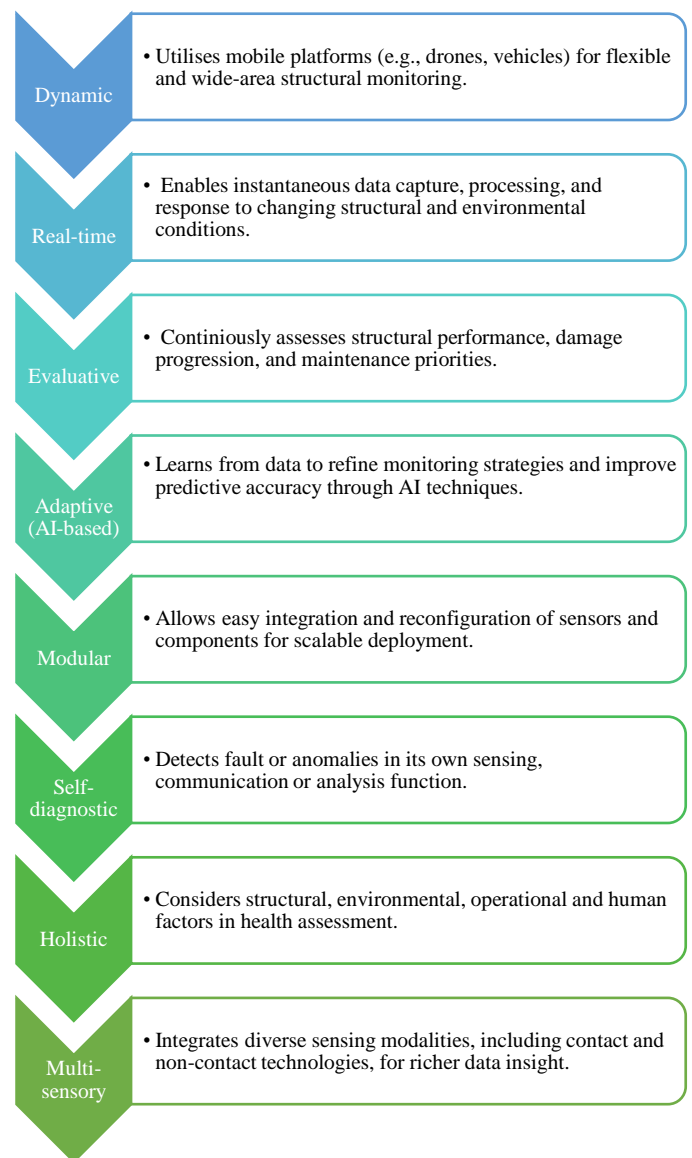

Figure 1. Elements of DREAM-SHM framework

Rather than functioning as static systems for passive data collection, DREAM-SHM envisions infrastructure as active learning, self-reflective, and responsive entities, capable of anticipating change, optimising performance, and supporting lifecycle decisions with unprecedented insight and autonomy. The DREAM-SHM system is inherently computational, relying on advanced data processing, predictive algorithms, machine learning, and cloud computing to support its highly adaptive and intelligent functionality. It operates through a robust digital backbone that enables the processing of vast amounts of real-time data, the prediction of future conditions, the optimisation of structural health, and the dynamic adjustment of environmental parameters.

### 3.1 From Traditional to Dreaming Structures

Conventional SHM systems provide snapshots of structural conditions based on sensor data. In contrast, DREAM-SHM envisions a system that continuously "dreams." That is, it reflects on past data, analyses current performance, and simulates future outcomes. Much like human brain consolidates information during sleep [42, 43], DREAM-SHM uses advanced analytics, AI, and IoT integration [44] to consolidate multisource data and learn structural behaviour patterns over time. This cognitive leap transforms infrastructure into living digital twins, constantly updating their condition, adapting to changes in the environment, and providing valuable feedback to engineers and designers.

### 3.2 Integrating Contact and Non-Contact Sensors with IoT and Data Processing Fusion

In a DREAM-SHM framework, both contact and non-contact sensors are integrated into a broader Internet of Things (IoT) ecosystem. IoT enables sensor networks to communicate, synchronise, and share real-time data through cloud computing or edge processing devices. Contact-based sensors (e.g., strain gauges, accelerometers) provide high-fidelity, localised data critical for detecting internal stress, fatigue, or localised failures, while non-contact sensors (e.g., vision systems, thermography, radar) expand coverage, capture surface conditions, and enable remote inspections.

These sensors generate large, multidimensional datasets that require careful processing and alignment to create a coherent and reliable model of the structure's condition. Advanced data fusion algorithms are applied to integrate multimodal data from multiple sources, resolving discrepancies caused by noise, sensor faults, or varying environmental conditions [39]. Techniques such as Kalman filtering, Bayesian inference, and decision tree models [45] enhance the accuracy of the fused data by accounting for uncertainties and interdependencies across sensor inputs.

IoT platforms facilitate seamless connectivity between sensors, edge devices, data storage, and decision-making systems, enabling real-time alerts, remote diagnostics, distributed data storage, cloud analytics, and cross-sensor data fusion and redundancy to reduce uncertainty. The fusion of contact and non-contact sensor data within this infrastructure supports a comprehensive, context-aware SHM system capable

of interpreting data as part of a broader ecosystem influenced by environmental, operational, and human factors [44].

### 3.3 The Role of AI in Creating Self-Adaptive Structures

AI lies at the core of the DREAM-SHM system, functioning as the central engine that empowers intelligent data interpretation, autonomous decision-making, and adaptive system behaviour. By leveraging machine learning (ML) and deep learning (DL) techniques, the system can extract meaningful patterns, detect anomalies, and respond dynamically to evolving structural and environmental conditions [46].

Deep learning models, particularly Convolutional Neural Networks (CNNs) [12, 46-48], are instrumental in analysing visual inputs from vision-based sensors or thermal imagery from infrared cameras. These networks can automatically classify and detect structural anomalies such as cracks, deformations, corrosion, or delamination, significantly reducing the reliance on manual inspections. This automation increases the speed and accuracy of damage detection while minimising human error.

AI algorithms are trained on historical and real-time sensor data to enable predictive maintenance, allowing the system to forecast when and where damage is likely to occur. In addition to supervised learning, unsupervised learning approaches are used to uncover previously unseen patterns or emerging failure modes, enhancing the system's adaptability and sensitivity over time.

AI also plays a critical role in fusing data from multiple sensor modalities, including thermal, acoustic, visual, and vibration sources. By integrating these diverse inputs, AI improves fault detection accuracy and reduces false positives. Furthermore, AI enables the autonomous operation of robotic inspection platforms, such as UAVs, which can plan flight paths, adjust actions in real time, and focus on areas of concern based on live feedback.

Reinforcement learning techniques further enhance the self-adaptive capabilities of the DREAM-SHM system. Through continuous learning, the system can optimise its monitoring strategies, improving how it prioritises sensor data, allocates resources, and adapts to changing structural and environmental conditions.

### 3.4 Dynamic, Self-Reflective, and Adaptable Systems

The DREAM-SHM system represents a significant evolution in how infrastructure is designed, operated, and maintained. At its core, it enables dynamic, self-reflective, and adaptable behaviour through the seamless integration of cloud computing, the IoT, and AI. By combining real-time sensor data with intelligent analytics, the system continuously monitors, analyses, and responds to both internal structural health and external environmental conditions.

IoT-enabled sensor networks form the backbone of this intelligent infrastructure. These networks connect contact and non-contact sensors, environmental monitoring devices, and

operational systems, allowing continuous data transmission to cloud-based platforms. Cloud computing provides the scalable computational resources needed to handle large volumes of sensor data across wide geographic areas, making it possible for engineers, facility managers, and maintenance teams to access up-to-date structural health reports, plan maintenance, and respond to safety concerns in real time. Edge computing ensures that critical decisions can be made locally and rapidly, particularly when immediate intervention is required. For example, structural anomalies detected by sensors, such as sudden changes in strain or temperature, can trigger instant responses without needing to wait for centralised cloud processing.

This intelligent system also extends to the optimisation of internal environments. By monitoring temperature, humidity, and occupancy levels, DREAM-SHM can automatically adjust heating, ventilation, air conditioning (HVAC), or dehumidification systems. These adjustments not only enhance occupant comfort but also protect structural materials from accelerated degradation, such as corrosion in steel or cracking in concrete, caused by unfavourable environmental conditions.

Moreover, the system adapts to changing operational demands. If a room becomes highly occupied, ventilation can be increased, or air conditioning fine-tuned to maintain air quality and comfort. By learning usage patterns, tracking external weather forecasts, and recognising early signs of material fatigue, AI within the system can anticipate and prepare for future operational needs. This may include adjusting HVAC schedules ahead of temperature drops, deploying shading systems in response to sunlight exposure, or activating safety protocols in anticipation of extreme weather or seismic activity.

Ultimately, DREAM-SHM goes far beyond traditional monitoring. It creates an intelligent feedback loop where data, environment, and structural health are interwoven, enabling buildings and infrastructure to adapt in real time. This not only preserves structural integrity and enhances user wellbeing, but also significantly reduces energy consumption and carbon emissions, contributing to more sustainable and resilient built environments.

### 3.5 *Designing for Longevity Through Predictive Intelligence*

One of the transformative aspects of the DREAM-SHM system is its ability to influence future design practices, material selection, and lifecycle strategies through predictive insight. By collecting and analysing long-term structural health monitoring data, the system enables the refinement of design codes based on actual performance under diverse environmental and loading conditions. This data-driven feedback loop allows engineers to make informed decisions, enhancing structural reliability and efficiency over time.

Machine learning algorithms are central to this predictive capability. Trained on historical and real-time data from contact and non-contact sensors, such as accelerometers, infrared thermography, and ultrasound, the system detects early signs of damage and estimates future deterioration, fatigue, and failure.

Time-series forecasting models, including autoregressive integrated moving averages (ARIMA) and recurrent neural networks (RNNs) [49, 50], leverage trends in sensor data to guide proactive interventions that extend the service life of the structure.

Supervised learning techniques, including decision trees and support vector machines (SVM), classify structural conditions into actionable states, while reinforcement learning enables continuous model improvement as new data is acquired. By integrating predictive models with real-time monitoring, the system enhances structural safety, minimises operational costs, and maintains optimal performance.

This fusion of predictive analytics with adaptive control transforms infrastructure into self-reflective and intelligent systems. DREAM-SHM further supports generative design processes, where artificial intelligence proposes optimised structural forms and materials tailored to specific environmental and operational conditions. Such insight enables the design of modular, reconfigurable structures that can evolve over time in response to predictive indicators. In doing so, DREAM-SHM contributes to a new generation of infrastructure that is sustainable, resilient, and energy-efficient, with a significantly reduced carbon footprint.

### 3.6 *Unlocking the Next Generation of Intelligent Infrastructure*

The implementation of DREAM-SHM signifies a fundamental shift from static to living structures. These infrastructures think through artificial intelligence and predictive modelling, feel through extensive and multimodal sensor networks, communicate through Internet of Things platforms and edge computing, and adapt based on environmental conditions, user demands, and system health. By integrating advanced sensing, communication, and intelligence, future infrastructures will no longer be passive assets, but active participants in their maintenance and evolution.

In doing so, they offer immense societal benefits, including enhanced safety and reliability, reduced maintenance costs and downtime, improved energy efficiency and user comfort, and a deeper understanding of structural behaviour over time. The DREAM-SHM paradigm represents not merely a technological upgrade, but a philosophical reimagining of what infrastructure can be, structures that not only endure but evolve, guided by the very data they produce.

## 4 DREAM-SHM, CIRCULAR ECONOMY AND NET ZERO GOALS

The transition towards smarter infrastructure must be harmonised with global imperatives such as the circular economy and the pursuit of net zero carbon emissions. The DREAM-SHM framework, defined as Dynamic, Reflective, Evaluative, Adaptive, Modular, Self-diagnostic, Holistic, and Multi-sensory naturally aligns with these objectives by enabling more efficient, resilient, and sustainable infrastructure systems throughout their entire lifecycle.

### 4.1 *Enabling Resource Efficiency and Longevity*

One of the primary pillars of the circular economy is resource optimisation through prolonged material use, reusability, and

reduced waste [51]. DREAM-SHM contributes to this by allowing structures to continuously evaluate their health, detect minor degradations before they escalate, and schedule maintenance proactively. Such real-time diagnostics reduce the need for premature demolition or over-conservative replacement strategies. The *modular* and *adaptive* attributes of DREAM-SHM also support retrofitting and component-based upgrades, enabling structures to evolve without complete reconstruction, an essential strategy in circular design.

#### 4.2 Data-Driven Lifecycle Decision-Making

DREAM-SHM's use of AI and IoT technologies facilitates whole-life performance monitoring. This continuous data stream allows engineers, asset managers, and policymakers to make informed decisions that extend beyond first costs, incorporating embodied energy, operational efficiency, and end-of-life recyclability. For example, the system can inform decisions about optimal repair versus reuse, estimate embodied carbon for design alternatives, or determine the feasibility of adaptive reuse of ageing infrastructure.

#### 4.3 Supporting Carbon Emission Reduction

Smart structures equipped with DREAM-SHM do not only monitor their mechanical performance, they also track environmental parameters such as energy use, indoor temperature, humidity, and CO<sub>2</sub> levels. These insights enable buildings and infrastructures to dynamically adjust internal conditions to optimise comfort and reduce energy consumption, especially under varying occupancy patterns or extreme climate conditions. Integration with renewable energy sources and smart energy grids can further reduce reliance on fossil fuels, directly supporting net zero building operations.

Moreover, DREAM-SHM facilitates operational carbon tracking, where the carbon cost of maintenance activities and material replacements can be quantified in real-time. This capability encourages low-carbon interventions, the use of environmentally friendly materials, and the minimisation of transport or logistical carbon footprints.

#### 4.4 Designing for a Regenerative Future

The holistic nature of DREAM-SHM, combined with its dynamic and evaluative features, can help shift the infrastructure sector from a linear to a regenerative model[52]. Rather than just sustaining performance, future structures can be designed to learn, evolve, and regenerate over time. By treating structures almost like living systems, ones that sense, learn, and adapt, DREAM-SHM lays the foundation for self-regulating and self-improving built environments.

This continuous evolution aligns with the vision of net positive design, where buildings not only minimise harm but actively contribute to ecological and social value. For instance, a bridge equipped with DREAM-SHM could dynamically coordinate traffic to reduce congestion-related emissions or monitor its own runoff water quality and feed data back into environmental management systems.

#### 4.5 Digital Twin Synergies

Another key synergy lies in the integration of DREAM-SHM with digital twins[53, 54], creating a real-time, data-enriched virtual model of the structure. These twins can simulate environmental impacts, forecast degradation under climate

stressors, and test low-carbon renovation scenarios before implementation. This predictive capability enhances resilience planning and supports sustainability certification and reporting frameworks.

#### 4.6 Energy Efficiency and Sustainable Power Supply

For DREAM-SHM to be deployed at scale and operate autonomously, it must also be energy-conscious. The system leverages low-power wireless sensor networks (WSNs)[55], which minimise energy usage through efficient communication protocols and duty cycling. Where possible, sensors and edge computing units are powered by renewable sources, including solar panels mounted on structures and wind energy microgenerators integrated into exposed components. Additionally, the framework supports energy harvesting, converting ambient vibrations, thermal gradients, or even electromagnetic noise into small but continuous power sources for embedded sensors. This self-sufficiency allows long-term deployment without frequent battery replacements, reducing both maintenance burdens and electronic waste. By embedding energy-awareness into its architecture, DREAM-SHM aligns itself with net-zero goals not only in terms of what it monitors but how it functions, enabling smarter, cleaner, and more self-reliant infrastructures.

#### 4.7 Example of potential performance of a DREAM-SHM system

To demonstrate the potential of the DREAM-SHM framework, imagine a long-span bridge operating under extreme weather conditions and subject to cyclical loading. During a sudden windstorm, real-time data from accelerometers, fibre optic strain sensors, and vision-based surface monitoring systems are synchronised through the IoT layer and processed at the edge. The AI engine identifies anomalous vibration patterns that signal early-stage fatigue in a critical joint. At the same time, thermal imaging highlights abnormal heat signatures associated with bearing friction. The digital twin continuously simulates the structural state and projects the need for a targeted inspection as conditions stabilise. In response to predictive outputs, the system autonomously modifies traffic flow and delivers a real-time alert to maintenance teams. Concurrently, environmental control systems within nearby infrastructure are adjusted to reduce energy use due to temporary low occupancy. This scenario illustrates how the DREAM-SHM framework functions as an adaptive, multi-sensory, and context-aware system, supporting decision-making under dynamic operational demands.

## 5 CONCLUSION

This paper presents a conceptual perspective for a future SHM system: DREAM-SHM as summarised in Figure 2.

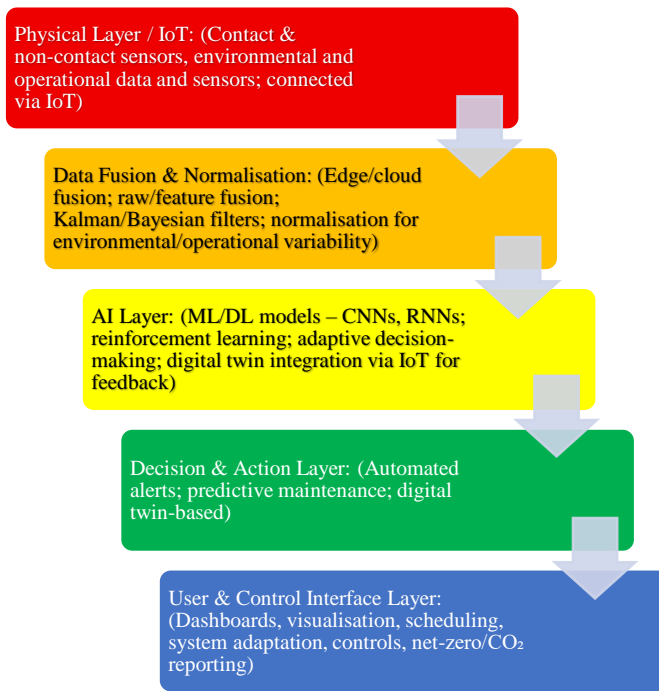

Figure 2. Schematic of the layers of FREAM-SHM framework

This system represents a significant leap forward in structural health monitoring and management. By combining advanced sensor technologies, AI, IoT, and predictive analytics, it provides a comprehensive solution for real-time, adaptive, and sustainable infrastructure management. The computational framework driving the system ensures it can process vast amounts of data, predict future structural performance, and optimise operational conditions dynamically.

While the DREAM-SHM framework offers transformative potential, its implementation at scale presents several challenges primarily rooted in interdisciplinary coordination. Successful deployment requires the integration of diverse expertise across structural engineering, data science, sensor technologies, and artificial intelligence, which demands not only cross-disciplinary collaboration but also specialised training to bridge gaps in knowledge and practice. From an ethical standpoint, careful consideration must be given to the types of human and operational information shared with the system, particularly in contexts involving surveillance, usage patterns, or sensitive infrastructure behaviour. In addition, maintaining cybersecurity and the resilience of communication networks becomes critical, as the framework relies on distributed sensing, edge processing, and cloud-based integration. Despite these challenges, the practical realisation of DREAM-SHM remains promising. The system unlocks the next generation of intelligent infrastructure, where structures are not only monitored but also able to self-adapt and self-maintain. By doing so, DREAM-SHM promotes safety, efficiency, and sustainability in the built environment, while also providing a unifying platform that encourages collaboration between academia and industry. It serves as a compelling motivation for advancing research, developing standards, and forging partnerships that can help turn this vision into reality.

**ABSTRACT:** As global infrastructure ages and demands on new and existing structures increase, effective monitoring programs are essential for managing risk and public safety. This paper provides a practical guide for practitioners to design and implement structural health monitoring (SHM) systems, leveraging the combined expertise of the authors, who have extensive experience with leading equipment manufacturers.

Building on the 10 Steps of Data Acquisition System Design, the paper outlines best practices for developing robust monitoring systems tailored to bridges, dams, and other critical infrastructure. These steps include defining objectives, selecting appropriate sensors, communications design, data acquisition (DAQ) system design, power system considerations, civil works and mounting structures, installation, and managing data effectively.

A significant focus is placed on sensor and DAQ selection, exploring their critical roles in SHM system performance. The paper covers practical techniques for selecting, installing, maintaining, calibrating, and verifying sensors across traditional analog, frequency, and digital technologies. Examples from large channel count wired systems and distributed wireless monitoring systems are shared to illustrate diverse applications.

This paper aims to deliver actionable insights and practical wisdom, equipping attendees with the tools to overcome real-world challenges and achieve reliable, scalable, and long-lasting SHM implementations.

**KEY WORDS:** Structural Health Monitoring (SHM); Data Acquisition System Design; Sensor Selection; Critical Infrastructure Monitoring; Risk Management; Monitoring System Implementation; Wireless and Wired Monitoring

## 1 INTRODUCTION

Improvements and technological developments in sensors, data acquisition systems, and software in recent years have enabled engineers to implement advanced monitoring solutions on critical Structural Health Monitoring (SHM) projects worldwide. These systems often comprise hundreds or even thousands of sensors, delivering real-time performance data through synchronized acquisition platforms and intuitive visualization tools.

These developments, coupled with a rising demand for timely and reliable data, often exceed the capability of that which can be manually collected or interpreted, and thus necessitates the need for robust automation for real-time monitoring to detect potential hazards in advance.

Today, automated monitoring systems are far more cost-effective, reliable, and user-friendly than ever before, making them feasible not only for large projects with many sensors, for a more comprehensive assessment of structural behavior, but also for smaller-scale projects which, until recently, were rarely considered for, or enjoyed the benefits of automation.

There are also those projects, which started out as being manually read, but later moved to automated systems because of one or all the following: being unable to find enough qualified staff to read all the instruments, being unable to safely access the instruments to read them manually and being unable to obtain reliable data through manual readings.

While automated monitoring systems help reduce the burden on project owners by enabling reliable and timely data collection without interfering with ongoing construction

activities. They also facilitate the early identification of potential issues, allowing for prompt implementation of corrective measures. Moreover, the development of wireless network technologies has made it easier to expand or reconfigure monitoring systems quickly, with minimal disruption to both the existing setup and the construction process. To support this progression from concept to implementation, Figure 1 illustrates a logical sequence of design steps that guide the development of a robust SHM system.

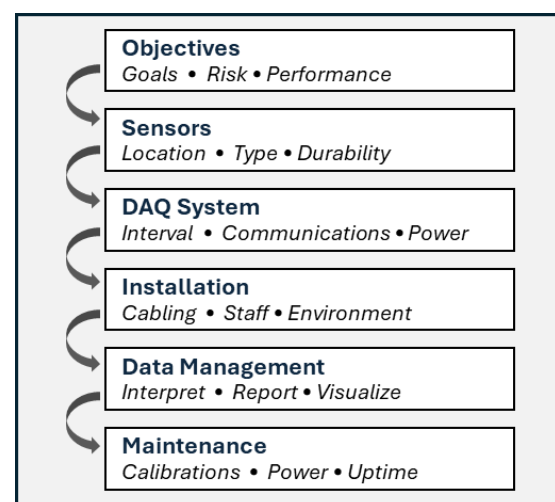

Figure 1: An overview of the SHM design process.

## 2 MONITORING OBJECTIVES

The success of any SHM project, whether automated or manual, hinges on meticulous planning, precise execution, and the development of an action plan (or plans) to address the findings based on the collected data. Peck's Observational Method laid the foundational philosophy for most monitoring programs, which Dunnicliff further enhanced with a detailed, systematic approach.

Essentially, Peck emphasized the importance of defining the geotechnical questions that need to be answered and then selecting the appropriate instruments and their placement to help answer those questions; stating, without a question, there is no need for instrumentation. Dunnicliff expanded on this by underscoring the necessity of defining the purpose of the instrumentation, asserting that it should only be used if there is a valid, defensible reason.

### 2.1 *Define the Appropriate DAS*

Before the Data Acquisition System (DAS) is designed, consideration should be given to the present (and future) scope of the monitoring system, with a bias on starting simple, using systems that are easily scalable as the project needs grow, and only implemented when required, after the initial system is functioning and is well understood.

Other considerations should determine the choice between site vs cloud hosted platforms, subscription vs capital expenditures (CAPEX), the ultimate sensor, DAS, and software suppliers, the maintenance requirements and who will be ultimately responsible for operation of the DAS the over the life of the project. When these decisions have been made, we can then start to look at sensor selection and DAS design in earnest.

### 2.2 *Stakeholders and their Interests*

Structural Health Monitoring (SHM) projects often involve a wide range of stakeholders, each with distinct objectives, responsibilities, and perspectives on data utility. Key stakeholders typically include project owners, engineers, contractors, regulators, insurers, asset operators, and in some cases, the general public. Project owners and developers are primarily motivated by risk reduction, cost control, and regulatory compliance, often seeking early warnings to avoid catastrophic failure and unplanned downtime. Engineers use monitoring data to validate design assumptions, assess structural behavior under real-world conditions, and guide adaptive decision-making during construction or operation. Contractors may rely on SHM data to sequence work safely, protect temporary works, or defend against claims. Regulators and permitting authorities seek assurance that infrastructure meets safety and environmental standards, with SHM providing a traceable, defensible record of performance. Insurers may view monitoring as a tool to reduce liability and claims exposure by demonstrating proactive asset management. Operators and maintenance teams use SHM systems to prioritize interventions, plan maintenance efficiently, and extend the life of the structure. Finally, for high-visibility projects, community stakeholders and the public may demand transparency and accountability—especially when safety is a concern—making clear, visual communication of monitoring data essential. Understanding these varied

motivations is crucial in designing a system that delivers the right data to the right people at the right time.

## 3 SENSORS

Sensors general definition, sensors are devices that detect and respond to physical input from the environment in which they are installed. Inputs may include parameters such as temperature, strain, pressure, deformation and inclination, or other environmental or structural conditions. Sensors then convert their input into signals that can be read by an observer, with a portable readout instrument, or with an electronic system, such as a computer or DAS.

The choice of any sensor is determined, for the most part, by the application and the environment in which they are to be deployed. As they must function satisfactorily, often under very harsh conditions, throughout the life of the project, they should be as simple in concept as is consistent with their function (with respect to accuracy, repeatability and response time).

Additionally, they should be robust and reliable, to be durable under the environmental and operating conditions in which they will be deployed and, ideally, have a satisfactory (well proven) performance history. Moreover, the sensors should provide optimum cost benefit ratios to deliver acceptable performance throughout the life of the project considering the sum of purchase, installation, maintenance and monitoring.

For critical applications, and/or at primary monitoring locations, consideration should be given to adopting back-up instruments, maybe of a different technology to corroborate the measurements provided and/or to substitute in the event of primary sensor failure or damage.

### 3.1 *Sensor Selection*

In keeping with the intent of this paper, with respect to best practices and practical wisdom, it is appropriate, at this point, to remind ourselves of the systematic approach to designing monitoring systems as defined by John Dunnicliff in his renowned book, "Geotechnical Instrumentation for Monitoring Field Performance" published in 1988. In this context he identified 25 important steps to be considered and, wherein, the selection of the sensors comes in at step number 8, after steps addressing; the project conditions, mechanisms which control behavior, the purpose of the instrumentation and the parameters to be measured, the predicted magnitudes of change, the remedial action to be made and the responsibility of the various stakeholders. Readers are encouraged to read more on this subject in Chapter 26 of the aforementioned reference.

When selecting a sensor, several factors need to be considered to ensure it meets the requirements of your application. Following are some key factors:

**Type of Measurement** - The primary consideration is to choose a sensor which can detect the measurand, i.e. the specific physical quantity, object or property to be measured (e.g., temperature, pressure, strain, load etc.).

**Environmental Conditions** - Consider factors such as temperature, humidity, chemicals and electromagnetic interference which can affect the sensor performance. Keep in mind too, not only any limitations of the sensor in adverse environments, but also and associated cabling or conduits.

**Durability and Lifespan** - For harsh or long-term applications, sensor ruggedness and reliability are critical, check with the manufacturer for compatibility and compliance.

**Measurement Range** - Ensure the sensor's measuring range aligns with the physical range of the application to obtain precise readings. While choosing a sensor with a range greater than that which is likely to be measured may be considered safe, be mindful of any corresponding loss in accuracy and resolution.

**Accuracy and Precision** - Ensure the sensor provides the necessary accuracy (how close a measurement is to the true or actual value) and precision (how close repeated measurements are to each other) for your application

**Resolution/Sensitivity** - Understand what the smallest change in measurand is that the sensor can deliver and check to determine that the DAS to which the sensor will be connected can discriminate such changes (see also Measurement Range above)

**Response Time** - As some applications (esp. real-time systems, and where dynamic measurements are required) often need sensors with fast response times, ensure that the selected sensor can satisfy same or, with the appropriate DAS, be readily converted from one taking static measurements to dynamic measurements.

**Excitation and Power Consumption** - Is especially relevant in battery-powered or remote systems, therefore it is necessary to ensure the DAS can deliver the required excitation and, at the same time, not introduce any errors into the measurements.

**Output Type and Signal Conditioning** - Understand whether the sensor outputs analog or digital signals, or communicates via protocols like I2C, SPI, etc. and if the associated DAS requires protection circuits and signal conditioners to minimize electrical noise and errors. (Digital sensors are often preferred over analog sensors as they can reduce errors during data conversion)

**Size and Mounting Constraints** - It is important to understand the physical dimensions and weight of the sensor, and how and where it will be installed. Make sure adequate space is available for installation and that any fixtures required for mounting will not affect sensor operation or performance. Ensure that the physical size or weight of the sensor does not negatively impact the environment being measured.

**Calibration and Maintenance** - Understand any calibration and maintenance requirements required for the sensor to continue to deliver according to its stated accuracy or, where sensor access and recalibration is not possible, opt for sensors with proven long-term stability (See also Section 3.3)

**Price and Availability** - Does the price of the sensor meet the budget and is it readily available for deployment according to the project schedule and/or in the event replacements are needed. Consideration might also be given to the budget for more costly (reliable) sensors for long-term applications where replacement is not possible.

Careful consideration of these factors will help you choose a sensor that is efficient, reliable, and cost-effective for your specific needs.

### 3.2 Sensor Installation

Sensor performance is often only as good as the way in which it was installed. Therefore, it is critical that the correct installation procedures are followed and documented. Of

course, installation methods will vary according to sensor type but adhering to the following guidelines will help deliver reliable performance and accurate data.

#### Plan Installation Procedures (Dunnicliff)

- Prepare written step-by-step procedures well in advance of scheduled installation dates
  - Including a detailed listing of required materials and tools
- Prepare installation record sheets
- Plan staff training
- Coordinate installation plans with the construction contractor
- Plan access needs and any protection of the installed instruments from damage/vandalism
- Prepare installation schedule consistent with the construction schedule.

#### Pre-Installation Tests (Dunnicliff)

- Check the Documentation
  - Check, by comparing with procurement document,
  - That model, dimensions, and materials are correct
  - That quantities received correspond to quantities ordered
- Check the Instruments
  - Check the cable length(s)
  - Check tag numbers on instrument & cable
  - Verify that all components fit together in the correct configuration
  - Check all components for signs of damage in transit
- Check Data Provided by the Manufacturer
  - Examine factory calibration curve & tabulated data, to verify completeness
  - Examine manufacturer's final quality assurance inspection checklist, to verify completeness
- Function Checks
  - Connect to readout & induce change in parameter to be measured
  - Make and remake connectors several times, to verify correct functioning
- Calibration Checks (Note: This is an approximate check only)
  - Check 2 or 3 points if possible
  - Allow sensors to come to thermal equilibrium
  - Check Zero reading
  - Calibrate any Readout Instruments (used during installation and troubleshooting) regularly

### 3.3 Sensor Calibration & Maintenance

Where accuracy, reliability and consistency are required it is particularly important that sensors are calibrated correctly and in accordance with internationally recognized standards.

**Accuracy** - Certain sensors may drift over time and, if not regularly calibrated, can report biased data. Calibration

guarantees that the sensor output is traceable to a known standard or reference which is critical when taking trustworthy measurements for confident decision making. (Where sensors are inaccessible after installation consider using types with proven long-term stability).

**Consistency** – Where different sensors are used in any one project, calibration allows data from each device to be compared over time. For example, two temperature sensors, from the same batch, may read slightly differently unless calibrated.

**Safety and Compliance** – It goes without saying that incorrect readings can lead to safety hazards including loss of reputation, asset and or life. Therefore, it is common practice for regulatory standards to require periodic calibration to maintain certification and indemnity.

**System Performance** – In digital twins, where historical data is integrated with, and relies upon, updates from sensors in DAS to represent near real time status, it is of paramount importance that sensors are properly calibrated as small inaccuracies can propagate and degrade the system's overall performance or decision-making.

**Cost Savings** - Accurately calibrated sensors help prevent inaccurate data from causing false conclusions, resource waste, and or project failures and delays.

Similarly, sensor maintenance is equally important as it contributes to ensuring accuracy, reliability, and longevity, all of which are critical for making informed decisions, maintaining asset quality, complying with safety standards, and avoiding costly downtime or repairs.

## 4 DESIGN - DATA ACQUISITION SYSTEM

A DAS—also referred to as a DAQ, ADAS, or ADAQ—is the electronic backbone of any SHM program. It serves to collect, condition, log, and transmit sensor data from the field to the end user or database. Effective DAS design must align with the sensor types and quantities, sensor placement, measurement timing requirements, communication protocols, and site-specific environmental constraints. Additionally, DAS architecture should anticipate future scalability, integration with other systems, maintenance access, and power availability.

### 4.1 System Architecture & Scalability

DAS architectures for SHM systems typically fall into two categories: **centralized (wired)** and **distributed (wireless)**. In practice, hybrid approaches are often adopted to best suit varying site conditions, sensor layouts, and project phases.

**Centralized (Wired) System** – Often built using a customizable datalogger or modular components, a centralized system offers the flexibility and expandability to read a wide variety of sensors and can often be expanded to be a high channel count or high speed system.

Advantages include:

- Easier serviceability and diagnostics via a single access point
- Superior time synchronization across measurements
- Suited for real-time or safety-critical applications

- Flexibility in supporting advanced measurements and redundancies
- Robust power backup options

Additional considerations or challenges may include:

- Longer sensor cable runs may increase cost
- Higher initial setup time and effort

**Distributed (Wireless) DAS** – These involve smaller, self-contained DAS nodes placed closer to sensor clusters and typically use radio, LoRa, or cellular protocols for data transmission.

Advantages include:

- Reduced cabling complexity
- Modular installation
- Natural electrical isolation (air gap) for surge protection

Additional considerations or challenges may include:

- Requires management of wireless networks and data synchronization
- Battery-powered nodes may limit lifespan or require frequent servicing
- Multiple access points for maintenance

**Scalability** – A good DAS design should accommodate changes in monitoring scope over time. Scalability should include:

- Additional sensor capacity (via modularity or spare channels)
- Upgradeable communications infrastructure
- Data routing to multiple stakeholders or databases
- Power system upgrades (e.g., larger solar arrays, battery banks)
- Lifecycle support—ensure vendors provide long-term maintenance and part availability over the next 1, 5, or 10 years.

### 4.2 System Timing

Time management is central to a reliable monitoring program, understanding the different timing intervals is needed to ensure that the system operates as intended. Pro-Tip: just because you can collect data fast doesn't necessarily mean that you should. Timing considerations may include:

- **Sampling Rate:** Frequency of raw sensor measurements
- **Recording Interval:** Frequency of data logging, which may include statistical reduction (min/max/avg)
- **Transmission Interval:** Frequency of data being sent to the database/user
- **Measurement Synchronization:** How critical it is for measurements from different sensors or systems to be time-aligned. This becomes increasingly important—and potentially more complex—when multiple data acquisition devices are deployed across a site, especially when correlating events across a site.

### 4.3 Data Collection

The frequency of data collection and transmission should align with the decisions that rely on that data. Data must be transmitted—and reviewed—at intervals no longer than the maximum time allowed to respond to undesirable system behavior. For instance, a safety monitoring system may require data transmission every second to enable timely alarms that protect personnel. In contrast, a system used for regulatory reporting might only need to collect data monthly or quarterly, often in conjunction with manual site inspections.

### 4.4 Communications

Communications are typically considered in two layers: onsite communication between sensors, loggers, and gateways; and offsite communication from a device to the cloud, server, or database. Each layer offers various communication methods, but these can generally be categorized into two types—wired and wireless—each with its own set of considerations.

**Wired-Onsite:** Ideal for permanent installations, wired onsite systems offer high reliability and noise immunity but require protected cable routing and can be more costly initially but may have a lower total cost of ownership (lower maintenance). Onsite wired systems may use a combination of copper or fiberoptic cables to address communication distance or electrical noise interference challenges. A wired onsite system is generally built for the specific and exclusive needs of the monitoring system.

**Wireless-Onsite:** Enable fast, modular deployment in difficult locations but require careful planning for power, interference, and network management. Generally built using radios that offer a point-to-point or mesh network communication. Wireless performance and protocols used are based on the selected wireless technology.

**Wired-Offsite:** Wired offsite connections deliver secure, consistent performance but is reliant on existing network infrastructure or it may need to be added. Typically, this taps into an existing ethernet network that is already existing or needs slight improvements to accommodate the needs and connection points of the monitoring system.

**Wireless-Offsite:** Wireless offsite communication provides flexible, trench-free connectivity for remote sites, but it depends on external networks and typically requires a subscription. Most often, this involves using a cellular or satellite network managed by a third-party provider, accessed through a compatible modem and associated service plan.

**Pro Tip:** When considering a communication option, consider seasonal conditions, for example, a radio network installed in the winter/spring may work great but the added vegetation in the summer could significantly impact onsite radio performance or give consideration to winter conditions where deep snow may cover communication antennas.

### 4.5 System Power: Power Budgeting & Backup

The power system is the backbone of any remote data acquisition system and is often a primary point of failure if not properly designed. Power configurations can range from simple, single-use batteries that require periodic replacement to advanced systems incorporating solar panels, charge controllers, and rechargeable batteries—ideal for long-term or high-demand deployments. Self-contained DAS units often

favor compact, non-rechargeable batteries for their simplicity and reliability, while modular or scalable systems typically use rechargeable batteries paired with external charging sources such as solar or AC power. Because total power consumption depends on design decisions—like sensor type and duty cycle, logging hardware, communication method (e.g., radio, cellular, satellite), and data collection frequency—the power system should be specified last. When designing it, account for worst-case scenarios such as reduced battery performance in cold temperatures, limited sunlight during winter months, and extended outages caused by events like snow-covered solar panels.

### 4.6 Installation Considerations

A successful installation requires careful planning and thorough verification of sensor operation, wiring, communication links, and power systems—both in the office and in the field. Equipment should be securely mounted in enclosures designed to withstand environmental challenges. When selecting cabinets or enclosures, consider factors such as humidity, temperature extremes, corrosive environments (e.g., seawater or acidic mine conditions), lightning protection, and the need for secure mounting. A site visit before installation is essential to assess available utilities, site conditions, cable routing, and required structures for a quality setup. As with any project, qualified personnel are crucial to ensure proper handling, installation, and operation verification. Comprehensive documentation is key to a quality installation, outlining system operations, wiring, equipment labeling, and data access. Since deployed equipment often transitions through multiple field staff over time, well-documented and carefully executed installation practices help ensure the system's longevity, beyond the tenure of any individual staff member.

## 5 MAKING SENSE OF THE DATA

The objectives of a monitoring system must be clearly defined at the start of any project. The data produced should directly address the specific questions that need to be answered. The value of any monitoring system's data depends on its interpretability, reliability, and ability to be transformed into actionable insights for key stakeholders.

### 5.1 Data Interpretation

Interpreting sensor data depends on the type of measurement and the reference baseline used for comparison. Measurements with clear reference points—such as water level (relative to elevation) or tilt (relative to gravity)—are easier to understand, and thresholds can easily be established based on design specifications or comparing to other sensors. However, measurements like strain may be more relative and require establishing a baseline at installation or during an initial project event. Regardless of the sensor type, engineers must interpret data within the context of the monitored structure, considering sensor placement, behavioral characteristics, environmental conditions, and long-term performance trends.

### Questionable Data & Anomalies

All monitoring systems will generate data that raises questions at some point. Questionable data may stem from external

factors, such as environmental changes or nearby construction activities, or issues within the measurement system itself, such as sensor interference from electromagnetic noise, damaged cables, or inadequate power supply. Additionally, stakeholders might question data when it contradicts project schedules or crew activities, often to avoid disruptions.

When data is questioned, a useful first step is to ask: "Is what I'm seeing possible, or am I dealing with a faulty measurement?" In cases where the data could impact safety or project costs, the system should incorporate redundant measurements using different technologies to quickly verify whether the reported data reflects actual site conditions. While anomalies may initially appear alarming, they can often become part of the normal dataset as understanding of the system's behavior improves over time. Caution is needed when dismissing outliers as anomalies, as this could result in missing genuine early warnings. If a sensor consistently generates unreliable data, further investigation is necessary to address the root cause.

### 5.2 Reporting & Visualization

Data that cannot be easily understood or communicated effectively will not be used. The key question in determining how to report or visualize data is: who will use this data, and what format will best help them understand it? Technical users, such as engineers and scientists, may prefer raw data, like simple tables, for further analysis. In contrast, data intended for the general public should be presented visually, with clear indicators of what the data represents, where it's installed on the structure, and what thresholds exist and what to do if those thresholds are met. Many SHM projects involve multiple audiences, so data presentation should evolve to meet the needs of different stakeholders throughout the project's lifecycle.

## 6 CONCLUSION

Over the past ten years or so, modern DAS has played a key role in supporting site decisions that enhance the health and safety critical projects, and those working on them, all the while delivering significant time and cost savings during construction and operation and providing input for safer and more cost-effective designs.

Advances in sensor technology, data acquisition systems, and cloud computing have resulted in many monitoring programs involving a greater number of instruments than previously used, all of which collect data at much higher frequencies and generate vast volumes of information.

Thus, it is purported that a well-designed data acquisition system (DAS) will offer several key benefits, especially on projects which involve a large number and variety of sensor types:

**Data Integration Across Sensor Types** - Seamlessly collects and unifies data from diverse sensors (e.g., geotechnical, structural, environmental), enabling holistic analysis and reduces the need for manual aggregation or format conversions.

**Real-Time Monitoring and Alerts** - Enables high-frequency data collection and real-time transmission, which facilitates immediate alerts when thresholds are breached, thereby improving safety and responsiveness.

**Improved Data Quality and Reliability** - Minimizes data loss, signal noise, and errors through appropriate filtering, calibration, and validation, thus ensuring accurate and consistent data across all sensor types.

**Scalability and Flexibility** - Supports the addition of new sensors and or sensor types or locations without re-engineering the entire system and adapts to evolving project needs, whether during construction or long-term monitoring.

**Centralized Data Management** - Consolidates data into a single, accessible platform, reducing fragmentation and enhancing collaboration among engineers, analysts, and decision-makers.

**Efficient Data Processing and Visualization** - Supports automated analysis, dashboards, and trend detection, reducing time spent on manual review and enabling timely insights to inform decision-making.

**Reduced Operational Costs** - Lowers labor costs associated with manual readings and data handling, while minimizing downtime and damage through proactive maintenance.

**Enhanced Regulatory Compliance and Reporting** - Provides traceable, well-documented data logs to meet legal, environmental, or safety standards, and simplifies reporting for stakeholders and authorities.

In closing, the authors wish to remind readers that it still remains appropriate, that no matter how well an instrumentation DAS and monitoring program is designed, it will ever replace the need for site surveys and visual inspections. While monitoring can check specific points continuously, and alert if alarm conditions are exceeded (in a timely manner), site surveys and visual inspections (although less frequent) allow for "macroscopic" observations to be made, that a network of instruments could quite easily miss; be warned.

# From Insight to Action: Deploying SHM for a suspension bridge

Heikki Lilja<sup>1</sup>, Atte Mikkonen<sup>2</sup>, Eero Ukkonen<sup>3</sup>

<sup>1</sup>HLC Analytics, Finland; <sup>2</sup>SOFiN Consulting; <sup>3</sup>Savcor Oy

**ABSTRACT:** This paper presents the implementation of a structural health monitoring (SHM) system for a suspension bridge approaching the end of its service life. Constructed in the 1960s with a 220-meter main span, the bridge is the sole vital link to a region hosting key socioeconomic industries. Over time, heavy traffic—with vehicles often exceeding 80 tons—has led to pronounced fatigue issues. Throughout its operational life, extensive repairs—such as the addition of a cantilevered pedestrian lane, modifications to the bearing system, and hanger replacements—have been undertaken. More than a decade of monitoring via over 50 sensors has yielded comprehensive data that both ensures safety and informs maintenance strategies. A sophisticated finite element (FE) model, developed in 2023 and calibrated using real-time data, improved the correlation between simulated and actual performance. Following this, a streamlined near-real-time monitoring framework was established in early 2024 to promptly identify structural anomalies. Designed for adaptability, the SHM system can be implemented on various structures. This study highlights the importance of clear data presentation in enabling informed decisions that optimize infrastructure management and enhance operational safety.

**KEY WORDS:** SHM, suspension bridge, fatigue, data-informed decision making, safety, reliability, FEM, predictive maintenance, sustainability

## 1 BACKGROUND AND MOTIVATION

Ensuring the safety and longevity of aging infrastructure is increasingly challenging as many critical bridges worldwide approach or exceed their intended service life. Traditionally, structural integrity is assessed via periodic inspections—typically every three to six years—which may overlook gradual deterioration. Historically, bridge monitoring data has been analyzed on a case-by-case basis, a fragmented approach that hinders a comprehensive understanding of structural behavior over time. A shift toward a structured and standardized methodology is essential to interpret monitoring results more effectively, optimize sensor placement, reduce instrumentation costs, and fully leverage the rich datasets available. Grounded in big data principles, such an approach can transform stored information into actionable insights.

Constructed in the 1960s, the case bridge is the sole transportation route serving a region with vital socioeconomic industries. Unlike modern bridges, it was designed based on historical traffic load models that did not anticipate today's heavier vehicles and increased traffic density. Heavy trucks, often exceeding 80 tons, regularly traverse the structure, introducing forces well beyond the original design assumptions. Although various repairs have been undertaken over the years, concerns regarding progressive material fatigue and overall structural performance persist.

In response to these challenges, an SHM system was implemented to deliver real-time insights into structural behavior—facilitating early anomaly detection, proactive maintenance, and a reduction in the risk of sudden failures. By integrating continuous monitoring with analytical tools, this system represents a significant advancement in managing aging infrastructure.

Figure 1. The case bridge.

## 2 CHALLENGES IN MAINTAINING AGING BRIDGES

A significant portion of the bridge network was constructed over 50 years ago, using traffic load models that are no longer representative of current conditions. At the time of design, fatigue considerations were not always fully incorporated into design practices, leading to unforeseen long-term issues. Suspension bridges, such as the case bridge, face particularly complex challenges. Increased traffic loads exacerbate non-linear deformations and amplify fatigue effects, contributing to localized failures.

Traditional periodic inspections suffer from significant blind spots. Critical issues such as fatigue cracks and unforeseen deformations can evolve and propagate well between scheduled evaluations, resulting in missed opportunities for early intervention. This limitation underscores the urgent need for continuous, data-driven monitoring to capture dynamic structural behaviors in real time.

While periodic inspections provide valuable assessments, they

often fail to capture detailed long-term behavioral trends. Undetected fatigue cracks, excessive displacement, or gradual load redistribution may develop between inspections, increasing the risk of structural failure. This growing need for a proactive approach has driven the development of Structural Health Monitoring (SHM) systems. By continuously tracking critical parameters, SHM provides timely insights into bridge performance, allowing for early interventions and more informed maintenance decisions.

### 3 KEY STRUCTURAL CHALLENGES AND REPAIRS OF THE CASE BRIDGE

One of the problems detected has been the formation of fatigue cracks in the wind bracings, which has altered the bridge's behavior. In some cases, these changes have been noticeable under traffic loads, with visibly increased vibrations and unexpected movement patterns. However, assessing whether the main load-bearing components have also been affected remains a challenge.

Another significant concern was the corrosion of the hangers, particularly the shorter ones. Due to their positioning, these hangers experienced greater angular movements as the main cable deformed under traffic loads. This fluctuation in stress accelerated wear, leading to localized material deterioration. In 2020, a heavily corroded hanger was removed and subjected to laboratory testing, which provided crucial insights into the remaining safety margins of the hangers. The results confirmed that the less-corroded hangers were still within operational limits.

Figure 2. Corroded hanger

Figure 3. Installation of temporary hanger bars.

Additionally, the ongoing construction of a new cable-stayed bridge to the west of the case bridge has introduced further challenges. The transportation of construction materials over the existing bridge has led to increased loads, while related

activities—such as the drilling of large-diameter steel piles and controlled blasting—have induced minor disturbances. The continuous monitoring system has furnished real-time insights into the bridge's condition, thereby ensuring its safe operation throughout these construction activities.

These challenges illustrate the limitations of relying solely on periodic inspections. Although past repairs addressed specific damage, they did not provide a comprehensive picture of the bridge's evolving condition. This underscores the critical need for continuous monitoring to detect subtle structural changes before they escalate into major failures.

### 4 DESIGN AND IMPLEMENTATION OF SHM SYSTEM

The case bridge is equipped with over 50 sensors, including strain gauges, displacement sensors, accelerometers, as well as temperature and wind sensors. These instruments provide a comprehensive dataset for assessing the bridge's structural behavior under varying conditions. Over its lifespan, additional sensors were installed to monitor specific concerns, such as localized fatigue-prone areas; however, until recently, data analysis was performed sporadically and primarily in response to observed anomalies.

In 2023, the construction of a new bridge adjacent to the case bridge prompted a shift toward a more structured and systematic data analysis framework. The client required assurance that the existing bridge could safely serve its final years of operation while construction was ongoing. Consequently, a daily evaluation system was introduced to track changes in load distribution, deformations, and stress concentrations over time.

This transition from sporadic analysis to continuous monitoring has provided deeper insights into the bridge's behavior, significantly enhancing the ability to detect subtle structural changes before they escalate into critical issues. By integrating real-time sensor data with analytical tools, the monitoring framework has evolved from a reactive assessment method into a proactive instrument for infrastructure management.

### 5 FINITE ELEMENT MODEL CALIBRATION

Before beginning the more detailed structured data analysis phase, a state-of-the-art nonlinear finite element (FE) model of the case bridge was developed. This model was designed to replicate the bridge's actual behavior under modern traffic loads, using sensor data for validation. However, early comparisons between the model and real-world measurements revealed significant discrepancies, indicating that the first iteration did not fully capture the actual structural response.

This phase was crucial in enhancing the understanding of the bridge's performance. Iterative refinements identified previously overlooked structural traits, leading to a more accurate representation of the bridge's behavior. To ensure reliable comparisons, known heavy vehicles with documented

axle weights were used as test loads during operation, allowing for direct validation of the model against real-world conditions.

Figure 4. 3D visualization of the FE model.

For example, calibration provided insights into the behavior of the elastomeric bearings between the deck structure (a concrete slab with longitudinal steel girders) and the main steel truss. The bridge deck was observed to move unpredictably in both longitudinal directions, raising concerns until the behavior was computationally verified and found to be harmless, given the bridge's remaining service life.

Figure 5 deck structure supported by the steel cross truss by elastomeric bearings.

This movement had not been anticipated; the elastomeric bearings had deteriorated to such an extent that their response was no longer elastic and, therefore, not linear. Instead of behaving elastically, the bearings acted as fixed supports until the friction between the rubber and steel was overcome, causing them to slide. This resulted in residual movement, which initially caused confusion until it was successfully captured in the FE model and understood. A comparison of monitoring results and the FE model (depicting the movement of the concrete slab relative to the cross beam) is shown in Figures 6 and 7.

Figure 6. relative displacements while a vehicle crossing the bridge (monitored results). Staggered displacements showed the friction exceeded on the bearing leading to residual displacement at the end.

Figure 7. Analysis results of the differential displacement between the deck and the cross truss. Elastic bearings (left) vs nonlinear (sliding) bearings.

Another complex aspect addressed was the behavior of the replaced hanger. The original corroded hanger, consisting of a pair of spiral cables arranged perpendicular to the bridge axis, was replaced with two steel bars. Unlike the cables, the new steel bars run along the bridge axis, allowing for their installation before dismantling the existing hangers. However, this configuration complicates load distribution predictions. Additionally, the longitudinal steel bars are susceptible to bending, particularly when the superstructure sways in the bridge's longitudinal direction. A refined analysis helped define the expected range of stress variations and identify conditions requiring closer monitoring—such as instances when a hanger comes into contact with the edge of its recess.

Figure 8 compares the monitoring readings in 4 strain gauges to the FE model under service loads.

Figure 9. Hanger arrangement resulting in bending stresses due the superstructure longitudinal movement,

Figure 10. Hanger arrangements in the FE model.

Most of the main elements were easier to model; as an example, Figure 11 shows the typical behavior of main truss stresses and Figure 12 shows the typical behavior of the stresses in cross beam diagonals.

Figure 11. Main truss stresses (measured/modelled).

Figure 12. Cross beam diagonal stresses (measured/modelled).

The calibration of the FE model against monitoring results provided assurance that the behavior of the bridge is well understood, enhancing the potential for data-driven decisions.

## 6 REAL-TIME MONITORING FRAMEWORK

To manage the vast amounts of sensor data efficiently, an automated preselection of loading events was introduced. This system relies on a designated "trigger sensor"—in the case bridge, the maximum deflection of the main span. Each day, the ten most severe loading events are identified, ensuring that comparisons are made based on similar traffic conditions.

Once trigger events are selected, a full one-minute dataset is retrieved for all sensors, ensuring that both immediate effects and short-term recovery behaviors are captured. To establish a reference point for long-term monitoring, the first 30 days of operation were designated as the baseline, against which all subsequent readings are compared.

For comparative analysis, stress and displacement fluctuations under traffic loads were selected. These results provide insights into structural response variations and were also utilized for fatigue analysis of critical details.

The real-time monitoring system is accompanied by a standardized dashboard, which presents weekly summaries of key indicators. This allowed the Client to easily track trends

without needing to analyze raw data manually. While the current monitoring system does not yet fully utilize advanced AI tools, its structured approach has already demonstrated reliability, providing trustworthy insights that inform safety decisions.

The work done in the calibration of the FE model offered such detailed insights into the bridge's behavior that it significantly enhanced our interpretation of the monitoring results, enabling us to differentiate between normal operating patterns and potential anomalies.

Figures 13 to 15 illustrate the primary views of the dashboard, which facilitates the detection of both long-term trends and short-term changes in the bridge's behavior. The dashboard is engineered to emulate the analytical interpretations of an experienced structural engineer, significantly reducing the time required for data interpretation while still necessitating periodic expert review—an achievement made possible by advances in AI. Notably, the fatigue view has spurred a spin-off project aimed at developing comprehensive fatigue assessment software applicable to any structure monitored by the system, including preliminary studies on HFMI-treatment in line with the forthcoming second-generation Eurocodes.

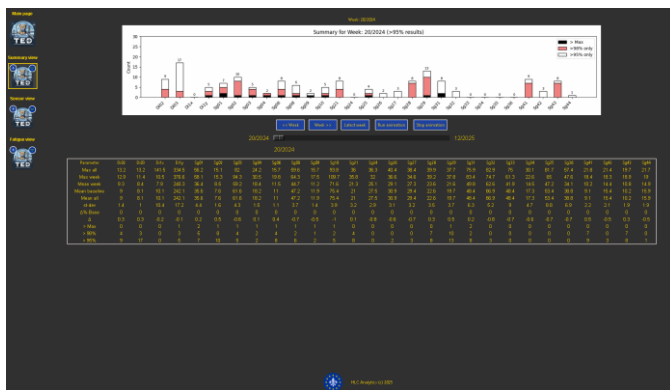

Figure 13. Summary view of the dashboard.

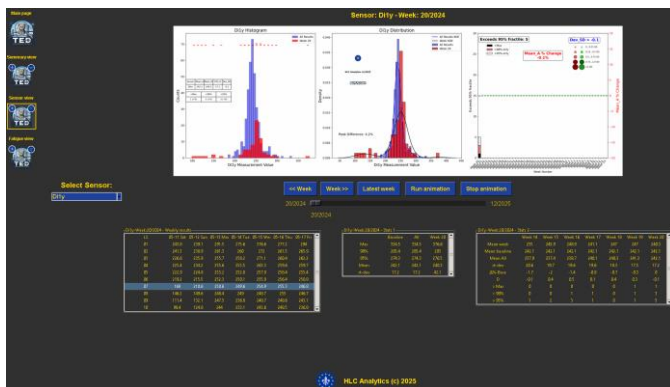

Figure 14. Detailed sensor-view of the dashboard.

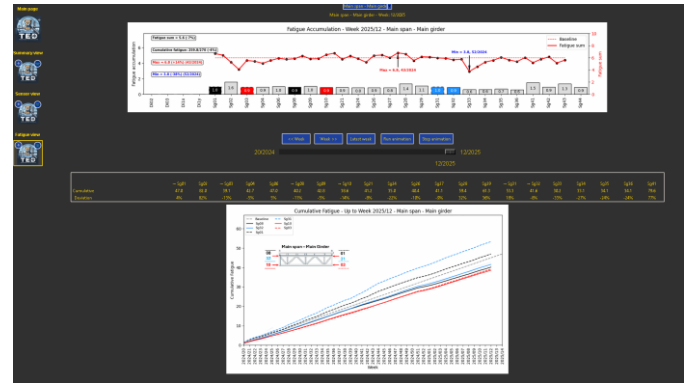

Figure 15. Fatigue-view of the dashboard.

The dashboard will provide clear alarms when anomalies are detected, offering users the ability to explore the data further. Each meaningful event can be visualized as needed, enabling a deeper understanding of the bridge's condition and facilitating informed decision-making.

In addition to these dashboard views, a largely automated weekly report and other analytical insights are provided. The implementation of this system reduces the active expert time required from hundreds of hours to single-digit hours per report. Naturally, any detected changes in behavior can trigger more in-depth studies.

## 7 EXAMPLES OF ABNORMALITIES DETECTED WITH THE INSTALLED SHM-SYSTEM

The new hangers have occasionally exhibited higher stress values, indicating that relative motion is occurring between the hangers and the deck. This behavior is likely driven by temperature-induced movements of the main cables, although displacements from heavy traffic loads are also contributing—especially if the deck does not fully return to its original position after loading. As a result, this relative motion may cause the hanger bars to contact adjacent structural components, leading to elevated strain gauge readings. Since the hanger bars are designed with considerable built-in safety factors, these modest increases (occasionally up to 50%) in sensor readings do not presently signify an immediate structural risk; however, if not adequately addressed through maintenance, they could eventually evolve into more critical issues.

The changes in the behavior are well seen when the fatigue accumulation for the hanger bars is plotted for each week (see Figure 16), from week 47/2024 the Fatigue accumulation increases strongly.

Following the removal of a cover plate (see Figure 17), stress levels temporarily decreased, only for similar patterns to re-emerge a few weeks later. Although the current stress levels are not critically hazardous, the repeated contact between the hanger bars and adjacent structural elements could eventually lead to fretting fatigue cracks. As a precaution, immediate repairs to widen the openings around the bars were

recommended. These stress increases were quickly detected by the dashboard, which employs AI algorithms with accuracy comparable to that of a human expert, ensuring that such anomalies are reliably flagged.

Figure 16. Sudden increase in fatigue accumulation of new hanger bars

Figure 17. Contact of the hanger bar and cover plate

Additionally, significant deflections and stress variations were detected sporadically, often coinciding with instances when heavy vehicles failed to comply with the new restrictions. Camera footage confirmed that two—or sometimes even three—heavy vehicles crossed the bridge simultaneously (see Figure 18). Although the occurrence of multiple heavy vehicles clearly violates the established restrictions, these restrictions remain essential, as frequent violations could have a much more detrimental impact than isolated incidents.

Figure 18. Two heavy vehicles at main span

## 8 BROADER APPLICATIONS OF THE SHM SYSTEM

The development of the SHM dashboard was carried out in close collaboration with the Client responsible for the bridge's safety. Their involvement ensured that the system presented clear, actionable information, making it easier to interpret monitoring data without requiring specialized expertise. As a result, the dashboard became a practical tool for real-time decision-making, rather than just a data visualization platform.

Bridging the gap between large-scale monitoring efforts and local stakeholders is crucial. Often, local communities must place their trust in decisions made at a national or corporate level. By bringing monitoring tools closer to end clients and asset owners—through transparent, standardized, and analytically robust dashboards—we empower them with the insights needed for informed decision-making. This approach not only enhances transparency but also fosters a culture of shared responsibility and improved safety at the local level.

Due to its successful implementation, the system was designed with scalability in mind, allowing it to be applied to other projects with minimal modifications. The fundamental approach—selecting relevant loading events, establishing a baseline, and tracking deviations—can be adapted to any bridge or infrastructure type. In fact, this methodology extends beyond bridge SHM and can be used in any time-series data analysis application where there is a need to detect long-term trends or sudden changes in any monitored metric.

Furthermore, a deep understanding of the bridge's structural behavior enables the optimization of sensor placement. This refined design not only enhances data quality but also reduces the number of sensors required, thereby lowering the overall costs of individual monitoring projects.

Recognizing this potential, developers began shifting focus toward building a next-generation standardized SHM analysis

dashboard. The next iterations will incorporate AI-assisted automated damage detection and advanced pattern recognition, allowing engineers to identify anomalies without needing to manually go through raw data. Importantly, all collected data has been stored in a structured format, ensuring that future enhancements—such as machine learning-based predictive maintenance—can be integrated without requiring a complete system overhaul.

Even in its current form, without full AI-driven analysis, the SHM system has proven reliable and trustworthy, providing the data necessary for the Client to make informed maintenance decisions. As computational power increases, real-time monitoring will continue evolving, allowing asset owners to shift from reactive to fully predictive maintenance strategies, ultimately reducing costs and improving safety across critical infrastructure networks.

## 9 CONCLUSIONS AND FUTURE PERSPECTIVES

Effective infrastructure management relies not just on data collection but on extracting meaningful insights from vast amounts of sensor information. To make data-informed decisions, monitoring systems must filter out irrelevant readings while capturing every critical structural event. In this project, a trigger-based system was implemented to identify the most relevant high-load situations per day, ensuring that engineers could track changes in bridge behavior over time without being overwhelmed by excessive data.

The high-flying promise of adopting a structured and analytical approach in SHM lies in transforming ‘known unknowns’ into ‘known knowns.’ By systematically standardizing data analysis, we can significantly enhance the reliability of our decision-making processes. This increased understanding naturally leads to improved safety, cost reductions, and substantial socioeconomic benefits. Ultimately, a more data-informed framework will pave the way for more predictive and preventative maintenance strategies.

Future iterations of the system will incorporate more trigger-sensors, improving detection accuracy and allowing for a more detailed understanding of how different parts of a structure respond to varying loads. Additionally, with advancements in automated data processing and machine learning, monitoring systems will not just detect anomalies but ultimately also predict future deterioration trends, enabling truly proactive maintenance strategies.

For long-term viability, monitoring frameworks must remain scalable and adaptable, allowing new technologies to be integrated without major system overhauls. Greater emphasis should also be placed on load testing and FE-model calibration, ensuring that monitoring data is interpreted within a robust engineering framework.

As SHM systems become more mainstream and data handling becomes more systematic, there is a significant opportunity for transfer learning. By systematically analyzing results from a diverse range of structural configurations, it will be possible to

enhance the understanding of different structural behaviors. This transfer learning process has the potential to greatly amplify the benefits of SHM in the future, enabling more accurate predictions and more efficient maintenance strategies for a wide variety of infrastructure types.

We are confident that soon, extremely cost-efficient real-time SHM systems will become a standard part of infrastructure management, allowing asset owners to make fully data-driven maintenance decisions. This shift will significantly reduce long-term costs while improving the safety and reliability of critical infrastructure worldwide.

# Use of Monitoring for Highway Bridges on Federal Highways in Germany – Current Status and Future Development

Iris Hindersmann<sup>1</sup>, 0000-0002-9875-1106

<sup>1</sup>Federal Highway and Transport Research Institute, Brüderstraße 53, 51527 Bergisch Gladbach, Germany  
email: hindersmann@bast.de

**ABSTRACT:** The use of monitoring for bridges on federal highways is currently not widespread. Monitoring is primarily used when damage is already present or when deficits resulting from the recalculation or which occur due to the design. The potential of monitoring to support maintenance towards a predictive lifecycle management approach is not being fully utilized.

As part of the exchange with the structure managers in Germany and a literature search, it has been shown that the challenges lie in the lack of standardization, insufficient expertise, and missing fundamental principles. To address these challenges, various research projects have been planned and carried out. These include the “Documentation on Monitoring of Bridge Structures,” the “Guideline – Strategic Use of Monitoring for Civil Engineering Structures,” the “Birth Certificate for Bridge Structures,” and the project on “Standardized Data Models.”

This article aims to present the challenges and initial solution approaches from these projects. The goal is to illustrate support options for the increased and targeted use of monitoring in bridge structures on Germany’s federal highways. Additionally, the article provides a classification of these challenges within the European context.

**KEY WORDS:** monitoring, road bridge, standardization

## 1 INTRODUCTION

The bridges on federal highways face a variety of challenges. The main causes include the significant increase in traffic, especially in freight transport, the advanced age of the bridges, and a backlog of maintenance measures. Monitoring offers a way to address these challenges. It can be used effectively to ensure availability by detecting, assessing, and tracking safety reserves, changes, and weaknesses, thereby enabling predictions of future behavior. Additionally, monitoring allows for the recording of actual loads and impacts.

The data obtained through monitoring can support and optimize maintenance management, as it enables a more precise assessment of the current condition and better forecasting of condition changes. This, in turn, helps gain valuable time for necessary repair measures or replacement constructions.

However, the full potential of monitoring has not yet been realized. This article discusses the use of monitoring in Germany, as well as challenges in Europe, and particularly Germany. It serves as a foundation for identifying necessary developments and projects that can promote a more extensive and targeted application of monitoring.

## 2 MONITORING – CURRENT STATUS

### 2.1 General

Monitoring refers to the overall process of recording, analyzing, and evaluating structural responses and/or impact factors using a measurement system over a representative

period. This includes tracking the temporal development of the measured variable through continuous, periodic, or event-based measurements, both on a global and local scale [1].

The effective use of monitoring encompasses the entire process, from the “definition of the research question” to the “evaluation.” This process ensures that monitoring contributes to answering open questions related to a structure. [1; 2].

The goal of monitoring is to obtain additional information about the condition of the structure. This information serves as a basis for describing the current state and deriving forecasts for future behavior. The results can then be used to make maintenance decisions on a more informed basis.

### 2.2 Current use of monitoring

A survey conducted by the Federal Ministry of Transport in 2020 revealed that the use of monitoring for bridges on federal highways is limited to existing damage and deficits. The 100 monitoring measures identified in the survey primarily focused on bridges built between 1960 and 1980 and reflected the typical distribution of bridge types on federal highways, with a particular emphasis on prestressed concrete bridges (Figure 1 and Figure 2). The monitoring measures were mostly carried out to capture the structural response using deformation and temperature sensors [3].

Figure 1: Age of the structures with monitoring

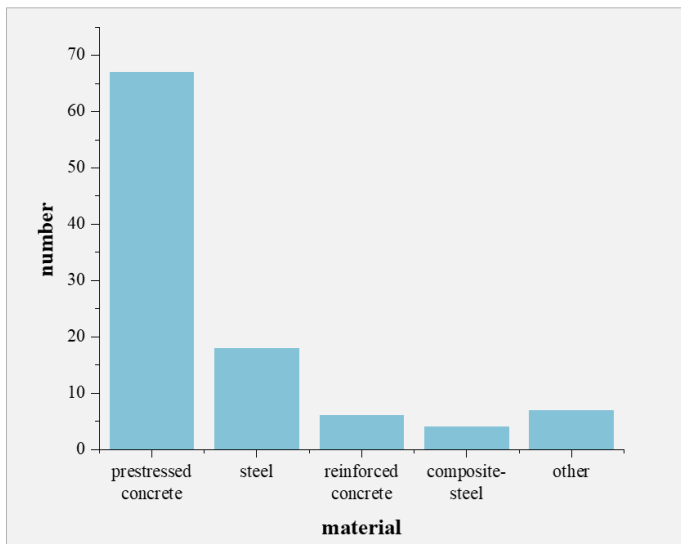

Figure 2: Material of the bridges with monitoring

The potential that monitoring offers to support maintenance decisions through additional information is not being utilized. Decisions are made on a case-by-case basis, relying on the individual knowledge of the structure managers and their supporting teams.

### 2.3 Cost-benefit of monitoring

Compared to other compensatory measures such as traffic restrictions, the use of monitoring is applied significantly less frequently. However, the benefit-cost ratio of using monitoring as a compensatory measure is very high. Monitoring allows for the continued operation of a structure under traffic. Alternative traffic-related compensatory measures would include speed limits, the closure of individual lanes, or even entire bridges. Reference [4] demonstrates that alternatives to monitoring have significant economic impacts. These impacts include, for example, congestion costs and detour costs, which in turn lead to increased environmental pollution and loss of travel time.

Increased use of monitoring can therefore also have positive effects on the economy, the environment, and social aspects.

### 2.4 Use cases of monitoring

To enable a structured analysis of the previous case-by-case decisions regarding monitoring measures, the existing application examples were categorized according to the reasons for implementing monitoring. The goal was to enable a standardized assessment. During the evaluation of the previous monitoring applications, it became evident that a systematic approach can be derived in relation to individual use cases. Use cases are known from the BIM methodology and are derived from the project goals [5].

The following commonly used use cases can be derived: "Monitoring of known locally identified damages," "Monitoring for deficits from recalculations and construction," "Monitoring for determining loads and impacts," and "Construction-related monitoring." (Figure 3) [6; 7].

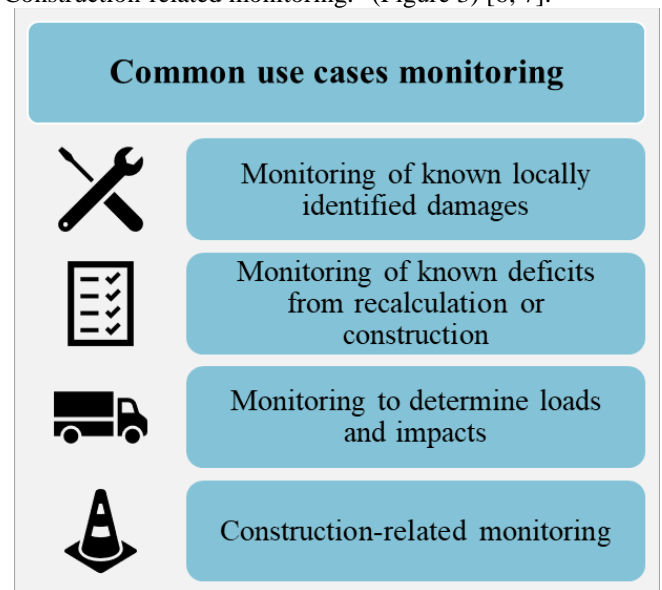

Figure 3: common use cases of monitoring (Modified according to [6])

Monitoring of known locally identified damages is used when structural inspections reveal damages such as corrosion or fatigue cracks. Typically, a local monitoring system is employed to track the progress of damage. The goal is to extend the remaining service life and ensure adequate safety.

Monitoring for known deficits arising from recalculations or due to construction-related factors is used when deficits are identified in a structure or in structures with a similar design. However, visible damage does not necessarily need to be present at this stage. In this case, a global monitoring system can be used to capture the overall structural response, or a local monitoring system can be employed to monitor critical areas. Examples of this use case include structures with stress corrosion cracking or joint connection issues.

Monitoring for determining impacts is used to capture external factors such as traffic loads or climatic conditions. For instance, Bridge-Weigh-in-Motion (B-WIM) systems can be used to determine actual traffic loads. This information is particularly useful in the recalculation of bridges starting from recalculation stage 3 [8].

Monitoring during construction is used to track the performance of structures in real-time while they are being built or if construction work is taking place directly next to the

structure. This type of monitoring allows for immediate identification of issues such as unexpected deformations or material behavior, enabling timely adjustments. It helps ensure that the structure is being constructed according to design specifications and that any potential risks are mitigated early in the process. Examples include monitoring during the construction of new bridges or during major rehabilitation projects.

In addition to the common use cases, it is also possible to derive use cases with initial use examples, such as the monitoring of special structures or future use cases such as the certificate of birth. However, these applications currently play a subordinate role in the maintenance of structures.

### 2.5 Challenges in the use of monitoring

The reasons for the limited use of monitoring on federal highway bridges so far are diverse. Figure 4 provides an overview of the challenges that arise throughout the entire process, from planning to evaluation. The main causes include a lack of standardization, insufficient expertise, and missing fundamental principles [9].

Figure 4: challenges in the use of monitoring

One challenge in the use of monitoring is the lack of standardization. Currently, monitoring is decided on a case-by-case basis, and there are no standardized guidelines for tendering, awarding, evaluating, or selecting a monitoring system. Defining use cases [6], describing individual monitoring methods [10], or outlining processes and stakeholders [1; 2] could help address this issue. In this context, templates for tender documents could, for example, provide valuable support.

Another crucial aspect of the lack of standardization is the absence of an established regulatory process. Currently, the use of monitoring is neither mandated nor recommended in any official guidelines. As a result, a key challenge is demonstrating the economic benefits of monitoring. In cases where damage or deficits are already present, the necessity is usually straightforward to justify, as all alternatives involve compromises in safety or availability. However, if monitoring is to be used proactively as a basis for better maintenance decisions in the future, the cost-effectiveness of the measure must be evaluated. This requirement has led to only sporadic use so far. Approaches from projects such as the “Economic

Feasibility Study of Monitoring” offer valuable solutions but are rarely applied in practice [4]. The establishment of standardized processes is still pending. However, with the revision of DIN 1076, monitoring can be integrated into the structural inspection and maintenance process [11; 12]. This step is crucial for a more widespread and targeted use of monitoring. Additionally, incorporating monitoring aspects into existing guidelines, such as the “Manual for the Awarding and Execution of Freelance Services in Road and Bridge Construction” (Handbuch für die Vergabe und Ausführung von freiberuflichen Leistungen im Straßen- und Brückenbau - HVA F-StB), could further support the standardization process [13].

Another important aspect is the lack of expertise. Monitoring involves a high level of complexity, for example, in preparation of a monitoring plan, selecting the appropriate monitoring concept from various offers, or evaluating the results in terms of their significance for structural maintenance. The acquisition of the necessary expertise is not a standard part of the training for those responsible for infrastructure. Therefore, it is essential to either obtain this knowledge independently or compensate for gaps by involving specialized personnel, such as engineering office. The lack of expertise also results in an absence of confidence in applying monitoring effectively, making it difficult to recognize its benefits for structural maintenance.

In some areas, fundamental principles for the use of monitoring are still missing. This is particularly evident in data management. Efficient data collection, reduction, analysis, and storage, as well as the development of user-friendly solutions for all stakeholders, are crucial. At the same time, data security and ownership must be ensured, especially when granting usage rights to third parties. Additionally, integrating monitoring data with structural models and embedding them into maintenance management systems to derive relevant key performance indicators is another essential step toward the broader and more targeted application of monitoring.

## 3 PROJECTS TO SUPPORT THE TARGETED USE OF MONITORING

### 3.1 General

At present, various fundamental principles for the targeted and standardized use of monitoring are available. The currently existing foundations include:

- DBV Guideline: "Monitoring: Planning, Tendering, and Operation" (DBV-Merkblatt - Monitoring: Planung, Vergabe und Betrieb“) [1]
- DGZfP Guideline B 09: "Continuous Monitoring of Structures" (DGZfP-Merkblatt B 09 „Dauerüberwachung von Bauwerken“) [14]
- Directive SE05: "Detection of Tendon Wire Breaks Using Acoustic Emission Analysis (Richtlinie SE05: Detektion von Spanndrahtbrücken mit Schallemissionsanalyse) [10]

In addition to these guidelines, several projects have been initiated with the goal of promoting the more widespread and targeted use of monitoring, thereby addressing various challenges. The following research projects have been initiated, conducted, or supported by the Federal Highway and Transport

Research Institute (Bundesanstalt für Straßen- und Verkehrswesen BAST):

- Documentation: "Monitoring in Bridge Structures" (Erfahrungssammlung "Monitoring bei Brückenbauwerken") [15]
- Guideline: Strategic Use of Monitoring for Engineering Structures (Leitfaden – Strategischer Einsatz von Monitoring für Ingenieurbauwerke) [2]
- "Birth Certificate" for Bridge Structures (Geburtszertifikat für Brückenbauwerke) [16]
- Documentation on the Application of Innovative Methods in Condition Assessment, with a Focus on Standardized Data Models (Erfahrungssammlung über die Anwendung innovativer Verfahren in der Zustandserfassung insbesondere bzgl. standardisierter Datenmodelle) [17]

The following sections introduce these projects and illustrate how they contribute to developing solutions for existing challenges.

Table 1 consolidates the challenges and current projects of BAST. It assesses the extent to which these projects are suitable for addressing the existing challenges. The results presented in Table 1 are further elaborated in the chapters discussing each individual project.

Table 1: Consolidation of Challenges and Current Projects

challenges	lack of standard-ization	lack of expertise	lack of fundamental principles
documentation of monitoring experience		++	
guidelines to the strategic use of monitoring	+	++	+
birth certificate	+	+	+
standardized data models	+	+	++

### 3.2 Documentation: "Monitoring in Bridge Structures"

In recent years, documentations have been created on several topics commissioned by the BAST. These serve to compile and systematize the experiences gained so far in specific areas [15; 18]. As such, they represent an initial step in preparing a topic for practical application. The documentations have always been structured in an analogous manner, with examples of applications related to bridges being compiled after an initial categorization.

The documentation on monitoring is divided into two main sections: one focuses on the state of the art in monitoring, and the other presents a collection of examples of monitoring measures carried out in Germany [15].

The main section "State of the Art in Monitoring of Structures" defines the monitoring objectives, which primarily focus on capturing various structural responses, such as deformations or crack developments. The measurement techniques applied in practice are assigned to the respective measurement objectives. Additionally, information about the functioning and performance of the measurement technology, as well as the information gained, is provided. Notes on the limitations of monitoring and quality assurance supplement this section.

The second main section contains a collection of examples of selected monitoring measures. The categorization in this part is based on the monitoring objectives developed in the first main section. Building on this, specific monitoring projects and their results are described. The reasons for monitoring, relevant structural features, measurement goals, employed measurement technology, responsibilities in the monitoring process, information gained, and data management are detailed. Additionally, statistical evaluations on tenders, awards, and the responsibilities of the stakeholders in the monitoring process are presented.

The documentation, with its structured and uniform presentation of examples, provides a good entry point into the topic and can contribute to building the necessary expertise in this field.

### 3.3 Guideline: Strategic Use of Monitoring for Engineering Structures

The Guideline - Strategic Use of Monitoring for Engineering Structures was developed based on the requirements of infrastructure managers [2]. The goal of the guideline is to provide a practical guide for the targeted use of monitoring in engineering structures, particularly bridges. The project aims to support infrastructure managers throughout the entire process of planning, implementing, and evaluating monitoring measures.

The research project combined literature reviews, expert interviews, online surveys, and workshops to compile challenges and essential foundations for the strategic use of monitoring. The report defines use cases for monitoring, ranging from monitoring localized damage to the use of digital twins for predictive lifecycle management, and describes the project participants and the process from defining the issue to evaluating the monitoring. Furthermore, the guideline includes practical recommendations for tendering, awarding contracts, contract design, economic analysis, and is supplemented by checklists to support infrastructure managers.

Another key topic is data management; client data requirements were developed to ensure structured storage and analysis of monitoring data.

A key reason for the limited use of monitoring by infrastructure owners is the lack of expertise and standardized procedures. The project can help by providing standards and presenting fundamental principles. Additionally, it plays a significant role in building expertise to address the complexity of the topic. With standardized use cases, a defined process, and potential support services, this project can address these challenges. This also applies to the missing fundamental principles in data management. The development of client data

requirements has made a first step toward creating foundations in this area.

### 3.4 Birth certificate for bridge structures

The research project aims to develop a comprehensive concept for a "birth certificate" for bridge structures and the foundations for a prototype implementation on a real bridge [2]. The birth certificate serves as the basis for condition monitoring and maintenance planning throughout the entire lifecycle of a structure. Central to this concept is the so-called zero measurement, where the initial condition of the structure – immediately after completion and before being opened to traffic – is captured in detail and systematically using various parameters. This reference state will later serve as a basis for comparison to detect, document, and evaluate changes and damages at an early stage.

The concept defines a wide range of parameters: Physical parameters such as material strains, displacements, as well as natural frequencies and modes provide insights into the load-bearing behavior, while chemical aspects such as chloride content, carbonation depth, and moisture content of the concrete offer essential information about durability. Additionally, the geometric properties of the bridge are recorded – for example, through a georeferenced 3D structural model created photogrammetrically or by scanning methods. This model allows precise localization of all recorded parameters and forms the foundation for future deformation analyses and damage-focused condition assessments.

The birth certificate will be created in a standardized, easily accessible form as a PDF document, containing references to all data sets, models, and measurement data, which will then be stored in the SIB-BW infrastructure database. Furthermore, all information related to the birth certificate will be located within the 3D model, and the data will be linked. This will provide a foundation for supporting predictive lifecycle management through Digital Twins. This represents a crucial step toward more sustainable and efficient use of infrastructure resources.

The project constitutes an important effort to lay the groundwork for the targeted use of monitoring. With the birth certificate, a comprehensive overview of the structural behavior before the opening to traffic is provided. This captures a reference state that will serve as the basis for future deviations. As a result, the acceptance of monitoring can be increased, and a valuable contribution to the standardization and development of expertise in this field can be made.

### 3.5 Foundations for data management in structural maintenance

A workshop with infrastructure managers, the necessary foundations for data management in structural maintenance were developed. It became clear that standardized data models and defined interfaces are essential.

As a first step, a project on "Documentation on the Application of Innovative Methods in Condition Assessment, Particularly Regarding Standardized Data Models" was initiated.

The success and utility of innovative methods, such as the use of monitoring, strongly depend on structured and standardized data management. A relevant foundation of data management

consists of data formats and models. The data model here refers to a model of the data to be described and processed in structural maintenance and their relationships with each other. Data models help in structuring, presenting, and understanding data, and serve as a plan for organizing, connecting, and storing the data. For all datasets used and generated in the context of maintenance, including planning and construction, data models and their metadata are required. The goal is to determine structured and standardized data formats, data models, and metadata for the data collected during structural maintenance.

This project aims to establish the missing foundations in the field of data management and standardization.

## 4 IMPLEMENTATION OF MONITORING IN THE EU

The use of monitoring in Europe is not harmonized, as demonstrated by the Horizon 2020 project "IM-SAFE." The main goals of IM-SAFE include the development of new European standards for the monitoring, maintenance, and safety of transport infrastructures. This aims to enable well-founded decisions regarding maintenance needs and optimized maintenance strategies [19].

The following technical and organizational challenges were identified during the project [20]:

- Different national regulations and standards complicate the creation of unified European standards. While some countries focus on preventive maintenance, others prioritize reactive measures after damage has occurred.
- Technological advancements require continuous adaptation, but it is complex to incorporate rapid technological changes into standardization processes. As a result, implementations often lag current technological possibilities.
- Heterogeneous responsibilities and interests between public and private infrastructure operators may exist.
- Standardization of data formats and protocols is necessary to enable interoperable use of collected information.
- The implementation of standardized monitoring and maintenance procedures requires significant investments.

Despite these challenges, there are efforts to achieve greater harmonization in standardization. These include initiatives at the European level, as well as the development of new technical solutions that enable more flexible and efficient adaptation to existing standards.

Other European countries already have regulations for the standardized use of monitoring:

In Austria, the RVS 13.03.01 guideline on the monitoring of bridges and other civil engineering structures allows for special inspections (e.g., monitoring) to assess damage. Monitoring does not replace structural inspections but can be used as an additional objective method. Monitoring objectives could include the measurement-based documentation of structural conditions or the early detection of critical structural conditions [21].

In Switzerland, the guidelines for the monitoring and maintenance of civil engineering structures mandate the use of monitoring within the framework of zero and control measurements [22].

Lombardy, in its newly developed bridge monitoring guidelines, has set the following objectives: increasing safety, efficient maintenance strategies, standardized monitoring, and integrating innovative technologies. To achieve these goals, sensor-based monitoring with various sensor technologies will be used for the continuous collection of key structural parameters. Furthermore, real-time data analysis through the implementation of digital platforms and AI-supported decision-making will be introduced to automate pattern recognition in sensor data for the identification of potential damage. The monitoring will support periodic inspections, and the data will be integrated into existing maintenance strategies. Additionally, the creation of digital twins, including for scenario simulation, is planned. This approach is currently being implemented in nine pilot projects [23].

## 5 CONCLUSION

The use of monitoring in federal highways is currently limited to a few applications. In all cases, it is a case-by-case decision. To promote and target the use of monitoring to support structural maintenance, ways must be found to address the current challenges (lack of standardization, insufficient expertise, and missing fundamental principles). An overview of the challenges and monitoring use in Europe shows that similar challenges exist here as well. Initial solutions, foundations, and new projects are available, but they still need to be implemented on a larger scale.

email: T. Kurihara [t.kurihara@tepsco.co.jp](mailto:t.kurihara@tepsco.co.jp), M. Saeki [saeki@rs.tus.ac.jp](mailto:saeki@rs.tus.ac.jp)

**ABSTRACT:** Due to recent extreme weather conditions, there have been many reports of damage to infrastructure. For example, two power transmission towers collapsed due to landslides in 2022. The landslides may not only cause the tower collapse but also cause the base displacement. The base displacement of only a several millimeters can generate secondary stress, resulting in member deformation and insufficient strength of the steel tower members. Therefore, the towers that are at risk of landslides are surveyed once a year to investigate the progress of base displacement. However, the on-site investigation creates other risks, such as delays in detection and accidents during the travel to the site. So, the authors have been developing the tilt monitoring system of the power transmission towers. In the tilt monitoring system, one tilt sensor is installed on each of the four main members of the tower. The progress of base displacement is monitored by checking whether the observed tilt change exceeds a set threshold. In the current system, the threshold value is tentatively set to be 0.05 degrees. This system has already been installed to about one hundred towers in the field. In this study, a full-scale experiment is newly conducted to examine the optimal installation location of the tilt sensors to monitor the base displacement. In this experiment, ten tilt sensors are placed on each of the four main members, and the sensitivities to the base displacement are examined in detail.

**KEY WORDS:** Transmission towers; Base displacement; Remote monitoring; Tilt sensor

## 1 BACKGROUND AND OBJECTIVE

Due to abnormal weather in recent years, there have been many disasters in Japan, such as landslides and river flooding caused by heavy rain. The heavy rains of July 2021 caused a large-scale mudslide on the embankment of Atami City, which is still fresh in our memory. At the time of the disaster, an observation station in Atami City, which was relatively close to the disaster site, recorded an accumulated rainfall of 488mm, the highest rainfall ever recorded in July in the local history [1]. This mudslide disaster led to revisions of fill regulations to ensure safety of fills and effective penalties. In addition, when heavy rainfall and flood warnings are issued, the Japan Meteorological Agency has begun to issue detailed evacuation information, but even so, many lives have still been lost.

Power transmission towers have also been damaged by heavy rains and landslides. Two transmission towers collapsed in 2022 due to landslides caused by heavy rainfall. Although there was no direct loss of life at that time, approximately 120,000 households experienced large-scale power outages. Damage

caused by landslides on transmission towers also includes displacement of tower bases due to landslides in the vicinity of the towers. This base displacement of only a few millimeters can cause secondary stress from the base, resulting in member deformation and insufficient strength. If this base displacement is detected too late and progresses, the member will buckle, requiring large-scale repair work or reconstruction.

The management of towers where landslides are a concern is conducted once a year to check the progress of base displacement by surveying. However, there is a risk of on-site attendance and delay in detection. Therefore, the authors propose tilt monitoring to remove these risks. Figure 1 shows the operational image proposed by the authors. In the proposed method, tilt sensors are installed on the four legs of a transmission tower and single pipe piles driven near the collapsed soil surface, and the measured values are monitored remotely. When an abnormality is detected, an alert is sent out and the risk is assessed by analyzing the observed data.

Figure 1. Operational image diagram

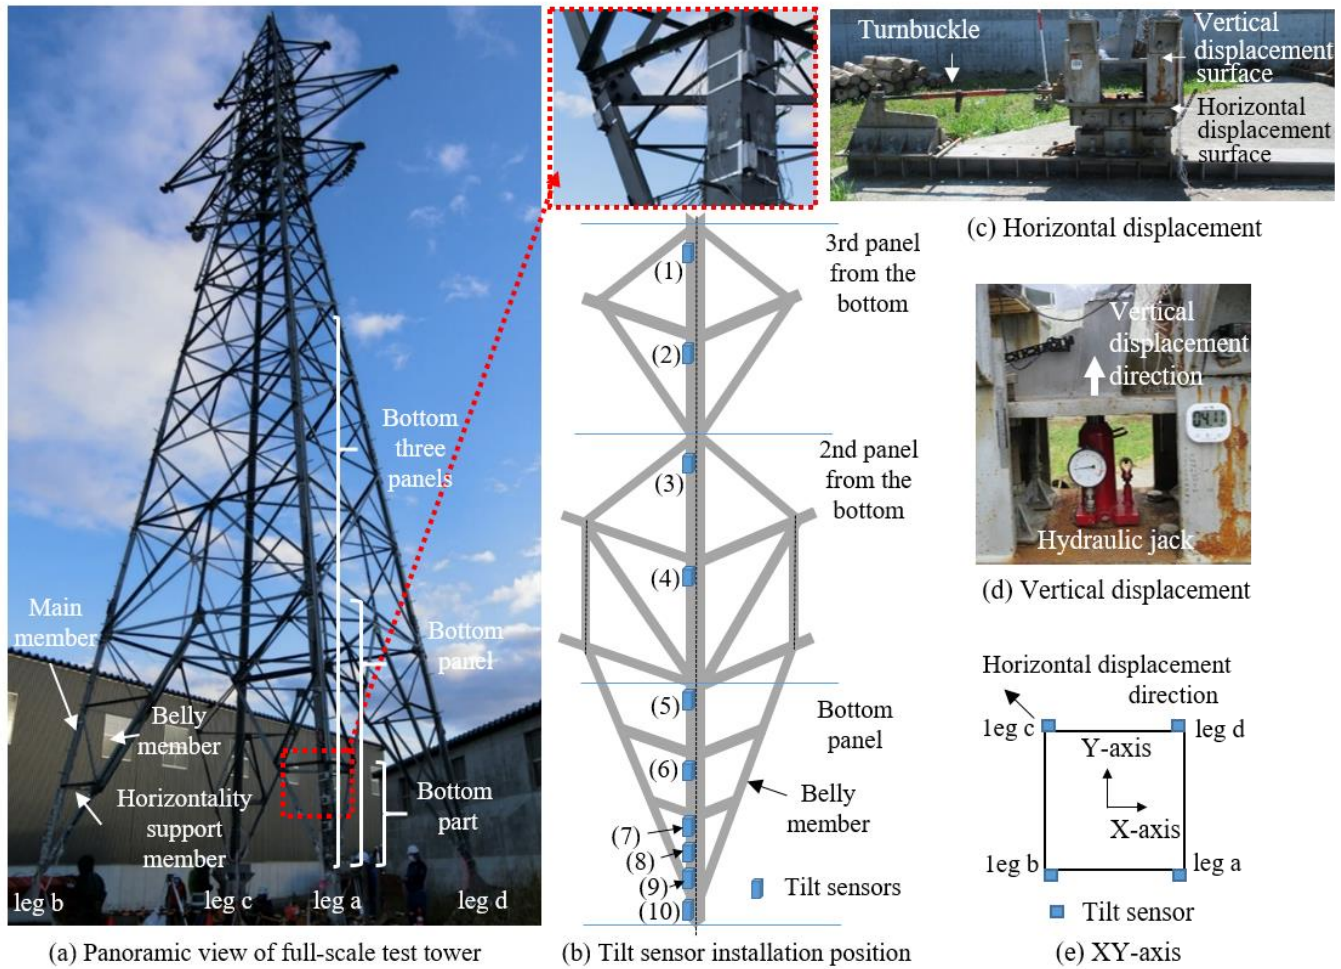

Figure 2. A full-scale test steel tower and test overview

This system is already in use on about 100 transmission towers in the real field. A provisional threshold value of 0.05deg is proposed based on the results of a full-scale test conducted previously. This value of 0.05deg corresponds to the allowable base displacement described in the non-statutory standard JEC-5101-2022 [2]. The allowable base displacement is defined by Equation (1), (2). In the equation,  $V$  is the allowable vertical base displacement,  $B$  is the distance between legs, and  $H$  is the allowable horizontal base displacement.

$$V[\text{mm}] = B[\text{mm}]/1200 \quad (1)$$

$$H[\text{mm}] = B[\text{mm}]/800 \quad (2)$$

Equation (1), (2) is not a legal requirement of the “Ministerial Ordinance Establishing Technical Standards for Electrical Equipment and Interpretation Thereof”. The equations are used as a control standard value for safety purposes [3].

In the test results previously conducted to calculate the above threshold values, the three tilt sensors installed on the same member had different sensitivity to tilt change [4]. This suggests that the sensitivity of tilt change may differ depending on the installation location, even for the same member. In this study, the number of tilt sensors was increased and retested, and the results indicated the best locations for observation.

## 2 PREVIOUS TEST RESULT

### 2.1 Overview of the test tower

The results of the previous test are presented here. Figure 2 (a) shows a full-scale test steel tower. This steel tower is made of L-shaped section steel, with a tower height of 28.20 m, a distance between legs of 6.08 m, and a tower weight of 10.3 tons. Generally, a transmission tower consists of main members, belly members, and support members. The main members and belly members are structural members, and the support members are designed as buckling stiffeners. For convenience of explanation, the legs of the tower are designated as leg a to leg d, as shown in the lower part of the photograph in Figure 2. The coordinate system xyz is set up with the center of the four legs as the origin, the x axis parallel to the ab plane (in the line orthogonal direction), the y axis parallel to the ad plane (in the line direction), and the z axis points upward perpendicular to the ground. Figure 2(b) shows the installation of the tilt sensor on one member, where all four legs are installed in almost the same way. The section from the ground to the connection between the horizontal members and the main member is called the bottom panel, and the section sandwiched between the belly members is called the panel. Since the influence of base displacement is generally

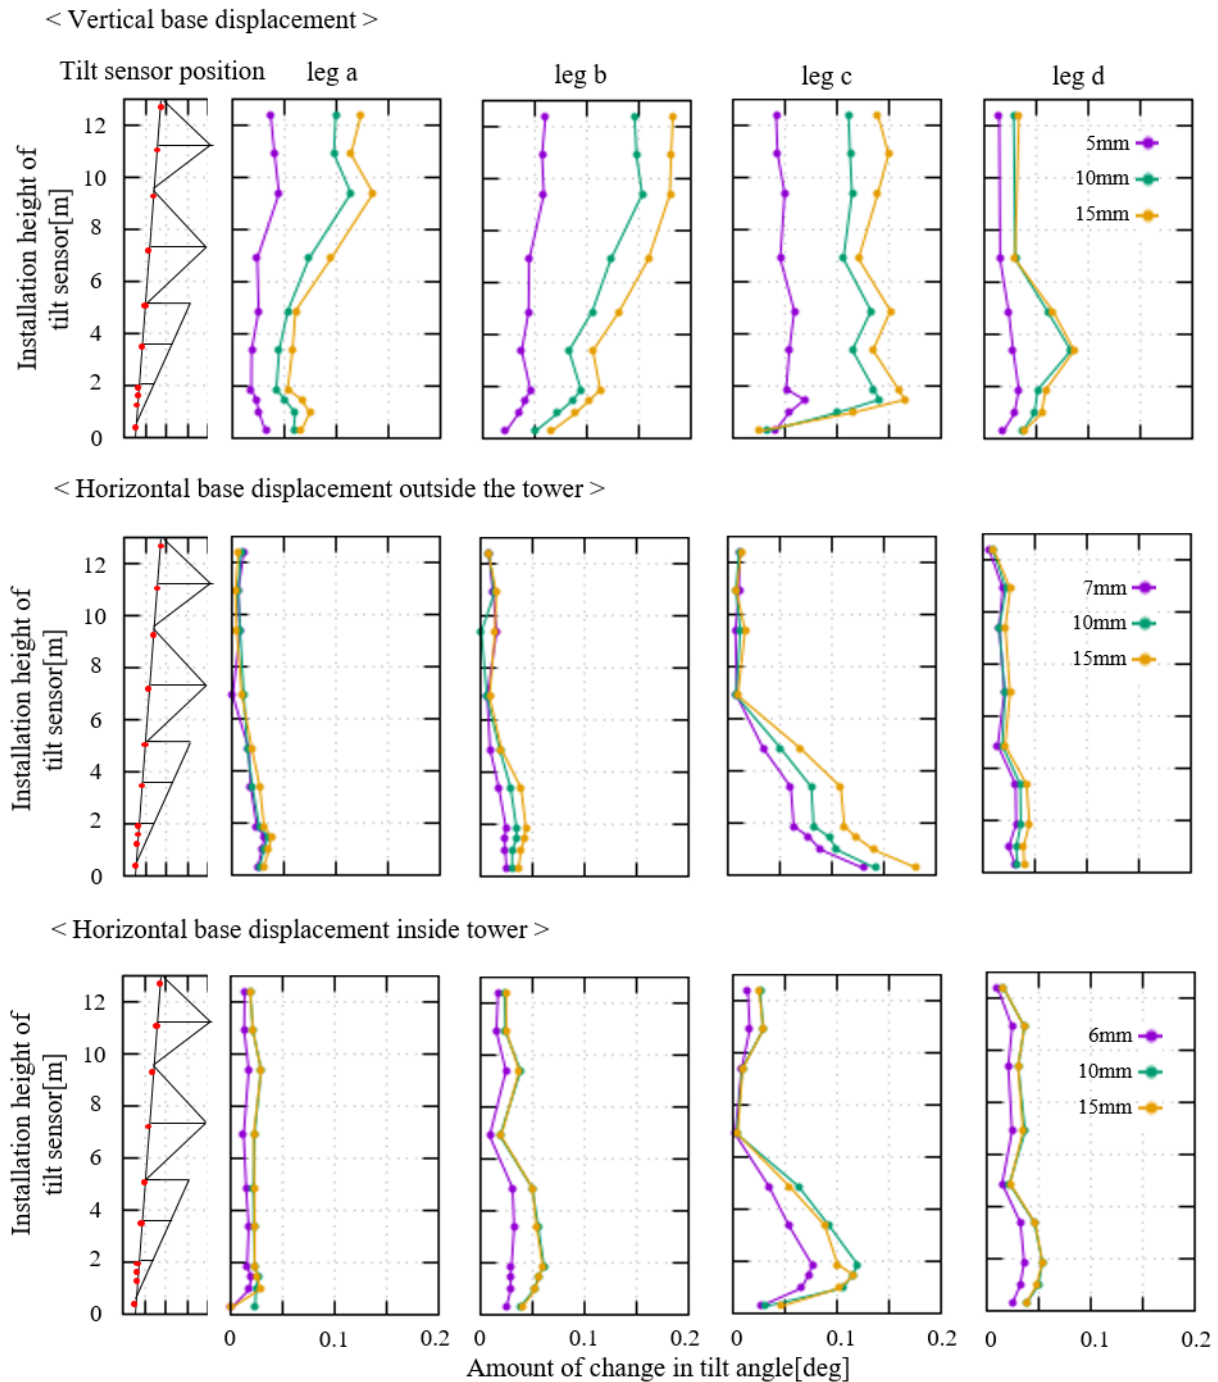

Figure 3. Relationship between tilt change and base displacement

considered to be limited to the third panel from the bottom, ten tilt sensors were installed per main member leg from the bottom to the third panel [5]. Since structural eccentricity due to joints may affect the tilt change at the lowest section, tilt sensors were installed at three locations to check. The tilt sensors near the member intersections could not be installed until a short distance from the intersections, so they were installed 10 cm lower from the intersections. The sensors measured tilt in the x-axis and y-axis directions with a measurement interval of 1 minute and a resolution of 0.0035 deg. The tilt sensor was glued

to the member, and the top and bottom of the sensor were fixed with stainless steel bands.

## 2.2 Forced base displacement method

The three legs except leg c are completely fixed. Only leg c is a movable leg; leg c has vertical upward displacement and horizontal displacement at an angle of 45 degrees to the inside and outside of the tower. Figures 2(c) and 2(d) show how the forced base displacements were given. As shown in Figure 2(c), the fixed point is located approximately 2 m from the movable leg in the outward direction of the tower. A turnbuckle was fixed between that fixed point and the movable leg to provide

Figure 4. Analysis Model and Results

horizontal base displacement inward and outward. The horizontal displacement surface is not vertically constrained, so when the leg c is displaced horizontally, it may also be displaced vertically. As shown in Figure 2(d), vertical displacement was displaced by hydraulic jacks. The boundary of the legs is housed in a box-like frame that allows vertical movement but does not allow horizontal movement.

The allowable vertical base displacement was 5 mm, and the allowable horizontal base displacement was 7 mm, calculated from the formula for allowable base displacement. Tilt changes at base displacements of 10 and 15 mm were also observed.

### 2.3 Tilt change due to base displacement

The results of the test are shown in Figure 3. The top row of Figure 3 shows the results of vertical displacement, the middle row shows the results of horizontal displacement outside the tower, and the bottom row shows the results of horizontal displacement inside the tower. The vertical axis is the installation height of the tilt sensor, and the horizontal axis is the vector composite change in tilt angle. Unfortunately, leg d was the furthest away from the data logger, so some data was missing due to poor radio communication.

Figure 3 shows that when leg c is displaced vertically upward by 5 → 10 → 15 mm, the overall change in tilt angle at each measurement point becomes larger. Focusing on legs a, b, and c, the amount of change in tilt angle was greater at the top than at the bottom panel. During allowable vertical displacement,

the three sensors installed on the same member at the lowest section differ in tilt change by a maximum of 0.02 deg. Also, leg c shows that the member is bent.

Next, the results for horizontal displacement are shown. As in the case of vertical displacement, the change in tilt angle increases with the increase in base displacement. However, the amount of change for main members other than leg c, which is subjected to forced displacement, is considerably smaller than that of leg c by approximately 30 % or less.

During allowable horizontal displacement, the three sensors installed on the same member of the lowest section show that the tilt change differs by a maximum of 0.04 deg. In particular, a large tilt change can be seen in the movable leg at the time of horizontal displacement outside the tower, even though it is the same component.

## 3 ANALYSIS MODEL AND RESULTS

The change in tilt of the lowest part due to base displacement be confirmed by analysis. The analytical model was created using ADINA (ver. 9.4). The analytical model created is shown in Figure 4 (a). The analytical model was made up of nodes at the member intersections and a beam element between the nodes. The analytical model was subjected to the same forced base displacements as in the test, and the member stresses, displacements of the member nodes, and member tilt were calculated and compared with the test results. The test tower

has only one movable leg (leg c). When the leg c was displaced horizontally, the vertical displacement was fixed and rotations were free as the boundary condition. On the other hand, the boundary conditions were free for vertical displacement and rotation in all directions when the vertical displacement was given to leg c.

The tower used for the full-scale test did not have any electric cables. Therefore, an analytical model without the weight of the wires and tension loads was used in the analysis. Bolt slippage model [6] was considered in the analytical model. The steel tower consists of members joined by bolts. Since there is a bolt clearance of 1.5 to 2.0 mm, the bolts may slip when base displacement occurs. To account for the deflection of the main column members identified in the test results, the main column members were divided into the bottom to the fourth panel of horizontal members. In addition, a model was also created to account for the cross-sectional area of the overlapping joints of the main column members and the eccentricity of the joints of the main column members. Tilt changes were compared in these models.

The above analytical model was used to perform the analysis, and Figure 4 (b), (c) shows a comparison of the analytical and experimental results at the allowable base displacement. The vertical axis is the steel tower height, and the horizontal axis is the vector composite change in tilt angle. Figure 4(b) shows that the eccentric model has the smallest error of 0.001 degrees in the range of 1.5 m to 1.9 m from the lowest point of the analytical model. Figure 4(c) shows the comparison results for the horizontal displacement outside the tower. As with the vertical displacement, the eccentricity model had an error of 0.004 degrees at 1.5 m to 1.9 m from the lowest point. Both vertical and horizontal displacements showed a large change in tilt and sensitivity at the lowest point. This analytical model is a simplification of the actual structure. Therefore, the accuracy of the model should be improved by refining the model in accordance with the actual situation. In this model, it can be said that the experimental data can be almost explained by refining the model up to the joints of the main column members. However, the model was not able to represent changes in tilt near the bottom of the tower. This is due to the shape of the base of the tower. As shown in Figure 4(d), there are areas near the base of a transmission tower in actual operation where only the main member is present. This area is called the bottom main leg. In general, the bottom main leg of a transmission tower in actual operation is about 300 mm. In contrast, the bottom main leg of the test tower was conducted is indicated as 500 mm on the drawing. In addition, the test tower has no concrete base. Therefore, the boundary between the tower and the base is ambiguous, and the length of the bottom main leg is also ambiguous. From the above, the authors believe that the difference in tilt change near the ground is due to the effect of the bottom main leg. In addition, a comparison of the case in which the eccentricity of the main column joints and the cross-sectional characteristics of the main column joints were taken into account showed that the maximum difference in tilt change was only 0.004deg.

## 4 RETEST RESULT

### 4.1 Test overview

The results of previous tests and analyses reveal that the bottom tilt change is highly sensitive to the sensor location. Therefore, a full-scale test was conducted again to investigate the sensitivity of the tilt change of the lowest section. The target tower was the same as in the previous test (Figure 2). In this experiment, 10 tilt sensors were installed on the main member of the legs as shown in Figure 5. Note that all four legs were installed in almost the same manner. However, the measurement interval of the tilt sensors was changed to 20 seconds to obtain more detailed data.

The base displacement was targeted at the allowable base displacement of 5 mm vertically and 7 mm horizontally. As in the previous test, vertical displacement was performed with hydraulic jacks and horizontal displacement was performed with turnbuckles.

### 4.2 Test result

Figure 5 shows the change in tilt of all sensors at the allowable base displacement. The horizontal axis is the tilt change along the x-axis and the vertical axis is the tilt change along the y-axis. From left to right: vertical displacement, horizontal displacement outside the tower, and horizontal displacement inside the tower. Purple dots indicate leg a, green dots indicate leg b, blue dots indicate leg c, and yellow dots indicate leg d. The one square interval in the figure indicates 0.05deg, and the red circle indicates the threshold value. The leg c of Id3 has no data because the sensor has failed. Also, the Id10 of leg c has too large tilt changes (-0.109, 0.144) to display the dots on the figure when the horizontal displacement outside the tower is given. The dots are plotted in the hidden upper left corner of the figure. The findings from Figure 5 are summarized below. The threshold value was exceeded only in the leg c where the base displacement was given.

The leg a has a larger tilt change from the top to the bottom. The leg b has the same tilt change at all points, but there is a twisting movement to the right in the upper to lower tilt change. The leg c subjected to base displacement showed a greater tilt change toward the top. The direction of the tilt change at Id10 was inverted from that of the other sensors. The threshold value was exceeded at any point when the height was 130 cm or more from the ground (Id6 or more). The leg d has the same tilt change at all points, but there is a twisting movement to the left in the upper to lower tilt change.

Except for leg c, the tilt change was very small at all locations. The tilt change was greater toward the lower part of leg c. Tilt change exceeding the threshold was observed below 150 cm from the ground (Id5 or less). Except for leg c, the tilt change was the same at all locations. The amount of tilt change was larger than the horizontal displacement outside the tower and was about the same as the vertical displacement. In leg c, the tilt change was greater toward the bottom. In addition, the tilt change occurred in the opposite direction to the other legs. Tilt changes that exceeded the threshold were observed when the leg was less than 150 cm from the ground (Id5 or less).

From the above, the recommended location for the tilt sensor is in Id 5 and 6. In addition, only the base displacement leg exceeded the threshold when the allowable base displacement was loaded. Therefore, the leg that exceeds the threshold value

may be considered the leg where base displacement occurred. The direction of base displacement is determined by the total tilt change of the four legs.

Vertical displacement: Total tilt change of the 4 legs > Maximum tilt change of 4 legs

should be taken in the installation position when conducting actual monitoring.

It is easy to check the direction of inclination in more detail by checking the difference between ID2 and ID9. Vertical base displacement is larger for ID2 at the top when comparing ID2

Figure 5. Test result

Horizontal displacement outside: Total tilt change of the 4 legs  $\hat{=}$  Maximum tilt change of 4 legs

Horizontal displacement inside: Total tilt change of 4 legs < Maximum tilt change of 4 legs

This test confirmed that the tilt change varies with base displacement, even for the same member. Therefore, care

and ID9. Horizontal base displacement is larger for ID9 near the ground when comparing ID2 and ID9. Thus, if several sensors can be installed, the direction of base displacement can be easily ascertained.

#### 4.3 Re-comparison with analysis

The results of the analysis presented in Chapter 3 were compared with the results of the present measurement. The

Figure 6. Re-comparison with analysis

results are shown in Figures 6(a) and 6(b). In Figures 6(a) and 6(b), the vertical axis is the steel tower height and the horizontal axis is the tilt change. The tilt change was assumed to be a vector in the line direction and in the direction orthogonal to the line. Figure 6(a) shows the comparison results of vertical base displacement and Figure 6(b) shows the comparison results of horizontal base displacement outside the tower. The black dots are the results of the previous test, the green line is the results of the analysis, and the purple line is the results of the latest test.

Figure 6(a) shows that the trend of tilt change was consistent with the previous test results. However, there was a difference of about 0.01deg at 2.0m. The retest was conducted two years later. Therefore, the authors consider it to be the effect of rust and other factors that were not present last time. Also, the last test was in October and the current test was in May. The difference in temperature may have affected the expansion of the materials. Compared to the analysis results, the overall trend was similar, but the height directions did not match. However, the locations between 1.4 m and 1.6 m were in general agreement with the analysis.

Figure 6(b) shows that the overall tilt change was smaller than the previous result, but the trend of tilt change was consistent. The trend was consistent with the analysis results. The factors contributing to the overall small change in tilt are considered to be the same as for the vertical displacement. From the above, it was found that the trend of tilt change due to base displacement was generally consistent for the 1.4 to 1.6 m point.

## 5 CONCLUSION

As a result of the full-scale test, only the displacement leg had a large tilt change that exceeded the threshold value for vertical displacement. In the horizontal displacement, the tilt changes

also exceeded the threshold value only for the displacement leg. This indicates that base displacement is most likely to occur at the leg with the greatest change in tilt. The recommended location is between 1.4 m and 1.6 m, which was in high agreement with the analytical calculations.

Horizontal displacement and vertical displacement can be determined by comprehensively checking the tilt changes of the four legs. The direction of base displacement can be determined by the sum of the tilt changes of the four legs as follows.

Vertical displacement: Total tilt change of the 4 legs > Maximum tilt change of 4 legs

Horizontal displacement outside: Total tilt change of the 4 legs  $\approx$  Maximum tilt change of 4 legs

Horizontal displacement inside: Total tilt change of 4 legs < Maximum tilt change of 4 legs

If the direction of base displacement is to be determined in more detail, it is desirable to install the sensor near the base in addition to the recommended position of 1.4 m to 1.6 m. The reason for this is that the closer to the ground, the greater change in inclination can be observed due to horizontal displacement, so by checking the difference in inclination from the recommended position, the direction of base displacement can be determined more clearly.

The results of this test showed that by installing tilt sensors on the four legs at the recommended locations, it is possible to determine the leg where base displacement occurred and the direction of base displacement.

## ACKNOWLEDGMENTS

We are very grateful to Hokkai Electric for their cooperation in the experiment.

**ABSTRACT:** Physics-informed structural health monitoring, which integrates realistic physical models of material behavior, structural response, damage mechanisms, and aging processes, offers a promising approach to improve monitoring capabilities and inform operation and maintenance planning. However, the associated technical challenges and model requirements are context-specific and vary widely across applications. To illustrate the relevance and potential of the topic, two application examples are presented. The first focuses on monitoring the modal characteristics of a prestressed road bridge, where strong sensitivity to temperature variations limits the diagnostic capabilities of conventional vibration-based global monitoring. The discussion highlights how environmental influences can obscure structural changes, and emphasizes that purely data-based approaches are inherently limited to detecting anomalies and do not enable comprehensive condition diagnostics. The second example explores a physics-informed monitoring approach for prestressed concrete bridges affected by hydrogen-induced stress corrosion cracking. By combining acoustic emission data with a calibrated acoustic model of the structure, it is possible to detect and localize wire failures. As an outlook, the integration of mechano-electro-chemical models for stress corrosion cracking is discussed, enabling predictive assessments of the strand condition.

**KEY WORDS:** Physics-informed SHM; Diagnostics, Prognostics, Structural Assessment, Structural Integrity Management

## 1 INTRODUCTION

Civil engineering structures are subject to damage, aging and deterioration processes such as fatigue, corrosion, shrinkage, creep, and scour – all of which can affect their safety and serviceability. Additionally, they are exposed to environmental and operational variations. In particular, fluctuating structural temperature distributions caused by changing environmental conditions may alter structural behavior and, in some cases, even impact structural capacity. Moreover, structures may experience rare and extreme events during their service lives – such as storms, floods, fires, explosions, earthquakes, extreme traffic loads or ship impacts – which can also impair safety and serviceability. Some structures may even already exhibit damage, which could progress to a critical state, affecting structural performance.

To effectively manage the structural safety and serviceability of engineering structures, owners and operators require information on loads and their effects, environmental influences, operational conditions, and the structural condition. This information forms the basis for assessing and forecasting structural performance, thereby enabling informed decisions on operation and maintenance.

Structural health monitoring (SHM) – in the sense of monitoring the condition of a structure – is intended to support diagnostics, prognostics, structural assessment, and maintenance planning. Diagnostics involves inferring the current condition or changes in structural characteristics from measurements or observations that are indirectly related to them. In this process, environmental and operational variability must typically be taken into account, as their impact on structural behavior can alter the measured signals, thereby potentially masking the presence of damage.

Ideally, the diagnostic information obtained through SHM is used to predict the future structural condition and to quantitatively assess structural safety and serviceability.

Research in SHM for engineering structures has a long history [1]. While significant progress has been made in the field, in practice, SHM is primarily used to measure loads and their effects, collect structural response data as a basis for calibrating structural models, and monitor known damages locally [2]. SHM-informed diagnostics, prognostics, structural assessment, and maintenance planning for engineering structures remain an evolving field.

This contribution discusses the potential and challenges of integrating physical modelling into SHM to enhance these tasks. At its core, physics-informed SHM couples physical models that describe the processes influencing structural condition and capacity with models of the structural performance, and continuously updates them with inspection and monitoring data from the actual system [3]. Within this framework, physical models are also employed to link measurements and observations to the structural condition and damage states, thereby providing an indirect connection to the processes driving deterioration and structural damage.

The paper is organized as follows: Section 2 provides a more detailed discussion on the motivation for adopting a physics-informed approach in SHM, drawing from our group's long-term monitoring experience of a road bridge in Berlin. Section 3 then explores the potential and challenges of applying physics-informed SHM to extend the lifetime of prestressed concrete bridges subject to stress corrosion cracking. Finally, Section 4 provides concluding remarks.

## 2 THE MOTIVATION BEHIND PHYSICS-INFORMED SHM: THE WESTEND BRIDGE EXPERIENCE

### 2.1 Westend Bridge

Our group's research related to SHM began in 1994 with the continuous monitoring of the Westend Bridge. This example is also used because the bridge is currently being demolished. The 30-year measurement project is likely to be one of the longest in the world. The Westend Bridge in Berlin, which has been carrying heavy traffic for several decades, had suffered a number of damages since its construction. Strengthening work was repeatedly required to ensure adequate load-bearing capacity in the long term. Figure 1 shows the normal operating conditions at the start of the monitoring measure. Figure 2 and Figure 3 are recent photos taken shortly before and during disassembly respectively.

Figure 1. Westend Bridge in service.

Figure 2. Westend Bridge in recent years, featuring implemented safety measures.

Figure 3. Demolition of the Westend Bridge, April 2025.

Among other things, it was found that the coupling joints of the bridge deck had opened. Under the influence of external loads and temperature changes, significant changes in joint width were observed during inspection and finally monitored by measurement. It was found that above a certain temperature, the crack width of the joint increased disproportionately under traffic load.

Westend Bridge is or was a prestressed concrete box girder bridge, commissioned in (1965) with full prestressing. It has 7 spans and a total length of 237m. The cross-sections of the bridge proved to be problematic: The flat three-cell box girder has a tendency to high residual stresses due to temperature, but also a significant influence of the asphalt layer on the structural behavior and a significant influence of the nominally non-structural components (rails and caps) was identified. The effect of temperature variations in the structure has not been considered in the design.

The prestressing tendons are coupled at couplers. Shear reinforcement and concrete cover (chloride ingress) have been shown to be inadequate. In addition, the bridge is subject to heavy traffic. As a result, the bridge has been strengthened several times.

The bridge reacts non-linearly due to temperature changes and high traffic loads. The coupling joint has opened due to traffic loads at high temperatures, resulting in increased fatigue demands on the prestressing tendons. Temperature variations affect the stiffness of the asphalt, change the stress/strain state within the section and lead to longitudinal cracking in the webs and base plate.

From a detailed modelling perspective, the degree of fixation between the columns and the box girder is unknown, as is the degree of fixation between the columns and the foundation.

The management of the structural data is similar to that of a normal existing bridge: Data and information about the bridge is recorded and stored in printed documents and drawings. Minimal or no as-built documentation is available. There is no information on actual physical parameters (e.g. material properties). The lack of physical information in the documentation and the lack of digitization of the data are a major obstacle to the introduction of a SHM system.

### 2.2 SHM Installation and global damage detection

An SHM system has been installed for the purpose of identifying damage or changes in structural characteristics based on data indirectly related to these damage/changes in structural characteristics.

At the beginning, an experimental modal analysis was carried out with a hydraulic shaker from EMPA. The bridge was then equipped with geophones, temperature sensors and local strain gauges in one section for a continuous monitoring.

At the time of initial installation, the aim was to identify structural changes based on a shift in natural frequencies. This initial diagnostic idea quickly proved to be flawed, as the bridge has a strong dependence of its natural vibration behavior on the structural temperatures (Figure 4). Possible approaches to understanding the temperature dependency were subsequently analyzed in a diploma thesis [4]. A major influence for this bridge is attributed to the significant stiffness contribution of the asphalt at low temperatures.

Figure 4. Dependence between natural frequency and temperature (or changes in structural behavior due to temperature effects).

Detection of damage or changes in structural properties has been further explored using signal processing techniques for dynamic data in [5]; This attempt provides a feature that is sensitive to global and significant structural damage/changes in structural properties. The procedure eliminates the effect of temperature-dependent periodic variations by normalizing the vibration data.

Figure 5. Statistical damage indicator derived with the novelty detection method [5].

In this example, the global damage identification can optimally show that there is a change in the measurement data and possibly in the building response. Such an anomaly would generally be recognizable after a few measurement intervals (e.g. 10-minute intervals), see Figure 5. It would then be possible to start a diagnosis as to whether there is a measurement error or whether a change in the structure is actually the cause of the changes in the measurement signal. As no information about the size and location of the damage can be determined, further damage diagnosis is only possible on site and, depending on the structure, involves considerable effort.

### 2.3 Physical modelling

It is not possible to infer the structural safety and service ability from variations in the natural frequency alone.

The SHM at Westend bridge as previously outlined lacks information on damage location, damage size and damage evolution. One of the most serious problems, however, is that it is not clear whether and to what extent the structural changes represent damage relevant to structural safety.

	<b>Asphalt Layer:</b> Strong temperature dependence of asphalt stiffness; contributes to overall structural stiffness, but not to structural load-bearing capacity.
	<b>Concrete – RC and prestressed:</b> Stiffness can vary <ul style="list-style-type: none"> <li>Stiffness depends on temperature and humidity</li> <li>Cracks of coupling joints may open with temperature and effect capacity</li> </ul>
	<b>Combination</b> How can the individual mechanisms be distinguished?

Figure 6. Influence of temperature on structural components.

As shown in Figure 6, a load-bearing contribution of the asphalt layer is not relevant to safety. However, if cracks open in the reinforced concrete under temperature, a temperature load represents real damage to the load-bearing structure. In reality we see a combination of both mechanism which have to be separated in a structural assessment.

In order to enable a more precise analysis, it is usually necessary to switch from a model-free data analysis to a model-based data analysis. Figure 7 shows a general scheme. Identifying a structural model is a necessary step that must be accompanied by an assignment of physical material and component properties.

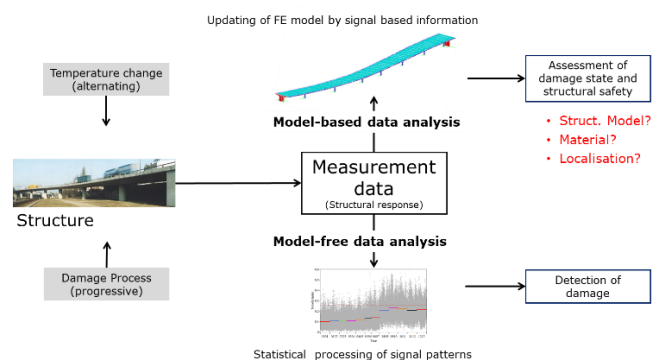

Figure 7. Updating scheme for SHM that accounts for temperature fluctuations, which may mask structural damages.

Figure 8. left: Vibration mode identified from measurements (top) vs vibration mode determined via finite element modelling (bottom). right: Identified and numerical natural frequencies

Various detailed FE models were created for the Westend Bridge and adapted to reality by means of experimental modal analyses. The models make a significant contribution to understanding the structural behaviour. The updated model is good, see Figure 8, but unfortunately not very sensitive to severe damage when compared to environmentally induced changes. The general lack of a link between the modal parameters and the (local) strength properties continues to prevent a substantial structural assessment.

#### 2.4 What can be learned from Westend bridge

The key findings from the Westend Bridge monitoring can be summarised as follows:

- Data management: Construction documents are available in paper form. These are primarily planning data (not as built, no material parameters). The data storage is not linked to ongoing digital data management.
- A global damage detection has been successfully implemented. However, the detection of a specific damage or of changes in structural characteristics was not possible. Global damage detection provides incomplete diagnostic information, no information on type, location and size of damage.
- To obtain complete diagnostic information based on SHM data it is necessary couple data with physical models. A physical model should consist of a structural model and its physical parameters describing local strength and deterioration characteristics.
- The Westend Bridge has many weak structural points, but specific hot spots are difficult to identify. What becomes apparent is that a scenario-free monitoring is extremely difficult. A monitoring task becomes easier the more clearly the potential damage scenarios can be described. This is particularly the case when disturbances such as temperature fluctuations mask changes in the structure's condition.  
→ Chapter 3 presents a scenario-orientated approach for a physics-based SHM procedure.

### 3 PHYSICS-INFORMED SHM OF BRIDGES SUBJECT TO STRESS CORROSION CRACKING

Numerous incidents in Germany have shown that concrete bridges containing prestressing steel susceptible to hydrogen-induced stress corrosion cracking experience a characteristic deterioration process [6-8]. Damage typically initiates during

the construction phase due to a mechanical-electrochemical mechanism triggered by aggressive ambient conditions. As the bridge enters its operational phase, and the prestressing ducts are grouted, damage continues to develop due to fatigue crack growth caused by dynamic traffic loads and temperature fluctuations. Over time, this can result in the failure of individual prestressing wires, each of which emits acoustic signals upon breaking. If a critical number of wires fail, the structural integrity of the bridge can be severely compromised, potentially leading to substantial damage or even collapse. In this context, the following section discusses the challenges and potentials of physics-informed SHM to extend the lifetime of bridges identified as vulnerable to this specific deterioration process.

A fundamental prerequisite for SHM-informed, model-based integrity management of bridges is the implementation of a consistent digital data management. Such a system must provide storage and access to all relevant physical information across the design, construction, and operational phases of a bridge's lifetime. It must be able to handle heterogeneous data objects, including design reports, quality control protocols, inspection records, sensor data, and assessment results. Furthermore, the system should support automated workflows that integrate this diverse data with model-based methods to enable accurate diagnosis and prediction of structural condition, as well as assessment of structural safety.

The first step in developing a physics-informed strategy for monitoring and managing the structural integrity of concrete bridges susceptible to stress corrosion cracking is to thoroughly analyze the potential failure modes resulting from the loss of a significant number of prestressing wires. It is crucial to ensure that the bridge possesses sufficient structural redundancy so that the failure of prestressing strands does not lead to sudden, catastrophic collapse. This redundancy is typically provided through reinforcement, which allows for large deformations after strand failure – acting as warning signs before failure and preventing brittle, unannounced collapse. Furthermore, it must be demonstrated that observable indicators accompany significant damage to prestressing strands. Examples of such indicators include horizontal longitudinal cracks in the webs of box girders or beams [6]. The appearance of these signs suggests advanced damage and necessitates immediate action, including bridge closure for detailed assessment, reinforcement measures, or potential decommissioning.

If the previously discussed conditions are fulfilled—in addition to the requirements that the bridge is intact, shows no signs of significant damage to the prestressing tendons, and retains sufficient load-bearing capacity (potentially confirmed through a proof load test)—then a dedicated monitoring strategy can be implemented. In this case, the evolution of stress corrosion cracking, specifically the failure of individual prestressing wires, can be monitored using acoustic emission techniques. Following the detection of a tendon failure event, a detailed visual inspection of the bridge has to be carried out to check for any newly developed visible indicators of advanced damage.

The primary aim of acoustic emission monitoring is to detect failures of prestressing wires in time and space [9, 10]. This identification problem is currently approached by utilizing pure data-based signal processing methods. However, by adopting a

physics-informed strategy—combining physical modeling of the acoustic wave propagation from wire failures with measured data—the accuracy of rupture identification can be significantly improved. In this approach, data and modeling of wire failures are brought together by identifying the model prediction that best explains the measured acoustic signal, either through optimization or Bayesian updating. Research has been initiated at BAM to develop and validate this combined methodology [11].

The first step in a physics-informed approach to diagnosing wire failures from acoustic emission signals is the development of an acoustic reference model that accurately captures the acoustic properties of the structure. This model can be established and refined using data collected during in situ reference tests. A valuable source of such data comes from the sampling of prestressing wires, which emit acoustic signals when cut. These samples, typically taken to check for defect initiation and perform material testing, provide relevant emission characteristics that support model development.

Within a physics-informed approach to SHM, the reference model is a central component of a reference certificate or birth certificate, if created at the beginning of the structure's lifetime, as outlined in the upcoming revision of DIN 1076 [12]. The reference certificate contains all information required to develop and describe the reference model, including the underlying assumptions, the data used for its calibration and validation, as well as calibration and validation results. It is incorporated into the structure's data management system to ensure traceability and long-term use.

The first major application of the calibrated reference model is the optimization of sensor placement for the acoustic emission monitoring system. Sensor locations are selected to maximize the system's ability to perform the intended diagnostic tasks. This can be achieved, for example, through model-based value of information (VoI) analysis [13].

As an outlook, a physical model of the deterioration process can provide a basis for predicting the condition of prestressing tendons. The initiation of stress corrosion cracking during the construction phase may be described using mechano-electro-chemical principles [14], while crack propagation during the operational phase can be modeled through fracture mechanics [15]. Material properties and data on the initiation and evolution of the deterioration process from laboratory tests can be used to calibrate the model. Fatigue demands resulting from traffic loads and temperature variations are incorporated via models of the respective actions and a structural model to simulate the evolution of damage over time. Capturing the stochastic nature of the deterioration process is essential to ensure realistic predictions. By coupling the deterioration model with diagnostic information from acoustic emission monitoring and visual inspection, predictions can be continuously updated. Furthermore, integrating the deterioration model with a structural model allows for assessments of safety and serviceability throughout the structure's extended lifetime [16].

Currently, BAM is developing a physics-informed SHM procedure within the research project ReSKoMB, aimed at enabling the safe extension of the service life of prestressed road bridges suspected to be affected by stress corrosion cracking. The procedure is being developed using the

Baumgarten Bridge near Potsdam as a reference structure (Figure 9).

Figure 9. Baumgarten Bridge near Potsdam.

A key element of the procedure is the collection of prestressing wire samples taken directly from the bridge, providing essential information about the current condition of the wires (Figure 10).

Figure 10. Sampling of prestressing wires from an existing road bridge for material testing (source: LS Brandenburg).

These material samples are subject to various tests, including non-destructive testing to detect defect initiation. Additionally, laboratory experiments are conducted to study the onset of damage through stress corrosion cracking and the subsequent growth of fatigue cracks under cyclic loading (Figure 11).

Figure 11. Fracture surfaces of two prestressing wires after a fatigue test. Green: pre-existing defects, red: crack propagation during the fatigue test, light gray: residual fracture surface [6].

A physical model of the damage processes is then developed based on these tests, allowing for predictions of the time to wire failure. To enhance these predictions, object-specific traffic load models are developed for the bridge. As part of this modeling, traffic loads are classified based on vibration measurements, enabling a more accurate representation of the actual loading conditions (Figure 12). This work builds on a project funded by the German Research Foundation within the Priority Programme "Hundred Plus" [17]

Figure 12. Classification of vehicles crossing a road bridge using machine learning techniques. The classification is based on acceleration signals [17].

Further, diagnostic information from acoustic emission monitoring, enhanced with physical modeling of acoustic wave propagation from wire failures, is used to update the predictions (Figure 13). This work is being performed as part of a parallel project at BAM called SimAS, which focuses on acoustic modeling techniques to improve the diagnosis of wire failures based on acoustic emission data [11].

As an alternative to acoustic emission methods, the project is also exploring the potential to detect wire failures using acceleration signals recorded with MEMS sensors, a method which has been successfully used in a previous project with progressive severing of prestressing wires (Figure 14).

Additional information on visible indicators of critical damage, such as horizontal longitudinal cracks in the bridge webs, is obtained through automated UAS-based inspections

[18], which is triggered by continuous monitoring of prestressing wire failures.

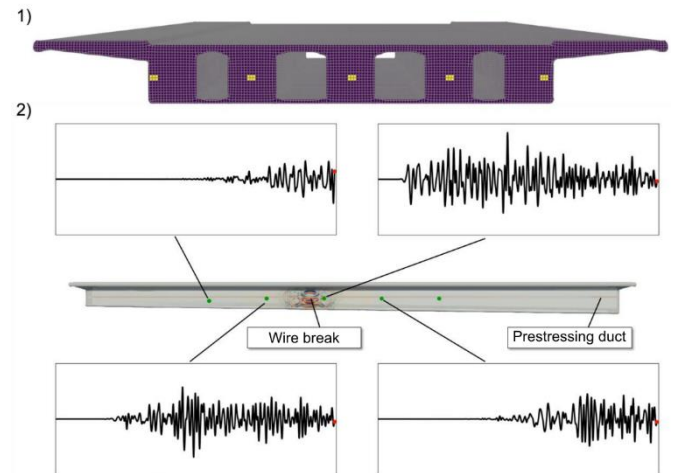

Figure 13. Simulation of acoustic wave propagation from a prestressing wire fracture in a box girder bridge. 1) Numerical mesh. Different material properties for concrete and wires (e.g., sound speed, density, damping) can be assigned to the elements. 2) Side view of the bridge with a simulated wire failure and several point evaluations of the simulated sound emission. [11].

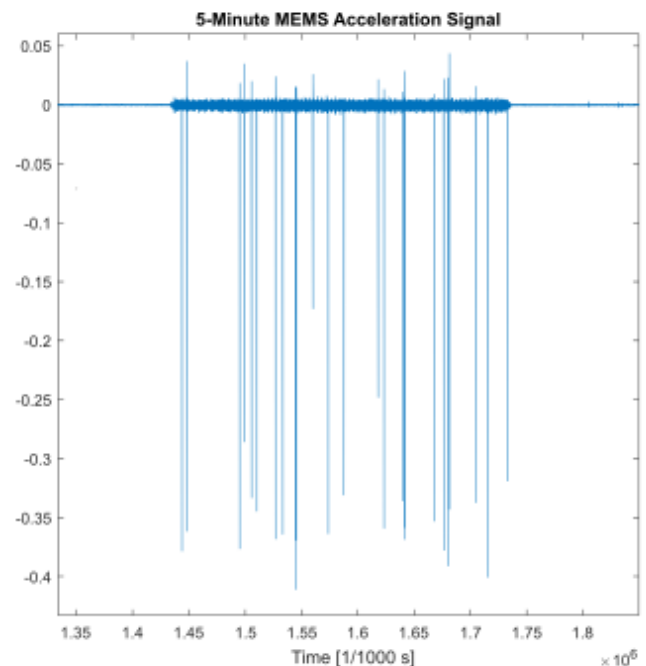

Figure 14. Accelerations measured with MEMS sensors on a bridge during progressive severing of prestressing wires [6].

#### 4 CONCLUDING REMARKS

As outlined in this contribution, physics-informed SHM holds significant potential to enhance diagnostics, prognostics, structural assessment, lifetime evaluation, and planning of operation and maintenance activities. By incorporating physical models into the SHM process, this approach offers a promising way to account for operational and environmental

variations that typically challenge conventional diagnostic methods.

However, the effectiveness of physics-informed SHM ultimately depends on the inherent sensitivity of the monitoring system to damage. These methods cannot compensate for a lack of sensitivity in the underlying measurement technique – rather, they can only leverage and enhance existing capabilities. Thus, careful consideration must be given to the selection and design of monitoring systems.

Implementing physics-informed SHM approaches requires proper digital data management to enable automated and scalable workflows. It is also associated with substantial modeling effort, making it essential to assess the return on investment for each application context.

These challenges and opportunities will be discussed further with the community at the upcoming CSHM-10 workshop in 2026, to be held in Berlin. As a dedicated forum for experts in SHM and non-destructive evaluation (NDE), CSHM-10 will provide an ideal platform to explore how physics-based models and monitoring data can be effectively combined to improve the safety, resilience, and efficiency of civil infrastructure systems.

## ACKNOWLEDGMENTS

**ABSTRACT:** Anchored structures are an essential part of infrastructure corridors, as they enable high cuts and the reinforcement of existing structures. As pre-stressed elements, anchors allow for economical construction with low-deformation, making them critical components for ensuring stability. Consequently, comprehensive monitoring is often required alongside inspections, especially when the reliability of the load-bearing elements is in question - e.g., due to creep or corrosion of metallic components. Based on research activities due to the ageing of such structures, several options have been investigated to retrofit load measurement devices to already installed pre-stressed anchors. In addition to different types of coupling methods, this paper presents first results from a trial in which, through the retrofitting of an external thread to strands, a new method for load monitoring is investigated. These methods are particularly useful when information about the current anchor load is lacking, as they provide better insight into the condition of the tension elements and, furthermore, the overall behavior of the structure. The paper shows some approaches already in use and the results of an initial test series, in which the potential of a new approach to amend a load measuring device to an already installed pre-stressed anchor is investigated and validated.

**KEY WORDS:** Anchor testing, Load monitoring, Existing structures, Asset management, Retrofitting.

### 1 ANCHORED STRUCTURES

Due to their ability to transfer large tensile forces into deeper or more competent strata, anchored structures using tension elements are often an economical design option in geotechnical engineering. Grouted anchors [1] & [2]], in particular, can be used to reduce deformations, allowing for more compact and slender geometries. Examples of such structures include newly constructed anchor and pilaster walls (Figure 1), as well as structures that have been subsequently anchored during refurbishment or repair (Figure 2).

Figure 1. Anchored pilaster wall.

Figure 2. Pre-stressed anchors used for the remediation of a cantilever retaining wall.

Over the designed service life of up to 100 years, such technically demanding structures require increased inspection and maintenance. In Austria, the specifications for structure operators are defined in the FSV guidelines [2]. The inspection procedure for anchored structures is identical to that for non-anchored retaining structures. On the one hand, the focus is on the surrounding terrain, drainage system and structural

components, which are typically made of reinforced concrete. On the other hand, anchors undergo a more intensive assessment to determine their state of preservation. Inspections (or checks) are generally carried out every 3 to 6 years and must be performed manually and visually during on-site activities.

In addition, the special inspection of tension elements and anchored structures is described in detail in a separate working paper [5]. The aim of these activities is not only to determine the current condition of the structure, but also to detect changes in the state of preservation or the development of damage patterns on the tendons, in order to assess their impact on safety and reliability.

At the end of such an inspection, and in addition to the assessment, recommendations for necessary measures are provided. Alongside the suggestion to carry out special inspections, this may include advices on implementing monitoring systems for the structure. The aim is, on the one hand, to gain a better understanding of the structure's behaviour, and on the other hand, to integrate these systems into alarm and warning plans - especially for severely damaged structures - in order to enable early response to potential or imminent failure.

## 2 INSPECTION AND DAMAGE IDENTIFICATION ON ANCHORED STRUCTURES AND TENDONS

As a structure ages, the requirements for inspection and maintenance increase in order to ensure an accurate and conclusive assessment of its condition. The regular performance of inspections [6] enables the early detection of defects and thus forms the basis for a long-term, continuously optimized maintenance strategy. The scope of [2] covers all structures in which anchorages [1] have been installed. Therefore, this guideline includes a wide range of applications - from anchored retaining structures (see [5]) to pier footings and anchored bridge abutments, as well as retrofitted anchored structures ([7]). For inspection purposes, a distinction has to be made between the structure itself and the relevant structural components. In this context, the term "structure" also includes the adjacent terrain at the head or base of the structure.

Relevant structural components of anchored structures cannot be completely examined during inspections (i.e. they can only be examined to a limited extent). This is, on the one hand, due to the apparent free length and the bond length (see Figure 3) of a pre-stressed anchor, which are located in the subsoil and thus not accessible. On the other hand, for many structures, the anchor heads were sealed during construction and are therefore not directly visible.

As with other structures, damage or an increase in damage can also be observed over time on anchored structures and the installed tendons. In addition to damage to the structural components (e.g. concrete elements and shells), corrosion damage to the metallic components of pre-stressed anchors is particularly critical. For permanent anchors with a designed service life of up to 100 years, corrosion protection for all components must be ensured. When it comes to tension elements and anchored structures, a general distinction can be made between two types of corrosion.

Oxygen corrosion refers to a chemical process in which iron and steel materials oxidize when they interact with oxygen and an electrolyte (e.g. water). The product of this process is

commonly referred to as rust. This rust layer is generally very porous and, in contrast to other reaction products (e.g. the pyrolysis layer of burned wood), provides little or no protection against the progression of the process. The corrosion can only be halted by removing one of the reaction partners (oxygen or water) or by passivating the surface. In contrast to oxygen corrosion, stress corrosion cracking typically occurs in pre-stressed steel elements under prolonged tension. These stresses can result either from an externally applied load or from internal constraints. Additionally, hydrogen atoms, which may be produced from oxygen corrosion, penetrate the metal lattice. This slight disturbance in the metal's microstructure forms a crack capable of growth under the influence of tensile stresses. These chemical reactions and processes can occur in pre-stressing steels, which are sensitive to such damage. In the case of high-strength steels, commonly used for tendons, the process is referred to as hydrogen-induced stress corrosion cracking. In contrast such a process generally does not produce any significantly recognizable damage pattern during propagation, and can therefore not be clearly identified by the reaction products.

Figure 3. Parts of a pre-stressed anchor.

In the absence of corrosion protection and when environmental conditions are conducive to corrosion, uniform surface corrosion can affect the entire cross-section. This is mainly observed on exposed steel components, strands and bars with insufficient corrosion protection. In contrast to uniform surface corrosion, pitting corrosion occurs at points where the corrosion protection is absent or inadequate in certain areas of the cross-section. This corrosion phenomenon is typically found in improperly manufactured or cracked grout bodies. In chloride-contaminated environments (e.g. de-icing agents), such phenomena are also more likely to occur. This process begins in a relatively small area on the surface and spreads relatively quickly into the interior, significantly reducing the cross-section locally.

As mentioned above, corrosion damage to anchored structures and tendons mainly occurs in unprotected or inadequately protected areas of the structure. Some of these areas are a result of the design itself, while others stem from the manufacturing process or associated weaknesses and deficiencies.

Figure 4. Corroded tension elements of the external parts of strand anchors.

Corrosion damage to insufficiently protected outer surfaces of the anchor (Figure 3 area A) can lead not only to a visual impairment of the anchored structure but also to a loss of load-bearing capacity of individual tendons or even the failure of an entire anchor over time. However, due to the often rather massive design of the anchor head components, some reserves remain. Improperly filled anchor head niches or protective covers often lead to increased corrosion, which can manifest as the release of reaction products or visible rust plumes. As shown in Figure 4, exposed components of the anchor, which are subjected to weathering and environmental conditions, are particularly susceptible to corrosion. Such damage can usually be detected by a visual inspection of the anchor head.

The most critical point is found in the section directly behind the anchor head (Figure 3 area B). Defects in the inner anchor head can occur during construction, but also due to ageing or volatilization of the corrosion protection material. The absence of corrosion protection at the anchor head (see Figure 5) can be considered severe damage to both the tendon and the anchored structure.

In addition to the two types of damage in the anchor head area, corrosion processes can also occur along the entire anchor length. Likewise, ageing effects on the grout material can occur along the entire apparent free length, potentially leading to corrosion of the tension element (Figure 3 area C). Due to the load transfer from the tendon into the underground along the bond length and the associated tensile stresses in the grout body, cracks may develop. These cracks create damaged areas in the corrosion protection (Figure 3 area E), serving as potential sources for corrosion. Especially in the transition zone between the apparent free length and the bond length (Figure 3 area D), cracks occur more frequently due to the strong increase of the stresses in the grout body [8]].

Figure 5. Corroded strands within the anchor head area.

Furthermore, if design documents or long-term monitoring data are available, the inspection of the structure can usually be carried out by trained personnel without major difficulties. However, if no or only limited geological, geotechnical and structural information is available at the time of inspection, a more detailed investigation is required to make a reliable assessment of the structure's condition.

### 3 MONITORING OF ANCHORED STRUCTURES

As already mentioned, it is often necessary to implement appropriate monitoring measures during the maintenance phase of a structure, especially if significant defects are identified. In addition to deformation monitoring, the pre-stressing force is a key parameter for anchored structures. Throughout the service life of an anchor, the anchor load can either be observed with installed monitoring systems, or assessed by performing lock-off-tests. While a monitoring system, such as load cells, offer the possibility to survey the anchor load over a longer period (depending on the monitoring interval), a lock-off-test only determines the load acting on the anchor at the time of testing.

#### 3.1 Anchor Lock-Off-Testing

Regarding the safety assessment of anchors and anchored structures in Austria (e.g. [7] & [9]), the normative rules of EN 1537 [1] are supplemented by the requirements outlined in the RVS guidelines [3] and a Working Paper [4]. To ensure the capability of an anchor or the functionality of a preliminary anchor system design, three different test types - namely, investigation, suitability and acceptance tests - are performed. A lock-off-test solely indicates the load currently applied to an anchor. In general, the anchor load depends on a variety of factors and can be influenced by daily and seasonal fluctuations (e.g. temperature, groundwater), but can also vary due to damage (e.g. corrosion) or creep effects. Taking these factors into account, however, a lock-off test can provide an accurate assessment of the anchor's condition and functional efficiency.

Research (e.g. [10] & [11]) and the results of safety assessments on anchors have shown that anchors, especially the anchor head, are often exposed to de-icing agents and salt, making them highly susceptible to corrosion damage. Such damage is usually not detectable through the results of lock-off tests. Therefore, in addition to a lock-off-test, endoscopic examinations [12] can provide valuable insights into the

condition of an anchor. Especially the visual inspection of the anchor head area can help to detect manufacturing defects or corrosion damage in the anchor head.

Besides – mostly durability related – damages to an anchor (e.g. [10] & [13]), an increasing number of corrosion damages to reinforcement elements (e.g. [11] & [14]) can be observed.

The result of an anchor lock-off test can be seen in Figure 6. This load-deformation-diagram illustrates the compression and slippage of the test setup (green line) alongside with the elastic elongation of the anchor strand. The intersection point, marked by the two equalisation lines in Figure 6, represents the point where the anchor head lifts off the anchor plate (or the structure), which defines the currently applied anchor load.

Figure 6. Deformation-load-diagram of an anchor lock-off test.

In comparison to the test loads in a suitability or acceptance test of anchors (e.g. [1], [15] & [17]), the determine of the lock-off load is not described in normative or design regulations. As this load reflects the current state of the anchor and is therefore subject to change over time, making it therefore often necessary to define the lock off load  $P_A$  in advance based on knowledge and experience. The number of strands or the diameter of the bar, for example, can provide information on this and define the limits and boundaries for such tests in combination with a preceding endoscopic surveillance of the anchor head and a stepwise load increase during the testing process.

### 3.2 Anchor load monitoring

By monitoring the anchor forces, any changes (both decreases and increases) in the anchor force and their resulting effects on the structure, or the potential failure of the anchor, should be recorded in a timely manner. This is necessary to comply with the requirement of Eurocode 7 [17], Chapter 8.3, which states that *'the effects of anchor failure must be taken into account'*, even though there are limited specifications in terms of standards and calculation methods (see [18], [19] & [20]) for how this requirement should be addressed.

For this purpose, anchor load measuring devices are used, typically installed during the construction of the structure. In addition to electrical force measuring devices (e.g. eddy current) or traditional systems based on strain gauges, hydraulic measuring devices as shown in Figure 7 are commonly used.

Such measuring devices are usually installed at the anchor head and are equipped with analogue reading devices. However, the accuracy of these readings is often limited, influenced by factors such as viewing angle and accessibility. Additionally, these measuring devices are usually exposed to weathering, ranging from temperature changes, rain and wind to harsh environmental conditions like snow, frost and the effects of de-icing agents used during winter maintenance.

Figure 7. Anchor load plate installed during the construction of the structure.

## 4 RETROFITTING LOAD MEASUREMENT DEVICES ON PRE-STRESSED ANCHORS

If assessing the state of preservation, the results of a lock-off test or the need for more comprehensive information on the behaviour of an anchor require it, digitising existing measuring equipment or installing force measuring devices may become necessary.

The following sections present various approaches for implementing such measures, as well as the key considerations related to planning, execution and data interpretation.

### 4.1 Digitalization of load measurement devices

Force measuring devices installed on structures, such as shown in Figure 7, usually feature only an analogue reading, limiting their ability to provide close-meshed time series or assess temperature-related behaviour of the structure. To address this limitation, the digitalisation and real-time collection of measurement data have therefore been increasingly used for such existing elements.

Although force measuring devices can already be digitised during installation - i.e. during the production of the anchorage - this was often not done, or the technology was not yet available at the time the anchorage was installed. In the following, however, the digitalisation of already installed anchor load plates is briefly discussed - a possibility to add digital data acquisition to almost all installed and still functional devices.

Figure 8 shows an example where an existing anchor load plate with an analogue reading device was upgraded with a

digital data acquisition unit. The exact implementation steps involved are listed in [21]]. In addition to digitising the anchor load measurement, environmental factors such as the outside temperature, humidity and structural temperature at different depths should also be recorded to gain a comprehensive understanding of the structure's behaviour.

Figure 8. Digitization of an already installed anchor load plate.

This type of digitisation process, combined with the installation of both analogue and digital data acquisition systems, can offer significant added value for the structure and inspection personnel. While the analogue reading allows for a fast check of functionality and a direct determination of the anchor force, the digital interface enables the collection of comprehensive time series data on the behaviour of the anchor. An example of this is shown in Figure 9.

Figure 9. Time series of digitized anchor load cells in relation to temperature.

The diagram shows the recorded anchor loads of three anchors (M1 to M3) alongside the measured air temperature (from -10°C to +13°C) over an observation period not further defined here. A clear correlation between changes in air temperature and the recorded anchor loads can be observed. Furthermore, the anchor load responds almost immediately to changes in temperature, suggesting that these variations are largely attributable to the thermal expansion of the measuring device or the structural elements of the wall.

#### 4.2 Retrofitting load measurement devices on anchor heads

If no load measurement devices are present on a structure, or if additional pre-stressed anchors are to be equipped with such

systems, several retrofitting options are available. If the anchor head offers a thread (either internally in the wedge plate or externally), a force measuring device can be retrofitted relatively easy - enabling a short-circuit setup similar to a lock-off test. Alternatively, the existing tendon overhang can be used for attaching a measurement device. However, this is rarely feasible with existing anchorages in Austria, necessitating the exploration of alternative solutions. Two such approaches are briefly described below.

Figure 10 shows the first retrofitting possibility, which involves attaching an additional press chair to facilitate the subsequent lifting of the anchor head via two threaded rods. This enables the creation of a load short circuit through the installation of a new anchor load plate. However, this design is only possible if suitable contact points are available on the anchor head (e.g. free strand holes, internal threads, bayonet at the wedge plate) that allow the anchor head to be properly engaged. In this particular case, the approach was possible because only two strands were installed in a four-strand wedge plate, leaving two free strand holes. Threads were cut on-site into these unused holes to accommodate the threaded rods.

Figure 10. Example of retrofitting an anchor load plate on a partially occupied anchor head.

The figure below shows a special type of anchor known as a wire anchor. Its distinctive feature is that the wires within the drill hole are bundled by a rod attached in the centre. This system, referred to as a PZ anchor [22], allows for relatively straightforward attachment of a new load short circuit and the retrofitting of an anchor load plate, due to the presence of a fine-threaded rod at the anchor head.

Both options share a common factor in that they involve considerable effort. Sufficient expansion paths must be available to enable a load short circuit and the geometric requirements for attaching an anchor load plate must also be met. It should also be noted that such interventions, such as the on-site installation of threads in installed wedge plates, represent a significant impact on the system. This may raise concerns not only regarding liability but also with respect to durability and integrity. Nevertheless, in cases where

significant changes in anchor loads are suspected, the added value of enabling anchor load measurement typically outweighs these concerns and becomes the primary focus of such investigations and considerations.

Figure 11. Example of retrofitting an anchor load plate for tensile elements or anchor heads with threaded component.

#### 4.3 Retrofitting load measurement devices on anchor strands

Often, there is insufficient strand overhang, the wedge holes of an anchor head are occupied and other structural components required to create a force-locking connection are unavailable. As a result, the options listed in Chapter 4.2 for retrofitting an anchor load plate to existing pre-stressed anchors may not be feasible. Nevertheless, to accurately assess the behaviour of the structure, it would be beneficial to obtain information about any potential changes in the pre-stressing force.

One possible option is to cut an external thread on the existing strand overhang. From a practical point of view, this section of the tendon is usually 15 - 20 mm long, which may allow a fine thread to be screwed on and subsequently a threaded nut to be fitted. An example for testing purposes is shown in Figure 12 and Figure 13. A fine thread M16x1 (core diameter 14.92 mm) was screwed onto a strand with an outer diameter of 15.6 mm. The manufacturing test demonstrated that even with low pre-stressing forces on the strand and a resulting small wedge bite, the thread could still be successfully installed.

Figure 12. External thread retrofitting to a pre-stressed anchor strand.

The embossed thread on the strand overhang allows for the creation of a force-locking connection between the strand, which would otherwise only be gripped by friction, and other structural elements. An example of this can be seen in Figure

13, where two nuts were screwed onto the embossed thread of the strand to facilitate a tensile test.

Figure 13. External thread used for the application of a threaded nut on an anchor strand.

The result of a series of tests showed that a force-locking connection can be achieved by installing an external thread onto the overhang of already installed anchor strands. Obviously, the amount of load that can be transmitted depends on the length of the thread, the pitch and the condition of the strand. More detailed investigations are currently underway. Nevertheless, this first series revealed the following points:

- It is possible to emboss an external thread onto the overhang of already installed, pre-stressed anchor strands;
- There is no unacceptable mechanical damage to the high-strength steel strands due to cold forming during the cutting process;
- With sufficient strand overhang, it is possible to achieve a force-locking connection;
- An externally applied thread on strands can be used to attach threaded nuts for force input or transmission.

This approach therefore enables the creation of a subsequent force-locking connection with the individual strands of a pre-stressed anchor. This can facilitate the installation of threaded rods to extend the strands, simplifying the execution of lock-off testing or enabling the retrofitting of force measuring devices, as shown in Chapter 4.1 and 4.2.

Furthermore, innovative and new measuring devices, such as the e-Bolt [23]], could also be implemented in anchor technology. This system consists of a nut that, in addition to securing and transmitting loads, also serves as a measuring device. Such systems are already used in various measurement applications, for example to measure the pre-load force of dynamically stressed objects like noise barriers along railways. Beyond retrofitting force measuring devices, this technology could also enable the digitization of anchor force measurement.

## 5 CONCLUSIONS & SUMMARY

There are several methods to assess the condition of anchored structures, particularly the condition of the tension elements. In addition to traditional structural inspections, monitoring data is often used. Typically, geodetic surveys, readings from existing measuring devices and, if necessary, special tests to determine the material properties are used to record any changes regarding the state of preservation of anchors and anchored structures.

Since lock-off testing is associated with higher personnel costs and potential restrictions, such as road closures or other impacts on the availability of infrastructure, it is usually

conducted on a limited number of anchors and at periodic intervals. If such tests are not possible, for example due to the shape and type of anchorage, or if a continuous time series of the currently applied anchor load is required, retrofitting a force measuring device may be an appropriate solution.

One of the most common options is to attach anchor load measurement devices directly to the anchors under consideration. However, this is only possible if such provisions have already been accounted for during the planning stage. These measuring elements can be enhanced with continuous data acquisition by digitising the measuring devices, providing comprehensive information on the behaviour of the structure. In addition to possible seasonal influences such as temperature, monitoring can also be implemented in order to detect damage processes or imminent failure of single elements or the anchored structure itself.

Current investigations and research activities in this area indicate that, in addition to various methods of coupling to the anchor head construction of pre-stressed anchors, it is also possible to retrofit anchor load measurement equipment by subsequently cutting threads onto the strand overhang. This approach allows for the use of a force-locking mechanism to attach measurement devices or to enable additional lock-off testing.

This article has attempted to compile a comprehensive overview of the available options for retrofitting anchor load measurement solutions. Given the decline in the state of preservation of anchored structures and tension elements, along with their frequent use in geotechnical engineering, such retrofitting solutions are expected to receive increasing attention in the future.

## ACKNOWLEDGMENTS

The investigations and developments presented in this article were conducted as part of a series of service and research projects. Among other things, the concept for attaching threads to existing strand protrusions was developed as part of the SaRAS - Safety and Risk of Anchored Structures - research project, which was initiated by VÖBU and funded by the Austrian Research Promotion Agency (FFG).

**ABSTRACT:** Structural health monitoring (SHM) is a key method for assessing the condition of civil infrastructure, detecting and localizing damage through continuous data acquisition. Damage detection methods are divided into physically based approaches, using finite element (FE) models, and data-driven approaches, relying on signal processing. A key challenge in SHM is the lack of data from the damaged state, which complicates the validation of the technique. However, the successful deployment of SHM systems on real civil infrastructure depends mainly on their reliability. For non-destructive testing (NDT) systems, the Probability of Detection (POD) is an accepted approach for quantifying reliability. In contrast to NDT, there is no generally applicable procedure to assess the reliability of SHM systems.

This study addresses this gap by evaluating SHM reliability with POD models and data generated from calibrated FE models. These FE models are calibrated through Bayesian inverse methods. To manage computational challenges, generalized Polynomial Chaos Expansion (gPCE) surrogate models are employed. These methods are tested using vibration-based measurements on a laboratory-scale four-degree-of-freedom (4-DOF) wood frame. The results highlight the use of MAPOD and limitations of the method, emphasizing their potential to enhance SHM reliability and enable smarter infrastructure systems.

**KEY WORDS:** MAPOD; SHM; Bayesian inverse methods; vibration-based measurements.

## 1 INTRODUCTION

Structural Health Monitoring (SHM) is a key method for assessing the condition and integrity of civil infrastructure through continuous or periodic data acquisition. By deploying sensor networks, SHM systems are capable of detecting and localizing damage of structures, thereby enhancing maintenance strategies and extending service life. Damage detection methods in SHM are typically categorized into two major classes: physics-based methods, which utilize for example finite element (FE) models to simulate structural behavior; and data-driven methods, which rely on signal processing, statistical analysis, and machine learning [1].

A major challenge in SHM is the lack of damaged-state data, which complicates the validation and benchmarking of diagnostic techniques. This issue becomes critical when aiming to ensure the operational reliability of SHM systems in real civil infrastructure applications. While Non-Destructive Testing (NDT) technologies benefit from standardized reliability assessment procedures such as the Probability of Detection (POD), the SHM community is still developing a generally applicable methodology for quantifying SHM system reliability.

POD is a metric used to evaluate the performance of Inspection system of NDE. POD quantifies the likelihood that a flaw of a given size will be reliably detected by the inspection system NDE. POD curves have been widely applied in the aerospace and nuclear power industries to ensure structural safety [2–4]. The conventional approach for estimating POD curves as used in the aerospace industry is based on empirical testing as outlined in MIL-HDBK-1823A [2]. This approach requires the generation of a sufficiently large and representative data set covering a range of flaw sizes. Two primary techniques are commonly used: the **Hit/Miss** method and the **â vs. a**

(response vs. flaw size) method. These procedures form the foundation of standardized POD analysis in NDE.

In contrast, the Model-Assisted Probability of Detection (MAPOD) approach integrates physics-based model simulation for estimating POD. MAPOD aims to extend and complement the basic MIL-HDBK methodology by reducing (though not eliminating) the need for physical testing samples.

The application of MAPOD has been investigated in several studies [7–9]. Smith et al. [8] successfully conducted a fully model-assisted POD validation for immersion ultrasonic inspection targeting embedded flat-bottom holes. Their results demonstrated equivalence to those obtained using the conventional MIL-HDBK-1823 approach.

Knopp et al. [7] explored a MAPOD approach for evaluating crack detection in a two-layer airframe structure with countersunk fasteners using Eddy Current Testing (ECT). The study involved 171 fasteners, including 38 with known cracks, with crack lengths ranging from 0.69 mm to 4.29 mm. Physical models were calibrated with experimental data, and 5000 synthetic data points were generated via Monte Carlo simulation for MAPOD estimation. The results showed excellent qualitative agreement between the empirical and simulation-based POD curves, although uncertainties in the input parameters were not explicitly addressed.

By leveraging FE models or numerical simulations, MAPOD can significantly lower the time, cost, and logistical complexity of traditional POD studies [7]. This numerical simulation-based method has great potential in evaluating the reliability of SHM systems, where empirical data is often limited or difficult to obtain.

This study proposes a framework for evaluating the reliability of SHM systems using POD and MAPOD models. The framework is enhanced by simulated data generated from

finite element (FE) models, which are calibrated in the reference/undamaged state using Bayesian inverse methods to capture uncertainties and improve prediction accuracy based on experimental observations. As a result, simulations of parametric variations, such as the initiation and progression of damage, can be conducted with higher accuracy, thereby improving the predictive capability and overall reliability of the SHM system.

To address the computational demands of FE simulations, surrogate models based on generalized Polynomial Chaos Expansion (gPCE) theory are employed.

The calibration of the FE model is performed by applying a Polynomial Chaos Expansion-based Kalman Filter (PCE-KF). This method is validated using a laboratory-scale experiment involving a four-degree-of-freedom (4-DOF) wooden frame subjected to vibration-based measurements. The measurements are performed under both reference and changed states, where the changes are introduced through controlled mass variations.

The results demonstrate the feasibility of applying MAPOD techniques within the SHM context and provide insight into the limitations and practical considerations of this approach. Ultimately, this work contributes to the development of reliable SHM systems for civil infrastructure.

## 2 METHODOLOGY

The overall workflow proposed for the MAPOD construction is illustrated in Figure 1, while a detailed explanation of each component is provided in the subsequent sections.

Figure 1. MAPOD model building process

### 2.1 Experimental Setup

A laboratory-scale four-story wooden frame structure is designed to simulate the response of four degrees of freedom system. To achieve this, the column dimensions are carefully adjusted to ensure that the stiffness in one translational direction is significantly greater than in other translational or rotational directions. The column cross-section is 300 mm by 6.4 mm. The total height of the wooden frame is 1000 mm, with a width of 500 mm. Each story has a height of 250 mm. The

beam cross-section is 60 mm by 60 mm. The columns are constructed from laminated wood sheets, while the beams are made of solid wood. The mass of each structural element is determined by weighing the components prior to assembly. The frame is instrumented with triaxial accelerometers to record its vibration response under random excitation induced by a handheld rubber hammer. A data acquisition system from Dewesoft and MMF KS903B100 triaxial accelerometers are used in this experiment. The experimental setup is illustrated in Figure 2, and the structural geometry and mass is summarized in Table 1.

Table 1. Structural geometry and mass

Geometry [mm]		Mass [gr]	
Column cross-section	300x6.4	Column 1	885
		Column 2	915
		Beam 1st Floor	1122
H, Height	1000	Beam 2nd Floor	1060
		Beam 3rd Floor	1046
Beam cross-section	60x60	Beam 4th Floor	1020
L, Length	500	Triaxial Accelerometer	11

Figure 2. Experimental setup

The measurements are conducted under both reference (undamaged) and changed (damaged) states. The changed state is simulated by incrementally adding mass to the fourth floor of the structure. For each state, vibration responses are recorded for 90 seconds at a sampling rate of 1000Hz, with each test repeated at least 15 times to ensure statistical consistency. The experiments are performed over several days, from March 24<sup>th</sup> to March 29<sup>th</sup> 2025, to ensure sufficient data collection and to capture a broader range of variability even under stable environmental conditions.

All experiments are conducted under constant room temperature ranges and humidity conditions. This experimental setup serves as the basis for validating the MAPOD analysis compared to real physical test data. Details of the measurement set and repetition are provided in Table 2.

Table 2. Measurement set

Measurement Set	Added Mass [gr]	[%] to the Mass of 4 <sup>th</sup> floor	Repetition
Reference	0	0	267
Mass 1	25	2.4 %	69
Mass 2	51	4.9 %	55
Mass 3	75	7.3 %	20
Mass 4	102	9.9 %	70
Mass 5	153	14.8 %	66
Mass 6	204	19.8 %	55
Mass 7	255	24.7 %	15

## 2.2 Finite element model and Bayesian updating

A three-dimensional finite element (FE) model of the four-story wooden frame structure is developed in Ansys to simulate its modal dynamic response. The model geometry reflects the actual dimensions of the physical structure, incorporating column and beam cross-section. Shell elements are used to represent the thin column sections, while beam elements are used to represent beams. The beam-column connections are assumed to be rigid. The boundary conditions simulate fixed line support at the base, consistent with the physical setup.

Material properties are initially assigned based on measured values. The material density is then calculated as the ratio of mass to volume for each element. The elastic modulus is unknown and is treated as random variable in wood properties. In addition to the elastic modulus, the thickness of the columns is also modeled as a random variable, accounting for imperfections in the thickness of the wood elements. The elastic modulus and column thickness are then treated as input random parameters in the Bayesian model updating. Meanwhile the natural frequencies and mode shapes obtained from modal analysis are used as output (observed) parameters for the Bayesian model updating.

## 2.3 Polynomial Chaos Expansion based Kalman Filter

A Bayesian model updating approach is applied to minimize discrepancies between the outputs of the FE model and the experimental measurements. The uncertain parameters, such as elastic modulus and thickness of columns, are treated as random input parameters  $\mathbf{Q} \in \mathbb{R}^{N_n}$  where  $N_n$  is the number of input parameters, modeled as Gaussian independent variables

$$\mathbf{Q} = \mathcal{N}(\boldsymbol{\mu}_Q, \mathbf{C}_Q) \quad (1)$$

where  $\boldsymbol{\mu}_Q \in \mathbb{R}^{N_n}$  is the vector of mean values and  $\mathbf{C}_Q \in \mathbb{R}^{N_n \times N_n}$  is the covariance.

The system random inputs are transformed by a forward model operator  $\mathcal{M}$  into the outputs  $\mathbf{Y} = \mathcal{M}(\mathbf{Q}) \in \mathbb{R}^{N_m}$  where  $N_m$  is the number of measured outputs. The measurement  $\mathbf{Z} \in \mathbb{R}^{N_m}$  is affected by an error  $\mathbf{E} \in \mathbb{R}^{N_m}$ , which follows a normal distribution and combines linearly with the measured output

$$\mathbf{Z} = \mathcal{M}(\mathbf{Q}) + \mathbf{E}, \mathbf{E} = \mathcal{N}(0, \mathbf{C}_E) \quad (2)$$

where  $\mathbf{C}_E \in \mathbb{R}^{N_m \times N_m}$  is error covariance. The scope of the Bayesian updating is to improve the estimation of the random input  $\mathbf{Q}$  given output measurements  $\mathbf{z}$ . An efficient approach to

Bayesian updating consists in applying the linear Bayesian Filter

$$\mathbf{Q}' = \mathbf{Q} + \mathbf{K}(\mathbf{z} - \mathbf{Y}) \quad (3)$$

where  $\mathbf{Q}$  are prior parameter estimates,  $\mathbf{Q}'$  are the posterior,  $\mathbf{z}$  are output measurements,  $\mathbf{Y}$  are measured system outputs and  $\mathbf{K}$  is the Kalman Gain

$$\mathbf{K} = \mathbf{C}_{QY}(\mathbf{C}_Y + \mathbf{C}_E)^{-1} \quad (4)$$

where  $\mathbf{C}_Y$  is the system outputs covariance,  $\mathbf{C}_E$  is the error covariance and  $\mathbf{C}_{QY}$  is the covariance between system inputs and outputs.

The application of the linear Bayesian filter requires to assess the above mentioned covariances. This process is not straightforward in the case of implicit and/or non-linear forward model operators. To speed up the uncertainty propagation process and the application of the linear Bayesian filter, it is possible to represent each random variable in polynomial chaos expansion (PCE) form

$$\begin{aligned} \hat{\mathbf{Q}} &= \sum_{\mathbf{j}} \hat{q}_{\alpha} \boldsymbol{\Phi}_{q,\alpha}, & \hat{\mathbf{Y}} &= \sum_{\mathbf{j}} \hat{y}_{\alpha} \boldsymbol{\Phi}_{y,\alpha}, \\ \hat{\mathbf{E}} &= \sum_{\mathbf{j}} \hat{e}_{\alpha} \boldsymbol{\Phi}_{e,\alpha}, & \hat{\mathbf{Z}} &= \sum_{\mathbf{j}} \hat{z}_{\alpha} \boldsymbol{\Phi}_{z,\alpha} \end{aligned} \quad (5)$$

where  $\hat{q}_{\alpha}$ ,  $\hat{y}_{\alpha}$ ,  $\hat{e}_{\alpha}$ ,  $\hat{z}_{\alpha}$  are coefficients,  $\boldsymbol{\Phi}_{[\cdot],\alpha}$  multi-variate orthogonal polynomials for the quantity  $[\cdot]$ , and  $\mathbf{j}$  represents the set of multi-indices  $\boldsymbol{\alpha}$  truncated to the polynomial order  $p$ . In this case, the linear Bayesian filter takes the following form

$$\hat{\mathbf{Q}}' = \hat{\mathbf{Q}} + \mathbf{K}(\hat{\mathbf{z}} - \hat{\mathbf{Y}}) \quad (6)$$

and the covariances required to calculate the Kalman Gain can be analytically computed by the expansion coefficients. Detailed information about the polynomial chaos expansion based Kalman filter (PCE-KF) can be found in Rosic et al. (2012) and Rosic et al. (2013).

## 2.4 POD estimation and reliability metrics

The POD curve in this study is estimated using the  $\hat{a}$  vs.  $\hat{a}$  approach. The  $\hat{a}$  vs.  $\hat{a}$  model POD is a technique used in NDT to quantify the capability of a detection system based on continuous damage indicators. Unlike hit/miss POD methods, which rely on binary detection outcomes, the  $\hat{a}$  vs.  $\hat{a}$  model POD utilizes a continuous detection metric  $\hat{a}$  that reflects measurable differences in the system's response between undamaged and damaged states. This approach allows for an assessment of detection performance, particularly in systems where subtle changes in dynamic characteristics, such as natural frequencies or mode shapes, are used to infer damage. In vibration-based monitoring, such metrics are often derived from modal parameter shifts or other features sensitive to structural changes.

The  $\hat{a}$  vs.  $\hat{a}$  model involves fitting a linear function to the response feature,  $\hat{a}$ , as a function of the parameter of interest  $\mathbf{a}$ ,

$$\hat{\mathbf{a}} = \beta_0 + \beta_1 \mathbf{a} + \epsilon \quad (7)$$

where  $\beta_0$  and  $\beta_1$  are parameters that are estimated by performing a fit to the data and  $\epsilon$  is a noise term,  $\epsilon \sim \mathcal{N}(0, \sigma^2)$ . The noise term  $\epsilon$  is assumed to follow a normal distribution. The aforementioned parameters  $\beta_0$ ,  $\beta_1$  and  $\sigma$  are estimated in

the usual way by deploying ordinal least squares. We can ignore the more elaborated Tobit regression modeling from MIL-HDBK-1832A [2], because the observed  $\hat{a}$  values (see below) are far away from their natural bounds.

When multiple response features are available, a representative scalar value is needed to consolidate the relevant information into a single damage-sensitive metric. To address this, the Mahalanobis distance (MD) is employed as a fault indication metric. The Mahalanobis distance is a multivariate measure that accounts for correlations between variables, providing a statistically normalized distance of an observation from a reference distribution. For an observation vector  $\mathbf{x}_i$  (e.g., the measured eigenfrequencies of a structure at a specific time or condition), and a reference data set (e.g., the average eigenfrequencies in the undamaged state) characterized by mean vector  $\boldsymbol{\mu}$  and covariance matrix  $\boldsymbol{\Sigma}$ , the Mahalanobis distance is defined as

$$D_M(\mathbf{x}_i) = \sqrt{(\mathbf{x}_i - \boldsymbol{\mu})\boldsymbol{\Sigma}^{-1}(\mathbf{x}_i - \boldsymbol{\mu})} \quad (8)$$

To determine the statistical decision threshold for damage detection, the confidence interval approach based on the Chi-squared distribution is employed. Since the Mahalanobis distance  $D_M$  follows a Chi-squared distribution with degrees of freedom equal to the number of variables  $d$ , the decision threshold is defined as:

$$T = \sqrt{\chi_{1-\alpha, d}^2} \quad (9)$$

Where  $\chi_{1-\alpha, d}^2$  denotes the critical value from the Chi-squared distribution at a confidence level of  $1 - \alpha$ , and  $d$  is the dimensionality of the feature. For example, at a 99.9% confidence level and  $d = 3$ , the threshold is  $\chi_{0.999, 3}^2 = 16.27$ , corresponding to a Mahalanobis distance threshold of  $T = \sqrt{16.27} \approx 4.03$ . This captures the upper 0.1% of the reference distribution and yields a very strict false alarm rate.

The Probability of Detection (POD) as a function of damage size  $a$  is expressed as:

$$POD(a) = \Phi\left(\frac{a - \mu_a}{\sigma_a}\right) \quad (10)$$

Where  $\Phi(\cdot)$  is the cumulative distribution function of the standard normal distribution, and  $\mu_a$  and  $\sigma_a$  are suitable parameters controlling the shape of the POD curve. These parameters are derived from the linear regression model, with  $\mu_a = (T - \beta_0)/\beta_1$  and  $\sigma_a = \sigma/\beta_1$ , where  $\beta_0$ ,  $\beta_1$  and  $\sigma$  are the model parameters. The threshold corresponding to a 90% detection probability,  $a_{90}$  with  $POD(a_{90}) = 0.9$ , is then calculated as  $a_{90} = \mu_a + 1.645 \cdot \sigma_a$ . To account for the uncertainty in this threshold, the value  $a_{90/95}$ , representing the damage size for 90% POD with 95% confidence bounds, is computed using the Delta method referred to MIL-HDBK-1832A [2]. These performance metrics are used to assess and compare the detection capabilities of the SHM system. Following the same methodology, the Probability of Detection (POD) is also calculated using data generated from the calibrated finite element (FE) model.

### 3 ANALYSIS

#### 3.1 Data Analysis/Operational Modal Analysis

The recorded vibration data are analysed using operational modal analysis (OMA) to identify the dynamic parameters of the wooden frame. OMA is chosen because it enables the extraction of modal parameters under ambient or operational conditions without requiring controlled excitation forces. Using Artemis Modal Pro 7.2 software, the OMA is performed, and the natural frequencies ( $f$ ), damping ratios ( $\zeta$ ), and mode shapes of the structure are estimated. Based on the analysis results, four resonance frequencies are identified, corresponding to the four translational modes of the wooden frame. Figure 3 illustrates the identified mode shapes of the wooden structure in the reference state.

Figure 3. Mode shapes and frequency of wooden frame in reference state

OMA is also performed for all added mass configurations. Modal tracking is carried out to identify the mode similarities between each configuration to the reference state, with the Modal Assurance Criterion (MAC) threshold set to greater than 80%. The tracked resonance frequencies across all data sets are presented in Figure 4.

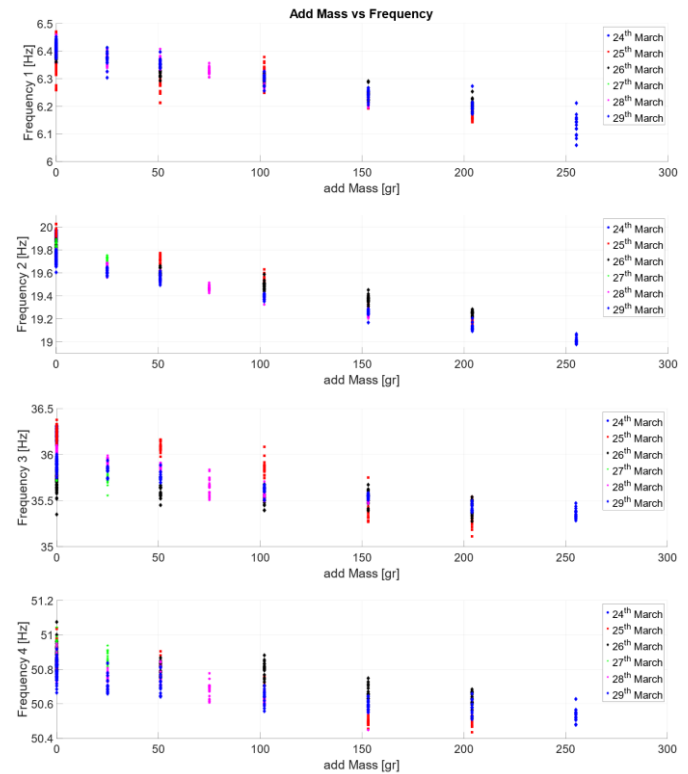

Figure 4. Tracked frequency (MAC > 80%) for the reference state and various added mass configurations

From Figure 4, it can be observed that the addition of mass on the fourth floor affects the dynamic response of the structure, particularly the resonance frequencies. As the added mass increases, the natural frequencies tend to decrease, which is consistent with the theoretical expectation that an increase in mass leads to a reduction in the system's stiffness-to-mass ratio. In addition to the frequency shifts, the damping ratios of the structure were also examined; however, no clear trend was observed in relation to the parameter changes. Furthermore, the first four dominant mode shapes remained largely unchanged, indicating that the modifications had minimal influence on the modal characteristics.

The results of the Operational Modal Analysis in the reference state, as shown in Figure 3, are used as the baseline data for calibrating the FE-model through a Bayesian model updating approach. An overall Operational Modal Analysis, as shown in Figure 4, is used to compute the empirical Probability of detection.

### 3.2 Bayesian model updating

A finite element (FE) model of the structure is developed using Ansys Mechanical, based on the given structural conditions. The FE model is then calibrated through Bayesian updating to estimate random model parameters. In this study, two key parameters are considered: the elastic modulus of the columns and the column thickness, as previously described. The FE-Model in Ansys is illustrated in Figure 5.

Figure 5. FE-Model in Ansys Mechanical

Initially, the prior distributions of the uncertain model parameters defined by their mean ( $\mu$ ) and standard deviation ( $\sigma$ ) are established based on engineering judgment and available data. The Bayesian model updating is performed using the generalized Polynomial Chaos-based Kalman Filter (gPC-KF) approach. These methods incorporate measurement uncertainties to update the parameter distributions, resulting in posterior distributions ( $\mu'$ ,  $\sigma'$ ) that reflect improved estimates conditioned on the observed vibration data. The summary statistics of both prior and posterior distributions are presented in Table 3 and the resulting posterior approximation distribution is shown in Figure 6.

The results of the Bayesian updating process show a reduction in the standard deviations of the posterior distributions, indicating improved parameter certainty in a model calibration. To assess the accuracy of the updated FE model, its predicted mean resonance frequencies – computed

using the mean values of the parameters from the posterior distributions – are compared against those obtained from Operational Modal Analysis (OMA) in the reference state, as detailed in Section 3.1. The relative difference between the simulated and experimental frequencies observed for the four modes is 0.54%, which is well within the maximum relative error of 0.6% in reference data. This close agreement confirms the reliability of the Bayesian-updated model.

Table 3. Prior and posterior of random parameters

Parameter	Elastic Modulus of Column	Thickness of Column
Prior	4000, 400	6.4, 0.32
Mean value, standard deviation ( $\mu$ , $\sigma$ )	[MPa] $\sigma = 0.1\mu$	[mm] $\sigma = 0.05\mu$
measurement error	0.6 %	
Posterior	3800, 316	6.18, 0.18
Mean value, standard deviation ( $\mu'$ , $\sigma'$ )	[MPa] $\sigma' = 0.083\mu'$	[mm] $\sigma' = 0.29\mu'$
relative difference	0.54 %	
$\epsilon_i = \frac{ f_{i\_FE\ model} - f_{i\_OMA} }{f_{i\_OMA}}$		

Figure 6. Results from updating with Bayesian model updating approach

Table 4. Comparison of resonance frequencies between the updated finite element (FE) model and experimental measurements from Operational Modal Analysis (OMA)

Mode No.	Frequency FE-Model	Frequency OMA	relative difference [%]	MAC [%]
1	6.39	6.40	0.21	97
2	19.91	19.81	0.53	90
3	36.16	35.97	0.54	90
4	50.81	50.56	0.10	98

Following the successful calibration of the FE model in the reference state, a Monte Carlo simulation is performed to generate modal frequency data for various added mass configurations. Based on the posterior distributions of the elastic modulus and column thickness, combined with discrete

added mass values to simulate different structural states, 120 samples of frequencies are generated for each state. The additional masses varied from 0 to 200 grams in increments of 25 grams. The resulting dataset is then used as the input for computing the Model-Assisted Probability of Detection (MAPOD), providing a statistical basis for assessing the detection performance under varying conditions.

### 3.3 Simulation of Model-Assisted Probability of Detection

This section presents a comparative analysis between the experimental Probability of Detection (POD) and the Model-Assisted POD (MAPOD) derived from the simulations. The comparison aims to validate the simulation framework and assess its capability to replicate detection performance observed in physical experiments. The observed strategy is based on changes in modal frequencies associated with varying levels of added mass, simulating structural changes/damage.

Figure 7 illustrates the comparison of resonance frequencies identified from OMA experimental data measurements and those predicted by the calibrated FE model, demonstrating

good agreement and confirming the effectiveness of the model updating process. Modes 1 and 2 are highly sensitive to the added mass, showing noticeable shifts in frequency. In contrast, Mode 3 exhibits only minor changes, while Mode 4 shows the least response to mass variation. This behavior is to be expected, as higher-order modes typically require more energy to be effectively excited and are thus less influenced by localized changes in structural mass [16,17]. Therefore, only Modes 1, 2, and 3 will be considered for further POD estimation, as they exhibit measurable sensitivity to the added mass and are thus more suitable for damage detection analysis.

To evaluate the consistency between the experimental POD and the MAPOD derived from simulated data, Mahalanobis distances from the 1<sup>st</sup>, 2<sup>nd</sup> and 3<sup>rd</sup> modes are computed and plotted against the corresponding flaw sizes, as shown in Figure 8. Finally, the POD curves are presented in Figure 9, comparing the empirical POD derived from experimental data with the MAPOD computed from the simulation results.

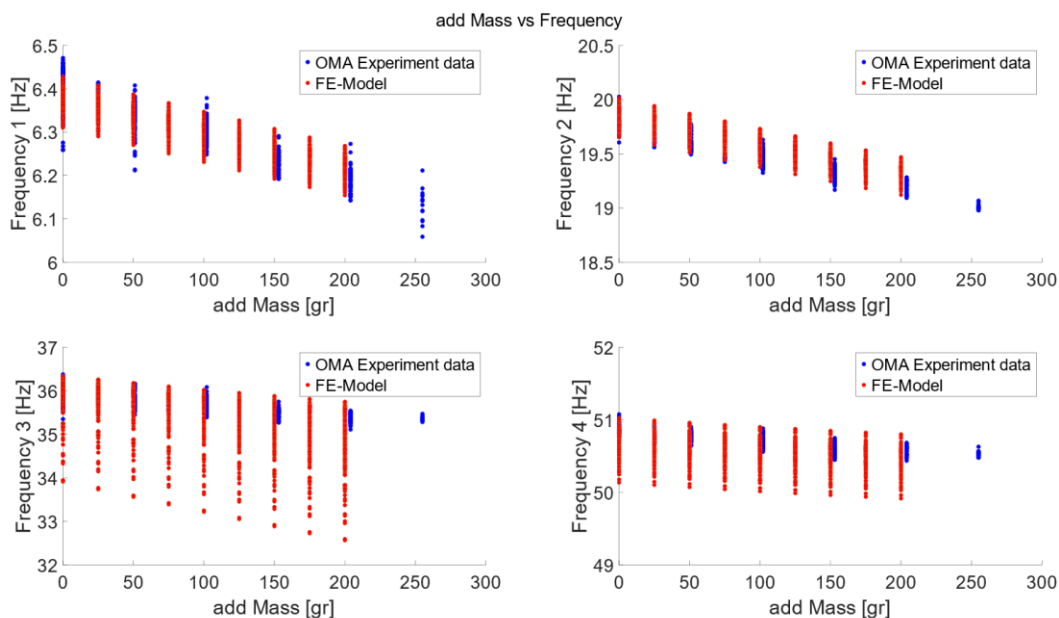

Figure 7. Added Mass-Frequencies comparison from OMA experimental data and FE-Model

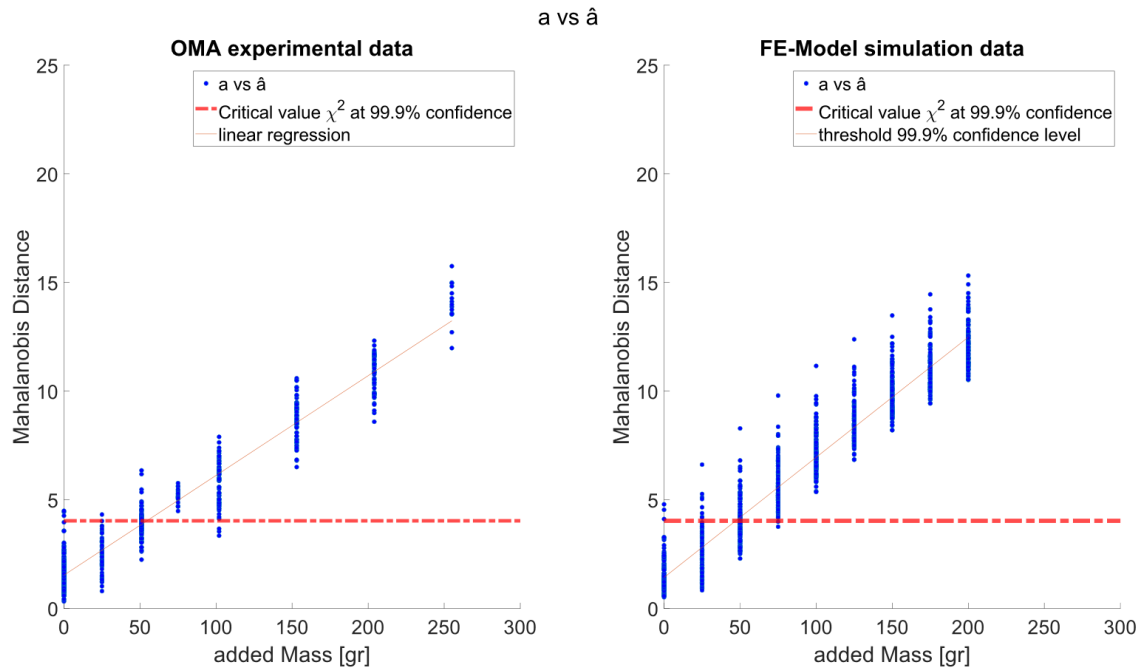

Figure 8.  $a$  vs  $\hat{a}$  for OMA experimental data and FE-Model

Figure 9. POD OMA experimental data and FE-Model simulation data

From Figure 9, the experimentally derived  $a_{90/95}$  value from the POD curve is 77.81 grams, while the simulated MAPOD yields an  $a_{90/95}$  of 71.42 grams, representing a relative difference of 8.2%. This  $a_{90/95}$  value corresponds to 7.0% of the total mass of the fourth floor. These results indicate that the POD derived from the calibrated FE model in the reference state provides sufficient predictions of the structural response to varying added mass conditions on the fourth floor. The alignment between the experimental and simulated POD curves demonstrates that the simulation-based MAPOD can approximate the experimental detection, supporting its application for scalable and cost-effective SHM reliability assessments.

#### 4 CONCLUSION AND OUTLOOK

This study presents a framework for evaluating the reliability of Structural Health Monitoring (SHM) systems using Probability of Detection (POD) and Model-Assisted POD (MAPOD) approaches. A laboratory-scale 4-DOF wooden

frame structure was used as a case study, with varying mass configurations to simulate structural changes. Experimental modal data were collected using Operational Modal Analysis (OMA) and used to calibrate a Finite Element (FE) model through Bayesian updating. The updated FE-Model served as the basis for generating simulated response/modal data through Monte Carlo simulations under various mass configurations, enabling the construction of MAPOD curves.

The comparison between experimental POD and MAPOD simulation data shows the relative difference with less than 10% deviation in key detection metrics such as a  $a_{90/95}$ . The MAPOD approach can effectively supplement physical testing by providing scalable, repeatable reliability assessments with reduced experimental effort.

#### Outlook:

Future research should aim to extend the MAPOD framework by incorporating more complex damage scenarios—such as sequential cracking or cross-sectional area reduction leading to structural stiffness degradation—exploring a wider range of

SHM sensing techniques and expanding the set of observed response features beyond the four considered in this study. Furthermore, integrating environmental and operational variability into the model could further enhance its predictive robustness. Finally, applying this method to real-scale structures will be a crucial step toward broader implementation in practical SHM deployments.

**ABSTRACT:** Structural Health Monitoring (SHM) is vital for ensuring the safety and longevity of infrastructures, utilizing various sensor-based techniques to detect damage, assess performance, and monitor long-term deterioration. Traditional methods, such as visual inspections, lack precision and are prone to human error, whereas more advanced techniques like vibration-based monitoring, acoustic emission, strain gauges, and GNSS offer real-time damage detection and millimeter-level precision but often require complex planning and high costs. The presented 6D sensor, developed for infrastructure monitoring, accurately measures complex displacements and rotations, offering enhanced precision through a combination of machine learning and mathematical algorithms. When paired with low-cost, high-precision GNSS systems, it provides comprehensive real-time data on both localized and large-scale structural movements, improving insights into infrastructure behavior under various environmental conditions and loads. This paper explores the integration of 6D sensors with GNSS technology, discussing the advantages of real-time monitoring for predictive maintenance and presenting insights from ongoing project results.

**KEY WORDS:** IoT, Sensors, AI, SHM, 6D, GNSS

## 1 INTRODUCTION

Structural Health Monitoring (SHM) is essential for ensuring the safety and longevity of bridges, employing various techniques to detect damage, assess performance, and monitor deterioration over time. Traditional methods, such as visual inspection [1], are widely used due to their simplicity and cost-effectiveness but often lack precision and are prone to human error. More advanced techniques include vibration-based monitoring [2], which identifies global structural changes through dynamic responses, and acoustic emission [3] methods that detect stress waves from internal cracks. Both offer real-time damage detection but vary in sensitivity and applicability.

Strain gauges and fiber optic sensors (FOS) [4]-[6] provide localized measurements of stress and deformation with high accuracy. FOS excels in long-term durability and precision but comes with higher installation costs. Laser scanning and LiDAR [7] are effective in capturing surface deformations and creating detailed 3D models but can be limited by weather conditions. GNSS [8][11] is used in infrastructure structural health monitoring to provide high-precision, real-time measurements of large-scale displacements and deformations, enabling accurate tracking of structural movements over time for enhanced safety and maintenance planning.

Emerging technologies like wireless sensor networks (WSN) [9],[12] enable real-time data collection of multiple physical measurement parameters reduced costs, but allowing data fusion and better remote data interpretation.

## 2 TECHNOLOGY OVERVIEW

### 2.1 Magnetic 6D-Sensor

The continuous monitoring of the structural integrity of transportation infrastructure requires precise and reliable measurement methods.

The 6D sensor from SuessCo is based on a magnetic field sensor array that measures position and rotation relative to a permanent magnet with high accuracy [13]. The system captures movements in all six degrees of freedom (X, Y, Z as well as roll, pitch, and yaw) and achieves a repeatability of  $\pm 50 \mu\text{m}$  in the translational axes and  $\pm 0.1^\circ$  in the rotational axes. This is accomplished through a combination of machine learning and mathematical algorithms that allow precise recalculation of the measured values in real time. The high precision and easy installation make these sensors particularly suitable for monitoring critical infrastructure components such as bridge bearings.

Using an array of magnetic field sensors for position determination offers significant advantages, particularly due to the overdetermined nature of the system, which enhances accuracy and reduces the impact of external influences. With multiple sensors, the system collects redundant data, allowing it to cross-reference measurements and filter out inconsistencies caused by magnetic stray fields, interference from electrical fields (such as those from power lines), and thermal fluctuations. The overdetermined setup enables compensation for temperature-induced changes in the magnetic field, ensuring that the sensors remain accurate even in varying thermal conditions. This redundancy improves robustness, compensates for local anomalies, and results in more precise and stable position determination.

Self-diagnostic feature ensures that the sensor operates reliably by detecting potential faults, calibration drift, or performance degradation in real time. As a result, the system can immediately alert operators to any issues, reducing the risk of inaccurate data or sensor failure.

Therefore, accurate recalculation of the position is performed on a webserver to allow the usage of low performance microprocessors. Transmitting the sensor data is possible via

Wi-Fi or LTE-M allowing worldwide usage. For the 6D sensor also an external antenna is used to increase RF performance. An external battery pack with cable connection allows long time measurements with measurement frequencies down to 15 minutes and sending intervals of 1h. The Battery pack can be placed where they can be reached easily. The sensor itself has dimensions of 170 mm x 100 mm x 45 mm for a 60 mm x 30mm x 20mm measurement range allowing direct installation inside bridge bearings for example. This design features a physically separated sensor array and reference point. Unlike traditional systems, where precise alignment between components is often required, the 6D sensor allows the sensor array and reference magnet to be installed independently of each other. Traditional systems often require meticulous positioning to ensure accurate data collection, which can be labor-intensive and time-consuming. This flexibility is especially beneficial in challenging environments, such as bridges or large infrastructure, where precise alignment may be difficult to achieve. Additionally, a separated system is more adaptable to various structural configurations, improving scalability and reducing the risk of installation errors.

Additionally, a 3D version of this sensor type is available. It has internal antennas and batteries further reducing the footprint by sacrificing the euler angle values.

## 2.2 Low-cost high-precision GNSS

Both commercially available systems and in-house developments have demonstrated reliable measurement performance in various studies [11][12][14]. For comparison, 3D polar measurements from tachymetric monitoring systems were used as a reference. In recent years, a range of GNSS multi-frequency OEM boards with corresponding antennas has become available [15]. Before deploying GNSS technology for automated monitoring, it is crucial to evaluate its performance, particularly its 3D accuracy and long-term stability. Optimal results are generally achieved through the analysis of 24-hour session averages [11][12][14], which can also be evaluated on an hourly basis by incrementally extending the evaluation window. However, this approach introduces latency, which reduces the system's responsiveness.

An alternative method involves RTK-GNSS for direct deformation measurements, with some OEM boards supporting a measurement frequency of up to 100 Hz. Manufacturers have integrated carrier-phase ambiguity resolution algorithms into GNSS boards, and through efficient transmission of RTCM correction data via NTRIP, these receivers can deliver RTK positions in standardized NMEA format. Additionally, affordable antennas are now widely available, and their impact on measurement accuracy has been thoroughly investigated in several studies [8],[10],[15]. On-site data is transferred to a web service where the Wa2 module [15] computes, analyzes, and adjusts each baseline combination. However, this method is not suited for large-scale network extensions due to its inherent limitations.

Further testing with the open-source software RTKLib [16] has shown comparable accuracy, with ambiguity fix rates ranging from 95% to 100%. Using this approach, the GNSS system was implemented and tested in various pilot projects. In one such project, GNSS measurements provided results comparable to those from tachymetric systems. GNSS is particularly effective in tracking absolute deformation trends

over extended periods in outdoor environments, offering greater insights than a four-week total station measurement. This capability enhances safety on construction sites. Although GNSS systems can operate independently of other monitoring systems, their high-power consumption remains a limitation for long-term, battery-powered applications. Addressing this issue is a key focus of future developments.

## 2.3 Installation and mounting

The 6D sensors are mounted directly on or inside the bridge bearings to precisely detect movements and rotations. This type of installation is particularly suitable for monitoring thermally induced displacements caused by temperature changes. The sensors can be configured to detect even the smallest changes in bearing position, which may indicate structural issues.

The 6D sensors are designed to be installed even in hard-to-reach areas, such as bridge bearings or expansion joints. The physical separation between the sensor array and the reference magnet allows flexible installation without requiring precise alignment of components. In many cases, the sensors can be mounted directly in polymer or roller bearings using magnets. However, depending on the complexity of the bearing structure, detailed planning in advance is necessary. For this purpose, creating a digital model of the bearing is recommended to precisely design the mounting structure and ensure optimal sensor placement. This approach minimizes installation errors and allows for perfect integration, especially in bearings with complex geometries.

For monitoring large-scale displacements, particularly of bridge piers and foundations, GNSS systems are used. These systems detect movements in the sub-centimeter range and are especially effective in open, unobstructed environments. When installing GNSS systems, the cable length to the antenna is limited. To bridge longer distances, expensive signal amplifiers are often required. Therefore, it is important to define during the planning phase where the GNSS antenna and the processing unit should be positioned to minimize signal loss.

To simplify the installation of GNSS antennas, we have developed a custom 3D-printed component that allows the antennas to be mounted directly onto standard satellite dish brackets. These mounts are not only stable and widely available but also easy to install, offering a cost-effective solution for most standard applications.

For more complex requirements, it may be beneficial to develop custom mounts specifically tailored to local conditions to ensure the optimal performance of the GNSS systems.

# 3 SENSOR INTEGRATION AND DATA FUSION

## 3.1 Combining 6D-Sensors and GNSS

The combination of using high precision 6D sensors to measure bridge bearings, along with advanced GNSS technology, provides a comprehensive solution for monitoring and quantifying the behavior of bridges under various conditions. The 6D sensors, capable of capturing movements in all six degrees of freedom, three translational (X, Y, Z) and three rotational (pitch, yaw, roll)—offer precise insights into the thermal expansion and contraction of bridge structures. Thermal movements, which occur due to temperature fluctuations, can cause significant structural shifts, particularly in bridge bearings. With the 6D sensors, it becomes possible to

detect and quantify these minute thermal movements, providing engineers with real-time data to assess how the bridge reacts to environmental changes.

In addition to thermal movements, the 6D sensors can also capture the influence of external loads, such as wind pressure or traffic. The dynamic load exerted by vehicles crossing the bridge, combined with the fluctuating forces of wind, can cause stress and movement within the structure. By continuously monitoring these factors, the sensors help assess how well the bridge is handling daily operational stresses. This data is crucial in predicting potential issues and mitigating risks, allowing for proactive maintenance and increased safety.

When paired with a GNSS system, such as a high-precision multi-frequency GNSS module, the monitoring system becomes even more powerful. GNSS technology provides sub-centimeter accuracy in measuring the movement of the bridge's supporting pillars. While the 6D sensors offer detailed data on the local movements at the bearings, the GNSS system can monitor the larger-scale displacements of the bridge's foundations or pillars. This combined approach enables a thorough understanding of whether observed movements are due to thermal expansion of the bridge deck or are indicative of potential structural issues with the bridge's pillars or foundations.

For example, if the sensors detect movement at both the bearings and the pillars, the GNSS system can help differentiate between the natural thermal expansion of the bridge deck and actual shifts in the foundation. This distinction is crucial because movements caused by thermal expansion are usually temporary and reversible, whereas foundation movements could signal more serious issues, such as settlement or structural fatigue.

Moreover, the integrated system can operate continuously, providing real-time data on the structural health of the bridge. Such monitoring is essential for infrastructure located in areas subject to environmental stresses like fluctuating temperatures, high winds, or heavy traffic. By combining these two advanced technologies, engineers gain a better understanding of the bridge's behavior under various conditions, leading to more informed decision-making regarding maintenance schedules and potential reinforcements. In the long run, this can help extend the lifespan of critical infrastructure while ensuring the safety of its users.

This integration of 6D sensor technology with GNSS monitoring is part of a broader trend toward smart infrastructure, where real-time data is leveraged to optimize performance and prevent catastrophic failures. The ability to continuously monitor both short-term factors, such as thermal expansion, and long-term movements of the bridge's pillars offers a level of detail previously unavailable through traditional surveying methods alone. With further developments, especially in reducing power consumption for GNSS systems, the future of bridge monitoring promises even more efficient, reliable, and autonomous systems.

### 3.2 Communication and data transmission

The presented sensors use state-of-the-art encryption to protect the data during transmission. When data is sent from the sensors to the webservice, it is encrypted to prevent any unauthorized access or tampering while it's in transit. Data transmission is provided as an integrated service, eliminating

the need to manage SIM cards, mobile plans, or network connectivity. This streamlined approach allows for effortless deployment and continuous monitoring with minimal technical oversight. The used LTE-M [17] standard is part of the 4G standard leading to nearly global coverage without any additional checks, only 4G coverage needs to be present. LTE-M normally uses lower frequencies with lower data rate leading to more penetration and coverage than 4G. Most countries offer detailed LTE-M coverage maps, allowing users to accurately check reception in advance and ensure reliable connectivity in the deployment area.

Wi-Fi serves as an additional, efficient method for providing internet connectivity to the sensor, particularly in environments where LTE-M coverage may be unavailable, such as tunnels, mine shafts, or lower basement floors. This alternative communication method is advantageous in settings where the penetration of cellular signals is limited due to physical obstructions or underground conditions. By utilizing existing Wi-Fi networks, the sensor can maintain reliable data transmission in these challenging environments.

High data transfer rates, provided by Wi-Fi connections, are particularly beneficial for transmitting large datasets or high-frequency measurement updates in real time. In industrial or remote monitoring applications, utilizing Wi-Fi ensures continuous sensor operation without the reliance on extensive cellular infrastructure. This capability is especially valuable in areas where stable, high-speed communication is critical for maintaining data integrity and operational efficiency.

The use of Wi-Fi [18] in such scenarios is further supported by modern advances in mesh networking and extended-range Wi-Fi technologies, which improve coverage and signal stability even in hard-to-reach areas. For example, industrial-grade Wi-Fi routers and repeaters can be used to strengthen signals and extend network coverage to areas that would otherwise be unreachable by standard Wi-Fi systems. Wi-Fi's adaptability, combined with robust encryption protocols, ensures secure data transmission and minimizes the risk of loss or interference, making it a suitable solution for reliable infrastructure monitoring in challenging environments.

### 3.3 Webservice with dashboards

SuessCo developed and provides a web service as an infrastructure solution providing the ability to collect, process, visualize, and manage data from connected devices, such as sensors. It is commonly used for integrating various sensors and IoT devices, enabling real-time data monitoring and control. Web services support data collection through different protocols like MQTT, CoAP, and HTTP, and can process this data using custom logic for actions and alerts. Target applications are remote monitoring and control of IoT devices in sectors like infrastructure monitoring, smart cities, and agriculture.

While this web service provides robust data processing capabilities, it is also possible to configure it for collecting sensor data without relying on any specific platform's native dashboard or visualization tools. In this case, the sensors would send their data via a web service instead of using a predefined interface, allowing them to manage the data independently. This approach offers more flexibility in terms of integrating with alternative visualization platforms or custom-built solutions. Users can access, analyze, and display data from

their sensors in a more customizable manner, enabling a variety of applications such as advanced data analysis or machine learning.

#### 4 CASE STUDIES

The following chapter presents and analyzes various case studies involving bridges, buildings, and other infrastructure. These projects provide valuable insights into the practical applications of monitoring technologies and the findings related to structural integrity. At the request of the involved clients, the projects have been anonymized to ensure confidentiality.

The values in the following chapter are zeroed by subtracting the initial measurement, allowing for the detection of relative displacements and ensuring comparability.

##### 4.1 Bridge bearings influenced by unintentional manipulation, surface treatment and flood disaster

The first pilot project, which was successfully transitioned into an ongoing monitoring project and has now been running for over four years, involves the monitoring of a steel-element road bridge. Initially, it was unclear whether the end elements at the abutment were impacting, which is why the sensors were first installed there. However, once it was proven that this was not the case, the sensors were subsequently relocated to the bearings of the central pier in the river over the course of the project.

Figure 1. Images of the Monitored Roller Bearing: Left: Condition at installation with corresponding axes; Right: Sensor after maintenance work, displaced and sandblasted

Since July 1, 2022, the sensors have been operating at their new position and have been continuously monitoring the bridge — including during the flood event in 2024, which provided valuable data on structural integrity.

The following section includes both an analysis of the effects of unintended sensor displacement during bridge renovation work (see Figure 4 and Figure 5) and a detailed evaluation of the measurement data collected during the 2024 flood.

The diagram in Figure 2 shows, in the upper part, the sensor's positional displacements along the x-axis (blue), y-axis (green), and z-axis (red). The lower part of the diagram displays the internal temperature of the sensor. The measurements, recorded at 15-minute intervals, are presented here as daily average values.

Figure 2. Measurement data for monitoring a roller bearing: effects of unintended displacements during maintenance work and wildlife damage

As expected, significant fluctuations can be observed along the x-axis due to the thermal expansion of the bridge element. In October 2022, a sharp and abrupt change is visible, which can be attributed to a mechanical shift in the sensor setup (see Figure 1, right). During this period, the sensor was also sandblasted, but this had no relevant impact on the measurement results.

A disruption in sensor data in March 2023 was caused by wildlife damage—specifically, pigeons pecking at the cable. In December 2023, the sensor failed due to a hardware defect, which has already been resolved in the new hardware version of the sensor. Aside from these events, the data shows a very good correlation with the expected thermal expansion and only minor movements along the y- and z-axes.

The diagram in Figure 3 consists of three subplots showing the positional displacements of a sensor along the x-, y-, and z-axes ( $\Delta X_0$ ,  $\Delta Y_0$ ,  $\Delta Z_0$ ) as a function of temperature. The measured data points are displayed as blue violin plots with error bars, illustrating the distribution of values at different temperatures. The number of measurements per temperature interval is indicated along the bottom of the x-axis. A different sensor is used in Figure 3 than in Figure 1 and Figure 2. The Sensor in Figure 3 is mounted on a polymer bearing and summarizes historical data from the year 2021.

**Top subplot ( $\Delta X_0$  position):** Shows a strong linear correlation between temperature and displacement along the x-axis. The linear fit (orange line) has a slope of 0.75 mm/°C, indicating thermal expansion of the monitored bridge element, which also aligns well with the expected values. The data spread is relatively small, indicating consistent thermal expansion.

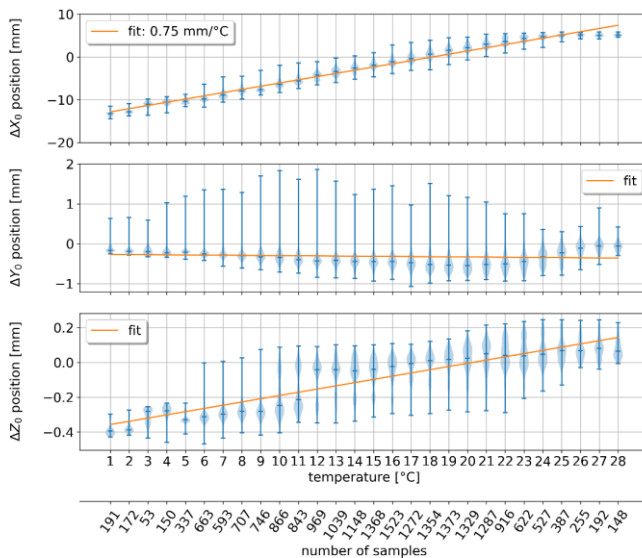

Figure 3. Representation of the Thermal Dependence of Positional Displacement Based on Historical Data.

Middle subplot ( $\Delta y_0$  position): No significant correlation is observed between temperature and displacement along the y-axis. The data shows high scatter, indicating non-systematic influences, possibly due to mechanical impacts or disturbances. The fit is nearly flat, suggesting that no temperature-induced movement is expected along this axis.

Figure 4. Daily Average Values Independent of the Sensor's Measurement Interval in Figure 1. The data shown is from the year 2024 and includes a flood event in September.

**Bottom subplot ( $\Delta z_0$  position):** A slight correlation between temperature and displacement along the z-axis is evident; however, the effect is much weaker than along the x-axis. The linear fit shows a small but consistent displacement, indicating minimal thermal movement in the vertical direction. The data scatter is moderate, and the amplitude is significantly smaller compared to the other axes, suggesting lesser influences in this direction.

The diagram in Figure 4 illustrates how the bridge responds to seasonal temperature fluctuations and simultaneously shows the impact of exceptional events such as the flood disaster in September 2024. Monitoring data is essential for assessing the

structural integrity of the bridge during such extreme situations. The diagram presents the positional displacements of the sensor along the x-axis (blue), y-axis (green), and z-axis (red) throughout the year. The x-axis shows significant variation, with displacements increasing up to 30 mm, indicating thermal expansion of the monitored bridge element. In contrast, the y- and z-axes show only minimal movement, suggesting that the bridge remains largely stable in those directions.

The lower subplot shows the temperature trend over the course of the year. A clear seasonal pattern is visible, with temperatures falling below 0°C in winter and rising above 20°C in summer.

From September 13 to 20, 2024, the bridge was affected by a flood disaster, yet no significant anomaly is visible in the measurement data. The diagram clearly shows that while the displacements along the x-axis temporarily dropped during the flood event, the behavior was consistent with previous temperature fluctuations. Even after the flood, no significant changes in the measurement values were observed. This indicates that the bridge did not suffer any lasting damage from the flood and that its structural integrity remained intact.

Figure 5. Same Bearing as in Figure 4, but with Detailed Data at 1-Hour Intervals for the Month of September.

This example highlights the importance of continuous monitoring at bridge bearings: On one hand, continuously collected data allows for immediate response to unexpected deviations; on the other hand, it enables the assessment of changes before and after exceptional events such as flooding. This makes it possible to detect potential damage early—during and after such events—and to take targeted action, significantly improving the long-term safety of the infrastructure.

In Figure 5, the data for September is shown at the actual measurement interval of one hour. Even at this higher temporal resolution, no unexpected movements are visible. Even during the flood disaster from September 13 to 20, 2024, the measurements display stable behavior consistent with the typical pattern of thermal expansion. Furthermore, the peak temperature recorded here is significantly higher than the air temperature, as the sensor housing is exposed to direct sunlight.

#### 4.2 Bridge bearing with transverse displacement

In another bridge project, measurements were conducted at multiple points along a curved bridge located on a creeping slope. The results (Figure 6 and Figure 7) showed that individual bearings exhibited consistent but slow displacement along the y-axis—that is, transverse to the roller bearing's intended direction of movement.

Figure 6. A 6D sensor installed on a roller bearing of a railroad bridge

This motion leads to wear on the bearing's retaining plates. It has not yet been conclusively determined whether the bearings reach a point at which they can no longer compensate for the movements, which could result in unanticipated stresses within the bridge structure.

Figure 7. Measurement Results of the Roller Bearing on a Curved Bridge Showing Increased Y-Axis Movement Leading to Wear of the Bearing's Retaining Plates.

Notably, these displacements could not be detected using conventional measurement systems such as total stations or rail surveying; only the wear itself had previously been observed. The precise and multi-axis sensors enabled more detailed detection that was not possible with other methods and thus provided valuable insights into the maintenance strategy.

#### 4.3 Measurement of crack formation on a natural stone railway viaduct

In this project, several sensors were installed on different cracks of a natural stone railway viaduct. The cracks either ran directly through the stones or along the joints between them. The sensors were strategically placed to monitor both types of cracks and to analyze potential differences in deformation behavior.

Figure 8. Mounting of the Sensor Above a Crack in the Natural Stone of a Railway Viaduct.

The goal was to monitor the behavior of the cracks: Are they stable, or do they show dependencies on temperature and humidity fluctuations? presents the results from one of these sensors, whose position is shown in Figure 8. In this project, the sensors and reference points could be mounted directly using stone screws or bonded threaded rods, without the need for additional mounting materials. This method enabled a secure and stable attachment directly to the natural stone, allowing for efficient and durable installation.

Figure 9. A significant and irreversible change is visible along the y-axis (green). However, the amplitude of this displacement is only about 0.4 mm, indicating a very small but still measurable change.

In Figure 9, only very small changes can be observed overall, as the total amplitude range on the y-axis is just about 1 mm. Nevertheless, a significant and irreversible displacement is evident starting in April 2023. Compared to the measurement

data from the bridge bearings, the values recorded here differ considerably, confirming the thermal stability of the sensor. This crack exhibits the most active movement among all measured points; however, it was determined that most cracks are generally stable. Therefore, it was decided to reduce the measurement interval to one hour in order to maximize battery life. If necessary, the interval can be remotely adjusted again.

#### 4.4 Crack measurement in a building with supplementary GNSS measuring points

As part of the subway construction works in Vienna, the groundwater level had to be lowered, which led to significant cracking in surrounding buildings even before the actual tunneling began. For this project, several 3D and 6D sensors () as well as GNSS measurement points were installed on the exterior walls of the affected buildings. The GNSS system [11],[12] used in this project (Figure 10) was developed in collaboration with Werner Stempfhuber. The 3D and 6D sensors were easily mounted using conventional screws, while the installation of the GNSS brackets on the building facade had to be carried out by specialized personnel.

Figure 10. Left: Mounted GNSS antenna on the exterior wall of the residential building. Right: 6D sensor mounted in a building corner near the GNSS antenna.

By combining these two measurement systems, it was possible to precisely monitor the relationship between the cracks and the surrounding walls, while the absolute GNSS system additionally allowed for the detection of potential subsidence of the entire building or individual sections. This approach increases the significance of the measurements and provides the private property owner with reliable data to demonstrate to the construction client any potential effects of the construction work on their property. At the same time, monitoring enables early warning in the event of sudden significant movements, allowing the developer to intervene in time to prevent further structural damage.

Positive feedback also came from the residents of the building, who now feel somewhat safer due to the continuous monitoring of the visible cracks in the structure.

In Figure 10, the sensor is located inside the building, as indicated by the significantly more stable temperature profile compared to previous case studies. Notably, a jump along the z-axis (red) is visible in September (high amount of rain). Although the initial change in September measured only 0.6 mm over a period of about two weeks, it marked the beginning

of a continuous increase in movement. By February 2025, the sensor recorded a total displacement of up to 2.3 mm. This deviates significantly from the crack's previous behavior and indicates a structural issue.

Figure 11. The change in z-axis behavior (red), of the Sensor shown in Figure 10, observed in September 2024, was triggered by heavy rainfall and led to a structural damage event in February 2025.

A different 3D sensor shows even greater displacements (see Figure 12), starting in September 2024 and peaking at up to 10 mm along the x-axis in February 2025. This increased movement is likely due to the sensor's alternative mounting configuration.

Figure 12. Even higher x-axis peak in February of 2025.

Similar behavior has also been observed in other 3D sensors throughout the building, suggesting that the structural movement is not limited to a single location but affects the entire structure. This indicates a widespread response of the building to external influences, likely requiring a comprehensive structural assessment.

However, these observations were not limited to the 3D sensors inside the building—four GNSS sensors installed at each corner of the structure also exhibited similar behavior. The GNSS points are numbered clockwise, starting from the southeast corner of the building.

Figure 13. GNSS Point 1 in the south east corner of the building.

Figure 14. GNSS Point 2 in the south west corner of the building.

Figure 15. GNSS Point 3 in the north west corner of the building.

Figure 16. GNSS Point 4 in the north east corner of the building.

For the initial monitoring period (July 2024 to early February 2025), all sensors exhibited only minor fluctuations within a  $\pm 5$  mm range across all axes. This behavior is consistent with expected seasonal thermal expansion and contraction, as confirmed by the relatively stable and slowly varying temperature profile. Unfortunately due to a power fault there is missing data from beginning to mid-January.

However, a significant and abrupt shift in the displacement data was observed across all GNSS sensors starting in early February 2025. This event was not associated with any comparable temperature anomaly and is thus interpreted as a non-thermal structural movement. The magnitude and direction of the displacements varied by sensor location:

**GNSS 1 (Southeast Corner, Figure 13):** Displacements of approximately  $-30$  mm in the north direction and  $-20$  mm in height were recorded, accompanied by an increase of  $+25$  mm in the east direction.

**GNSS 2 (Northeast Corner, Figure 14):** This sensor registered the largest displacements, with  $-40$  mm in the north, and the vertical direction, and  $+20$  mm in the east. The scale of movement suggests significant subsidence and lateral displacement.

**GNSS 3 (Northwest Corner, Figure 15):** Moderate movement was recorded, particularly to the north with  $-30$  mm and east  $+20$  mm directions. But height stays very stable compared to all other sensors.

**GNSS 4 (Southwest Corner, Figure 16):** Displacements at this location were also substantial, with movements of approximately  $-20$  mm in the vertical axis and  $+20$  mm in the east direction.

The synchronized onset and consistent directional trends of the displacements across all sensors strongly suggest a global response of the building structure, likely triggered by high rain period in September of 2024 and leading to a massive structural movement in February 2025. Given the known construction activities related to subway excavation in the vicinity, it is plausible that the observed displacements are a direct consequence of these works.

The GNSS and 3D position data thus provides reliable and high-resolution evidence of structural movement, which is essential for assessing building integrity and potential damage progression. This type of sensor-based monitoring offers a valuable basis for initiating countermeasures, engaging with

responsible parties, and supporting claims for damage compensation.

## 5 CONCLUSIONS

The multi-year investigations clearly demonstrate the advantages of combining 6D sensors with GNSS measurement systems for monitoring the structural integrity of infrastructure and buildings. This integrated approach offers a significantly enhanced perspective on structural motion detection: while 6D sensors enable detailed analysis of local displacements across all degrees of freedom, GNSS systems provide highly accurate measurements of absolute positional changes. The synergy between these two technologies not only increases the informative value of the measurements but also improves the monitoring of structures under variable environmental conditions, such as temperature fluctuations or groundwater drawdowns—factors that present particular challenges in urban settings.

The deployment of these systems in the presented projects has resulted in a robust data foundation, allowing stakeholders to produce well-founded evidence of potential structural impacts caused by construction activities or environmental influences. Continuous data acquisition supports the early detection of damage risks and contributes significantly to the safety and longevity of the monitored structures. Particularly noteworthy is the real-time monitoring capability enabled by the integrated system, which allows for immediate response to unexpected structural movements and thereby minimizes the risk of significant damage.

Looking ahead, the focus will be on further optimizing the energy efficiency of the deployed sensors and expanding the integration of AI-assisted anomaly detection. These developments will further enhance the precision and operational efficiency of monitoring systems while reducing maintenance costs. The insights and experiences gained from the current projects provide a solid basis for future advancements aimed at improving the reliability and sustainability of monitoring solutions in demanding infrastructure environments.

**ABSTRACT:** This work presents an evaluation of promising sub-structuring and machine learning SHM approaches suitable for high-rise buildings, based on real data from an 18-story steel-moment resisting framing building, tested at an E-Defense facility in Japan. This building is instrumented with a relatively dense set of sensor arrays and is subjected to different excitation levels until full collapse. The main contribution of this study is to demonstrate the practical feasibility of the proposed sub-structuring approach in conjunction with machine learning when relying on different levels of response measurements. The study assesses the accuracy and reliability of the estimates of the dominant modal features of the structure and can subsequently provide a probabilistic measure of confidence in the extent and location of changes/damage if an anomaly is detected, as well as the propagation of damage throughout the structure's life span. Due to the minimal computational resources needed to implement the sub-structuring approach, it is shown to be quite efficient for near-real-time applications where important structures need to be continuously monitored for sustainability as well as resiliency requirements.

**KEY WORDS:** Parametric identification; Nonparametric identification; Damage detection; Structural health monitoring; Condition assessment; High-rise building.

## 1 INTRODUCTION

Structural Health Monitoring (SHM) and condition assessment of high-rise buildings through vibration signature analysis have been extensively studied over time. SHM approaches for damage detection and condition assessment are generally classified into two main categories: local and global methods. Local methods focus on analyzing specific, limited areas of a structure using localized measurements. In contrast, global methods provide a comprehensive understanding of the system's condition by utilizing data from a distributed network of sensors. The selection of an appropriate method depends on several factors, including the problem's scope, the sensor network's configuration, the structural topology, and the level of detail required for the assessment.

Recent advancements in dense sensor networks, capable of collecting extensive data, have enabled the application of advanced data processing algorithms. These algorithms can effectively identify, localize, classify, and quantify changes or damages in civil infrastructure, including high-rise buildings, which are the primary focus of this study.

Prior to utilizing the identified vibrational signature of a structure for health monitoring, it is essential to comprehend the dynamic behavior modeling of high-rise buildings. This modeling is inherently complex due to various factors, including uncertainties in geometrical characteristics, material properties, nonlinear material behavior, foundation modeling, and soil effects. Therefore, integrating experimental and numerical data analysis enhances methods for identifying and localizing damage or changes within structural systems.

Extensive research in damage and change detection, as well as system identification for linear structural systems, has yielded numerous sophisticated global approaches based on vibration data analysis in both the time and frequency domains [13-15]. However, there is a notable lack of studies that leverage the topological features of the target structure to improve the detectability of minor changes. By employing appropriate substructuring techniques, these methods demonstrate superior sensitivity to small variations in the structural characteristics of the system under observation compared to global system identification methods.

In this study, one-third full-scale 18-story high-rise building was developed and instrumented with state-of-the-art instrumentation, installed on each floor and operated by E-Defense in Japan. This detailed testbed facilitated the creation of various data-driven, input-output, reduced-order models based on nonparametric identification approaches presented in [1-6], which have been successfully applied to both analytical and experimental data [7-8]. The approach discussed here does not require prior knowledge of the system characteristics (i.e., linear versus nonlinear) and is applicable to linear, nonlinear nonhysteretic, and hysteretic systems, without restrictions on the type of probing signal used for identification. However, it is limited to structures with chain-like topology, as will be subsequently explained in the study.

Several damage configurations in the building's lateral load-resisting system were investigated using data from base excitation dynamic tests performed on the building. The processes of damage detection, localization, and quantification were conducted by examining the variability in the primary features of the developed reduced-order models. It is important to note that in this study, the identification approaches were applied deterministically. The effects of variability in environmental or operational conditions, as well as uncertainties in modeling, measurement, and data analysis

processes, were not considered in the identified change-sensitive features (i.e., stiffness-like parameters and modal parameters) of the structures.

## 2 FORMULATION CHAIN-ID

Consider a multi-degree-of-freedom (MDOF) system with a chain-like topology, as illustrated in Figure 1. This system comprises  $n$  lumped masses, each with a magnitude  $m_i$ , subjected to base excitation and/or directly applied forces  $F_i$ . The lumped masses are interconnected by linear elements, whose restoring forces are primarily dependent on the relative displacement and velocity between the masses. The equations of motion for this system can be expressed as described by [9].

$$\ddot{x}_n + G^{(n)}(z_n, \dot{z}_n) = \frac{F_n}{m_n} \quad (1a)$$

$$G^{(n)}(z_n, \dot{z}_n) = \frac{F_n}{m_n} - \ddot{x}_n \quad (1b)$$

$$G^{(i)}(z_i, \dot{z}_i) = \frac{F_i}{m_i} - \ddot{x}_i + \frac{m_{i+1}}{m_i} G^{(i+1)}(z_{i+1}, \dot{z}_{i+1}) \quad (1c)$$

for  $i = n-1, n-2, \dots, 1$

where  $G^{(i)}(z_i, \dot{z}_i)$  is the mass-normalized restoring force function of the element connecting  $m_i$  and  $m_{i-1}$ ;  $x_i$  is the absolute acceleration of the mass  $m_i$ ;  $z_i$  the relative displacement between two consecutive masses; and  $\dot{z}_i$  the relative velocity between two consecutive masses. Equation (1) can be rewritten in more compact form as follows:

$$G^{(i)}(z_i, \dot{z}_i) = \sum_{j=i}^n \frac{F_j}{m_j} - \sum_{j=i}^n \bar{m}_{ij} \ddot{x}_j \quad (2)$$

where  $\bar{m}_{ij} = \frac{m_j}{m_i}$  represents the ratio between the lumped masses  $m_j$  and  $m_i$ . This approach assumes that the acceleration time responses  $\ddot{x}_i$  are available from observations, along with the applied forces  $F_i$  and/or the base excitation, as well as the values of the lumped masses  $m_i$ .

In addition, each of the estimated restoring force functions can be converted to a power series of the form

$$G^{(i)}(z_i, \dot{z}_i) = \sum_{q=0}^{q_{\max}} \sum_{r=0}^{r_{\max}} a_{qr}^{(i)} z_i^q \dot{z}_i^r \quad (3)$$

## 3 BUILDING DESCRIPTION AND CONFIGURATION

To evaluate the fundamental characteristics and validate the proposed methodology for earthquake responses and damage assessment in high-rise buildings, the data obtained from the shaking table test conducted at E-Defense in Japan are analyzed. E-Defense, operated by the National Research Institute for Earth Science and Disaster Resilience (NIED), is a 3D full-scale earthquake testing facility featuring the world's largest shaking table. The testbed is an 18-story moment-resisting frame structure, measuring 25.3 meters in height and weighing approximately 4179 kN, scaled down to one-third of a full-scale building [12]. Figure 2 and Figure 3 provide an overview and outline of the test specimen, respectively.

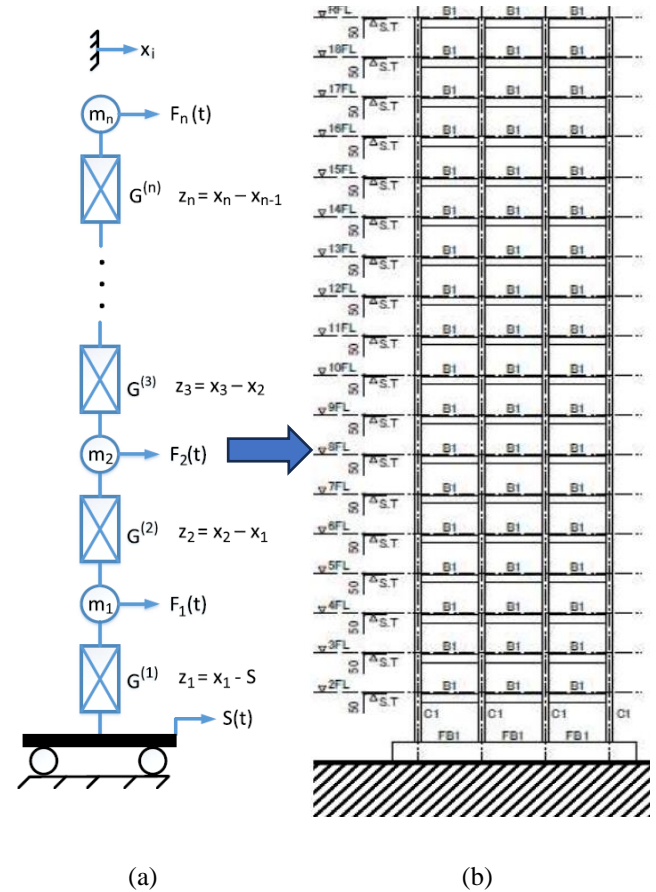

Figure 1. Modeling of the 18-story building used in this study: (a) reduced order representation (mathematical model), and (b) experimental setup.

Figure 2. Overview of testbed.

Figure 3. Outline of test specimen (a) floor plan and (b) structural framing elevation.

The floor plan measures 2000 mm by 3 spans in the longitudinal X-direction and 5000 mm by 1 span in the transverse Y-direction. The structure consists of moment-resisting frames with box-shaped steel columns measuring 200 mm by 200 mm, and H-shaped steel beams measuring 270 mm by 85-95 mm in the X-direction and 250 mm by 125 mm in the Y-direction. Servo-type three-axis accelerometers are installed at the corners of the X1 and Y1 bay on each floor of the test building. Measurement records from all floors and roof, totaling 18 accelerometers, are utilized for response estimation and damage evaluation in this study. The sensor signals are sampled at 200 Hz. The test specimen was subjected to a uniaxial excitation in the X-direction, with a first natural period of approximately 1.15 seconds in the X-direction.

The earthquake input motion is an artificially created Tokai, Nankai, and Tonankai consolidated-type earthquake occurring at the Nankai Trough, assumed to be recorded at Tsushima, Aichi Prefecture, Japan (Takahashi et al., 2013). Its peak ground acceleration (PGA) is about 300 cm/s<sup>2</sup>, with a velocity response spectrum value (pSv) of approximately 110 cm/s for periods between 0.8 and 10 seconds, and a duration of about 460 seconds. In the shaking table test, the input motion was scaled down to one-third of the original form to match the scale of the test specimen. The maximum excitation levels are set to various levels and applied to the test specimen multiple times.

Figure 4 shows the acceleration time history of the input motion to the testbed. Figure 5 illustrates the root mean square (RMS) for absolute acceleration, velocity, and displacement time-history for all floors in x- direction for the testbed. Figure 6 shows computed for relative displacement, relative velocity, and restoring force time-history for all floors in x-direction based on Equations 1 and 2.

Figure 4. Acceleration time history of input motion for  $pSv=110\text{cm/s}$ .

Figure 5. Computed RMS for absolute acceleration, velocity, and displacement time-history for all floors in x-direction.

## 4 DAMAGE IDENTIFICATION

### 4.1 Sample Data Processing

The acceleration responses were acquired from each floor of the testbed at a sampling frequency of 200 Hz. Corresponding velocity and displacement time histories were obtained through digital signal processing and numerical integration. Additionally, it was assumed that the building slabs were rigid; therefore, the available acceleration measurements corresponded to the acceleration response of the structure at each slab's geometric center. It is important to note that the experimental data contains all sources of measured uncertainty as the data was recorded from a real physical structure. To create a set of data, the time-history record for each structural state/configuration was partitioned into 40 ensembles with 20% overlap (i.e., in a sliding window of 30-second duration). Each ensemble includes more than five fundamental periods of the system.

### 4.2 Decomposition Approach

The building structure was utilized to demonstrate the results of implementing the proposed approach detailed in the second section of the paper, aimed at constructing a reduced-order model for the building structure. The decomposition approach for restoring force identification was executed using a third-order polynomial in both normalized variables  $z_i$  and  $\dot{z}_i$  for all floors in the building structure. The selection of a third-order polynomial was intentional to illustrate that the nonparametric identification approach discussed is capable of autonomously detecting whether the system is linear or nonlinear.

Once the relative displacements and velocities were computed, the ChainID identification approach was applied to develop the associated nonparametric representation for each floor in the 18-story building structure by calculating the corresponding restoring force coefficients for each floor in the reference structural configuration. Figure 7 illustrates sample time-history plots for the relative displacement  $z_i$ , relative velocity  $\dot{z}_i$  and measured mass normalized restoring force  $G^{(14)}$  between the 14<sup>th</sup> and 13<sup>th</sup> floors, in the x-directions.

Figure 6. Computed RMS for relative displacement, relative velocity, and restoring force time-history for all floors in x-direction.

The analysis of the identified restoring force coefficients (i.e., power series coefficients  $a_{qr}^{(i)}$  for all building floors indicated that the linear term associated with relative displacements in the nonparametric representation (i.e.,  $a_{10}^{(i)}$ ) had the most significant contribution to the restoring force  $G^{(i)}$ , while the nonlinear terms were negligible. Figure 8 summarizes the identified mean of mass-normalized stiffness-like coefficient ( $a_{10}^{(i)}$ ) for all floors in x-direction.

For brevity, only the identification results computed for the 14<sup>th</sup> floor will be presented and discussed in this section. The power series coefficients  $a_{qr}^{(14)}$  of the nonparametric representation for the 14<sup>th</sup> floor are summarized in Table 1. It is evident that the mass-normalized stiffness-like coefficient  $a_{10}^{(14)}$  was the dominant term in the nonparametric representation.

It can be seen from Table 1 that only the linear terms in the identified model are found to be dominant. However, for the 1<sup>st</sup> floor, nonlinear terms had more contribution due to the presence of plastic hinges at the damaged location, as will be discussed in the upcoming section. It is important to mention that the same control parameters were used to perform the analysis without making any assumptions regarding the presence or absence of nonlinear response features. Figure 9 illustrates the time-history of the measured (experimental data) and reconstructed (after the application of ChainID approach) mass-normalized restoring forces for the 14<sup>th</sup> floor in the reference configuration in the x-direction. The two curves are essentially identical, indicating that the reduced-order model was able to replicate the dominant behavior of the 14<sup>th</sup> floor.

Figure 7. Sample relative displacement  $z_i$  and relative velocity  $\dot{z}_i$  computed between the 14<sup>th</sup> and 13<sup>th</sup> floors. The third row presents the measured restoring force time-history for element  $G^{(14)}$ .

Figure 8. Identified mean of mass-normalized stiffness-like coefficient ( $a_{10}^{(i)}$ ) for all floors in x-direction.

Table 1. Identified mass-normalized restoring force coefficients  $a_{qr}^{(14)}$  for the 14th floor.

q\r	X-direction			
	0	1	2	3
0	0.00	2.10	-0.13	0.00
1	2276	0.90	0.20	0.00
2	12.30	3.20	0.00	0.00
3	78.00	0.00	0.00	0.00

Figure 9. Comparison of measured and estimated restoring forces  $G^{(i)}$  for 14<sup>th</sup> floor in x-direction. Solid lines correspond to measured restoring force time-history; and dotted lines correspond to reconstructed restoring force time-history.

### 4.3 Damage Detection

To visualize the primary dynamic features of the system, the experimental phase plots (blue line) and the reduced-order representation using the ChainID approach (dotted red line) as well as the restoring force surface, are compared for the 14<sup>th</sup> and 1<sup>st</sup> floors, as shown in Figure 10.

It can be seen from Figure 10 (a), the reconstructed reduced-order model successfully captured the dominant linear dynamic characteristics of the 14<sup>th</sup> floor. Similarly, the reconstructed restoring force surface is planar, despite the use of a third-order expansion in both state variables (i.e., relative displacement and relative velocity) to characterize the dynamics of the 14<sup>th</sup> floor. The actual restoring force measurements are plotted as a point cloud, as shown in the second row of Figure 10 (a).

It is important to note that the data set under discussion was obtained from the testbed, where significant damage was observed on the 1<sup>st</sup> floor. This damage was characterized by the formation of plastic hinges at several columns, indicating a localized failure mechanism. The presence of plastic hinges suggests that the columns experienced substantial stress and deformation, leading to a reduction in their load-bearing capacity. This observation is crucial for understanding the structural behavior and integrity of the building under dynamic loading conditions.

The presence of plastic hinges and damage in the columns of the 1<sup>st</sup> floor led to the anticipated nonlinear behavior of the floor. This nonlinear response is indicative of the significant stress and deformation experienced by the columns, restoring forces  $G^{(i)}$  versus relative displacements  $z_i$  for the 1<sup>st</sup> floor and corresponding estimated restoring force surface for the 1<sup>st</sup> floor in the x-direction. In the first row, solid lines correspond to phase plot for the measured restoring force, and dotted lines correspond to reconstructed restoring force. In second row, actual restoring force measurements were plotted as a point cloud, which compromised their structural integrity and load-bearing capacity. The formation of plastic hinges is a critical factor in understanding the overall dynamic performance and failure mechanisms of the building under applied loads.

Figure 10(b) illustrates that the presence of nonlinearity can be visually inspected from the reconstructed restoring force for the 1<sup>st</sup> floor ( $G^{(1)}$ ), compared to the restoring force plot for the 14<sup>th</sup> ( $G^{(14)}$ ) floor under the same excitation. The effects of the nonlinear element in the response of the 1<sup>st</sup> floor are evident in both phase plots of the restoring force when compared to the reference condition, as shown in Figure 10 (b). In the phase plot of restoring force and relative displacement, the change in the restoring force slope indicates a pinching effect in the introduced nonlinearity. This pinching effect is observed on both sides of the restoring force, as the introduced damage is symmetric.

Additionally, a nonlinear effect in the restoring force surface can be seen in the plot of restoring force versus relative displacement and relative velocity, which is a typical signature of damage features. It is important to note that the nonparametric reduced-order representation using the ChainID approach successfully captured the dominant features of the dynamics at the correct location within the modules where the damage elements occurred. This demonstrates the effectiveness of the ChainID approach in accurately identifying and characterizing the nonlinear dynamic behavior resulting from structural damage.

## 5 MODAL IDENTIFICATION USING GLOBAL IDENTIFICATION

In addition to the local identification of the dynamic properties of each floor in the building, the modal identification (i.e., modal parameters) of the building was accomplished using the identified restoring force coefficients, as detailed in [10]. The estimated modal parameters were compared to those directly identified by implementing the natural excitation technique (NExT) in combination with the eigensystem realization algorithm (ERA) [11] a global identification technique.

The estimated values for the modal parameters (i.e., natural frequencies and damping ratios) for the first four mode shapes in x- directions are summarized in Table 2. It is noteworthy that the natural frequencies estimated from the reduced-order models developed in this study closely align with those computed using the NExT/ERA approach. As shown in Table 2, the estimated damping ratios computed using the two different approaches are similar for the first mode shape; however, damping was not identified for the remaining modes. This discrepancy is attributed to the varying contributions of the different modal constituents in characterizing the restoring forces.

Figure 10. Phase plot of (a) restoring forces  $G^{(i)}$  versus relative displacements  $z_i$  for 14<sup>th</sup> floor and corresponding estimated restoring force surface for 14<sup>th</sup> floor in x-direction; and (b) restoring forces  $G^{(i)}$  versus relative displacements  $z_i$  for the 1<sup>st</sup> floor and corresponding estimated restoring force surface for the 1<sup>st</sup> floor in x-direction. In first row, solid lines correspond to phase plot for measured restoring force, and dotted lines correspond to reconstructed restoring force. In second row, actual restoring force measurements were plotted as a point cloud.

Table 2. Summary of natural frequencies and damping ratios for the first four lateral modes in the x-directions of the 18-story building structure, identified from the reduced-order model developed using ChainID and NExT/ERA approaches.

Mode	Chain ID		NExT/ERA	
	$\omega$ [Hz]	$\zeta$ [%]	$\omega$ [Hz]	$\zeta$ [%]
1 <sup>st</sup> mode	0.38	1.78	0.48	1.75
2 <sup>nd</sup> mode	0.81	-	0.82	0.40
3 <sup>rd</sup> mode	1.19	-	1.16	0.20
4 <sup>th</sup> mode	1.65	-	1.79	1.00

## 6 SUMMARY AND CONCLUSIONS

In this study, a one-third full-scale model of an 18-story high-rise building, developed under the E-Defense project, was constructed and instrumented to investigate the damage on individual floors. Sample results from these damage scenario models were used to evaluate the effectiveness and reliability of employing reduced-order models to detect, locate, and quantify changes or damages in a physical building structure.

Input-output data from the 18-story building under base excitation were used to develop reduced-order models for different floors. Two approaches were implemented: the nonparametric chain-like system identification approach (ChainID), which is the focus of this study, and a global identification approach (NExT/ERA). The results demonstrated that significant changes identified in the reconstructed restoring forces of the reduced-order models built using the ChainID approach could be correlated to the presence and location of the actual physical changes or damages, even in the presence of modeling, measurement, and data processing errors.

The initial findings of this study demonstrate that the structural health monitoring methodology presented is capable of accurately detecting, locating, and quantifying structural changes or damage in monitored systems, provided the necessary data set is available.

The presented work is part of an ongoing effort. Future developments will focus on evaluating the algorithm's sensitivity and effectiveness by analyzing multiple earthquake events with varying magnitudes. This will help assess the approach's capability in detecting, locating, and quantifying different levels of structural damage. Additionally, further studies aim to enhance the model's ability to predict potential structural failures under diverse seismic conditions.

**Abstract:** Specially, when it comes to such risky construction projects as the Changshui Airport Railway Tunnel, the ground settlements surrounding the structure will be observed and evaluated. This case study is a combination of advanced machine learning algorithms, which are augmented with MATLAB to reinterpret, visualize and analyze settlement trends based on real – world tunnel monitoring data. The research starts with some of the time – series data that had been registered in the tunnel (settlement, factors that impact settlement, temperature, etc.). K – means clustering and hierarchical clustering are used to classify the settlement patterns and the clustering result indicates the difference in settlement monitoring points. Finally, we have used the feature importance analysis to explore the most significant factors that affect settlement decisions and to know more about the settlement processes in tunnels. The discussion of the Random Forests, Gradient Boosting and Artificial Neural Networks regression models is provided to predict settlement patterns to enable predictive risk. Heatmaps, time – series graphs and scatter plots are some of the comprehensive visualizations constructed to convey the discovery and help in decision making. The indicators to assess the model performance are  $R^2$ , RMSE, MAE and the findings show how to forecast settlements in the most optimal manner. Besides presenting the utility of machine learning tunnel surveillance, the case study also provides data driven decision making framework in underground engineering projects.

**Keywords:** Tunnel Monitoring, Ground Settlements, Machine Learning, Data Visualization, Changshui Airport Tunnel, Underground Infrastructure

## 1. Introduction

Tunnel monitoring is a highly significant element of safety and life of underground infrastructure, especially in high – stakes projects, like airport tunnels (Bao et al., 2018). The geotechnical and environmental forces that control the settlement behavior of these structures are complex and may undermine the structural integrity of these structures (Muhammed et al., 2019). Monitoring is thus essential in the realization of the impacts and of the excavation works on the surrounding ground and structural stability. The conventional approaches, however, despite their usefulness, are time – consuming and prone to errors because they involve a lot of manual analysis that may need human interpretation (Hua et al., 2021). Monitoring systems generate a lot of data in the course of a tunnel project life cycle because of the technology development (Wang et al., 2020). It is also difficult to analyze such datasets to draw conclusions, identify trends and discover impact factors. Nevertheless, the existing practices fail to capture this information in a manner that would allow proactive maintenance and safety decision – making.

The given Case study examines the application of machine learning approaches that have been adopted in the MATLAB environment to solve the above – mentioned issues. Using the data of Changshui Airport Tunnel Monitoring, it aims to interpret, visualize and analyze settlement behavior using clustering algorithms, feature importance analysis and regression models, thus determining patterns, whether to fill or settle and which factors have a significant impact on ground activity. The introduction of machine learning based systems into the tunnel monitoring process is a paradigm shift, since such methods enable quicker and more precise

analyses due to automation of the extraction of complex datasets (Jin-miao et al., 2022). The results of the study can thus be used to make improved decisions, improve predictive maintenance and support the safety and efficiency of underground structures. The power of this study shows its ability to use the existing computational tools to produce engineering solutions that can have a significant real – life effect.

## 2. Settlement Monitoring and Prediction

Figure 1 is a summary of the settlement monitoring and prediction process, its challenges and developments. Settlement monitoring is an important aspect of safety and life of underground infrastructure in high-risk projects like airport tunnels (Jin-miao et al., 2022). The construction induced behaviors such as boring induced stresses, change in ground water level and geological heterogeneities are some of the causes of ground settlement (Ayasrah et al., 2020). These deformations can be hazardous and in case they are not identified or misinterpreted, they can result in structural instability, which can result in catastrophic failures (Ayasrah et al., 2020). Monitoring of landslides is achieved by surface and subsurface movements which are traditionally monitored by geodetic surveys, inclinometers and extensometers. Figure 1 represents the key areas of monitoring of settlements, including the traditional and contemporary approaches, and the utilization of the advanced instruments like machine learning and visualizations, to analyze large amount of data. It has been increasingly possible to obtain continuous deformation data, as newer forms of instrumentation have been developed well, including automated total stations, satellite-based InSAR (interferometric synthetic aperture radar) and fiber optic sensors, all modern (Karamvasis & Karathanassi, 2020).

Monitoring therefore plays a role beyond detection to mechanisms of settlement (Martins et al., 2020).

### 2.1. Machine Learning in Civil Engineering

Machine learning (ML) is easy to use and understand complex data and predict structural behaviors in civil engineering (Marsella & Scaioni, 2018). Various clustering techniques (E.g.: K-means clustering, hierarchical clustering, etc.) are increasingly being used in settlement monitoring to classify settlement patterns as well as to detect spatially heterogeneous risks (Vadyala et al., 2021). To illustrate, showed that clustering had the potential to significantly increase the ability to distinguish settlement behavior at up to eight monitoring sites and could be applicable in the implementation of sector-specific mitigation measures (Zhou et al., 2020). The most important machine learning techniques of settlement monitoring are clustering and regression models, which allow identifying patterns and predicting trends in ground deformation, as illustrated in Figure 1. All regression models, including RF, GB, and ANN, had better predictive performance and modeled settlement trend than statistical methods (Jin-miao et al., 2022). This type of models is particularly applicable when there are non-linear relationships and high dimensional data as is the case in geotechnical applications. Other related fields where ML can be applied, i.e. SHM and anomaly detection (Mousavi & Beroza, 2022). The former includes clustering methods which have been applied to identify deformation anomalies in bridge structures and regression models are widely applied to predict loads in buildings (Jasmine & Arun, 2021).

### 2.2. Advanced Data Integration and Visualization

The capability to successfully integrate the heterogeneous data, which are position, deformation, temperature and environmental parameters in a single effective mechanism has been one of the most remarkable issues in tunnel monitoring (Zhao et al., 2021). MATLAB, which has a vast array of tools to conduct machine learning and visualization, is a perfect candidate to conduct such workflows (Ma et al., 2021). Settlement dynamics can be shown in time-series plots, and areas with high-risk levels can be shown in heatmaps (Yan et al., 2019). Together with clustering and regression analyses, these visualizations may give a complete image of the behavior of ground and in responsivity.

### 2.3. Research Gap and Addressing

Although the ML techniques have shown promising progress in geotechnical engineering, studies have been mainly focused on specific tasks (Marcher et al., 2020). As far as the authors are aware, few studies have attempted to develop a coherent framework to interpret and visualize settlement data that include clustering, feature importance analysis, and regression modeling (Chen et al., 2022). The literature also shows evidence of the need of domain-specific adaptations in ML algorithms. Or, feature engineering based on site condition, geological and environmental driven feature engineering could be used in settlement prediction models (Fan et al., 2019). These methods, however, offer more access and utility of data, yet there is no standard workflow to those adjustments, and thus, the overall use of these models becomes cumbersome (Merghadi et al., 2020).

We suggested a machine learning pipeline that included clustering, feature importance, regression, and application of that regression with clustering to provide a general analysis framework (as illustrated in Figure 1) to be used in tunnel monitoring.

### 3. Data Preprocessing

Monitoring of settlement is an important process in the safety of high-risk infrastructure projects like tunnels during construction and long-term prevention and remedial maintenance of the infrastructure after construction (Tan et al., 2019). These techniques offer optimal solutions to capture high-resolution spatial-temporal trends but the traditional settlement monitoring methods (geodetic surveys, inclinometers) are time-consuming, subject to human error, and do not capture such trends (Wang et al., 2020). In this section, a step-by-step data-driven framework of the analysis of the settlement behavior in the Changshui Airport Tunnel will be discussed. Figure 2 gives a general description of the proposed framework.

#### 3.1. Data Preprocessing

The pre-processing of data is performed to clean, standardize and prepare the data to be utilized in future machine learning activities. Using MATLAB workspace, we can see that our original data has 13 columns and 10,704 rows. The notable variables are dated Measurement Time, Cumulative Settlement, Relative Settlement, Settlement Rate, Geological Grade, and Distance from Start. The selection of these variables reflects the time and space aspects of the settlement monitoring which constitutes the basis analysis of any type of settlement monitoring.

- Standardization of Time Intervals:** The time interval of data collection is not of regular nature (Time Interval Days) and is recorded in Measurement Time. Time matching functions in MATLAB where timestamps are converted to fixed equidistant time (e.g. 0.5 days, 1 day) to provide uniform time-based monitoring of settlement patterns.
- Missing Values:** Handling Missing Values in Missing Values: Interpolated Settlement Rate and Relative Settlement with the fill missing () function in MATLAB. Linear interpolation maintained the trends of time in the data to avoid bias.
- Normalization of Variables:** Cumulative Settlement, Settlement Rate, and Geological grade were normalized by the min-max scaling by using the normalize () function of MATLAB. This process minimizes the differences between the applications of different systems that improve the performance of the machine learning models.
- Detect and Remove Outliers:** The sensor errors and environmental disturbances that caused the sudden anomalies in the settlement rates were detected by using the Z-scores to detect statistical outliers and examine sudden spikes by plotting time-series data.

### 3.2. Clustering Analysis

Settlement behaviors were used to mine, which was done through clustering analysis. This step exposes spatial settlement patterns and points out areas of intervention. Clustering Techniques:

- a. K-Means Clustering: The variables such as Settlement Rate, Cumulative Settlement, Geological Grade were used as inputs. Elbow Method was used to determine the best number of clusters using within-cluster sum of squares (WCSS). The MATLAB assigned the monitoring points to various clusters using the K – means () function.
- b. Hierarchical Clustering: The results of K-means were confirmed through the hierarchical clustering which provided a hierarchical view of settlement behaviors. The hierarchical relationships between the settlement points were visualized with the help of the linkage () function in MATLAB that produced a dendrogram.
- c. Clustering Results: Cluster 1: Monitoring points outside structural elements (i.e. tunnel border), i.e. the address which was above the maximum settlement value; Cluster 2: intermediate settlement rates -> transitional zones; Cluster 3: Stable regions with thin layers.

### 3.3. Feature Importance Analysis

The feature importance analysis shows the most important factors in the determination of settlement behavior (Oh et al., 2021). This procedure increases the interpretability of the predictive models and follows the geotechnical principles. The following is the outline of feature importance analysis:

- a. Supervised Learning Models: To rank predictor variables Random Forest (RF) and Gradient Boosting (GB) models were applied. Dependent Variables: Settlement Rate, Cumulative Settlement Predictor variables: Geological Grade, Distance from Start, Monitoring Point Elevation and Time Interval Days
- b. Feature Importance Ranking: The RF and GB models provided feature importance scores of all the predictors. The strongest features were: Geological Grade: The main factor that affects settlement, which means the effect of soil properties; Distance from Start: Settlement is not evenly distributed along the length of the tunnel; Time Interval Days: Settlement behavior varied greatly depending on the time of year.

### 3.4. Predictive Modeling

Predictive modeling was also carried out to forecast settlement patterns in order to carry out proactive maintenance. It entailed a split of the data into 80 percent training and 20 percent test and the models were ranked based on their capacity to predict Cumulative Settlement.

- a. Training and Testing: Single supervised machine learning models were trained and tested: Random Forest (RF): It is interpretable and robust; Gradient Boosting (GB): Very accurate iterative model; ANNs: Can capture potential non-linear relationships and required tuning up; The robustness was achieved by cross-validation.

- b. Evaluation Metrics: Models were tested on  $R^2$ :  $R^2$  is a measure that compares the predicted values with the actual values in the training data; RMSE (Root Mean Square Error): How large is the error of the prediction; MAE (Mean Absolute Error): A measure to normalize the error of the prediction.

### 4. Graphical Analysis and Data Interpretation

Some of the visual outputs and the interpretation applied in this section include Feature Importance, Predictive Modeling, and other statistics that are used to monitor and predict on settlements. Dataset Summary: The target variable Cumulative Settlement was initially analyzed statistically and then feature importance analysis was done. The most important statistics are:

Rows in Dataset: 10,704; Missing Values: 841 (preprocessing step); Minimum Settlement Value: 0; Median Vela Value: 14.1412; Settlement Value Max: 2,064.6; Average Settlement Value: 940.1619; Standard Deviation: 1,019.7

Following data cleaning, 9863 rows remained to be used in train and evaluation. Such preprocessing steps were followed to ensure data reliability in the execution of the following model.

#### 4.1. Analysis of Feature Importance

The results are displayed graphically with measures Table 1. Numerical Insights from ANN Feature Importance.. Figure 3 below is a bar chart that indicates the importance of each feature (e.g. Time Interval Days, Distance from Start, Monitoring Point Elevation, Relative Settlement) to the prediction of settlement rates using Random Forest (RF) model. As we observe, Monitoring Point Elevation is the most influential predictor with an importance of 50, which dwarfs the other features. Monitoring Point Elevation remains the most influential predictor in the List of Features in Gradient Boosting with an importance by value of more than 10,000 as in Figure 4. With the permutation-based importance, the ANN indicates that the most important predictor of settlement rates is Monitoring Point Elevation with an importance score of approximately 1,000 as indicated in Figure 5. The importance score of Monitoring Point Elevation is overwhelmingly high (1,028.8246). The architecture of ANN employed in the prediction of settlement in Changshui Airport Tunnel is shown in Figure 6. The model has an input layer that has the four main predictors of interest, which are Time Interval Days, Distance from Start, Monitoring Point Elevation, and Relative Settlement, which cover the effects of time, distance, and elevation on settlement, and the effects of relative settlement.

Random Forest Figure 3 – Monitoring Point Elevation is the most important, and all others (Time Interval Days, Distance from Start, Relative Settlement) are practically 0. Gradient Boosting Figure 4 - The importance score of Monitoring Point Elevation is about 10,000, which again confirms its importance. ANN Figure 5 The permutation-based analysis of ANN shows that Monitoring Point Elevation has an extremely high importance score of 1,028.8246, which is far higher than any other feature. Temporal (Time Interval Days) and spatial (Distance from Start) features were of moderate

importance in all models: Random Forest Figure 3 – Time Interval Days and Distance from Start are rather insignificantly contributing yet still distinguishable compared to Relative Settlement. Gradient boosting Figure 4 in this case, these features have small but distinctly visible impact.

#### 4.2. Analysis of Model Performance Metrics

Figure 7 shows that the random forest (RF) model possesses a good prediction power ( $R^2$  close to 0.90). Similarly, the Root Mean Square Error (RMSE) is also very small, implying that the difference between the actual value and the predicted value is less. Thus, we can say that RF is very efficient when it comes to this dataset. The MAE (Mean Absolute Error) indicates the average absolute error between the predicted and actual values and as it can be seen, it is very low and hence RF can make accurate predictions. In Figure 8, Gradient Boosting (GB) has similar  $R^2$  values ( $\sim 0.90$ ) to RF, which means that it performs well in predicting.

In Figure 9 it reflects the data non-linearities more than RF and GB since the third ANN model has the greatest degree of accuracy in the terms of  $R^2$ . RMSE of ANN is slightly greater than GB but in general ANN is more able to capture the patterns but that can also be a sign of ANN overfitting or high variance in localized predictions. The grouped bar chart Figure 10 in Figure 7, Figure 8, Figure 9 gives a summary of the performances of the model in terms of  $R^2$ , RMSE, and MAE of the RF, GB, and ANN. The three models are remarkable in accuracy ( $R^2$  close to 0.90). However: ANN does get a bit better in  $R^2$ , so it is now the most successful model in the sense of understanding complex interactions. The RMSE of GB is lower than other models, which means that the predictions of GB are better in magnitude, especially in the pleasant regions. These results in Figure 10 showed that the choice of the model depends on the application, ANN is better to work with highly non-linear data, GB is the preferred method to minimize catastrophic errors, and that RF is a universal and interpretable solution.

#### 4.3. Residual Analysis

The residual plot of RF Figure 11 indicates that the residuals are between -60 and +60. The majority of them are clustered at the zero line, which shows that the accuracy of many of the predictions was reasonable, but the dispersion of residuals, particularly at higher values, provides a clue as to how this model performed poorly on some of the cases where the predictions were relatively too distant to the actual value. Figure 12 The range of residuals is -2 to +2 in Gradient Boosting, which is much narrower, showing much higher precision compared to RF. The Figure 13 ANN shows the least range of residuals, -1.2 to +0.2 residuals that are tightly clustered around zero. This means that it is the most accurate in predicting among the models, and it has the fewest errors and excellent generalization abilities. Based on Figure 14 these findings are pointing out that ANN is the most effective in capturing complex relationships in the data and therefore it would emerge as the most accurate model in predicting settlement. Combined Residual Plot - RF, GB and ANN The combined residual plot displays residuals of RF, GB, and ANN. RF has the broadest scope of residuals between -60 and +60, thus performing the worst in the minimization of

prediction error. ANN residuals are the closest to each other, and they are well within the range of -1.2 to +0.2, which is exceptionally precise.

#### 4.4. Settlement Risk Analysis

The Actual Settlement and the RF, GB, and ANN model predictions of spatial settlement risks are shown in Figure 15 below. Actual Settlement (Top Left) The baseline comparison is provided by this heat map because it indicates the settlement values that actually took place. It demonstrates the actual pattern of settlement risk by subterrains as reflected by the data recorded in Figure 15. However, at the higher risk regions at Figure 15, there are minute differences. This means that RF will only capture the overall trend and will not be in a position to follow the minor details, particularly in cases where the values of settlements are extreme. GB Predicted Settlement (Bottom Left) The gradient boosting heat map would see it to be in good fitness to real settlement. ANN Predicted Settlement (Bottom Right): ANN is the most accurate model among RF and GB and it gives the closest resemblance to the actual settlement. All the heatmaps show that ANN gives the most accurate approximation of spatial settlement risks, then Gradient Boosting, and then Random Forest. It also agrees with the results that were obtained previously that ANN is more accurate overall, especially on complex data, GB is moderately accurate; RF is less accurate in extreme cases as indicated in Figure 15.

#### 4.5. Error Distribution Analysis

Figure 16 Error Histogram (RF, GB, ANN) The histograms of RF, GB, and ANN give a detailed statistic of the accuracy errors of the three models. The Errors variance is very broad in RF & a range of approximately -60 ~ +60 is essentially eminent. When the value of minimum is high, it means that the model is not as precise as other models. The GB histogram range is lower, with a range of mostly between -2 and + 2, which means that it minimizes errors and is more stable in performance. The distribution of errors is the most concentrated in ANN and the errors are near -0.01 and +0.01 and this indicates that ANN predicts settlement values more accurately than other networks. Figure 17 Grid density plot of Errors RF, GB and ANN The mixed density plot indicates the variations in the distribution of the various errors of these three models to indicate the difference in performance. This Figure 17 graph therefore reinstates the ability of ANN to generalize complex patterns and to be highly accurate in the predictions.

#### 4.6. Clustering Analysis

The Elbow Method to validate the number of the optimal clusters in the K-Means clustering analysis (Schubert, 2023). The y-axis indicates the within-cluster sum of squares that is an indicator of the compactness of the clusters and the x-axis indicates the number of clusters. Figure 18, The decrease in WCSS as  $k = 1$  to  $k = 2$  means that the variance can be explained by two clusters only to a reasonable extent. WCSS begins to flatten out after  $k=2$ , the returns to adding more clusters are getting small. K mean clustering  $k=2$ , frequencies of prevailing settlement patterns in the data set. X: The following scatter plot presents the outcome of K-Means clustering of the settlement data. The data are shown as color-

coded clusters: red = Cluster 1, green = Cluster 2, blue = Cluster 3. In these two axes, the x-axis (Feature 1) would show something like Time Interval Days and the y-axis (Feature 2) could show Distance from Start. The clusters indicate spatial settlement patterns: Cluster 1 (red): The regions of maximum movement, most probably in the area of structural features or ground disturbance. 4465 points, Cluster 2 (green): The regions of transition with average settlement rates and medium stability. 1341 points, Cluster 3 (blue): Stable areas, where there are few changes in the settlement, corresponding to less vulnerable areas. 4057 points. The Euclidean distances between clusters are plotted on the y-axis and the data points (e.g., monitoring locations) on the x-axis Figure 20. The vertical lines are also branched vertically on the height of the dendrogram where the significant differences are found and this is another evidence that there are three main groups that are identified in the hierarchy. Table 4. Feature Importance of Each Cluster Model.

## 5. Results

A detailed analysis of the Changshui Airport Tunnel based on various state-of-the-art machine learning algorithms-Random Forest (RF), Gradient Boosting (GB), and Artificial Neural Networks (ANN) was conducted to analyze and predict the settlement behaviors. we are presenting the results with performance metrics and feature importance of all the models. Model Performance Metrics Table 2. Model Performance Metrics for Each Model summarizes quantitative performance metrics of each model, presented in Figure 7. Performance Metrics – RF.. These results indicate that ANN model is more accurate in predicting the settlement behavior, which proves its strength and reliability in predicting the settlement behavior more accurately than the other models. Table 3. Feature Importance of Each Model below shows the importance of each feature to the respective models. The importance scores enable us to know the values of features that are most closely associated with model predictions. In addition, the significance scores are also graphically illustrated in Figure 3, Figure 4, Figure 5, which indicates that Feature 3 is dominant in all models, which is a significant environmental or geotechnical factor. The total residuals are presented in Figure 14, which indicates that ANN has predicted very little wrong. The heatmap plots of the actual and predicted settlement were very similar, and this fact proved that the ANN predictions are the closest to the actual ones, and the predictions of GB and RF were the second. This spatial disaggregation plays an important role in the proper depiction of risk distribution. The error distribution in each model is described and shown in Figure 16, which shows the frequency of the prediction errors that have been observed in some ranges. Elbow Method determines the number of clusters as illustrated in Figure 18. In order to get a meaningful segmentation of settlement patterns the elbow plot indicates that the optimal number of clusters is three. The outcome of the clustering can still be visualized, which is K-means clustering of data points in Figure 19 and the dendrogram of hierarchical clustering in Figure 20, which confirm the segmentation results based on hierarchical relationships between individual points of settlement.

## 6. Discussion

The study demonstrates that geotechnical monitoring can be enhanced considerably with the assistance of deep analysis based on ML to process complicated data sets(Ritter & Frauenfelder, 2021). The concentration of monitor location to some clusters that depict characteristics assists in the development of particular place of resident behaviors. In general, Cluster 1 had 4,465 points (marked as RESILIENT / STABLE on the map) and we can use these areas as reference areas, or even a baseline of comparison of how we can improve and others areas came out as Cluster 2, which had 1,341 points and marked as THREATENED on the maps, which are transitional or Undeveloped areas, which need more care and attention with interventions more proactive. These clusters are consistent with the predictive data of machine learning models (ANN, GB, etc.) that showed Monitoring Point Elevation as the most correlated parameter, which confirms that the higher settlement was observed in the sites of well locations that were in Cluster 2. The clustering results give the necessary information and confirmations to help in maintenance planning and resources allocation besides confirming the model predictions.

### 6.1. Analysis of Improved Model Effectiveness, Interpretation and Consequences

The ANN is the solution to risk prediction and mitigation in tunnel scenarios because of its excellent capacity to comprehend complex, non-linear relationships in geotechnical data(Ramezanshirazi et al., 2019). On the other hand, GB and RF were good alternatives, and GB reduced prediction errors by iterative refinement and RF was easy to interpret. The elevation of the monitoring point was also identified as a critical factor in all the models since the feature significance analysis revealed the critical importance of the elevation changes in influencing the tunnel settlements(Apoji et al., 2022). According to this conclusion, the influence of the elevation changes on the stress distribution and the following settlement patterns is considerable, which is consistent with the geotechnical principles (Figure 3, Figure 4, and Figure 5).

Both models possessed some advantages within the context of geotechnical data, Random Forest: It was very robust and provided interpretable results and therefore it can be applied to problems where the impact of a specific feature is of interest. Gradient boosting was very good in minimizing the prediction error and managing the interaction between features. This meant that it was suitable in the modeling of the non-linear dynamics of the settlement data. Artificial Neural Networks: Have proven to be very accurate in handling complex data structure, but they are very demanding in terms of processing power and they need to be fine-tuned to avoid overfitting.

### 6.2. Prospective Research Directions

The proactive management of infrastructure is being embraced by integrating machine learning (ML) in tunnel monitoring(Plevris & Papazafeiropoulos, 2024). Machine learning enhances tunnel safety and life by identifying potential danger zones early enough due to its ability to process and analyze large volumes of data. Nevertheless, the

indictment also points to areas that should be further investigated, to enhance the effectiveness of machine learning in the area of tunnel monitoring: These are the incorporation of real-time data inputs to enable adaptive responses to environmental deviations, and a data-driven dynamic update of predicted models as part of a real-time processing solution (Zhang et al., 2020). Cross-Project Validation: experiments are conducted on a number of tunnel projects to determine the generalizability of the models to standardize ML applications in civil engineering.

## 7. Conclusion

Further use of machine learning methods in this field may assist us in getting nearer to the realization of the role of different parameters in the monitoring of tunnel (as a part of Geotechnical Engineering) and the qualitative side of Geotechnical engineering as perceived through the eyes of a geotechnical engineer. This paper was restricted to the monitoring of tunnel in Changshui and the monitoring system is comprehensive to monitor the deformation patterns of Changshui. Security aspects of Geotechnical Engineering Which are likely to be messages of improved predicting performances and functional profitability of the Geologist economical relevant hazard mapping linked with geological changes (Wu et al., 2021). Therefore, Random Forests, Gradient Boosting Machines, and Artificial Neural Networks have been applied effectively in enhancing the accuracy and reliability of settlement predictions, which is essential to the stability, as well as sustainability, of tunnel infrastructures (Yan et al., 2019). This was the main area/work in the investigation of the possibilities of these models, where, as they have a good understanding of complex and nonlinear data interactions, in the sense of the higher  $R^2$  and lower RMSE and MAE on the Artificial Neural Network, the best results were obtained. These excellent results demonstrate the potential of sophisticated ML models to become a disruptive technology to traditional geotechnical monitoring practices that allow the risk assessment and mitigation plans to go much deeper than ever before. The effective use of these technologies can also be extended to other geotechnical events that are high risk (Wang et al., 2021). Moreover, the use of machine learning methods must be applied to various project scenarios in other studies, which will allow a better idea of whether/what algorithms can be used in different construction conditions in real time.

**ABSTRACT:** Physics-Informed Neural Networks (PINNs) seamlessly integrate the predictive capabilities of neural networks with established physical principles. By integrating constraints such as displacement and force boundary conditions alongside governing equations, PINNs can generate digital twins of physical systems and processes. This fusion allows for more accurate modelling and simulation of complex physical phenomena, bridging the gap between data-driven approaches and traditional physics-based methods. Nevertheless, the practical implementation of PINNs remains challenging, primarily due to numerous influential hyperparameters and the complex nature of modelling the governing physics through partial differential equations (PDEs). This challenge becomes especially critical in the context of dynamic loads, where higher-order PDEs encompassing both spatial and temporal domains, alongside relevant structural parameters and generalised (distributed) load's function, must be carefully optimised during the PINNs training process. This study presents a novel application of PINNs model, developed, trained, and validated using real-world bridge monitoring data, for the inverse problem of predicting structural parameters of a girder subjected to moving loads. Two case studies are considered. In the first, PINNs model is utilised to estimate the structural parameters of a bridge girder under varying levels of noise in the data. In the second, the model is trained with actual field monitoring measurements to estimate structural parameters while predicting girder deflection and other internal forces. The findings advance the existing body of knowledge in structural health monitoring (SHM) by demonstrating a practical PINNs-based solution for bridge girders under moving loads.

**KEY WORDS:** PINNs; Inverse problem; Parameter identification; Neural networks (NNs); SHM.

## 1 INTRODUCTION

Bridges are critical components of transportation infrastructure, and ensuring their safety and longevity through structural health monitoring (SHM) is a top priority [1]. Over time, bridges are subjected to environmental deterioration and repetitive traffic loads that can induce damage or stiffness degradation, potentially reducing their service life [2]. A key aspect of SHM is structural parameter identification – determining properties such as stiffness (flexural rigidity) – which enables the assessment of a structure's condition [3].

Recently, physics-informed neural networks (PINNs) have emerged as a promising tool for tackling inverse modelling problems [4], [5]. PINNs are a type of deep learning framework that embeds physical laws—often expressed as partial differential equations (PDEs)—into the neural network's training process. Instead of relying solely on labelled input-output pairs, PINNs are trained to predict outputs that both fit observed data and satisfy governing physics. This is achieved by incorporating physics-based constraints, such as PDE residuals, into the loss function alongside data-fitting terms [6]. For instance, PINNs have been employed to enforce structural dynamics and damping evolution equations while matching measured responses [3].

In the context of inverse problems, the primary objective of PINNs is to estimate unknown parameters within partial PDEs based on observed data. PINNs have been applied to various domains, including fluid dynamics, where they determine density, velocity, and pressure fields for one-dimensional Euler equations from observed density gradient data [7]. Rasht et

al.[8] utilised PINNs for seismic imaging, estimating wave speed from observed data in full waveform inversions. Current advancements have further extended the application of PINNs to SHM, particularly in civil engineering structures such as bridges and beams. For example, in the context of railway bridges, PINNs have been employed for structural analysis and monitoring, addressing challenges such as load distribution modelling, SHM, and failure prediction under dynamic train loads [9]. Moreover, studies have demonstrated the ability of PINNs to predict structural response from sparse sensor data, even in the presence of noise for Kirchhoff–Love plates under static loads [10]. These applications highlight the capability of PINNs to integrate data fidelity with physical consistency, making them particularly suitable for SHM tasks, where field measurements are often limited.

However, a key challenge lies in applying PINNs to identify structural parameters of beams subjected to moving loads using real-world data. This research aims to address this challenge by proposing a novel approach that integrates physics-based modelling with real-world monitoring data to improve the accuracy and reliability of structural parameter identification.

The main contributions of this study are as follows:

- The development, training, and validation of PINNs to solve the problem of a bridge girder subjected to a moving load. In doing so, this work addresses the challenge of incorporating higher-order PDEs spanning both spatial and temporal domains.

- Demonstration of how PINNs can predict structural parameters, alongside other outputs such as deflection and its derivatives.
- A thorough examination of the PINNs' performance and predictive accuracy under varying levels of data noise. By testing the models across a range of signal-to-noise ratios, the study evaluates their robustness, providing insights into their reliability and resilience in practical settings where data imperfections are common.
- An investigation of the PINNs' adaptability and generalisation capabilities when trained on real-world monitored data from a bridge.

This paper is organised as follows: Section 2 introduces the problem definition and outlines the methodology. Section 3 provides discussions on Case Studies 1 and 2, along with their respective results. Section 4 presents the conclusions and recommendations for future research.

## 2 METHODOLOGY

This section considers the architecture of a fully connected feedforward neural network and describes the PINNs setup for inverse problems. Specifically, it includes an explanation of PINNs model hyperparameters and the loss function terms for a bridge girder with a moving load. The analysis includes a detailed discussion on the training of PINNs, as well as the investigated and selected hyperparameters of the neural networks.

### 2.1 Neural networks Architecture

The network consists of hidden layers (H), each formulated to process inputs recursively. For each hidden layer  $h$ , where  $h$  ranges from 1 to H, the output  $f(h)$  is determined by Equation (1):

$$f(h) = \sigma(W(h)f(h-1) + b(h)) \quad (1)$$

Here,  $f(0)$  signifies the initial input to the neural network. The function  $\sigma(\cdot)$  denotes the nonlinear activation function, which is crucial for enabling the network to model complex patterns. The weight matrix  $W(h)$  and the bias vector  $b(h)$  pertain to the  $h$ -th hidden layer respectively [11].

The output of the neural network, denoted as  $u$  (i.e., *beam's deflection*), is derived from the last hidden layer's output through the Equation (2):

$$u = W(H+1)f(H) + b(H+1) \quad (2)$$

In this formulation,  $W(H+1)$  and  $b(H+1)$  represent the weight matrix and bias vector of the output layer, respectively. The entire set of parameters within the network, which includes all the weights and biases for each layer, is collectively denoted by  $\theta$  as listed in Equation (3):

$$\theta = \{W(1), b(1), \dots, W(H), b(H), W(H+1), b(H+1)\} \quad (3)$$

This parameter set  $\theta$  encapsulates all elements necessary for the neural network's function, facilitating a unified approach to training and adjustment during the learning process.

The structure of this neural network combines linear operations and nonlinear activation functions. Utilising

activation functions that are infinitely differentiable, such as hyperbolic functions, the architecture enables the calculation of derivatives of any order for the output relative to the input of the neural network via automatic differentiation [4], [5]. These derivatives are instrumental in incorporating basic physical principles into the loss functions used in PINNs.

### 2.2 Framework of PINNs for inverse problems

PINNs presents an approach for addressing forward and inverse problems in partial differential equations (PDEs) across various systems [4]. A typical inverse problem for a simple beam (girder) subjected to a moving can be described by the following formulation:

1. Governing Equation: The Bernoulli-Euler beam theory [12] is widely used to describe beam behaviour under bending. This theory neglects shear deformation and rotational effects [13], which are typically minor in mostly bending conditions. Previous studies [14], [15] have numerically modelled bridges using this theory, focusing on moving loads that simulate vehicular traffic. Therefore, this paper briefly presents only the essential PDE needed for developing PINNs.

For a linearly elastic beam, the vertical deflection,  $u(x, t)$  along the  $z$ -direction satisfies the PDE shown in Equation (4) [14], [16]:

$$EI \frac{\partial^4 u(x, t)}{\partial x^4} + \mu \frac{\partial^2 u(x, t)}{\partial t^2} = P \delta(x - vt) \quad (4)$$

Where:  $\frac{\partial^4 u(x, t)}{\partial x^4}$  is the beam's curvature under bending,  $EI$  is the flexural rigidity,  $\frac{\partial^2 u(x, t)}{\partial t^2}$  represents beam acceleration due to vibration,  $\mu$  is the constant mass per unit length,  $P$  is the moving load magnitude,  $v$  is the load's constant speed,  $\delta$  is the Dirac delta function modelling the instantaneous position of the moving load.

This paper employs a Gaussian-based approach to approximate the Dirac delta function, leveraging its smoothness and regularity [17]. The approximation is defined by Equation (5):

$$P \delta(x - vt) \approx \frac{1}{\beta \sqrt{\pi}} e^{-\frac{(x-vt)^2}{\beta^2}} \quad \text{as } \beta \rightarrow 0 \quad (5)$$

Where  $\beta$  the regularisation parameter governs the approximation's smoothness and accuracy. The  $vt$  term specifies the vehicle's position as the product of speed and time since it entered the structure.

2. Initial (IC) and Boundary (BC) conditions: The beam is assumed to be at rest initially. This is given in mathematical form in Equations (6) and (7). Equation (6) indicates that vertical deflection  $u(x, t)$  is zero along the whole length of the beam at  $T = 0$ , while Equation (7) indicates the beam is perfectly still, experiencing no vibration, at  $T = 0$  [14], [16].

$$u(x, t) = 0 \text{ for } x \in [0, L], \quad T = 0 \quad (6)$$

$$\frac{\partial u}{\partial t}(x, t) = 0 \text{ for } x \in [0, L], \quad T = 0 \quad (7)$$

For a simple beam supports at its two ends. The beam cannot move vertically but is free to rotate about y-axis at these locations, namely at  $x = 0$  and  $x = L$ . The latter necessitates that the corresponding force quantity - the bending moment, which is directly proportional to the beam curvature and computed as the second derivative of  $u(x, t)$ , must always be zero at  $x = 0$  and  $x = L$ . Equations (8), and (9) mathematically represent these boundary conditions.

$$u(0, t) = 0, \text{ and } u(L, t) = 0, \text{ for } t \in [0, T] \quad (8)$$

$$\frac{\partial^2 u}{\partial x^2}(0, t) = 0, \text{ and } \frac{\partial^2 u}{\partial x^2}(L, t) = 0, \text{ for } t \in [0, T] \quad (9)$$

3. Loss function: In this study, we develop PINNs to predict structural parameters and internal forces—such as deflection and moment—in a bridge girder under a moving load of known magnitude and constant speed. Unlike traditional neural networks, which minimise the mean squared error (MSE) using training data, PINNs incorporate additional loss terms to enforce the governing partial differential equation (PDE), initial conditions, and boundary conditions, ensuring physically consistent predictions [18]. Accordingly, let us assume that  $\gamma$  represents parameters related to the physics of the system—some or all of which may be unknown and must be estimated in inverse problems. To achieve this, PINNs are trained to minimise a composite loss function ( $\mathcal{L}$ ), which can be expressed as in Equation (10).

$$\mathcal{L}(\theta) = \alpha_f \mathcal{L}_f(\theta) + \alpha_i \mathcal{L}_i(\theta) + \alpha_b \mathcal{L}_b(\theta) + \alpha_d \mathcal{L}_d(\theta) \quad (10)$$

Where  $\Theta = \{\theta, \gamma\}$ , with  $\theta$  as neural network parameters defined in Equation (3) and  $\gamma$  as unknown physical parameters to be estimated (EI, flexural rigidity),  $\mathcal{L}_f$  for the PDE,  $\mathcal{L}_i$  for the initial conditions,  $\mathcal{L}_b$  for the boundary conditions, and  $\mathcal{L}_d$  for the measured data. Each term is scaled by a corresponding weight— $\alpha_f$ ,  $\alpha_i$ ,  $\alpha_b$ , and  $\alpha_d$ . With prediction of PINNs,  $u(x, t; \theta)$ , the individual loss terms are expressed by Equations (11-15):

$$\mathcal{L}_f(\theta) = \frac{1}{N_f} \sum_{i=1}^{N_f} \|F[g(x_i, t_i; \theta); \gamma]\|^2 \quad (11)$$

$$g(x_i, t_i; \theta) = EI \frac{\partial^4 u(x_i, t_i; \theta)}{\partial x^4} + \mu \frac{\partial^2 u(x_i, t_i; \theta)}{\partial t^2} - P \delta(x_i - vt_i) \quad (12)$$

$$\mathcal{L}_i(\theta) = \frac{1}{N_i} \sum_{i=1}^{N_i} \left\| u(x_i, t_i; \theta) + \frac{\partial u(x_i, t_i; \theta)}{\partial t} \right\|^2 \quad (13)$$

$$\mathcal{L}_b(\theta) = \frac{1}{N_b} \sum_{i=1}^{N_b} \left\| u(x_i, t_i; \theta) + \frac{\partial^2 u(x_i, t_i; \theta)}{\partial x^2} \right\|^2 \quad (14)$$

$$\mathcal{L}_d(\theta) = \frac{1}{N_d} \sum_{i=1}^{N_d} \|D(x_i, t_i; \theta) - u(x_i, t_i; \theta)\|^2 \quad (15)$$

Where  $N_f, N_i, N_b$ , and  $N_d$  are the number of data points (collocation points) in training datasets:

- PDE residual:  $\{(x_i, t_i) : 0 \leq i \leq N_f, 0 \leq x_i \leq L, 0 \leq t_i \leq T\}$
- Initial condition:  $\{(x_i, 0) : 0 \leq i \leq N_i, 0 \leq x_i \leq L\}$ ,
- Boundary condition:  $\{(0, t_i) \text{ and } (L, t_i) : 0 \leq i \leq 2N_b, 0 \leq t_i \leq T\}$ , and
- Data points:  $\{(x_i, t_i) : 0 \leq i \leq N_d, 0 \leq x_i \leq L, 0 \leq t_i \leq T\}$ , respectively.

The minimiser of  $\mathcal{L}(\theta)$  can be expressed by Equation (16):

$$\theta^* = \arg \min_{\theta} \mathcal{L}(\theta) \quad (16)$$

where  $\Theta^* = \{\theta^*, \gamma^*\}$  with  $\theta^*$  and  $\gamma^*$  being the optimal parameters and the estimated unknown parameters, respectively, and  $\arg \min(\cdot)$  is the arguments of the minimum.

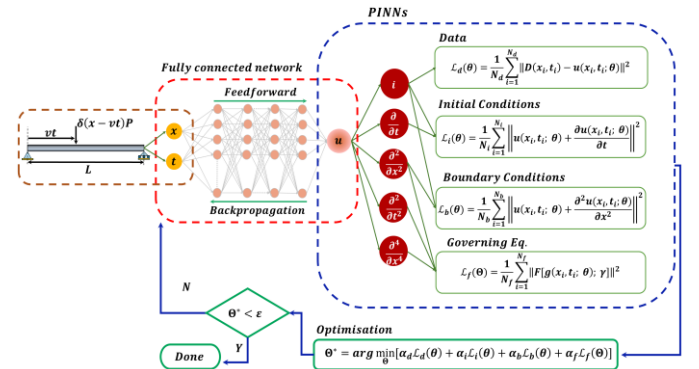

Figure 1. Physics-informed neural networks (PINNs) Schematic for an inverse problem of a beam with moving loads.

### 2.3 Training of PINNs

Figure 1 presents a schematic overview of the PINNs framework configuration. The setup consists of a fully connected feed-forward neural network (NN) that takes spatial and temporal inputs ( $x, t$ ) to predict the solution  $u(x, t)$ —representing the expected deflection at a given location and time on the bridge's girder—and to estimate unknown physical structural parameters ( $\gamma$ ). The training process is guided by the composite loss function defined in Equation (10) and optimised as shown in Equation (16). The training of the PINN is guided by the combined loss function given in Equation (10) and optimised as showed in Equation (16). Training the PINNs involves careful tuning of various hyperparameters, including the number of hidden layers, the number of neurons per layer, the choice of activation functions, the number of collocation points in the training dataset, optimiser configurations, and loss weighting factors.

Table 1 provides a summary of these hyperparameters, detailing their respective ranges and final selected values. The NN architecture, comprising five hidden layers and 64 neurons per layer, was chosen after testing various configurations. The Tanh activation function was selected due to its non-linear characteristics, outperforming others such as ReLU, SiLU, and Sigmoid. The collocation points, set at 2500 for the PDE, 2000

for the boundary conditions, and 1000 for the initial conditions, provide a balance between computational efficiency and the resolution needed to accurately enforce the underlying physics. Adam optimiser was employed for its reliable convergence characteristics, and the learning rate was scheduled to decrease quadratically with epochs, starting from an initial value of  $10^{-2}$ . Additionally, an adaptive loss-weighting strategy was used to balance the various terms, scaling each component relative to the smallest observed loss. Furthermore, the number of training iterations (epochs) was chosen to be 60,000, from a tested range of 10,000–100,000, to achieve robust convergence and accurate results.

The code presented in Table 2 is written in Python [19] and leverages PyTorch [20], a robust deep learning library. The PINNs in this implementation employ the 32-bit single-precision floating-point (FP32) format, which serves as PyTorch's default precision. The training process takes place on a computer system featuring an NVIDIA RTX A4000 GPU and an Intel Core i9-14900K processor.

Table 1. Hyperparameters for PINNs: Tuning ranges and selected values.

Hyperparameter	Range	Chosen Value
No. of Layers	3-9	5
No. of Neurons	32-186	64
Activation function	ReLU, SiLU, Sigmoid, Tanh	Tanh
Collocation points	PDE: 1500-3000	2500
	BC: 1200-2400	2000
	IC: 600-1200	1000
Optimiser	SGD, Adam, L-BFGS-B, Adagrad	Adam
Optimiser Learning rate	Decays quadratically over epochs, based on the following scheduler: $\varphi_0 = 10^{-2}, \varphi_1 = 0.70\varphi_0$ $\varphi_i = \left(1 - \left(\frac{i}{N}\right)^2\right)\varphi_0 + \left(\frac{i}{N}\right)^2\varphi_1, \quad i = 0, \dots, N$ N being the number of epochs.	
loss weighting factors	An adaptive weighting strategy is used [18]: $\alpha_f = \frac{\mathcal{L}_f}{\mathcal{L}_{min}}, \alpha_i = \frac{\mathcal{L}_i}{\mathcal{L}_{min}}, \alpha_b = \frac{\mathcal{L}_b}{\mathcal{L}_{min}}, \alpha_d = \frac{\mathcal{L}_d}{\mathcal{L}_{min}}$ $\mathcal{L}_{min}$ is the minimum among $\mathcal{L}_f, \mathcal{L}_i, \mathcal{L}_b, \mathcal{L}_d$	
Iterations (Epochs)	10,000-100,000	60,000

### 3 CASE STUDIES

The Bascule Bridge in Exeter, as shown in Figure 2, is investigated in this study. The bridge features a 17.28-metre simply supported lifting span, a 6.7-metre-wide carriageway, and a 2-metre-wide footway along the parapet. Its structural configuration includes two longitudinal girders, 17 cross beams, and a composite aluminium deck. This research focuses on the east girder, where sensors measure vertical stiffness. Since the girders are pinned at both ends, each can be approximated as a simply supported beam. The cross beams, bolted to the vertical web stiffeners, primarily transfer shear forces and provide lateral resistance, contributing little to the girders' vertical stiffness. Parameters in Equation (4), outlined in Table 3, are

based on section properties derived from structural drawings supplied by Exeter City Council, Devon, UK, as described in [21].

Table 2. PINNs Pseudo-code for the identification of structural parameters in a beam under moving loads.

#### Algorithm

**Input:** Spatial and temporal collocation points and measured data  $(x_i, t_i)$ .

**Output:** Optimal parameters  $\theta^*$  and estimated unknown parameters  $\gamma^*$ :  $\theta^* = \{\theta^*, \gamma^*\}$ .

#### Initialisation:

- 1: Initialise neural network architecture parameters  $\theta$
- 2: Generate random dataset for  $N_f, N_i$  and  $N_b$
- 3: Prepare the measured data points  $N_d$
- 4: Define the total loss functions:  $\mathcal{L}(\theta) = \alpha_f \mathcal{L}_f(\theta) + \alpha_i \mathcal{L}_i(\theta) + \alpha_b \mathcal{L}_b(\theta) + \alpha_d \mathcal{L}_d(\theta)$
- 5: Initialise the loss weights:  $\alpha_f, \alpha_i, \alpha_b, \alpha_d$
- 6: Initialise the structural parameters  $\gamma$

#### Training:

- 7: Set the optimiser: Adam.
- 8: Set  $N$ : Define the maximum number of training iterations
- 9: **WHILE** converge not reached **DO**
- 9.1: **FOR**  $k = 1$  to  $N$  **DO**
- 9.2: **FOR** each batch of points in  $N_f, N_i, N_b, N_d$  **DO**
- 9.3: Compute loss function:
  - $\mathcal{L}_f(\theta)$ : PDE residual at  $N_f$
  - $\mathcal{L}_i(\theta)$ : Initial condition at  $N_i$
  - $\mathcal{L}_b(\theta)$ : Boundary condition at  $N_b$
  - $\mathcal{L}_d(\theta)$ : Measured data mismatch at  $N_d$
- 9.4: Update loss function weights  $\alpha_f, \alpha_i, \alpha_b, \alpha_d$
- 9.5: **END FOR**
- 9.6: Compute the total loss  $\mathcal{L}(\theta)$
- 9.7: Update parameters  $\theta = \{\theta, \gamma\}$  using Adam optimiser based on the gradient of  $\mathcal{L}(\theta)$
- 9.10: **END FOR**
- 9.11: **END WHILE**
- 10: Save the trained model: Store the optimised parameters  $\theta^* = \{\theta^*, \gamma^*\}$
- 11: Deploy the model: Use the trained PINNs to predict the structural response.

Table 3. Dimensions and properties of the Bascule bridge main girder (symmetrical I-section).

Dimensions	Value	Properties	Value
Length	17.28 m	Elastic Modulus (E1)	205 GPa
Depth	926.60 mm	Moment inertia (I)	$50.40 \times 10^8 \text{ mm}^4$
Flange width	307.70 mm	Mass per unit length ( $\mu$ )	289 kg/m
Flange thickness	32 mm		
Web thickness	19.50 mm		

Figure 2. Bascule bridge, constructed in 1972, carrying the A379 over the Exeter Canal in Devon, England, UK.

### 3.1 Case Study 1

In this case study, PINNs are trained to model the effects of a 37 kN axle load, representing the front axle of a truck. This axle load magnitude corresponds to those used in a controlled loading test previously conducted on the Bascule Bridge, as detailed in [22]. The truck's total load consisted of front axles weighing 67.20 kN and rear axles weighing 89.80 kN each. Axle spacing was 2.00 metres between the first and second axles, 3.10 metres between the second and third, and 1.40 metres between the third and fourth. During the test, the truck crossed the bridge in 3.342 seconds, travelling in the lane closest to the east girder, which was estimated to bear approximately 55% of the total load. For the time configuration, the front axle is estimated to take a total of 2.43 seconds to cross the bridge. This timing reflects the sequence and delay with which each of the four axles engages with the bridge as observed during the field tests. Based on these observations, the first front axle enters the bridge at  $t = 0$ , and the fourth rear axle exits at  $t = 3.342$  seconds. The truck's speed is calculated using the span length of the bridge (17.28 m), the distance between the first and fourth axles (6.50 m), and the total crossing time of 3.342 seconds. This yields a vehicle speed of 7.115 m/s. Using this speed and the known axle spacings, the times at which the first front axle entered and exited the bridge are determined.

### 3.2 Synthetic data under varying signal-to-noise ratios

In this case study, the objective is to estimate the bridge's main girder flexural stiffness (EI), deflection, and its derivatives. This requires generating training data for the PINN model, as described in Section 2. To achieve this, we developed a finite element (FE) model comprising 10 beam elements in ANSYS APDL [23]. The model was solved using a transient analysis with 1,000-time steps, providing the synthetic data needed for training. A total of 100 points were randomly selected across the spatial and temporal domains to represent the deflection solution. However, SHM data often contain noise due to environmental and operational factors, such as temperature fluctuations, variable live loads, and sensor inaccuracies. To reflect these real-world conditions, we introduced white Gaussian noise into the simulated data. Incorporating this noise increases the fidelity of the synthetic data, making it more representative of the challenges encountered in real-world SHM

data analysis. In addition to estimating the girder's stiffness and deflection, another objective of this study was to assess the adaptability and performance of PINNs when trained with and without noise.

Various noise levels are evaluated by considering different signal-to-noise ratios (SNRs). White Gaussian noise is added to the deflection data generated by the finite element (FE) model, as defined by Equation (17):

$$u_{noise} = u + \mathcal{N}(0, \sigma^2) \quad (17)$$

Where  $u$  is the true deflection predicted by the FE model, and  $\mathcal{N}(0, \sigma^2)$  represents white Gaussian noise with a mean of zero and a standard deviation  $\sigma$  determined by the target SNR. The SNR in decibels (dB), is given by Equation (18):

$$SNR(dB) = 10 \log_{10} \left( \frac{\text{Signal Power}}{\text{Noise Power}} \right) \quad (18)$$

In this study, four SNR levels—10, 20, 30, and 40 dB—are considered and are illustrated in Figure 3. A lower SNR, such as 10 dB, indicates significant noise levels, making the prediction task more challenging. In contrast, a higher SNR, like 40 dB, suggests that noise has only a minor effect.

Figure 3. Influence of signal-to-noise ratio (SNR) on deflection data quality.

### 3.3 Results and discussion of Case Study 1

The results presented in Tables 4 and 5 highlight the performance of the PINNs in predicting the flexural rigidity (EI) and internal forces (deflection and moment) of a Bascule bridge girder under various signal-to-noise ratio (SNR) conditions. The analysis assesses prediction accuracy using relative error percentages (Re%) for EI, as well as Root Mean Square Error (RMSE), Coefficient of Variation (CV%), and Normalised Mean Bias (NMB%) metrics for deflection ( $u$ ) and moment ( $M_x$ ) at different time instances. Table 4 indicates that PINNs can provide accurate estimates of EI even in noisy conditions. When using clean data, the relative error is only 0.24%. As noise increases, the error rises slightly, reaching 0.96% at 10dB. However, the PINNs still demonstrate strong robustness, with errors staying below 1% even under the lowest SNR conditions. For higher SNR levels, such as 30dB and 40dB, the errors drop

to 0.34% and 0.29%, respectively. This trend confirms that the PINNs can effectively handle varying noise levels, maintaining a high degree of accuracy in estimating the bridge girder's flexural rigidity.

Table 5 examines deflection and moment predictions at different time instances under varying SNR conditions. As expected, lower SNR values lead to higher RMSE, CV, and NMB percentages, reflecting the impact of noise on prediction accuracy. For instance, at 10dB, deflection RMSE ranges from 0.161 mm to 0.178 mm, and CV percentages are as high as 8.26%. In contrast, under a better condition (30dB and 40dB), these values are significantly reduced, with RMSE as low as 0.036 mm and CV percentages dropping to around 1.45%–2.05%. The moment prediction metrics follow a similar pattern, showing that as SNR improves, RMSE and CV percentages consistently decrease. The results of this case study demonstrate that PINNs can accurately predict both flexural rigidity and internal forces in a bridge girder, showing robustness against noise and the potential for practical application in SHM tasks.

Furthermore, Figure 4 illustrates the ability of the PINN trained with data of 40 dB SNR to accurately predict both the beam's deflection and its internal forces, including moments. The data presented in the figure corresponds to a specific time instance,  $t = 1.22$  seconds. Although this example focuses on a single time point for demonstration purposes, the PINN methodology can similarly generate deflection and its derivatives at any chosen moment.

The results displayed in the figure highlight an agreement between the PINN predictions and the FE results. The PINN accurately reproduces the deflection and moment profiles along the beam, aligning closely with the established FE data. This consistent match provides further validation of the PINN's reliability and effectiveness.

Table 4. PINNs predictions of flexural rigidity (EI) for a Bascule bridge girder across varying SNR.

SNR	EI Actual (N.m <sup>2</sup> )	EI predicted (N.m <sup>2</sup> )	Re%
Clean	1,033,610	1,036,091	0.24
10dB	===	1,043,533	0.96
20dB	===	1,041,879	0.80
30dB	===	1,037,124	0.34
40dB	===	1,036,607	0.29

### 3.4 Case Study 2

In this case study, a PINN model is used to predict the flexural rigidity and structural behaviour of a girder, informed by strain measurements from sensors installed on the bridge's main girder during a truck crossing. The objective is twofold: to examine the PINN's ability to represent real-world structural behaviour and to assess how measurement data influences its accuracy and generalisation. Four weldable strain gauges were installed, two on the top flange (S1 and S2) and two on the bottom flange (S3 and S4), to measure bending strains along the girder's longitudinal axis as shown in Figure 5. These sensors, featuring a 5.84 mm active grid length and a resistance of 120  $\Omega$ , were deployed and documented as detailed in [12]. The strain data were collected at 2000 Hz, then baseline-adjusted and smoothed. Figure 6 illustrates the strain time histories

recorded by sensors S1 to S4, confirming that the truck took approximately 3.342 seconds to cross, consistent with Case Study 1.[22].

Table 5. PINNs predictions metric errors of deflection and moment for a Bascule bridge girder across varying SNR and different time instances.

SNR	Time (Sec)	Deflection (u)			Moment (Mx)		
		RMSE (mm)	CV %	NBM %	RMSE (kN.m)	CV %	NBM %

(a) Beam deflection ( $u$ , mm)

(b) Moment distribution ( $M_x$ , kN.m)

Figure 4: Case Study 1 – comparing PINNs predictions to finite element (FE) results: (a) beam deflection and (b) moment distribution at  $t = 1.22$  seconds.

Unlike Case Study 1, which trained the PINN on a single axle load, this case study models the effect of the entire truck. The truck is represented as four axle loads, spaced at known intervals. The combined load function is approximated as a sum of Dirac delta functions,  $\delta_j$ , which are expressed in Equations (19) and (20). The load ( $P$ ) due to all axles is formulated as:

$$P = \sum_{j=1}^4 p_j \cdot \delta_j(t_j, v, L) \quad (19)$$

Where  $\delta_j(t_j, v, L)$  is defined as:

$$\delta_j(t_j, v, L) = \frac{1}{\beta\sqrt{\pi}} e^{-\frac{(x-v(t-t_j))^2}{\beta^2}} \quad (20)$$

The parameters are:  $L$ , the beam length;  $v$ , the vehicle speed;  $p_j$ , the load for the  $j$ -th axle;  $\beta$ , the regularisation parameter of the Gaussian approximation for  $\delta_j$ ; and  $t_j$ , the time lag for the  $j$ -th axle relative to the first. Incorporating this Dirac delta approximation into the governing PDE yields Equation (21):

$$EI \frac{\partial^4 u(x, t)}{\partial x^4} + \mu \frac{\partial^2 u(x, t)}{\partial t^2} = \sum_{j=1}^4 p_j \cdot \delta_j(t_j, v, L) \quad (21)$$

In addition, the PINN training process includes a data loss term,  $\mathcal{L}_D$  as defined in Equation (15), which quantifies the discrepancy between sensor measurements and the PINN's predicted strains. The strain  $\varepsilon$  is linked to the beam's curvature  $\frac{d^2 u(x, t)}{dx^2}$ , as shown in Equation (22):

$$\varepsilon = -y \frac{d^2 u(x, t)}{dx^2} \quad (22)$$

Here,  $y$  is the distance from the neutral axis. This relationship allows  $\mathcal{L}_D$  to be computed by comparing measured and predicted strains. The formulation of  $\mathcal{L}_D$  is given in Equation (23):

$$\mathcal{L}_D(\theta) = \frac{1}{N_d} \sum_{i=1}^{N_d} \left\| -y \frac{d^2 u(x_i, t_i; \theta)}{dx^2} - \varepsilon(x_i, t_i; \theta) \right\|^2 \quad (23)$$

$\mathcal{L}_D$  is then incorporated into the overall loss function (Equation 10) to guide the PINN's training and improve its alignment with the observed data.

Figure 6. Raw strain measurements from sensors S1 to S4 on the main girder of a bascule bridge as a truck crossed.

### 3.5 Results and discussion of Case Study 2

The results presented in Table 6 highlight the impact of incorporating real-world strain measurements on the accuracy of PINN predictions for the bridge girder's flexural rigidity (EI). When trained without sensor data, the PINN predicted an EI value that deviated from the actual parameter by over 14%, underscoring the limitations of relying solely on physics-informed constraints. In contrast, the inclusion of strain data from only one sensor S2 reduced the relative error to approximately 1.6%, demonstrating a substantial improvement in predictive performance. This outcome suggests that integrating field measurements enables the PINN to capture the structural behaviour more effectively, enhancing its generalisation and reliability. The ability of PINNs to leverage sparse sensor data offers advantages for SHM applications, providing engineers with more precise estimates of key structural parameters. Additionally, Figure 7 demonstrates the predictive efficacy of the PINN trained with measured data. The model was trained utilising strain data from sensor S2, with the sensor's location and strain time profile shown in Figures 5 and 6, respectively. The displayed results indicate the model's prediction at the position of sensor S4. Accordingly, the results underline the potential for PINNs, when combined with real-world data, to serve as robust tools for both assessing current structural performance.

Table 6. PINN predictions of flexural rigidity (EI) for a Bascule bridge girder with and without sensor Data.

Strain data	EI Actual (N.m <sup>2</sup> )	EI predicted (N.m <sup>2</sup> )	Re%
No	1,033,610	1,178,315	14.16
Yes	===	1,050,458	1.63

#### 4 CONCLUSIONS

This study demonstrates the application of a physics-informed neural network (PINN) framework to accurately predict both structural parameters — flexural rigidity (EI) — and structural responses (e.g., deflections and moments) of a bridge girder under a moving load. The investigation is based on two case studies that evaluate the PINN's performance, accuracy, and generalisability, offering valuable insights into its practical application for SHM. In Case Study 1, the PINN was trained under varying levels of synthetic noise to assess its robustness. In Case Study 2, the PINN's ability to integrate real-world strain measurements was explored. Using field measurements, the model achieved significant improvement in prediction accuracy.

The following points summarise the key outcomes from this study:

1. The PINN maintained reasonable accuracy even at low signal-to-noise ratios (SNRs), with predictions becoming increasingly reliable as noise levels decreased. The study revealed that at higher SNRs, the PINN effectively captured the bridge's flexural rigidity, achieving relative errors below 1% and confirming its capacity for precise parameter estimation.
2. In Case Study 2, the PINN trained without sensor data overestimated the girder's flexural rigidity. Incorporating field measurements reduced the relative error from 14% to approximately 1.6%. This demonstrates the value of integrating field data into the PINN framework, enabling more accurate reflection of real-world structural behaviour.
3. The study showed that even a limited number of strain sensors could provide sufficient constraints to enhance the PINN's generalisation and performance, reinforcing its practical utility.
4. The findings show that integrating field measurements not only enhances the accuracy of the flexural rigidity estimation but also allows the model to reflect actual structural behaviour. This demonstrates the PINNs' potential as a practical tool for SHM.

Overall, this research illustrates a novel application of PINNs and contributes to the existing body of knowledge in structural

health monitoring (SHM) by introducing a PINN-based approach for estimating the structural parameters of bridge girders. Future work will focus on extending the use of PINNs to damage detection scenarios and integrating multiple PINNs to model more complex structural systems comprising assemblies of discrete elements.

**ABSTRACT:** The inspection, maintenance and monitoring of existing infrastructure are critical aspects for ensuring a proper structural performance during their lifespan, also guaranteeing their capacity vs. the ultimate limit state. The use of structural health monitoring systems has become increasingly important for managing infrastructural assets, not only to detect structural damages and degradation phenomena but also to evaluate the performance of structures subjected to retrofit interventions. This is achieved using signal processing techniques that integrate statistical methods and machine learning algorithms within the framework of statistical pattern recognition. The proposed framework introduces a novel statistical analysis framework aimed at characterizing the *normal* behaviour of structures, detecting potential damage development. The method is applied to a suspended steel truss healthcare facility, demonstrating its effectiveness in characterizing its typical structural behaviour, detecting any onset of possible structural decay. While the method is demonstrated on a specific case study, it is designed to be adaptable to a wide range of structural systems. The ultimate objective is to develop a reliable analysis tool for the early detection of damage, thereby enhancing the efficiency of maintenance strategies and ensuring long-term structural safety.

**KEY WORDS:** Structural health monitoring, statistical pattern recognition, damage detection, data analysis.

## 1 INTRODUCTION

Infrastructure systems play a crucial role in modern society, making it essential to ensure their functionality under both normal and extraordinary loading conditions. Maintenance, inspections, and structural monitoring are fundamental for preserving resilience [1]. In recent decades, traditional inspection systems have been increasingly replaced by structural health monitoring (SHM) systems, particularly for structures that are highly exposed to atmospheric actions and external loads, such as bridges and wind turbines [2], but also for historical buildings [3], [4]. SHM has been introduced to support owners and authorities to find optimal life-cycle management solutions and, ultimately, to prevent structural failures. This is achieved through a damage identification strategy, which encompasses the detection, diagnosis, and prognosis of damage [5].

These systems rely on the implementation of a monitoring-based strategy, which includes real-time measurement of structural responses and data analysis to identify anomalies and/or damage at an early stage [6]. In this context, damage is defined as any alteration in the material and/or geometric properties of bridge components that negatively affect the bridge's current or future service performance and safety [5]. Another significant application of SHM systems involves the assessment of retrofit interventions on existing structures. Specifically, SHM can be used to determine the most suitable intervention strategy, evaluate the structural response after the intervention, and monitor the structure's behaviour throughout the different phases of the intervention [7], [8].

This study proposes a robust framework for processing SHM data from existing infrastructure, with the goal of enabling early detection of structural anomalies or damage. The

proposed methodology combines time series modelling using statistical algorithms for the characterization of normal structural behaviour, filtering out environmental influences—such as temperature—and identifying deviations indicative of potential structural issues.

The manuscript is structured as follows: Section 2 describes the case study and presents the initial analyses conducted on the structure; Section 3 introduces the SHM data and provides preliminary evaluations; Section 4 details the proposed data analysis framework and its application to the case study; finally, Section 5 presents the conclusions and outlines directions for future research.

## 2 DESCRIPTION OF THE CASE STUDY

The analysed structure is a suspended steel truss that serves as the roof of a strategic infrastructure located in northern Italy. The building was completed in 2008. This structure is particularly complex because, as illustrated in Figure 1, the truss system supports the upper three floors through steel columns subjected to tensile stresses. The roof is directly connected to continuous concrete walls that extend from the foundations to the roof.

The building, and specifically its roof, underwent a retrofit intervention aimed at enhancing the strength of the connections within the roof structure. Following the retrofit process, the installation of a SHM system was defined with the objective of assessing the effectiveness of the strengthening interventions, monitoring the real time safety conditions of the structure, and supporting infrastructure owners in identifying optimal life-cycle management solutions.

Figure 1. Schematic representation of the structure

### 2.1 Operational modal analysis of the case study

Before the design of the SHM system an operational modal analysis (OMA) was performed with the aim of identify dynamic parameters of the steel truss structure and better understand the complex behaviour of the entire steel structure. This type of analysis is commonly performed on various types of structures like bridges [9], historical buildings [10], and timber structures [11].

The OMA was performed by installing eight piezoelectric monoaxial accelerometers in different positions and configurations on the roof, resulting in a total of 33 measurement locations. The results of the modal identification are presented in Figure 2.

Figure 2. First mode shapes of the structure

These results indicate that the longitudinal and transverse modes exhibit a behaviour involving the overall structure, whereas vertical modes are related to individual truss elements, without demonstrating a global structural response. Table 1 presents the modal frequencies and the corresponding complexity of the mode shapes obtained from the OMA analysis. The analysis was conducted using the frequency domain decomposition method with Artemis Modal Pro software.

Table 1. Principal vibration frequencies

Mode type	Frequency [Hz]	Complexity [%]
1 <sup>st</sup> Longitudinal	1.66	0.899
1 <sup>st</sup> Transversal	1,953	1,741
2 <sup>nd</sup> Transversal	2,539	5,886
1 <sup>st</sup> Vertical	5,078	18,075
2 <sup>nd</sup> Vertical	16.992	6.052
3 <sup>rd</sup> Vertical	17.969	19.657

### 2.2 Description of the monitoring system

The SHM system was installed in 2021 to monitor both static and dynamic parameters, enabling the acquisition of the structure's modal characteristics and the evaluation of stress in the most heavily loaded elements of the truss roof. Additionally, thermocouples and ambient temperature sensors were implemented to assess the environmental conditions of the site, as temperature is one of the primary sources of variability in structural systems [12]. The setup for the analysis of vibration characteristics was based on the results of the OMA analysis reported in section 2.1. In this context, 11 uniaxial piezoelectric accelerometers were installed on the steel truss elements.

Ambient temperature sensors were installed in two different locations to assess variations in ambient temperature and humidity within the roof structure. Additionally, a wind sensor was used to investigate potential interactions between this external load and the structural behaviour of the building.

The data acquisition system selected for the monitoring system is structured around a primary acquisition unit (master), which is connected to the infrastructure's LAN for remote data transmission. This master unit is linked to two subordinate units (slaves) via a backbone running along the extrados of the roof, which, in turn, are connected to both static and dynamic sensors. Figure 3 shows the configuration of the SHM system implemented for the case study.

The evaluation of stresses was conducted through the installation of 24 vibrating wire strain gauges on the truss elements, equipped with an internal temperature sensor, complemented by 4 steel thermocouples to assess the influence of temperature on the steel elements. Both types of sensors were welded onto the steel elements of the roof structure, as shown in the configuration presented in Figure 4. A relevant

number of sensors was installed on the vertical steel elements connecting the lower floors to the roof, as these components are critical to the floor stability.

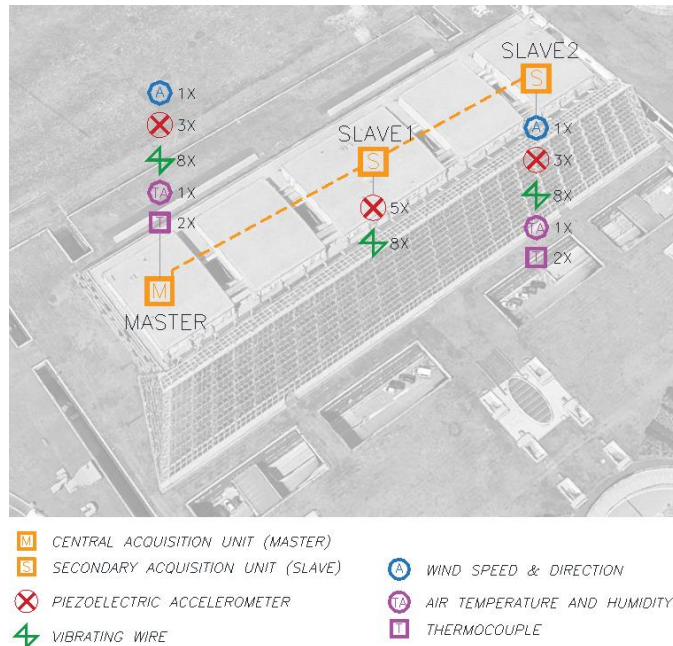

Figure 3. Configuration of the SHM system

Figure 4. Typological configuration of vibrating wire strain gauges and thermocouple sensors in the truss structure

### 3 ANALYSIS OF THE MONITORED DATA

In this paper, only the data related to the static sensors are presented, with a particular focus on the analysis of strain sensor measurements.

Figure 5 illustrates the strain behaviour over a three-year period for five sensors. In some of that, such as VW.01 and VW.03, strain variations closely follow seasonal temperature fluctuations. Conversely, in other cases, such as VW.02, the strain behaviour appears independent of temperature variations.

This observation is further emphasized by analysing the correlation between strain sensor data and temperature variations. In Figure 6 the strain measurements are plotted against ambient temperature fluctuations to assess the extent to which thermal effects influence structural behaviour. This comparative analysis helps distinguish temperature-dependent responses from other potential factors affecting strain variations.

Figure 5. Strain sensors behaviour – block A

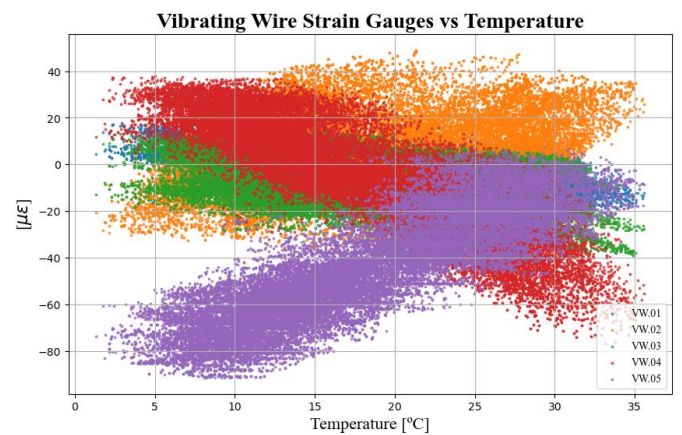

Figure 6. Representation of the strain observation against the temperature value

The behaviour of some sensors exhibits a linear correlation with temperature, whereas others do not show this dependence, as observed in the cases of VW.02 and VW.06. Noticeably, VW.02 appears to be completely uncorrelated with temperature; however, distinct patterns can still be identified. Specifically, its behaviour reflects a horizontal translation of an inclined line along the horizontal axis.

This pattern is influenced by temperature variations occurring during specific periods of the year. When analysing the behaviour of an individual sensor in relation to temperature, with measurements categorized by month (Figure 7), it becomes evident that each period of the year corresponds to a distinct structural state of the element. Furthermore, after one year, the sensor's behaviour tends to return to a state similar to that of the previous year, indicating a recurring annual trend.

After an on-site inspection, it was found that this behaviour was likely caused by friction grip bolted connections which, due to possible loss of preload, converted into standard shear connections. As a result, the structural elements exhibited a different behaviour compared to the expected response of roof elements subjected to daily and seasonal temperature variations. It emerged that some sensors exhibited a typical linear relationship with temperature variations, while others displayed a distinct behaviour characterized by multiple linear trends that were temperature dependent.

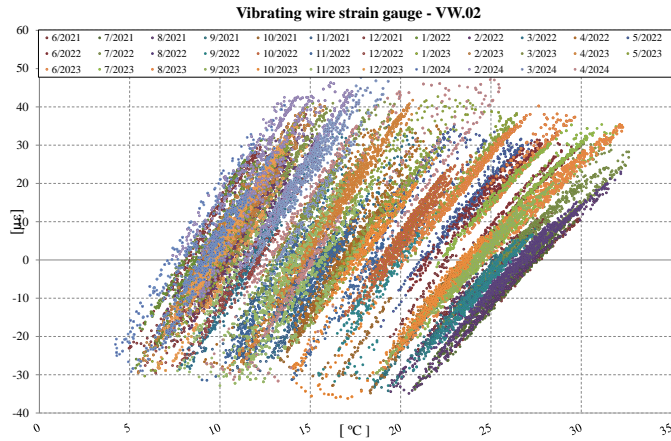

Figure 7. Representation of strain sensor respect to external temperature, divided by period

#### 4 STATISTICAL ANALYSIS OF THE STATIC SENSORS

The adopted methodology consists of several phases. First, a data-cleaning process is performed on the raw data and the entire timeseries was divided in three different groups: train dataset, covering two years, in which the statistical algorithm was trained; validation dataset, spanning in the next ten months, used to define the warning and the alarm boundaries for the control chart; and the test dataset consisting on thirty days, using to validate the entire statistical process. In this phase also an under sampling was performed and the median of each four hours was assumed like the values.

Then, for each sensor, a time series model is estimated to capture the natural variations in the data while accounting for daily and seasonal cycles. By employing this approach, the estimated model effectively represents the expected sensor behaviour under normal operating conditions. Additionally, the model enables the removal of the influence of steel temperature, from the signal.

The developed monitoring system is designed to track real-time prediction errors generated by each estimated model. Specifically, a control chart is implemented for each sensor, based on a statistical control metric and equipped with alert and alarm thresholds. The control chart triggers an alarm when deviations from the expected behaviour are detected. Furthermore, it is designed to differentiate between temporary anomalies and structural anomalies, as specified in the system requirements.

##### 4.1 Statistical model development

The forecasting methodology used in this study is based on the seasonal autoregressive integrated moving average with exogenous variables (SARIMAX) model. This class of autoregressive models is extensively applied in SHM to detect structural anomalies, particularly in time series data analysis for damage identification [5], [13]. By leveraging past observations and incorporating external influencing factors, SARIMAX models effectively characterize the expected behaviour of a system over time [14].

In this application, temperature readings from thermocouples served as exogenous inputs. The autoregressive (AR) components define the present response as a function of previous observations, while the moving average (MA)

components refine predictions by accounting for past errors. To enhance accuracy, the model also integrates seasonal components to capture periodic fluctuations occurring on both daily and annual scales. The generalized formulation of this model is expressed as:

$$\begin{aligned} (1-B)^d(1-B^S)^Dy_t &= \phi_1y_{t-1} + \phi_2y_{t-2} + \dots + \phi_p y_{t-p} \\ &+ \Phi_1y_{t-s} + \Phi_2y_{t-2s} + \dots \\ &+ \Phi_Py_{t-PS} + \theta_1\epsilon_{t-1} + \theta_2\epsilon_{t-2} \\ &+ \dots \theta_q\epsilon_{t-q} + \theta_1\epsilon_{t-s} + \theta_2\epsilon_{t-2s} \\ &+ \dots \theta_Q\epsilon_{t-Qs} + \epsilon_t + \beta X_t \end{aligned} \quad (1)$$

Where:

- B is the lag operator, such that:

$$\begin{aligned} (1-B)y_t &= y_t - y_{t-1} \\ (1-B^S)y_t &= y_t - y_{t-s} \end{aligned} \quad (2)$$

- $\phi_1, \dots, \phi_p$  are the autoregressive parameters.
- $\theta_1, \dots, \theta_q$  are the moving average parameters.
- $\Phi_1, \dots, \Phi_P$  are the seasonal autoregressive parameters.
- $\theta_1, \dots, \theta_Q$  are the seasonal moving average parameters.
- $\epsilon$  represents an error term, assumed to follow a Gaussian distribution.
- $X_t$  represents the temperature recorded by the temperature.

The selection of the model, including the determination of the parameters p, d, q, P, D, Q, as well as the subsequent estimation of model coefficients, was guided by the second-order Akaike information criterion. This criterion was employed to optimize model selection by balancing goodness-of-fit and complexity, ensuring an optimal trade-off between model accuracy and overfitting.

The results of the models for the sensor VW.01 are presented in Figure 8 where the entire time series was reported, and in Figure 9 where only the results for the test dataset is presented. The figures show the relatively low and uncorrelated behaviour of the residuals that's denotes the good behaviour of the algorithm for this type of analysis.

Figure 8. Representation of the results of the SARIMAX model for the entire time series for sensor VW.01

Figure 9. Representation of the SARIMAX model for the test dataset for sensor VW.01

In Table 2, different metrics are presented to compare the model's performance for the analysed sensors. The used metrics include root mean square error (RMSE), mean absolute error (MAE), median absolute error (MedAE), and the coefficient of determination ( $R^2$ ) for the test dataset residuals.

The model's performance demonstrates generally strong predictive capability, with high  $R^2$  values in most cases. A subset of three sensors exhibits optimal performance, characterized by minimal error metrics and an  $R^2$  of 0.99, indicating an excellent model fit. Another group of ten sensors shows good performance, with moderate error values yet maintaining high  $R^2$ , suggesting the model effectively captures underlying patterns. However, five sensors present higher error values, with some displaying lower  $R^2$ , particularly those with RMSE exceeding 2, which may indicate limitations in the model's predictive accuracy for these cases.

Table 2. Residuals metrics values

Sensor	RMSE	MAE	MedAE	$R^2$
VW.01	0.81	0.63	0.52	0.86
VW.02	0.94	0.69	0.55	0.99
VW.03	0.93	0.71	0.56	0.92
VW.04	1.35	0.98	0.73	0.94
VW.05	0.62	0.42	0.25	0.99
VW.06	0.60	0.38	0.25	0.99
VW.07	1.08	0.85	0.70	0.99
VW.08	1.17	0.83	0.61	0.99
VW.09	2.26	1.74	1.36	0.97
VW.10	2.68	1.95	1.41	0.77
VW.11	0.37	0.29	0.23	0.99
VW.12	1.08	0.78	0.51	0.95
VW.13	2.64	1.90	1.47	0.88
VW.14	2.02	1.48	1.08	0.93
VW.15	1.53	1.20	1.01	0.99
VW.16	1.03	0.75	0.61	0.99
VW.17	1.31	0.97	0.68	0.88
VW.18	1.25	0.95	0.74	0.80
VW.19	1.77	1.30	0.81	0.96
VW.20	0.69	0.52	0.40	0.99

## 4.2 Control chart development

For the monitoring phase, an adaptive exponentially weighted moving average (AEWMA) control chart is proposed [15], [16]. This type of control chart integrates exponential smoothing with an adaptive mechanism that allows for a faster response to significant changes. As a result, the control statistic is dynamic and adjusts based on observed variations.

The mathematical formulation of this adaptive statistic is given by:

$$S_i = S_{i-1} + \varphi(x_i - S_{i-1}) \quad (3)$$

Where  $\varphi$  is defined as:

$$\varphi(e) = \begin{cases} e + (1 - \lambda)k & \text{se } e < -k \\ \lambda e & \text{se } -k \leq e \leq k \\ e - (1 - \lambda)k & \text{se } e > k \end{cases} \quad (4)$$

The advantage of this generalization lies in its ability to enable the control statistic to respond more rapidly to abrupt and high-intensity deviations, specifically when  $|e| > k$ . In this case the values used for the analysis are  $\lambda = 0.1$  e  $k = 3$  [15].

By incorporating exponential smoothing, the AEWMA control chart is able to detect anomalies that develop gradually over time. However, its adaptive nature also allows for the identification of sudden, unexpected deviations.

This adaptability will later be leveraged to distinguish transient anomalies, which return to a normalized operational state within a short time frame. In essence, this type of control chart enables differentiation between structural anomalies, which persist over time, and transient anomalies, which resolve naturally after a brief period.

## 4.3 Definition of warning and alert boundaries

To determine the warning and alarm thresholds associated with the control statistic described in the equation (3), a statistical approach is employed based on the concept of mean time to false alarm. Specifically, the average run length ( $ARL_0$ ) represents the expected number of observations that occur before a false alarm is triggered.

The selection of alert thresholds is carried out by specifying a predefined  $ARL_0$  value. Once this value is established, the corresponding threshold can be determined using statistical simulation techniques.

In particular, the thresholds are computed to ensure compliance with the  $ARL_0$  criterion through the bisection method, as discussed in Qiu (2013) [17]. This approach ensures that the alarm system maintains a controlled balance between sensitivity and reliability.

## 4.4 Results of the analysis

In this section the results for the application of the AEWMA control chart for different sensors are shown. Figure 10 reports the results of the AEWMA control chart and the boundaries definition for the test dataset of the sensor VW.01. It shows a good behaviour that has value around zero, even if in the last part the behaviour of the control chart denotes a linear trend that is contained into the defined boundaries elsewhere.

Figure 10. Control chart for VW.01 test dataset

In Table 3 the boundaries for all the vibrating wire sensors are reported. It shows that the value of the boundaries is different one to each other and, clearly, the higher value is related to the timeseries that shows more difficulties for the model to fit the data and determine higher residuals value also in Table 2. But, caused by the limits were defined with the same  $ARL_o$ , we aspect that the resilience of the control chart is the same for all the sensors.

Table 3. Evaluation of the boundaries of each sensor

Sensor	RMSE	MAE	MedAE	R2
VW.01	0.607	1.156	0.607	1.156
VW.02	3.735	8.950	3.735	8.950
VW.03	1.258	2.729	1.258	2.729
VW.04	8.620	10.540	8.620	10.540
VW.05	0.878	6.292	0.878	6.292
VW.06	0.318	1.150	0.318	1.150
VW.07	4.264	5.465	4.264	5.465
VW.08	15.821	35.360	15.821	35.360
VW.09	5.335	7.336	5.335	7.336
VW.10	7.513	20.983	7.513	20.983
VW.11	0.372	0.542	0.372	0.542
VW.12	1.624	3.294	1.624	3.294
VW.13	11.633	16.041	11.633	16.041
VW.14	7.964	9.995	7.964	9.995
VW.15	6.237	8.872	6.237	8.872
VW.16	5.176	9.579	5.176	9.579
VW.17	3.223	7.446	3.223	7.446
VW.18	21.752	37.891	21.752	37.891
VW.19	7.421	10.413	7.421	10.413
VW.20	3.031	6.434	3.031	6.434

#### 4.5 Manual introduction of external perturbations

This paragraph analyses the behaviour of the control chart when different outliers appear in the time series.

In this case, an outlier was manually introduced into the test measurements. The variation was added at observation number 50 in the test dataset, with a value equal to twice the standard deviation of the validation dataset ( $12.0\mu\epsilon$ ). The control chart (Figure 11) shows two consecutive outliers at the point where the anomaly was introduced, indicating an isolated change in sensor behaviour.

Figure 11. Control chart found with introduction of instant changing of the timeseries

Instead, if a constant shift or a linear trend occurs at the same point in the time series, the variation in the control chart differs from the previous case. In Figure 12 a constant shift equal to twice the standard deviation of the validation dataset was introduced. Notably, in the subsequent observation of the time series, there is no opposite variation in the values.

Figure 12. Control chart found with introduction of shift in the observations

This analysis demonstrates how different types of anomalies can be detected using this statistical approach and how variations in the control chart can help distinguish between them. Specifically, it allows for the differentiation between instantaneous sensor variations and constant offsets or linear trends in the time series. These distinctions can differentiate appropriate maintenance strategies for both the structure and the SHM system itself.

Moreover, this type of control, associated with the first data cleaning phase, makes it possible to differentiate issues related to data acquisition—such as corrupted signals—which may result in uncorrelated spikes within the time series. These anomalies can be separated from other types of perturbations, such as constant shifts, linear trends, and correlated spikes, which are more likely to be associated with structural phenomena.

## 5 CONCLUSIONS

This article proposes a statistical approach for continuously evaluating data collected from SHM systems, supporting infrastructure authorities in making informed decisions for the life-cycle assessment of their assets. The proposed framework individually analyses static sensors along with their associated

external variables—in this case, thermocouples—to define the system's normal behaviour.

A SARIMAX model is applied to identify both long-term and short-term patterns in the sensor measurements, assess correlations with external variables, and filter out their effects from the data. Subsequently, the residuals are monitored using an AEWMA control chart, which does not only consider the current residual value but also accounts for deviations from previous residuals. This method further enables the differentiation of various types of anomalies.

The control chart within the proposed framework enables the differentiation of various types of signal perturbations associated with different forms of structural degradation. Additionally, the data cleaning process and the control chart allow for the distinction between these structural anomalies and those arising from data acquisition issues.

For this case study, the framework demonstrated effective performance. The next phase of this research involves extending the framework to groups of sensors, ensuring that potential sensor-specific issues do not trigger unnecessary alarms or warnings for infrastructure authorities, thereby improving the robustness of the monitoring system. In the future, it will also be necessary to apply this type of control to various types of structures to verify and confirm its effectiveness under different conditions and with varying input parameters. This will help assess the system's reliability and adaptability across various structural and environmental scenarios.

**ABSTRACT:** The use of computer vision supported by artificial intelligence methods is growing in popularity for solving problems concerning the assessment of building and civil engineering structures. At the same time, SHM-class systems allow for the collection of large amounts of data. Despite the rapid development of machine learning and the increasing number of solutions supporting the process of technical condition diagnosis of objects, the amount of damage that can be detected in images using these algorithms is significantly limited. At the same time, due to the lack of publicly available datasets that can be used to train AI algorithms, the actual support of the civil engineer's work with these algorithms is limited to a few of the most common problems. This paper presents the current applicability of artificial intelligence methods for damage detection of buildings and engineering structures based on images. At the same time, the authors focus on showing the limitations for the development of artificial intelligence algorithms due to the lack of publicly available datasets. The paper identifies a research gap related to the lack of datasets for damage, pointing out the types of damage, types of damaged materials and solution classes not covered in research on the application of deep learning to the diagnosis of the technical condition of buildings and civil engineering structures.

**KEY WORDS:** SHMII-13; Extended Abstract; Deep learning; Dataset; Damage; Technical condition.

## 1 INTRODUCTION

The rapid development of artificial intelligence (AI) algorithms, including deep machine learning (DL), means that these methods are more and more often being used as tools to support the assessment of the technical condition of building and engineering structures. At the same time as SHM-class systems are adopted more widely, they facilitate the gathering of data on structural behavior, suitable for deep machine learning analysis. [1], [2]. The authors understand SHM-class systems as those that collect data about the structure's condition, analyze these data, and provide information when limit values are exceeded. This allows for early response to potential threats (e.g., informing about excessive strain in a structural element, which could lead to a reduction in load capacity) and supports the development of predictive maintenance strategies.

Researchers are implementing deep learning-based solutions for a wide range of data types. Satellite images [3], [4], Ground Penetrating Radar images [5], measurements from inclinometers and strain gauges [1], signals from devices passing over bridge structures [6], XCT images [7], damage images [8], video data [9] are being used.

The assessment of the technical condition of building and engineering structures can be carried out both on a global level (e.g., classification of damaged buildings after disasters [3], detection of ground deformations [4]) as well as with regard to building components (e.g., crack detection in brickwork masonry [8]), down to the level of detecting internal damage within materials (e.g., corrosion of reinforcement bars in concrete elements [7]).

This paper explores the current capabilities of applying deep learning and computer vision techniques to the damage

detection in buildings and engineering structures using image data. For the purposes of this study, the term "image" is defined specifically as a photograph depicting damage, as opposed to general raster data derived through digital processing of alternative data sources - such as structural vibrations transformed into spectrograms with Digital Signal Processing. Moreover, it should be noted that satellite images [3], [4], Ground Penetrating Radar images [5], XCT images [7] are not discussed here. The article particularly highlights limitations in the development of artificial intelligence algorithms due to lack of publicly available datasets. A research gap is discussed regarding the absence of damage datasets, in terms of damage types and types of damaged materials.

Neural network architectures and their associated performance are not the subject of this discussion. However, it should be mentioned that a likely solution to the problem of limited datasets for construction-related data may be the adaptation of architectures dedicated to Embedded Vision Systems.

## 2 OVERVIEW OF SOLUTION. DEVELOPMENT AND AVAILABILITY OF DATASETS

The application of deep learning in the assessment of the technical condition of buildings and engineering structures based on image data involves addressing tasks such as damage classification, detection, and segmentation. Researchers are using deep learning for the classification of damage such as paint deterioration [10], vegetation [10], cracks [10], [11], [12], [13], corrosion [10], [11], [12], spalling [11], [12], efflorescence [11], exposed bars [11], [12]. Object detection is used, among others, for problems such as cracks [14], [15], [16], spalling [14], [15], [17], pop-out [14], exposed rebar [14],

efflorescence [17]. Segmentation helps to solve problems such as cracks [16], [18], corrosion [19], mildew [19], ponding [19], exposed rebar [20], [21], delamination [20], [21], steel fatigue crack [22].

The development of deep learning algorithms is strongly dependent on the availability of data that can be used to train these models. Despite the wide range of damage types for which deep learning-based solutions have been developed, as described above, the number of open datasets (i.e., those available for download without the need to contact the author) remains significantly limited. As demonstrated by the research conducted by the authors of this publication [23], in the case of bridge structures, out of more than 120 identified damage types that may occur, yet open training datasets are available for only 10 of them. The lack of openly accessible datasets is a significant factor constraining the progress of deep learning algorithm development. In the lack of shared data, subsequent researchers are compelled to create new solutions from scratch, rather than refining or building upon existing methods.

Among the various research problems addressed in the field, crack detection - particularly in concrete and asphalt elements - emerges as the one for which the largest number of open datasets is available. Datasets have also been developed for components made of brick and structural steel. However, it is important to emphasize that, from an engineering point of view, the characteristics of cracks - especially their shape and size - differ significantly depending on the material. A considerable number of datasets are also available for issues related to the corrosion of concrete and reinforcing steel.

When categorized by material type, most identified datasets refer to damage in concrete and asphalt structures. In contrast, datasets concerning damage in timber and stone elements remain limited.

It is important to emphasize the existing imbalance between the range of damage types addressed in proposed solutions and the availability of corresponding datasets that have been made publicly accessible by the research community. A notable example is the detection of honeycomb defects, which, although investigated in scientific publications [24], [25]. In both cited cases, the datasets used in the experimental studies were not disclosed, and this specific type of defect is not represented in any existing public datasets. This situation highlights that, at present, the detection of honeycomb-related damage is only possible within individual research groups that maintain proprietary datasets, thereby limiting the broader applicability and scalability of deep learning methods for structural diagnostics.

To enable meaningful progress in this area, particularly regarding the development and refinement of algorithms targeting such defects, the creation and dissemination of open-access datasets is an essential prerequisite. Only then can the research community effectively train and improve deep learning-based diagnostic tools for widespread engineering applications.

For datasets, the following aspects should be noted [23]:

- Some of the open datasets are described in a not very detailed way and do not contain information relevant for the engineers (for example, the damage size).
- Some of the open datasets are shared in unusual locations (e.g., via the author's cloud storage, rather than on

dedicated data sharing websites like Zenodo, GitHub, kaggle, Mendeley Data).

- For many damage types, available open datasets were not identified. As important, there are datasets in which different damage types are labeled as a single damage type class. Re-labeling them, using classes dedicated to specific damage types, could increase the applicability of DL methods for diagnosis of the construction asset's technical condition.
- It should also be taken into account that a large number of datasets for a particular damage type does not mean yet that the problem of damage detection has been solved. Often, the developed solutions allow only to detect damage of a certain size or occurring on a surface with a similar appearance.

An essential aspect of applying deep learning methods for the assessment of a construction asset's technical condition is the manner in which datasets are prepared. Most publicly available datasets contain damage labels that are purely geometric in nature. Based on these annotations, it is possible to localize pixels within an image that correspond to a specific damage type. However, such data is strictly visual and lacks critical contextual information necessary for a comprehensive engineering assessment - such as expert evaluation, georeferencing, the material type of the damaged element, or the date of damage detection.

Consequently, solutions developed using such datasets primarily address visual recognition tasks and enhance the visibility of defects in imagery, but they do not resolve engineering-level diagnostic challenges.

Data should comply with the FAIR principles [26] - that is, they should be Findable, Accessible, Interoperable, and Reusable. The datasets should be hosted in a permanent way on servers and be accessible to train deep learning models at any time, interoperable between different systems and replicable for different construction structures.

The datasets used for training should pass technical validation and have a high level of rawness. They should not be processed before training, in particular, it is not good practice to collect a small amount of data and then augment the data to present this as a dataset. Augmentation - if it is planned to be executed - should be implemented as part of the model training process. In particular, it should be considered that for engineering problem solving, inadequate planning of the data augmentation process can result in the loss of information relevant to structural engineers, such as the direction of damage or its size.

### 3 CONCLUSION

The conducted analysis has demonstrated that algorithms based on deep learning and computer vision are a frequent subject of research. Although the solutions presented by researchers address the detection of a wide range of defects in concrete, steel, brick, and asphalt components, the number of publicly available datasets for training deep neural networks is significantly smaller.

This situation considerably limits the potential for developing deep learning algorithms for the assessment of a construction asset's technical condition. Moreover, the time that researchers must dedicate to creating their own datasets -

due to the lack of publicly available ones - could instead be allocated to improving the robustness or computational efficiency of deep learning algorithms.

However, in order to develop solutions that address engineering-level challenges (e.g., classification of the degree of damage), rather than solely visual tasks (e.g., identifying the damage area through pixel-wise prediction), it is necessary to establish guidelines for dataset creation. These datasets should include not only visual information but also metadata relevant from the perspective of structural and civil engineers.

**ABSTRACT:** Vision-based vibrational monitoring aims to extract the modal parameters of civil structures—such as natural frequencies—from recorded video data for Structural Health Monitoring (SHM) purposes. The use of drones for vision-based vibrational monitoring is particularly promising, as drones can access vantage points for video recording that may otherwise be difficult to reach. However, certain drawbacks exist, including potential limitations in resolution, stability, and environmental sensitivity. This paper explores the capabilities, opportunities, and limitations of using drones for vision-based vibrational monitoring. To evaluate technological limits, a target with controlled displacement is used to test various combinations of target distances, displacement amplitudes, and displacement frequencies. Additionally, factors such as environmental conditions and drone hardware are considered. The study defines the practical limits of this approach, aiming to determine the minimum displacement of a vibrating bridge that can be detected by drones. Case studies from the literature are used as benchmarks to identify the dynamic properties of different types of bridges.

**KEY WORDS:** drones, structural health monitoring, computer vision

## 1. INTRODUCTION

The deterioration of transportation infrastructure and the limited availability of resources have made Structural Health Monitoring (SHM) essential for supporting bridge management. Within the framework of SHM, vibrational monitoring relies on the global dynamic response of a structure—typically extracting modal parameters such as natural frequencies and mode shapes—to identify damage [1]. Traditionally, vibrational monitoring is performed using fixed systems installed on structures. However, the high cost of components and maintenance makes this approach viable only for a limited number of bridges [2]. Therefore, there is a growing demand for affordable, reliable, portable, and reusable SHM instrumentation to reduce monitoring costs. Among emerging sensing technologies, commercial devices such as smartphones, cameras, drones, and robotic sensors present promising applications [3]. For instance, smartphones can gather vibrational measurements with embedded accelerometers [4]. Moreover, advancements in computer vision techniques enable the extraction of displacement and vibrational data from videos recorded by commercial smartphone and drone cameras [5]. While smartphones and fixed cameras need the physical presence of an operator to record videos close to the target point, drones can be controlled remotely and can reach vantage viewpoints without compromising operator safety [6]. Moreover, in addition to vibrational measurements, drones can gather 2D images of multiple bridge components during the same inspecting session. When combined with advanced computer vision and machine learning techniques, these images can enable a fast and efficient system for surface damage and crack detection [7], [8]. However, being flying objects, drones experience in-flight vibrations and unwanted movements (referred as egomotion) that may interfere with their ability to record small structural vibrations of the bridge. As highlighted in [9], there

is still the need to assess the field of applicability of commercial drone technology for bridge dynamic identification. The goal of this study is to evaluate the capabilities and limitations of drone-based vision systems for vibrational monitoring. The final scope is to define the practical limits of their application in identifying the dynamic behavior of bridges. Two stages are involved. Firstly, a literature survey identifies the typical range of frequencies and displacements for bridges with different materials, structural typology and span. Secondly, experimental tests are performed to assess the limits of applicability of vision-based approach using drones. The results of the tests are compared with the displacement and frequency range exhibited by real-scale bridges.

This paper is structured as follows. Section 2 describes the typical range of vibrational displacements and frequencies for different types of bridges. These ranges are then compared in section 3 with drone vision-based system capabilities determined with laboratory tests. Results are critically discussed in section 4 while section 5 presents conclusions. The overall flowchart is shown in Figure 1.

Figure 1: flowchart of the paper.

## 2. LITERATURE SURVEY

This section reviews existing literature to evaluate the typical behavior of bridges in terms of deflections and natural frequencies. This preliminary analysis, combined with the

results presented in Section 3, will support the assessment of the feasibility of a vision-based approach using drones. Table 1 presents displacement and frequencies data for various types of bridges, including pedestrian bridges, masonry bridges, concrete bridges, and cable-stayed bridges. The row of the table are organized in ascending order based on the length of the

Table 1. Vibrational displacements and frequencies of different types of bridges, ordered by main span length.

[22]	Suspended bridge, 1410 (main span)	2x heavy trucks	200	n.a.	n.a.	n.a.	Vision-Based fixed camera

main span. Deflections are divided into static and dynamic: static deflections are caused by the quasi-static presence of the load (for instance a truck when the truck itself is on the bridge), while dynamic deflections are the residual free-vibration amplitudes experienced around the static deflection baseline and once the load is released. This distinction is important because static deflections are typically an order of magnitude larger than dynamic deflections, making them easier to

measure. However, static deflections are not suitable for the dynamic characterization of the bridge (i.e., extraction of natural frequencies). For this purpose, dynamic deflections during the transient period after unloading are typically used. In Table 1, static deflections are presented with a positive sign, meaning they are pointing downwards, while dynamic deflections are reported with the ± sign, referring to their oscillation around the static deflection. It is possible to observe

the significant variation of the displacement range (from  $<1$  mm to  $\approx 200$  mm) for different combinations of span and stiffness. All the deflections are caused by defined forcing loading conditions (for instance a truck or a train). Conversely, vibrations caused by environmental solicitations are generally too small to be detected by a vision-based system [23]. This poses a challenge for dynamic extraction, as the time frame valid for the extraction of modal parameters is just limited within a few seconds after the excitation. Moreover, the loading itself may present some peculiar periodicity that is not related to the bridge, therefore affecting the result with spurious peaks in the spectral content. This is the case of trains passing over a bridge, where the periodicity is given by bogies passing over the sampling point [19], or of people walking over a pedestrian bridge, where walking has specific frequency.

Table 1 also presents the first two identified frequencies, when available. The peaks of the bridge frequency spectrum should be compared with the dominant peaks of the drone egomotion spectrum. If the bridge frequency peak overlaps with the drone egomotion peak, it becomes more difficult to accurately capture the dynamic behavior of the bridge using drones.

From Table 1, it emerges that, when a conventional load such as a heavy truck passes, static deflections are between  $1/20000$  and  $1/5000$  of the bridge span, while dynamic deflections are between  $1/50000$  and  $1/10000$  of the bridge span. These estimates provide a useful reference for the expected vibration amplitudes of a bridge and help define the range of applicability of the vision-based approach using drones presented in Section 3.

### 3. LABORATORY TESTS

The laboratory tests were conducted using a commercial DJI MINI 2 drone, which was directed at a moving target oscillating vertically. Two experimental setups were tested. In the first setup, the moving target was simulated on a screen, representing a concrete-like surface with a sinusoidal displacement time history in the vertical direction, controlled

by user-defined displacement amplitude and frequencies. In the second setup, the target was a physical point subjected to vertical sinusoidal displacement driven by a pre-programmed shaker, see Figure 2. The tests aim to determine under which conditions the input (known) oscillation frequencies can be identified from the resulting time-domain and frequency-domain plots. For the video-target case, displacements ranged from  $\pm 0.25$  mm to  $\pm 10$  mm, with frequencies between 0.5 Hz and 15 Hz. For the physical-target case, displacements ranged from  $\pm 0.5$  mm to  $\pm 2.5$  mm, with frequencies between 1 Hz and 5 Hz. In both cases, the drone, with its camera recording the target, was flown at varying distances between 1.5 m and 10 m. Different video lengths were tested, ranging from 10 to 60 s. Videos were recorded in 4K resolution ( $3840 \times 2160$ ) at 30 frames per second (fps). Tests were conducted both indoors and outdoors, yielding similar results. Under outdoor conditions, the increased drone oscillations caused by gentle wind gusts were compensated for by more accurate positioning provided by the Global Navigation Satellite System (GNSS). In both cases, also a fixed target was tracked for the sake of measuring the drone egomotion.

From the recorded video, a script using Kanade-Lucas-Tomasi tracking [24], [25], was employed to extract the time history of vertical and horizontal displacements. From these displacement data, velocities and acceleration were also computed. Finally, the Fast Fourier Transform (FFT) algorithm was applied to the displacement, velocity, and acceleration data to analyze their frequency content.

Figure 2 presents the results of a test conducted in the second setup. In the test, the drone was flown at a distance of 10 m, recording the vertical oscillation of the target, which had an amplitude of  $\pm 2.5$  mm (total range 5 mm) and a frequency of 3 Hz. In Figure 3, time histories of displacements, velocities and accelerations of a fixed reference target (orange) and the oscillating target (blue) are shown, in both horizontal (X) and vertical (Y) direction. The displacement of the fixed target is exclusively due to drone egomotion. The low-frequency

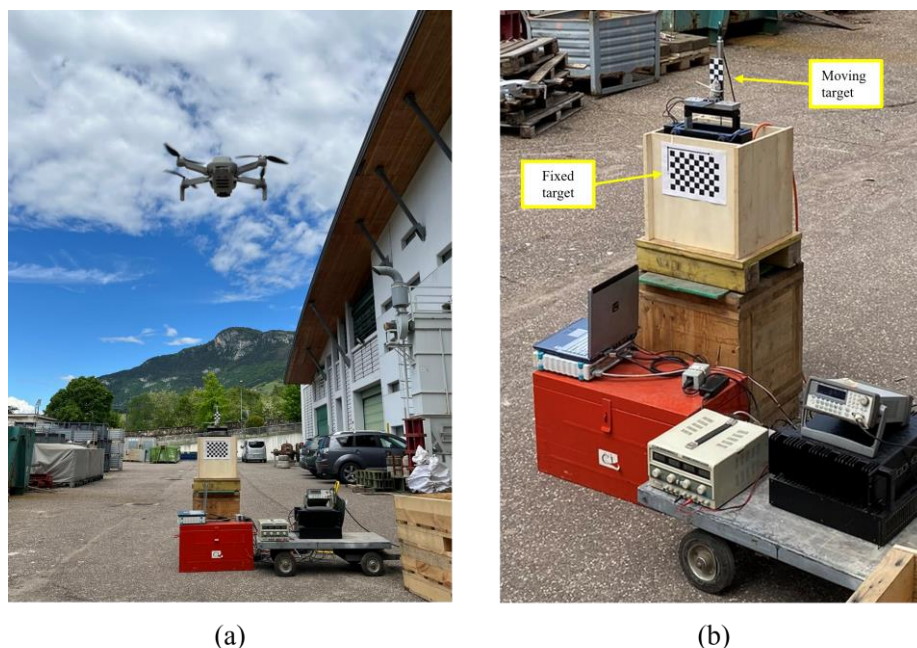

Figure 2. Experimental setup: (a) Drone and targets; (b) Detail of targets.

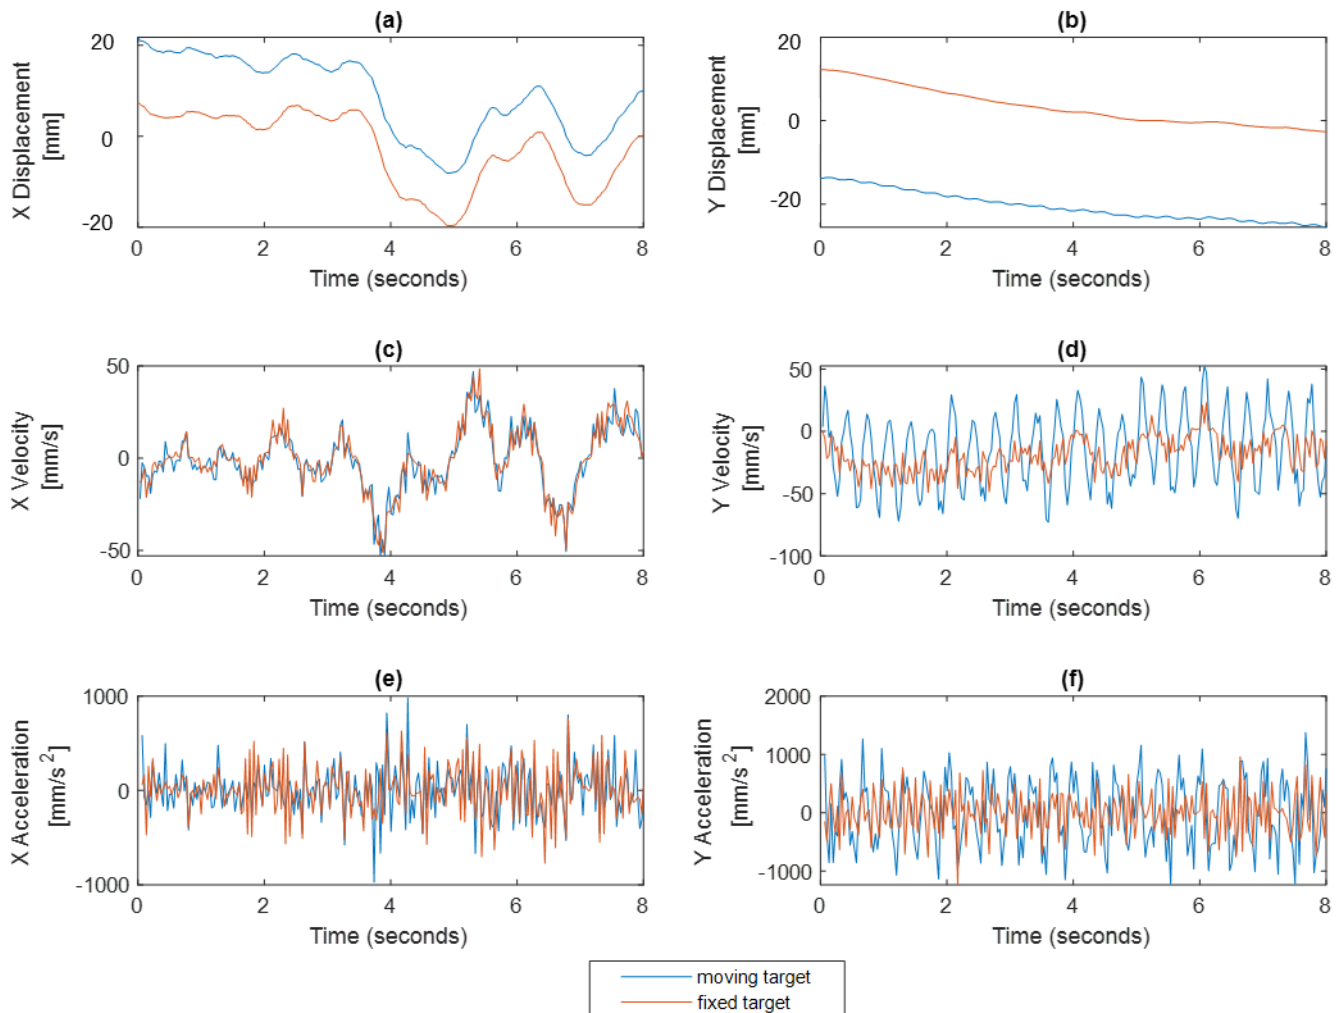

Figure 3. Time histories for a point with 5 mm / 3 Hz oscillation; drone camera at 10 m distance. Time histories of: displacement, (a) x direction and (b) y direction; velocity, (c) x direction and (d) y direction; acceleration, (e) x direction and (f) y direction.

oscillations, especially in the X direction, are due to drone egomotion. Conversely, high frequency vibrations of the moving target are due to the shaker user-defined vibrations. Figure 3 shows spectra of displacement (a), velocity (b) and acceleration (c) in horizontal and vertical direction, for the time histories shown in Figure 2. In Figure 3, a prominent peak in the frequency spectrum of the vertical acceleration and velocity corresponds to the shaker's oscillation frequency.

Results from all the tests provide valuable insights. In particular, some quantities have proven more effective for analyzing the results. Spectra of acceleration and velocity are less sensitive to low-frequency disturbances, resulting in sharp and easily detectable peaks. Conversely, spectra of displacement tend to present less distinct peaks near the

frequency of interest. As the frequency of the input excitation increases, the spectrum of acceleration becomes clearer, while the spectrum of velocity becomes less distinct. As a general rule, if the spectrum of acceleration does not allow for capturing the peak, the spectra of velocity and displacement are unlikely to succeed either. For this reason, the spectrum of acceleration is used as the primary means for identifying the frequency of interest.

The results are summarized in presence of moderate noise, yet low enough to avoid missing real and distinguishable peaks. Results confirm that for the range of frequency above 3 Hz the performance of vision-based tracking is optimal, and sub-millimetric displacements can be captured. On the other hand, at lower frequencies, the drone non-compensated egomotion (which typically falls within the 0–2 Hz range) negatively

affects the results. In this low-frequency range, only displacements with larger amplitudes are detectable if egomotion compensation are applied. Drones with better optics might have a wider range of detectable displacements, while heavier drone might suffer less from egomotion disturbance. Table 2, where the comparison is shown for a distance of 1.5 m, that is a compromise between optical precision and safety distance to avoid collision, using data from both setups. For simplicity, the results have been categorized into two groups: Yes (Y) when the peak in the acceleration spectrum was clearly visible, and No (N) when the identification was uncertain. There are several criteria for peak detection [26]. In this study, the criterion used to distinguish between Yes and No involved calculating the ratio between the peak value and the average signal in the spectrum. If the ratio exceeded 5, the result was marked as Yes; otherwise, it was marked as No. The threshold of 5 was selected because it is high enough to allow clear identification of the peak even in the

captured. On the other hand, at lower frequencies, the drone non-compensated egomotion (which typically falls within the 0–2 Hz range) negatively affects the results. In this low-frequency range, only displacements with larger amplitudes are detectable if egomotion compensation are applied. Drones with better optics might have a wider range of detectable displacements, while heavier drone might suffer less from egomotion disturbance.

presence of moderate noise, yet low enough to avoid missing real and distinguishable peaks. Results confirm that for the range of frequency above 3 Hz the performance of vision-based tracking is optimal, and sub-millimetric displacements can be

#### 4. CRITICAL DISCUSSION

The results obtained in section 3 can be critically compared with the data presented in section 2. When a heavy load passes over a bridge, the resulting static displacement is typically a few millimeters; once the load is released, the amplitude of free vibrations usually falls below 2–5 mm. In a controlled laboratory test, a low-cost drone demonstrated the ability to detect the dynamic behavior of vertically oscillating targets even for oscillations of less than 1 mm, provided that the free vibration frequency is above 2 Hz — allowing for the decoupling of drone egomotion from target vibrations. Based on these findings, drones might be capable of identifying the first frequency of selected bridges, provided that (i) the bridge is loaded by a heavy vehicle, (ii) the bridge is sufficiently flexible, and (iii) its first natural frequency does not coincide with the dominant frequencies of the drone's egomotion. Given those constraints, bridges that might be suitable for the capability of the existing drone technology are:

- Pedestrian bridges spanning more than 20 m, as those presented in [13], [15];
- Slender mid-span concrete and steel bridges, spanning more than 40 m, as those presented in [16], [17].

Conversely, short-span bridges and arch bridges of all materials are typically too stiff to exhibit significant displacement. Moreover, long-span suspended and cable-stayed bridges typically have low frequency modes that overlap with drone egomotion peaks, hindering vision-based dynamic identification with drones. It must be remarked that results from Table 2 are based on a controlled environment with sinusoidal oscillations; in contrast, the free vibrations of real bridges are less regular and, therefore, more challenging to be captured.

It must also be noted that the experiment was performed using an entry level commercial drone, weighing less than 250 g and costing less than 500€. Using a superior category drone could improve the results for three key reasons: (i) higher quality camera, (ii) reduced oscillations due to increased weight, and (iii) more stable hovering with enhanced gimbal stabilization. A list of suitable drones with their specifications is provided in Table 3. It must be remarked that drone weighting less than 250

grams can be flown with less restrictions in European Union, while heavier drones typically require pilot training.

Table 3. Commercial drone specifications.

Model	Year	Weight (g)	Camera	Obstacle Avoidance	Cost (€)
DJI Mini 2	2020	249	12 MP, 4 K/30 fps	Downward	~450
DJI Mini 4 Pro	2024	249	48 MP, 4 K/60 fps; HDR	Omni-directional	~800
Autel Evo Nano +	2023	249	50 MP, 4 K/30 fps	Forward/Backward	~800
Potensic Dreamer Pro	2022	745	12 MP, 4 K/30 fps	None	~500
DJI Air 3	2023	720	24 MP wide + 5 × tele	Omni-directional	~1,100
DJI Mavic 3 Pro	2022	895	4/3" 20 MP + tele + wide	Omni-directional	~2,100

Results could be improved by applying inertial-based egomotion compensation using data from accelerometers [6] or vision-based egomotion compensation using external reference points, such as background features [27]. However, most commercial drones, including the DJI MINI 2, do not allow access to accelerometric data, making inertial-based egomotion compensation unfeasible.

## 5. CONCLUSIONS

This study presented a comparison between bridge dynamic behavior and capabilities of drone vision-based dynamic monitoring. The literature review assessed the typical dynamic displacement ranges of bridge with varying length, material and static scheme. Laboratory tests validated the usage of vision-based dynamic monitoring on drones for vibrations happening with frequencies above 2 Hz and displacement ranges above 1 mm. These values match with properties of pedestrian bridges and of slender mid-span concrete and steel bridges. Further on-field tests should be conducted to verify the applicability to real cases. Improving egomotion compensation is expected to enhance the accuracy of dynamic identification using drones. The need to perform dynamic monitoring, with the constraint of the presence of a passing vehicle, introduces new challenges, such as the need to perform vibrational monitoring using very short and transient time histories, which falls outside the traditional framework of operational modal analysis.

**ABSTRACT:** Although recent advances have been widely gained in UAV-based visual inspection for bridges, the accuracy and generalization ability of recognition model highly rely on sufficient, complete, and high-quality annotations. Current damage segmentation models are often trained in a fragmented manner based on substantial pixel-level labels for specific structural components and damage types, lacking universality and robustness under real-world open scenarios. This study establishes a universal unsupervised image segmentation model of multi-type component and damage for vision-based autonomous UAV inspection of bridges using a teacher-student network architecture. The inputs are unlabeled image pairs after data augmentation including random clipping, rotation, illumination transformation, and color transformation. The pre-trained backbone of original DINO is adopted as frozen image feature extractor to obtain high-level feature representations, and a CNN-based segmentation head with learnable parameters is designed to generate dense segmentation maps with strong point-wise correlations. A synthetic loss function, comprising a correlation loss and a contrastive loss, is proposed for model training. The proposed method is validated on a unified multi-scale imageset including various structural components and surface damage for cable-supported bridges and concrete bridges. The recognition accuracy, generalization ability, and robustness under complex background are demonstrated.

**KEY WORDS:** UAV Bridge Inspection; Universal Unsupervised Segmentation; Teacher-Student Network; Cross-level Feature Alignment; Contrastive Learning.

## 1 INTRODUCTION

Maintaining safe operation throughout the entire life cycle of bridge structures is crucial. Timely and accurate identification of surface damage (such as cracks, corrosion, etc.) not only provides a basis for scientifically formulating maintenance strategies but also effectively prevents structural performance degradation, significantly reducing major safety risks like collapse and instability. For decades, bridge inspection has primarily relied on manual methods. However, this approach is not only time-consuming and labor-intensive but also susceptible to inspector experience, environmental conditions, and fatigue factors, resulting in issues such as strong subjectivity, low efficiency, and poor consistency, making it difficult to ensure reliability and timeliness in practical applications [1].

In recent years, computer vision technology has demonstrated significant advantages in image-based structural health monitoring and damage identification, providing an efficient and reliable alternative to traditional manual inspection methods. By integrating digital image processing with machine learning algorithms, computer vision enables automated identification and quantitative analysis of structural surface damage. Early research mainly focused on traditional image processing methods like edge detection and threshold segmentation, but their performance heavily relied on manual parameter tuning and showed limited generalization capability for damage features in complex environments. With breakthroughs in deep learning, data-driven methods represented by convolutional neural networks (CNNs) have exhibited outstanding performance in automatic feature extraction and damage pattern recognition, greatly improving

the accuracy and adaptability of structural health monitoring systems. However, these methods still depend on manually designed features as input and face challenges in robustness across complex real-world scenarios and generalization across different damage types [2].

Deep learning achieves end-to-end automatic mapping between images and object annotations through deep neural networks, with CNNs as multi-level feature extractors being the most extensively studied [3-5]. Existing structural damage identification methods are typically developed based on specific datasets covering only limited damage types and application scenarios, resulting in constrained generalization capability for new damage categories or under disaster conditions [6-7]. Moreover, these methods often require large amounts of annotated data to achieve ideal performance, but the nonlinear and sparse nature of structural damage makes high-quality annotated data difficult to obtain in practice [8-9]. Consequently, identification accuracy is easily affected by sample size, class balance, and damage diversity. However, real-world engineering applications demand models that maintain good generalization across diverse scenarios while achieving high-precision identification performance on unannotated data [10-11]. To overcome the limitations of existing methods trained separately on different datasets, it is necessary to develop a universal visual recognition model for structural damage that can accurately identify multiple damage types while maintaining stable performance in complex backgrounds and multi-scale real-world scenarios [12].

In the field of structural health monitoring, unsupervised and self-supervised learning paradigms are gradually becoming key technological pathways to address few-shot damage detection

challenges [13-14]. Currently, although contrastive learning-driven unsupervised semantic segmentation methods have shown potential in general computer vision domains, their adaptation to bridge UAV visual inspection scenarios faces significant bottlenecks: on one hand, there is a need to develop a universal segmentation framework adapted to Transformer architectures; on the other hand, the challenge of pixel-level damage parsing in real-world environments with massive unannotated data must be overcome (although certain few-shot learning algorithms have been proposed [15-17], a proper number of samples with pixel-level annotations should be required in advance). To address these challenges, this study proposes a large vision model for universal structural damage segmentation. The main scientific contributions are summarized as follows:

(1) We propose an unsupervised structural damage segmentation method based on teacher-student network knowledge distillation, using unlabeled augmented image pairs as input. The dual-branch architecture incorporates pre-trained frozen Transformer backbones and fine-tunable CNN segmentation heads.

(2) We design a dual-strategy collaborative mechanism combining cross-level self-supervised correlation learning and cross-network contrastive learning. The former achieves feature alignment through point-to-point correlations between high-level features and dense segmentation maps, while the latter maintains instance similarity and separability through feature vector comparison between teacher-student networks.

(3) We construct a joint optimization objective integrating correlation loss and contrastive loss. The student branch is rapidly updated via gradient descent, while the teacher branch is stably adapted through momentum-based exponential moving average, achieving end-to-end fine-tuning of the segmentation head.

The remainder of this paper is organized as follows. Section 2 introduces the network architecture of the proposed universal unsupervised damage segmentation model. Section 3 describes the investigated imageset of multi-scale multi-type structural components and surface damage. Section 4 presents a series of test results to demonstrate the effectiveness, robustness, and generalization capability of the established model under real-world inspection scenarios with complex background disturbances for cable-supported bridges and concrete bridges. Finally, Section 5 concludes this paper.

## 2 METHODOLOGY

The architecture of the proposed universal structural damage segmentation model is illustrated in Figure 1, employing an unsupervised learning paradigm based on collaborative optimization of teacher-student networks through an end-to-end self-supervised knowledge distillation mechanism for effective feature learning. Distinct from conventional approaches dependent on manual annotations, our framework integrates three fundamental components: a data augmentation module, a Transformer-based frozen feature extraction backbone, and a tunable CNN segmentation head. A specially designed hybrid loss function combining feature-space correlation loss with instance contrastive loss enables the network to autonomously identify essential damage characteristics in unsupervised settings. During deployment,

input images undergo sequential processing through the frozen feature extraction backbone, optimized segmentation head, and semantic clustering-based post-processing module to generate pixel-accurate structural damage segmentation results, with the complete pipeline demonstrating enhanced robustness for practical engineering applications. This integrated approach effectively bridges the gap between unsupervised learning and precise damage identification in complex real-world scenarios while maintaining computational efficiency throughout the segmentation process.

Figure 1. Model architecture for universal unsupervised segmentation of multi-type structural component and damage.

For each individual instance of input image, feature maps with the same dimensions of channel, height, and width are obtained before and after the segmentation head. For each branch of student and teacher networks, spatial points on feature maps before the segmentation head are noted as  $f_{chw}$  and  $g_{ch'w'}$ , while spatial points on feature maps after the segmentation head are noted as  $s_{chw}$  and  $t_{ch'w'}$ , respectively. The feature correspondence  $F_{hwh'w'}$  between  $f_{chw}$  and  $g_{ch'w'}$  and segmentation correspondence  $S_{hwh'w'}$  between  $s_{chw}$  and  $t_{ch'w'}$  are obtained by calculating the point-wise cosine similarity as

$$F_{hwh'w'} = \frac{\sum_{c=1}^C f_{chw} \times g_{ch'w'}}{\|f_{chw}\|_2 \times \|g_{ch'w'}\|_2} \quad (1)$$

$$S_{hwh'w'} = \frac{\sum_{c=1}^C s_{chw} \times t_{ch'w'}}{\|s_{chw}\|_2 \times \|t_{ch'w'}\|_2} \quad (2)$$

For  $N$  input images within an input batch, the feature correspondence tensors and segmentation correspondence tensors could be denoted as  $F_1, \dots, F_N \in \mathcal{R}^{H \times W \times H \times W}$ ;  $S_1, \dots, S_N \in \mathcal{R}^{H \times W \times H \times W}$  with four-dimensional elements of  $F_{hwh'w'}$  and  $S_{hwh'w'}$ .

The dense semantic correlation loss  $L_{corr}$  is calculated based on feature correspondence tensors and segmentation correspondence tensors by

$$F_{hwh'w'}^{SC} = F_{hwh'w'} - \frac{1}{HW} \sum_{h',w'} F_{hwh'w'} \quad (3)$$

$$L_{corr} = -\sum_{h,w,h',w'} (F_{hwh'w'}^{SC} - b) \max(S_{hwh'w'}, 0) \quad (4)$$

where  $F_{hwh'w'}^{SC}$  denotes the feature correspondence tensor after spatial centralization,  $b$  is a hyperparameter to avoid model collapse and ensure a positive correlation loss value for loss descending.

The contrastive loss between the teacher-student networks is defined as

$$L_{cont} = -\sum_{i=1}^N \log \left\{ \frac{\exp[\text{Sim}(q_i, k_+)/\tau]}{\sum_{j=1}^K \exp[\text{Sim}(q_i, k_j)/\tau]} \right\} \quad (5)$$

where Sim denotes the cosine similarity between two vectors,  $q_i$  denotes the  $i$ th query feature vector obtained from the student branch for the  $i$ th image in a batch,  $k_+$  denotes the feature vector obtained from the teacher branch as the positive sample of the corresponding query image,  $N$  denotes the batch size,  $k_j$  denotes the  $j$ th referenced feature vector in the feature dictionary,  $K$  denotes the queue length of the preset feature dictionary,  $\tau$  denotes a temperature hyperparameter to enhance an exponential amplification effect.

The synthetic loss function is defined by a weighted sum of correlation loss and contrastive loss as

$$Loss = \alpha L_{corr} + (1 - \alpha) L_{cont} \quad (6)$$

where  $\alpha$  denotes the weight coefficient of the correlation loss.

Upon completion of training, the system can directly generate predicted segmentation results for new test images using the frozen visual backbone network and optimized segmentation head. As shown in Figure 2, the prediction network incorporates a semantic clustering post-processing module consisting of K-means clustering and fully connected Conditional Random Field (CRF). Based on predefined label-category mapping relationships, the system automatically associates pixel-level annotations with specific categories including structural components, surface damage, and background. For newly added categories, only a single annotated sample is required to update the label mapping table. It should be noted that as standard post-processing modules for unsupervised image segmentation, the specific implementations of K-means clustering, fully connected CRF, and label alignment can be referenced in existing literature. To highlight this study's core contribution - the construction of a large-scale model for universal structural damage segmentation - the relevant implementation details are omitted here for brevity.

Figure 2. Schematic of prediction network structure with post-processing of semantic clustering.

### 3 IMPLEMENTATION DETAILS

This study addresses the key scientific challenge of unsupervised semantic segmentation for multiple types of structural damage under complex engineering conditions, proposing an integrated analytical framework that combines multi-source environmental interference factors with intrinsic structural features. Specifically, by fusing multi-dimensional key characteristics—including environmental background noise interference, macro-structural morphological features, micro-component texture details, and spatial distribution patterns of cable systems—we developed a dedicated scene model for damage detection in typical bridge structures such as cable-stayed bridges and concrete bridges. As illustrated in

Figure 3, representative damage samples from the two-level structural damage image database constructed in this study are presented.

#### Cable-supported and Concrete Bridges

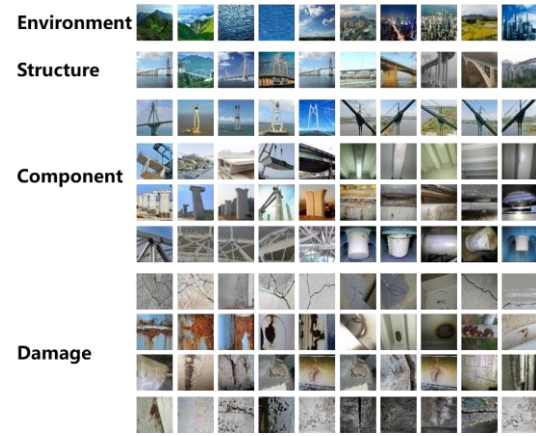

Figure 3. Representative images of hierarchical structural damage with multi-scale information for cable-supported and concrete bridges.

A total of 20K images with varying resolutions were standardized to a uniform resolution of  $1,024 \times 1,024$  pixels. Each resized image was subsequently partitioned into  $224 \times 224$  patches using a sliding window approach with a 100-pixel stride, thereby generating an extensive collection of image patches while circumventing potential feature degradation associated with direct downsampling. From this collection, 128 patches were randomly sampled to constitute the input batches for the proposed methodology.

It must be particularly emphasized that implementing traditional supervised CNN-based semantic segmentation models on such large-scale image patches inevitably encounters multiple computational challenges. Specifically, the exponential growth in computational complexity caused by high-resolution input space, coupled with the enormous manual annotation costs and time resources required for pixel-level labeling, constitutes two fundamental bottlenecks. These core limitations fundamentally undermine the feasibility of traditional supervised learning paradigms in the current application scenario, thereby significantly diminishing their practical value.

Through extensive experimental validation and parameter tuning, this study has ultimately determined the hyperparameter configuration scheme for model training as shown in Table 1. It is particularly important to note that while the current parameter settings may not represent the global optimal solution, empirical research demonstrates that this configuration ensures the large vision model for general structural damage segmentation achieves satisfactory segmentation accuracy, maintains excellent robustness against complex background interference, and exhibits strong generalization capability for new scenarios. Based on this, the primary objective of this research is not to pursue the optimal combination of hyperparameters, but rather to systematically validate through experiments the technical feasibility and practical effectiveness of the proposed large vision model in achieving general structural damage segmentation in real-world detection scenarios.

Table 1. Configurations of key training hyperparameters.

Hyperparameter Variables	Values
Number of images included in each batch	128
Dimension of feature representation after patch embedding	512
Length of query, key, and value vectors in attention mechanism	64
Number of multiple attention heads	8
Number of stacked transformer blocks	6
Dimensions of extracted feature maps by frozen visual backbone	16, 16, 8
Length of query and referenced feature vectors in preset feature dictionary	64
Number of feature queue size	12,800
Positive parameter to avoid model collapse in correlation loss	0.18
Weight coefficient of correlation loss	0.67
Temperature coefficient of contrastive loss	0.07
Learning rate in stochastic gradient descent updating of student network	5e-4
Momentum in exponential moving average updating of teacher network	0.999
Number of training iterations	5,000

To obtain quantitative evaluation metrics for semantic segmentation, a set of test images are pre-labelled with pixel-level annotations, and the following pixel accuracy (PA), mean intersection-over-union (mIoU), and frequency-weighted intersection-over-union (FWIoU) are calculated by

$$PA = \frac{\sum_i p_{ii}}{\sum_i \sum_j p_{ij}} \quad (7)$$

$$mIoU = \frac{1}{N_C + 1} \sum_{i=0}^{N_C} \frac{p_{ii}}{\sum_{j \neq i} p_{ij} + \sum_{j \neq i} p_{ji} - p_{ii}} \quad (8)$$

$$FWIoU = \frac{1}{\sum_{i=0}^{N_C} \sum_{j=0}^{N_C} p_{ij}} \sum_{i=0}^{N_C} \frac{p_{ii} \sum_{j=0}^{N_C} p_{ij}}{\sum_{j \neq i} p_{ij} + \sum_{j \neq i} p_{ji} - p_{ii}} \quad (9)$$

where  $p_{ij}$  denotes the number of pixels in the  $i$ th class (actual category) classified to the  $j$ th class (predicted category), the total number of pixel categories equals  $N_C + 1$ , including 1 for the background and  $N_C$  for the foreground, and  $N_C$  is determined by actual label categories of selected test images.

The proposed large vision model for universal structural damage segmentation is trained and tested under the software environment of PyTorch 1.8 and Python 3.7 on a 48G GPU of NVIDIA RTX A6000, and the average training time with the reported hyperparameter configurations is about 48 hours to obtain a well-trained model.

## 4 RESULTS AND DISCUSSION

Figure 4 shows some representative prediction results on coarse-grained segmentation of main bridge structures: (a) for cable-supported bridges and (b) for concrete bridges. The test PA, mIoU, and FWIoU are 97.17%, 91.47%, 94.64% for cable-support bridges and 92.72%, 82.46%, 86.98% for concrete bridges. The results show that main components of pylon, cable, girder, deck, and pier can be generally identified from entire images of bridge structures.

Figure 4. Representative predictions on coarse-grained segmentation of main bridge structures.

Figure 5 shows some typical prediction results of fine-grained damage segmentation on bridges, including concrete cracks, spalling, exposed rebar, seepage, salt damage, rebar fatigue cracks, coating peeling, and corrosion. Table 2 lists the evaluation metrics. The results show that this method can effectively detect various bridge damages from close-range images. Moreover, it can distinguish between combined concrete spalling and rebar exposure, as well as separate severe and slight corrosion areas.

Figure 5. Representative predictions on fine-grained multi-type structural damage for bridges.

Table 2. Evaluation metrics for multi-type structural damage segmentation of bridges.

Bridge structural damage type	PA	mIoU	FWIoU
Concrete crack	96.19%	69.85%	93.35%
Concrete spalling/rebar exposure	98.97%	74.12%	98.30%
Water seepage/salt petering	88.28%	75.15%	79.21%
Steel fatigue crack	96.21%	68.07%	94.69%
Coating spalling/steel corrosion	91.07%	75.39%	84.83%
Fire burning	95.85%	76.22%	93.02%

Figure 6 shows some representative prediction results on new bridge components and ship collision damage, and Table 3 shows the corresponding evaluation metrics. The results suggest that the proposed method have achieved generalization capacity on unseen categories of bridge components and damage apart from the existing structural components and surface damage included in the training imageset. Figure 12(a) shows that despite some misrecognitions of background boats with similar color to cable clamp, key components of cable-suspension bridges such as cable, suspender, cable clamp, and bolts on steel plate can be individually recognized. Figure 12(b) demonstrates that even for a never-appeared emergency of ship collision, the deck scratch, buckling and deformation of steel plate, coating spalling, and handrail failure fragments could be generally identified. It should be noted that some misrecognitions have been observed between the cable plane and distant background and that spurs-like pixels occur along the boundary of damage regions. Possible reasons might attribute to similar material and morphological features with indistinguishable member edges. Geometrical constraints of different component and damage regions would be further considered to address these issues in future study.

Figure 6. Representative predictions on new bridge components and ship collision damage.

Table 3. Evaluation metrics for segmentation of new bridge components.

New bridge component type	PA	mIoU	FWIoU
Bolt	81.39%	63.88%	70.97%
Steel plate	82.25%	69.24%	70.21%
Cable	96.23%	78.87%	93.84%
Suspender	96.70%	81.51%	94.37%
Cable clamp	95.19%	61.46%	90.96%

Furthermore, the effectiveness and necessity of the proposed method are demonstrated via performance comparisons between the proposed model and SCSEgamba [18], a recently-reported supervised structural damage segmentation model. The model architecture of SCSEgamba is shown in Figure 7. The core architecture incorporates a structure-aware visual state space (SAVSS) module and a multi-scale feature segmentation (MFS) head. The SAVSS captures continuous textures of multi-directional cracks through an innovative structure-aware scanning strategy and dynamically enhances crack features using a lightweight gated bottleneck convolution (GBC). Meanwhile, the MFS integrates multi-scale information to generate refined segmentation maps. Using a unified dataset (containing both concrete cracks and spalling/exposed reinforcement damages), we trained SCSEgamba for 100 epochs using the default training setups and selected the optimal model (with minimal validation loss) for evaluation. Quantitative results demonstrate that our method outperforms SCSEgamba across all three metrics (PA, mIoU, and FWIoU) for both crack and spalling/rebar exposure damage types (see detailed values in Table 4).

Figure 8 presents typical comparative results between the proposed method and SCSEgamba in structural damage

segmentation. The experimental results demonstrate that compared to the blurred boundaries and missed reinforcement detections generated by SCSEgamba, our method can more accurately capture fine crack branches and complex boundary contours of spalling areas. Particularly in the identification tasks of concrete spalling and exposed reinforcement damage, the proposed teacher-student network architecture effectively enhances recognition robustness in weak-texture regions through the synergistic optimization mechanism of feature distillation and contrastive learning. Experimental results indicate that this method can precisely capture edge irregularities in spalling areas while maintaining high sensitivity to exposed reinforcement textures in low-contrast environments, ultimately achieving pixel-level precision in damage segmentation.

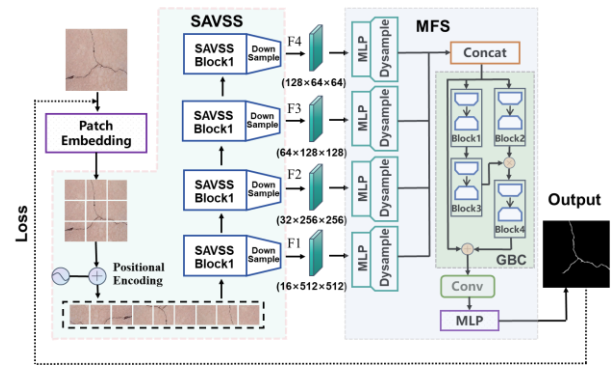

Figure 7. Model architecture of SCSEgamba as comparative validation (reproduced from [18]).

Table 4. Performance comparison with supervised crack segmentation model SCSEgamba on multi-class damage.

Method	Bridge structural damage type	PA	mIoU	FWIoU
SCSEgamba [18]	Concrete crack	96.11%	65.20%	92.77%
Ours	Concrete crack	96.19% (↑)	69.85% (↑)	93.35% (↑)
SCSEgamba [18]	Concrete spalling/rebar exposure	82.38%	60.47%	85.43%
Ours	Concrete spalling/rebar exposure	95.19% (↑)	61.46% (↑)	90.96% (↑)

Figure 8. Some representative comparative results of structural damage segmentation between the proposed method and SCSEgamba.

## 5 CONCLUSIONS

This study proposes an unsupervised structural damage semantic segmentation framework based on relational learning and contrastive learning. By constructing a cross-scale feature interaction mechanism and a dynamic negative sample mining strategy, the framework achieves robust recognition and pixel-level localization of multiple types of structural damage in complex engineering scenarios without manual annotation. It effectively addresses the strong dependency of traditional supervised segmentation paradigms on large-scale fine-grained annotated data and the resulting limitations in model generalization. The main research conclusions are as follows:

(1) Based on a teacher-student network knowledge distillation framework, a unified semantic segmentation architecture for multiple types of structural components and surface damages was constructed. Each branch of the teacher-student network contains a pre-trained Transformer visual backbone and a fine-tunable CNN segmentation head.

(2) Using randomly augmented unlabeled image pairs as input, a pre-trained DINO backbone is employed as a frozen feature extractor to generate high-level feature maps. A CNN segmentation head with learnable parameters is designed to produce dense segmentation maps that maintain strong point-wise correlations with the high-level feature maps.

(3) Proposed an inter-layer correlation learning strategy between high-level feature maps from the frozen backbone network and dense segmentation maps from the fine-tuned segmentation head, achieving cross-level feature alignment for different structural components and damage regions within a single image. Developed a contrastive learning module with normalized feature aggregation between teacher-student branches to quantify intra-instance similarity and inter-instance discriminability across different images.

(4) A synthetic loss function comprising a correlation loss and a contrastive loss is designed. The segmentation head is efficiently fine-tuned by fastly optimizing the student network with direct error backpropagation by gradient descent and stably adapting the teacher network with exponential moving average by momentum updating.

(5) This study constructs a multi-scale image dataset encompassing various types of bridge structures and their damage patterns. Through systematic comparative experiments, the proposed model has demonstrated outstanding segmentation accuracy, strong generalization capability, and excellent robustness under complex background interference. The experimental results indicate that the large-scale visual model developed in this study has successfully achieved deep visual understanding of unlabeled bridge component damage images and effectively mastered their unsupervised learning mechanism.

**ABSTRACT:** Civil structures inevitably experience anomalies and damage, especially during disasters like earthquakes, tsunamis, and hurricanes, causing performance degradation or even collapse. Identifying such anomalies plays an extremely critical role in the maintenance and life extension of civil structures. This study proposes a novel approach based on video data due to its accessibility and rich temporal-spatial information for anomaly detection in large-scale civil structures by integrating transfer learning (TL) techniques with optical flow. Given the low importance of structural Region-of-Uninterest (RoU) like windows and doors, TL with BEIT+UPerNet pre-trained models identifies them. The extended node strength network then leverages video data to focus on structural components and detect disturbances in the nonlinearity vector field. The approach was validated using open video data from E-Defense, capturing two large-scale structural shaking-table tests that featured both pronounced shear cracks and tiny cracks. The detection and quantitative analysis results confirmed the method's effectiveness in detecting structural anomalies and improved computational efficiency by approximately 10%, with a positive correlation observed between this efficiency gain and the proportion of structural RoUs in the video. This study advances anomaly detection in large-scale structures, offering a promising approach to enhancing safety and maintenance practices for critical infrastructure.

**KEY WORDS:** Anomaly detection; Optical flow; Transfer learning; Video data; Node strength network; Shaking-table test

## 1 INTRODUCTION

Engineering structures often sustain damage throughout their service life, deteriorating over time due to various environmental and mechanical factors. Both immediate and prolonged damage contribute to the aging of structures and a subsequent reduction in their service life, highlighting the importance of the structural health monitoring (SHM) process [1].

In recent years, the traditional reliance on manual inspection and scheduled maintenance has evolved with the integration of advanced imaging technologies and machine learning (ML) [2]. For instance, Ji et al. [3] proposed vision-based measurement methods for deformation estimation and cracks identification and demonstrate much higher efficiency and provide more useful information than the traditional measurement techniques. Wu et al. [4] developed an improved algorithm based on YOLOv5s which made mAP@0.5 (mean Average Precision when IoU equal 0.5) values improve by around 10%. Furthermore, Xiong et al. [5] proposed a novel computer vision model based on YOLOv8 for automated concrete bridge crack detection. Structural cracks, as a representative form of anomaly event, can serve as indicators of the deterioration in structural service performance.

The authors previously conducted research on anomaly event detection, focusing on nonlinear occurrences, and validated the efficiency of their proposed methods through a small-scale frame model shaking table test [6]. This method detects nonlinearity in structural vibrations using video data, with feature extraction performed via optical flow techniques. However, a significant challenge persists across the field: the high computational costs associated with the analysis process. Addressing this issue is crucial for advancing SHM technologies and methodologies.

This study introduces a novel method for detecting anomalies due to structural nonlinearity in video data, validated through a

3-D full-scale shaking table test conducted by NIED. The method involves extracting nonlinear disturbances from anomaly events in the velocity vector field estimated by optical flow, constructing an extended node strength network, and applying a morphological opening operation for feature extraction and enhancement. This study presents two key advancements for applying the method to general video data. First, the developed algorithm, which was previously applied only to small-scale experimental models, is now tested on large-scale engineering structures to assess its effectiveness in real-world scenarios. Second, to address the challenge of excessive computational time, we integrate a transfer learning (TL) algorithm to initially identify and filter out the Region-of-Uninterest (RoU), thereby enhancing identification efficiency.

The remainder of this extended abstract is organized as follows: Section 2 presents the framework of the proposed algorithm, while the detailed mathematical formulations are omitted due to the page limit of the extended abstract. Section 3 describes the 3D large-scale shaking table tests, including concrete and wooden building tests, followed by the identification results of TL for structural RoU. It also compares visualization results before and after anomaly events (pronounced shear cracks and tiny cracks) to demonstrate the feasibility of the proposed method. Additionally, a morphological opening operation is introduced to enhance features and denoise visualization results. Computational efficiency, with and without TL, is also compared in Section 4. Finally, conclusions are presented in Section 5.

## 2 METHODOLOGY

The proposed method for detecting structural anomaly events during earthquakes, relying solely on video data, integrates TL with an extended node strength network. Figure 1 illustrates the framework of this method and the flowchart detailing the subsequent steps.

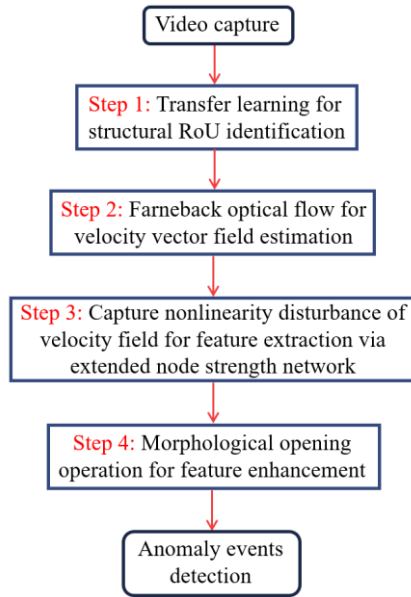

Figure 1. Flowchart of the proposed method

### 2.1 Transfer learning for RoU identification

Recently, Transformer-based models have gained attention for image recognition as alternatives to Convolutional Neural Networks (CNN). Transformers excel at capturing long-distance dependencies, which partly accounts for their superior performance compared to CNN. However, Transformers generally require large amounts of training data. TL addresses this issue by allowing models trained on extensive datasets to perform effectively on specific tasks with smaller datasets. Consequently, BEiT [7], a transformer-based model, was employed, leveraging TL to segment the RoU components. BEiT utilizes the BERT approach [8], a widely used transformer-based model in natural language processing, for image recognition. BEiT treats images as sequences of words and learns to extract features through a masked part-prediction task.

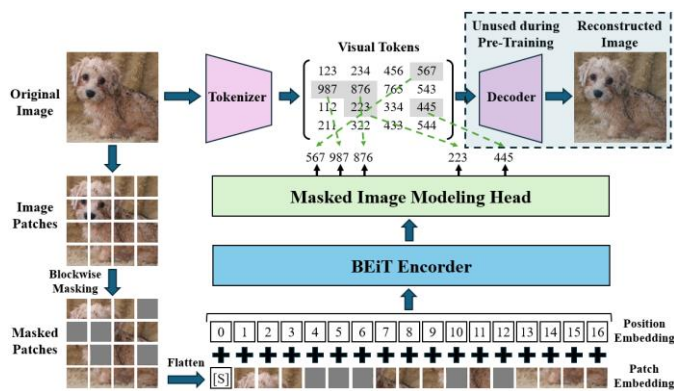

Figure 2. The overview of pre-training BEiT

After pre-training BEiT using Masked Image Modeling (MIM) as shown in Figure 2, the BEiT+UPerNet model, pre-trained for semantic segmentation, was further trained to segment the RoU, specifically targeting windows and doors. An example of RoU recognition for removing the window parts of a building using NIED video data is shown in Figure 3. These images depict the frames before and after RoUs

recognition. In the detected area, pixel values are set to zero, allowing for the removal of these pixels in the subsequent anomaly event detection process. By successfully identifying the structural RoUs, video data that exclusively contains structural component information is utilized, thus improving the computational efficiency of the feature extraction process.

Figure 3. An Example for structural RoUs identification based on TL (a) original frame (b) processed frame

### 2.2 Anomaly events detection by proposed extended node strength network

The anomaly event detection method for video data, as detailed in [6] is summarized here and shown in Figure 4. The method comprises three main steps: (1) estimating the velocity field using Farneback optical flow, (2) extracting anomaly features with the extended node strength network, and (3) enhancing features through a morphological opening operation. This approach allows for the visualization of the timing and location of anomalous events, which result from local disturbances in the vector field caused by nonlinear structural vibrations.

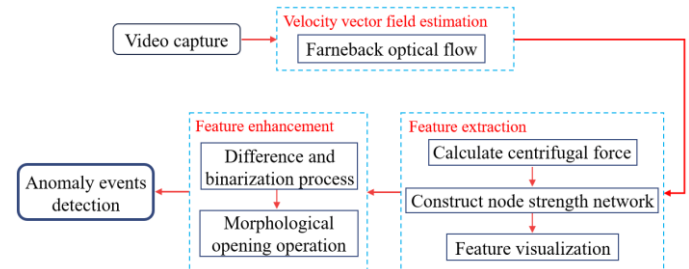

Figure 4. Flowchart of the anomaly events detection method

## 3 ANOMALY EVENT DETECTION FOR 3D SCALED SHAKING TABLE TEST

In this section, the proposed method is validated using two cases from a full-scale shaking table test conducted by the National Research Institute for Earthquake Science and Disaster Resilience (NIED) in Hyogo, Japan. The test included a 1/3 scale model of a six-story Reinforced Concrete (RC) building and a three-story full-scale wooden house. The example frames for the two cases are shown in Figure 5.

Figure 5. Example frames for (a) RC building (b) wooden house

TL is first applied to identify the RoUs and the results are represented in the black area of Figure 6. Then, Farneback optical flow is employed to estimate the velocity field, the results for the damage frame of the two cases are shown in Figure 6. The length of the arrows represents the instantaneous velocity of the pixel points, while the direction of the arrows indicates the velocity direction. In Figure 6(a), It is observed that the occurrence of shear cracks caused a distinct nonlinear change in velocity within the affected area. However, Figure 6(b) reveals that only short arrows are present in the area of the tiny crack, making it difficult to identify the crack solely by evaluating the velocity field. This limitation is due to the fact that changes in velocity cannot uniquely identify anomalous events, as other regions, such as window edges and areas around wires and bolts, also show velocity variations.

Figure 6. Results of velocity field estimation: (a) RC building (b) wooden house

To represent the anomaly event and enhance its features, an extended node strength network, and a morphological opening operation are utilized. After feature enhancement, as illustrated in Figure 7, nearly all noise areas are effectively removed and only the highlighted area near the crack is retained. The results demonstrate the occurrence of anomalous events and indicate improved detection effectiveness.

Figure 7. Results of anomaly detection: (a) RC building (b) wooden house

#### 4 DISCUSSION FOR COMPUTATIONAL EFFICIENCY

In this study, a key advantage of combining TL is the improvement in computational efficiency. Early identification and removal of RoUs reduce the number of input pixels needed for subsequent node strength network construction. Table 1 compares computational efficiency before and after employing TL for structural RoU identification. Additionally, we expanded our dataset for comparison by incorporating data from the 4-story steel structure shaking-table test mentioned in Figure 3. Table 1 illustrates a positive correlation between improvements in computational efficiency and the proportion of structural RoUs. The selected test cases demonstrate an average efficiency improvement of approximately 10%. In practical applications, analyzing cases with a larger proportion of structural RoUs results in greater efficiency gains.

Table 1. Comparison of computational efficiency after using TL.

Case	Computing time sec/frame		Improve- ment ratio	RoU proportion
	Before	After		
Four-story steel building	64	59	7.81%	8.59%
Six-story RC frame building	159	144	9.43%	9.66%
Three-story wooden house	249	224	10.04%	10.21%

#### 5 CONCLUSIONS

This study proposed a novel anomaly detection algorithm that focused on nonlinearity occurrence by combining deep learning techniques with an optical flow-based extended node strength network. The approach stems from the observation that such events cause nonlinear disturbances in the velocity vector field, which can be estimated from video data. Additionally, structural RoUs, such as doors and windows, are often not the primary focus of structural health monitoring. Pre-identifying these areas before initiating damage detection can significantly enhance the efficiency of the process.

# Development of a Wireless Stereo Vision System for 3D Displacement Online Long-Term Monitoring of Tall Structures

Miaomin Wang, Ki-Young Koo

Vibration Engineering Section, Faculty of Environment, Science and Economy, University of Exeter, Exeter, EX4 4QF, UK

**ABSTRACT:** This paper presents a novel wireless stereo vision system for 3D displacement monitoring of tall structures. The system uses two GNSS wireless camera nodes to capture images of a target and calculate its 2D displacement independently. Each node uploads its data to the cloud, where 3D displacement is reconstructed using a triangulation technique. This system has several advantages over traditional cable-based stereo vision systems for tall structures: 1) The distance between the two camera nodes is not limited, allowing flexible deployment to optimise measurement accuracy for structures of varying heights. 2) It avoids transmitting large volumes of image data between the cameras and the 3D image-processing computer, reducing the need for high network bandwidth. 3) It simplifies the stereo calibration process by eliminating the need for a checkerboard, which is often impractical to be positioned in the field of view of the cameras in tall structure applications. An outdoor test was conducted to validate the system, with the cameras placed about 200 m from the target and 100 m apart. The results showed a measurement accuracy of approximately 1 mm within the horizontal plane.

**KEY WORDS:** Computer Vision, Structural Health Monitoring, Stereo Vision, Wireless Sensor, 3D Displacement Measurement.

## 1 INTRODUCTION

Vision-based systems provide a contactless alternative to traditional sensors. They enable the collection of structural displacement data for structural health monitoring (SHM). As a result, these systems have become popular in the SHM field. The imaging process projects objects in 3D space onto a 2D image plane [1]. Therefore, a single camera can only measure 2D displacement unless special calibration patterns are used.

To measure displacement in 3D, two cameras are combined into a stereo vision system. The depth information of objects is obtained through triangulation. Usually, both cameras are connected to a common controller computer via Ethernet cables. Before measurement, stereo calibration is performed to determine the essential matrix between the images from the two cameras. Next, the controller triggers and synchronizes the two cameras simultaneously to capture images. These images are then transmitted to the controller for processing, including stereo rectification, stereo correspondence, and 3D point reconstruction. Stereo vision systems have been successfully applied to measure the 3D displacement of structures such as wind turbines [2] and bridges [3].

However, measurement accuracy in depth decreases when the measurement distance increases if the distance between the two cameras (the baseline) remains constant. For tall structures, the distance between cameras and structures can be significant. To maintain measurement accuracy in depth, a baseline of potentially hundreds of meters is required. In such cases, conventional cable-based stereo vision systems become impractical.

To address this limitation, cable-free stereo vision systems have been developed. Yang et. al [4] introduced a mobile stereo vision system with an adjustable baseline distance. Images from the cameras are transmitted wirelessly to a controller computer. Sumetheeprasit et. al [5] developed a stereo vision system using two drone-mounted cameras with a variable baseline. However, existing cable-free stereo vision systems mainly target short-term, offline measurements. Long-term online monitoring poses additional challenges, such as ensuring

long-term synchronized image capture, managing the large bandwidth needed for wireless image transmission, and performing real-time stereo image processing. These challenges complicate the long-term online monitoring of tall structures.

This paper presents a novel wireless stereo vision system designed for long-term online monitoring of 3D displacement in tall structures. Figure 1 illustrates the overall workflow of this system:

- 1) The left and right cameras are strategically positioned to target a common point on the structure.

- 2) Stereo calibration is performed by measuring the relative geometrical relationship (the essential matrix) between the two cameras using GPS-RTK. A world coordinate system is established, with the origin located at the center of the left camera. The Z-axis extends from the center of the left camera toward the center of the right camera. The Y-axis points vertically upward, and the X-axis is defined according to the right-hand rule. This approach simplifies coordinate system transformation during 3D reconstruction.

- 3) Both cameras are simultaneously triggered by 10 Hz pulse-per-second (PPS)-based signals to capture synchronized images.

- 4) Reference images from both cameras are selected, and feature points are detected using the deep learning algorithm SuperPoint [6]. These detected points are matched using the LightGlue algorithm [7]. Bounding boxes around these matched point pairs serve as candidates for selecting a tracking target using the zero-normalized cross-correlation (ZNCC) algorithm.

- 5) The cameras capture images every half hour or one hour to document illumination changes throughout the day. The ZNCC scores of candidate targets across these images are calculated, and the bounding box with the highest ZNCC score is selected for long-term tracking.

- 6) Measurement begins, with each camera independently processing its captured images to determine the 2D pixel position of the selected target.

7) The extracted 2D data from each camera is automatically uploaded to Amazon Web Services (AWS) S3 for storage.

8) AWS Lambda computes the 3D displacement using the uploaded 2D data from both cameras.

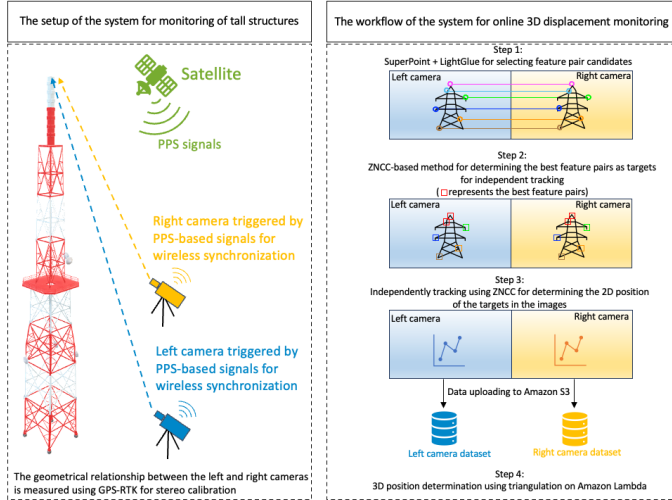

Figure 1. The workflow of the wireless stereo vision system.

## 2 WIRELESS STEREO VISION SYSTEM

### 2.1 Hardware

The wireless stereo vision system consists of left and right camera nodes, each with identical hardware components. Each node includes a SONY IMX296 camera with a lens, two Raspberry Pi 4B computers, a GNSS board, a GNSS antenna, and a 4G module. The camera can be triggered by external signals. To wirelessly trigger both cameras simultaneously, PPS signals are used. Once the first Raspberry Pi receives the PPS signal from satellites, it generates a 10 Hz trigger signal to control the camera's image capture. The PPS signal from the satellites occurs precisely at the start of every second, providing nanosecond-level accuracy. To ensure durability for long-term field operation, the hardware components of each camera node are enclosed in a CCTV camera housing.

Figure 2. The hardware of the left/right camera.

### 2.2 software

The software workflow for online 3D displacement monitoring is shown in Figure 1 and described in the Introduction. This section explains how 3D displacement is calculated from the 2D data captured by the two cameras.

In the proposed system, unlike conventional stereo vision systems, the left and right cameras are not permanently fixed during manufacturing. Instead, their relative positions can be

adjusted according to different scenarios. Therefore, stereo calibration must be performed before each measurement. Stereo calibration determines the essential matrix, which describes the geometric relationship between the image planes of the two cameras. This essential matrix combines the intrinsic parameters of the two cameras and a fundamental matrix.

Typically, the two cameras are placed far apart, with a large overlapping field of view (FOV), aimed at the top of the monitored structures. In this setup, using a calibration pattern to directly obtain the essential matrix is challenging. As a result, the intrinsic camera matrices and the fundamental matrix are calibrated separately.

The intrinsic matrices of the two cameras,  $K_{left}$  and  $K_{right}$ , can be obtained using Zhang's calibration method [8]. The fundamental matrix is calculated using GPS-RTK, as shown in Figure 3. The calibration process for the fundamental matrix follows these steps:

1) The coordinates of the left and right cameras, as well as the structure's ground level, are measured using GPS-RTK. A world coordinate system is defined with the origin at the center of the left camera. The camera centers are adjusted to point toward the target, and the roll angles are set to zero. The yaw angles of both cameras are then calculated. The left camera is located at  $(0, 0, 0)$ , and the right camera at  $(0, V, S)$ .

2) The target's coordinates in the world coordinate system are determined based on structural drawings. The pitch angles of the cameras are then calculated. The rotation matrix from the left camera's coordinate system to the world coordinate system is:  $R_{left} = R(Yaw_{left}) R(Pitch_{left}) R(Roll_{left})$ , where

$$R(Yaw_{left}) = \begin{bmatrix} \cos(Yaw_{left}) & -\sin(Yaw_{left}) & 0 \\ \sin(Yaw_{left}) & \cos(Yaw_{left}) & 0 \\ 0 & 0 & 1 \end{bmatrix}$$

$$R(Pitch_{left}) = \begin{bmatrix} \cos(Pitch_{left}) & 0 & \sin(Pitch_{left}) \\ 0 & 1 & 0 \\ -\sin(Pitch_{left}) & 0 & \cos(Pitch_{left}) \end{bmatrix}$$

$$R(Roll_{left}) = \begin{bmatrix} 1 & 0 & 0 \\ 0 & \cos(Roll_{left}) & -\sin(Roll_{left}) \\ 0 & \sin(Roll_{left}) & \cos(Roll_{left}) \end{bmatrix}$$

The translation vector from the left camera to the world coordinate system is  $T_{left} = (0, 0, 0)$ . Similarly, the rotation matrix and translation vector for the right camera are:  $R_{right} = R(Yaw_{right}) R(Pitch_{right}) R(Roll_{right})$  and  $T_{right} = (0, V, S)$ .

3) The fundamental matrix  $F$  between the left and right cameras is calculated by  $F = (R_{right} T_{right})^{-1} (R_{left} T_{left})$ . Then the essential matrix  $E$  is obtained as  $E = (K_{right})^T F K_{left}$ .

Figure 3. The determination of the foundation matrix.

### 3 VALIDATION TEST

To evaluate the measurement accuracy of the system, an outdoor experiment was conducted. The experimental setup is shown in Figure 4. A vertical cantilever, 2 meters in height, was used as the measurement target. The left and right camera nodes were placed at long distances from the cantilever—189 meters and 195 meters away, respectively. The baseline distance between the two cameras was 93 meters.

(a)

(b)

(c)

Figure 4. The setup of the validation experiment.

The stereo vision system measured the 3D displacement of an artificial target (concentric circles) placed at the top of the cantilever. For reference, the horizontal displacement was also measured using a separate 2D vision-based system. A chessboard target was used for this reference measurement.

The results from the stereo vision system were compared with those from the 2D reference system, as shown in Figure 5. The average root mean square error (RMSE) between the two measurements was 1.02 mm.

Figure 5. The measurement results of the validation experiment.

Email: r.u.khan@utwente.nl, r.kromanis@utwente.nl

**ABSTRACT:** Visual inspection remains the most fundamental and widely used method for assessing the condition of bridges. This process involves observation of structural surfaces at a close distance to identify visible signs of deterioration such as cracking, spalling, corrosion, and delamination. Traditionally, human inspectors perform visual inspections manually. This labour-intensive process is associated with many limitations, for example, subjectivity to an inspector's interpretation, difficulty accessing structural components, management of large volumes of unstructured data and the lack of consistent historical records. Recent advancements in computer vision and artificial intelligence have enabled considerable progress toward automating visual inspections. However, the full automation of visual inspections in practical, real-world scenarios remains constrained by several challenges: (i) the continued need for human intervention, (ii) the limited availability of high-quality labelled datasets, (iii) the generalizability of existing models, and (vi) the lack of standardized inspection protocols. In this positioning paper, we present an overview of the current state of automated visual inspection for defects identification in bridges. It reviews key open-source datasets of defects and state-of-the-art deep learning models. We give our forward-looking perspective on fully automated defects identification systems that align with standardized visual inspection guidelines.

**KEY WORDS:** Visual Inspection; Defects Identification; Condition Assessment; Automated Bridge Inspection; Computer Vision; Structural Health Monitoring (SHM); SHM at Local level.

## 1 INTRODUCTION

Bridges are critical components of our transportation infrastructure. Rigorous and timely inspections are needed to ensure their long-term performance and operational safety, and to avoid catastrophic failures. In general, bridge inspections are classified as general, principal, and special inspections. Each type of inspection serves a distinct purpose, i.e., from basic visual checks, to more in-depth often involving touching distance examinations, to address specific concerns or unusual events such as accidents (e.g., collisions by heavy loads trucks) or natural disasters (e.g., earthquake, flooding) [1]. Among these, visual inspection is the most employed method, particularly during general and principal inspections. It involves systematic observation of the bridge's surface to detect visible signs of deterioration such as cracking, corrosion, spalling, and delamination. These observable defects serve as initial indicators of potential structural issues and guide/suggest evaluation or maintenance actions.

The traditional visual inspection, while primary for initial defects detection, is inherently labour-intensive and often requires close-proximity access to structural elements, which is frequently unfeasible in hard-to-reach locations [2]. The process is also highly subjective, relying heavily on the individual expertise and judgment of trained inspectors. Research indicates a substantial probability (approximately 50%) of inconsistent classification of concrete defects when different inspectors evaluate the same defects [3]. This poses a significant challenge, as the availability of experienced personnel is steadily declining [4]. Inconsistencies often arise from the disconnect between the on-site surveyor and the off-site expert who interprets and documents findings, leading to a

potential mismatch between observed conditions and reported assessments. Also, inspections typically generate a huge amount of unstructured data, including images and reports. Historical inspection reports are rarely utilized in subsequent evaluations due to inadequate data organization and retrieval systems. This lack of continuity poses a challenge for inspectors to accurately visualize and locate previously identified defects, complicating re-localization of defects and trend analysis over time, which involves monitoring defects progression across inspections, identifying deterioration patterns, and anticipating future degradation or necessary interventions. These challenges collectively highlight the need for integrated, data-driven, and automated visual inspection workflows that improve consistency, traceability, and long-term asset management of bridges.

Recent advancements in computer vision (CV) and artificial intelligence (AI) have matured to a level that enables the enhancement and partial automation of visual bridge inspections [5], [6]. These technologies are promising for digitizing inspection workflows, making them significantly fast, reliable, and repeatable. By using AI-driven image analysis, defects identification, and data management systems, bridge visual inspections can be completely automated and independent of subjectivity. Previous literature reviews [7], [8] on CV and deep learning (DL) based bridge visual inspection, have provided foundational overviews of the field up to 2020. While valuable, these reviews have limitations that necessitate an updated perspective. For instance, [7] comprehensively covers structural health monitoring (SHM) with an emphasis on CV-based defects detection (e.g., cracks, spalling, delamination, rust, and bolt loosening). However, its scope is

restricted to datasets and algorithms available prior to 2020, thereby omitting crucial post-2020 advancements in both novel defect types and state-of-the-art AI-driven techniques. Similarly, [8] offers a broad exploration of DL-based SHM, encompassing CV, unmanned aerial vehicles (UAVs), vibration-based methods, and physics-informed approaches, effectively linking traditional machine learning with modern DL strategies. Nevertheless, it lacks critical discussion on the practicalities of real-world applications of visual inspection, the availability of experimental/test datasets, and open-source implementations, thus highlighting a significant gap in addressing deployment challenges and reliability of automated visual inspection. This collective gap highlights the urgent need for a contemporary position that re-evaluates automated visual inspections considering recent research advances and emerging trends, with a focus on improvements in the enrichment of defects dataset, DL-based defects identification algorithms, and practical deployment strategies.

In this positioning paper, we critically evaluate the current state-of-the-art in available defects datasets and DL-based defects identification algorithms, systematically identify the principal barriers to real-world implementation, and propose a forward-looking perspective on the future development of automated visual inspection of defects for bridges. The rest of the paper is organized as follows: Section 2 describes the dataset utilized for bridge defects detection, including data sources and characteristics. Section 3 details the baseline algorithms and the proposed enhancements for defects recognition. Section 4 provides a perspective on the future overview of automated visual inspection. Finally, Section 5 summarizes the overall position paper and draws conclusions.

## 2 RELEVANT DEFECTS DATASETS

Most highway bridges are reinforced concrete (RC) bridges [9]. While a reliable identification of RC defects is essential, existing datasets are often limited in size and class diversity, raising concerns about their real-world applicability and suitability as benchmarks. Over the past decade, significant progress has been made through datasets enabling binary classification [13, 23, 24, 25], multi-class classification [1, 7, 26], multi-label classification [16], binary semantic segmentation [8, 27], and multi-label semantic segmentation [10, 28, 29]. Each dataset contributes to advancing defects assessment methodologies reviewed in this section.

### 2.1 Binary-class classification

The Cambridge Bridge Inspection Dataset (CDS) [10] combines two primary data sources to enhance defects recognition in RC structures. The first source comprises 21,284 high-resolution images captured from 10 RC highway bridges in Cambridge. The focus is on critical structural elements such as decks, columns, piers, and abutments. Since these bridges are in good condition, the dataset lacks sufficient diversity of defects. To address this limitation, a second set of 22,121 images was incorporated from the U.S. Federal Highway Administration and the Georgia Department of Transportation, enriching the dataset with a variety of examples of defects. All images are categorized into two classes “healthy” and “potentially unhealthy,” providing a foundational binary classification benchmark for structural condition assessment. This hybrid approach ensures broad applicability. SDNET [11]

is also a large-scale binary annotated image dataset designed to train, validate, and benchmark AI-driven crack detection models for concrete structures. Comprising over 56,000 images of cracked and non-cracked surfaces of diverse structural elements such as bridge decks, walls, and pavements. The dataset captures a wide range of crack widths, from 0.06 mm to 25 mm, enhancing its applicability to real-world scenarios. SDNET incorporates various challenging conditions such as shadows, surface roughness, scaling, edges, holes, and background debris, simulating shared challenges encountered in visual inspections. While the dataset covers many structural elements, its initial version suffered from labeling inaccuracies, which may require preprocessing or correction for reliable model training. Despite this limitation, SDNET remains a valuable resource for advancing automated structural defects assessment.

The Image-based Concrete Crack Database (ICCD) [12] is developed using 1,455 high-resolution crack images captured via smartphone from suspension bridge towers and anchor chambers in Dalian, China. To ensure diversity, images were taken at varying distances (0.1 – 1.0 m) and under different lighting conditions (daylight, nighttime, direct sunlight, and shaded surfaces), simulating real-world inspection conditions. These images were then cropped into  $256 \times 256$  px patches and manually labeled into two classes – cracked and uncracked concrete. Through data augmentation, the final dataset was expanded to 60,000 images, significantly enhancing its utility for training robust DL models in automated crack detection. This approach improves generalization and addresses variability in real-world visual inspection scenarios. The Bridge Crack Dataset (BCD) [13] is specifically designed for robust crack detection in bridge inspection scenarios. The original dataset consists of 2,068 images of bridge cracks, which were processed and augmented to generate 6,069 image patches, optimizing them for DL applications. To enhance real-world applicability, the dataset intentionally includes challenging conditions such as bridge shading, water stains, and bright light reflections, common obstacles in field inspections. By incorporating these complexities, BCD serves as a valuable benchmark for developing generalizable and noise-resistant crack classification models, ensuring practical utility in automated visual inspection systems. While these datasets provide valuable benchmarks for binary crack detection, they suffer from critical limitations, for example, CDS [10] lacks natural defects diversity, SDNET [11] has labeling errors, ICCD [12] relies on artificial augmentation, and BCD's [13] small scale and synthetic challenges may not reflect real-world complexity.

### 2.2 Multi-class classification

The Bearing Condition State Classification dataset [14] comprises 947 annotated images of structural bridge bearings. The annotations adhere to the condition state assessment guidelines outlined by the American Association of State Highway and Transportation Officials [21] and the Bridge Inspector's Reference Manual [22]. The dataset categorizes steel corrosion into four distinct condition states: good, fair, poor, and severe. Detailed annotation guidelines, along with explanatory examples, are provided to ensure consistent and accurate condition assessment. The dataset serves as a valuable resource for visual inspection and deterioration assessment of

bridge bearings. The Multi-classifier Dataset (MCDS) [3] consists of 38,408 annotated images capturing various deterioration patterns in concrete structures. Defects are classified into eight distinct categories including spalling, cracks, rust staining, efflorescence, scaling, abrasion/wear, exposed reinforcement, and general defects. This comprehensive taxonomy enables detailed analysis of concrete degradation assessment and supporting visual inspection.

### 2.3 Multi-label classification

Concrete DEfects BRIDGE Image (*CODEBRIM*) dataset [16] is the largest and most realistic multilabel dataset for RC deterioration classification. The dataset categorizes defects into six distinct classes: crack, spalling, exposed reinforcement bar, efflorescence, corrosion, and background. The unbalanced version of *CODEBRIM* consists of 7,729 annotated image patches extracted from 30 bridges, selected to represent diverse deterioration levels, defects sizes, severity, and surface textures. High-resolution images were captured under different weather conditions and using multiple cameras at different scales. To address accessibility challenges, a subset of data was acquired via UAV for defects located at elevated positions. Despite its comprehensiveness, *CODEBRIM* present a key challenge for real-world transferability. The dataset is composed of cropped image patches, where original images are subdivided into rectangular segments based on maximum defects dimensions. This approach may disrupt contextual information, which is critical for holistic defects assessment.

### 2.4 Binary-class semantic segmentation

The *UAV75* dataset [17] comprises 75 images featuring pixel-wise manual annotations for binary semantic segmentation tasks. This dataset provides precise delineation of target features at the pixel level, enabling detailed analysis of structural characteristics. The fixed image dimensions and binary classification scheme facilitate consistent model training and evaluation, while the limited sample size positions this dataset as a specialized benchmark for targeted applications in structural assessment. Kulkarni et al. [18] introduced *CrackSeg9k*, currently the largest and most diverse binary crack segmentation dataset, comprising 9,255 images aggregated from ten preexisting sub-datasets including *Crack500*, *Deepcrack*, *SDNET*, *CrackTree*, *GAPs*, *Volker*, *Rissbilder*, *Noncrack*, *Masonry*, and *Ceramic*. The dataset addresses key limitations in individual source datasets (e.g., noise, distortion) through standardized preprocessing, while maintaining diversity in surface materials (concrete, masonry) and crack morphologies. Despite its focus on binary crack segmentation as shown in Figure 1, the dataset's practical utility depends on recognizing at least nine distinct defect types. Notably, *CrackSeg9k* homogenizes acquisition conditions including camera pose, lighting, and hardware across sub-datasets to minimize confounding variables. This curation enhances its reliability for benchmarking semantic segmentation algorithms in visual inspection for RC defects applications.

### 2.5 Multi-label semantic segmentation

The Structural Defects Dataset (S2DS) [20] is the first multi-class semantic segmentation dataset for RC defects analysis, containing 743 annotated images of RC bridges. It classifies five defect types: cracks, spalling, corrosion, efflorescence, and

vegetation along with control points for georeferencing as shown in Figure 2. While the dataset is pioneering in enabling multi-class segmentation and features high-quality manual annotations by a trained expert, its limited size and diversity raise concerns about real-world applicability. The *dacl10k* dataset [5] represents the first large-scale benchmark for multi-label semantic bridge defects segmentation, featuring 9,920 annotated images sourced from bridge inspections in Germany between 2000 and 2020. Developed to support AI-assisted defects recognition and documentation, the dataset aligns with structural inspection guidelines, focusing on defects that can be legally assessed. It includes 19 classes as shown in Figure 3 categorized into concrete defects, general defects, and objects, capturing complex real-world scenarios where multiple defects often overlap. The *dacl1k* dataset [19] addresses critical limitations in existing RC defects datasets by providing 1,474 uncropped, real-world inspection images with multi-label annotations across five damage classes including Crack, Efflorescence, Spalling, Bars Exposed, Rust, and a No Damage category, derived from diverse sources including authorities and engineering offices. Unlike datasets such as *CODEBRIM* (which uses cropped patches) or *MCDS*, *dacl1k* preserves raw image heterogeneity varying in camera types, poses, lighting, and resolutions to better reflect real inspection challenges. However, while its diversity enhances practical applicability, the dataset's small size (1,474 images) and moderate label count (2,367 total labels) raise concerns about statistical robustness and class balance. Despite the shortcomings, *dacl1k* represents a step toward bridging the gap between controlled research datasets and actual field conditions, though larger-scale, more granular annotations and rigorous benchmarking remain unmet needs for reliable *RC defects* assessment.

Figure 1. CrackSeg9k's categorization of crack types [18]

## 3 DEFECTS IDENTIFICATION MODELS

Dong et al. study [7] provide a detailed review of computer vision-based structural health monitoring at local level (CV-SHM-LL), outlining various applications and methodological approaches. The work scrutinizes a wide range of models designed for localized analysis, including both patch-based and pixel-based techniques. Additionally, it discusses traditional methods alongside data-driven machine learning approaches. However, it is limited to approximately eight types of structural defects. Cha et al. [8] provides a broad overview of DL-based SHM techniques applied to various infrastructure systems, such as bridges, and different construction materials like concrete and steel. The study extensively reviews the historical development of DL architecture, as illustrated in Figure 4. However, it does not explore deeply into the precise

Figure 2. S2DS Classes and Labels: crack (black), spalling (red), corrosion (orange), efflorescence (blue), vegetation (green), and control point (purple) [20]

application of visual inspection methods for bridges defects identification and their real-world implementation challenges.

Hüthwohl et al. [10] proposed an automated method for detecting intact concrete areas using image segmentation and classification. By applying morphological operations to generate boundary masks, their approach filters out defects-free regions, optimizing inspection efficiency by concentrating analysis on potential damage zones. Dorafshan et al. [11] introduced SDNET dataset and benchmarked performance using AlexNet [23], validating the dataset's utility for algorithm development. Li et al. [12] developed a convolutional neural network (CNN) based crack detection method using an enhanced AlexNet [23], overcoming traditional limitations like noise sensitivity. Their model achieved 99.06% validation accuracy and was deployed as a smartphone app for real-world use. Xu et al. [13] developed an end-to-end CNN-based crack detection model. Achieving 96.37% accuracy without pre-training, it outperformed traditional methods and showed potential as a versatile feature extraction module for other networks.

Hüthwohl et al. [3] developed a three-stage multi-classifier system for concrete defects detection in bridges using fine-tuned deep neural networks trained on multi-source inspection data. Their approach first identifies five defect types along with defects-free areas, then detects exposed reinforcement, and finally recognizes rust staining. The approach achieves 85% average classification accuracy. Mundt et al. [16] developed a meta-learning approach for automated CNN design targeting multi-defects concrete classification. Using their CODEBRIM dataset containing images with overlapping defects, they employed MetaQNN [24] and ENAS [25] reinforcement learning methods to generate optimized architectures. The resulting CNNs achieved higher multi-target accuracy than manually designed models while using fewer parameters, with validation accuracy serving as the reinforcement learning (RL) controller's reward signal. Benz et al. [17] presents CRACKNAUSNET, a transfer learning-based CNN for crack detection in unmanned aircraft system (UAS) imagery,

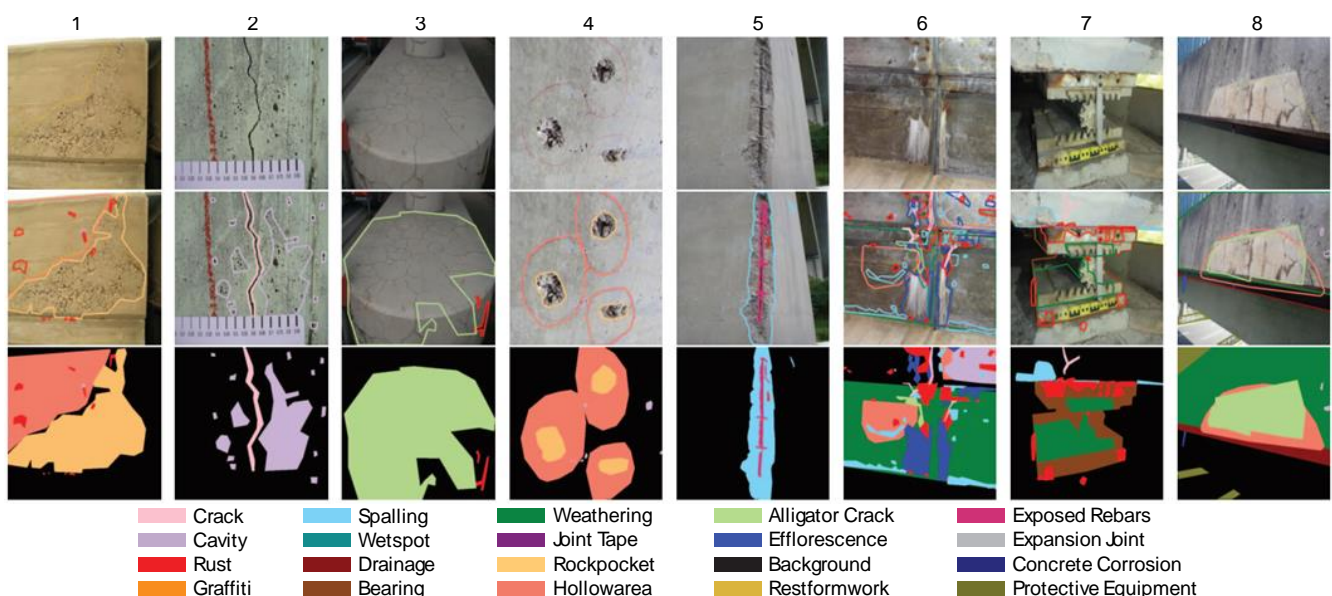

Figure 3. dacl10k dataset and labels [5]. The font size of the caption has been adjusted for clarity.

Figure 4. Popular architectures of DL over the years [8]

adapting TerausNet [26] with VGG16's [27] first 16 layers as a pre-trained encoder. The model addresses UAS-specific challenges (low resolution, faint cracks, planking artifacts) using the novel UAV75 dataset, which includes a dedicated class to mitigate planking-induced false positives, where inspection planks were mistakenly identified as defects. While achieving 75% average accuracy on UAV75 outperforming existing approaches, the model's performance declined on external datasets, indicating dataset-dependent effectiveness.

Kulkarni et al. [18] proposed an advanced crack segmentation framework combining YOLOv5 [28] for detection, DINO for unsupervised feature extraction, and FPN-based models [29] for precise segmentation. Their approach utilizes self-supervised transformer attention to enhance CNN performance, overcoming challenges like crack variability and background noise. The method was validated on a newly compiled, meticulously annotated dataset demonstrating improved generalization across diverse crack types and surfaces.

The study [20] proposed a hierarchical multi-scale attention (HMA) model for multi-label semantic segmentation using an HRNet-OCR backbone to oversee objects of varying sizes. The model employs contrastively learned attention maps to dynamically fuse multi-scale features, enhancing pixel-level and contextual representations through transfer learning from Cityscapes. A significant contribution is the line-based tolerant IoU metric designed specifically for crack detection, addressing the shortcomings of conventional area-based metrics (IoU/F1). The evaluation compared CNN-based architectures (DeepLabV3+, FPN with MobileNetV3 / EfficientNet encoders, some with auxiliary losses) and Transformer-based SegFormer (trained with Dice loss). All models used Adam optimization with cosine learning rate scheduling, ImageNet initialization, and 512×512 input resolution over 30 epochs, demonstrating the approach's effectiveness particularly for challenging crack segmentation tasks.

The dacl-challenge [6] aimed to advance automated defects identification in bridges using its large, real-world dataset. It benchmarked CV models as shown in Figure 5 for accurate, detailed detection and classification of bridge defects and components.

a) *Baseline Model:* The dacl-challenge baseline employed SegFormer [30] MiT-b1, pre-trained on ImageNet-1k [23]. This model features a multi-label segmentation head and a compact encoder with 13.1M parameters. For the challenge, SegFormer was trained for 10 epochs on the development set and 30 epochs on the final test set.

- b) *First Place Approach (Sheoran):* The top-performing solution by Sheoran utilized an ensemble of predictions from several models. Initially trained with MMsegmentation, the models were adapted to the segmentation-models-pytorch library for multi-label handling. The training process incorporated diverse augmentations and the RangersLars optimizer. Predictions from six distinct models were aggregated for specific classes, leading to enhanced overall performance.
- c) *Second Place Approach (Bridge Protector):* Bridge Protector's approach involved training the Mask2Former model [31] with an InternImage-H [32] backbone using the MMsegmentation framework. Pre-trained weights from the ADE20K dataset [33] were utilized. To address the multi-label nature of the data, the problem was divided into 19 individual binary segmentation models, one for each class. The outputs of these 19 models were then combined.
- d) *Third Place Approach (Winning Wieners):* Winning Wieners combined a feature pyramid network (FPN) [29] with a multi-axis vision transformer (MaxViT) [34] as the backbone. MaxViT integrates convolutional blocks with the attention mechanism of vision transformers. The xlarge version of MaxViT, pre-trained on ImageNet, was used. The model was trained using a five-fold cross-validation strategy, resulting in an ensemble of five models. Prediction-level threshold optimization was performed for the final ensemble.

Top-performing approaches heavily used transfer learning and adapted existing architectures, potentially limiting exploration of novel structural defects segmentation techniques. Their performance is more sensitive to training configurations than architectural innovation. While ensemble learning improved the results (see Figure 5) their computational cost warrants investigate efficient high-performance strategies. The bar chart presented here shows only the top performance values for defects (objects excluded), compared to the baseline performance. While many deep learning-based approaches for structural defects identification in bridge infrastructure achieve high accuracy using CNNs, transformers, and ensemble methods, their generalizability is often constrained by dataset dependency, high computational demands, and reliance on pre-trained architectures. Future research should prioritize the development of specialized models and training strategies tailored to visual structural assessment, moving beyond generic transfer learning paradigms.

#### 4 FUTURE OVERVIEW OF VISUAL INSPECTION

Over the past decade, different AI and CV-based methodologies have been proposed for the identification of

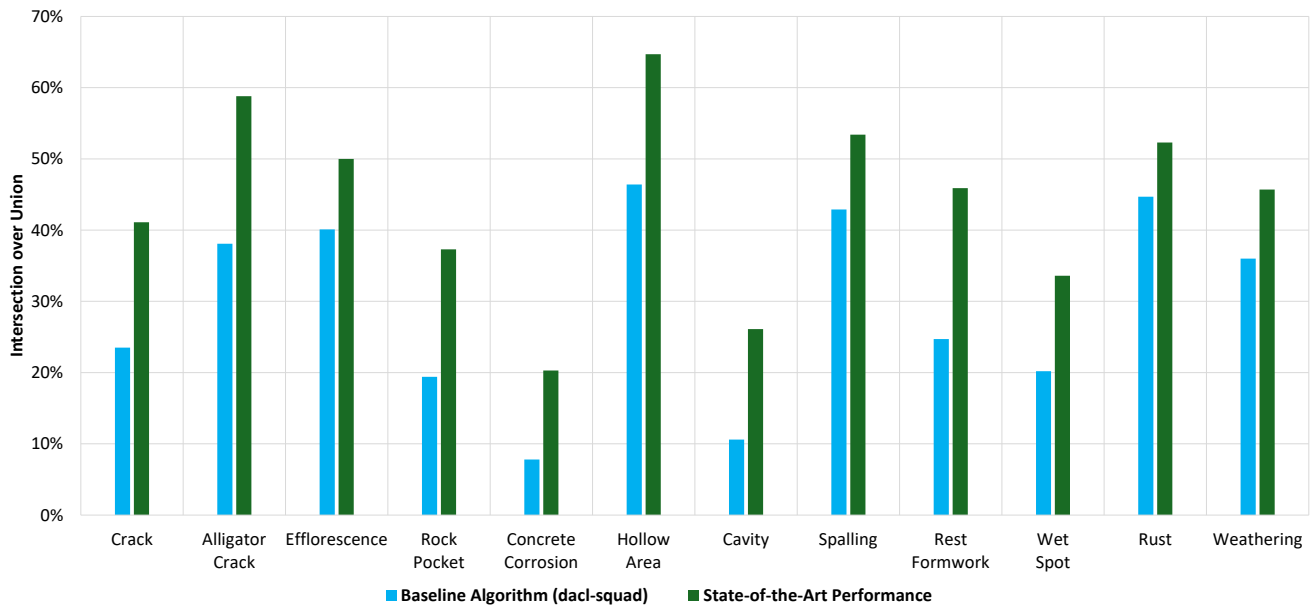

Figure 5. dacl-challenge: state-of-the-art performance achieved vs. baseline algorithm accuracy (% IoU) [6]

local-level defects [7], [8], [36], [37], [38], [39], [40], [41]. However, despite promising results in controlled research settings, many of these solutions have not yet achieved the robustness or scalability approaches for deployment in real-world environments. Most current approaches fall short of industrial standards and remain insufficient for fully automating visual inspections under diverse operational conditions. Thus, while foundational technologies are in place, further developments, validations, and standardizations are necessary to enable their widespread adoption in bridge inspection practices.

Despite all current advancements, the complete automation of visual bridge inspection remains unrealistic at present. This is primarily due to the complexity of standardized inspection protocols such as NEN 2767 in the Netherlands [42], AASHTO in the United States [21], CS 450 in the UK [43], CSA-S6 in Canada [44], AS5100.7 in Australia [45]. These standards define a multi-layered assessment framework, spanning from general structural classification to detailed defects evaluation. For example, NEN 2767 organizes infrastructure assessment across five hierarchical levels. Figure 6 represents inspection levels with an example decomposition for a RC bridge.

- Level-1.** Element Group (i.e., type of bridge such as reinforced concrete) bridge,
- Level-2.** Elements (i.e., main parts of that bridge such as handrail),
- Level-3.** Building Components (i.e., sub-parts of element such as the structural frame of a handrail and protective coating),
- Level-4.** Materials (i.e., material type of each building component (e.g., steel for the structural frame and paint for the protective coating),
- Level-5.** Defects (i.e., defect types of building component, like corrosion and rust in case of steel handrail, color peel off in case of paint coating).

During visual inspection, inspectors primarily interact with bridge at material and defects levels. For each observed defect, the inspector manually assigns three critical parameters including severity, extent, and intensity. These judgments, informed by domain expertise, are used to calculate the condition score for each building component (Level-3), which are then aggregated to yield scores for Elements (Level-2) and the overall condition index for the entire Element Group (Level-1). In the NEN 2767 standard the condition score ranges from 1 (very good) to 6 (very poor). It quantifies the current condition of inspected components of the inspected bridge based on observed defects.

While CV techniques have made substantial progress in defects identification (i.e., detection, localization, and classification of defects such as cracks, corrosion, or spalling), the current state of approaches are not yet capable of reliably performing the significant evaluation required by inspection standards. Specifically, automatic quantification of defects parameters (severity, extent, and intensity), contextual cause analysis, and risk assessment still require manual measurements and expert's (e.g., inspector's) interpretation. As a result, human oversight remains essential, and existing AI-based inspection systems are best viewed as decision-support tools rather than fully autonomous solutions.

To fully understand the current limitations in automating bridge inspections, it is important to examine the fundamental challenges associated with defects identification across multiple levels. In SHM, first Rytter in 1993 [46] and then Worden et al. in 2004 [47] outlined hierarchical levels of damage identification including damage detection, localization, classification, assessment, and prediction. While damage refers to changes in structural properties that adversely affect performance, defects in the visual inspection refer to observable surface-level anomalies. An equivalent framework of object detection as previously highlighted in [48] and now in further extended form, as shown in Figure 7, can be applied to CV-based defects identification. The following levels for

object (or defects, in this case) identification are defined: detection, localization, classification (or segmentation), quantification, and propagation. Currently, most CV-based approaches [6] in bridge inspection have achieved automation up to the classification (or segmentation) level, identifying and labelling regions of interest such as cracks or corrosion patches [7], [8]. However, progressing to quantification is essential to comply with inspection standards, which require precise evaluation of defects parameters (severity, extent and intensity) to calculate the condition score of a component (refer to Figure 6).

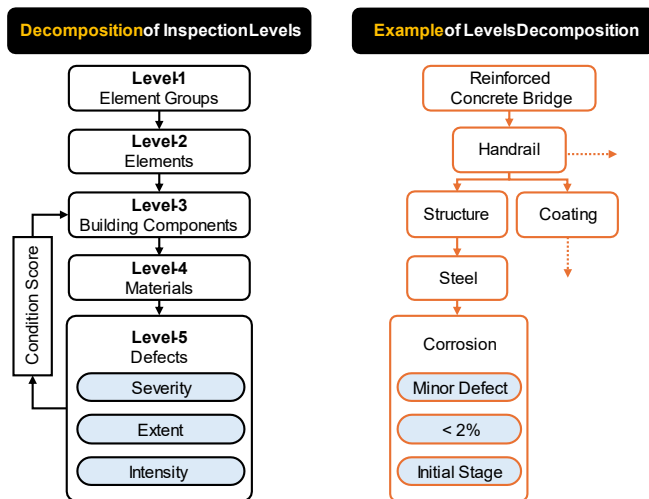

Figure 6. Decomposition and example of levels of inspection process in NEN 2767 standard

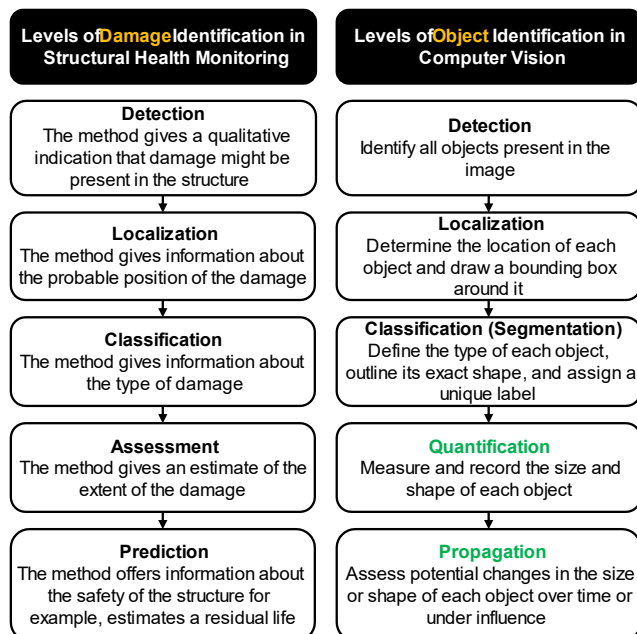

Figure 7. An identification analogy between damage identification [24], [25] and object (or defects in this case) identification

While limited success has been achieved in quantifying specific types of defects (e.g., crack width and length) [49], [50], [51], [52], [53], the methods are not generalized across the

wide spectrum of defects encountered in practice. For instance, NEN standard alone defines approximately 128 distinct defect types relevant to bridge visual inspection, each with distinct characteristics and assessment criteria [42]. This diversity presents a significant challenge for developing universal quantification algorithms. Once automated systems can reliably assign defects-level (Level-5) condition scores as shown in Figure 6, this would enable near-complete automation of the visual inspection process and facilitate systematic and periodic data collection at the local (defects) level.

To address these limitations and pave the way for practical CV-SHM implementation, this paper proposes an automated visual inspection system with a future direction, as conceptually illustrated in Figure 8. The proposed system is envisioned as a continuously evolving ecosystem, driven by progressive enhancements in defects identification capabilities and adherence to established inspection standards, such as the Dutch NEN2767 standard. It is initially trained on a comprehensive dataset synthesized by merging existing state-of-the-art datasets, specifically curated to encompass a diverse range of defect types. A user-friendly application is developed in close collaboration with visual inspection experts to ensure seamless integration with current inspection workflows. Once it achieves a satisfactory level of performance, the system is deployed across various on-site inspection platforms, including mobile devices, tablets, drones, and augmented reality (AR) headsets. In its operational phase, the system functions as a semi-autonomous tool for human inspectors. It provides real-time defects predictions, allowing inspectors to contribute their expertise through manual annotations and comments. All data, including system predictions and human input, are securely stored on a cloud platform, facilitating continuous expert evaluation and ongoing system refinement. Furthermore, the system integrates AR tools to analyze historical defects data, including location and characteristics, to predict future defects propagation over time. This predictive capability empowers initiative-taking maintenance strategies and enhances the long-term sustainability of bridges and other civil infrastructures.

## 5 CONCLUSION

This paper reviews RC defects datasets for bridges and state-of-the-art algorithms and proposes an automated visual inspection system for computer vision-based structural health monitoring at local level (CV-SHM-LL) that integrates deep learning methodologies with standardized inspection protocols and human expertise to advance bridge inspections. Addressing current limitations in data availability, holistic component-level defects evaluation, and deployment feasibility, this study aims to translate theoretical advancements into practical solutions for enhanced SHM. The following conclusions can be drawn from this positioning paper:

- To improve the reliability, robustness, and resilience of the inspection systems, it is necessary to utilize and integrate comprehensive and diverse datasets with unique types of defects, and state-of-the-art prediction models.
- For the inspection system to be useful in real-world scenarios, it must be able to quantify defects by determining their extent, severity, and intensity. This will allow for a step-by-step approach to reach level of quantification as shown in Figure 7.

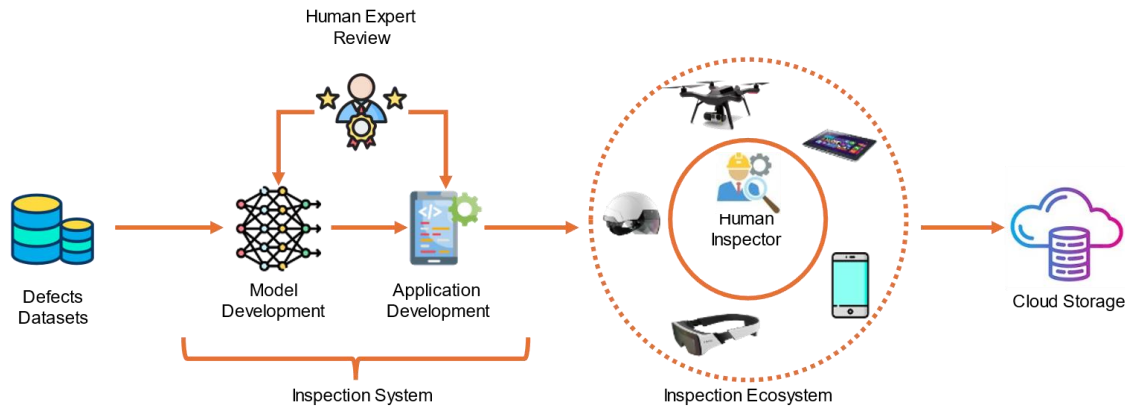

Figure 8. Proposed visual inspection system and future overview of CV-SHM-LL

- Inspection standards must be applied to connect surface-level observations with a deeper understanding of overall structural behaviour. This will bridge the gap to achieving insights into global structural performance.

Future research should focus on the deployment of lightweight neural networks and integration of augmented reality (AR) features on handheld edge devices. This interface should enable the visual overlay of previously identified structural anomalies onto the physical infrastructure. This capability would facilitate targeted inspection efforts and the identification of how defects propagate over time. By leveraging computational models, such an AR-enhanced system should aim to provide inspection personnel with intuitive, real-time data to enable efficient and comprehensive structural evaluations.

## ACKNOWLEDGEMENT

This project has received funding from the European Union's Horizon 2022 research and innovation programme under grant agreement No. 101119554 "BRIDGITISE" (call HORIZON-MSCA-2022-DN-01).

**ABSTRACT:** This study presents an integrated intelligent framework for bridge inspection that synergizes Mixed Reality (MR) technology, deep learning-based object detection, and domain-specific engineering knowledge. Utilizing Microsoft HoloLens 2 as the hardware platform, the system captures real-time 3D bridge surface imagery and deploys the optimized YOLOv11n-ZY model—enhanced with a ZZ convolutional module, YY attention mechanism, and SPPF-LSKA fusion module—to automatically detect and classify multi-category defects including cracks, corrosion, and spalling. Detection results are visualized within an MR interface and dynamically assessed through embedded expert knowledge. Validated on a custom dataset containing 4,176 images of 12 defect types under complex backgrounds, the proposed model achieves 40.3% mAP50 at 60 FPS with only 2.87 million parameters, outperforming existing YOLO variants. Implementation at the case study bridge demonstrates real-time defect localization, 3D model updating, and closed-loop maintenance functionality. The framework advances intelligent infrastructure management by establishing a scalable pipeline for accurate defect assessment and lifecycle-oriented bridge maintenance.

**KEY WORDS:** HoloLens 2; Object detection; YOLOv11; Visualization interface; Intelligent bridge operation and maintenance.

## 1 INTRODUCTION

As a critical component of modern transportation infrastructure, bridges are essential for maintaining socio-economic stability and ensuring public safety [1]. Consequently, their structural safety, stability, and health status are of paramount importance.

At present, traditional inspection methods, while capable of detecting visible defects such as cracks and corrosion, are constrained by inefficiency, heavy dependence on specialized knowledge, and challenges in handling complex environments, limiting their application in modern bridge inspection [2]. However, with the rapid development of computer vision technologies, deep learning-based object detection algorithms (e.g., YOLO, Faster R-CNN) have gradually been introduced into industrial defect detection, achieving significant improvements in efficiency and accuracy.

In the field of bridge defect detection [3], Mixed Reality (MR) technology has also provided novel solutions to traditional inspection approaches. Utilizing devices like HoloLens 2, 3D models can be projected into the real world, enabling engineering personnel to observe bridge surfaces from multiple angles and dimensions, thereby enhancing defect identification accuracy. For instance, certain Chinese bridge institutes have integrated 3D laser scanning with BIM technology to control modeling errors within  $\pm 2\text{mm}$  [4]; however, algorithm robustness in complex environments still requires further improvement.

The integration of emerging technologies such as deep learning, augmented reality (AR), and mixed reality (MR) has rendered bridge defect detection more efficient, precise, and intelligent [5]. At the same time, machine learning approaches have been integrated for defect detection in concrete structures

in the past few years [6]. Nonetheless, adaptability to complex environments and capabilities for lifecycle management still need enhancement to better meet practical operational demands.

This study aims to develop an intelligent bridge defect detection system by integrating multiple technologies. The research focuses on two main objectives.

First, HoloLens 2 is leveraged to develop a mixed reality system that enables 3D visualization, virtual-physical integration, and multi-dimensional defect observation.

Second, the system combines real-time scanning data processed by YOLOv11 with pre-constructed 3D virtual models to create an innovative bridge inspection framework supporting long-term intelligent operation and maintenance.

## 2 UNITY-BASED 3D BRIDGE MODEL AND HOLOLENS 2 DEPLOYMENT

### 2.1 Case Study Bridge Information

This study selects the Wenxi Bridge (Figure 1) in Suijiang New County, Yunnan Province, China, as the exemplar bridge for the visualized intelligent bridge inspection platform. By leveraging the 3D scanning capabilities of HoloLens 2, comprehensive structural information of the bridge was collected. Through comparison with preliminary design drawings, discrepancies between the actual bridge structure and the original plans—caused by on-site construction adjustments or undocumented modifications—were effectively resolved, enabling the successful creation of a 3D model of the Wenxi Bridge in Unity.

Figure 1. Case study bridge - Wenxi Bridge.

The deck width of the case study Bridge is 9 m + 2×1.5 m (pedestrian walkways). The superstructure comprises 9×30 m prestressed concrete simply supported T-beams arranged in three-span continuous units. The substructure includes column piers, U-shaped abutments, and ribbed abutments, with foundation types consisting of spread foundations and pile foundations.

## 2.2 Characteristics of Mixed Reality (MR) Technology and HoloLens 2

Mixed Reality (MR) technology digitizes physical environments and integrates them with virtual objects to create a visualized interactive space where physical and virtual elements coexist. Compared to Virtual Reality (VR) and Augmented Reality (AR), MR not only superimposes virtual entities into real environments but also achieves precise spatial mapping and real-time interaction between virtual objects and physical spaces, forming a spatially consistent mixed reality environment [7].

Microsoft HoloLens 2 (Figure 2), the second-generation MR device released by Microsoft, demonstrates technical advantages in bridge defect detection [8].

Figure 2. HoloLens 2.

## 2.3 Unity Model Deployment on HoloLens 2

The mixed reality (MR) application development for HoloLens 2 is based on the following software and toolkits: Windows 10 SDK, Visual Studio 2023, HoloLens 2 Emulator, Unity 2022.3.53f1c1, Unity Hub, and MRTK 2.8. To ensure efficient development and deployment, the hardware configuration listed in Table 1 was adopted:

Table 1. Computer Hardware Configuration.

CPU	GPU	RAM	Storage	Display
i9-14900HX	RTX 4070	64GB	3TB SSD	2560x1600 / 240Hz / 18-inch

Deployment Workflow is described as follows. "Developer Mode" on both the host computer and HoloLens 2 within the Windows operating system is firstly enabled. And the following procedures are adopted.

### (1) Project Creation:

Create a new project via the Unity Hub integrated development environment and access the Build Settings interface. Select Universal Windows Platform (UWP) and execute the "Switch Platform" operation. This process automatically performs platform compatibility checks and restructures project resource formats through the underlying engine to meet UWP-specific technical requirements.

### (2) MR Toolkit (MRTK) Integration:

Import the Mixed Reality Toolkit using the Mixed Reality Feature Tool (MRFT).

The core principle involves modifying the manifestation configuration file to guide the Unity engine in correctly identifying and loading MRTK modules. Upon returning to the Unity environment, the system automatically initiates dependency detection and resource loading. Compared to traditional methods, MRFT integration effectively avoids dependency conflicts [7], significantly reducing the complexity of managing mixed reality toolchains.

### (3) Unity Project Configuration:

As mixed reality applications fall under the extended reality (XR) domain, activate Unity's built-in XR framework. After configuring the Player module, navigate to the XR Plug-in Management section and install the plugin management component. Enable the "Initialize XR on Startup" parameter and activate "Windows Mixed Reality" to ensure precise hardware-software compatibility, laying the foundation for subsequent MR development.

### (4) Unity Project Export:

Select the target scene file and configure parameters: (1) Set device compatibility to "Any Device" for universal platform support. (2) Select the x64 architecture for optimal runtime efficiency. (3) Optimize auxiliary parameters based on specific development requirements. Initiate the conversion of the Unity project to a Visual Studio solution via the Build button, establishing a standardized framework for application compilation and deployment.

#### (5) Deployment to HoloLens 2 Device:

Open the completed project in Visual Studio 2023 and proceed to the deployment parameter configuration phase. Simultaneously, ensure that the host development environment and the target device are connected to the same wired or wireless local area network (LAN), with sufficient network bandwidth to meet real-time transmission requirements for application image files, thereby guaranteeing the validity of the deployment process.

Within the Visual Studio integrated development environment (IDE), sequentially perform three critical configurations: (1) Program compilation using Debug mode; (2) Selection of the ARM64 instruction set architecture to align

with the target device's hardware specifications; (3) Configuration of remote computer deployment options.

Subsequently, input the target device's network IP address in the debugging parameters module and set the authentication protocol to Universal (Unencrypted) mode. After completing the above parameter configurations, initiate the compile-deploy automation process via the Start Debugging command.

This mechanism synchronously executes the generation of application binary files, their transmission, and device-side loading, establishing a complete end-to-end deployment pipeline. Through the above workflow, the Unity-based 3D model of the case study Bridge was successfully deployed on HoloLens 2, achieving 3D visualization as demonstrated in Figure 3.

Figure 3. 3D Model layout diagram of case study Bridge.

To accurately simulate defect morphologies under real-world conditions and enable interactive analysis of damage data within the HoloLens 2 digital model, high-fidelity defect simulations were integrated into the case study bridge model. Leveraging HoloLens 2's augmented reality system, 3D defect visualization and spatial mapping were implemented [10]. This framework, combined with depth perception and multi-source data fusion algorithms, supports three critical technical requirements: on-site auxiliary defect diagnosis, remote collaborative structural assessment by experts, and dynamic coupling analysis of multidimensional human-machine interaction

### 3 DATASET CONFIGURATION

This work referenced and adapted the data collection standards of the VisDrone2021 [11] dataset, employing methods including web crawling, video frame extraction, and filtering of multiple publicly available bridge defect datasets [12]. Simultaneously, to enhance the model's generalization capability and prevent overfitting, data augmentation techniques—such as random rotation [13], random occlusion, color jittering, Gaussian blur, and noise addition—were applied to the dataset [14], as shown in Figure 4.

Figure 4. Defects on the bridge.

The experimental dataset for this study was ultimately compiled and generated, containing 4,176 images. Label files for the dataset were created using the labeling tool, with a total of 32,201 annotated bounding boxes. These annotations encompass bridge defect information across multiple categories, including exposed reinforcement, spalling, corrosion, water seepage in wet joints, mold growth, and cracks, as illustrated in Figure 5. The dataset aligns with the simulated defect conditions previously generated on the Unity bridge model.

Figure 5. Spalling & Exposed reinforcement.

Distinct from traditional bridge defect datasets that focus on one or several common types of surface-level defects, the self-constructed dataset employed in this study—"Small-Target Detection Dataset for Multi-Category Bridge Defects under Complex Background Interference"—simultaneously incorporates 12 bridge defect types, including those with low occurrence frequencies. To replicate real-world inspection scenarios and simulate the scanning and observational perspectives of inspectors wearing HoloLens 2 for subsequent comparative analysis and digital model superimposition tasks, no image or semantic segmentation [15] is performed on bridge defects in this dataset, preserving full panoramic small-target detection and recognition. Furthermore, unlike conventional small-target datasets, bridge defect images in real-world scenarios exhibit challenges such as blurred backgrounds, high inter-defect similarity, strong deceptive features, and extremely

small defect targets. These characteristics lead to core technical detection challenges, including weak multi-scale target sensitivity, significant complex background interference, insufficient fine-grained feature representation, and high inter-category similarity. Through the aforementioned diverse image augmentation methods, the dataset is further enriched and expanded to enhance robustness. The highly challenging "Small-Target Detection Dataset for Multi-Category Bridge Defects under Complex Background Interference" imposes greater demands on subsequent target detection and recognition tasks.

## 4 YOLOV11 ALGORITHM

### 4.1 YOLOv11 Model Introduction and Advantages

Ultralytics recently released YOLOv11, designed as a detection model achieving state-of-the-art (SOTA) performance across multiple tasks. The architecture of previous models has been optimized, enabling YOLOv11 to attain cutting-edge

performance in diverse tasks (object detection, segmentation, pose estimation). The overall network architecture is illustrated in Figure 6.

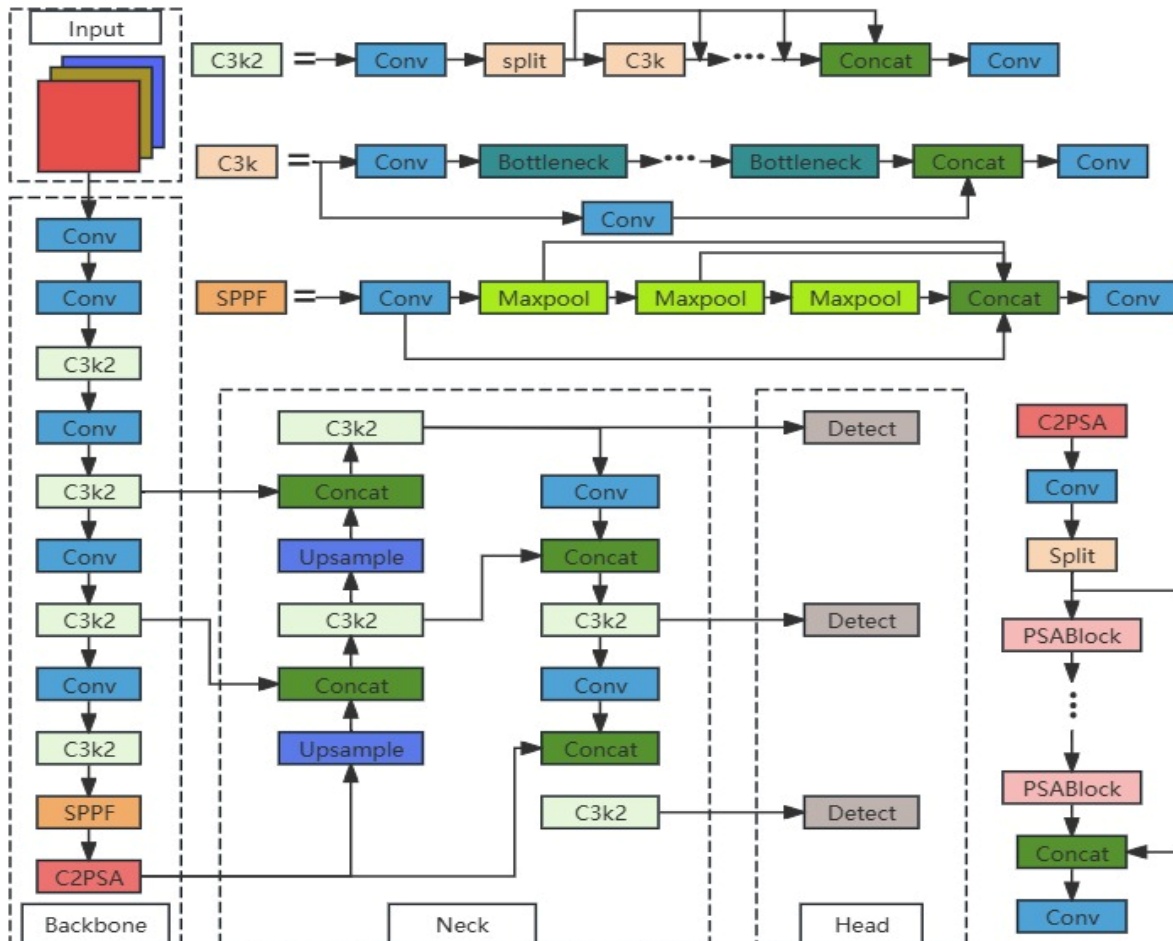

Figure 6. Overall network architecture diagram of YOLOv11.

Compared to YOLOv8, YOLOv11 reduces parameters by 22% on the COCO dataset while achieving higher mean Average Precision (mAP), as shown in Figure 7. Simultaneously, its inference speed is approximately 2% faster

than YOLOv10, reaching 60 frames per second (FPS), making it one of the fastest object detection models and providing enhanced support for real-time applications.

Figure 7. Performance comparison diagram between YOLOv11 and previous versions.

This study innovatively proposes the YOLOv11n-ZY model, an optimized and improved framework based on YOLOv11, to address core technical challenges in bridge defect detection tasks, including weak multi-scale target sensitivity, significant complex background interference, and insufficient fine-grained feature representation.

By deeply integrating the new ZZ convolutional module, new YY attention mechanism module, and SPPF-LSKA fusion module, a collaborative optimization system is constructed. The model adopts a hierarchical feature processing architecture, embedding three innovative modules into the feature extraction layer, attention enhancement layer, and multi-scale fusion layer, respectively, thereby establishing a complete technical chain from microscopic feature analysis to macroscopic semantic correlation. The three modules achieve compatible deep integration through granular allocation of computational resources and functional positioning: The ZZ module focuses on enhancing multi-granularity extraction efficiency of low-level features. The YY module implements domain-adaptive calibration during feature transmission. The SPPF-LSKA module accomplishes complementary fusion of multi-level semantic features. These three components collectively establish a progressive optimization pathway of “feature encoding → attention enhancement → pyramid fusion.”

At the parameter optimization level, the three modules respectively introduce learnable convolutional kernel scale ratios [17], dynamic attention weights [18], and large-kernel decoupled computation mechanisms. Through joint backpropagation, these components synergistically optimize the detection loss function. This hierarchically deployed collaborative paradigm provides a technical solution that combines theoretical innovation and engineering value for intelligent bridge defect detection.

#### 4.2 Simulation Environment

The simulation was conducted on a Windows 11 operating system with 3T memory and an RTX 4070 GPU (64GB VRAM). Python 3.8 was utilized, with the PyTorch framework (Torch 1.12.0 version). The YOLOv11n-ZY model was trained

for 200 epochs with a batch size of 32 and a learning rate of 0.01.

To evaluate the comprehensive performance of the model, this experiment adopts the following quantitative evaluation metrics: parameter count, precision (P), recall (R), mean average precision (mAP), frame rate (FPS), and F1-score. These metrics collectively characterize the model’s robustness across detection accuracy, computational efficiency, and multiple confidence thresholds [16].

The mathematical definitions of precision and recall are given in Equations (1) and (2), where TP (True Positives) denotes the number of correctly detected positive samples, FP (False Positives) represents the number of positive samples incorrectly classified as negative, and FN (False Negatives) indicates the number of undetected positive samples. The F1-score is defined by Equation (3), which is essentially the harmonic mean of precision and recall. In the field of object detection, mAP serves as a core evaluation metric, quantified through the weighted average of precision values across confidence thresholds, with its computational methodology detailed in Equations (4) and (5).

$$P = \frac{TP}{TP+FP} \quad (1)$$

$$R = \frac{TP}{TP+FN} \quad (2)$$

$$F_1 = 2 \cdot \frac{P \cdot R}{P+R} \quad (3)$$

$$AP = \int_0^1 p(r) dr \quad (4)$$

$$mAP = \frac{1}{n} \sum_{i=1}^n AP(i) \times 100\% \quad (5)$$

In the equations, the mAP reflects the balance between the detection precision and recall of the model across all categories (unit: %); mAP50 refers to the mAP value when the IoU is 0.5; AP<sub>i</sub> is the average precision of the *i*-th category; and *n* is the total number of categories.

#### 4.2.1 Comparison Experiments

To further validate the detection performance of the improved YOLOv11n-ZY model proposed in this paper, the algorithm is compared and analyzed with common algorithms in this field, and the results are shown in Table 2.

Table 2. Comparative Experimental Results.

Model	mAP50/%	P/%	R/%	Params/10 <sup>6</sup>
YOLOv5s	33.8	37.0	39.7	7.82
YOLOv8n	33.4	40.5	36.7	3.01
YOLOv8s	35.1	40.7	39.1	11.13
YOLOv11n	34.9	44.6	37.8	2.58
YOLOv11s	36.3	43.0	41.1	9.41
Ours	40.3	49.3	41.1	2.87

According to the experimental results in Table 2, compared to the detection results of previous official Yolo series models (Yolov5s, Yolov8n, Yolov8s), the proposed Yolov11n-ZY algorithm in this study achieves significant improvements in mAP50 by 6.5%, 6.9%, and 5.2%, while reducing parameter sizes by 4.95 MB, 0.14 MB, and 8.26 MB, respectively. Compared to the baseline model YOLOv11n and its series counterpart YOLOv11s, the Yolov11n-ZY algorithm achieves accuracy improvements in mAP50 of 5.4% and 4%, respectively, despite a slight increase in parameter size. In summary, the proposed algorithm outperforms other methods in the accuracy of "multi-category bridge defect small target detection under complex background interference," including mAP50, precision (P), and recall (R), while maintaining real-time performance and achieving an optimal balance in model size.

## 5 VISUALIZATION INTERFACE DESIGN

The visual interactive interface of the proposed detection and recognition system integrates the YOLOv11n-ZY model for bridge defect detection and recognition, featuring multi-modal input source processing capabilities (including static images, video streams, real-time camera capture, and batch file processing). A multi-threaded parallel processing mechanism is adopted to ensure real-time responsiveness of the human-machine interaction interface. Detection results are visualized in real-time through the graphical interface, with dynamic parameter adjustment functions (confidence threshold, IoU threshold) and detection process control interfaces (start, pause, terminate detection, and result storage). The specific visual interface system is shown in Figure 8.

Figure 8. Visualization interface for bridge defect object detection.

In the input source selection unit, specify the camera capture device or local file path; dynamically configure the confidence threshold (Conf) and Intersection over Union threshold (IoU) of the target detection model through slider controls. The background processing thread is automatically initialized upon configuration completion.

The system routes the processing results to the main thread, transmitting bounding box-annotated detection images via

the (*send\_detect\_img*) signal and category statistics via the (*send\_detect\_info*) signal. Finally, the streaming inference approach governs the actual inference loop, as illustrated in Figure 9, which includes: reading input sources (images, videos, camera streams, etc.), preprocessing, executing model inference, processing post-inference results, and transmitting final recognition outcomes to the visualization main interface through signals.

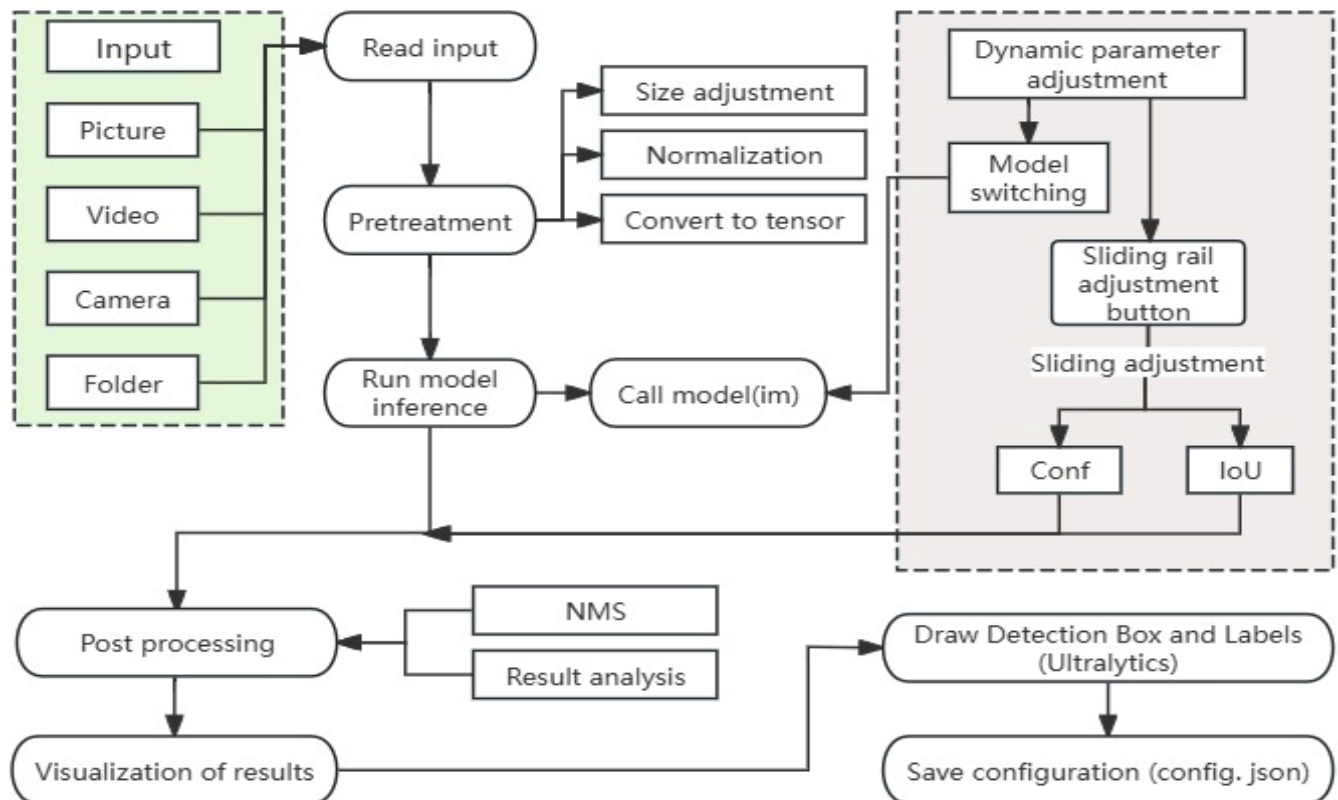

Figure 9. Flowchart of the visualization interface system operation.

## 6 CONCLUSION

Aiming at the bottleneck problems of low efficiency and insufficient accuracy in traditional bridge inspection methods, this paper proposes a "Comprehensive Visual Intelligent Bridge Inspection Platform" that integrates Mixed Reality (MR) technology, deep learning algorithms, and domain-specific bridge engineering knowledge. By leveraging the high-precision spatial perception capabilities of the HoloLens 2 device, the optimized architecture of the YOLOv11n-ZY model, and multimodal human-computer interaction technologies, a bridge defect detection system with real-time inspection, dynamic visualization, and full lifecycle management functions has been successfully established. Experimental results demonstrate that the improved YOLOv11n-ZY model significantly outperforms existing mainstream algorithms in detecting multi-category small-target defects under complex background interference, achieving a detection precision (mAP50 of 40.3%). Simultaneously, the MR technology facilitates closed-loop management of defect localization, remote collaboration, and dynamic 3D model updating. This study not only provides an efficient and reliable technical pathway for intelligent bridge operation and maintenance but also offers theoretical support and practical exemplars for the deep integration of mixed reality and deep learning in infrastructure inspection. Future work will focus on optimizing the lightweight deployment capability of the model, further enhancing the precision of the algorithm, expanding multi-source sensor data fusion mechanisms, and exploring a

digital twin-based predictive system for bridge performance throughout its lifecycle to advance the engineering application and standardized development of intelligent infrastructure inspection technologies.

## 3D projection of AI-derived concrete cracks on a Hydro Dam outlet tower

Ludvig Emgård<sup>1</sup>, SPOTSCALE

<sup>1</sup>Spotscale AB, Storgatan 42, 58223 Linköping, Sweden  
email: ludvig.emgard@spotscale.com

**ABSTRACT:** In a Structural Health Monitoring (SHM) project, a hydro-dam's outlet tower in Northern Sweden required inspection and assessment. This was due to the lack of digital records regarding existing damage and the client's concerns about its progression. The tower's location in a lake made traditional inspection methods like scaffolding or skylifts extremely difficult. The concrete engineering expert hired for the evaluation was uncomfortable with rope access, making data collection an expensive and cumbersome task. The structure is significantly affected by fluctuating water levels in the lake, leading to suspicions of certain types of damage (e.g., freeze-thaw damage, erosion damage).

For this project, a Phase One P3 camera was used to capture thousands of 100-megapixel images from every angle of the tower. Every inch of the concrete surface was covered by at least five different images.

From these images, a 3D reconstruction was created using Spotscale's proprietary software pipeline<sup>1</sup>, which is specifically designed for high-resolution processing. Subsequently, each image was analyzed by Spotscale's machine learning algorithm to detect cracks, spalling, and visible rebar. For every pixel on the 3D model, all images that observed that pixel were analyzed, and this information was used to project the best possible representation of the damage onto the model, creating a 3D texture of the damage.

The results revealed a distinct crack pattern, identified with a 98.7% confidence level when compared to human assessment of the same cracks. This provided the dam owner with a comprehensive understanding of the overall damage and an overview of the most severely affected areas.

**KEY WORDS:** 3D reconstruction; Machine learning; Crack identification; 3D visualization.

### 1 INTRODUCTION

Structural Health Monitoring (SHM) plays a crucial role in ensuring the safety and longevity of infrastructure. In this project, an outlet tower connected to a hydro-dam in Northern Sweden required inspection due to the absence of reliable digital records of past damage, combined with recent concerns about deterioration. The structure, situated in a lake and measuring approximately 30 meters in height, posed significant logistical challenges for traditional inspection techniques such as scaffolding, skylifts, or rope access.

Figure 1. An overview of the tower structure

Given these limitations and the client's need for high-resolution documentation, a remote sensing approach was adopted, enabling comprehensive data collection without direct human contact with the structure.

### 2 DATA

#### CAPTURING

To achieve detailed visual coverage of the entire concrete surface, a PhaseOne P3 camera with an 80 mm lens was mounted on a drone platform. A total of 3,000 ultra-high-resolution images (11664 × 8750 pixels each) were captured in a single day of fieldwork. The drone operated at a consistent distance of approximately 4 meters from the structure, resulting in a ground sampling distance (GSD) of 0.2 mm. This resolution ensured that even fine surface anomalies were detectable.

Every area of the structure was photographed from multiple angles, with at least five images covering each point on the surface, enabling robust 3D reconstruction and redundancy in damage analysis.

High-resolution imaging using the PhaseOne P3 setup involves pre-planned flight paths or starting coordinates for drones or stationary setups for static structures. This ensured complete coverage and minimized data gaps. The image collection for the needed accuracy was performed with a minimum of 80% overlap, with 7-10 meters distance to the object, ensuring that every defect was visible in at least 5 different images from different angles.

### 3 DATA PROCESSING

The captured imagery was processed using Spotscale's proprietary photogrammetry pipeline, optimized for handling high-resolution inputs and generating accurate 3D models. The resulting models are both metrically correct and visually intuitive, making them ideal for expert inspection and annotation.

Following model generation, Spotscale's AI-based damage detection system was applied. This system analyzes all available views of each pixel on the surface to detect features such as cracks, spalling, and exposed rebar. The AI consolidates information from overlapping images to create a high-fidelity texture projection of damage across the entire 3D surface, producing a visual damage map with sub-millimeter precision.

### 4 RESULTS

The final output was a detailed 3D model textured with detected damage patterns. The AI identified a prominent and recurring crack pattern, which was verified with a 98.7% confidence level when benchmarked against expert human assessments. Figure 2 illustrates the resulting damage map, with clearly visible areas of cracking and localized spalling. The damage texture allowed for both global overview and close-up inspection, enabling prioritization of critical zones for further manual investigation or remedial work.

By applying the AI interpretation, concrete experts can predict future decay such as concrete loss from the surface (spallings). The Spotscale software further enables the expert to measure depth on spallings that occurred in a sub-mm accuracy depth representation.

### 5 CONCLUSION

The combination of ultra-high-resolution imaging, advanced photogrammetry, and machine learning provided a complete and reliable overview of the structural condition of the outlet tower. The results were instrumental in helping concrete specialists understand the underlying causes of the damage, including environmental factors such as freeze-thaw cycles and water erosion.

Beyond the immediate inspection, this methodology offers several benefits: it reduces inspection time and cost, minimizes safety risks, and produces a digital baseline for future comparisons. The success of this project demonstrates the value of remote sensing and AI-powered analysis in modern infrastructure monitoring.

The AI algorithms are also able to detect and classify cracks based on predefined criteria, such as width and orientation. Each single crack can be interpreted as a separate object and represented either in projected raster on the geometry or as a 3D polyline along the center line (medial axis) of the crack (not performed on this specific project). To achieve this kind of geometry, the crack pixels are analyzed from several different viewpoints and compared before projected on the mesh. This analysis significantly enhances the robustness of the Spotscale approach. The ability to transform the pixels to 3D polylines (vectors) enables the possibility to

automatically determine medium and max width over the crack length and establish the length in three dimensions.

This innovative approach to non-destructive testing unlocks new possibilities in infrastructure monitoring, making it possible to conduct inspections with greater frequency, precision, and ease. Structures and areas that were previously inaccessible or hazardous to manually inspect—such as the undersides of bridges, confined spaces inside industrial facilities, or elevated constructions—can now be examined in high detail without requiring extensive scaffolding or safety interruptions.

The ability to assess these components without disrupting day-to-day operations or public life significantly broadens the application of this technology. For instance, critical assets like highway bridges, retaining walls, and overpasses can be inspected while traffic continues to flow, eliminating the need for costly detours or shutdowns. Similarly, energy and water utilities can maintain full operational output during inspection processes, reducing the risk of service interruptions and increasing overall efficiency.

With more precise data on structural health, renovation efforts can be optimized both spatially and chronologically. Repairs can be strategically localized and planned based on the most urgent needs, which minimizes waste and maximizes the lifespan of concrete infrastructure. Over time, this data-driven approach contributes to a more sustainable and resilient built environment, where maintenance decisions are grounded in actual structural behavior rather than estimations or reactive measures.

Figure 2. Resulting 3D projected AI interpretation of crack pattern

**ABSTRACT:** The dynamics and complexity of stochastic traffic flows play a crucial role in the management of infrastructure such as bridges. This study presents a computer vision-based method for random traffic flow identification and load estimation that integrates the YOLOv8 object detection model and the DeepSORT multi-target tracking algorithm. By utilizing high-resolution bridge surveillance video, the method can accurately identify vehicle type, axle count, and traffic flow. A case study conducted on an actual bridge validates the effectiveness of the method. The results show that the accuracy of vehicle identification based on 24-hour video data is more than 93%, the statistical error is less than 10%, and the temporal distribution of traffic flow matches well with the actual situation. This study provides a new technical reference for AI-based bridge traffic management and low cost structural health monitoring solutions.

**KEY WORDS:** Random traffic flow; Computer vision; Bridge monitoring; Object detection; Object tracking; Traffic flow statistical analysis.

## 1 INTRODUCTION

Stochastic traffic flow is one of the key research areas in traffic flow analysis, which is characterized by randomness and uncertainty in dynamic parameters such as vehicle arrival time, spacing, speed and type. In bridges and other critical infrastructures, the characteristics of random traffic flow can lead to irregular spatial and temporal load distributions, which can seriously affect the design safety and operational efficiency of the infrastructure. Stochastic traffic flow is equally crucial to understanding the performance of bridges under dynamic loading.

Studies [1], [2] linked traffic-induced dynamic amplification factors to bridge fatigue life, while [3] emphasized bridge health monitoring under frequent heavy traffic flow. [4], [5] investigated the effect of random traffic flow on bridge dynamics under consideration of pavement roughness and proposed structural maintenance strategies.

Therefore, accurate identification and statistical analysis of stochastic traffic flow is not only the basis for understanding traffic dynamics, but also an important tool for optimizing transportation systems and improving infrastructure performance.

Traditional methods for stochastic traffic flow statistics usually rely on dynamic weighing systems or radar techniques. Although these methods can capture key traffic flow parameters to some extent, they face limitations such as lack of real-time performance, limited accuracy, and high cost. In recent years, with the rapid development of computer vision technology, its application in the field of intelligent transportation has become a focus of research. Deep learning-based target detection and multi-target tracking technologies provide new solutions for real-time traffic flow information acquisition. By analyzing video streaming data, computer vision techniques can efficiently identify and quantify vehicle types, numbers, speeds, and lane distributions, providing the possibility of real-time monitoring of random traffic flows. However, how to improve the robustness of recognition and the accuracy of statistical analysis in complex and changing

environments remains one of the main challenges in current research.

The aim of this study is to develop an integrated approach for recognizing and statistically analyzing random traffic flows using computer vision to address the challenges in traffic flow research. The study integrates YOLOv8 object detection and DeepSORT multi-target tracking techniques to achieve real-time monitoring and accurate characterization of traffic flow in complex dynamic environments. The practical applicability of the method in stochastic traffic flow statistics is verified through a case study.

## 2 COMPUTER VISION-BASED FOR RANDOM TRAFFIC FLOW RECOGNITION

### 2.1 Video data capture settings and processing

High-resolution cameras are deployed on the bridge deck to capture real-time multi-lane traffic data, including vehicle types, counts, speeds, and directions. Data is collected across seasons and traffic conditions to ensure diversity. This non-intrusive method improves accuracy and efficiency over manual monitoring, avoids physical interference, and reduces costs compared to sensor networks.

Video data undergoes preprocessing (frame extraction, resolution normalization, and augmentation) to enhance model robustness. A labeled dataset of 12,000 images, annotated with vehicle types and axle counts, is split into training (75%), validation (15%), and testing (10%) sets for model development and evaluation.

### 2.2 Traffic flow object detection and tracking principle

This study employs an integrated approach combining YOLOv8 for vehicle detection and DeepSORT for multi-object tracking to analyze bridge traffic flows. YOLOv8, the latest iteration of the YOLO series, demonstrates superior speed and accuracy in vehicle detection. The algorithm processes images through a grid-based system ( $S \times S$ ), where each cell predicts bounding box coordinates ( $x, y, w, h$ ) and classification probabilities via convolutional neural networks. Experimental

validation yielded a training loss of 0.9 and F1 score of 0.88, with vehicle detection precision reaching 93% for cars, 85% for buses, and 89% for trucks.

DeepSORT enhances the system's capability by maintaining vehicle trajectory continuity across video frames. The algorithm integrates five key phases: (1) initial detection using YOLOv8 outputs, (2) feature extraction for appearance-based identification, (3) motion prediction via Kalman filtering, (4) data association through the Hungarian algorithm, and (5) state updates for refined tracking. This multi-stage process ensures reliable vehicle tracking in complex traffic scenarios while assigning persistent unique IDs to each vehicle.

### 3 ACTUAL BRIDGE TRAFFIC FLOW IDENTIFICATION AND STATISTICAL RESULTS

This study validates a computer vision-based stochastic traffic flow analysis method through a case study of an urban bridge in eastern China. High-resolution cameras were strategically deployed on the bridge for continuous 24/7 monitoring over two weeks, capturing comprehensive traffic data including vehicle types, counts, speeds, and directions. The collected dataset enables evaluation of the method's performance in complex multi-lane environments, demonstrating its practical applicability for real-world traffic monitoring and analysis.

Using the YOLOv8 and DeepSORT algorithms, all vehicles on the bridge over a 24-hour period were successfully identified and tracked, shown in Figure 1. Vehicles, along with their axle counts, were categorized into seven types: 2-axle passenger cars, 2-axle buses, 3-axle buses, 2-axle trucks, 3-axle trucks, 4-axle trucks, and trucks with more than 4 axles. The recognition accuracy for each vehicle type was as follows: passenger cars 94%, trucks 90%, and buses 89%, with an overall vehicle recognition accuracy exceeding 93%. The model demonstrated robust performance during both peak traffic periods and low-traffic intervals.

Figure 1. Vehicle identification results

According to the statistics of one-day traffic flow, passenger vehicles accounted for the highest proportion of total traffic flow, which was 6,820 vehicles, accounting for 73.5% of the total traffic flow. In contrast, buses and trucks accounted for a relatively small proportion of 19% and 7.5% respectively, which is about 9.3% error compared with the actual total traffic flow on the bridge based on WIM data, proving its practical value in actual traffic monitoring and analysis.

The results of the statistical analysis of the distribution of traffic flow on the bridge in 24 hours are shown in Figure 2. The 7:00-9:00 and 17:00-19:00 are the peak traffic flow, with more than 400 vehicles passing through every half hour respectively; the off-peak traffic flow is relatively stable. Nighttime traffic is significantly reduced. The proportion of trucks in the nighttime traffic has increased, and buses account for about 20% of the total traffic, which is mainly concentrated in the morning and evening peak hours. The time series analysis of the traffic flow reveals the fluctuation pattern of the traffic flow throughout the day, and the intensive traffic flow period corresponds to the peak commuting hours in the city, which provides intuitive data support for traffic management and bridge maintenance.

Figure 2. Full-day vehicle distribution

### 4 CONCLUSION

This study combines YOLOv8 and DeepSORT algorithm to propose a computer vision-based method for random traffic flow recognition and analysis of bridges. The method can efficiently and accurately realize real-time monitoring and statistical analysis of traffic flow and provide technical support for structural health monitoring of bridges, with the advantages of low cost and easy deployment. In the future, the performance can be further optimized through efficient deep learning algorithms, multimodal data fusion and edge computing.

# A novel approach to bridge repair using photogrammetry and additive manufacturing

Raguez Taha<sup>1</sup>, Didem Ozevin<sup>1</sup>

<sup>1</sup> Department of Civil, Materials, and Environmental Engineering, University of Illinois Chicago,  
842 W Taylor Street Chicago, IL USA  
email: rtaha2@uic.edu, dozevin@uic.edu

**ABSTRACT:** Traditional inspections of aged steel bridges rely primarily on visual assessment, often depending on qualitative analysis and requiring expert engineering judgement. Additionally, these methods are often labor-intensive, time-consuming, and costly, limiting their feasibility for widespread implementation. Accurate condition assessment, due to corrosion loss, remains a challenging factor in structural inspection, complicating the evaluation of its impact on bridge performance. This paper presents a novel workflow that integrates smartphone-based photogrammetry and metal additive manufacturing (AM) to improve condition assessment and enable data-informed repairs. High-resolution 3D models of a corroded decommissioned steel beam retrieved from a Chicago Transit Authority bridge were generated using a photogrammetry pipeline optimized for image quality and overlap. These models allowed for precise quantification of section loss and the design of custom-fit repair parts. A proof-of-concept repair component was fabricated using metal 3D printing and designed to restore the original geometry of a corroded flange section. While mechanical validation of the repair part is ongoing, this workflow demonstrates the potential for scalable, low-cost integration of digital imaging and AM in bridge maintenance.

**KEY WORDS:** Photogrammetry, Additive manufacturing, Smartphone, Bridge inspection, SHM.

## 1 INTRODUCTION

In the United States, there are more than 617,000 bridges, and 42% of them are at least 50 years old. About 7.5% are in “poor” condition (or structurally deficient) [1]. Although these bridges are classified as being in poor condition, they are not considered unsafe. However, they require significant maintenance and rehabilitation and are at a higher risk of future closures and weight restrictions. Illinois has the third-largest bridge inventory in the U.S., with 2,405 bridges in poor condition, most of which are locally owned. This creates a significant maintenance backlog. To address this issue, the Illinois Department of Transportation has adopted a cost-effective, continuous maintenance strategy to prevent the need for major rehabilitation [2].

These maintenance strategies rely on visual inspection methods, which require expert engineers and are often subjective, depending on the engineer's expertise. While some nondestructive evaluation (NDE) methods are used, more accurate NDE techniques are often very expensive and require trained personnel to collect and process the data. As a result, they are not widely implemented. A major issue that steel bridges face is corrosion, and quantifying corrosion becomes difficult when relying solely on visual inspections. Additionally, the current repair technologies for corrosion loss are not effective in the long run. The most common repair method for corrosion is reinforcing the affected area with built-up shapes on both sides, which are either bolted or welded to the existing structure. While this 'sandwiching' method restores the cross-sectional area, it does not address the underlying corroded plate, which remains exposed. Corrosion damage can continue to grow, leading to earlier repair needs.

The absence of a cost-effective, easy-to-use method for accurately assessing corrosion loss in steel bridges highlights

the need for a more effective approach to documenting and evaluating bridge conditions, as well as for implementing better repair strategies.

This study proposes a practical workflow that integrates smartphone-based photogrammetry and metal additive manufacturing (AM) to enhance the condition assessment and repair of corroded steel bridge components. By utilizing high-resolution 3D reconstructions generated from smartphone-based photogrammetry, this approach enables precise quantification of section loss, improved visualization of deterioration patterns, and more data-driven repair recommendations for aged steel bridges. Additionally, it uses metal additive manufacturing to produce custom repair parts based on the 3D reconstruction models generated from the photogrammetry analysis. By directly translating detailed digital models of the deteriorated sections into precise, tailored components, this approach not only ensures a perfect fit but also improves the overall quality and efficiency of repairs. It reduces material waste by using only the necessary amount of material, minimizes labor by automating the production of repair parts, and shortens repair times by streamlining the manufacturing process. The goal of this proof-of-concept study is to evaluate the feasibility of this workflow as a scalable, low-cost solution that can be incorporated into existing maintenance practices.

## 2 BACKGROUND

### 2.1 *Photogrammetry in structural health monitoring*

Photogrammetry has become a powerful tool in structural health monitoring (SHM), offering a non-contact, high-precision method for assessing and documenting structural conditions. In a study by Valença et.al, photogrammetry was shown to be a reliable alternative to LVDT methods for SHM,

especially in inaccessible environments. They developed a methodology using photogrammetry to generate accurate 3D measurements on long-span beams and pedestrian bridges in Aveiro, Portugal. They were able to achieve an average accuracy in the displacement accuracy of 0.1 mm in steel connection tests, which focused on the 'strong beam/column/weak beam' connection [3].

Recently, Unmanned Ariel Vehicle (UAV) photogrammetry has been utilized to create high precision 3D models for dam monitoring to enhance the damage detection and emergency inspection capabilities [4]. In this study, researchers successfully generated detailed 3D models, achieving a Root Mean Square Error (RMSE) of 3.00 cm and 3.95 cm in the horizontal and vertical directions, respectively, when compared to the Ground Control Points (GCPs) [4].

Backhaus et. al combined UAV photogrammetry and structured light scanning to enhance the structural health monitoring of concrete bridges. UAV data was used for crack detection, while SLS scanning was used to obtain detailed measurements. The study found that UAV could detect cracks as small as 0.05 mm [5].

These studies demonstrate that photogrammetry is a reliable method for SHM, enabling accurate damage detection and 3D reconstruction. Its application has shown to improve the effectiveness of structural assessments which would enhance the safety and maintenance planning in the future.

## 2.2 Additive manufacturing in civil engineering

Additive manufacturing is a process of joining materials layer by layer to create an object from a 3D model (ASTM Standard F2792-12a, 2012). Additive manufacturing enables greater geometric flexibility, allowing for the creation of complex shapes and structures [6-9]. In civil engineering, AM has been utilized in the optimization of connections such as the Nematov façade node [10] and lighting pole nodes [11]. Additionally, it has been utilized in the construction of steel and concrete bridges as well as houses and offices, more notably the MX3D metal pedestrian bridge, Castilla-La Mancha concrete bridge in Madrid, and Winsun houses and offices in Dubai [12-14].

Limited research has been conducted on utilizing AM as a repair technology except most recently in a study by Zhang et al, which investigated the effectiveness of laser additive manufacturing (LAM) for repairing corroded steel bridge beams. This study specifically focused on the mechanical properties and microstructural characteristics of the repaired materials were investigated [15]. The researcher found that the AM repair successfully restored the mechanical properties of the defective specimen.

## 3 METHODOLOGY

This approach can be broken down into three main steps: image capturing, image reconstruction, and repair manufacturing. Further explanation of each of these steps is discussed next.

### 3.1 Image capturing

Capturing high-quality images is the foundation of reliable 3D reconstruction in photogrammetry. Several variables influence the accuracy and resolution of the resulting model. These variables include image resolution, image overlap percentage, and the camera setup. Image resolution depends on

the camera specifications. For example, Agisoft Metashape—used in this study—recommends a minimum resolution of 5 megapixels to achieve suitable model detail. In this study, smartphone cameras were used to demonstrate a low-cost, accessible method for data collection. Another key factor is image overlap, which ensures that surface features are captured from multiple perspectives. A high overlap percentage allows the software to accurately identify and match common points between images. This is critical for generating a consistent and complete point cloud.

Figure 1. Photogrammetry variables and camera setup.

The overlap ratio is defined using the relationship between the field of view ( $\beta$ ) and the camera rotation angle ( $\alpha$ ), as shown in Equation (1):

$$\text{Overlap ratio (\%)} = \frac{\beta - \alpha}{\beta} \quad (1)$$

In this equation,  $\beta$  represents the camera's field of view, and  $\alpha$  is the angular increment between successive images. A smaller  $\alpha$  (i.e., closer spacing between photos) leads to higher overlap and better reconstruction accuracy.

Camera orientation and distance to the object also influence data quality. For best results, the object should be captured from multiple angles (e.g., top, side, diagonal views), maintaining consistent lighting and focus. Figure 1 illustrates the recommended image acquisition setup and key photogrammetry variables.

### 3.2 Image reconstruction

Once images have been captured, the photogrammetric reconstruction process is carried out using Agisoft Metashape. The first step is to upload and review all images, removing any that are blurry or do not contribute additional information about the object. This pre-processing step helps optimize both processing time and model quality. Next, the alignment step generates a sparse point cloud to estimate the camera positions based on the common features detected across the image set. Following alignment, a dense point cloud is generated using depth maps. Using a higher accuracy setting during this step helps preserve finer details.

After generating the dense cloud, Metashape constructs a 3D mesh that interpolates the point cloud data into a continuous surface. A confidence map is also produced, indicating the software's certainty in reconstructing each part of the model. Areas with low confidence may correspond to regions with poor image coverage or lighting inconsistencies and should be reviewed to assess the need for additional images.

Finally, a texture layer is applied to the model, projecting the original image data onto the 3D surface to create a realistic visual representation. At this point, the model can be exported for further analysis or used to design a custom repair part.

### 3.3 Repair manufacturing

After the 3D model is finalized in Agisoft Metashape, it is exported to Autodesk Fusion for design of the repair component. The goal is to digitally reconstruct the missing or deteriorated geometry based on the scanned surface.

To begin, a solid rectangular block is positioned over the corroded area in Fusion. This block is finely meshed to capture the geometry of the underlying surface with high resolution. The Modify → Intersect tool is then used to trim the repair block to match the corroded profile of the scanned model. The result is a 3D repair component that conforms precisely to the section loss, as illustrated in Figure 2.

Figure 2. Reconstructed section of 3D model corroded section exported from Autodesk Fusion software.

Once the repair part has been reconstructed, a model is create which can then be sent to an appropriate 3D metal printing system to print the part. After which, this part can be fixed to the corroded section using epoxy and welding. Epoxy will be used to bond the corroded section to the repaired part and fill any gaps that were not captured during the printing process. Welding will be applied around the edge of the part, to ensure the repair part and the existing structure act as one system and it reducing the likelihood of the repair part detaching under flexural loading.

## 4 RESULTS AND DISCUSSION

To evaluate the proposed workflow, a section of the bottom flange from a naturally aged steel beam—retrieved from a decommissioned bridge in Chicago—was selected for reconstruction. This section exhibited visible corrosion, making it a suitable test case for photogrammetry-based defect capture. Various configurations were investigated to determine the optimal case for on-site inspections. The linear configuration, which focuses on a localized section, proved to be the most feasible option given the limitation of the existing structures on site.

This method was applied to a girder measuring approximately 1675 mm (5'-6") in length. The bottom flange of the girder was because visible corrosion was detectable. The initial test used 6 images, and a test used 108 images. This model was also used to create the repair part, as shown in Figure 2. From these two tests, it is evident that the number of images impact the confidence of the Metashape software in accurately reconstructing the features with the given images. As shown in Figure 3, with 6 images, the confidence level in the middle of the section increases as the overlap increases.

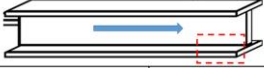

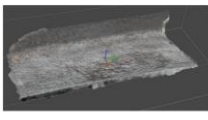

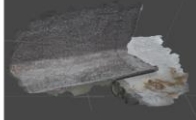

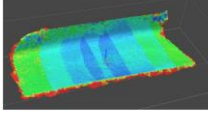

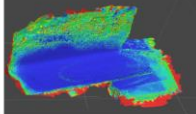

Image capturing configuration		
Number of images	6	108
Metashape reconstruction		
Confidence map		

Figure 3. Reconstruction of bottom flange of aged steel beam using different number of images.

To further validate the workflow, a prototype repair part was fabricated using PLA plastic, based on the 3D model generated from the 108-image dataset. The purpose of this prototype was to assess the feasibility of capturing fine geometric details required for accurate fitment during future metal printing. The PLA part aligned well with the corroded geometry, suggesting that the photogrammetric model is suitable for generating repair components, as illustrated in Figure 4.

Figure 4. Reconstruction of bottom flange of aged steel beam using different number of images.

While this prototype was not intended for mechanical testing, it serves as a low-cost validation of the model-to-manufacture transition. Future work will include metal AM fabrication and mechanical testing to assess structural performance and long-term durability of the printed repair.

## 5 CONCLUSION

This study presented a proof-of-concept workflow that integrates smartphone-based photogrammetry and additive manufacturing (AM) for the inspection and repair of corroded steel bridge components. The results demonstrate that high-resolution 3D models can be generated from smartphone images, even under field-like conditions, and used to design repair components that closely match the original geometry.

Initial tests using a naturally aged steel beam confirmed that image overlap and quantity significantly affect reconstruction quality. A prototype repair part was successfully fabricated in PLA based on the photogrammetry-derived model, supporting the feasibility of transitioning from image capture to repair part fabrication.

While promising, this workflow is still in its early stages. Future efforts will focus on transitioning from proof-of-concept to full-scale implementation. This includes fabricating repair components using metal additive manufacturing processes and performing mechanical tests—such as tensile and flexural loading—to evaluate the structural integrity of the repaired sections. Additional research will assess the scalability of the workflow for larger or more complex bridge components, ensuring it can be applied to diverse geometries and field conditions. The impact of environmental factors on photogrammetric accuracy, such as lighting variability, surface reflectivity, and site accessibility, will also be explored. Finally, a quantitative comparison between this workflow and traditional repair methods will be conducted, evaluating differences in cost, material efficiency, labor requirements, and repair duration to better understand the practical advantages and trade-offs of the proposed approach.

With further development, this approach has the potential to provide a cost-effective, accurate, and scalable tool for condition assessment and customized repair in routine steel bridge maintenance.

## ACKNOWLEDGMENTS

This work was partially supported by the GAANN program for the project EXTending Civil Infrastructure RESiliency for Multihazards and Extreme Events (EXTREME), the Chancellor's Undergraduate Research Award, and the Chicago Transit Authority for the donation of aged steel beams and girders. We would also like to express our sincere thanks to Stephanie Bonilla, Undergraduate Research Assistant, for her contributions to image capturing.

**ABSTRACT:** In response to the issues of high cost, limited monitoring accuracy, and susceptibility to environmental factors in traditional hydraulic structure displacement automation monitoring methods, a non-contact intelligent monitoring method based on machine vision image super-resolution reconstruction is proposed. This method uses artificial targets as markers and combines a high-order image degradation model with a camera to analyze real monitoring scenarios, carry out image data collection, and perform displacement calculation. It innovatively introduces a feature fusion attention mechanism to improve the Real-ESRGAN network and generator, enabling the reconstruction of image contours and fine details to enhance displacement calculation accuracy. Laboratory and field test results show that this method can effectively improve image resolution and clarity, achieving sub-pixel and millimeter-level precise monitoring of hydraulic structure surface displacement. Compared with traditional super-resolution algorithms and target tracking methods, the improved Real-ESRGAN algorithm performs the best, with a coefficient of determination ( $R^2$ ) of up to 0.9975, an average absolute error (MAE) as low as 0.5552, and residual errors controlled within 5mm. The edge contours and details in the images are successfully reconstructed, effectively improving the displacement monitoring accuracy of hydraulic structures based on machine vision.

**KEY WORDS:** Machine vision displacement monitoring; Image super-resolution reconstruction; Real-ESRGAN improvement; Feature fusion attention mechanism; Hydraulic structure safety monitoring.

## 1 INTRODUCTION

As critical infrastructure in water resource management systems, hydraulic engineering projects play a pivotal role in ensuring water security and sustaining watershed economic development. Efficient and stable operation of these structures not only guarantees essential water supply for socio-economic sustainability but also serves as a vital safeguard for regional ecological security [1,2]. In the field of structural health monitoring (SHM), accurate surface displacement measurement forms the basis for safety assessment and early warning systems [3]. However, existing monitoring technologies exhibit notable limitations: traditional displacement measurement methods are not only costly but also susceptible to environmental interference, while demonstrating inadequate responsiveness to sudden structural risks [4-6].

A further complication arises from the multi-physics coupling effects (including hydraulic loads, thermal stresses, and mechanical vibrations) that hydraulic structures endure during service. These complex interactions induce nonlinear deformation behaviors, potentially leading to progressive damage or even catastrophic failure, posing dual threats to both structural integrity and economic viability [7]. Consequently, there is an urgent need to develop intelligent, automated displacement monitoring methods and establish digitalized smart monitoring systems to enhance lifecycle safety management of hydraulic structures.

Current displacement monitoring techniques for hydraulic structures can be broadly categorized into contact-based and non-contact approaches [8]. Contact-based methods, such as strain gauges and fiber-optic sensors, suffer from complex installation and environmental sensitivity, making them unsuitable for long-term monitoring [9, 10].

In the field of non-contact structural monitoring, laser displacement sensors[11][12], machine vision[13][14], total stations[15][16], and Global Navigation Satellite Systems (GNSS) [17][18] have emerged as critical technologies for deformation monitoring of large-scale hydraulic structures such as sluice gates and dams, owing to their non-invasive nature and operational flexibility.

Laser displacement sensors employ optical triangulation principles, utilizing photoelectric receivers including position-sensitive detectors (PSD), charge-coupled devices (CCD), and complementary metal-oxide-semiconductor (CMOS) sensors to achieve high-precision displacement measurements. However, the measurement accuracy of this technology exhibits an inverse correlation with monitoring distance due to the inherent limitations of laser reflection-based triangulation, significantly reducing its suitability for long-range monitoring scenarios. Furthermore, the installation requirements for reflective targets impose additional constraints on deployment flexibility, particularly for vertical displacement monitoring of hydraulic structures[19].

GNSS technology has demonstrated robust capabilities in dynamic displacement monitoring for structural health monitoring (SHM) and seismic engineering applications. Nevertheless, its sampling frequency is constrained by satellite signal update rates, limiting its effectiveness in high-frequency vibration monitoring. Compared to conventional sensors such as accelerometers, GNSS also exhibits inferior measurement accuracy in the vertical direction[20].

Total stations, as multifunctional surveying instruments, integrate high-precision distance measurement, angular measurement, coordinate acquisition, and elevation determination, making them widely applicable in engineering surveying and structural monitoring[15][16][21]. However, in

practical applications for dam displacement monitoring, these instruments face challenges such as unfavorable cost-benefit ratios, line-of-sight obstructions at measurement points, and operational complexity, which hinder their widespread adoption in large-scale engineering projects.

To address these challenges, machine vision-based displacement monitoring enhanced by image super-resolution reconstruction has emerged as a promising solution. By employing deep learning algorithms to recover fine details from low-resolution images, this method overcomes the precision constraints of traditional vision-based measurements while avoiding the range limitations of laser displacement sensors and the environmental dependencies of drone-based remote sensing. Compared to fiber-optic sensing and conventional SHM systems, this approach offers superior flexibility, cost efficiency, and adaptability, providing a novel pathway for high-precision, automated displacement monitoring of hydraulic structures.

Recent advances in computer vision have demonstrated its potential in SHM applications. such as the Harris corner detection method[22], the Lucas-Kanade (LK) optical flow matching algorithm[23], and template matching algorithms[24] are employed. For instance, Yoon et al. [23] combined Harris corner detection with the Lucas-Kanade (LK) optical flow algorithm to achieve high-precision displacement tracking in building structures. Brownjohn et al.[25] deployed a vision-based monitoring system on the Humber Bridge, validating its engineering applicability. Bocian et al. [26] extracted modal parameters of cable-stayed bridges using template matching and sparse LK optical flow, enabling vibration characteristic analysis. Kohut et al.[27] applied digital image correlation (DIC) to measure structural deflection, providing intuitive deformation indicators.

Algorithmic optimizations have further enhanced performance: Wu et al. [28] improved computational efficiency in template matching for real-time monitoring; Molina-Viedma[29] integrated phase-based motion magnification with digital image processing techniques [30] to identify the modal shapes of a cantilever beam, thereby overcoming the limitation of conventional digital image methods in accurately capturing high-frequency structural vibrations. Khuc et al. [22] refined Harris corner extraction with FREAK descriptors for sub-pixel matching accuracy. Guo et al. [31] leveraged projection correction to enhance displacement measurement under seismic conditions.

Despite these advancements, machine vision-based monitoring for hydraulic structures—particularly gates and dams—remains underdeveloped due to complex operational environments and stringent safety requirements. Existing systems still face data acquisition constraints, lacking a mature framework for deformation monitoring.

This study proposes a non-contact intelligent monitoring method integrating machine vision with image super-resolution reconstruction to address the cost, precision, and environmental limitations of conventional techniques. The methodology employs artificial targets as fiducial markers, coupled with high-resolution imaging and higher-order image degradation modeling, to achieve precise displacement data acquisition. At the algorithmic level, we innovatively introduce a feature fusion attention mechanism to enhance the Real-ESRGAN

network, specifically improving its contour detail reconstruction and texture recovery capabilities. This approach is expected to significantly elevate displacement calculation accuracy, offering a cost-effective, intelligent solution for hydraulic structure safety monitoring.

## 2 DEEP LEARNING-BASED SUPER-RESOLUTION METHODS: OPTIMIZATION AND APPLICATION OF GENERATIVE ADVERSARIAL NETWORKS

This study aims to transcend the limitations of conventional image resolution through deep learning techniques, thereby providing higher-precision machine vision measurement solutions for structural displacement monitoring in engineering applications. The following sections will focus on image super-resolution algorithms based on Generative Adversarial Networks (GANs), offering in-depth analysis of their core principles, network architectures, and optimization strategies.

### 2.1 Image Super-Resolution Based on Generative Adversarial Networks

The Super-Resolution Generative Adversarial Network (SRGAN) architecture primarily consists of two core modules engaged in adversarial competition: the Generator and the Discriminator, as illustrated in Figure 1. During model training, low-resolution (LR) images serve as input data to the generator network, which performs nonlinear transformations through deep neural networks to produce high-resolution (HR) images. Subsequently, both the generated super-resolution images and authentic HR images form the input sample space for the discriminator, which evaluates the authenticity probability of input samples through feature extraction and pattern recognition. Within this adversarial training framework, the generator optimizes its parameter space to minimize the distribution divergence between generated and real samples, aiming to produce super-resolution images with high visual fidelity. Concurrently, the discriminator continuously enhances its discriminative capability to maximize identification accuracy of generated samples. This minimax game process achieves dynamic equilibrium that ultimately enables the generator to produce super-resolution reconstruction results perceptually indistinguishable from genuine high-resolution images.

Figure 1. Architectural illustration of the Generative Adversarial Network framework

### 2.2 Image Super-Resolution Based on Generative Adversarial Networks

The Enhanced Super-Resolution Generative Adversarial Network (ESRGAN) represents an advanced generative adversarial network for super-resolution that achieved state-of-the-art performance in the field of image super-resolution at its time of introduction. This method primarily builds upon the aforementioned SRGAN architecture while implementing several key improvements.

To enhance model stability and generalization capability while reducing computational complexity, ESRGAN eliminates all

batch normalization layers from the original SRGAN framework and replaces the basic residual blocks with Residual-in-Residual Dense Blocks (RRDBs). Each RRDB consists of three dense blocks, with each dense block comprising five convolutional layers. The RRDB architecture effectively combines the advantages of dense connections and multi-level residual networks while removing block normalization, thereby reducing computational overhead while simultaneously minimizing artifacts in generated images. ESRGAN further modifies the loss function to produce more realistic super-resolution outputs through two principal innovations: (1) replacing the original feature extractor with a VGG16 network, and (2) introducing a Relativistic average Discriminator (RaD) to substitute the conventional discriminator architecture. The BN-free residual block and Residual-in-Residual Dense Block (RRDB) structure are shown in Figure 2.

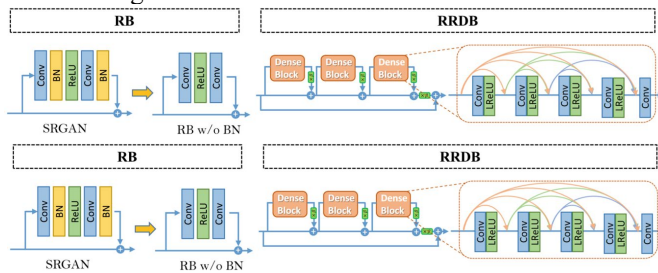

Figure 2. The BN-free residual block and Residual-in-Residual Dense Block (RRDB) structure

### 2.3 High-Order Image Degradation Model

This study innovatively proposes a high-order degradation modeling approach that overcomes the limitations of traditional first-order models, enabling more accurate simulation of complex, multi-stage and multi-factor coupled image degradation processes in real-world scenarios.

Through systematic analysis of interaction relationships among various degradation mechanisms, we extend the conventional first-order model to a more expressive second-order degradation model. This model achieves precise simulation of real degradation processes through the following innovative designs:

Incorporation of temporal characteristics in the degradation process to simulate multi-stage degradation in practical imaging systems;

Establishment of an adaptive coupling mechanism for degradation parameters to reflect nonlinear superposition effects of different degradation factors;

Achievement of optimal balance between computational complexity and model accuracy through a carefully designed second-order approximation scheme.

As illustrated in Figure 3, the constructed second-order degradation model generates low-resolution images that better approximate real-world scenarios through meticulously designed degradation path combinations. Training datasets synthesized based on this model effectively enhance the generalization capability of super-resolution networks under complex degradation conditions. Experimental results confirm that compared to networks trained with traditional degradation models, those trained with the second-order degradation model

demonstrate significant advantages across various real-world test datasets.

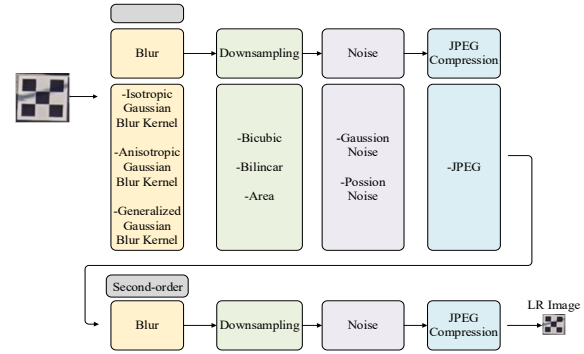

Figure 3. Advanced-order image deterioration model

### 2.4 Generator Architecture

The generator network begins with a primary feature extraction module, which takes the low-resolution (LR) image obtained from the high-order degradation model as input and extracts shallow features using a  $3 \times 3$  convolutional layer. This process is formulated as:

$$F_{primary} = \text{Conv}(I_{LR}) \quad (1)$$

The advanced feature extraction module, located at the core of the generator, serves as a bridge between shallow and deep representations. It extracts multi-level high-level features through stacked fundamental blocks for subsequent reconstruction. Based on the original Real-ESRGAN network, we improve this module by introducing: Coordinate Attention Residual-in-Residual Dense Blocks (CARRDBs), a feature fusion layer and a global spatial attention block.

The CARRDB is an enhanced version of the original RRDB, incorporating a Coordinate Attention (CA) submodule after each Dense Block to refine local feature extraction. All activation functions use Leaky ReLU for faster convergence. The output of each CARRDB is fed into the next residual group for deeper feature extraction while being directly propagated to the feature fusion layer.

The feature fusion layer aggregates all CARRDB outputs through channel-wise concatenation, followed by a  $1 \times 1$  convolution for dimensionality reduction:

$$F_{GF} = H_{GFF}(\text{Concat}(G_1, \dots, G_D)) \quad (2)$$

The first component of this module is an upsampling layer that performs convolutional operations on  $F_{high}$ , followed by pixel shuffling to generate high-resolution feature maps from low-resolution inputs. This process can be mathematically represented as:

$$F_{up} = \text{Shuffle}(\text{Conv}(F_{high})) \quad (3)$$

Where :  $F_{primary}$  denotes the primary output features,  $\text{Conv}(\cdot)$  represents the convolutional operation,  $I_{LR}$  indicates the input low-resolution image,  $F_{GF}$  corresponds to the advanced fused features with output size of,  $H_{GFF}(\cdot)$  stands for the convolutional operation,  $\text{Concat}(\cdot)$  signifies the feature concatenation operation,  $G_i$  refers to the output features of the  $i$ -th CARRDB (Cascaded Residual-in-Residual Dense Block),

$F_{up}$  represents the upsampling output result,  $Shuffle()$  denotes the pixel shuffle operation.

Figure 4. The architectural configuration of the conventional Real-ESRGAN generator

## 2.5 Attention Mechanism

Building upon the Real-ESRGAN framework, this study incorporates two attention mechanisms—Coordinate Attention (CA) and Spatial Attention (SA)—to enhance the network's image reconstruction performance. The implementation details of these attention mechanisms are elaborated below.

The Coordinate Attention (CA) mechanism captures long-range dependencies along two spatial directions while preserving precise positional information. This capability facilitates improved extraction of fine-grained features. Compared to alternative attention mechanisms, CA exhibits advantages such as fewer parameters and easier implementation. A schematic diagram of its structure is presented in Figure 5.

The coordinate attention mechanism is implemented through two distinct computational stages. Initially, channel attention is decomposed into dual one-dimensional feature encodings along the orthogonal X-axis and Y-axis directions, thereby addressing the inherent limitation of conventional spatial pooling methods in preserving precise positional information. For an input feature map of dimensions  $C \times H \times W$ , directional average pooling operations are independently performed along each spatial axis, generating orientation-aware feature representations  $z_c^h(h)$  and  $z_c^w(w)$ , as formally expressed.

Subsequently, the coordinate attention weights are generated through the following procedure: The output features from both directional encodings undergo concatenation, followed by channel dimensionality reduction via a  $1 \times 1$  convolutional layer and nonlinear activation. These operations yield the intermediate feature representation  $m$ , formally expressed as:

$$m = \delta(\text{Conv}[z^h, z^w]) \quad (4)$$

The intermediate feature  $m$  is then partitioned into two separate feature tensors,  $m^h$  and  $m^w$ , which subsequently undergo channel-wise dimensionality expansion via independent  $1 \times 1$  convolutional layers. These expanded features are activated using the Sigmoid function to generate coordinate-level attention weights. This process is formally expressed as:

$$\begin{cases} g^h = \sigma(\text{Conv}_h(m^h)) \\ g^w = \sigma(\text{Conv}_w(m^w)) \end{cases} \quad (5)$$

Where :  $g^h$  and  $g^w$  denote the attention weight maps along the X-axis and Y-axis directions, respectively. By applying these weights to the input features, the calibrated output feature map is obtained as:

$$y_c(i, j) = x_c(i, j) * g_c^h(i) * g_c^w(j) \quad (6)$$

Where :  $x_c(i, j)$  and  $y_c(i, j)$  denote the values at coordinate  $(i, j)$  in channel  $c$  of the input and output feature maps, respectively.

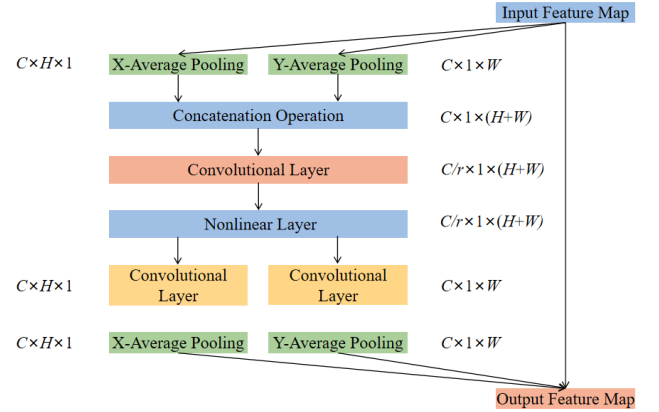

Figure 5. Architectural illustration of the Coordinate Attention module

The spatial attention mechanism captures critical spatial information within feature maps by dynamically weighting different regions of the image based on their relative importance. This enhances the model's ability to focus on semantically significant spatial locations, thereby improving the effectiveness of super-resolution reconstruction. The fundamental architecture of this mechanism is illustrated in Figure 6.

Figure 6. Architectural illustration of the Spatial Attention Module

For the input feature map  $X$ , a  $1 \times 1$  convolutional layer is first applied to perform channel dimensionality reduction, yielding the output feature map  $X'$ , as formally expressed by:

$$X' = \text{Conv}(X) \quad (7)$$

Subsequently, a  $7 \times 7$  max-pooling operation with stride 3 is applied to  $X'$ , followed by two  $3 \times 3$  convolutional layers to extract spatial attention features. To restore the feature map to its original dimensions, bilinear interpolation  $F_{linear}$  is employed for upsampling. The resultant features are then element-wise summed with  $X'$ , yielding the intermediate feature representation  $X_{mid}$ , as mathematically formulated below:

$$X_{mid} = F_{linear} \left( \text{Conv} \left( \text{ReLU} \left( \text{Conv} \left( F_{pool}(X') \right) \right) \right) \right) + X' \quad (8)$$

Finally, a  $1 \times 1$  convolutional layer is employed to restore the channel dimensionality of the output features to match the input feature map, followed by activation via the Sigmoid function  $\sigma$  to generate the final spatial attention weights. These weights are then multiplied element-wise with the input feature map  $X$  to produce the output feature map  $Z$ , as mathematically formulated below:

$$Z = \sigma(F(X_{mid})) \odot X \quad (9)$$

### 2.6 Discriminator Architecture

The high-order degradation model employed in this study exhibits significantly greater complexity than conventional low-order degradation models, inevitably leading to an orders-of-magnitude increase in computational demands. To address the consequent challenges in discriminator design, we propose an innovative U-Net architecture with spectral normalization (SN) to replace traditional VGG-based discriminators (as illustrated in Figure 7). This architectural modification offers two key advantages:

First, the spectral normalization technique effectively constrains the Lipschitz constant of network parameters, ensuring convergence within a predefined parameter space, thereby significantly enhancing training stability. Second, the U-Net's fully convolutional architecture enables pixel-wise discrimination, which maintains global semantic coherence while facilitating refined evaluation of local texture details, ultimately improving the visual realism of generated images. Experimental results demonstrate that the proposed design achieves substantial improvements in modeling fine-grained features without compromising overall image quality.

Figure 7. Spectral Normalization-incorporated U-Net Structure

## 3 CASE STUDIES AND ANALYSIS

### 3.1 System Configuration and Dataset Composition

To address the lack of specialized image datasets for hydraulic structure displacement monitoring, this study employs a transfer learning strategy. The model is pretrained on DIV2K, a widely adopted benchmark dataset in computer vision. DIV2K contains 800 high-quality 2K-resolution images (see Figure 8), encompassing diverse texture features and edge structures. This dataset has been proven to exhibit strong generalization performance in image super-resolution tasks, ensuring that the model learns robust generic feature representations before fine-tuning for hydraulic structure-specific scenarios.

Figure 8. Representative high-resolution images from the DIV2K dataset

The network training strategy of the proposed algorithm is largely consistent with the original Real-ESRGAN model, with minor adjustments made to certain training parameters. In terms of global settings, the HR patch size is set to 256, the batch size to 48, and the Adam optimizer is employed. The network training process consists of two distinct phases. Initially, a Real-ESRNet model is trained using the L1 loss function based on a pre-trained ESRGAN model, with the iteration number set to  $1 \times 10^6$  and the learning rate to  $2 \times 10^{-4}$ . Subsequently, the trained Real-ESRNet model is utilized as the generator initialization for the enhanced Real-ESRGAN, which is further trained with a combination of three loss functions: L1 loss, perceptual loss, and GAN loss. In this phase, the iteration number is set to  $4 \times 10^4$  and the learning rate to  $1 \times 10^{-4}$ .

### 3.2 Image Super-Resolution Reconstruction Quality Evaluation

The proposed algorithm is trained to achieve a  $4 \times$  super-resolution model, meaning it reconstructs input images at four times their original resolution. To evaluate the algorithm's performance, high-resolution (HR) images were first captured using a high-definition camera in several small- and medium-scale hydraulic engineering machine vision displacement monitoring scenarios. These images served as the reference HR images. Artificial targets within the images were cropped and selected as regions of interest (ROIs) for super-resolution reconstruction. The cropped images were then subjected to a high-order degradation process to generate low-resolution (LR) images. Subsequently, the trained model was applied to perform  $4 \times$  upsampling, producing super-resolution (SR) reconstructed images.

To assess the quality of the super-resolved images, two metrics were employed: Peak Signal-to-Noise Ratio (PSNR) and Structural Similarity Index (SSIM). The definitions of these metrics are as follows:

Peak Signal-to-Noise Ratio (PSNR) measures the ratio between the maximum possible signal power and the mean squared error (noise power). A higher PSNR value indicates less distortion and better image quality, with the unit expressed in decibels (dB).

$$PSNR = 10 \lg \frac{F^2}{MSE} \quad (10)$$

Where:  $F$  denotes the maximum grayscale value of the image,  $MSE$  represents the mean squared error of the image.

The Structural Similarity Index (SSIM) provides a comprehensive quality assessment by evaluating three key attributes: luminance, contrast, and structural fidelity. The SSIM metric is bounded within the range  $[0, 1]$ , with higher values indicating better preservation of image integrity and lower distortion.

$$SSIM = l(x, y)^\alpha \cdot c(x, y)^\beta \cdot s(x, y)^\gamma \quad (11)$$

Where:  $l(x, y)$ 、 $c(x, y)$ 、 $s(x, y)$  represent the luminance, contrast, and structural measure functions, respectively;  $\alpha$ 、 $\beta$ 、 $\gamma$  denotes the adjustment parameter.

To validate the superiority of the proposed method, five super-resolution approaches - BIC, SRCNN, SRGAN, SRFBN, and Real-ESRGAN - were applied to the LR images for comparative performance evaluation, with the results illustrated in Figure 9.

(a) Scenario 1: Machine Vision Surveillance Imagery of a Control Gate

(b) Scenario 2: Machine Vision Surveillance Imagery of a Reservoir

(c) Scenario 3: Machine Vision Monitoring Image of a Ship Lock

(d) Scenario 4: Machine Vision Monitoring Image of a Reservoir

Figure 9. Super-Resolution Reconstruction Results for the Four Scenarios

The figure provides an intuitive comparison of the image reconstruction performance among different super-resolution methods. Among them, the interpolation-based BIC method performs poorly, merely enlarging the original low-resolution image without effectively restoring the texture and edge details of the target in the image. In contrast, several deep learning-based methods yield significantly better results, though with notable variations in performance. While the four other algorithms (excluding the proposed method) can reconstruct the main contours of the image reasonably well, they still fall short in recovering fine textures and edge details.

By comparison, the proposed algorithm demonstrates the best performance. When compared to the original high-resolution (HR) image, the super-resolved (SR) image generated by our method achieves a more realistic restoration in terms of both overall visual quality and fine texture details. Moreover, owing to the improvements in feature fusion and attention mechanisms, our approach delivers more refined edge and contour reconstruction.

To further quantify the performance differences, the PSNR and SSIM evaluation curves of images reconstructed by different

super-resolution algorithms are plotted in Figure 10. The results clearly indicate significant disparities among the algorithms, with the proposed method exhibiting superior performance in both metrics.

### 3.3 Verification of Displacement Monitoring Accuracy Improvement

The purpose of image super-resolution reconstruction is to compensate for insufficient resolution from an algorithmic perspective when the hardware capabilities of machine vision cameras are limited or the available image resolution is low, thereby improving displacement monitoring accuracy. Therefore, it is necessary to validate the effectiveness of image super-resolution through machine vision displacement monitoring experiments.

To accurately quantify and analyze the improvement in displacement monitoring accuracy, this study selects an open-source experimental dataset for investigation. In 2018, the University of California, San Diego conducted a series of shake table tests to study the lateral response characteristics of cold-formed steel frame building structures. The related design schemes, test reports, videos, and data were all publicly released. This experiment provides comprehensive video recordings and measured data from various sensors, making it highly suitable for verifying displacement monitoring accuracy in this study.

For this research, a specific shear wall specimen from the test series was selected, and its dynamic test video data under seismic loading were analyzed. The vibration input was scaled from the recorded ground motion of the 1994 Northridge earthquake in Los Angeles, USA, ensuring the specimen remained elastic throughout the test. The experimental setup of the shake table test is illustrated in Figure 11. Specifically: Displacement sensors were installed on the side of the load-transfer beam at the top of the specimen to measure lateral displacements induced by horizontal loading.

A machine vision camera\*\* was positioned directly in front of the specimen to record the entire dynamic testing process. This configuration allows for a comparative evaluation of displacement measurements obtained from traditional sensors and machine vision-based methods, facilitating an assessment of the accuracy enhancement achieved through super-resolution reconstruction.

Figure 11. Overview of the Shaking Table Field Test

The checkerboard-pattern artificial target installed on the load-transfer beam at the top of the specimen served as the region of interest (ROI) for machine vision-based displacement monitoring. The specific geometry and dimensions of this target are illustrated in Figure 12. The sensor-measured displacement data recorded during the vibration test are presented in Figure 13.

Figure 12. Shape and Dimensions of the Artificial Target

(a) Accelerometer measurement data

(b) Displacement sensor measurements

Figure 13. Experimental sensor data recorded during vibration testing

During the experimental testing process, the images were captured at close range using a high-quality camera, resulting in high-resolution footage that meets the requirements of machine vision-based displacement monitoring under normal conditions. Therefore, the actual captured monitoring images were treated as high-resolution (HR) images, and displacement monitoring was performed on the HR image sequence. The tracking target was a checkerboard-pattern artificial target, and the calculated results are presented in the following figures and tables. The results demonstrate that the machine vision-based displacement monitoring using high-resolution images achieved high accuracy, closely matching the measured displacement values from sensors, thereby validating the effectiveness of the machine vision approach.

To evaluate the accuracy improvement effects of different super-resolution methods, the original HR images (120×120 pixels) of the target region were first degraded according to the higher-order degradation model proposed in this study, generating corresponding low-resolution (LR) images (30×30 pixels) as the baseline LR images for the accuracy enhancement validation experiment (all super-resolution algorithms were

applied to these LR images for enhancement). Subsequently, the bicubic interpolation (BIC) method was employed to perform  $4\times$  upsampling super-resolution reconstruction on the LR images, producing corresponding BIC super-resolution (SR) images ( $120\times120$  pixels) for comparative analysis with other super-resolution algorithms. The entire process is illustrated in Figure 14 below.

Figure 14. Processing results of artificial target images

For the low-resolution (LR) images, the proposed algorithm in this study was employed to perform super-resolution (SR) reconstruction, and the results were compared with those of other SR methods, as illustrated in the following figure. As shown in Figure 15, the visual differences among the outputs of different methods can be easily observed. Among them, the BIC and SRCNN super-resolution algorithms exhibited the poorest performance, with noticeable blurring visible to the naked eye. The other four algorithms achieved better reconstruction results, but the proposed method outperformed them all, achieving the highest scores in both PSNR and SSIM metrics. When comparing the super-resolved images generated by the proposed method with those obtained from the original Real-ESRGAN (before improvements), it is evident that the proposed method produces images with sharper edges and more detailed textures, demonstrating the effectiveness of the introduced feature fusion and attention mechanism enhancements.

Figure 15. Super-resolution reconstruction results of the target image

To further analyze the quality improvement effects of image super-resolution, corner detection was performed on different types of images using OpenCV's goodFeaturesToTrack detector, followed by cornerSubPix refinement for sub-pixel accuracy. All detection parameters remained consistent throughout the process, and the resulting corner detection outcomes are illustrated in Figure 16. Given the noticeable differences in performance among the algorithms, the superiority of each method can be clearly determined based on the number and positional accuracy of detected corners.

Taking the original high-resolution (HR) image as a reference, a total of 16 inner checkerboard corners and 5 outer corners were detected, with their positions precisely aligned to the edges and intersections of the checkerboard pattern. The

comparison among different super-resolution algorithms revealed significant discrepancies. For instance, BIC and SRCNN exhibited evident corner misalignment and missing detections, failing to fully capture the expected number of corners. In contrast, the proposed method demonstrated the best performance, detecting the same number of corners as the HR image while maintaining accurate positional correspondence, further validating its effectiveness.

Figure 16. Corner detection results for images reconstructed using different super-resolution methods

Subsequently, target tracking and displacement calculation were performed on the reconstructed image sequences obtained from the aforementioned super-resolution methods, yielding the corresponding displacement time-history curves for each method, as illustrated in Figure 17. The results demonstrate that the low-resolution (LR) images without any processing exhibited degraded tracking performance due to substantial loss of effective information and noise contamination, leading to unsatisfactory displacement monitoring results. Specifically, the displacement curve of the LR images displayed significant fluctuations and drift phenomena, particularly in the intermediate segment with larger vibration amplitudes (as clearly observed in the zoomed-in subplot). The resulting errors substantially exceeded the acceptable threshold, rendering the displacement monitoring results unreliable.

In contrast, the six curves derived from super-resolution-processed images exhibited significantly improved performance, mitigating the accuracy degradation caused by image resolution reduction to varying degrees. Among these, the Bicubic Interpolation (BIC) algorithm demonstrated relatively inferior performance, while the proposed feature-fusion-enhanced Real-ESRGAN algorithm with attention mechanisms achieved the best results. The displacement curve generated by the proposed method closely aligned with both the sensor-measured displacement curve and the vision-based measurement curve obtained from high-resolution (HR) images, outperforming even the original Real-ESRGAN algorithm. This comparative analysis further validates that the proposed model improvements contribute effectively to enhancing displacement monitoring accuracy.

Figure 17. Vibration displacement monitoring results using different super-resolution methods

Finally, four evaluation metrics—Mean Absolute Error (MAE), Mean Absolute Percentage Error (MAPE), Root Mean Square Error (RMSE), and the Coefficient of Determination ( $R^2$ )—were employed for further quantitative assessment. The corresponding residual box plots and evaluation metric radar charts are presented in Table 1 and Figure 18, respectively. The results demonstrate that the proposed method consistently outperformed all other approaches across all evaluation metrics, achieving an  $R^2$  value of 0.9975, which is remarkably close to the monitoring results obtained from the high-resolution (HR) images. Although the proposed method cannot fully compensate for the degradation caused by image downsampling, it significantly mitigates the impact of resolution reduction compared to other methods, exhibiting superior performance.

The residual box plots reveal that the monitoring results based on HR images exhibited the highest accuracy, with residuals fluctuating only within a very narrow range. Considering that this case involves large-amplitude vibration displacement, which inherently introduces error drift in target tracking, the BIC super-resolution algorithm displayed the largest residual fluctuations, while the residuals of other algorithms also exceeded 5 mm. In contrast, the proposed method effectively confined the residuals within 5 mm, demonstrating a substantial improvement in monitoring accuracy over competing approaches.

Table 1 Displacement monitoring accuracy evaluation across different super-resolution methods

Test Category	MAE	MAPE	RMSE	$R^2$
Visual HR	0.101	0.316	0.233	0.999
Visual LR	3.822	0.495	6.697	0.918
BIC	1.954	0.416	3.355	0.972
SRCNN	1.488	0.393	2.522	0.982
SRGAN	1.114	0.373	1.856	0.991
SRFBN	0.928	0.362	1.525	0.993
Real-ESRGAN	0.741	0.351	1.195	0.995
Proposed Method	0.555	0.340	0.870	0.997

#### 4 CONCLUSION

Departing from conventional approaches that rely on hardware upgrades (e.g., higher-resolution cameras, precision optical lenses) or subpixel algorithm refinement, this research innovatively explores image super-resolution (SR) reconstruction based on deep learning, proposing a software-algorithm-level solution for breakthrough accuracy enhancement in displacement monitoring. The key research contributions and findings are systematically summarized as follows:

A thorough analysis of image degradation processes and super-resolution reconstruction principles was conducted. An SR reconstruction model was innovatively developed using a generative adversarial network (GAN) architecture. By establishing a multi-factor coupled higher-order degradation model, the study accurately simulates complex imaging processes in real-world engineering environments, significantly improving the algorithm's adaptability to various degraded images.

The study innovatively integrates Coordinate Attention (CA) and Spatial Attention (SA) mechanisms into the Real-ESRGAN framework, constructing a feature fusion attention network. The CA mechanism enables channel-space feature co-optimization, while the SA mechanism enhances the representation of critical regions. Without modifying hardware configurations, this approach significantly improves target feature discriminability, providing a reliable foundation for high-precision displacement monitoring.

The proposed method was rigorously validated through engineering case studies, assessing both image quality metrics and displacement monitoring accuracy. Comparative experiments with five state-of-the-art algorithms demonstrate the superior performance of the proposed method, which effectively restores edge and contour details in reconstructed images. Moreover, the displacement monitoring results derived from the SR-enhanced image sequences exhibit significantly improved accuracy, offering an innovative technical pathway to overcome the precision limitations in machine vision-based monitoring of hydraulic structures.

**ABSTRACT:** The structural integrity and safety of high-rise buildings rely heavily on effective deformation monitoring. Global Navigation Satellite System (GNSS) techniques are frequently utilized to monitor these deformations; yet, despite their great accuracy, they possess possible limitations due to high costs. Thus, this research investigates the potential of low-cost GNSS receivers for monitoring deformations in high-rise structures. The study focuses on incorporating low-cost GNSS receivers to capture slow motion movements caused by factors such as solar radiation and temperature fluctuations as well as dynamic movements induced by forces including wind loads and seismic forces. The performance of low-cost GNSS receivers is assessed against high-precision geodetic-grade GNSS receivers through a series of experiments conducted on a high-rise building under both slow-motion and dynamic conditions. The study primarily investigates the U-blox F9P dual-frequency GNSS receiver with Leica AS10, Tallysman TWI, and U-blox patch antennas. Results indicate that low-cost GNSS receivers demonstrate significant potential for capturing accurate and precise deformation measurements. The selection of GNSS antenna is found to significantly influence the overall quality of the GNSS data. However, the results indicate that with proper configuration, these low-cost receivers can be successfully integrated to develop an efficient and sustainable deformation monitoring system for high-rise buildings.

**KEY WORDS:** High-rise buildings; geodetic monitoring; Low-cost GNSS

## 1 INTRODUCTION

Structural Health Monitoring (SHM) is vital for ensuring safety, maintenance, and structural integrity of infrastructure. Structural Health Monitoring (SHM) facilitates continuing observation of structural performance, allowing for early problem detection, hence reducing the likelihood of failure and lowering maintenance costs. The necessity to implement novel SHM systems becomes critical as rapid urban expansion leads to significant structural development across the world [1], [2].

High rise buildings in particular, are exposed to both slow and dynamic deformations which necessitates for specialised monitoring techniques [3]. High-rise structures undergo continuous slow movements due to factors such as solar radiation and dynamic movements due to wind load and seismic activities. The conventional monitoring approaches for high-rise buildings require expensive installation efforts, along with other significant expenses and requirements such as time, physical and human resources [4].

Global Navigation Satellite Systems (GNSS) have emerged as a better option for deformation monitoring in recent decades, owing to advancements in high-quality GNSS receivers and effective processing techniques [5], [6]. GNSS-based monitoring systems now provide a precise system to observe both static and dynamic movements of structures [7], [8]. GNSS acquires multiple satellite signals to determine accurate positional coordinates, thereby facilitating the effective collection of long-term deformations, while simultaneously monitoring real-time dynamic motions. Modern geodetic grade GNSS receivers equipped with dual-frequency capability

mitigate atmospheric errors and improve their accuracy in location measurement [9]. High-rate GNSS receivers provide data acquisition exceeding 10 Hz, hence enabling the observation of sudden structural displacements during events such as earthquakes and wind-related phenomena [10]. GNSS operates more effectively in conjunction with other sensors, such as accelerometers, as it enhances monitoring precision and accuracy. However, the significant high cost of a GNSS monitoring station which will allow mm level positioning, limit their application in deformation monitoring applications [9], [11], [12].

Low-cost GNSS receivers have emerged as a viable alternative for structural monitoring. These receivers, considerably more economical than geodetic-grade alternatives, include dual-frequency functionality that improves positioning precision and reduce atmospheric errors [7], [9], [11]. Recent improvements in low-cost GNSS technology have resulted in the creation of multi-constellation receivers that employ signals from GPS, GLONASS, Galileo, and BeiDou to enhance positional precision and signal accessibility in urban settings [13]. The cost-effectiveness of these receivers, typically priced under £500, renders them a practical option for extensive implementation in structural monitoring applications. This is evidenced by the findings of several researchers who have utilized low-cost receivers for monitoring deformations of bridges and other infrastructure [9], [11], [14].

Experimental validation is essential to evaluate the feasibility of low-cost GNSS receivers for monitoring both slow and dynamic deformations in tall buildings. Prior research has illustrated the effective utilisation of low-cost GNSS for bridge

monitoring, emphasising its capability for monitoring structural displacements. Researchers have employed low-cost GNSS receivers to observe the deformation and oscillation of suspension and cable-stayed bridges, attaining sub-centimeter precision in both static and dynamic assessments. Recent studies indicates that employing suitable data processing methodologies, including Precise Point Positioning (PPP) and Real-Time Kinematic (RTK) corrections, enables low-cost GNSS to yield accurate displacement measurements equivalent to those from high-end geodetic GNSS receivers [7], [9], [11].

Despite considerable advancements in bridge applications, the accuracy of low-cost GNSS in high-rise structural health monitoring remains mostly unexamined. High-rise structures present additional obstacles, including multipath effects, signal obstructions, and dynamic loading conditions, requiring further investigation to evaluate the reliability and accuracy of low-cost GNSS in this context [15], [16]. This study attempts to assess the performance of low-cost dual-frequency GNSS receivers in monitoring the deformations of high-rise buildings and to compare their findings with geodetic grade GNSS receivers and other traditional surveying techniques such as total station-based monitoring.

Thus, the ultimate objective of this study is to assess the feasibility of low-cost GNSS receivers in high-rise structural health monitoring, hence advancing the creation of low-cost and sustainable monitoring solutions. The results will offer significant insights into their precision, accuracy, and limitations supporting further developments in SHM technology.

## 2 SLOW MOVEMENT SIMULATION

This experiment aimed to assess the performance of a low-cost GNSS system during periodic horizontal displacements. The Tallysman TWI low-cost GNSS antenna was evaluated using a low-cost receiver (U-blox F9P) through the experiment.

The Tallysman TWI antenna is engineered to provide precise GNSS performance in low-cost applications. It has a compact, lightweight design and facilitates multi-constellation, dual-frequency signal reception, rendering it appropriate for high-precision positioning. The durable design guarantees reliable signal quality and phase centre stability, crucial for applications necessitating precise and reproducible measurements [17], [18]. The U-blox F9P is a high-performance, low-cost GNSS receiver that facilitates multi-band and multi-constellation tracking, encompassing GPS, GLONASS, Galileo, and BeiDou. Engineered for accurate positioning applications, it provides real-time kinematic (RTK) functionalities. U-blox receivers has been incorporated for several deformation monitoring observations in the recent past [19], [20].

The experimental set up comprised with a movement simulation device which was utilised to simulate 1 cm horizontal (along E-W axis) movements every hour. Dual frequency GNSS data were collected with 1 Hz sampling rate

and the reference data were obtained through a Leica TS30 Robotic Total Station.

The experimental setup is depicted by figure 1.

Figure 1: Left- Tallysman TWI antenna and U-blox F9P receiver, Right: The movement simulation device

Collected data were processed through RTKlib processing software. RTKlib is an open-source software which has been utilised and validated in many GNSS applications and research [7], [9]. The software has been included into the analysis of GNSS data within the context of Structural Health Monitoring, owing to its capacity to assess carrier phase and pseudo range residuals. This enables users to gain a thorough comprehension of the quality of GNSS data and fluctuations in noise [21], [22], [23]. The following GNSS processing parameters were utilised in the post processing of the experimental data.

Parameter	Value
Processing mode	Kinematic (PPK)
Elevation mask	7°
Filter Type	Combined
Ephemeris	Broadcast
Ionospheric Correction	Broadcast
Tropospheric Correction	Saastamoinen

### 2.1 Analysis and Results

This study highlights the horizontal and vertical movements recorded by the Tallysman TWI low-cost GNSS antenna with the U-blox F9P low-cost GNSS receiver against the movements recorded by the Robotic Total Station. In figure 2 and 3 is depicted the horizontal and vertical movement time series of the Tallysman antenna for different satellite combinations as GPS only, GPS and Galileo and GPS, Galileo and Beidou.

Figure 2: Horizontal (E-W) movement recorded by the Tallysman TWI antenna connected to U-blox F9P low-cost GNSS Receiver for GPS only, GPS/Galileo, GPS/ Galileo and Beidou Satellite combinations.

Figure 3: Vertical movement recorded by the Tallysman TWI antenna connected to U-blox F9P low-cost GNSS Receiver for GPS only, GPS/Galileo, GPS/ Galileo and Beidou Satellite combinations.

All satellite combinations follow a similar trend in both Horizontal and vertical movements. The vertical movement observations show a comparatively higher noise levels than the horizontal observations. The following mean errors have been obtained during each movement for the different configurations.

Movement	Error (mm)		
	GPS	GPS/GAL	GPS/GAL BDS
H 01	3.78	2.52	1.87
H 02	0.92	1.09	0.9
H 03	1.86	1.22	0.28
H 04	3.49	2.84	4
Mean	2.51	1.92	1.76
V 01	2.46	3.91	5.92
V 02	3.6	5.66	4.61
V 03	3.81	2.94	4.69
V 04	3.65	11.95 (outlier)	12.06 (outlier)
Mean	3.38	4.17	5.07

For horizontal movements, the results were evident by the mean errors where the combination of GPS, Galileo and Beidou signals showed the best performance for the GNSS setup. This agrees with the findings of other studies where the use of multiple satellite systems increase the number of visible satellites and the satellite geometry thereby minimizing the noise [24], [25].

However, for the vertical observations the use of GPS only provided the best performance compared to the other combinations. This may result from enhanced signal stability, well-defined orbital characteristics, and advanced error modelling of GPS, especially in the vertical dimension. Furthermore, multi-GNSS integration may result in inter-system biases and discrepancies in vertical positioning due to fluctuations in satellite elevation angles, hardware delays, and ionospheric delay modelling among various systems, thereby compromising vertical accuracy if not adequately corrected [26], [27], [28].

A Welch Power Spectral Density (PSD) analysis was conducted to further explain the noise characteristics of the GNSS set up. The Welch technique calculates a signal's power distribution by segmenting the data, applying a window function, and averaging the periodogram. In GNSS data analysis, Welch PSD is especially effective for identifying signal artefacts, multipath effects, or oscillator instabilities, which appear as frequency-specific abnormalities in the spectrum domain. The resultant spectrum discusses the fundamental noise structures, which is essential for enhancing the reliability and precision of satellite-based positioning systems [29], [30].

The Welch PSD of the Tallysman antenna for different satellite combinations as GPS only, GPS and Galileo Only and GPS, Galileo and Beidou for horizontal and vertical movements have been depicted in figures 4 and 5 respectively.

Figure 4: Welch PSD for horizontal (E-W) movement recorded by the Tallysman TWI antenna connected to U-blox F9P low-cost GNSS Receiver for GPS only, GPS/Galileo, GPS/ Galileo and Beidou Satellite combinations.

Figure 5: Welch PSD for vertical movement recorded by the Tallysman TWI antenna connected to U-blox F9P low-cost GNSS Receiver for GPS only, GPS/Galileo, GPS/ Galileo and Beidou Satellite combinations.

The PSD results further indicate that the integration of GPS, Galileo, and Beidou satellites will result in the least amount of noise. Thus, a combination of multiple satellite constellations is suggested for optimum results with Tallysman TWI low-cost antenna and the U-blox F9P low-cost GNSS receiver. However, further experimentation is necessary to assess the impact of atmospheric errors and multipath toward the low-cost antennas and further tests will be carried out to test different atmospheric models for a deeper performance and noise analysis.

### 3 DYNAMIC MOVEMENT SIMULATION

A dynamic movement simulation test was conducted to assess the performance of Tallysman Antenna with the U-blox F9P receiver. This test was conducted through controlled vibrations of specific frequency range, incorporating the APS 113 shaker [31]. The APS 113 is a long-stroke, air-bearing electrodynamic shaker designed for the precise calibration and evaluation motion transducers. It delivers a force output of 133 N and a peak-to-peak displacement of 158 mm, operating within a frequency range up to 200 Hz. The air-bearing system ensures minimum friction, hence diminishing noise and distortion. Through the shaker a controlled vibratory platform was introduced to simulate a real-world oscillation [32].

The Tallysman TWI antenna was tested with the U-blox F9P receiver for vibrations at frequencies of 0.1 Hz and 0.25 Hz, produced by an analogue signal generator. The selection of low-frequency simulations aimed to recreate long-range oscillations, which are the primary vibrations of high-rise buildings caused by wind load. Three vibration amplitudes in the E-W direction (i) below 1 cm (ii) around 2-3 cm, and (iii) around 6-7 cm were manually introduced for 10 minutes. The accuracy of the GNSS data were determined through the E-W amplitudes compared against the measurements collected through LeicaTS30 Robotic Total Station. Same observation

and processing parameters as the slow movement simulation test were utilised for this test.

Figure 6: Left- The APS 113 shaker used for the experiment with Tallysman TWI, U-blox Patch and Leica AS10 Geodetic antennas. Right- U-blox F9P receivers connected to the antennas and Raspberry Pi devices to log the data.

#### 3.1 Analysis and Results

Displacement time series were obtained for the three introduced amplitude values. The exact oscillating amplitude cannot be controlled by the APS 113 shaker hence, the amplitudes were manually controlled and the RTS observation was taken as the reference amplitude [33].

Figure 7: The amplitudes recorded by the Tallysman TWI antenna connected to U-blox F9P low-cost GNSS Receiver for 0.1 Hz shake table oscillation.

Figure 8: The amplitudes recorded by the Tallysman TWI antenna connected to U-blox F9P low-cost GNSS Receiver for 0.25 Hz shake table oscillation.

Figures 7 and 8 depict the displacement time series at frequencies of 0.1 Hz and 0.25 Hz, respectively. The results indicate that the Tallysman antenna closely replicates the displacement achieved by the RTS. Further, the mean errors of positive and negative peaks were determined to provide further insight into the noise levels. The overall absolute error recorded by the Tallysman antenna with U-blox receiver is 0.6 mm for 0.1 Hz oscillation and 2.5 mm for 0.25 Hz oscillation.

The mean error of each amplitude value can be summarised as follows:

	Amplitude (mm)		Absolute Error (mm)
	RTS (Reference)	Tallysman (Observed)	
0.1 Hz	4.1	3.3	0.8
	17.0	16.4	0.6
	29.7	30.1	0.4
0.25 Hz	5.0	7.8	2.8
	16.6	17.6	1.0
	27.1	30.6	3.5

The mean amplitude values obtained from the Tallysman- U-blox low-cost GNSS configuration validate the feasibility of utilising such systems for monitoring dynamic movements.

#### 4 CASE STUDY

A preliminary case study was performed on a 220-meter-high residential building utilising a low-cost GNSS setup that included a Tallysman antenna and a U-blox F9P receiver. The building, a concrete-steel composite structure, serves as an effective testbed for structural monitoring because of its vulnerability to deformation under environmental pressures.

In high-rise structures, the variations of solar radiations and wind forces are among the most significant factors influencing structural performance [1]. Thermal impacts induce differential expansion between concrete and steel, potentially leading to internal tensions and long-term deformations due to the disparity in thermal expansion coefficients [1], [34]. The impacts are particularly evident in composite systems, where restricted expansion can result in cracking or the accumulation of residual strain over time. Wind-induced lateral loads concurrently create building wobble and oscillations, which compromise structural stability and affect serviceability and

occupant comfort [35], [36], [37]. Comprehending these environmental factors is crucial for the advancement of resilient high-rise structures and facilitates the larger incorporation of low-cost GNSS as an effective instrument for structural health monitoring.

Data for this case study were gathered using an 11-hour, 1 Hz GNSS data collection conducted on the building's rooftop. The reference data were acquired using a full geodetic GNSS configuration consisting of a Leica AS10 antenna and a Leica AS10 receiver. The rover stations were strategically positioned to minimize multipath interference, which is a common challenge in GNSS measurements due to signal reflection from nearby surfaces such as walls, windows, or metallic structures. To mitigate multipath errors, several strategies were implemented during the setup and data collection phases. First, the rooftop was chosen as the primary location to ensure a clear line of sight to the satellites and to minimize the presence of reflective surfaces in the vicinity. The GNSS antennas were mounted on the handrails of the building with sufficient height to reduce signal reflection from the ground.

During the planning stage, satellite geometry and the surrounding environment were carefully analysed using software-based sky plots to select observation periods with optimal satellite visibility and reduced likelihood of low-angle reflections. The rover stations were placed at locations with minimal obstruction and reflective surfaces, avoiding

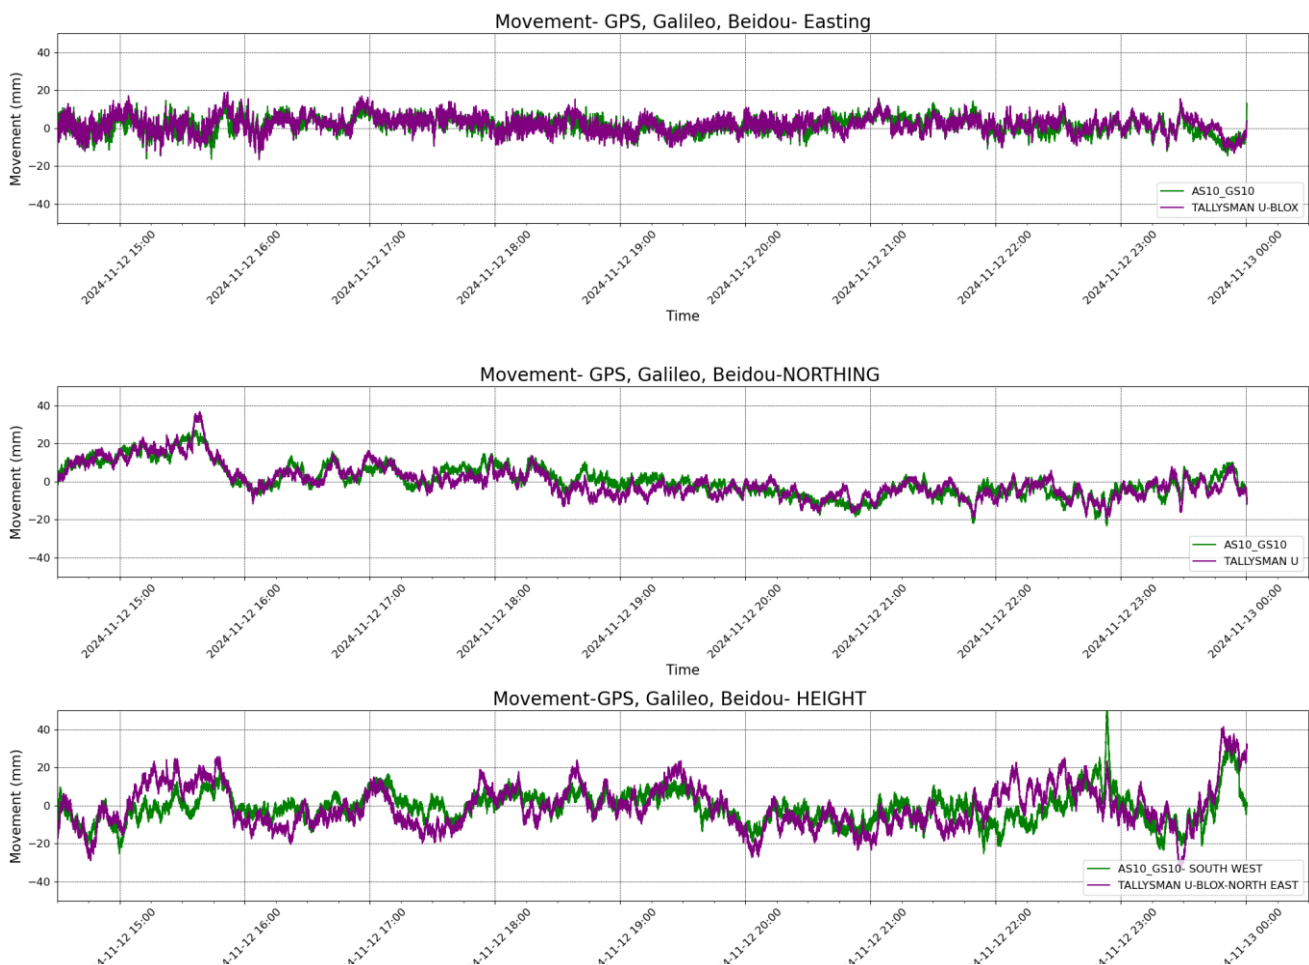

proximity to glass façades or metallic rooftops that could induce strong signal reflections. While these strategies significantly reduced the impact of multipath interference, it should be noted that completely eliminating multipath is unfeasible in real-world settings, particularly in urban or semi-urban environments.

Figure 9: Tallysman TWI antenna connected to the handrail of the building rooftop. Right- U-blox F9P receiver connected to the antenna and Raspberry Pi device to log the data.

#### 4.1 Analysis and Results

The data were post-processed via a short baseline double difference solution through RTKlib software. The Base Station is a continuously operating reference station (CORS) equipped

with a full geodetic setup and a baseline distance of 5.1 km. A time series analysis is conducted for the GPS, Galileo and Beidou satellite constellations to identify the positional variations in Northing, Easting and Height components of the monitoring points. As depicted by the time series in figure 10, the Tallysman antenna combined with the U-blox receiver

For the further understanding of the long-term variations in position, a moving average was calculated for a rolling window of 300s (5 minutes).

Figure 11: Moving average variation of the low-cost system and fully geodetic system.

demonstrates precision comparable to that of a full geodetic configuration. Although a dataset of 10 hours is inadequate for delivering comprehensive information into building movement, it sufficiently illustrates the potential of the low-cost system. This is further demonstrated by the following standard deviation values.

	Standard Deviation (mm)		
	E	N	H
Low-cost	4.50	8.50	11.31
Geodetic	4.23	8.08	7.63
Difference	0.27	0.42	3.68

Based on figure 11, it is evident that the low-cost GNSS setup share the similar trend as the geodetic setup. Adhering to the same trend suggests that the temporal variations and directional changes observable in the positional data of both configurations demonstrate similarly over time—indicating that, despite variation in accuracy, the low-cost setup can capture the same movement patterns and positional dynamics as the high-precision geodetic reference.

However, further testing on high-rise buildings is needed to assess the performance of low-cost GNSS systems over long-term deployments. Short-term tests do not capture the gradual effects of component wear, thermal drift, or mounting stability issues that may reduce accuracy over time. Weather conditions such as heavy rain, snow, or high winds can also impact signal quality by causing attenuation, multipath reflections, or antenna

movement. In addition, variations in the ionosphere and troposphere can introduce delays that low-cost receivers may not correct effectively. Long-term studies under different weather and seasonal conditions are therefore essential to better understand noise levels and reliability, and to guide improvements in system design and calibration.

## 5 CONCLUSION AND FUTURE DIRECTIONS

This paper presented the results of control experiments testing Tallysman TWI low-cost GNSS antenna with U-blox F9P dual frequency low-cost GNSS receiver in slow moving conditions and dynamic motion conditions. It further presented results from an initial case study conducted on a high-rise building testing the low-cost system.

The results indicate that the low-cost system can reach a comparable precision with the geodetic systems and can obtain sub-centimeter accuracy through rigorous observation and processing methods, such as the use of multiple satellite constellations for observations [7], [9]. The horizontal component can reach an accuracy of less than 5mm for both slow motion and dynamic motion conditions which depicts the potential of low-cost systems in achieving a sub-centimeter accuracy. The noise levels in the vertical component are generally higher than that of the horizontal movements, however, they are still less than a couple of centimeters.

The case study on the building further demonstrates the efficiency of low-cost systems, since they exhibit comparable accuracy and precision to full geodetic configurations in practical scenarios when atmospheric and multipath challenges are not completely mitigated. The findings of this work align with the results of other research on the utilisation of low-cost GNSS systems for monitoring deformations in flexible structures, such as tall buildings and bridges [7], [9], [14].

This work is part of an ongoing study evaluating various low-cost technologies under diverse atmospheric and environmental circumstances. Subsequent investigation will involve testing low-cost systems for long-term deformation observations across various environmental conditions and seasons. This will facilitate better understanding of the accuracy and precision of low-cost devices, as well as their suitability for long-term deployment. It will further evaluate the fluctuations in noise under various atmospheric circumstances, so facilitating the identification of methods to mitigate or minimise those errors.

**ABSTRACT:** The transport infrastructure is reaching in many cases the end of its effective life cycle. The present condition is attributable to a combination of ageing and progressive deterioration as traffic volumes continue to increase. However, it is possible that even recently constructed bridges may already have significant structural damage. Consequently, the maintenance management of existing bridges is becoming increasingly important. However, there is often a lack of up-to-date information on the actual condition of the structures. This is because measuring infrastructure is merely the final stage of the monitoring process, given that tactile sensors are extremely time-consuming and labour-intensive to use. Additionally, due to these principles, measurements can only be taken at a few selected points. The combination of these limitations offers great potential for the use of non-contact profile laser scanning (PLS) in the context of load testing of bridge structures. The structure is scanned with a high-frequency laser beam without the necessity of entering the structure. The spatially distributed displacement measurements obtained in this manner provide a significantly higher density of spatial information about the structure than was previously feasible. Until now, dynamic investigations have been primarily conducted in the domain of profile scanning. This study primarily focuses on static load tests, where spatial resolution and measurement precision can be further enhanced. Two case studies are presented, illustrating non-contact PLS measurements for load testing: one example is on a 160 m arched railway bridge, and the other example is on a steel-concrete composite motorway bridge. It has been demonstrated that a precision of a few tenths of a millimetre can be attained with a spatial resolution in the centimetre range.

**KEY WORDS:** profile laser scanning (PLS); displacement; bridge monitoring; load testing; SHM; SHMII-13; Full paper

## 1 INTRODUCTION

Against the background of an ageing infrastructure and the clear trend towards faster trains, higher track utilisation and increasing freight traffic on the roads, reports about the poor condition of the transport infrastructure, decaying bridges and the problems of steel or prestressed concrete bridges from the 1960s and 1970s are becoming increasingly frequent. Damage to newer bridge structures is rarely reported [1], as the quality of planning and execution as well as testing and monitoring should generally ensure appropriate quality.

In order to cover the entire spectrum, two completely different structures are considered in the following:

A motorway bridge from the 1960s, which has basically reached the end of its life due to the enormous freight traffic on the Brenner motorway and the expansion to three lanes per direction. And a railway bridge that is only a few years old and has already suffered massive damage due to manufacturing defects.

What both structures have in common is that assessing the condition of existing bridges is becoming an increasing challenge when important decisions have to be made about cost-intensive replacement or renovation measures, especially if these become necessary after just a few years. In this context, precise knowledge of the actual structural behaviour is a valuable tool for condition assessment, which in many cases can lead to an extension of the remaining service life and thus to considerable benefits for bridge owners and society.

The actual structural behaviour is usually determined by experimental investigations, which may include measurements

of accelerations, velocities, strains, inclinations and/or temperatures [2-4]. In addition, displacement measurements based on linear displacement transducers (LVDT) are used to determine relative displacements at abutments [2], between neighbouring superstructures of the same bridge [5] or the width of existing cracks. This type of displacement measurement is possible in principle, as a fixed reference point can be used for the installation of the sensor.

Another important parameter of the structural behaviour would be the absolute vertical displacement of the bridge. This can provide direct information about the actual stiffness of the structure, which in turn can be used in the updating process of the structural model [6, 7].

However, the direct measurement of absolute displacements with classical LVDTs is usually very complex, if not impossible, due to the lack of fixed reference points [4] or because the bridge is simply too high. To close this gap, significant progress has been made in recent years in the field of non-contact displacement measurement. Corresponding sensors enable the measurement of structural displacements without the need to attach sensors to the structure. Suitable technologies for non-contact displacement measurements include terrestrial laser scanning (TLS) [8, 9, 10, 11, 12], laser vibrometer [13, 14], image-based total stations [15], and microwave interferometry [10, 16, 17, 18].

Compared to other non-contact measurement techniques, which only allow measurements at one point, TLS or profile laser scanners (PLS) can also be used to perform spatially distributed measurements. The spatial resolution offers the

advantage that larger areas of the structure can be monitored with only one sensor, allowing a deeper understanding of the structural response in an efficient way.

This study expands the application of PLS by demonstrating its capability for dense, high-precision deformation monitoring on two large-scale bridges under static loading. The novel aspects include the spatial resolution achieved, the scale of the structures examined, and a worst-case precision evaluation strategy, which has not been systematically addressed in previous studies.

Before going into more detail on TLS and in particular its use as a PLS for dynamic and static load tests in section 3, the two investigated bridges are presented in section 2.

## 2 INVESTIGATED BRIDGES AND PERFORMED LOAD TESTS

As mentioned in Section 1, the following section presents load tests on two quite different bridges, which will first be discussed in more detail in this section.

### 2.1 Motorway bridge

The Austrian Brenner motorway is part of the European route E45, which crosses Europe in a north-south direction from northern Finland to southern Italy. The Alpine crossing in Austria is an important part of the route and is also crucial for cross-border freight transport in Europe. The motorway route across the Alps was mainly built in the 1960s, and the bridge under investigation was also built during this period.

Fig. 1: View of the motorway bridge: span 7.

The bridge was originally designed for two lanes in each direction, but a third lane was added in the 1980s due to the increasing amount of traffic. However, the basic load-bearing structure of the bridge has remained essentially unchanged over the years. As an important part of a European transit route, the structure must therefore be carefully monitored.

The structure itself consists of a steel-concrete composite construction and is designed as a 7-span continuous girder, with the outer spans having a length of 70 m and all other spans having a length of 84 m. The total length is therefore 560 m.

Part of this monitoring strategy was a load test, which was carried out in May 2023. One direction of travel on the motorway bridge was temporarily closed in order to place two trucks, each weighing 50 tonnes, on the bridge to create

different load scenarios. In addition, four quasi-static tests were carried out.

The profile laser scanner measurements focussed on the outermost span (span 7) next to the southern bridge abutment, as shown in Figure 1.

In addition to the profile scanner, 3D TLS [19, 20, 21], fibre optic sensors [19, 21, 22], dynamic and static total stations [19, 20, 23], a terrestrial microwave interferometer, modular digital camera total stations [24], GNSS [21] and acceleration sensors [21] were used.

### 2.2 Railway bridge

The railway bridge is a 370 m long double-track railway overpass designed as an arch bridge. The longest span is 165 metres. The track is up to 71 m above the valley floor and is straight in the construction area at a design speed of 300 km/h, see Figure 2.

Fig. 2: View of the railway bridge.

The bridge structure has only been under traffic for a few years and already shows significant construction-related damage. In the course of the structural inspection, structural defects and concrete spalling were initially recognised and appropriate repair measures were planned. During the repair work, it turned out that the gravel pockets and the severe segregation of the structure were not only localised, but affected large areas of several square metres, see Figure 3.

Fig. 3: Damaged area with heavily segregated concrete structure.

The damage is due to segregation and washing out processes during concreting. In order to determine the full extent of the damage, structural diagnostics were carried out on the entire arch bridge. The investigations confirmed the assumptions regarding the poor concrete quality of the arch concrete. The results raised questions about the serviceability and stability of the structure under traffic.

As a mathematical analysis of the damage alone was not conclusive, the owner decided to carry out a load test. The static load test was carried out with five locomotives with a total weight of 550 tonnes in various load positions. In order to be able to determine the deformations under the applied load as simple and reliable as possible, a non-contact PLS was used.

### 3 TERRESTRIAL LASERSCANNING (TLS)

TLS such as the Z+F IMAGER 5016 make it possible to digitise the entire environment in a 360° panorama in the form of a 3D point cloud. During the scanning process, a high-frequency rotating mirror deflects the laser beam and the TLS also rotates around its vertical axis. This sequential recording process produces a high-resolution point cloud of the visible environment, see Figure 4.

The non-contact distance measurement of the Z+F IMAGER 5016 works according to the AMCW method (Amplitude Modulated Continuous Wave). To obtain the absolute distance value, the phase shift between the reflected and emitted signal is used, which is induced by the light path in the intensity-modulated periodic signal. To resolve the phase ambiguities and thus determine the absolute distance, several wavelengths are modulated onto the carrier wave. In addition, the user is provided with the amplitude (intensity), which represents the ratio of emitted to received energy, see grey scales in Figure 4.

Fig. 4: Extract from the 3D point cloud of span 7 of the motorway bridge. Intensity values are shown as grey scales.

In principle, the measurement method is characterised by a very high spatial resolution, but in turn only allows a low

temporal resolution. In addition, the single point precision is in the millimetre range and is therefore not sufficiently accurate for most monitoring applications.

#### 3.1 Profile laser scanning (PLS) dynamic

In contrast, a profile laser scanner (TLS in profile mode, 2D) [8, 10, 25, 26] only uses the high-frequency rotating deflection mirror, but there is no rotation around the standing axis, see diagram in Figure 5 and section of a profile in Figure 6.

Fig. 5: Schematised representation of PLS.

As special properties of the sensor are important for bridge monitoring applications, these are explained in more detail in the following.

##### 3.1.1 Measuring Frequency

The usable measurement frequency for deformation monitoring of bridges with the Z+F IMAGER 5016 in profile mode depends on the rotation speed of the deflection mirror, which is up to 55 Hz. It should be noted that there is a relationship between temporal and spatial profile resolution: at the same laser measurement rate, doubling the measurement frequency halves the spatial resolution.

##### 3.1.2 Measurement Precision

The precision of the measurement depends significantly on the energy reflected back from the structure and thus on its backscattering properties in the corresponding wavelength band, since the phase measurement precision is directly coupled to the signal-to-noise ratio (SNR) of the reflected signal [27].

For the Z+F IMAGER 5016, as is common practice in the TLS field, the manufacturer provides range measurement standard deviations for different surface reflectivities and ranges. These are based on a fixed laser measurement rate of 127 kHz and range from 0.2 mm to just under 10 mm.

However, these accuracy specifications are not very meaningful in practice and only cover a very small range of applications: The specified reflectivity of the structure to be measured is usually not known and can also vary spatially. In addition, the measurement geometry plays a crucial role in the specification of realistic measurement uncertainties; it is partly responsible for the occurrence of predominant forward reflection, i.e. the shallower the angle of incidence, the greater the potential for forward reflection and low SNR. The

measurement geometry is also critical for the derivation of the projected vertical deformations. Furthermore, no reflectors are to be used in the application scenario considered, so an accuracy specification based on a defined reflector is not meaningful.

For TLS in general, the stochastic modelling of the range measurement based on the registered intensities [28,29] is possible and allows a practical (insitu) determination of the range precision. This approach takes into account all effects affecting the measurement process (surface reflectivity, measurement geometry, atmosphere, etc.).

### 3.1.3 Spatial Resolution

With the Z+F IMAGER 5016 the range is part of the raw measurement. The range resolution is 0.1 mm and is defined by the size of the modulated fine scale used in combination with the implemented phase measurement.

The actual spatial resolution of a profile scanner is defined by the rotation speed of the deflection mirror, the laser measurement rate and the divergence angle of the laser beam. The actual spatial resolution is usually lower than the angular resolution specified by the manufacturer for two reasons:

- Depending on the choice of parameters, the laser spots of successive measurements overlap to a greater or lesser extent, which reduces the actual resolution on the surface of the structure.
- The rotational speed causes an additional deformation of the laser footprint in the profile direction (elongation), as a corresponding angular range is always covered during the measurement time. This can be interpreted as a larger "true" divergence angle or as an increasing overlap of successive measurements according to [30, 31].

Another aspect when considering the spatial resolution actually available in practical applications is that the single-point precision of a PLS is usually not sufficient for the requirements of the application scenario [8]. Therefore, in order to achieve the required precision, an averaging of neighbouring measurement points is performed (class formation), which further reduces the spatial resolution of the profile scanning in favour of a qualitatively better derivation of displacements.

Two examples are given below to give an idea of the spatial resolution that can be achieved:

- 20,000 points are measured per profile at a measurement frequency of 55 Hz, which corresponds to a theoretical angular increment of  $0.018^\circ$ . If 75 adjacent points are combined (class formation, see colour coding in Figure 6), the actual available angular increment is reduced to  $1.35^\circ$ , which corresponds to a spatial resolution of 0.24 m at a distance of 10 m.
- If the measurement frequency is reduced to 14 Hz, 80,000 points are measured per profile and a spatial resolution of 0.06 m at a distance of 10 m is achieved.

Depending on the measurement geometry, deformation time series with a precision in the sub-millimetre range can be derived from the spatially distributed time series generated in this way.

Compared to other measurement techniques for monitoring applications, which only allow measurements at a single point, PLS thus also allow a spatially distributed recording of the structural response. The spatial resolution offers the advantage

that larger areas of the structure can be monitored and verified with a single sensor, which enables a deeper understanding of the structural response in a very efficient way.

Fig. 6: Extract from profile measurement, with coloured representation of class formation.

### 3.1.4 Projection of displacements

The purpose of using a PLS for deformation monitoring of bridges is to obtain deformations in a defined direction (usually vertical or horizontal). Therefore, the "raw" measurements need to be projected in the desired direction. For projection, it is usually assumed that the vertical displacement of a bridge is dominant, while possible horizontal components are considered negligible. Since the raw measurements of a profile scanner consist of distance and internal angle measurements, the projection of deformations is inherent and possible with high accuracy. The manufacturer specifies an angular accuracy of  $0.004^\circ$  for the Z+F IMAGER 5016. The horizon reference is provided by an internal dynamic compensator which operates in the same accuracy range as the angle encoders. The dynamic compensator also detects and corrects for low frequency movements of the sensor during the measurement.

Up to this point, it has been assumed that there is only vertical displacement of the bridge structure due to an applied load. However, it is possible that there is an additional horizontal displacement component. As the PLS is a 2D sensor, these can be measured directly at suitable locations (vertical areas) if the displacement is in the profile direction.

### 3.2 Profile laser scanning (PLS) static

For use in static load tests, the temporal dimension plays a subordinate role, but in static profile laser scans the precision and spatial resolution can be further increased by additional temporal averaging during the load retention phases.

With a load retention phase of 5 minutes, at least 4,200 profiles are measured. This corresponds to 315,000 individual measurements in the example defined above with 75 points per class and profile that can be used for further derivation of the measured values, which enables a significant increase in precision.

The major challenge in static load tests with profile laser scanners is to keep the external conditions constant so that, for example, no tilting of the tripod occurs, e.g. due to solar radiation or unstable ground. TLS, like almost all non-contact measuring sensors, are sensitive to atmospheric conditions, which in extreme cases, e.g. due to rain or fog, can completely prevent measurement.

#### 4 QUASI-STATIC LOAD TEST

For quasi-static load tests, the speed at which the load (truck or locomotive) passes over the measurement object (bridge) is usually kept low in order to minimise dynamic effects that could falsify the result. This is in favour when using profile scanners, as the overall measurement rate of approximately 55 Hz is not comparable with conventional sensors and the spatial resolution has to be reduced at higher repetition rates.

Accordingly, it makes practical sense in these cases to use the lowest repetition rate of 14 Hz, as this allows up to 80,000 points per profile to be measured and maximises the spatial resolution.

For the two sample bridges, a quasi-static load scenario was only carried out for the motorway bridge, which is why this section focuses on the measurements at the Brenner Pass.

The quasi-static load test was performed with two trucks of 50 tonnes each, which crossed the entire bridge directly one behind the other at a speed of 5 and 30 km/h respectively. The position and speed of the two trucks were monitored using GNSS so that the resulting displacements could be synchronised with the position of the trucks.

The measurements with the PLS took place in span 7, the scanner was located approx. 13 m below the bridge and a main girder was measured. As the bridge is located in a curve, the horizontal measuring range on the main girder was limited to approx. 50 m of the total span length of 70 m due to the curvature of the bridge.

In this case, approx. 75 measuring points are averaged per class, so that ultimately 117 classes, i.e. 117 spatially distributed displacement time series can be derived, whose standard deviations are in a sector around 0.1 mm. The standard deviation tends to increase towards the edge due to the deteriorating geometry.

Figure 7 shows a section of the measurement results for a crossing at 5 km/h. In the upper diagram, a time series approximately in the centre of the field is shown in black. In addition, three coloured markers show the times at which the two trucks are located in the middle of span 5 (blue), in the middle of span 6 (red) and in the middle of span 7 (yellow). The design of the bridge as a continuous girder is evident here, as the measured span (span 7) already reacts to the loads in the other spans and rises or falls accordingly.

This representation as a time series based on just a single analysed class corresponds to the result that an LVDT would provide.

In the lower diagram in Figure 7, the points in time marked in different colours (trucks on span 5, span 6, span 7) are shown in full spatial resolution with 117 classes in the corresponding colour. The PLS enables the evaluation of the bending line for the entire scanned field section at any point in time.

The data gap in the centre of the diagram is caused by a combination of installed sensors (cabling) and a reinforced, heavily bolted area (see Figure 4 in the centre of the main girder).

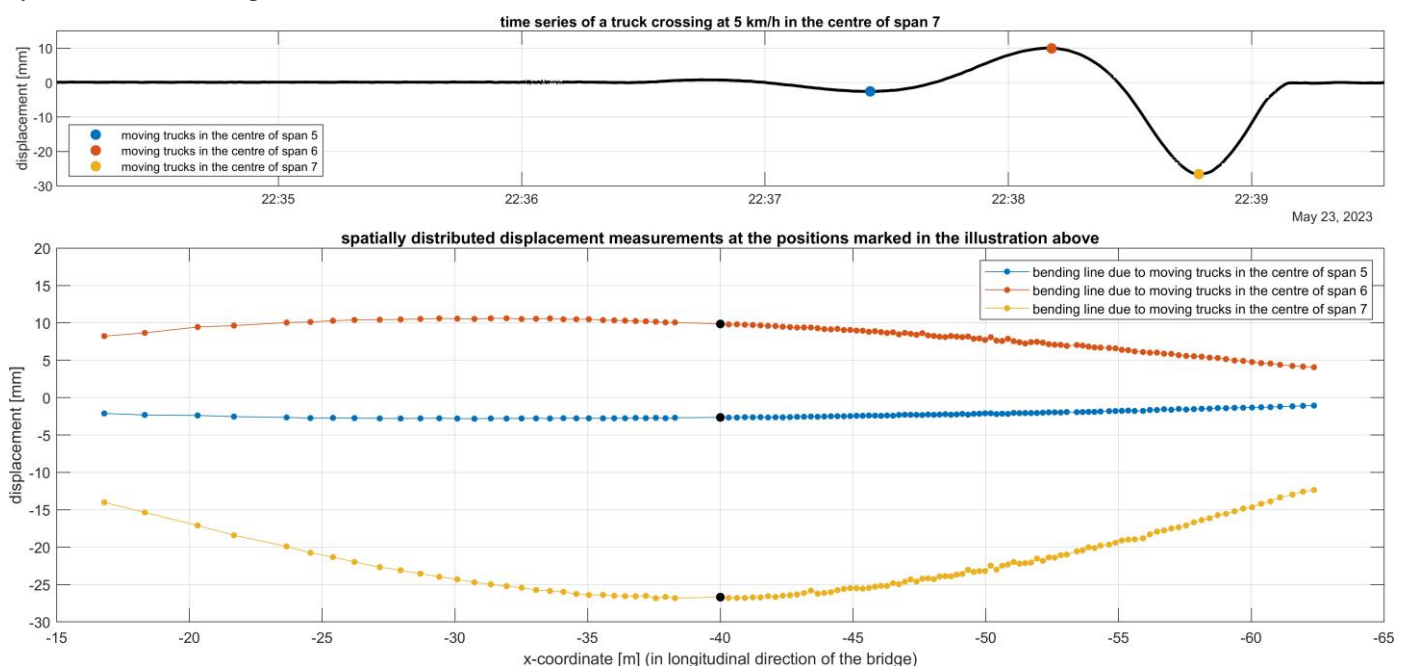

Fig. 7: Exemplary results of the evaluation of a quasi-static load test: In the upper diagram a simple pointwise time-displacement representation can be seen, while the lower diagram shows the potential of profile scanning, as a bending line can be analysed over the entire visible area at any point in time.

Fig. 8: Results of the evaluation of four static load tests: In the upper diagram, the bending lines of the two load positions are each shown twice. The lower diagram shows the differences between the respective tests and provides an estimate of the achievable precision of the measurements using profile scanning.

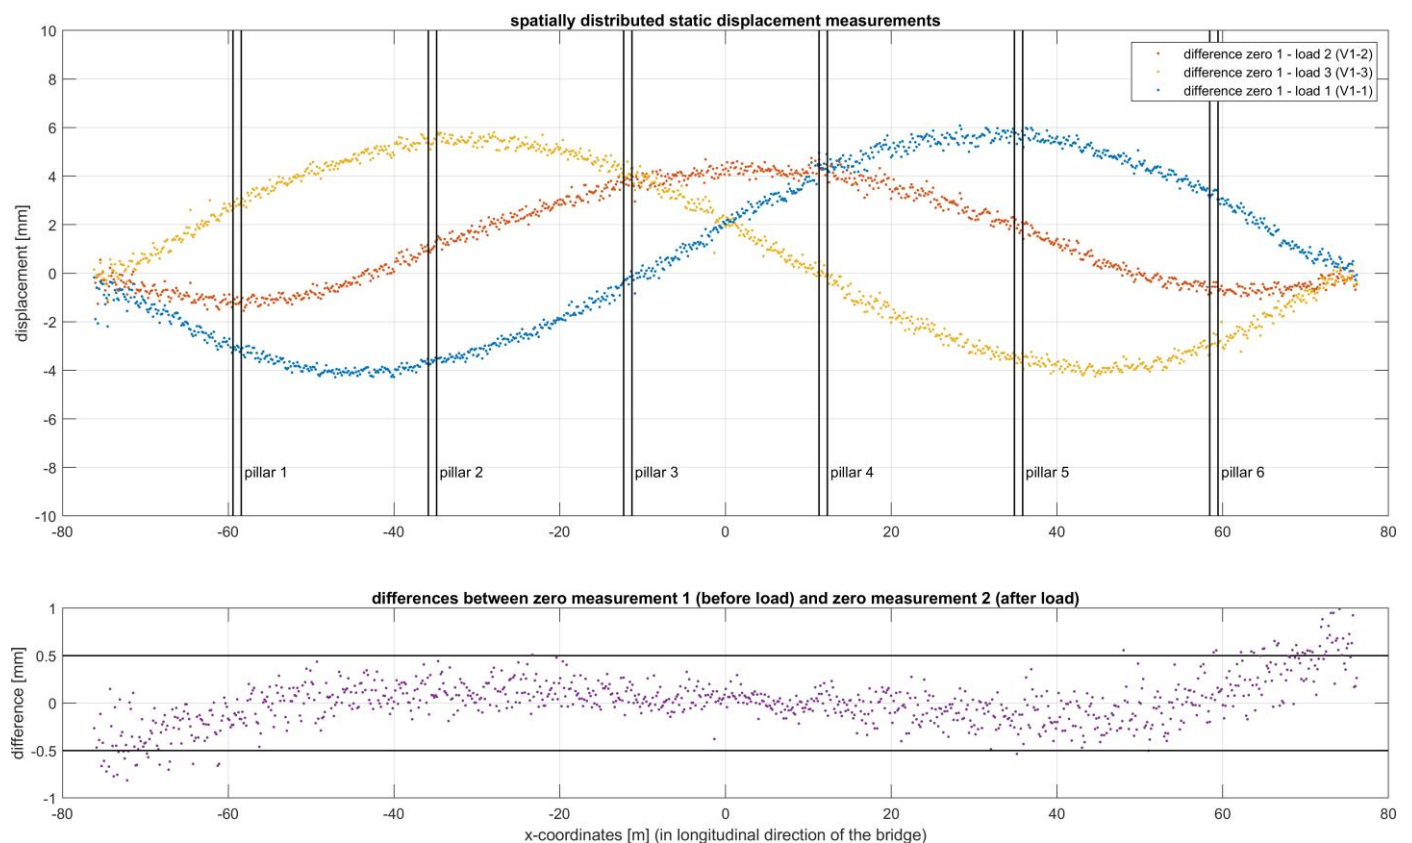

Fig. 9: Results of the evaluation of three static load positions: The upper diagram shows the bending lines induced by the load positions. The lower diagram shows the differences between two independent zero measurements (bridge without load) before and after the actual measurements.

## 5 STATIC LOAD TESTS

A static load test was conducted on both structures: This entailed the deployment of two trucks (with a total weight of approximately 100 tonnes) on the motorway bridge and five locomotives (with a total weight of approximately 550 tonnes) on the railway arch bridge. For each bridge different load configuration were tested and the structural response was measured using static profile laser scanning (PLS).

As outlined in Section 3.2, the enhanced spatial resolution in static profile scanning enables a measurement point spacing of 10 cm across the full scan range in both cases. This enabled the acquisition of over 400 spatially distributed displacement measurements on the motorway bridge and almost 1000 on the railway bridge (see upper diagrams in Figures 8 and 9). Those diagrams illustrate the measured displacements for the various load configurations, which are colour-coded according to the load configuration. As illustrated in Figure 7, analogous data deficiencies have been observed to occur due to external factors such as sensor interference or bolted connections.

In comparison with previous PLS applications, this study introduces a significantly higher density of measurement points on large-scale infrastructure due to the use of static PLS and demonstrates the feasibility of applying PLS as a primary deformation measurement technique during full-scale static load tests.

In order to provide further illustration of the precision potential of static PLS, two novel evaluation strategies were applied: For the motorway bridge (see Figure 8), a comparative analysis of repeated load positions was conducted (see lower diagram). For the railway bridge (see Figure 9), the evaluation is based on two independent zero measurements (see lower diagram). It is important to note that both approaches provide a conservative estimate of measurement precision under realistic test conditions. This is due to the fact that they account for potential systematic effects, such as slight variations in load positioning or residual structural deformations.

Despite the presence of these influencing factors, the deviations between the individual tests for the Brenner motorway remain predominantly below 0.25 mm, with systematic offsets of 0.1 mm and 0.05 mm, respectively, as previously described.

For the measurements at the railway bridge, a vertical precision of 0.5 mm was specified in the area of the piers (-60 m to 60 m) that support the track on the arch. As illustrated in the lower diagram of Figure 9, this order of magnitude could be sustained. The deviations exhibit a slight increase towards the edge, a phenomenon that can be attributed to the substantial dimensions of the structure and the deteriorating measurement geometry towards the edge. Furthermore, a discernible residual systematic remains identifiable in the observed discrepancies, potentially attributable to residual deformation of the bridge arch. Irrespective of the underlying cause, this further distorts the precision estimate, thereby leading to the expectation of even better results.

For the profile scanning and load retention phases, a duration of five minutes was deemed adequate for both bridges. Consequently, a test involving three load retention phases and double zero measurement could be conducted in approximately 30 minutes under optimal conditions. However, it was

necessary to deviate from this ideal procedure for the two static load tests. It was determined that load retention phases of 10 minutes would be implemented on the Brenner motorway, a measure necessitated by the substantial deployment of individual sensors (see Section 2.1).

In the case of the arch bridge, only profile scanning was used and a load retention phase of 5 minutes was planned, although this had to be extended in some cases due to fog passing through.

## 6 CONCLUSION

Compared to conventional sensors, PLS can be used to obtain a large number of spatially distributed measurements with just one sensor, which enables an extremely efficient measurement and also a previously unimaginable understanding of the structural reaction.

Even for the quasi-static load test, it was possible to derive over 100 spatially distributed displacement time series over a range of almost 50 metres. The analysable range of the section was not limited by the sensor, but by the radius of curvature of the bridge.

Implementing static load tests enhances spatial resolution by enabling the temporal averaging of additional measurement data. This assertion is substantiated by the case study of the railway bridge, in which the deformation of the entire 160 metre arch was captured using almost 1,000 measurement points. Despite challenging environmental and structural conditions, sub-millimetre precision of up to 0.5 mm was achieved in the critical areas.

Unlike previous PLS applications, this study uses static PLS as the primary measurement method for full-scale static load tests on large infrastructure. The high density of measurement points, over 400 on the motorway bridge and almost 1,000 on the railway bridge, enabled detailed, spatially resolved deformation analysis for various load configurations. To assess measurement precision under realistic conditions, two innovative evaluation strategies were employed. The first involved repeated load configurations on the motorway bridge and the second involved two independent zero measurements on the railway bridge. Both approaches yielded conservative estimates of precision, which is advantageous when accounting for systematic effects such as variability in load placement and residual deformations.

The findings demonstrate not only the technical feasibility of static PLS in such scenarios but also its robustness under non-ideal conditions, including sensor interference, structural complexity, and environmental influences such as fog. The study demonstrates the potential of static PLS for precise, efficient, and large-scale deformation monitoring in structural testing contexts.

**ABSTRACT:** This paper presents an integrated structural health monitoring (SHM) system combining multi-sensor networks with geospatial GNSS technologies to enhance infrastructure resilience. Developed by the authors, the system unites millimeter-accurate TEXTant® GNSS monitoring with MSS® leak detection and environmental parameter sensing, all synchronized via the TEX-Sky Monitoring Cloud. Validation efforts included comparative field testing against International GNSS Service (IGS) standards at GFZ Potsdam, demonstrating millimeter-level positioning precision. Real-world deployments—including the Aquitaine Bridge (France), slope monitoring for mining operations (Germany), tank basin and catch basin monitoring at a chemical facility (Germany), and the first station of the cross-border Asia Minor GNSS Network—confirmed the system's operational robustness. Time-synchronized multi-sensor datasets enable predictive maintenance, early anomaly detection, and asset life extension. The modular and scalable system architecture adapts flexibly to diverse infrastructure contexts. Future integration with machine learning technologies is anticipated to enhance pattern recognition and anomaly detection. This work highlights the role of synchronized, multi-parameter monitoring as a foundation for next-generation infrastructure management and public safety.

**KEY WORDS:** Structural Health Monitoring (SHM), GNSS, Multi-Sensor Systems, Autonomous GNSS Monitoring, TEXTant, TEX-Sky Monitoring Cloud, MSS Leak Monitoring, Big Data Analytics, Predictive Maintenance, Tectonic Monitoring

## 1 INTRODUCTION

The increasing age of global civil infrastructure, combined with escalating environmental stresses and rising usage demands, has highlighted critical vulnerabilities in bridges, tanks, basins, slopes, and other key structures. Traditional inspection practices—largely reliant on manual surveys and infrequent assessments—often fail to detect the early-stage, progressive deformations that precede catastrophic failures. Recent advancements in geospatial positioning, sensor miniaturization, and wireless data technologies offer unprecedented opportunities for real-time, high-precision structural health monitoring (SHM). Among these, Global Navigation Satellite System (GNSS) monitoring, capable of millimeter-level displacement measurements, has emerged as a core technology. When augmented with complementary sensing modalities—such as leakage detection, corrosion monitoring, and environmental parameter tracking—an integrated, multi-sensor SHM network becomes feasible. This paper presents the development, validation, and practical deployment of such an autonomous multi-sensor SHM system, rooted in high-precision GNSS science, geodetic surveying, and real-world engineering applications. Field-tested at critical infrastructure sites—including the Aquitaine Bridge in France, containment structures in the chemical sector in Germany, and a planned tectonic GNSS monitoring network across Asia Minor—the system demonstrates the viability of scalable, time-synchronized, automated infrastructure health management.

The system's foundation lies in two core technologies developed in-house: the TEXTant® GNSS movement monitoring system and the MSS® Leak Monitoring system. Since 2011, the MSS® system has been successfully deployed in landfill and hazardous waste facilities, starting with the first permanent installation at a power plant in Eemshaven, Netherlands. Building upon this experience, the TEXTant® GNSS system introduces fully autonomous, millimeter-accurate displacement monitoring without dependence on local reference networks. Both technologies are unified under the TEX-Sky Monitoring Cloud, a scalable, modular platform enabling synchronized multi-sensor integration, advanced data analysis, and future AI-assisted pattern recognition. The development of this platform addresses urgent needs for resilient, autonomous, and real-time infrastructure monitoring to enhance public safety, optimize maintenance strategies, and support sustainable asset management.

## 2 SCIENTIFIC BACKGROUND AND MOTIVATION

The urgent need for continuous, high-resolution monitoring of civil infrastructure becomes increasingly apparent as traditional inspection methods often fail to detect subtle but critical early-stage deformations. As Ghaffarian et al. (2023) emphasized, aging structures and increased environmental stress demand real-time monitoring solutions. While several commercially available GNSS systems can achieve millimeter-level precision using base-rover configurations, they depend on local reference infrastructure and often require significant setup and must all be post-processed by experts. These constraints render them impractical for fully autonomous real-time PPP monitoring

across multiple or remote sites. Motivated by these challenges, the authors developed a new system architecture aiming to bridge the critical gap between high-precision monitoring and full automation.

As Elsaïd (2025) demonstrated, low-cost, multi-frequency GNSS receivers can achieve comparable accuracy to high-end systems when calibrated and combined with precise point positioning (PPP) software. PPP enables centimeter- to millimeter-level positioning accuracy by combining precise satellite orbits, clock corrections, and advanced error modeling, without reliance on local differential reference stations (Teunissen & Montenbruck, 2017).

Moreover, a significant gap persists: there is a lack of fully autonomous GNSS-based SHM systems capable of delivering millimeter-level real-time accuracy without requiring expert recalculations. Traditional IGS stations, for example, do not recalibrate continuously, and thus their displacement data may not reflect real-time changes critical to detecting early-stage structural degradation. Millimeter accuracy is essential because slight, continuous movements—caused by temperature, dynamic loads, or tectonic effects—can serve as precursors to catastrophic failures such as bridge collapses, landslides, dam breaches or earthquakes. Monitoring vulnerable and aging infrastructure without such precision carries unacceptable risks. The collapse of the Carolabrücke in Dresden, Germany, in September 2024, illustrates the fatal consequences of undetected structural fatigue (City of Dresden, 2024).

Therefore, the TEXTant® GNSS system was conceived with three key objectives: to provide continuous, unmanned, millimeter-accurate monitoring; to automate data processing and alarm generation without human intervention; and to support early hazard detection across a wide range of critical infrastructure types. It operates autonomously 24/7, with real-time or daily processed datasets accessible through the TEX-Sky Monitoring Cloud.

The importance of rapid deployment and flexibility was highlighted when, just one month after the completion of the TEXTant® system's one-year trial phase, a devastating earthquake struck Turkey and Syria in February 2023. Responding immediately, the first TEXTant® GNSS station for tectonic monitoring was donated to the city of Adana, Turkey, and installed in April 2023 atop the City Hall with support from Mayor Zeydan Karalar. The Adana station now delivers daily millimeter-level movement results to the TEX-Sky Monitoring Cloud, marking the first operational node of the Asia Minor GNSS Network project.

Beyond GNSS-based monitoring, integrated multi-sensor networks further expand system resilience. Cawley (2018) highlighted the necessity of linking strain, acoustic, and environmental data streams to enhance the robustness of predictive analytics. Multi-sensor systems like TEXTant®, when combined with leak detection, corrosion monitoring, and environmental sensing, offer unprecedented opportunities for proactive, data-driven maintenance strategies.

### 3 TEXTANT® GNSS TECHNOLOGY: DEVELOPMENT AND VALIDATION

#### 3.1 System Design and Autonomy

The TEXTant® GNSS system was developed by the authors as a modular, autonomous monitoring solution designed to meet the millimeter-accuracy requirements of geodetic infrastructure monitoring. The device architecture includes an energy-efficient processing unit, solar power modules, and the capacity to host up to four GNSS antennas per station. The entire system is configured for fully autonomous operation, from data acquisition to daily processing, and network transmission via secure cloud protocols.

#### 3.2 PPP Algorithm and Accuracy Optimization

Building on the scientific foundation presented, the development of the GNSS-based monitoring solution centers on the integration of autonomous, low-cost multi-frequency receivers configured to operate without dependence on local reference networks. The approach leverages precise point positioning (PPP) as its core processing strategy, supported by algorithms specifically refined for structural health monitoring applications.

In Elsaïd's doctoral research (Elsaïd, 2025), the implementation of improved dynamic modeling within GNSS algorithms was shown to increase both stability and precision in real-world environments. The TEXTant® system developed through this research was subjected to rigorous field testing, including comparative validation with a conventional geodetic reference system. Results revealed a convergence between autonomous GNSS solutions and classical base-rover measurements, confirming the capability for millimeter-accurate displacement tracking over long time periods.

#### 3.3 Field Validation at GFZ Potsdam

A pivotal phase in this validation process was conducted at the IGS station POTS, located at the German Research Centre for Geosciences (GFZ) in Potsdam, Germany. The developed TEXTant® system was connected in parallel to the existing geodetic Javad receiver at the GFZ, sharing the same GNSS antenna. This configuration enabled a direct comparison under identical atmospheric and signal conditions.

Figure 1. Comparative analysis of the developed TEXTant® GNSS system (23-day dataset) and the GFZ reference system (90-day dataset), demonstrating consistent millimeter-level precision (Elsaïd, 2025).

As detailed in Elsaid's thesis, a 23-day dataset collected from the TEXtant<sup>®</sup> receiver was compared against a 90-day reference dataset from the GFZ system. The comparative analysis yielded exceptional results: horizontal and vertical deviations remained within millimeter thresholds, and no long-term drift or divergence was observed throughout the monitoring period (Elsaid, 2025).

Elsaid emphasized that despite the economical and compact design of the TEXtant<sup>®</sup> device, the results demonstrated its capacity to meet professional-grade geodetic standards. The thesis further highlighted the device's resilience under fluctuating atmospheric conditions and its reliable convergence behavior during daily sessions.

Figure 2. TEXtant<sup>®</sup> GNSS station initiating autonomous operation and data processing upon activation.

### 3.4 Cross-Validation with Bernese and NRCAN

Further scientific credibility was added through collaboration with the Canadian Geodetic Survey (NRCAN), where raw GNSS datasets from TEXtant<sup>®</sup> were submitted to the Natural Resources Canada PPP server for validation. The NRCAN PPP analysis confirmed the integrity and reliability of the device's positioning performance. Additionally, Bernese GNSS Software, a respected academic processing tool developed at the University of Bern, was used for post-processing, yielding comparable accuracy (Elsaid, 2025).

Hardware-level accuracy was validated by comparison with the co-located IGS reference station at GFZ, equipped with a high-grade Javad GNSS receiver. Despite its simplified electronics and energy-saving design, the TEXtant<sup>®</sup> system achieved millimeter-accurate results closely matching the IGS benchmark, demonstrating scientific and operational robustness.

### 3.5 Deployment and Scalability of the TEXtant<sup>®</sup> System

A critical innovation of the TEXtant<sup>®</sup> development is the deployment of solar-powered, autonomous GNSS stations requiring minimal maintenance. As highlighted by Liu et al. (2016), low-power GNSS configurations enable extensive, scalable monitoring across geographically distributed assets without compromising precision.

TEXtant<sup>®</sup> units operate fully independently, automatically processing data and uploading daily results to the TEX-Sky Monitoring Cloud. Field deployments—including the Aquitaine Bridge and landslide-prone slopes in Germany—validated the system's capability to detect millimeter-level displacement, including thermal expansion effects and gradual settlement trends.

These applications demonstrate the robustness and scalability of the TEXtant<sup>®</sup> concept, enabling broader use in earthquake-prone regions, industrial facilities, and coastal infrastructure. Furthermore, the modular architecture supports integration of supplementary sensors such as accelerometers, leak detectors, and strain gauges, providing a comprehensive and expandable framework for structural health diagnostics.

## 4 THE TEX-SKY MONITORING CLOUD ARCHITECTURE

The TEX-Sky Monitoring Cloud represents the data infrastructure backbone of the multi-sensor SHM platform. Developed to support continuous, time-synchronized acquisition and correlation of high-frequency monitoring data, the cloud-based system functions as a central interface for real-time infrastructure condition analysis. Its architecture enables

integration across multiple sensor nodes and locations, transforming raw data into accessible and actionable insights. Monitoring networks benefit significantly from centralized cloud-based storage and synchronized databases. As noted by Wu et al. (2018), cloud platforms offer scalability and interoperability, two essential features for long-term SHM in complex environments. Within this architecture, each GNSS or auxiliary sensor station independently uploads data via secure protocols, with redundant backups to ensure data integrity. The system maintains strict time-stamping and correlation rules across parameters such as displacement, leakage, temperature, or vibration, thereby enabling consistent multi-variable analysis.

By enabling daily automated reports and long-term pattern visualization, the TEX-Sky Monitoring Cloud supports transition from reactive to preventive maintenance regimes. This shift aligns with Su et al. (2018), who emphasize that cloud-enabled SHM platforms foster predictive analytics through longitudinal data analysis. The TEX-Sky interface provides stakeholders with graphical dashboards, alarm notifications, and exportable analytics, tailored to engineering, operational, or regulatory needs.

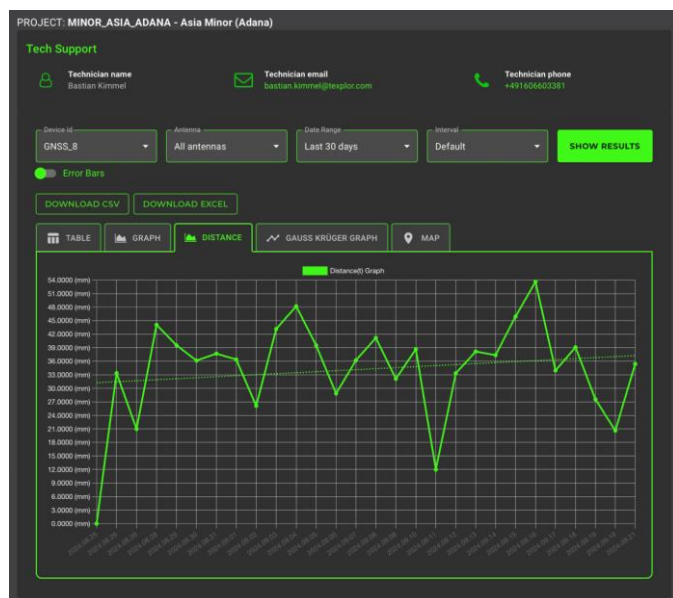

Figure 4. TEX-Sky interface displaying visualized GNSS results, including Gauss-Krüger and UTM coordinates.

The TEX-Sky Monitoring Cloud was developed in-house to support flexible, scalable integration of diverse sensor types. Its modular database structure not only enables real-time SHM across multiple sites but also prepares the platform for future machine learning applications. By continuously expanding the database design, the system already allows seamless transfer of automatically generated monitoring data into AI-based anomaly detection tools, ensuring technological adaptability for evolving SHM needs.

Dang et al. (2022) describe such systems as forming the foundation of Digital Twin implementations, enabling structures to be mirrored in real-time for deeper analysis. While such features remain under development, the system architecture already supports seamless upgrades. Collectively,

the TEX-Sky Monitoring Cloud transforms raw sensor data into centralized knowledge—paving the way for more resilient, data-informed infrastructure management.

## 5 MULTI-SENSOR NETWORK INTEGRATION

An essential component of advanced structural health monitoring (SHM) is the ability to integrate various sensor types into a single, interoperable network architecture. The system developed by the authors merges geospatial GNSS data with time-synchronized readings from multiple environmental and structural sensors, including MSS<sup>®</sup> leak detection, humidity, temperature, corrosion, inclination, and accelerometers. The integrated network ensures comprehensive infrastructure monitoring across dynamic and static parameters.

The two key pillars of this multi-sensor network are the TEXtant<sup>®</sup> GNSS system for precise movement tracking and the MSS<sup>®</sup> Leak Monitoring system for sealing integrity control. Since 2011, the MSS<sup>®</sup> leak monitoring system has been successfully deployed across a wide range of applications and several continents, including hazardous waste landfills, mining operations, and chemical containment basins, starting with its first major deployment at a power plant project in Eemshaven, Netherlands.

The MSS<sup>®</sup> leak detection technology is central to monitoring the integrity of sealed systems, particularly for tank farms and containment basins. Its use of conductive cord networks and automated alerting mechanisms has proven effective in early detection of micro-leaks, contributing to environmental safety and regulatory compliance. As demonstrated in deployments such as the tank basins monitored since 2020, this technology reduces inspection effort while ensuring 24/7 leak monitoring capacity.

The interoperability of all sensor modules relies on the synchronized timing and unified data architecture provided by the TEX-Sky Monitoring Cloud. Each sensor type, regardless of its function or installation context, transmits data tagged with precise timestamps, allowing multi-dimensional correlation and anomaly detection. The TEX-Sky Monitoring Cloud itself was independently developed by the authors to serve as a flexible, modular database architecture. It is designed for the long-term storage, processing, and visualization of synchronized SHM data, and it is continuously updated to remain compatible with machine learning (ML) techniques for anomaly detection and predictive analytics.

Kazmierski et al. (2018) note that modular SHM architectures enhance adaptability, enabling sensor types to be added or removed depending on project-specific risks and requirements. This modularity is especially crucial for retrofitting existing infrastructure, where different physical layouts and constraints may exist.

The integration strategy employed supports preventive and predictive maintenance practices by providing a more holistic view of structural conditions. Furthermore, combined datasets improve diagnostic confidence: for example, identifying correlated patterns between displacement, moisture ingress, and thermal expansion.

With ongoing development, future sensor classes—including gas sensors, advanced corrosion probes, and customized client-

specific sensors—may further extend this multi-sensor network’s diagnostic capacity. By consolidating diverse sensing modalities within a unified, scalable system, the platform demonstrates the technical feasibility and operational benefits of fully integrated SHM for modern infrastructure.

## 6 FIELD DEPLOYMENTS AND CASE STUDIES

This section presents the implementation of the authors’ system in diverse real-world environments to evaluate its performance, scalability, and scientific contribution to structural health monitoring (SHM).

### 6.1 Aquitaine Bridge Monitoring (France)

The Aquitaine Bridge in Bordeaux, completed in 1967, is one of France’s major river crossings and represents a landmark of civil engineering from the postwar period. Given its age and strategic importance, it was selected as an ideal candidate to validate the TEXTant<sup>®</sup> GNSS monitoring system under real-world operational conditions. The bridge’s susceptibility to thermal expansion, structural aging, and dynamic traffic loads provides a comprehensive environment to assess long-term monitoring technologies.

Figure 5. GNSS antenna installation on the 90-meter-high pylon of the Aquitaine Bridge in Bordeaux, France.

Since April 2022, an autonomous TEXTant<sup>®</sup> GNSS station has been continuously operating on one of the 90-meter-high pylons. The system collects millimeter-precise daily displacement data across the X, Y, and Z axes in the ECEF (Earth Center Earth Fixed) coordinate system, processed automatically through precise point positioning (PPP) without the need for local base stations.

The monitoring initiative is carried out in cooperation with Cerema Sud-Ouest. Validation against conventional geodetic measurements confirmed the system’s accuracy. As John Dumoulin, MA (Cerema), reported, the TEXTant<sup>®</sup> system reliably delivers absolute millimeter-accurate displacement values on a daily basis without requiring a fixed reference station (Dumoulin, 2025).

Analysis of the time-synchronized monitoring data has revealed a clear correlation between structural displacement and ambient temperature variations. Specifically, movements

along the X-axis exhibit a direct correlation with temperature, while displacements along the Y-axis are inversely correlated. These findings reflect thermal expansion and contraction effects acting asymmetrically on the bridge structure. The observed patterns provide insight into seasonal deformation behavior and demonstrate the utility of high-resolution GNSS data for capturing structural response under environmental loading.

Future plans include the addition of temperature sensors and strain gauges to further enrich the TEX-Sky Monitoring Cloud database with synchronized multi-parameter datasets.

Figure 6. Correlation between X-axis movement (green) and temperature variations (°C, red) from 2022–2024.

Figure 7. Correlation between Y-axis movement (green) and temperature variations (°C, red) from 2022–2024.

Figure 8. Correlation between Z-axis (height) movement (green) and temperature variations (°C, red) from 2022–2024.

### 6.2 Asia Minor Cross-Border GNSS Network

The Asia Minor GNSS Network was initiated as a donation-based scientific infrastructure project following the devastating

Turkey–Syria earthquakes in February 2023. The project aims to establish a cross-border tectonic monitoring and early warning system in one of the most geodynamically active regions worldwide.

Tectonic complexity in the area is driven by the interaction of the African Plate, Arabian Plate, and Anatolian Block. Near the city of Adana, the northward motion of the Arabian Plate compresses the Anatolian Block, forcing it westward along the East Anatolian Fault. This geodynamic regime results in frequent high-magnitude seismic events, making the region a critical focus for real-time geodetic monitoring initiatives. The first TEXTant<sup>®</sup> GNSS station was successfully installed atop the City Hall in Adana in April 2023, with the support of the local administration. The GNSS station has been operating autonomously since then, delivering daily millimeter-precision displacement data in X-Y-Z axes. It reliably records both the gradual tectonic drift of the Anatolian Block and abrupt height anomalies associated with seismic events exceeding magnitude 5.

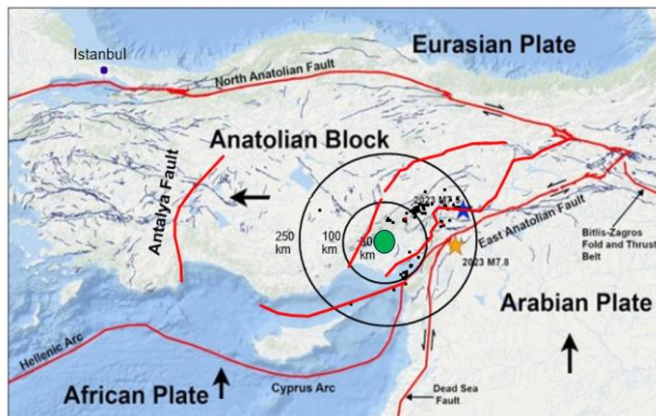

Figure 9. TEXTant<sup>®</sup> GNSS station in Adana (green), recorded earthquakes (black), and earthquakes >5M magnitude (red).

Figure 10. Displacement tracking at the TEXTant<sup>®</sup> GNSS station in Adana: Easting (blue), Northing (green), and Height (red) changes.

In collaboration with the CNRS National Center for Geophysics in Lebanon and the University of Jordan, preparations are underway for the installation of two additional TEXTant<sup>®</sup> GNSS stations. Discussions regarding station

placement are ongoing, and the delivery and commissioning are scheduled for 2025. These installations mark the next steps in expanding the Asia Minor Network.

The broader objective is to establish a cross-border GNSS infrastructure covering six countries—Turkey, Syria, Lebanon, Jordan, Egypt, and Saudi Arabia. All recorded data are automatically processed via PPP algorithms and archived within the TEX-Sky Monitoring Cloud, facilitating scientific collaboration, seismic risk research, and the future development of regional early warning systems.

This initiative represents the first operational cross-border PPP-based GNSS tectonic monitoring network in the Asia Minor region.

### 6.3 Landslide Risk Monitoring (Germany)

In a geologically sensitive mining region in Germany, an autonomous TEXTant<sup>®</sup> GNSS monitoring network was deployed to monitor slope stability. The project area was characterized by historic mining activities, creating a heightened risk of slope destabilization and landslides over time.

Two solar-powered TEXTant<sup>®</sup> GNSS stations, equipped with a total of six antennas, were installed on the potentially unstable slope. These stations operate autonomously and transmit daily displacement results in X, Y, and Z axes to the TEX-Sky Monitoring Cloud, where the time-synchronized datasets are automatically processed and archived.

Previously, the slope was inspected at intervals by land surveyors, with weeks-long delays between measurements and data interpretation. The introduction of daily, continuous GNSS monitoring significantly enhanced the ability to detect subtle deformations at an early stage. Regular automated reports now document absolute movements in local coordinate systems, offering actionable insights into both spatial displacement and temporal trends. These visualized datasets are used to create detailed deformation maps, illustrating where and by how much the terrain is shifting.

This deployment demonstrates how continuous GNSS-based monitoring provides superior resolution, frequency, and responsiveness compared to traditional manual surveying, contributing to improved risk mitigation strategies for landslide-prone areas.

Figure 11. GNSS antenna connected to an autonomous TEXTant<sup>®</sup> station powered by a solar energy system.

#### 6.4 Industrial Multi-Sensor SHM (Germany)

At an industrial site in Germany, a multi-sensor SHM system was implemented to monitor the structural integrity of critical containment infrastructure exposed to heavy operational loads, fluctuating groundwater conditions, and tidal forces from the nearby Elbe River. The aim was to reliably assess structural status, extend service life, and minimize costly manual inspections that disrupt operations.

Since 2020, MSS<sup>®</sup> leak monitoring has been deployed across three containment structures: a storage tank, a concrete catch basin, and a reinforced concrete basin with a liquid liner. In total, 32 leak sensors were installed—eight around the tank, sixteen around the catch basin, and eight within the basin floor—embedded into both new and existing structures. Early-stage leak detection during commissioning enabled targeted repairs, demonstrating the system's preventive maintenance value.

Figure 12. Leak monitoring system with eight sensors embedded around the perimeter of the monitored tank using mounting sleeves.

In 2024, TEXtant<sup>®</sup> GNSS movement monitoring stations were added to the network, providing autonomous daily X-Y-Z displacement data with millimeter precision. This data is essential for detecting differential settlements and deformations linked to seasonal groundwater variations and river-induced soil dynamics.

A corrosion monitoring system, featuring 64 embedded sensors across both original and newly built concrete walls, enables comparative degradation analysis. Additionally, moisture sensors were installed between double-wall structures to monitor water ingress risks via resistance measurements.

All sensor modules are integrated into the TEX-Sky Monitoring Cloud, allowing centralized, time-synchronized data correlation and automated reporting. The system has been approved by TÜV-Nord, supporting regulatory compliance while optimizing inspection intervals. By reducing the need for frequent manual interventions, the multi-sensor SHM deployment contributes to enhanced operational reliability, environmental safety, and lifecycle cost savings.

Figure 13. The monitoring computer sends all multi-sensory results (movement, leakage, corrosion) to the TEX-Sky Monitoring Cloud.

These case studies demonstrate the adaptability, precision, and value of the authors' multi-sensor SHM system in diverse structural contexts, from heritage bridges to critical industrial assets and geohazard zones.

## 7 DISCUSSION: PREDICTIVE MAINTENANCE AND AI OPPORTUNITIES

The integration of time-synchronized data streams from geospatial and structural sensors provides a foundation for advanced data-driven maintenance strategies. As infrastructure systems age and face intensifying environmental pressures, the transition from reactive to predictive maintenance becomes increasingly necessary. Long-term datasets derived from autonomous monitoring technologies enable trend analysis, anomaly detection, and system-wide diagnostics—laying the groundwork for intelligent decision support systems.

A core advantage of synchronized SHM networks lies in their ability to generate longitudinal datasets that capture subtle structural changes over time. As Razali et al. (2020) note, big data analytics applied to sensor data can enhance preventive maintenance by identifying hidden correlations and early-warning indicators. The TEX-Sky Monitoring Cloud facilitates such analyses through automated reporting tools and correlation matrices spanning parameters like displacement, leak detection, inclination, and corrosion.

Furthermore, the platform supports early-stage integration with machine learning frameworks. According to Wu et al. (2018), AI-enhanced SHM platforms can extract latent patterns from high-volume sensor streams, offering insights unattainable through manual evaluation. The cloud's architecture, which time-aligns and stores multi-dimensional data across geographically distributed sites, enables the application of supervised learning algorithms for condition classification and anomaly detection.

The evolution toward data-driven maintenance is also aligned with Digital Twin paradigms. Dang et al. (2022) describe Digital Twins as dynamic virtual replicas of physical infrastructure, continuously updated through real-time sensor inputs. In our framework, the combination of daily GNSS-derived position data and environmental sensor feedback enables a similar mirroring of structural states, especially in applications like slope monitoring and tank basin surveillance. The benefits of such an approach are multifold: improved lifecycle predictions, optimized inspection intervals, targeted intervention planning, and enhanced safety margins. Ultimately, by embedding intelligence into SHM workflows, engineers can ensure that infrastructure resilience evolves in tandem with societal needs and technological capability.

## 8 CONCLUSION AND FUTURE PERSPECTIVES

This paper has presented the development, scientific rationale, and field validation of a modular, autonomous monitoring system that integrates multi-sensor technologies with advanced geospatial GNSS capabilities. Designed to achieve millimeter-level accuracy in displacement, leakage detection, and environmental monitoring, the system represents a fundamental shift toward data-driven, real-time structural health monitoring (SHM).

Central to this approach are two core technologies developed by the authors: the TEXTant<sup>®</sup> GNSS movement monitoring system and the MSS<sup>®</sup> Leak Monitoring technology. Their integration through the TEX-Sky Monitoring Cloud enables scalable, synchronized monitoring across diverse infrastructure types—from heritage bridges and industrial containment systems to tectonic plate boundaries and geotechnically unstable slopes.

Field deployments in France, Germany, and Turkey have demonstrated the system's scientific robustness, operational reliability, and its capacity to support predictive maintenance strategies. The introduction of fully autonomous, daily-updating monitoring solutions fills a critical technological gap, particularly where traditional inspection cycles or manual GNSS data post-processing fall short.

Continuous, unmanned monitoring systems capable of high-precision results offer new opportunities to prevent disasters

such as bridge collapses, dam breaches, and infrastructure failures due to undetected degradation.

Future work will focus on expanding cross-border SHM networks, contributing to the development of international standards for autonomous infrastructure monitoring, and strengthening global collaboration to enhance structural resilience.

**ABSTRACT:** Structural health monitoring (SHM) is crucial for ensuring the integrity and safety of infrastructure. Traditional vibration analysis techniques rely on sensors such as Inertial Measurement Units (IMU) and Global Navigation Satellite Systems (GNSS), total stations (TS) and fibre-optics (FO), which require a physical attachment to structures in the observation process. However, Light Detection and Ranging (LiDAR) offers a contactless alternative, enabling high-resolution, time-synchronized observations that capture spatially continuous deformation information. This paper presents an innovative framework for SHM that leverages LiDAR-based time-domain frequency analysis to monitor dynamic structural behavior effectively. By integrating spatio-temporal modeling techniques, we establish a robust methodology for detecting oscillations and deformations in infrastructure. Our approach enhances current SHM practices by providing a scalable solution that does not require physical sensor deployment. Thus, this methodology provides information in much higher spatial resolution compared to the aforementioned approaches. The proposed methodology is evaluated by controlled experiments, demonstrating its applicability to real-world SHM scenarios and its potential for continuous, non-invasive structural assessment.

**KEY WORDS:** Structural Health Monitoring; Laser Scanning; B-Splines; Harmonic Oscillation; Point Cloud.

## 1 INTRODUCTION

Structural integrity is a fundamental concern in civil engineering, necessitating continuous monitoring of deformations and vibrations in infrastructure. Bridges, buildings, and other structures are subject to environmental and mechanical forces, including wind, traffic loads, temperature variations, and seismic activity. These forces induce static and dynamic deformations, which must be accurately tracked to prevent structural failures.

Traditionally, SHM relies on point-based sensors such as Global Navigation Satellite System (GNSS) [1, 2], Inertial Measurement Unit (IMU) [3, 4], total stations [5], and fiber-optic (FO) [6, 7] sensors, which provide precise motion data but require physical attachment to structures (Fig. 1). Optical sensors, including cameras [8, 9, 10], Vibrometers [11, 12, 13, 14], and Light Detection and Ranging (LiDAR) [15, 16], offer contactless observations, reducing maintenance effort and enabling long-term deployment. Among these, LiDAR has gained prominence due to its ability to capture high-resolution, time-synchronized spatial data, making it well-suited for SHM applications.

While prior research has explored LiDAR-based monitoring, empirical validation and integration into SHM workflows remain limited. This study addresses these gaps by presenting a comprehensive framework for contactless structural vibration monitoring using LiDAR. Our research focuses on leveraging time-domain frequency analysis to capture oscillatory behavior and quantify structural deformations more effectively.

This paper addresses the following research questions:

- Can LiDAR-based time-domain frequency analysis provide reliable results for SHM applications?

- How does point-wise processing compare to area-wise processing in structural vibration analysis?
- Do observation residuals exhibit systematic patterns that can inform SHM decision-making?

We answer those questions applied to SHM methodologies by integrating 3D point clouds of LiDAR, that improve vibration analysis, uncertainty quantification, and structural condition assessment.

Figure 1. Potential 4D bridge monitoring with GNSS (green), IMU (blue) or LiDAR (red)

## 2 SPATIO-TEMPORAL PROCESSING

LiDAR sensors naturally observe their surroundings with a high point sampling rate of several MHz and a spatial resolution in the mm-level. This observation principle enables to record high frequent 4D (3D + time) deformation signals of structures, as displayed in Figure 1 in comparison to using IMU and GNSS sensors. To use LiDAR point clouds for vibration monitoring, we present within this work an implementation of spatio-temporal connections, which we evaluate experimentally. Therefore, we first introduce into our experimental setup within section 2.1 to show a coarse

overview of the object and used sensor. In section 2.2, we briefly describe our developed methodology to tackle 4D LiDAR data processing. Lastly, we discuss results regarding the outcome and limitations in section 2.3.

Figure 2. Experimental measurement setup

### 2.1 Experimental Setup

We evaluate our methodology using continuous observations of micro-electro-mechanical system (MEMS) LiDAR sensors to capture the periodic motion of a forced-excited acrylic glass sheet in Figure 2. This sheet is two by one meter and clamped on the upper and lower sides. Since it is also erected vertically, gravity acts asymmetrically on the test construction. Our experimental setup simulates real-world conditions by introducing controlled periodic excitation forces induced by a linear actuator with a frequency of about 0.3 Hz. Furthermore, we test the adaptability of our approach across different configurations and object geometries to assess its scalability. The selected process enables a continuous frequency mode description of a dynamically oscillating object, which ensures accurate spatial approximation and robust frequency estimation, enabling a fully automated analysis using low-cost sensors.

### 2.2 Methodology

Our approach harnesses LiDAR data to exploit its contactless observations and high sampling rate for time domain frequency estimation [17]. However, dimensions are limited to the LiDAR sensors used in respective monitoring settings [16]. To further enhance processing efficiency, we integrate point cloud observations within a time-domain framework directly. This reduces computational complexity by minimizing intermediate processing steps while maintaining spatial and temporal coherence.

In our workflow, we first implement an initial frequency estimation process based on spectral analysis techniques in the time domain, ensuring that dominant oscillation modes are accurately captured. Furthermore, consecutive points and their spatial neighborhoods facilitate establishing temporal and spatio-temporal connections, allowing direct oscillation modeling simultaneously in time and the metric space. By

introducing spatial B-spline modeling, we establish smooth spatial transitions between neighboring observations [16]. Additionally, we connect observations in time by their underlying periodic signal. With both spatial and temporal connections, we formulate spatio-temporal connections

$$w(u, v) = \mu(u, v) + \sum_{i=0}^N a(u, v) \cdot \cos(2\pi f_i t) + b(u, v) \cdot \sin(2\pi f_i t)$$

as a combination of the Fourier Series [18] and functions used in geometric modeling [19]. By employing a sophisticated mathematical model in time  $t$ , we approximate components like an immovable mean surface  $\mu(u, v)$ , amplitude variations, and phase shifts corresponding to frequencies  $f_i$  by Fourier parameters  $a(u, v)$  and  $b(u, v)$  [20]. Except frequencies, all components are described as geometric functions expressed with their first and second principal component  $u, v$  in Figure 3 and the movement in time along the third principal component  $w$ . Figure 4 displays the signal  $w$  along the time axis  $t$  (not sorted for  $u, v$ ) for experimental data of 100 sec: Clearly, the oscillations are visible.

Figure 3. Observation point cloud with its principal components  $u, v, w$ .

We further quantify parameter uncertainty to evaluate the reliability of estimated variables, thereby enabling robust movement and vibration analysis of spatially connected surfaces. Generally, our method simplifies the representation of periodic signals while preserving essential spatial characteristics for interpretation.

Figure 4. Part of the noisy time series observed along principal component  $w$

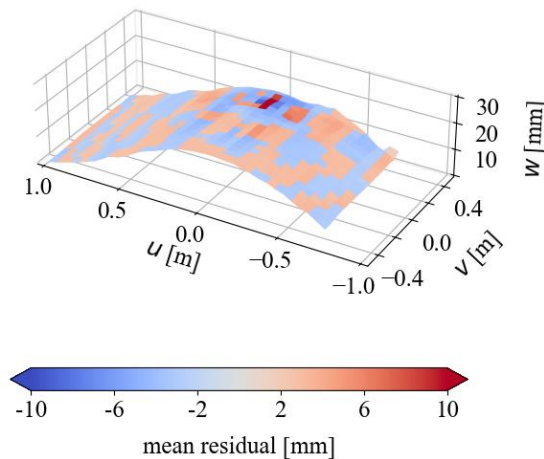

Figure 5. mode shape of the dominant amplitude with overall mean residuals as colors

### 2.3 Results and discussion

Our developed methodology effectively captures and describes enforced motion in both space and time. The integration of LiDAR-based time-domain frequency analysis offers a significant advancement in dynamic object monitoring, reducing reliance on traditional sensor frameworks. Moreover, it automatically combines observations compared to the individual processing of individual sensors e.g. IMU and GNSS.

Thus, we can explore interdependencies between parameters and their impact on results, highlighting the adaptability of our approach across different LiDAR systems. Besides the continuous amplitude shape shown in Figure. 5, we further analyze residuals from estimated parameters to identify systematic patterns that may indicate underlying structural characteristics in Figure 5. Therefore, our results show that continuous processing in the time domain produces higher fidelity reconstructions compared to point-wise approaches like mode description using IMU and GNSS sensors. Additionally, uncertainty propagation studies reveal the high sensitivity of estimated frequencies concerning sensor noise as well as environmental factors at the observation sight [16].

We further investigate the influence of different geometric modeling methods for establishing spatio-temporal relationships. The results indicate that B-spline modeling outperforms polynomial approximations in capturing smooth transitions while maintaining high-frequency response accuracy [16]. This highlights advantages of flexible basis functions in vibration analysis applications.

## 3 CONCLUSION

Our study demonstrates that LiDAR-based time-domain processing enables high-resolution monitoring of dynamic objects, offering advantages over traditional sensor-based methods as contactless observations and processing of the full object. The developed methodology ensures robust frequency estimation, efficient uncertainty quantification, and improved adaptability across different application domains.

Future research will extend our methodology to real-world scenarios such as bridge vibration analysis, integrating additional sensor modalities for enhanced robustness. Herein, we will also evaluate the limits of our approach in more detail.

Further improvements will focus on refining uncertainty quantification and optimizing computational efficiency to facilitate large-scale implementations. Additionally, we aim to investigate the potential for hybrid sensor fusion, combining LiDAR data with conventional methods to enhance the accuracy and robustness of vibration analysis in complex monitoring environments.

**ABSTRACT:** Geodetic monitoring of reclaimed landfills is essential in ensuring the geotechnical safety of slopes and for monitoring the process of landfill settlement caused by biological and physico-chemical decomposition of the deposited waste. Insufficient recognition of the size and directions of displacements may lead to severe damage to the landfill body (landslides, sinkholes) and endanger the environment and the life and health of people living near the landfill. Classic geodetic monitoring of such facilities is based on measurements of single control points (benchmarks) located on the landfill body, the displacements of which often do not represent actual changes occurring in the area of the entire facility. The solution to this problem is to use Light Detection and Ranging (LiDAR) technology, which allows surface measurement of the entire studied area, making it possible to obtain a complete image of changes in the geometry of the landfill body. This paper presents a case study of a reclaimed municipal solid waste landfill located in Poland for which monitoring was applied using Terrestrial Laser Scanning (TLS) and Airborne Laser Scanning (ALS) from an Unmanned Aerial Vehicle (UAV). The acquired 3D data made it possible to obtain reliable information on the deformation processes on the landfill's surface and to decide on the direction of development of the post-remediation landfill as a Renewable Energy Sources (RES) station with solar panels and a biogas plant.

**KEY WORDS:** LiDAR; ALS; TLS; Deformation monitoring; Landfill reclamation; UAV.

## 1 INTRODUCTION

Landfilling is still the most popular method of waste disposal in Poland. According to the Central Statistical Office (Główny Urząd Statystyczny - GUS) 2022 data, 259 active landfills in Poland and more than 600 landfills closed and partially or fully reclaimed. The 1999 European Union (EU) Landfill Directive and the EU's overall policy for sustainable waste management imply a gradual reduction in municipal waste sent to landfills. It also imposes technical and environmental requirements that landfills must meet, indirectly leading to the closure and rehabilitation of old, substandard landfills and the creation of new landfills that meet standards [1,2]. There will be a further increase in reclaimed landfills in the coming years. Municipal landfills are usually located near large cities, whose dynamic growth causes landfills to be integrated into the urban fabric over time. Often, in such cases, as compensation for the long-standing negative impacts of the landfill on the immediate neighborhood (unpleasant odor, birds), they are transformed into public facilities with recreational, park, sports, museum, or exhibition functions [3]. It is also common to use these facilities in electricity production (biogas plant, photovoltaic farm, wind farm). An example of such a landfill is the Słabomierz-Krzyżówka landfill site located in Poland, whose future post-remediation development has been earmarked for a photovoltaic farm and where energy is currently being produced from extracted biogas [4].

Geodetic monitoring of deformation is essential in ensuring safety at reclaimed landfills by monitoring the impassibility of critical states defined for slope stability and monitoring the uniformity of settlement of the landfill body. In their design, reclaimed landfills can be compared to earth structures made of anthropogenic materials, supplemented by protective structures

such as seals, drains, or reinforcements. The peculiarity of these structures is due to their large surface area (up to several tens of hectares), large volume (up to several million m<sup>3</sup>), considerable thickness (up to several tens of meters), and long-time operating period (several decades). Due to the high heterogeneity of the stored waste (different mechanical, physico-chemical, and biological-chemical factors), the course of the subsidence process is difficult to predict. Compared to soils, wastes show very high compressibility, making the site's settlement dynamic, especially during reclamation [5-8].

The dynamics of landfill mass settlement are variable over time. The subsidence process can be divided into three phases: immediate settlement, primary settlement, and secondary settlement. Immediate settlement (pseudo-consolidation) is caused by the load from the weight of the landfilled waste and the process of mechanical compaction of the waste, which can reach up to 20% of the initial thickness. Primary settlement is caused by biological and physicochemical decomposition processes (e.g., oxidation, incineration, digestion, leaching) of the deposited waste and by the creep process. The processes associated with biodegradation of waste take place over a long period (several to several years), and the settlement volumes resulting from these processes can reach about 20% of the initial thickness of the deposited waste [5, 9]. Secondary settlement is caused by mechanical creep, can last for several decades, and can amount to a few percent of the initial thickness of landfilled waste. The course of the landfill settlement process is shown in Figure 1.

Figure 1. Landfill mass settlement process [8].

The influence of water from precipitation is also a factor in the deformation of the landfill surface. Heavy and torrential rains can lead to soil leaching from the top layer covering and adding weight to the reclaimed landfill. Water infiltration into the landfill can destabilize the slopes and subsequent deformation. Short-term, heavy, and torrential rains are an increasingly frequent phenomenon in a changing climate. The elements of the water balance are shown in Figure 2.

Figure 2. Elements of the landfill water balance [8].

In Poland, the requirement for geodetic monitoring of landfills is set out in the Regulation of the Minister of the Environment of 30 April 2013 on landfills [10]. The Regulation specifies a minimum frequency of landfill surveying every 3 months during the operational and 12 months during the post-operational phases. The monitoring period for landfills is 30 years after closure. The monitoring defined in the regulation consists of controlling the settlement of the landfill's surface by geodetic methods based on measurements of displacements of control points stabilized on the facility's surface and in assessing the stability of slopes determined by geotechnical methods [11]. However, the regulation does not specify the number of monitoring points and their location on the landfill, so the monitored point movements often do not represent the entire landfill area.

Classical geodetic monitoring at landfills is based on the point method - measurements of individual controlled points (points of interest) located on the body of the landfill in various geodetic marks (metal tubes, concrete posts, granite posts). This method makes it possible to accurately determine the movements of the selected points - their size, direction, and speed. It also assumes that the observed points are representative of the phenomenon. A denser network of points

approximates the distribution of displacements more accurately but increases costs and time-consuming measurements. In practice, the determined displacements often do not reflect the actual changes occurring in the object area. Insufficient recognition of the magnitude and directions of these changes may lead to severe damage to the body of the landfill and consequently also endanger the environment and the life and health of people near the landfill [4,12,13].

A solution to this problem may be to use a surface measurement method using Light Detection and Ranging (LiDAR) technology. The surface method involves measuring the entire surface of an object - unstabilized points. This method makes it possible to observe any parts and the whole of the surveyed object. This method is free of the fundamental disadvantage of the point method - the surveyed surface is covered by a much larger number of points (in the LiDAR method, the surveyed surface is covered by millions of points). It is also possible to select observation points that depict the phenomenon depending on its dynamics. However, the disadvantage of this method is that the coordinates of the points are determined with less accuracy than in the point method. In the absence of pre-determined observation conditions and accuracy of results, a good solution is to use a hybrid method, a combination of point and surface methods. Such a strategy allows areas at risk of displacement to be detected and new stabilized points to be established in these areas [7, 13-17].

This paper presents a case study of the Słabomierz-Krzyżówka landfill site in Poland, where LiDAR-based geodetic monitoring was applied. The measurements used an approach using Airborne Laser Scanning from Unmanned Aerial Vehicles (ALS-UAV) and Terrestrial Laser Scanning (TLS). This paper presents the results of the annual monitoring of one of the slopes of the landfill, which was exposed to both deformations caused by the impact of landfill subsidence and surface water run-off caused by damage to the defenses by wild animals (wild boar, deer).

## 2 MATERIALS AND METHODS

This section presents the characteristics of the study area (Section 2.1) and the measurement equipment used (Section 2.2). The proposed methodology for determining slope deformation from TLS and ALS-UAV measurements is also described (Section 2.2).

### 2.1 Study area

The research object is the reclaimed municipal solid waste landfill "Słabomierz-Krzyżówka". The landfill is located ca. 40 km south-west of Warsaw. The landfill was established in 1970 on the site of an old pit after sand and gravel mining. From 1970 to 1992, unsegregated municipal and industrial waste was deposited in the landfill. From 2016 onwards, only construction ballast waste was deposited at the landfill, such as concrete and concrete rubble from demolition and renovation, mixed concrete waste, brick rubble, ceramic materials, non-conforming compost, and soil, soil, and stones. In 2022, the landfill was closed and rehabilitated. A degassing and drainage network and a vertical screen were built to prevent contaminants' escape. The target reclamation of the landfill was set for use as a Renewable Energy Station (RES) with solar panels and a biogas plant. Currently, the landfill site and its

technical facilities cover an area of approximately 14 ha, and the landfill covers an area of approximately 9 ha. The current height of the landfill body is approximately 27 meters measured from its base to the crown of the landfill. There are 15 controlled points (benchmarks) on the site to monitor the settlement of the landfill body. The current appearance of the landfill is shown in Figure 3.

Figure 3. View from the sky of the Słabomierz-Krzyżówka landfill with the study area (marked in red).

The study was carried out on one of the slopes of the landfill, which was exposed to negative external influences and was a representative part of the entire landfill. The study area is marked in red on Figure 3.

## 2.2 Methodology

The monitoring of the study area presented in this article was conducted over a one-year period from March 2023 to March 2024. The representative area of the slope selected in the study covers an area of approximately 2000 m<sup>2</sup>. Due to the vegetation on the landfill, the measurements were carried out in early spring to minimize the influence of the vegetation on the measurement results as much as possible. The survey adopted two approaches: the TLS and ALS-UAV methods. The TLS measurements used a Leica RTC360 scanner, and the ALS-UAV measurements used a LiAir S50 scanner with a Matrice M600 UAV. The LiAir S50 LiDAR system mounted on the platform consists of a scanner, Velodyne's VLP-16, and a Sony A6000 RGB camera. The specification of the instruments used is shown in Figure 4.

Method	TLS	ALS – UAV
Platform		
Features	Leica RTC360 Scanning range: 130 m Distance accuracy: ±2.0 mm (at 100 m) Scanning frequency: 2,000,000 pts/s	Matrice M600 with LiAir S50 Scanning range: 100 m Distance accuracy: ±30.0 mm (at 100 m) Scanning frequency: 300,000 pts/s
Reference targets	 	 DRTK station on reference point
Control targets	 	

Figure 4. Overview of the research measurements.

The measurements were related to reference grid points outside the object's influence area. The resulting point clouds from both methods were oriented in the same coordinate system. Reference matrix coordinates were determined in the PL-2000 coordinate system and PL-EVRF2007-NH height system. For the absolute georeferencing, the TLS scanner stations and reference targets were precisely tied to these external reference points, established through GNSS RTK and angular-linear measurements. The angle-linear network was then aligned using the least squares method. This allowed the TLS data to be transformed into a unified, absolute coordinate system compatible with the ALS-UAV data. For the ALS-UAV method, absolute georeferencing was achieved by integrating D-RTK GNSS corrections with onboard IMU data, UAV positioning sensors during the flight, and reference targets, ensuring precise alignment of the point cloud within the same coordinate system as the TLS data. Two measurement series were carried out (March 2023 and March 2024). A flowchart of the research methodology is shown in Figure 5. The research in flowchart consists of 4 stages: a preliminary study, fieldwork, data processing, and data analysis and results.

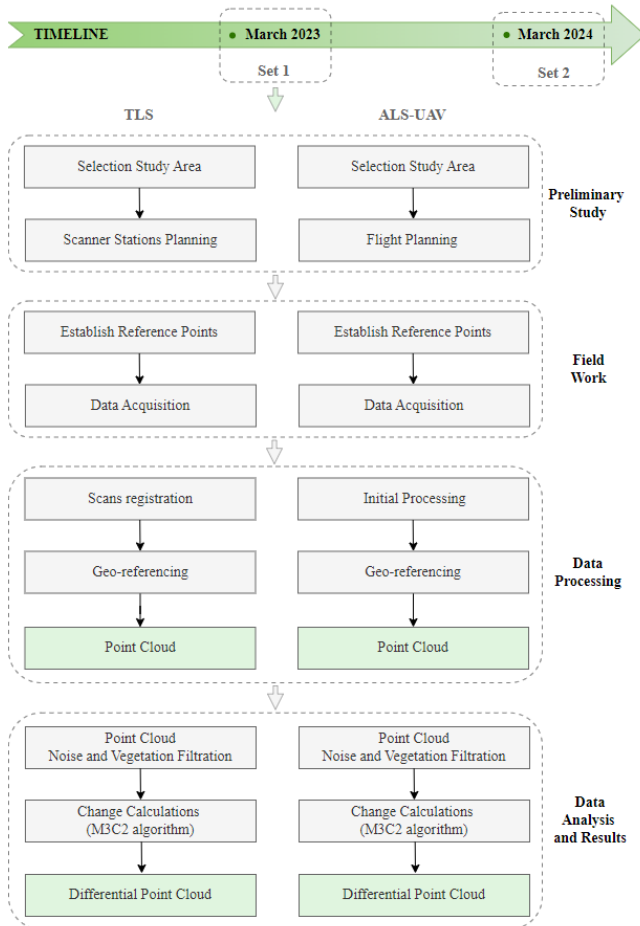

Figure 5. Flowchart of research methodology.

The TLS method first required planning the positions of the scanner stations and reference points (targets on tripods), which were referenced to the reference points (Preliminary study). The positions were planned so that the mutual coverage of scans from successive scanner positions was not less than 50%. It allowed the mutual orientation of the scans to be performed using the cloud-to-cloud (C2C) method. Additionally, overlapping stations were used to strengthen the “connections” between the scans. This strategy allowed mutual orientation of all sites even in the case of a weak “connection” - too few common points between scanner sites. The problem of mutual orientation of the scans is particularly relevant in the case of reclaimed landfills, which are overgrown with lush vegetation. Branches, leaves, and blades of grass moving in the wind can make it difficult to orient the scans using the C2C method. A solution to this problem may be the use of reference spheres. A diagram of the scanner positioning strategy is shown in Figure 6.

The Leica RTC360 scanner used in the survey has a dedicated Leica Cyclone FIELD 360 application, which allows a rough mutual orientation of the scans locally directly in the field. It enables the assessment of whether adjacent scans have the required percentage of mutual coverage and whether there is a need for additional stations. The scans were acquired at a resolution of 3 mm at 10 meters. A total of nine scans were acquired (Field work).

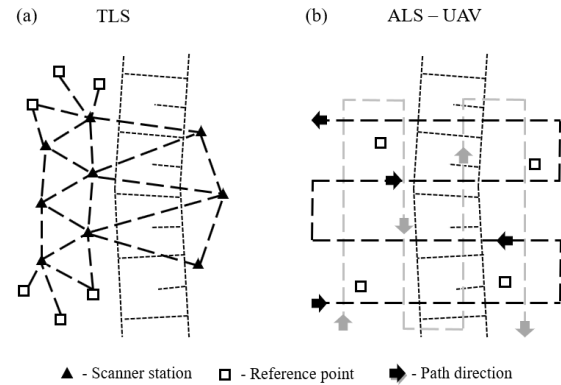

Figure 6. Scheme of measurements by a) TLS and b) ALS – UAV method.

Orientation of the scans was performed using the dedicated Leica Cyclone REGISTER 360 PLUS software (Data processing). The resulting point clouds were de-noised (SOR Filter) and filtered from vegetation (CSF Filter) in Cloud Compare v.2.13.2 [18]. The parameters of the applied filtering were selected empirically (Data analysis and results). The average density of the resulting point cloud was approximately 10,000 pts/m<sup>2</sup>.

(18).

The ALS-UAV method first required planning a flight path (Preliminary study). The flight was performed in two transversely oriented directions (Fig. 6) at an altitude of 50 m. The distance between each flight path was 20 m. During the flight, a D-RTK reference station was used for data reference (Fig. 4). The field-acquired data (Field work) was processed in the dedicated Green Valley LiDAR360 software. The geo-reference of the resulting point cloud was given based on the data from the D-RTK station and the antenna and IMU on board the UAV. As with the TLS data, the resulting point clouds were de-noised and filtered from vegetation in Cloud Compare. The average density of the resulting point cloud was approximately 250 pts/m<sup>2</sup>.

### 3 RESULTS

Based on the obtained point clouds, a differential point cloud was calculated in the Cloud Compare program, representing the deformation of the slope over the annual period for the TLS method (Fig. 7a) and ALS-UAV (Fig. 7b). Differential point cloud was calculated using the Multiscale Model to Model Cloud Comparison (M3C2) algorithm [19,20]. The M3C2 algorithm determines the distance along a local normal vector, estimated from each point's neighborhood. The method considers the surface's local orientation in the distance calculation process. The general principle of the algorithm is based on developing search cylinders along normal vectors to locally average the changes between two point clouds. The parameters in the M3C2 algorithm used were chosen empirically. The best results were obtained with a cylinder size of 25 cm, which was used in the study [19].

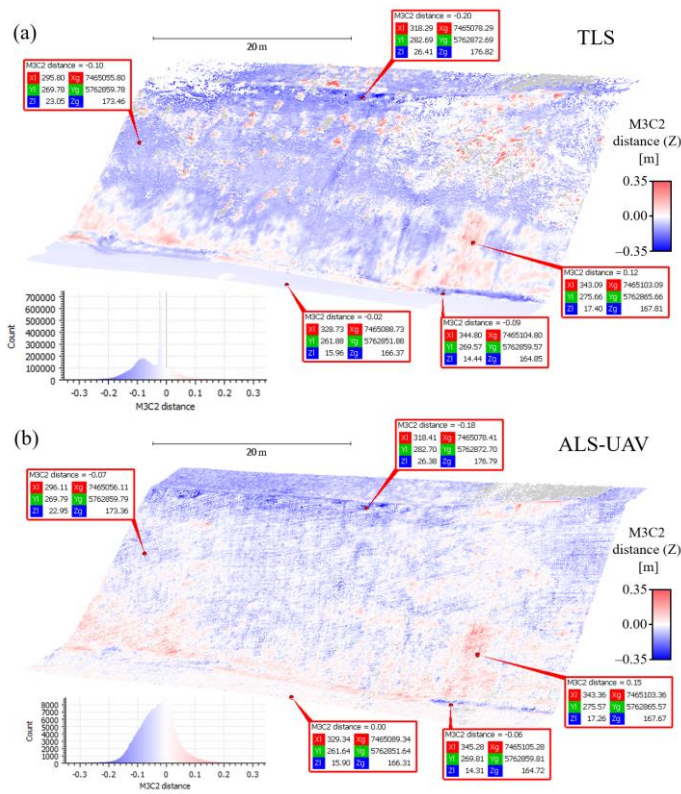

Figure 7. Differential point cloud showing vertical slope displacements from a) TLS and b) ALS-UAV.

Figure 7 shows deformations occurring between March 2023 and March 2024. Figure 7a shows the TLS measurement results, while Figure 7b shows the ALS-UAV measurement results. The blue color shows subsidence, while the red color shows uplift. The absence of changes is marked in white, as indicated in the legend. The range of these values is between -35 and 35 cm. Similar results can be seen in both figures. The most significant subsidence can be seen in the upper and middle parts of the slope, while uplift is noticeable in the lower part of the slope. The values of these changes are approximately -20 cm for the upper part of the slope, approximately -10 cm for the middle part of the slope, and 10 cm for the lower part. This is an expected result and is related to the plastic deformation of the slope caused by the dead weight of the soil and the compaction of waste embedded in the body of the landfill. A diagram of this phenomenon is better shown in Figure 8.

Figure 8. Diagram of the landfill slope deformation process over time.

Figure 8 shows the process of slope deformation over time. Settlement is noticeable in the upper part of the slope, while the slope in the lower part is uplifted by compression of the soil mass. Sometimes, uplift at the foot of the slope may also be caused by the so-called apparent uplift - surface water run-off and deposition of washed-out soil at the foot of the slope. Such a phenomenon can also be observed in Figure 7. At the foot of the slope, between the technical road and the slope, the dark blue longitudinal stripes are a remnant of washed-out soil, which the landfill workers removed as part of maintenance works. The values in this area are approximately -10 cm.

In Figure 7, characteristic features appearing in the two data sets are marked with red references to compare the results. The average difference between the selected points is approximately 3 cm. A differential point cloud was created to compare the two results better, showing the differences between the displacement results of the two methods, TLS and ALS-UAV (Fig. 8).

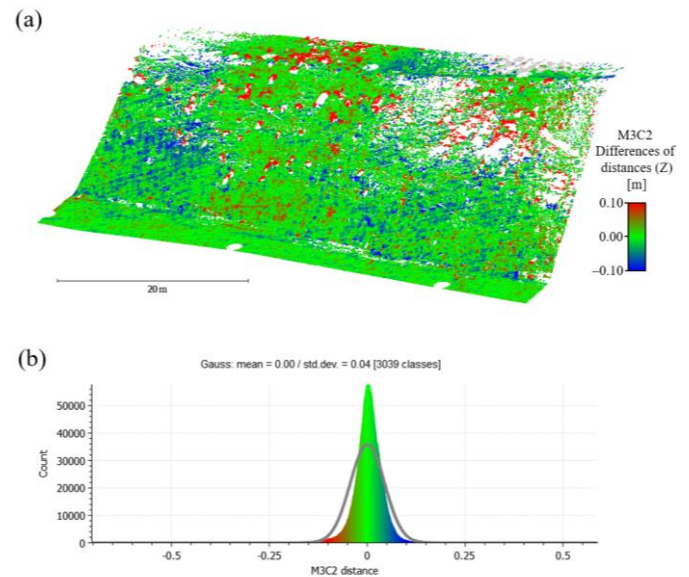

Figure 8. Differential point cloud of displacements from TLS and ALS-UAV (differences of vertical displacements) (a) and histogram of a differential point cloud of displacements (b).

Figure 8 shows the difference between the results of the TLS and ALS-UAV methods (Fig. 8a) and a histogram of the distribution of score values (Fig. 8b). The red and blue colors show significant differences in the results. In contrast, the green color indicates no differences in areas with low or zero values. These values range from -10 to 10 cm. Fig. 8 predominantly shows green points - close to the zero value. This means that the results of both methods were very similar. Possible differences are due to the accuracy of the two measurement methods, the different roughness of the point cloud, the different densities, orientation errors, and the effectiveness of the vegetation filtering. It can be assumed that the TLS method is more accurate than the ALS-UAV method and could be the reference method in the study. However, the TLS method in the application presented here has one key disadvantage - the unfavorable slope scanning angle. The laser scanner beam hits the slope at a vast angle, both in positions below and above the slope, preventing effective vegetation penetration. In contrast to the TLS method, in the ALS-UAV method, the laser beam

strikes almost perpendicular to the scanned area, allowing better vegetation penetration and ground scanning. The most significant differences between the two methods are particularly evident in the central part of the slope, where the ground scanner beam does not reach the ground but only scans the grassroots. This situation can lead to errors in interpreting phenomena occurring in the landfill regarding slope deformation processes.

The histogram in Figure 8b shows the statistical distribution of the differences between the TLS and ALS-UAV methods. The distribution has the character of a normal distribution, with a mean of 0.00 m, showing that there is no systematic shift between the methods. The standard deviation is 0.04 m, which means that most of the differences are within  $\pm 4$  cm, confirming both measurement methods' high consistency and precision.

#### 4 DISCUSSION AND CONCLUSIONS

This paper presents a case study of the Słabomierz-Krzyżówka landfill located in Poland and the results of annual measurements of one of the slopes of the landfill exposed to damaging factors causing its deformation, such as the influence of soil gravity, waste compaction, and surface water run-off. Two measurement methods were adopted in the study: TLS and ALS-UAV.

The results showed that both methods can be effectively used for periodic monitoring of the landfill surface. Similar results were obtained for both methods, demonstrating their effectiveness. Possible differences may be caused by:

- different accuracy of the measurement methods,
- different roughness of the point cloud,
- different density,
- different observation geometry,
- orientation errors,
- or the effectiveness of vegetation filtration.

The TLS method should be assumed to be more accurate than the ALS-UAV method, assuming a suitable measurement methodology. Nevertheless, each method has its advantages and disadvantages. In the case of the TLS method, it was possible to measure with high accuracy and resolution. The disadvantage, however, is the scanner's position, which, in the case of slope scanning, creates an unfavorably wide scanning angle and makes it impossible to scan the ground in the case of high vegetation. The partial solution to this problem can be telescopic tripods, which allow the scanner position to be raised several meters. Changing the scanner's height to a higher one may allow scanning the slope at a better angle but will not solve the problem completely. Another disadvantage is the time-consuming nature of the measurements. In paper [13] the authors compare the acquisition time and processing time of TLS and ALS-UAV measurements. The results show that scanning reclaimed landfills, by the TLS method, is 5 times more time-consuming than by the ALS-UAV method. In the case of large objects, it is necessary to set up additional control points to establish the measurements and maintain adequate accuracy of the results. The overabundance of measurement data can also be a problem. The scanner records two million points per second, which, in the case of measurements at the landfill, translated into the acquisition of approximately 70 million points per measurement site (when using the highest

resolution mode). In the case of the ALS-UAV method, an advantage is the ability to scan a large area of land, which is particularly useful in landfill measurements characterized by a large surface area (up to several tens of hectares). Another advantage is better vegetation penetration and the laser scanner's beam reaching the ground because of almost perpendicular laser beam to the scanned ground. However, the disadvantage of the ALS-UAV method is its lower accuracy than the TLS method. Measurement solutions of this type offer measurement accuracy similar to that of the GPS RTK method. One should also know that using UAVs in air traffic requires appropriate authorizations and competencies. Using this technology is impossible everywhere and under all conditions (direct vicinity of airports, detention centers, and military units).

An important aspect to consider when selecting a measurement method is cost-effectiveness, especially if both methods meet the required accuracy criteria. TLS, while offering higher accuracy, typically incurs higher operational costs due to longer measurement times and the need for specialized equipment and personnel. Conversely, the ALS-UAV method can rapidly cover larger areas, potentially lowering labor and time expenses. However, initial investment in UAV equipment and obtaining necessary flight authorizations can be significant. Compared to traditional surveying methods, both TLS and ALS-UAV provide improved efficiency and richer data, but the overall cost-effectiveness depends mainly on the specific project scale and requirements. Including an economic evaluation alongside technical factors offers a more comprehensive basis for choosing the optimal measurement approach.

The LiDAR monitoring applied allowed for a comprehensive assessment of slope deformation on an annual basis. Comparison of the data between the two measurement series made it possible to identify the general trends of the landfill slope settlement and the local deformations caused by external phenomena, such as surface erosion caused by rainwater.

The use of LiDAR technology - in both the TLS and ALS-UAV methods - significantly increased the efficiency of the measurements compared to the traditional point method. Thanks to the obtained point clouds, it was possible to detect displacements, visualize them spatially, and analyze the direction and intensity of deformation. The ALS-UAV method allowed a larger area to be measured quickly and comprehensively, while TLS provided data with a higher local resolution.

Periodic monitoring using LiDAR can be critical in the decision-making and design process. The ALS-UAV method allows data collection over a large area in a short time with high spatial and temporal resolution. It is also a non-invasive method. The person carrying out the measurement is not exposed to direct contact with factors negatively affecting human health, such as biogases or leachates. On the other hand, the TLS method provides high-accuracy data, allowing detection of even the smallest damage. The best way to monitor reclaimed landfills will be to integrate both methods and use each method's advantages. TLS data can also be a source for referencing or validating ALS-UAV data to improve accuracy.

**ABSTRACT:** Structural Monitoring (SM) is crucial in civil engineering for ensuring the safety, functionality, and longevity of civil infrastructure, especially bridges. As its importance grows, SM practices are guided mainly by national standards, leading to fragmented approaches and limited global integration. This paper examines SM guidelines, focusing on contributions from Germany, while exploring the broader international framework.

In Germany, key guidelines such as the DGZfP Merkblatt B09 and others offer structured methods and practice examples for long-term monitoring and performance assessment. Internationally, countries have developed their own SM frameworks. Amongst others, Austria's RVS Richtlinie 13.03.01, France's COFREND Livre Blanc, Canada's ISIS Guidelines, the ACI Report 444.2-21 from the USA, the TRB Circular E-C246 and the CIRIA Guideline from the UK contribute to a global understanding of SM. These guidelines address common technical, theoretical, and economic challenges across regions.

This paper highlights the need for international collaboration, identifying synergies and gaps to promote a unified approach to SM. It offers insights into global standards and how successful strategies can foster innovation and cohesion in SM practices worldwide.

**KEY WORDS:** Structural Monitoring, International Guidelines.

This paper adopts the term structural monitoring (SM) instead of the more commonly used structural health monitoring (SHM), following the definition provided in the Transportation Research Circular E-C246 [1]. While SHM is widely recognized, its interpretation varies across disciplines, leading to ambiguity, particularly regarding the meaning of "health" in an engineering context. By contrast, SM explicitly refers to the automated, technology-driven collection of structural data over time to objectively assess performance, without implying a predefined goal such as "health", thereby broadening its applicability. Adopting this terminology helps ensure clarity and consistency, emphasizing the role of continuous, instrumented monitoring as a valuable complement to conventional structural assessment methods.

## 1 THE IMPORTANCE OF STRUCTURAL MONITORING IN MODERN INFRASTRUCTURE GUIDELINES

The increasing complexity and age of infrastructure necessitate advanced monitoring techniques to detect and address potential issues proactively. SM is a critical practice for ensuring the safety, functionality, and longevity of civil infrastructure, particularly bridges. By continuously assessing structural conditions, SM enables the early detection of potential issues, allowing for timely maintenance and preventing failures. This proactive approach not only enhances public safety but also contributes to the sustainable development of infrastructure by extending its service life.

The evolution of SM has been marked by significant advancements in sensor technology, data acquisition systems, and analytical methods. Modern SM systems employ a variety of sensors to monitor parameters such as strain, vibration, and

temperature, providing comprehensive insights into structural performance. The integration of artificial intelligence and machine learning algorithms further enhances the ability to interpret complex data, facilitating automated damage detection and assessment.

Despite technological advancements, the implementation of SM is often shaped by national standards, resulting in fragmented methodologies and limited global integration. While Germany, for example, has developed comprehensive guidelines like the DGZfP Merkblatt B09 (2022) to standardize monitoring practices, similar guidelines exist in other countries, with many offering largely the same content. This suggests that the diversity in approaches is unnecessary. However, factors such as local or strategic interests, language barriers, lack of networking, economic considerations, varying financial framework conditions (such as budget constraints, funding availability, and investment priorities), the local acceptance of structural monitoring, and some isolated differences in scientific perspectives, though less prominent in practical implementation, continue to prevent a unified, global approach to SM. Additionally, the differing levels of acceptance of relatively new and unestablished methods in civil engineering, such as Structural Monitoring, remain a decisive factor, as some regions embrace innovative techniques while others remain hesitant to adopt them.

To address these challenges, there is a need for increased international collaboration and the development of standardized SM protocols. By harmonizing guidelines and sharing best practices, the global engineering community can enhance the effectiveness of SHM systems, leading to more resilient and sustainable infrastructure worldwide.

## 2 SM GUIDELINES IN GERMANY

In Germany, the significance of SM has been recognized through the development of a robust monitoring framework through a series of comprehensive guidelines, particularly for bridges and other civil engineering structures and aimed at standardizing monitoring practices. Together, these guidelines emphasize a data-driven approach for maintaining usability and availability of infrastructure and generally the preservation of structures.

These guidelines collectively contribute to a structured approach in SM within Germany, promoting uniformity in monitoring practices. The development of such guidelines is crucial, as it offers building owners and operators a framework for implementing effective monitoring systems, thereby enhancing decision-making processes related to construction and maintenance. By establishing clear protocols and methodologies, the guidelines aim to reduce fragmentation in monitoring approaches and promote a unified strategy for ensuring structural integrity.

### 2.1 DGZfP Merkblatt

Notably, the German Society for Non-Destructive Testing (DGZfP) has been instrumental in this endeavor. The publication of the DGZfP Merkblatt B 09 “Dauerüberwachung von Ingenieurbauwerken” [2] provided a cornerstone resource for owners, operators, and planners, detailing established methods for long-term monitoring and performance evaluation of civil engineering structures with a particular focus on concrete and prestressed concrete bridges. The document provides a practical guideline to help stakeholders implement effective monitoring solutions while considering the unique conditions of each structure. It delivers the necessary knowledge for the optimal design, installation, and operation of monitoring systems.

The guideline offers an overview of suitable technical systems and sensors designed for long-term structural monitoring. It differentiates SM from temporary inspection, emphasizing that monitoring does not replace regular structural inspections but serves as a crucial supplement by providing real-time condition assessments and detection of time-varying parameters.

A key focus of the document is the conceptual design of monitoring systems, from preliminary investigations, the definition of measured variables, the decision for or against a monitoring system, basic considerations for safety-relevant monitoring systems, the selection of suitable sensors, definition of measuring points, sensor connection/signal transmission, power supply, control, data verification, data storage, evaluation and alarming to the external communication connection and control of actuators.

It outlines the specific questions that monitoring can help answer. Unlike most other documents, which primarily describe existing sensor technologies and leave it to the reader to determine their applicability to a given monitoring task or rather generally to a question that may be answered with the help of SM, this guideline approaches monitoring from the end user's perspective, making it more accessible. The addressed monitoring tasks range from geometric aspects (strains, displacements, deflections, inclinations) to crack monitoring, force and strain measurements, vibration and shock monitoring,

material moisture, corrosion, prestressing wire breakage detection and the influencing factors of temperature, humidity, traffic loads, etc., which must always be taken into account.

Additionally, the leaflet emphasizes data management, ensuring that collected information is effectively processed and utilized. Like many other referenced documents, it also provides detailed examples of real-world implementations. [3], [4]

### 2.2 DBV Merkblatt

A different focus is set in the DBV Merkblatt “Brückenmonitoring” [5]. Issued by the German Society for Concrete and Construction Technology (DBV), the guideline addresses the monitoring of bridge structures, although it is also applicable to other engineering structures and buildings. It details the services that need to be tendered when implementing a structural monitoring system and highlights the economic considerations involved in such measures. It is less technical than the DGZfP guideline and aims specifically at administrations and engineering offices responsible for preparing tenders, helping them assess whether structural monitoring is a cost-effective option for their specific projects.

The guideline defines relevant actors and comprehensively structures the monitoring process in different phases, beginning with defining the monitoring task, followed by the development of a qualified monitoring concept, implementation planning, installation and operation, data processing, data analysis and concluding with the evaluation of monitoring results. The structured process is supplemented by considerations on quality assurance and information on tendering.

As structural monitoring is not yet a standardized service in civil engineering, the guideline also provides insights into the economic viability of monitoring measures, helping stakeholders evaluate the financial feasibility of these activities in relation to the benefits they bring.

### 2.3 DIN 1076

In the context of this compilation, the new DIN 1076 [6] is the most authoritative document in terms of recognition, dissemination, acceptance and legal validity. However, as a general standardization document, it takes a more global approach and does not provide detailed guidance on planning, tendering, or implementation of monitoring systems. The standard explicitly permits the use of monitoring systems under specific conditions and for certain purposes, recognizing their value in preventive structural preservation.

DIN 1076 highlights two key applications for monitoring in the context of the standard: supplementing regular structural inspections and addressing special situations, such as the end of a structure's service life or ensuring structural and traffic safety. It mandates that monitoring data must provide clear condition assessments that can be incorporated into overall structural evaluations. In safety-critical applications, the standard requires defining warning or threshold values along with clear instructions for responsible personnel.

Each monitoring application must follow a detailed, structure-specific assessment program covering the entire process (based on the DBV Merkblatt). The selected measurement methods must reliably detect the type, extent, and progression of damage or defects.

Overall, the standard takes a very conservative and selective approach to monitoring, limiting its scope to structural testing under DIN 1076. However, it leaves room for effective and beneficial use of monitoring in other defined applications.

In summary, DIN 1076 is very conservative and exclusive with regard to monitoring. Yet, it does not mandate the use of monitoring but defines specific applications where monitoring can be considered "in accordance with DIN 1076". However, the scope and reasons for using SM extend far beyond these applications, which are not covered by the standard but still remain valid and necessary. This flexibility allows for other approaches to use monitoring sensibly, effectively and profitably, which are defined in other documents within this compilation.

#### 2.4 *BASf Leitfaden*

The recent BASf "Leitfaden Strategischer Einsatz von Monitoring für Ingenieurbauwerke" [7] offers strategic recommendations for the use of monitoring in engineering structures. It summarizes the state of the art, limits and potentials for monitoring in Germany, taking particular account of the three documents [2], [5] and [6]. In addition, it explicitly addresses why the possibilities of monitoring have not yet been used to the extent that they could be and how acceptance could be improved.

Data management considerations form a large part of the guideline, as the sustainable storage of monitoring data, easy accessibility and systematic evaluation are central to effective monitoring projects.

#### 2.5 *BASf Erfahrungssammlung*

The complementary BASf "Erfahrungssammlung Monitoring für Brückenbauwerke" [8], compiled by the Federal Highway Research Institute (BASf), provides a comprehensive collection of practical experiences in bridge monitoring, complementing previous documents. It offers insights into the application, capabilities, and limitations of monitoring systems.

In its general section, the document outlines the state-of-the-art in bridge monitoring, reflecting the contents of the DGZfP and DBV Merkblatt. It follows a similar structure to the DGZfP Merkblatt, addressing key aspects from an end-user perspective, such as deformation, inclination, temperature, and crack monitoring, among others. It explains how different measurement techniques align with monitoring objectives and discusses their reliability, limitations, and quality assurance. The second part presents real-world examples, detailing the reasons for monitoring, the methods used, and key findings.

### 3 INTERNATIONAL SM FRAMEWORKS

SM practices have evolved worldwide to address regional infra-structure challenges and priorities. Despite variations in methodologies, national guidelines share common goals of ensuring safety, reliability, and long-term functionality of civil structures. This section explores international SM frameworks, focusing on selected approaches adopted in countries such as Austria, France, the US, Canada, and the UK.

#### 3.1 *Austria*

Austria's RVS guideline RVS 13.03.01 "Monitoring von Brücken und anderen Ingenieurbauwerken" [9] provides a structured framework for the monitoring of bridges and other

civil engineering structures, reflecting the country's commitment to SM. Compared to other referenced documents, it is relatively concise, comprising 32 pages, with a structure comparable to the DGZfP Merkblatt. One notable feature of the guideline is its classification of monitoring into local vs. global and static vs. dynamic approaches, each accompanied by a brief summary outlining the objectives and applicable sensor technologies. While this classification provides a structured perspective, it remains open to debate whether it offers significant practical advantages in the retrievability of information.

A novel aspect that distinguishes the RVS guideline from other standards is its Safety Management Plan (SMP), which defines action sequences, assigns responsibilities, and references pre-established warning and alarm thresholds. The guideline specifies the content of such a plan and introduces a process scheme incorporating a traffic light system (green, orange, red) to represent different alert levels, ranging from normal operation (green) to immediate intervention, such as bridge closure (red).

Additionally, an annex provides an overview of various measurement instruments referenced in the guideline, briefly explaining their principles of operation. A second appendix explores the role of the Internet of Things (IoT) in structural monitoring, emphasizing its relevance for data acquisition and management in modern SHM systems.

#### 3.2 *France*

The COFREND "Le Livre Blanc du SHM" [10] has a different focus and approach than other referenced international SHM guidelines. Rather than detailing the technical implementation of monitoring systems, it addresses overarching challenges associated with SM, including scientific and technological hurdles, regulatory concerns, and intellectual property issues.

This white paper is the result of discussions within COFREND's SM branch to develop a national strategy for SM in France. The document outlines key aspects of the field, such as its historical background, market potential, and major scientific and industrial challenges. It highlights the growing demand for SM in sectors like civil engineering, aerospace, and industrial equipment, where aging infrastructure and safety concerns drive the need for continuous monitoring solutions.

A central theme of the Livre Blanc is the necessity for structuring an SM industry in France. It emphasizes the need for standardized methodologies, interoperable systems, and regulatory frameworks to enable widespread adoption. Additionally, it discusses how digital technologies such as IoT, AI, and digital twins are transforming SM by enabling real-time monitoring and predictive maintenance.

The document also examines international approaches, comparing France's SM landscape with that of the US, Germany, and the UK. By advocating for a coordinated effort among stakeholders, the Livre Blanc aligns with the ambitions of the present paper, which aims to structure international efforts in SM. It reinforces the necessity of global collaboration, regulatory alignment, and knowledge exchange to drive innovation and ensure the reliability of SM systems worldwide.

### 3.3 Italy

The MIT guideline “Linee guida per la classificazione e gestione del rischio, la valutazione della sicurezza ed il monitoraggio dei ponti esistenti” [11], that has been continuously updated since its first publication, presents a discussion on the permanent and continuous monitoring of bridges, outlining the key principles, necessary technologies, and critical applications of SM systems. The chapter on monitoring is framed within a broader context of visual inspections, risk assessment, and safety evaluations, positioning SM as a complementary tool alongside routine inspections, load testing, and numerical degradation analysis. Rather than being an isolated process, continuous monitoring is presented as an integral component of a comprehensive strategy for bridge management, enhancing both preventive maintenance and decision-making processes.

The document carries a strong authoritative tone by advocating for the mandatory use of SM in high-risk scenarios, particularly for aging or strategically important bridges. It emphasizes the importance of long-term surveillance, particularly for large, complex, or high-risk structures, and highlights the operational requirements for implementing effective monitoring strategies.

The text underscores the necessity of carefully designing SM systems to ensure durability, accuracy, and maintainability. It addresses fundamental aspects such as sensor selection, network architecture, power supply, and data processing, with a strong emphasis on integrating SM data into a broader bridge management system. The document also details specific applications of SM, including structural, seismic, geotechnical, hydraulic, and landslide monitoring. For each of these, it describes the most suitable technologies and analytical methods, ranging from dynamic response measurements for structural assessments to advanced remote sensing techniques for landslide detection.

A key argument is that continuous monitoring enables early detection of structural deterioration, environmental hazards, and other risk factors, facilitating data-driven maintenance and decision-making. The discussion particularly stresses the value of integrating SM with real-time communication networks and automated data analysis to provide accurate, actionable insights into bridge behavior over time.

The UNI/TR 11634 guideline “Linee guida per il monitoraggio strutturale” [12], by reference of [13] and [14], establishes a structured approach to SM, emphasizing its role in supporting asset management decisions. It outlines the entire monitoring process, covering system design, implementation, and data analysis. The document provides criteria for developing SM systems and identifies appropriate methodologies for evaluating structural conditions based on different classes and types.

An aspect of the guideline is its focus on data processing methods, which leverage both data-driven and model-based techniques to assess structural integrity. It also defines the essential components of an SM system, detailing the processes for detecting structural damage and material degradation. Furthermore, the report discusses best practices for system installation, maintenance, and data acquisition to ensure effective monitoring and long-term performance.

### 3.4 United States

The ACI PRC-444.2-21 report “Structural Health Monitoring Technologies for Concrete Structures” [15] provides a comprehensive examination of structural monitoring (SM) technologies applicable to concrete structures. Building upon an in-depth discussion of relevant material properties and the unique characteristics of concrete, the report systematically explores available sensor types, their underlying physical principles, and the specific monitoring objectives they serve. Additionally, it outlines the necessary measurement equipment, deployment methodologies, and existing standards and codes of practice.

The report adopts an academic approach, extensively referencing scientific literature, thus enabling readers to deepen their understanding of the subject matter. Rather than presenting information in a condensed form, the document offers a thorough insight into sensor technologies, categorizing them into three main types: structural response sensors, environmental condition and load sensors, and supporting technologies.

Complementing this perspective, the Transportation Research Board’s Circular E-C246 “Structural Monitoring” [1] provides a broader, application-oriented discussion of SM. Unlike the ACI report, which focuses on technical aspects, this document addresses the practical implementation of monitoring systems from the perspective of potential clients rather than monitoring specialists. It highlights synergies between SM and traditional visual inspections, discusses key considerations for deciding when monitoring is warranted, and outlines the expected benefits.

The circular briefly introduces relevant sensor types based on their measured parameters, such as inclination, acoustic emission, and temperature. A notable aspect is the emphasis on a progressive diagnostic approach, wherein monitoring is continuously refined to determine whether more extensive data collection is necessary in a cost-effective manner. This process accounts for multiple factors, including preliminary information gathering, structural criticality, financial constraints, installation feasibility, durability, and data management. Moreover, the document distinguishes itself by addressing the financial return of SM investments, outlining strategies for evaluating cost-effectiveness in advance. A dedicated FAQ section further enhances its practical utility by succinctly answering common questions related to SM implementation.

### 3.5 Canada

Canada’s ISIS “Guidelines for Structural Health Monitoring” [16] represents one of the foundational references on SM included in this compilation. As an early comprehensive guideline outside the academic context, it contextualizes modern SM within the broader framework of various testing methodologies used to assess the in-situ condition and performance of structures under different load scenarios and potential damage conditions. The document systematically categorizes these methodologies based on the frequency and duration of measurements, distinguishing between static field testing, dynamic field testing, periodic monitoring, and continuous monitoring, the latter of which is now commonly referred to as structural monitoring.

Each of these testing approaches is introduced in detail, outlining its specific objectives, practical implementation strategies, and the potential benefits it offers for structural assessment. Moreover, the guideline provides multiple real-world case studies to illustrate the practical application and effectiveness of the described methods in diverse structural contexts.

The appendices of the manual offer additional technical depth, including explanations of the operational principles of selected sensor technologies, an introduction to data acquisition systems, and an overview of various algorithms used for vibration-based damage detection. While the sections on sensor technology and data acquisition have become somewhat outdated due to significant technological advancements since the publication of the manual, they still serve as a valuable foundation for understanding fundamental principles.

### 3.6 United Kingdom

The CIRIA guide “Structural Health Monitoring in Civil Engineering” [17] provides a comprehensive, low-level introduction to SM for various stakeholders, including infrastructure owners, operators, and engineers. The guide begins by defining SM and explaining its role in risk management for civil infrastructure. It highlights how SM can support intervention planning by providing valuable data to enhance safety, reduce costs, and extend the lifespan of assets.

A key focus of the guide is distinguishing between traditional visual inspections, periodic manual assessments, and automated continuous monitoring, emphasizing the advantages of sensor-based SM. The document underscores the importance of data quality, modeling, and redundancy in effective monitoring systems, recognizing data as the “currency” of SM.

The guide discusses the business and technological drivers behind SM adoption, outlining both proactive and reactive applications. It provides guidance on conceptual design and implementation, including sensor selection and system integration. A dedicated chapter addresses data management, storage, security, ownership, and analysis, ensuring the effective use of collected information.

Procurement considerations, risk assessment, and specification requirements are also covered in detail, offering a structured approach for organizations planning to implement SM. Additionally, the guide presents real-world case studies that illustrate the practical applications of SM, detailing the sensors used, data acquisition strategies, and resulting insights.

### 3.7 China

The accessibility of Chinese SM standards to the international community is often hindered by language barriers and differences in normative frameworks. Unlike widely adopted international standards, Chinese regulations and guidelines are primarily available in Mandarin, making it challenging for non-Chinese researchers and practitioners to engage directly with them. However, it is possible to gain indirect insight into the scope of Chinese SM standards by referencing available review documents, such as [18] or [19].

The extent of standardization efforts in China is remarkable, with a vast array of documents addressing various aspects of SM at multiple regulatory levels. These include national standards, which apply nationwide, professional standards that govern specific industry sectors, as well as provincial and

company-level regulations. An often-cited national standard in this context is the GB 50982 technical code [20], that is discussed in detail in [21].

Instead of detailing the full list of normative documents available in China in a reproduction of the aforementioned articles, it is noteworthy to highlight the early adoption and impressive breadth of topics already addressed within their SM standards. These standards begin with foundational aspects, including the definition of basic terms and concepts, and extend to more specific areas such as SM design standards, operational maintenance, and management practices for SM systems. Additionally, there are guidelines governing the construction and acceptance of SM systems, as well as those focused on massive data processing for SM applications. Notably, China's SM standards also include regulations tailored to specific infrastructure types, such as bridges, with comprehensive technical codes and specifications. These bridge-related standards cover critical aspects such as fiber optic monitoring systems, concrete bridge monitoring, threshold levels for intervention, and the selection and placement of sensors.

The breadth and depth of this standardization effort suggest a strong institutional commitment to SM, reflecting the country's large-scale infrastructure development and emphasis on long-term structural safety and reliability.

### 3.8 Others

One relevant document outside national application, of a very general nature, is the FIB Bulletin 109 [22]. One of the chapters is devoted to certain aspects of structural monitoring, in the wider context of structural condition survey (in particular NDT and load testing), condition assessment and sensor placement.

Other specific national standards or guidelines for SM in civil engineering are not prominently documented in the available literature. While [23] references a withdrawn Russian standard [24], comprehensive national frameworks remain scarce. Some ISO standards address related aspects, such as vibration monitoring, but do not specifically focus on structural monitoring as a whole. Instead, much of the existing knowledge is found in scientific literature and technical reports. Notable examples of research results include, amongst others, and without assessing their value above others without further review, the SAMCO report [25], the Sustainable Bridges Report [26], the SMooHS Report [27], or the recent IM-SAFE Reports [28], which provide valuable insights into monitoring methodologies, system design, and long-term structural assessment. However, these documents primarily originate from research initiatives rather than regulatory bodies, highlighting the ongoing need for standardized international guidelines in structural monitoring.

## 4 SYNERGIES AND CHALLENGES

A shared objective in structural monitoring (SM) guidelines is to ensure the safety, reliability, and longevity of civil infrastructure. These guidelines reflect the diverse needs, priorities, and technical capabilities of different countries, addressing common challenges and promoting best practices globally.

### 4.1 Synergies

Despite differences in local infrastructure conditions, economic constraints and environmental factors, there are surprisingly no

significant differences, only variations in focus, in methodologies, performance metrics and monitoring technologies. One reason for this may be that the technical challenges are comparable, which ultimately leads to similar guidelines. This basic agreement helps efforts to develop a unified approach. Therefore, a list of key aspects can be extracted from the different guidelines, which are relevant to be taken into account in a common effort for a harmonized monitoring strategy.

- Definition of terms and notations: While terminology is often similar across guidelines, differences exist. For example, the distinction between SM and structural health monitoring (SHM) varies. A clear definition of terms is crucial to ensure consistency and avoid ambiguity in communication and implementation.
- Promoting the benefits of SM: Guidelines highlight achievable goals, such as enhanced safety and risk reduction, while also acknowledging scientific technological challenges, i.e., what can not be achieved by employing SM. They emphasize early detection and prevention of structural degradation through continuous monitoring, proactive measures to mitigate risks, and data-driven strategies for assessing infrastructure health and performance.
- SM in civil engineering and other industries: Structural monitoring in civil engineering is placed in the broader context of its application in other industries, such as aeronautics, space, mechanical engineering, energy, and automotive sectors. These comparisons provide insights into cross-sector best practices and technological advancements.
- Locally governing codes, standards, and practices: SM guidelines must align with national and international regulatory frameworks, integrating with existing structural assessment methods such as visual inspections, load tests, and non-destructive testing. They also play a role in maintenance planning and intervention strategies.
- Criticality and asset value considerations: The relevance of SM depends on factors such as a structure's criticality, asset value, and degradation state. Guidelines help prioritize monitoring efforts based on risk assessment and long-term economic benefits.
- Monitoring-relevant characteristics of structures and materials: Guidelines address the unique monitoring needs of different structures and materials, considering their physical properties, environmental influences, and long-term durability. The focus is often on bridges, especially those of reinforced and prestressed concrete, most likely because a large proportion of the monitoring systems installed to date have been applied to such structures, and therefore a wealth of experience is available and the need for regulation is particularly great.
- Preliminary research and assessment: Prior investigations are necessary to determine monitoring scope, relevant parameters, priority structures, and measurement locations. NDT techniques play a crucial role in identifying potential vulnerabilities and optimizing monitoring strategies. Based on these investigations, numerical models and simulations play an essential role in the further planning of monitoring systems for complex structures, broadly defined problems and unclear structural behaviour, in order to be able to estimate the sensitivity of SM systems with regard to the desired objectives.
- Cost-benefit analysis of SM implementation: Guidelines provide methodologies for estimating financial benefits, considering cost-effectiveness and the value chain. Decision-makers can evaluate whether implementing SM is justified for specific projects.
- Monitoring process and stakeholder responsibilities: Information is provided on the entire monitoring process, including relevant stakeholders, their responsibilities, the division of tasks, and the coordination required to ensure effective decision-making.
- Procurement and tendering processes: Guidelines outline necessary specifications for tendering SM systems to ensure meaningful, comparable, and complete bids. They also address procurement considerations from a technical and administrative perspective.
- Conceptual design of SM systems: Developing an effective SM system requires extensive considerations, ensuring alignment with project requirements and stakeholder expectations. Guidelines offer insights into designing target-oriented systems tailored to specific infrastructure needs.
- Technical information on sensors and applications: Guidelines detail available sensor technologies, their capabilities, and the types of structural insights they provide. This includes both resistance- and load-related monitoring for comprehensive assessment. There are generally two different approaches: the (technical) contractor's view – what sensors are available and what can be achieved with them, and the (administrative) client's view – what tasks can be accomplished and what sensors are available to do so.
- Supporting technologies: Integration of local and global data transmission, communication systems, and energy supply and harvesting technologies plays a crucial role in ensuring effective SM system functionality.
- Practical implementation considerations: Guidelines address real-world challenges in SM deployment, including installation, maintenance, exchangeability, expandability, remote access and operational reliability, ensuring that systems function as intended over time.
- Ensuring data quality and management: Strategies for maintaining consistent data quality, handling short- and long-term storage, and ensuring accessibility and visualization are essential components of SM guidelines.
- Extracting meaningful insights for decision-making: Automated data analysis methods, i.e. how to (automatically) extract relevant knowledge about the monitored structure at the relevant time (preferably in real time) from the data for decision making, often referred to as “intelligence” in this context, i.e. feature extraction instead of mere data collection. This enables the detection, characterization, prognosis and risk assessment of degradation and damage and thus proactive maintenance. Some recent guidelines include artificial intelligence as a keyword.
- Alarm processes and safety considerations: Guidelines provide ways of establishing alarm chains, escalation

procedures and personnel responsibilities to ensure an effective response to critical structural conditions, particularly in safety-related applications. They provide information on the special features of safety-related monitoring systems, in which considerations such as availability, redundancy, verifiability, etc. play an extremely important role compared to other monitoring systems.

- Integration with broader digital systems: SM results can seamlessly integrate with building information modeling (BIM), digital twins, risk management systems, and structural databases to enhance decision-making and lifecycle management.
- Qualification of monitoring personnel: Training and certification requirements for personnel involved in SM are essential to maintain high-quality data collection, interpretation, and response measures. It should be noted that there are hardly any standardized qualification paths that can be queried or specified.
- Best practices and case studies: Guidelines often include a compilation of real-world monitoring projects, that showcase successful implementations and lessons learned to guide future applications in diverse environments. The technical and scientific depth of planning, execution, data analysis and results achieved in the examples vary widely.

Harmonization of regulatory practices requires a balance between regional needs and global best practice, while ensuring that local priorities are not undermined. Encouraging international collaboration and knowledge sharing can help create adaptable, yet standardized, SM guidelines that meet different infrastructure requirements.

#### 4.2 Challenges

The integration of SM practices on a global scale faces numerous challenges. While SM has proven effective in improving infrastructure safety, functionality, and longevity, achieving a cohesive international framework requires overcoming these obstacles through harmonization, technological accessibility, and policy alignment.

- Data Standardization and Interoperability: A major obstacle to global SM integration is the lack of standardized data formats and protocols. Different monitoring systems employ proprietary technologies, leading to inconsistencies in sensor calibration, data interpretation, and reporting formats. These discrepancies create challenges in comparing and integrating monitoring results. Establishing universal standards for data acquisition, processing, and analysis is essential for facilitating collaboration, ensuring data consistency, and improving the reliability of infrastructure assessments. Industry-wide cooperation and policy-driven initiatives can help create a unified data-sharing ecosystem.
- Economic and resource constraints: Reservations about the long-term economic viability of monitoring systems play an important role, as the costs of designing, implementing and operating a monitoring system on a (presumably) intact structure must be weighed against the future, currently fictitious and elusive, savings of a preventive maintenance strategy using structural monitoring. Expenses related to implementing and maintaining SM

systems is a significant barrier, particularly in regions with constrained infrastructure budgets. To mitigate these challenges, cost-effective solutions and scalable monitoring strategies must be developed. Encouraging public-private partnerships and leveraging emerging technologies such as energy-efficient sensors and cloud-based data storage can also help improve affordability and accessibility.

- Qualification of SM personnel: The effectiveness of SM depends on the expertise of personnel involved in data collection, analysis, and interpretation. However, specific training standards – if available at all – vary across regions, leading to inconsistencies in monitoring quality. Establishing global certification programs, standardized training curricula, and skill development initiatives can help ensure that SM personnel possess the necessary expertise to operate and maintain monitoring systems effectively.
- Communication barriers: A fundamental and very essential hurdle are the communication challenges that hinder international cooperation in SM implementation. Even within Europe, the exchange of information on directives is limited because guidelines they are written in national languages and are not available in English. At the international level, language barriers make it much more difficult to exchange information, as it is often not even possible to search for specific national regulations because the necessary keywords are unknown in the relevant language. Although this challenge is lessened by the digital possibilities of translation, it remains, as availability is still limited to individuals. An effort to provide English translations of relevant documents would be desirable. However, multilingual resources are by far the better option, as English is not the "world language" for everyone.
- Cultural barriers: The general openness to new technologies varies from region to region. The construction industry itself stands out as a particularly conservative industry, most likely because the financial investment values are very high and therefore the willingness to innovate is limited. Cultural differences and varying perspectives on risk management, maintenance priorities, and the perceived benefits of SM lead to inconsistencies in adoption and execution strategies. Differences in administrative procedures and organizational structures add to complexity. Effective collaboration requires fostering a culture of cooperation.
- Intellectual property rights and industrial espionage concerns: Fears regarding intellectual property rights and industrial espionage pose challenges in international SM collaboration. Companies and institutions may be reluctant to share proprietary monitoring technologies or data due to concerns over competition and data misuse. Establishing clear legal frameworks and international agreements on IP protection, data ownership, and ethical data sharing can help alleviate these concerns while promoting cooperative advancements in SM technologies.
- Data privacy and security concerns: Sharing sensitive infrastructure data across borders requires stringent cybersecurity measures and clear agreements on data

ownership and accessibility. Unauthorized access to monitoring data can pose security risks, including cyber threats and infrastructure vulnerabilities. Establishing robust rules for data protection, encryption technologies, and regulatory agreements is crucial for ensuring secure and ethical data exchange between stakeholders.

- The importance of a well-developed SM concept: A properly developed SM strategy is crucial for ensuring that monitoring efforts align with infrastructure needs and long-term maintenance goals. Without a clear conceptual framework, SM implementations lack focus and efficiency, leading to reservations in the implementation in other projects and thus the widespread use of SM.
- Availability of guidelines and standards: The accessibility of SM guidelines and standards significantly impacts their adoption and awareness. Documents that are not open-access or are only available in print form limit their distribution. Promoting open-access policies and digital dissemination can improve the reach and influence of SM best practices, fostering wider implementation and international collaboration.

Addressing these challenges calls for coordinated international efforts. By overcoming these barriers, the global engineering community can unlock the full potential of SM, ensuring safer, more resilient infrastructure for future generations.

To address these gaps, increased international collaboration is essential. It is most viable to appreciate the efforts that have been made by others and then embrace and integrate them in a joint effort, at least referencing and appreciating best practice.

Establishing common protocols, such as data exchange standards and unified terminology, can enhance the interoperability of SM systems. This alignment will not only improve the safety and performance of infrastructure but also pave the way for sustainable development and resilient infrastructure worldwide.

## 5 CONCLUSION: TOWARDS A UNIFIED GLOBAL APPROACH TO SM

The globalization of SM practices is essential for tackling shared challenges such as aging infrastructure, climate change, and rapid urbanization. While national guidelines serve as critical frameworks for monitoring and maintaining structures, international collaboration presents an opportunity to harmonize practices, facilitate knowledge exchange, and leverage technological advancements across borders.

SM has become a fundamental tool in ensuring the safety, reliability, and longevity of civil infrastructure. However, as infrastructure systems grow increasingly complex and interconnected, a unified global approach to SM is more crucial than ever. By fostering cooperation and standardization, nations can maximize the potential of SM technologies, creating a safer, more resilient, and better-integrated global infrastructure network.

Achieving global cohesion in SM requires a concerted effort to address existing disparities and align diverse methodologies. This endeavor can build upon the wealth of detailed and well-established guidelines outlined in this paper. The missing piece is a comprehensive synthesis that bridges regional differences

and integrates best practices into a cohesive framework, fostering interoperability and broader applicability.

Looking ahead, the convergence of SM with emerging technologies holds immense potential for transforming infrastructure management and preservation. The adoption of digital twins, for instance, could enable real-time monitoring, predictive maintenance, and advanced scenario modeling. Additionally, advancements in machine learning and artificial intelligence promise to revolutionize data analysis, providing deeper insights into structural behavior and enhancing decision-making processes.

As infrastructure networks become more complex and the demand for resilient systems continues to rise, SM will play an increasingly pivotal role in the global engineering landscape. The path forward lies in collaboration – sharing expertise, aligning methodologies, and driving innovation together. By embracing these principles, the global engineering community can solidify SM as a cornerstone of modern infrastructure management, ensuring a safer, more sustainable, and future-proof built environment for all.

**ABSTRACT:** With the advancement of digitalization and related technological developments, Structural Health Monitoring (SHM) has become a useful and increasingly widespread tool to assist in the maintenance management of bridges and other engineering structures. The process of implementing monitoring requires expertise in many fields such as civil engineering, bridge operation and maintenance, monitoring technology, and data analysis. In recent years, monitoring has moved from method and technology development to standard practice. However, the implementation of monitoring as a standardized process can be an obstacle, especially for bridge operators, due to a lack of practical experience combined with the various expertise required. This can affect several areas, such as determining the cost-effectiveness of a monitoring measure, proper tendering and contracting, quality control, analysis and evaluation of measurement data, and last but not least, data management. In order to support the introduction of monitoring technologies into the practice of infrastructure operators, several guidelines have been developed in Germany in recent years by different interest groups, each with a different focus and essentially complementing each other. This paper aims to provide an overview of four different recently published guidelines and to highlight their strengths and advantages.

**KEY WORDS:** Structural Health Monitoring; Guidelines.

## 1 INTRODUCTION

Germany's road and railway infrastructure faces several challenges, including a significant increase in traffic and a high average age of bridge structures. Bridge maintenance management is currently based on standardized inspections, which largely assess the condition of the structure visually and manually. At the same time, the development of procedures and technical requirements for Structural Health Monitoring (hereinafter referred to as "monitoring" for short) has by now progressed to the point where it is one of the most widely used tools for determining the structural condition of bridges and, if necessary, predicting developments. However, at present the use of monitoring is largely limited to event-related (reactive) actions while a great potential lies in the future support of predictive maintenance.

Surveys conducted among federal and state road authorities found that the use of monitoring is limited to existing damage and deficiencies [1]. According to the survey, barriers include a lack of knowledge about the applications and benefits of monitoring, the procurement process of monitoring services as well as the handling of data storage.

Due to the wide variety of construction methods and building materials, monitoring might vary greatly in its conception and implementation, depending on the specific object. Furthermore, there can be different approaches to the same objectives in terms of the parameters to be monitored, each with its own advantages and disadvantages. Therefore, there is no single approach that can be universally applied to the setup of monitoring systems for civil engineering structures. A recent challenge specific to Germany is that the current version of the German standard for bridge inspections DIN 1076 [2] does not include monitoring as part of the inspection process. This has led to a regulatory gap, as bridge authorities have not yet

established a systematic monitoring process. This will change in the near future with the introduction of a current revision of DIN 1076. The next version will include monitoring as a standard inspection routine [3].

The discrepancy between state-of-the-art monitoring methods and technology, on one hand, and the challenges associated with their implementation by bridge owners and operators, on the other, has become more apparent in recent years. One primary method to address this challenge is the implementation of guidelines that can provide direction and regulate the utilization of procedures to some extent. Several institutions have expressed a need for such guidelines, and they have taken steps to promote and facilitate their publication.

The German Concrete and Construction Technology Association (Deutscher Beton- und Bautechnik-Verein e.V. DBV) played a pioneering role in developing and publishing the "DBV-Guideline Bridge Monitoring - Design, Tender, and Implementation" (DBV-Merkblatt Brückenmonitoring - Planung, Ausschreibung und Umsetzung) in 2018 [4]. The document meticulously delineates a range of monitoring applications and, most notably, methodically analyzes and structures the bridge monitoring process into multiple steps. Concurrently, the players involved in the process were assigned to the individual steps. Those involved in the practical application found this structuring to be very helpful. Additionally, the guideline briefly addressed tendering and economic considerations.

As an extension of the support provided by guidelines, the German Society for Non-Destructive Testing (Deutsche Gesellschaft für Zerstörungsfreie Prüfung e.V. DGZfP) has published the "Guideline B09 Structural Monitoring" (Merkblatt B 09 Dauerüberwachung von Ingenieurbauwerken) [5]. The guideline is a comprehensive document that provides

a detailed overview of the conception of monitoring systems. It also includes a compilation of possible technical systems and sensors, depending on the specific tasks at hand. Additionally, aspects of data processing and data management are addressed. Operators of the structures are further supported by a compendium of best practice examples.

Despite the existence of published guidelines, the practical application of monitoring specifically for road bridges did not gain widespread traction. In response, the German Federal Highway Research Institute (Bundesanstalt für Straßen- und Verkehrswesen BAST) initiated a research project in 2023. The objective of the project was to produce a brochure-type guide that would provide practical application instructions for monitoring road bridge structures. As a brochure cannot be expected to address every potential issue or question that may arise in the context of a monitoring application in great detail, the compendium-type final project report, "Guideline - Strategic application of monitoring for engineering structures" (Leitfaden – Strategischer Einsatz von Monitoring bei Brückenbauwerken), was pre-published in 2024 [6]. This report encompasses both technical aspects and addresses economic feasibility, tendering, and contracting of monitoring services. It includes a collection of typical monitoring applications on road bridges, organized by use cases, describing their common usage and benefits, supplemented by model examples. Currently, the monitoring system operator generally holds the measurement data, with no principal data transfer to the client. As monitoring applications become more widespread, standardizing procedures and establishing data management systems becomes crucial. The road administration is responsible for storing processed measurement data in a machine-readable format to enable future evaluations. The project developed foundations for designing suitable data management systems and explored how user agreements for data description and transfer can be incorporated into contracts.

The final guideline in this series differs slightly from the previous guidelines. The primary focus of this guideline is the monitoring of prestressed wire breaks in prestressed concrete structures using the method of acoustic emission analysis, as opposed to the broader field of engineering structure monitoring. The DGZfP guideline "SE 05 - Detection of tendon wire breaks with acoustic emission" (Richtlinie SE 05 – Detektion von Spannstahlbrüchen mit Schallemissionsanalyse) aims to standardize the application of acoustic emission (AE) analysis for detecting prestressing wire breaks and to outline the method's capabilities and limitations [7]. It provides detailed instructions for planning, tendering, installation, operation, and evaluation of an AE monitoring system. The guideline also offers recommendations on technical and personnel requirements and quality standards to ensure a high-quality information system. Its scope includes bridge and engineering structures with bonded prestressing wires, though the described methods could also apply to unbonded post-tensioning systems.

The contribution presents a compilation of the four different guidelines developed and published in recent years in Germany. These guidelines aim to structure and regulate the conception and implementation of monitoring applications to support the introduction of monitoring into the practice of managing bridge and other engineering structures. In addition

to the guidelines presented here, several other documents have been published recently to assist those involved in the management of bridges and other engineering structures. For instance, these documents may include reports on a particular subject, such as corrosion monitoring of reinforced concrete structures [8], or documents that compile reports of applied monitoring activities in civil engineering, such as [9].

## 2 DBV-GUIDELINE BRIDGE MONITORING

The German Society for Concrete and Construction Technology (DBV) was the first to address the issue of harmonization approaches to planning and implementation of monitoring measures for engineering structures. In 2018, the DBV published the guideline "Bridge Monitoring - Design, Tender and Implementation" [4]. The guideline was developed by a consortium of bridge operators, monitoring providers, and representatives of the scientific community. This consortium was formed to consider the perspectives of all parties involved in the realization of monitoring projects.

### 2.1 Motivation and objectives

The primary objectives behind developing this guideline were twofold: first, to catalog potential use cases of structural health monitoring throughout the life cycle of engineering structures, and second, to describe the monitoring process in detail, including all its phases, in conjunction with clearly defining responsibilities. The guideline was developed to serve as a practical resource for the planning and execution of monitoring activities. While the guideline is centered on bridge monitoring, its principles can be applied to a variety of engineering structures and buildings.

### 2.2 Content of the guideline

The guideline underscores the importance of various monitoring applications across a structure's life cycle. However, the text also describes monitoring applications in the pre-construction, construction, and demolition phases. The list of use cases is not exhaustive, but it provides an overview of monitoring's potential.

The implementation of bridge monitoring entails more than just installing sensors on a structure and recording the measured values. To successfully receive the requested structural information based on monitoring, it must be understood as a comprehensive process, from the definition of the task to the extraction of the qualified answer. The success of a monitoring project hinges on a structured process with clearly defined phases and service profiles for all involved parties. The guideline suggests a systematic monitoring process comprising the following six sequential phases:

- Defining the monitoring objective and assessing its feasibility.
- Developing a monitoring concept.
- Detailed design of the monitoring system.
- Implementation, including installation, operation, and data acquisition.
- Data processing and evaluation.
- Assessment, where results are interpreted using supplementary analyses.

Stakeholders involved in monitoring projects have specific roles and responsibilities. While tasks are clearly assigned,

depending on project size and complexity, a limited number of experts may fulfill multiple roles. In complex projects, there may be a need for different specialists, particularly when advanced measurement techniques are required.

Quality assurance is critical at every stage of the monitoring process to ensure consistent, high-caliber standards. Internal quality control is always required, while external proofs may be necessary for critical projects. The guideline recommends a structured procedure for each of the three main subjects in terms of quality assurance: the monitoring concept, data integrity, and the key feature assessment.

Additionally, the process of tendering monitoring services is complex due to the specialized nature of SHM. A well-structured approach ensures coordinated data flow among stakeholders, leading to consistent quality. As defining monitoring services precisely in tenders can be challenging, functional descriptions focusing on objectives and expected outcomes can serve as an alternative. However, achieving comparable offers and execution quality remains a key challenge. The guideline delineates various approaches, contingent upon the complexity of the monitoring project.

Finally, the cost-effectiveness of monitoring must be assessed before any action is taken. Monitoring provides valuable information that can extend a structure's service life, reduce the need for costly upgrades, and improve risk management. Monitoring is essential for preventing unnecessary restrictions or interventions. It helps optimize infrastructure maintenance and safety. The guideline covers the net present value method and the downtime costs accounting method, and it includes examples that illustrate the economic benefits of monitoring measures. Additionally, the text presents a method for evaluating the risk associated with the uncertainty of the monitoring results.

### 2.3 Guideline summary

The proposed DBV-guideline "Bridge Monitoring - Design, Tender and Implementation" aims to catalog structural health monitoring use cases and describes the monitoring process with defined responsibilities. The process is structured in six phases, from defining objectives to result assessment. The guideline emphasizes quality assurance, addresses the complexities of tendering monitoring services, and discusses the cost-effectiveness of monitoring. While the primary focus is on bridge monitoring, the principles can be applied to other engineering structures as well. The guideline is intended to serve as a practical resource for the planning and implementation of monitoring actions, taking into account the perspectives of bridge operators and monitoring providers.

## 3 DGZFP-GUIDELINE B 09 STRUCTURAL MONITORING

### 3.1 Motivation and objectives

The DGZfP has developed the "Guideline B 09 Structural Monitoring" to assist owners, operators, and those responsible for structural maintenance, as well as qualified planners tasked with designing monitoring systems [5].

Guideline B 09 is a clear complement to the DBV guideline Bridge Monitoring. As the previous section explains, it focuses on the description of monitoring applications, the monitoring process, and economic considerations. The DGZfP B 09

guideline clearly states the objective: to provide readers with easy access to monitoring systems and to illustrate the conditions and limits under which monitoring specific structural parameters can serve as a useful supplement or alternative to manual structural inspections. It provides a solid foundation for a realistic assessment of the financial and time requirements from the initial idea to the evaluation of the results of structural monitoring.

The guideline provides detailed descriptions of the aspects to consider when designing continuous monitoring systems and examines tasks that can realistically be addressed by structural monitoring. It also discusses critical issues for data management and quality assurance. The document emphasizes practical relevance. The explanations of monitoring tasks are formulated from the perspective of typical structural engineering questions rather than from the perspective of sensor technology. The authors of the guideline made a point of including a catalogue of practical examples. This collection includes monitoring applications from various structures (bridges, wind converters, etc.), different building materials (steel, concrete, etc.), and different monitoring objectives (damage monitoring, load monitoring, etc.).

Given the increasing presence of providers of hardware and monitoring services in the marketplace, it is becoming increasingly important to have a common understanding of the factors that need to be considered during the various phases of structural monitoring. It is therefore imperative to ensure that monitoring systems reliably meet customer requirements for specific tasks and to avoid unrealistic expectations of potential results. According to the authors of the new DGZfP Guideline B 09 Structural Monitoring, this document makes a significant contribution to achieving this goal.

### 3.2 Content of the guideline

The guideline covers all essential technical steps that must be considered during the design and implementation of a monitoring project according to the current state of knowledge. The focus is on large-scale monitoring systems, i.e., sensor networks with multiple sensors at different locations, with special consideration of applications to reinforced and prestressed concrete bridge structures. The substantive chapters of the guideline are presented below.

**Conception of Continuous Monitoring Systems:** This chapter provides comprehensive guidance on the technical design of continuous monitoring systems. The necessary steps are described in detail along the measurement chain: The structure consists of the following: sensor connection, base station, and peripherals. The text starts by clearly explaining the preliminary investigations of existing structures. These investigations determine potential weak points, existing damage, and probable damage mechanisms. The text also describes the determination of measurement parameters. Next, we will critically assess whether monitoring is appropriate in each case. If the decision is positive, suitable sensors must be selected and suitable measurement locations determined. These locations must take into account the aspects described in the guideline.

The signals collected at measurement points are transmitted to a base station or central computer via cable or wirelessly, depending on the sensor type and system layout. The data converges at the base station, where it is processed, verified,

and stored. The text explains different data acquisition modes (time-controlled, event-based) and considers event detection, data volume, and energy consumption. Remote transmission components enable continuous monitoring, alarming, and data backup. Actuators trigger events like switching traffic lights. Data evaluation is automated and based on specific standards. Challenges in larger projects include ensuring reliable communication and appropriate measurement intervals.

**Monitoring Tasks:** This central chapter of the guideline deals with various typical construction issues that are fundamentally accessible to monitoring in civil engineering structures. For each monitoring task, only established methods and sensors are the topics of discussion. The selection and description of monitoring tasks is based on the practical experience and scientific expertise of the committee members. The authors of the guideline were aware that each structure is unique and that each type of sensor and sensor behavior is different. Generalizations are difficult to make, but they are necessary for a foundational document such as this guideline. Monitoring systems must be tailored to the task at hand. Therefore, it is essential to involve a monitoring expert in the design, planning, and implementation of monitoring projects.

The guideline covers the following monitoring tasks:

- Geometric quantities: Strain, displacement, deflection, tilt, cracks.
- Static and dynamic quantities: Force, Stress, Prestressing Force, Vibration, Shock.
- Material Properties: Material moisture, reinforcement corrosion, prestressing wire break detection.
- Environmental influences: Temperature, humidity, other environmental conditions, traffic characterization.

To improve comparability and readability, each monitoring task in this chapter is divided into four identical sections:

- Purpose.
- Sensors and Instrumentation.
- Data Analysis.
- Application and Limitations.

**Data Management:** The primary task of any monitoring system is straightforward: to collect data from the operation of the monitored structure. This data must be stored and analyzed automatically. It must be visualized, uniquely assigned, and accessible, while ensuring data security. As the scope of the measure increases, data management plays a decisive role. The guideline devotes a separate chapter to this topic, describing in detail the aspects of data management that must be considered for optimal use of monitoring data.

**Quality Assurance of Measurement Systems:** To ensure the highest quality monitoring results, which is critical for safety-related tasks, it is essential to consider several key aspects, outlined in this chapter. This chapter addresses topics such as personnel qualifications, quality assurance during design and tendering, installation planning, actual installation, and ensuring quality assurance during operation and data preparation and evaluation.

**Practical Examples:** The guideline concludes with a number of practical examples. We have thoroughly documented both large lighthouse projects and the monitoring of the "broad mass" on bridges, where a significant portion of the currently installed continuous monitoring systems are located. Each project is summarized on about three pages. The summaries

include a description of the structure, the task, the monitoring system installed, and the results.

### 3.3 Guideline summary

The new DGZfP Guideline B 09 Structural Monitoring is one of the most comprehensive publications in the guideline series to date. It comprehensively covers the entire technical process, from the decision for or against monitoring to the practical implementation of extensive instrumentation, focusing on the technical components of monitoring systems. A key feature is a catalog of practical examples that illustrate monitoring applications for different structures, materials, and objectives. The guideline's clear purpose is to provide a common understanding of essential considerations to ensure that systems meet client needs while avoiding unrealistic expectations, given the increasing availability of monitoring services.

## 4 BAST GUIDELINE FOR THE STRATEGIC APPLICATION OF MONITORING OF ROAD BRIDGES

### 4.1 Motivation and objectives

A 2020 survey of experts from federal and state road authorities conducted by the German Federal Highway Research Institute (BAST) [1] revealed that the use of monitoring is limited to existing damages and deficiencies, despite the publication of the DBV guideline. The survey identified three key barriers: a lack of knowledge about the applications and benefits of monitoring, the procurement process for monitoring services, and the handling of data storage. The use of monitoring will be actively promoted within the structure's maintenance committee groups. Operators of road bridges must be supported by best practice examples, training, and standardized procedures for the use of monitoring. The German standard governing road bridge inspections is currently being revised, and the next version will include monitoring as a standard inspection routine [3].

In response, BAST initiated a research project to produce a brochure-type guide for the practical application of monitoring road bridge structures. A booklet cannot cover all the issues and questions that may arise in the context of a monitoring application. An additional compendium-type report was published to address these issues and questions. This report must address technical issues and specifically cover the assessment of economic viability of monitoring, the tender and award process for installation and operation of monitoring systems, and the considerations for drafting contracts. The report is available for pre-publication on the BAST website [6].

### 4.2 Content of the guideline

The content of the guideline is based on the best possible applicability to the use of monitoring within the road bridge maintenance process.

**Monitoring use cases:** The various possible uses of monitoring are summarized in the following section in the form of monitoring use cases. The project-specific use cases are derived from the project objectives and represent processes that contribute to achieving the defined goals.

Several use cases have already been identified in [1], which are already frequently used in practice or have potential for future application. At present, monitoring is mostly limited to reactive measures, such as monitoring known damage or

deficits from recalculation or construction. However, the great potential of monitoring also lies in supporting predictive maintenance.

The use cases are structured in the form of fact sheets. This clear and plausible presentation of the comprehensive ways in which monitoring can be used to reduce barriers is essential. Each use case is thoroughly described, including the initial task, the implementation, and the benefits. Concrete examples are used to illustrate the application in practice.

The following list summarizes the various use cases, described in the guideline [10]:

- Known localized damages.
- Known deficits from recalculation or construction.
- Determination of effects.
- Support for regular inspection procedure.
- Accompaniment for major buildings.
- Maintenance and reinforcement measures.
- Load tests.
- Predictive life cycle management.
- Birth certificate.
- Measures during the construction period.
- Protection of buildings during neighboring construction work.

#### Monitoring Process and its Actors:

As described in the section on the DBV guideline, structural monitoring is a multi-stage process from the description of the objectives to the assessment of the monitoring results. The operating authority of the structure must implement a system that divides the task into phases and assigns actors responsible for processing each phase. The tasks of the phases can be tendered separately or combined. The phases are defined similarly to [4].

Economic feasibility studies: Bridge owners and operators must determine the benefit-cost ratio of any monitoring system before implementation. To evaluate this ratio, it is necessary to estimate the expected costs associated with the future use of a road bridge with and without monitoring. This is a complex task. The expected costs depend on future developments in the condition and performance of the bridge, the quality of the monitoring system and data processing, possible monitoring results, future decisions related to these monitoring results (i.e., decisions on actions such as traffic restrictions, inspection, maintenance, bridge replacement, etc.), the direct and indirect costs associated with these actions, and the costs of installing, operating, and maintaining a monitoring system. The difference between the expected cost of operating a bridge without and with monitoring is the value of monitoring provided by a monitoring system. If this metric is positive, the cost of a surveillance system is justified by its benefits. The guideline draws on literature and the expertise of the German road authorities. It highlights the similarities and differences between existing procedures for assessing the economic feasibility of maintenance measures and analyses for evaluating the benefit-cost ratio of monitoring systems. It also provides clear, practical advice on how to assess this ratio and discusses situations where such analyses are less relevant [11].

Procurement process: As previously outlined, one of the most challenging areas for bridge agencies in implementing monitoring into their daily operations is the management of tendering, awarding, and contracting activities. This is due to

the novelty of monitoring as a technique for determining bridge safety measures. The following aspects are the main areas of concern:

- What are the required services to be tendered and provided?
- Who are the players and which specifications and expertise potential bidders must provide?
- What are appropriate award criteria?
- What constraints need to be considered when drafting the contract?
- How should liability claims be regulated and formulated?

The guideline authors' experience with bridge monitoring bridges provides a solid foundation for the proposed procedure. Tendering is a viable option. Parts of the overall service can be tendered separately, depending on the requirements. There are also different types of tenders, depending on whether specific service points or the entire service is functionally tendered. The right choice is influenced by several factors. In addition to price, these include quality assurance criteria such as the qualifications of the bidders. This is especially crucial because vendors sometimes make exaggerated promises. When drafting contracts, it is essential to address specific issues that differ from a standard bridge inspection. It is essential to know how to deal with a temporary outage of parts the measurement equipment, e.g., due to vandalism. Minimum response times must be defined. Rules must be established for very long measurements to account for the additional costs of aging measurement equipment that may need replacing. Liability issues must also be addressed. The guideline provides clear recommendations for choosing the right type and scope of tender. The guideline also provides clear recommendations for negotiating contracts.

Further, the brochure includes checklists for the topics discussed above. These include tendering and awarding, as well as contract design and liability.

Measurement technology: Instrumentation combines all the technical components of a monitoring system. This includes not only the actual sensors, but also components for signal transmission, data processing, and storage. A classical monitoring system is made up of sensors, sensor connection components, data acquisition systems, and a measurement computer to which other external components can be connected. The guideline lists and presents the various aspects that influence the selection of measurement technology to assist in the best practice application of monitoring in bridge condition assessment. The selection of measurement technology is based on the monitoring concept, which considers all aspects of the technical implementation of a monitoring task in the monitoring system. In addition to the monitoring objective, this includes the type and size of the structure to be monitored, requirements for long-term stability or, if necessary, interchangeability, and economic criteria. It is essential that the selection of the sensor technology be based on clearly defined requirements. These requirements include the measuring range, measuring accuracy, sensitivity, measuring resolution, and sampling frequency. Finally, it is essential to consider potential technical and environmental influences.

The guideline clearly describes the different technical components of conventional monitoring systems. Additionally, new types of IoT (Internet of Things) monitoring systems,

typically organized in sensor network structures, are briefly discussed. The relationship between the measurement task and the measurement technology is presented to assist road bridge authorities. The previous section clearly outlined the most well-known and commonly used sensors. The sensors mentioned have clear applications, measurement, and target variables. The measurement principle is presented, and if necessary, comments on advantages and disadvantages or special notes on application limitations are given.

**Data Management:** Although managing monitoring data is challenging for road authorities, it is valuable for future inspections and new methods. Data management is covered in national and international literature. The focus is on solving data management challenges as a governmental task to preserve information for the long term. Only one third of the monitoring data is stored at road agencies due to difficulties in structuring and sharing data between private companies and public agencies. This means that data management recommendations are needed. Currently, specialized structural measurement service providers (SSMSPs) handle most of the data. Some advanced road authorities also act as SSMSPs.

Both SSMSPs and road authorities are responsible for storing monitoring data. SSMSPs are responsible for collecting and analyzing data, while road authorities are responsible for receiving, archiving, and sharing it. The requirements for road authorities were collected in user stories to help prioritize data management needs. These user stories are visualized as a user story map, which will help road authorities prioritize their requirements when evaluating data management software. The discussion revealed that road authorities must address SHM data governance and sovereignty but currently lack structured processes for receiving, archiving, and sharing SHM data, including quality control. To address this issue, two business processes were developed to facilitate the receipt of structured data.

The first process begins with an inspection request and involves creating an employer's data requirement (EDR) document that specifies data formats, metadata, and delivery cycles. After the road authority approves the EDR, the SSMSP delivers the data as agreed. Then, the road authority verifies the data delivery and makes it available in asset management systems.

The second process describes how stakeholders who oversee structural assessments use monitoring data. If the SSMSP performs the assessment, they must ensure the data is reusable and well-documented. This process includes negotiating a usage agreement and providing access to the data for automated and manual workflows.

Long-term data preservation should be independent of proprietary software to enable broad accessibility and new business opportunities.

#### 4.3 Guideline summary

The guideline was developed due to a lack of awareness regarding which structural use cases should be monitored to provide information or improve bridge integrity, and which measurement technology is appropriate. Most importantly, there is a lack of a standardized monitoring process, as well as an unknown set of parties involved in the process. Additionally, there is a lack of knowledge on how to determine the economic feasibility of monitoring and how to tender and award

monitoring services. Data management is another area of concern. The guide suggests approaches here and describes important boundary conditions that need to be considered.

The final document offers solutions to all these issues. In addition to the detailed guideline report, the most important statements are summarized and published in a short, concise brochure. Throughout the guideline development process, consultations and discussions were held with the target audience of state and federal road agencies. These consultations are seen as a necessary basis for successfully introducing and accepting the guideline. [10, 11].

## 5 DGZFP GUIDELINE FOR DETECTION OF WIRE BREAKS BY ACOUSTIC EMISSION ANALYSIS

### 5.1 Motivation and objectives

Prestressed concrete construction began in Germany in the 1950s. It was characterized by experimental approaches and diverse prestressing systems, although the relevant codes were slow to develop. The key was recognizing the need for high tensile strength in prestressing steel to maintain effectiveness despite creep and shrinkage. While tempering and alloying improved the strength of prestressing steels, it also increased their susceptibility to stress corrosion cracking (SCC). This issue affected steels from the 1950s to the 1970s, and in East Germany until the 1990s [12]. SCC can cause brittle fractures in prestressing steel that are observed during construction and are attributed to the storage, installation, and pre-grouting periods. Damage can also occur after prolonged use in well-built structures. Evaluating these structures is challenging due to the difficulty of inspecting internal tendons and detecting wire breaks. Some structures lack sufficient reinforcement to ensure safe load transfer when prestressing steel fails, which can lead to sudden failure. Many structures with vulnerable prestressing steel are still in use today, and significant damage continues to be observed.

The challenge lies in the limited accessibility of tendons embedded within concrete. In recent years, acoustic emission (AE) monitoring has become a key method for detecting prestressing wire breaks in Germany. AE was originally used to test high-safety industrial equipment, and its potential for construction was recognized in the 1990s. AE monitoring was first applied to suspension and cable-stayed bridges, followed by prestressed concrete bridges. AE offers continuous, comprehensive monitoring, enabling immediate detection and localization of damage. Through automated analysis, it provides reliable data on wire breaks, making it indispensable for owners. Affected structures can continue operating safely, which allows for better planning and resource management.

Ensuring safe and reliable bridge operation is critical. Regular inspections according to DIN 1076 are an important tool for this. Shorter inspection cycles are recommended for bridges with SCC-prone prestressing steel. Continuous monitoring methods, such as AE can detect wire breaks permanently and allow for the dynamic evaluation and adjustment of inspection intervals. AE monitoring significantly contributes to safe bridge operation by transitioning from a scientific method to a standardized procedure. In this context, the guideline SE 05 "Detection of prestressing wire breaks with acoustic emission" [7] establishes a framework for procurement and quality-assured operation.

The SE 05 guideline aims to standardize the application of AE monitoring for detecting prestressing wire breaks as well as outline the method's capabilities and limitations. The guideline provides detailed instructions for planning, tendering, installing, operating, and evaluating an AE monitoring system. The guideline also offers recommendations on technical and personnel requirements as well as quality standards to ensure an effective information system. The guideline's scope includes bridges and other engineering structures with bonded prestressing wires, though the described methods could also apply to unbonded tensioning systems.

### 5.2 Content of the guideline

The guideline is structured to help interested readers first understand the methodology and a proposed practical approach to applying AE monitoring for lifetime detection of wire breaks. After an introduction to the guideline, important terms, definitions, and abbreviations are presented.

**Methodology:** AE detects damage by capturing the elastic energy released as shock waves, which can be detected by surface sensors. This guideline explains this principle as it applies to monitoring prestressing wire breaks and provides basic implementation instructions. AE analysis requires high sampling rates and complex data analysis. Recommendations include the type of sensor, the frequency range, and pre-amplification. Piezoelectric sensors with a resonant frequency of 20-80 kHz are typically used to ensure sensitivity and minimize interference from low-frequency noise. Optimal sensor placement is critical for accurate detection and localization. Sensors should be strategically distributed based on the structure's geometry, material properties, and expected signal attenuation. The maximum allowable distance between sensors depends on factors such as signal strength, noise level, and the structure's damping characteristics.

The effectiveness of AE monitoring depends on distinguishing signals from background noise. Additionally, AE only detects active damage and not preexisting wire breaks. Complementary methods, such as non-destructive testing or invasive inspections, are required to establish baseline conditions at the start of monitoring.

**Implementation and service description:** After identifying the need for continuous monitoring, the system requirements must be defined and the procurement process initiated. Because each bridge has unique characteristics, such as structural geometry (e.g., box girder or T-beam), material properties (e.g., concrete type), and environmental factors (e.g., traffic load), each bridge requires a customized monitoring design. The guideline provides detailed instructions for acoustic analysis, sensor layout, and performance specifications.

**Qualification of provider:** As no official certifications exist, personnel and operational qualifications for AE monitoring can only currently be demonstrated by reference projects and experience. Design, installation, and operation must be performed by qualified personnel. Detailed recommendations for qualification verification are provided.

**Data analysis and reporting process:** This section outlines the steps from data collection to action. Automated analysis identifies potential wire breaks that require verification using additional methods or by engineers. Confirmed breaks are then used for structural evaluation. The discussion covers essential information for documenting candidate wire breaks.

**Appendices:** The appendices offer supplementary technical information, including recommendations for supervising wire removal via acoustic emission, methods for determining background noise levels and signal attenuation, and calculations for maximum allowable sensor distances based on structural geometry and material properties.

### 5.3 Guideline summary

This guideline introduces acoustic emission (AE) analysis as a tool for continuously monitoring prestressing wire breaks in concrete bridges. AE technology can detect and locate wire breaks in real time, offering critical information about the structural health of bridges. Therefore, it offers a unique opportunity to assess and manage structures at risk of stress corrosion cracking. AE is the only method that can directly detect wire breaks and requires specialized knowledge. This method applies to bonded prestressing systems but not to unbonded tensioning systems. However, it cannot detect wire breaks that occurred prior to the start of monitoring.

The increased interest and use of AE systems has led to better regulation of procedures and requirements, as recognized by the DGZfP committee. This resulted in the SE 05 guideline. This guideline, developed by multiple parties, represents accepted technical standards and provides detailed instructions for the procurement and quality assurance of AE systems during installation and operation.

## 6 CONCLUSIONS AND OUTLOOK

### 6.1 Conclusions

The reviewed German guidelines - DBV Bridge Monitoring, DGZfP B09 Structural Monitoring, BASt Strategic Application of Monitoring, and DGZfP SE 05 Detection of Wire Breaks Acoustic Emission Monitoring - collectively provide a structured framework for conceiving, implementing, and managing SHM in bridges and other engineering structures. The guidelines address different aspects, ranging from process structuring and economic assessment to technical system selection and quality assurance, and offer complementary strengths.

Despite these advances, the practical implementation of SHM is limited and is often restricted to event-driven responses rather than proactive and predictive maintenance. Key barriers include a lack of practitioner experience, challenges in procurement and tendering, and unresolved issues in data management and ownership. While the guidelines have helped clarify roles, standardize processes, and provide examples of best practices, they also reveal gaps, particularly the absence of a unified, one-size-fits-all approach and the need for harmonized data management systems.

The transition from technological development to standard practice is underway. However, widespread adoption requires technical solutions, organizational clarity, and contractual clarity. Collaboration among stakeholders, including infrastructure owners, service providers, and researchers, is essential to bridge the gap between advanced SHM technology and practical application. Every phase of SHM projects must include economic evaluation and quality assurance to ensure cost-effectiveness and reliability.

## 6.2 Outlook

The upcoming revision of the German bridge inspection standard, DIN 1076, is expected to accelerate the integration of monitoring into standard maintenance practice by incorporating SHM as a routine element. As SHM becomes more prevalent, the need for standardized data management and protocols for data sharing and ownership will grow. Future guidelines should address these topics in greater depth. Furthermore, future guideline editions must include regulations on personnel qualifications and calibration of monitoring hardware. Training programs and knowledge transfer initiatives should be developed to provide practitioners with the expertise necessary for the effective deployment of SHM. Guidelines should address differing expectations between practitioners (e.g., bridge operators) and SHM service providers to promote clear communication and user-friendly solutions.

A unified guideline or standard integrating technical, economic, and contractual aspects is needed to make it easier for practitioners to implement SHM, regardless of project size or complexity.

Future work should also focus on aligning German guidelines with European and international standards to facilitate cross-border projects and knowledge exchange. This includes adopting common terminology, data formats, and quality assurance procedures.

Additionally, future guideline issues should continuously integrate the results of ongoing research focusing on predictive analytics, integration with digital asset management systems, and the development of scalable, adaptable SHM solutions. SHM guidelines should support a shift from reactive to predictive maintenance by leveraging monitoring data to optimize infrastructure management and extend service life.

By fostering collaboration, harmonization, and continuous improvement, SHM guidelines can ensure the safety, reliability, and sustainability of critical infrastructure in Germany and Europe.

## EXTENDED ABSTRACT

**KEY WORDS:** Structural Health Monitoring; Italian Guidelines; Bridge management; Infrastructures.

### 1 INTRODUCTION

Bridge management plays a critical role in safeguarding transportation safety and functionality against aggressive environmental conditions, increasing load demands, and extreme events, making it an indispensable pillar of modern infrastructure systems. Recognizing the need for standardized practices, the Italian Ministry of Infrastructures and Transport issued the 2020 “*Guidelines for Risk Classification and Management, Safety Evaluation, and Monitoring of Existing Bridges*” [1]. These guidelines categorize bridges into five attention classes (ACs), determined by comprehensive assessments of structural and foundational conditions, as well as seismic, hydraulic, and landslide risks. Each attention class dictates specific analyses and Structural Health Monitoring (SHM) activities to enhance structural understanding and safety. This work provides a brief integrated overview of the 2020 Italian Guidelines in conjunction with the 2015 national “*Guidelines for Structural Health Monitoring*” [2], exploring their synergies and identifying key challenges in their application. The potential of SHM technologies is critically assessed, focusing on their role in evaluating structural performance and reducing uncertainties related to material properties and operational conditions.

### 2 THE ITALIAN GUIDELINES FOR BRIDGES

The Italian Guidelines for Bridges (IGB) are characterized by an innovative multi-level and multi-risk approach. The six levels of analysis present a progressive increment in complexity and detail, while the number of bridges that require this analysis should decrease. Level 0 consists of the collection of design information, structural and geometric data, road traffic information, and past maintenance interventions. This census and collection process involves the whole bridge portfolio, as well as levels 1 and 2. Level 1 corresponds to the visual inspection of bridges to verify the design geometry and evaluate the presence of defects, which are noted in the defectiveness sheets provided by the IGB for each structural element. The number of defects and their intensity establish the defectiveness level of the bridge. Further, level 2 evaluates the bridge AC, combining four risk types: structure and foundation, seismic, hydraulic, and landslide. For each risk type, a partial AC is defined as a combination of hazard, vulnerability, and exposure. The combination of the partial ACs leads to a total

AC for the bridge, which influences the application of the following level 3 and 4 analyses. Five ACs are defined, namely, low, medium-low, medium, medium-high, and high. Level 3 is a preliminary assessment of the bridge condition and is performed for bridges with a medium or medium-high AC to assess whether detailed analyses are needed. Level 4 represents a detailed structural analysis of the bridge according to the current standard, and it is mandatory for bridges in high AC. Structures are classified as: “adequate” if the analysis is satisfied for loads with a return period of 50 years, “operative” if the verification is satisfied for loads with a return period of 30 years, or “transitable” if it is verified for loads with a return period of 5 years. Transitable bridges need a maintenance intervention within 5 years, and during this period, can receive restrictions such as roadway partial closure or load limitations. Finally, level 5 corresponds to a resilience evaluation of roadways considering the consequences due to the loss of functionality of the bridge on the entire transport network. However, this level of analysis is not yet detailed in the current version of the IG.

### 3 THE ITALIAN GUIDELINES FOR MONITORING

The Italian Guidelines for Structural Health Monitoring (IGSHM) define the objectives and the minimum requirements for a monitoring system to be installed on a bridge. Two main objectives are identified: (i) the check of the structural performance with respect to specific limit states, e.g., collapse and serviceability, and (ii) the identification of a degrading effect in-act. Thus, based on the monitoring data, surveillance and maintenance activities can be planned, the service life of crucial assets can be evaluated (and extended), and innovative constructive methods or structural schemes can be investigated. Monitoring activities are distinguished in:

- occasional, when performed continuously for a limited period of time (from a few days to 1 or 2 years) to augment the knowledge of the structural performance before and after a rehabilitation activity,
- periodic, when performed continuously for a limited period of time (typically a few hours or days) every few years, to investigate specific degradation phenomena that may occur over time,
- continuous, when the monitoring system is permanently installed on the structure. This monitoring activity is

advised on complex structural systems (e.g., long-span bridges) or for structures that are subjected to rare, accidental, or exceptional actions (earthquakes, collisions, etc.).

While monitoring activities are defined depending on their scopes, the design process of an SHM system usually follows eight steps, herein illustrated in Figure 1.

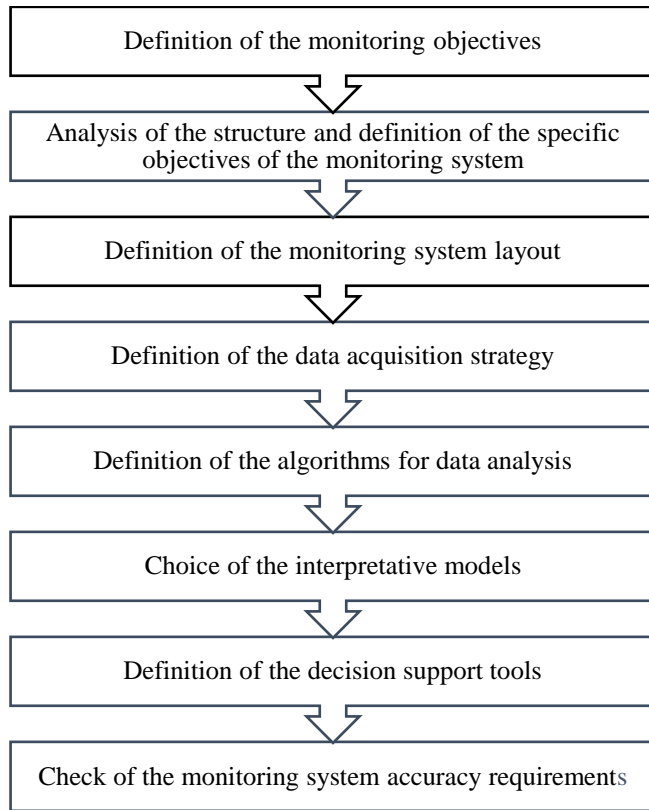

Figure 1: Steps in the design of a monitoring system according to [2].

The monitoring objectives, such as the knowledge of structural performance and the identification of in-act degrading phenomena, can be expressed in terms of an index (of damage, performance, or residual life) or through low-to-high classification (on damage or performance evolution). The estimation of such indices is based on the mechanical (both referring to the structural response and the actions that are applied to the structure), thermodynamic, chemical, or electromagnetic characteristics that are measured on the structure. The layout of the sensors is defined according to the structure types and static scheme, and the model that is used to interpret the collected data. In the case of a vibration-based monitoring system, the layout of the sensors should be conceived to effectively capture the mode shapes and natural frequencies. In doing so, the redundancy of the monitoring system is crucial to limiting the effects of malfunctions.

Therefore, the collected data are processed and interpreted. In some cases, the data already indicate the presence of damage (e.g., the scour depth or a crack size), while in some other cases, such as for a vibration-based monitoring system, data must be processed to estimate the natural frequencies and the mode

shapes. Damage can be detected by investigating the variation of such modal parameters.

Further, decision support tools can be developed based on the collected data by the definition of thresholds on the measured characteristics and associating them with warning alarms and/or interventions.

#### 4 THE ROLE OF SHM IN THE ITALIAN GUIDELINES FOR BRIDGES

Within the IGB, SHM is defined as an essential tool in the optimization of the management of critical infrastructure. Its role extends beyond data acquisition, as it augments structural understanding, reduces epistemic uncertainties, and enhances targeted maintenance scheduling. SHM systems are presented as complementary to inspections, destructive, and non-destructive testing methods, offering continuous information in bridge condition assessment. The real-time monitoring of stress responses, crack propagation, and displacements under operational and extreme load conditions, see Paragraph 6.2 of the IGB, can effectively support structural performance assessment and maintenance scheduling. Further, SHM data can allow for early warning by detecting anomalies and deterioration trends whenever periodic visual inspections are not performed. Emergency response planning can be supported by SHM, as for the cases of landslide (see Paragraph 4.4.2) or hydraulic (see Paragraph 4.5.1) hazards.

SHM is seen to contribute to both diagnosis and prognosis, aiding characterizing the current condition of the bridge and predicting its future behavior. As pointed out in Paragraph 6.3.3.5, SHM enables the calibration and update of bridge numerical models, reducing epistemic uncertainties related to material properties, loading conditions, and model assumptions. Also, as highlighted in Paragraph 7.6, SHM can optimize inspection scheduling by identifying zones of concern and providing long-term trends. The adaptive use of real-time data also supports the dynamic update of threshold values for alerts and interventions (see Paragraph 7.7), facilitating the transition from time-based to condition-based maintenance strategies. Furthermore, the integration of SHM data with Bridge Management Systems (BMS) can aid prioritizing interventions across a network of assets, enhancing long-term planning capabilities and aligning structural management with resilience and sustainability goals.

#### 5 MONITORABLE PARAMETERS IN THE ITALIAN GUIDELINES FOR BRIDGES

SHM can aid at Level 1, Level 2, and Level 4 of the IGB by automatically collecting data about the structural condition and refining the risk classification and the detailed analyses.

At Level 1, the automatic collection of data can both aid (i) detecting damage on bridge components that are not easy to inspect and (ii) investigating the evolution of defects in time.

Within Level 2, numerous parameters are considered in the definition of the attention class, which can be low, medium-low, medium, medium-high, and high. Defects that were detected during the inspections of Level 1, and other parameters proper to the four hazards (structural-foundational, seismic, hydraulic, and landslide) are examined, and an attention class is assigned to each bridge. SHM implementation is advised for medium-high and high attention classes.

A reclassification of the bridge attention class would consider the collected data from a monitoring system, therefore possibly repositioning the bridge in another attention class. Reclassifications are advised periodically or in the case interventions are implemented on the structure. Among the monitorable parameters that drive the risk-based classification, there are:

- Level of Defects, including all the possible defects that can be observed on bridge components,
- Average Daily Traffic, indicating the average number of vehicles that cross the bridge in a day,
- Frequency of commercial transit, indicating the average number of heavy loads, such as lorries, that cross the bridge in a day,
- Scour depth, indicating the erosion of soil or sediment by flowing water, particularly around bridge piers and abutments.

The level of defects is a primary parameter for the evaluation of the vulnerability within the structural-foundational risk, and it is characterized by gravity, intensity, and extension. As demonstrated in [3], the level of defects drives the attention classification – when the level of defects is high, the attention class is high regardless of the other parameters. Thus, the presence of defects with high or medium-high severity (and high intensity and extension) is defined as a critical condition for the attention classification [4]. Several monitoring techniques can be implemented to monitor the evolution of defects, such as extensimeters, tiltmeters, strain gauges, and accelerometers. Novel techniques include Interferometric Synthetic Aperture Radar (InSAR), video-based, and crowd-sensing [5].

The frequency of commercial transit is a parameter that characterizes the structural-foundational hazard within the attention class determination. Heavy loads, such as lorries, represent a criticality for bridge integrity management, as they may exceed the traffic load for which the bridge has been designed.

Further, the average daily traffic characterizes both the structural-foundational hazard and exposure. While together with the frequency of commercial transit is indicative of the traffic demand over the bridge, it is essential in estimating its exposure, i.e., the consequences in case of a collapse. Weight-in-motion systems can be implemented to investigate the load demand on bridges and eventually set limitations [6].

The scour depth is a crucial parameter in the hydraulic risk assessment, specifically for the evaluation of the hazard for the local scour. The scour depth can be monitored by, for example, a vibration-based monitoring system. A decrease in the natural frequency or a variation in the mode shapes may refer to a loss of stiffness in the support of a bridge pier caused by scour.

Noticeably, also the evaluation of the landslide hazard may be supported by SHM data, and its evolution may be monitored through several techniques, such as InSAR.

Within Level 4 of the IGB, SHM may be used to calibrate and update the numerical model that is built for the detailed analysis. Bridge components may be modelled accounting for the defect severity, extension, and intensity, as a local decrease of the component stiffness. Further, the traffic demand on the bridge can be evaluated and modelled to verify the bridge condition and impose traffic limitations. Digital twins (of

physical structures) can be created and continuously updated by SHM data.

## 6 CONCLUSIONS

This work provides a brief integrated overview of the Italian 2020 “Guidelines for Risk Classification and Management, Safety Evaluation, and Monitoring of Existing Bridges” (IGB) and the national 2015 “Guidelines for Structural Health Monitoring” (IGSHM). The role of Structural Health Monitoring (SHM) in the IGB is investigated. Monitorable parameters that can affect the attention classification of Level 2 and the detailed analysis of Level 4 are stated, and possible monitoring techniques are suggested.

**ABSTRACT:** Aging bridges were not designed for today's higher traffic loads and often fail to meet current requirements. However, complete demolition or reconstruction is rarely feasible due to resource limitations, sustainability concerns and economic factors. A key issue lies in conservative assumptions regarding loads and resistance. Structural health monitoring (SHM) addresses this by providing real measurement data for a more accurate assessment.

Monitoring produces large volumes of data that must be well-structured and stored for reliable assessments. This requires collaboration between civil engineers, measurement specialists, IT experts, and data analysts. As Building Information Modeling (BIM) adoption grows, standardized monitoring methods must ensure consistency and comply with the Single Source of Truth (SSoT) principle, enabling an integration of monitoring data in a BIM environment.

The ANYTWIN research project aims to develop a framework for structured data storage and processing. It examines how measurement data relates to time and location, defines metadata and information for evaluation criteria and assigns responsibilities for data provision. A processing method ensures data preparation, analysis, and data mining, while quality indicators enhance reliability. These findings contribute to a tendering template, helping to structure monitoring tasks and improve maintenance strategies.

**KEY WORDS:** Structural health monitoring (SHM); Standardization; Monitoring data; Data Quality; Quality Indicator; Tendering template.

### 1 INTRODUCTION

Existing bridges age over time and were not designed for today's significantly higher traffic loads. Many of these structures no longer meet the current verification requirements of the Eurocode. However, complete demolition or new construction is not a practical solution—on one hand, the necessary resources for demolition and reconstruction are lacking; on the other hand, such an approach would be neither sustainable nor economically viable.

A primary shortcoming in meeting verification requirements arises from the conservative assumptions made regarding both loads and resistance. This is where structural health monitoring becomes crucial: by collecting measurement data, a more precise and realistic assessment of the bridge's condition can be made [1][2]. SHM allows for the adjustment of both load assumptions and structural resistance based on actual measurements, thereby enabling more accurate verification.

The monitoring process generates vast amounts of data, which must be well-organized and properly stored to ensure a clear understanding of the bridge's condition. This requires close collaboration among civil engineers, measurement experts, IT specialists and data analysts. As part of the ongoing digitalization effort and the adoption of Building Information Modeling (BIM), this collaboration should be enhanced while adhering to the Single Source of Truth (SSoT) principle. In a digital environment, such as a digital twin, various datasets and information sources converge, interconnect, and depend on each other. A structured representation of these relationships is essential for seamless integration. While the IFC model primarily serves as a static representation, it provides key

information for monitoring, including the positions of individual measurement points, cable routing and other infrastructure details.

However, the digital twin extends beyond this by dynamically reflecting the current sensor status, generating meaningful analyses of physical parameters at these points, and integrating diagnostic method data for a more comprehensive assessment. This approach enables a real-time, data-driven understanding of structural conditions. All of this should be guided by the principle that the digital twin serves as the SSoT, ensuring that all information is consistently structured, linked, and accessible within a unified system.

To achieve this, monitoring methods should be standardized and incorporated into data-based load-bearing safety checks in civil engineering [3].

This is precisely the aim of the ANYTWIN research project [4], [5], [6]. The goal of the project is to establish a clear structure for collecting, storing and processing monitoring data. Different types of measurement data are analyzed and classified to ensure systematic storage. The project investigates how measurement data is connected over time and space, identifies key details necessary for evaluation, and defines responsibilities for data provision. A processing method is also developed to ensure that the data is transformed into clean and usable time series. Finally, the project establishes the quality requirements that the data must meet for specific verification purposes and defines quality indicators for assessment.

All these findings will contribute to the standardization of tendering processes, providing project owners with a comprehensive overview of monitoring tasks and the respective responsibilities of all involved experts. The objective is to generate significant value for the future maintenance and management of bridges [7].

## 2 IMPLEMENTATION OF MONITORING IN BRIDGE CONSTRUCTION

The implementation of monitoring in bridge construction is still not a standardized procedure and is typically conducted on a case- by-case basis [8], [9], [10]. However, a structured approach has been established, based on the recommendations of the DBV guidelines [11]. According to these guidelines, the monitoring process consists of six phases, ranging from defining the objective, planning, installation, and operation of the monitoring system to the evaluation and assessment of measurement results (see Figure 1). In practice, these phases have not yet been fully standardized.

Regardless of the specific task, certain measurement parameters and objectives have been identified as crucial for the effective implementation of monitoring.

Specifically, for damage detection and computational verification in structural monitoring, the following measurement objectives are relevant:

**Temperature & Environment:** Measures temperature differences and climatic effects (e.g., temperature sensors, humidity sensors, thermocouples, resistance thermometers, infrared detectors). These parameters are crucial for assessing thermal loads on structures.

**Moisture Measurements:** Detects humidity levels and influences such as corrosion or mineral formation that can lead to durability issues (e.g., humidity sensors, multi-ring electrodes).

**Fatigue & Cracks:** Identifies stress, strain, and early cracks (e.g., strain gauges, DFOS [12], Acoustic Emission Sensors (AE Sensors) [13]), which are strong indicators of structural load-bearing capacity.

**Deformation & Movement:** Monitors settlements, vibrations and inclinations (e.g., displacement sensors, tilt sensors, acceleration sensors, distance sensors). By analyzing geometric changes at micro, meso and macro levels, insights into bearing movements, expansion behavior, creep & shrinkage, and crack formation can be derived.

**Load & Traffic:** Detects overloads and load distribution (e.g., pressure sensors, laser measurement systems), which are critical for understanding structural performance under varying traffic loads.

**Vibration Monitoring:** Assesses dynamic structural properties, such as natural frequencies and damping values, which provide insights into fatigue behavior and potential damage (e.g., accelerometers, vibration velocity sensors).

**Acoustic Monitoring:** Captures sound events to track damage progression caused by localized failure events (e.g., AE Sensors [13]).

The selection of sensors depends on the measurement objective, type of structure, and environmental conditions and is adapted to specific requirements. Figure 2 illustrates some examples of sensors and measurement systems used for bridge monitoring.

### 3 TYPES OF MONITORING DATA AND SENSORS

The efforts to standardize the handling of monitoring data obtained in the context of SHM require a comprehensive examination and description of the characteristics and typical features of such data. This foundational understanding enables subsequent classification and the formulation of universally applicable procedures for processing, evaluation, data manipulation, and establishment of quality requirements.

The term 'monitoring data' refers to the entirety of data generated in the context of SHM. In typical monitoring processes, sensor measurement data constitute the predominant volume of data. However, for effective information extraction, it is crucial to link these data with metadata, defined as all data describing the measurement.

In the initial phase of this study, the measurement data are examined. Measurement data include all data that originate directly from sensing devices on the structure. To account for the increasing technological capabilities of system-on-a-chip (SoC) solutions and edge computing, the term is also applied to data generated through automated process steps close to the sensor or hardware level, provided that their characteristics allow them to be treated as measurement data.

To illustrate the range of potential measurement data sources, typical measurement methods and their use cases briefly presented in Section 2, serves as a reference. The list focuses on recognized and proven methods without claiming to be exhaustive.

The classification of measurement data can be based on various criteria and is generally necessary to address both software-related aspects in the creation of a storage and processing infrastructure, as well as content-related aspects for the metadata to be collected.

One fundamental property describes the data in relation to a *measurement location*. Three main variants can be distinguished: point measurement methods, line measurement methods, and field measurement methods.

- **Point measurement methods** (e.g., strain gauges) provide information about a discrete measurement point with a very small spatial extent relative to the structure being monitored.
- **Line measurement methods** (e.g., distributed fiber optic sensing (DFOS) [12]) generate measurement data along a line with high spatial resolution.
- **Field measurement methods** (e.g., photogrammetry) can be used for measurements over a larger (surface) area.

Figure 2. Example of Sensor Technology in Structural Monitoring in Use, © MKP GmbH

A second classification criterion characterizes *the temporal structure* of the measurement data. Continuous and discontinuous data can be distinguished:

- **Continuous data** are stored throughout the entire monitoring period with equidistant time intervals between consecutive data samples, typically with a low sampling rate (ranging from several minutes to hours).
- **Discontinuous data** are recorded over a typically short period of time at a high sampling rate. The recording time can be determined either by a predefined time pattern or by data-dependent trigger conditions.

Another classification option concerns *the temporal reference* of the measurement data. The simplest case is a direct assignment between the individual instantaneous value of the measurement signal and the timestamp. A further possibility is that the measurement data refer to a time-extended measurement interval, such as in the case of averaging. Even more complex time reference descriptions arise with methods like Rainflow counting or Fast Fourier Transform analysis (FFT).
