A fundamental category of properties for the storage structure of measurement data is *the dimension of the index* required to address a measurement value. Besides storage, this also determines the programmatic interfaces to processing algorithms. The most common attributes in this category are:

- 1 index value per single measurement value,
- 1 index value per n measurement values, and
- 2 index values per 1 measurement value.

For time series, the index always includes at least the timestamp. Additional index values may be required, for example, to identify a location or direction.

Finally, a classification can be made based on *the underlying measurement instrument(s)* of the data. This is mainly used when assigning technical metadata. A key distinction is whether the data originate from a single, clearly identifiable sensor (element) or whether a sensor combination, a sensor array, or an automated/autonomous processing algorithm (e.g., a Weigh-In-Motion (WIM) system) should be considered as the data source.

Table 1 provides an overview of the key characteristics of the measurement data (measurement location, temporal structure, temporal reference, index dimension, and technical data source) and categorizes them into subgroups (a to c). Each subgroup was formed by identifying up to three distinct properties for each feature. This classification facilitates the systematic organization and comparison of different types of measurement data and supports further analysis and processing.

Table 2 provides an evaluation of the characteristics describing the generated measurement data based on the

established classification system for specific measurement methods and sensor technologies. It categorizes different sensors according to common characteristics and highlights potential groupings.

To facilitate abstraction, a '1' is assigned to applicable feature variants and a '0' to non-applicable ones. Gray shading is used to highlight transitions within a category. A gray mark appears in the feature column 1 to 5 whenever the assignment within a feature category changes from 0 to 1 or 1 to 0.

Through this visual grouping, at least seven sensor groups can be identified. Sensors sharing the same color pattern are classified into the same category. In this case, temperature sensors up to acceleration sensors (Table 2) are grouped together, as they exhibit identical feature combinations across the evaluated categories. In contrast, the multi-sensor system differs from these sensors, which typically measure a single physical quantity. Instead, a multi-sensor system can generate multiple independent measurement variables. As a result, its classification varies, particularly in Feature 5 (technical data source).

Table 1. Presentation and classification of characteristics for describing the generated measurement data

Classification option	Property 1 (a)	Property 2 (b)	Property 3 (c)
Feature 1: measurement location	Point measurement method	Line measurement method	Field measurement method
Feature 2: temporal structure	Continuous time-series-data	Discontinuous time-series-data, segments with fixed time interval	Discontinuous time-series-data with event-driven time interval
Feature 3: temporal reference	Single instantaneous value	(statistical) value derived from a time span	Indirect value based of underlying data
Feature 4: index dimension	1 index per 1 measurement sample	1 index per n measurement samples	2 indices per 1 measurement sample
Feature 5: technical data source	Direct data - sensor alignment	Indirect data-sensor alignment	-

Table 2. Evaluation of characteristics for describing the generated measurement data from various measurement systems

Examples of measurement systems	Feature 1			Feature 2			Feature 3			Feature 4			Feature 5	
	a	b	c	a	b	c	a	b	c	a	b	c	a	b
Temperature sensors	1	0	0	1	1	0	1	1	0	0	1	0	1	0
Strain gauges	1	0	0	1	1	0	1	1	0	0	1	0	1	0
Displacement sensors	1	0	0	1	1	0	1	1	0	0	1	0	1	0
Acceleration sensors	1	0	0	1	1	0	1	1	0	0	1	0	1	0
Multi-sensor	1	0	0	1	1	0	1	1	0	0	1	0	0	1
Corrosion sensor	1	0	0	1	0	0	1	0	1	0	1	0	1	0
Weigh-in-Motion (WIM)	1	0	0	0	0	1	1	0	1	0	1	0	1	0
AE Sensors	1	0	0	0	0	1	0	1	1	0	1	0	1	0
DFOS	0	1	0	0	1	0	1	0	0	0	0	1	1	0
Laser scan	0	0	1	1	0	1	0	0	1	0	0	1	1	0
Tachymeter-total station	0	0	1	1	0	1	0	0	1	0	0	1	1	0

Considering the goal of this grouping, it is crucial for data structuring to determine how measurement values should be assigned to their respective IDs or timestamps. Only Feature 1 and Feature 4, which are marked with bold borders in the table, are representative in this context.

These groupings reflect common classification features, allowing them to be treated as uniform types when assigning descriptive metadata, organizing data storage, and designing input and output interfaces for data processing.

For Feature 1, continuity on the spatial scale does not impact data structuring, thereby reducing the number of groups to two. For Feature 4, the key question is whether data should be structured as an array or a matrix. This decision is essential for grouping, as both Features (1 and 4) can be combined. The result is a definite grouping of sensors, which simplifies data structuring and enhances the readability of the stored data.

#### 4 RELEVANT METADATA AND ADDITIONAL INFORMATION IN BRIDGE MONITORING

In addition to the actual measurement data, another essential category of data exists: metadata and metainformation. For evaluations and measurement-based verifications, obtaining specific data and information from the measuring point on the structure and metadata from the installed measurement system or sensors is of great importance. This data is needed to apply the calculation method in data processing and evaluation while ensuring traceability of time-based trends, providing a comprehensive understanding of the structure's behavior over time and at specific locations.

According to the definition in the ANYTWIN research project, *metadata* refers to numerical, machine-readable values that can be assigned to sensors or measurement systems. In contrast, *metainformation* consists of structured, interpreted content and descriptions provided by actors, such as textual explanations. Both types of data are characterized by their stability, as they are generally static and determined once. An exception is when a sensor is replaced, which necessitates an update of the metadata and metainformation.

Metadata is defined either during the development of the measurement concept or determined after sensor installation. It can be divided into two main categories:

1. **General metadata for sensor types** – Cross-sensor information, such as the measurement method, the unit of the electrical signal, and the function used to convert the electrical signal into physical values.
2. **Specific metadata for installed sensors and measurement points** – These are unique to each installed sensor, its measurement system, and the respective measuring location. They include:
  - Sensor characteristics: such as conversion factors and calibration parameters
  - Measurement parameters: such as sampling rate, measurement ranges and spatial resolution
  - Measurement point characteristics: such as material properties like modulus of elasticity or thermal expansion coefficient
  - Technical properties of the measurement system: such as frequency range and filtering methods

- Additional evaluation parameters like installation values, calibration data and sensor orientation

In addition to metadata, additional informative metainformation is available, providing details about the installed sensors and measurement techniques. This data is not necessarily included in the metadata and is not directly relevant for data evaluation. However, it is important for traceability, quality assurance, and functional verification of the sensors, for example, in assessing their lifespan.

Unlike metadata, metainformation does not have to be stored in a machine-readable format. While it may include similar categories as metadata, it provides additional details that do not directly contribute to data analysis, such as:

- Measurement parameters: Additional metrics, such as the maximum measurement range or sensor frequency range
- Influencing factors: Environmental conditions, temperature compensation, background noise
- Technical properties of the measurement system: Connection type, measurement amplifier specifications
- Structural properties of the measurement points: Sensor protection mechanisms, material characteristics, installation date, expected lifespan

Table 3. Overview of metadata and metainformation categories and actors responsibilities

	Monitoring specialist planner	Structural monitoring service provider
<b>General metadata for sensor type</b>		
Measurement method (relative/absolute)	-	✓
Unit of the electrical signal	-	✓
Function model	-	✓
<b>Specific metadata from installed sensors and measurement points</b>		
Sensor characteristics	-	✓
Measurement parameters	-	✓
Measurement point characteristics	✓	-
Properties of the measurement system	-	✓
Additional parameters for evaluation	✓	-
<b>Informative data for documentation and traceability</b>		
Measurement parameters	-	✓
Influencing factors	✓	✓
Technical properties of the measurement system	-	✓
Structural properties of measurement points	✓	✓

Metadata and metainformation are provided and documented by different actors involved in various phases of the monitoring process. The monitoring specialist planner defines general sensor metadata and metainformation during the planning phase and in the creation of the measurement concept. This includes key parameters of the measurement point, such as surface area or modulus of elasticity. The specialized service provider for structural measurements is responsible for recording and providing specific sensor metadata and metainformation during installation. Additionally, they handle sensor calibration and update metadata and metainformation during maintenance or sensor replacement to ensure measurement accuracy and data consistency.

Table 3 provides an overview of common metadata types and the corresponding roles of actors.

## 5 DATA PROCESSING MODEL

Structural monitoring encompasses the processes of data acquisition, including data transmission and management, as well as data analysis, which involves evaluation, validation, and plausibility checks. Based on this, an assessment of the current structural condition or a forecast of future structural behavior can be conducted. This sequential process can also occur cyclically, with the system continuously receiving new data. Prior to this cyclical process, the preparation of the monitoring measures can be implemented. The success of a monitoring project largely depends on a structured workflow, where the monitoring objective remains the central focus [11].

This section introduces the data processing model developed in the ANYTWIN research project for monitoring data. This model aims to combine various sensor types, short-term, long-term, and continuous measurements, as well as different data processing methods, including machine learning, into a single process.

The model is based on well-known data processing models (CRISP-DM, SEMMA, Fayyad, DBV guidelines, Farrar) and consists of eight main steps [11], [14], [15], [16], [17], [18]. These steps are highlighted in orange in Figure 3. Additionally, the feedback loop, highlighted in blue, ensures that the

collected data meets the required quality standards and that the resulting maintenance recommendations are well-founded and reliable. All process steps are iterative. This means that it may be necessary to go back and repeat previous steps to refine the analysis and improve the results.

Quality management is an ongoing process that spans the entire monitoring workflow – from defining the research objective to planning and installing the system, and finally to analyzing the collected data.

In the first step, the objective of the monitoring measures is defined, specifying which aspects of the collected data should be analyzed and evaluated. This includes determining which parameters need to be monitored, what results are expected, and what resources are available for the monitoring process. This step involves developing the monitoring concept and preparing a tender. Additionally, success criteria for achieving the monitoring goals must be established, and suitable quality assurance methods (such as quality indicators, threshold values, and compensation methods) must be selected.

In the second step, the measurement system is installed on the structure. This step may also include retrofitting an existing measurement system. It is essential to conduct quality checks immediately after installation, such as function tests and plausibility checks, to ensure proper system performance.

In the third step, data collection is conducted to acquire the necessary information for subsequent analysis, which captures the impacts and/or responses of the structure. This step marks the beginning of the cyclical process of data collection, processing, and evaluation. At this stage, quantifiable quality measures are applied for the first time to ensure an objective assessment of data quality, independent of the specific task (these measures are detailed in Section 6). These quality indicators are also used in the next steps of data processing as they serve to monitor changes in data quality.

The fourth step, data selection, involves choosing the necessary and relevant data to answer the formulated question. This selection can be spatial (e.g., sensors in specific structural areas) or temporal (e.g., data from summer months). When applying machine learning methods, this step also includes

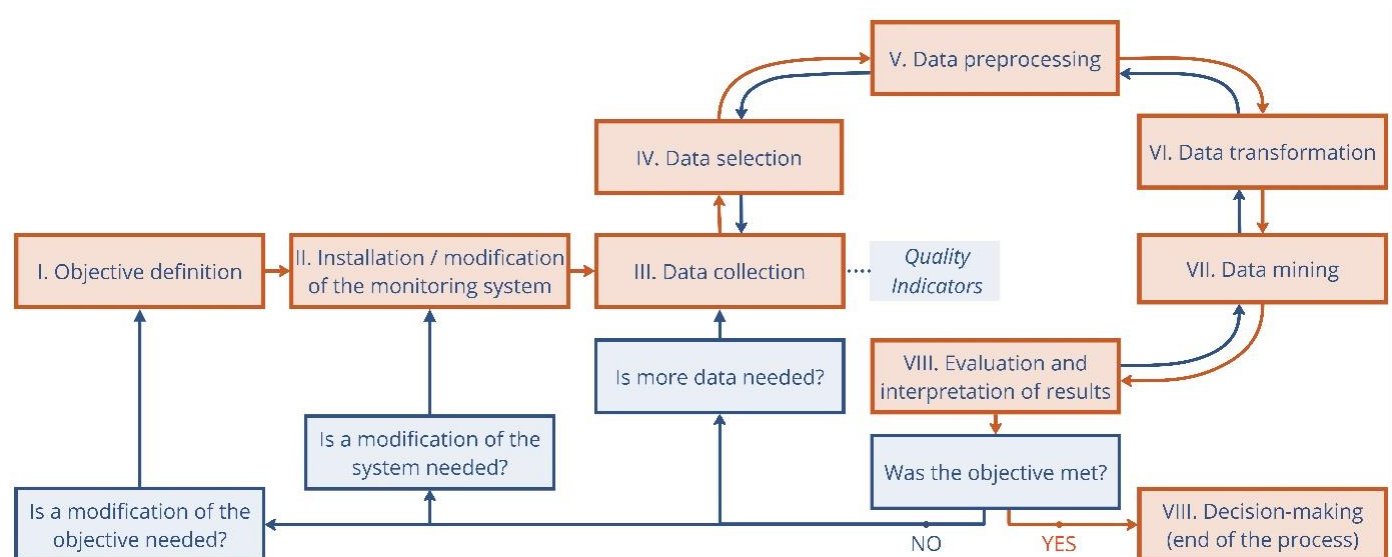

Figure 3. Data Processing Model in ANYTWIN project: Orange arrows represent the data processing workflow, while blue arrows illustrate the feedback loop, © Maria Walker, TUD.

selecting the data that will be used in the feature engineering process.

Data preprocessing follows (step five), which includes data preparation tasks such as converting electrical signals into physical measurements, temperature compensation, time synchronization, signal cleaning, and data normalization. After each preprocessing step, a new data quality assessment is performed. The goal of data preprocessing is to enhance the inherent (task-related) data quality [19].

In the sixth step, system-dependent data quality is addressed. Data from various sources and measurement systems are standardized into a common structure and enriched with metadata. This standardization ensures that the data can be automatically processed by data mining algorithms in the subsequent step.

The seventh step involves the actual data analysis or data mining, during which information is extracted from the data. This process may involve simple calculations, such as determination of mean values, maximum and minimum values, or counting algorithms, as well as the training and application of complex machine learning models to identify patterns in the dataset and to detect characteristic sequences in the data.

The final step involves the evaluation and interpretation of the data mining results in relation to the initial question and predefined success criteria. The findings are assessed based on their validity, novelty, usefulness, and understandability. Based on these insights, necessary actions are determined, such as rehabilitation, load reduction, maintenance, reconstruction, or further monitoring measures. Additionally, this step includes a final assessment of the entire monitoring process and of the installed monitoring system to ensure its overall effectiveness.

## 6 QUALITY ASSESSMENT OF DATA USING QUALITY INDICATORS

To ensure reliable analysis and evaluation of structural behavior, the quality of measurement data must be guaranteed. It is crucial to eliminate anomalies in measurement data and deviations in time signals to achieve precise data evaluation of the structure's performance. However, measurement anomalies and deviations are inevitable and can be caused by various factors, including:

- Electromagnetic interference, leading to signal noise or data distortion
- Direct interventions on-site, such as maintenance work or sensor replacements
- Transmission errors, resulting in incomplete or faulty data
- Malfunctions in the measurement system, caused by calibration errors or hardware defects

In monitoring systems, which encompass interconnected and complex structures of measurement technology, data transmission, and IT aspects, anomalies in measurement data can occur. Therefore, it is essential to implement appropriate quality assessment methods to detect measurement anomalies early, correct or remove them if necessary, and optimize the monitoring system to ensure the reliability of the measured values.

As part of the ANYTWIN project, the requirements from measurement-based verifications are considered to systematically assess data quality. For this purpose, quality indicators have been developed to enable a structured and

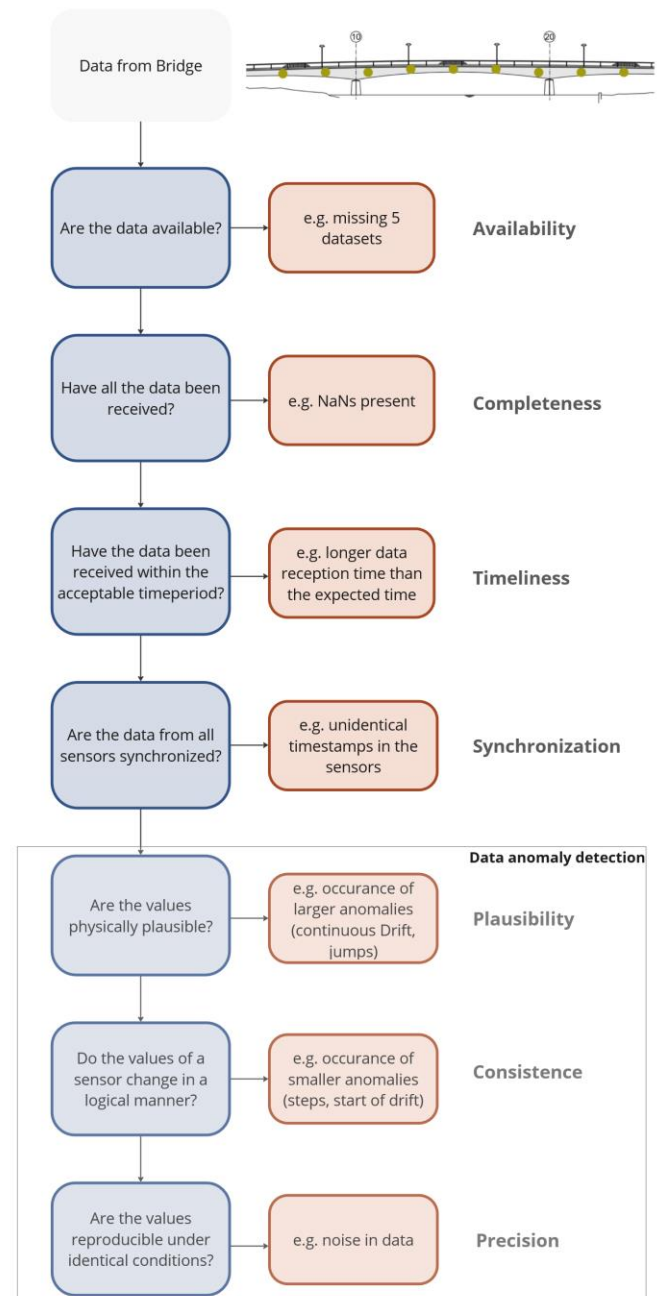

Figure 4. Overview of quality indicators and the addressed questions

objective evaluation of monitoring data in terms of its quality. The development of these indicators takes various use cases into account, including:

- Measurement-based verifications, allowing for a precise assessment of structural safety,
- Continuous monitoring with an integrated alarm system for early detection of deviations,
- Digital twins, enabling detailed modeling and data-driven evaluation of structural behavior.

For this purpose, both the status of the measurement system and the quality of individual time signals at the sensor level are analyzed. At the *dataset level*, key questions include:

- Are the data available, complete, and up to date?

- Are the measurements time-synchronized, ensuring that dependencies between two measured variables are reliably considered?

From these questions, the quality indicators availability, completeness, timeliness, and synchronization can be identified (see Figure 4).

**Availability:** Checks whether the expected measurement data has been received within a certain time window.

**Completeness:** Checks whether the received data contains all the required fields and sensor data records.

**Timeliness:** Checks if the measurement data arrives within an acceptable delay period.

**Synchronization:** Checks whether the multi-channel sensor data  $s$  is synchronized in time.

The indicators that assess the condition of the measurement system – availability, completeness, and timeliness – can be quantified by calculating the percentage of available and non-missing data points within a defined time-period. To evaluate synchronization, the timestamps of individually generated time series (each measurement system) are analyzed.

The second aspect, *the sensor level*, focuses on detecting potential measurement anomalies, such as outliers, jumps, unusual temporal trends, drift, or signal noise. Based on these possible signal anomalies, the following quality indicators can be identified:

**Plausibility:** Checks whether the received values fall within physically plausible limits, allowing the identification of measurement anomalies such as outliers or jumps that are visibly apparent.

To assess the plausibility of the data and determine whether it falls within a physically realistic range, initial filtering or thresholding can be used to define permissible limit values. Plausibility calculation involves verifying whether the measurement value lies within these physically plausible limits. In a second step, advanced regression methods can be applied to detect further apparent measurement anomalies in the signal.

**Consistency:** Evaluates whether the change in sensor values is consistent with respect to environmental changes. This enables the detection of drift and noticeable patterns in

temporal trends, such as step-like changes. While plausibility checks whether the data falls into a certain range, consistency compares current data with historical values and determines if the change in value is consistent with environmental changes (see Figure 5).

Consistency calculation is based on analyzing the differences between consecutive measurements. The standard deviation of these differences is determined and normalized by their mean value. A low standard deviation indicates high consistency, while a high standard deviation suggests irregular changes and, consequently, potential inconsistency. With consistency calculation, smaller or less apparent anomalies such as start of drift, step-formation can be detected.

**Precision:** Refers to the repeatability of measurements under identical conditions, ensuring the stability and reliability of sensor data. This helps to identify noise in the signal.

The precision of a measurement signal indicates the extent of value dispersion in repeated measurements. High precision means that the measured values are closely clustered, while low precision suggests random fluctuations and an increased level of noise. Mathematically, the precision assessment is based on the standard deviation of the measured values within a defined time window, relative to an acceptable variation range.

To quantitatively represent the indicators, the percentage of measured values that fall outside a defined tolerance range can be determined. Table 4 provides a comprehensive overview of the mathematical formulas used for detecting measurement anomalies, quantifying the indicators, and describing the relevant parameters.

The results of the quality indicators are also time series, but with a lower frequency than the actual measurement data, as they are based on aggregated time windows. Storing these indicators as time series allows for better integration into digital twins and facilitates the analysis of relationships between indicators, leading to a better understanding of the measurement data and its quality.

These indicators can be integrated into the partial safety factors of structural assessments as part of measurement-based verifications. This allows systematic consideration of

Figure 5. Example of temperature data containing implausible and inconsistent values

uncertainties related to measurement technology, data transmission, IT, and numerical aspects and quantification in the form of modified partial safety factors. However, further

research and development is needed to optimize these approaches and ensure their practical applicability.

Table 4. Overview of mathematical formulas for quantifying quality indicators

Indicator	Mathematical Formula for measurement errors detection	Quantification of the indicators	Description of the parameters
Availability	---	$\frac{N_{rec}}{N_{exp}} \cdot 100 \%$	$N_{rec}$ – Number of received data points $N_{exp}$ – Total number of expected data points
Completeness	---	$\frac{N_{comp}}{N_{exp}} \cdot 100 \%$	$N_{comp}$ – Number of complete data points (without missing fields) $N_{exp}$ – Total number of expected data points
Timeliness	$\Delta T = T_{now} - T_{last}$	$\frac{N_t}{N_{exp}} \cdot 100 \%$	$N_t$ – Number of data points received within the acceptable delay interval, $T_{max}$ with respect to current timestamp ( $\Delta T \leq T_{max}$ ) $N_{exp}$ – Total number of expected data points $T_{now}$ – Current time $T_{last}$ – Time of last received data
Synchronization	$\Delta T = T_{sync}$ $T_{sync} =  T_{S1,i} - T_{S2,i} $	$\frac{N_{sync}}{N_{exp}} \cdot 100 \%$	$N_{sync}$ – Number of synchronized data points $N_{exp}$ – Total number of expected data points $S_1$ & $S_2$ – Measurements from Sensor1 and Sensor2 $TS_{1,i}$ & $TS_{2,i}$ – Timestamp of Sensor1 and Sensor2 at row $i$ . $T_{sync} =  TS_{1,i} - TS_{2,i} $
Plausibility	Level 1: Filtering and thresholding Level 2: with/without ML-model	$\frac{N_{pl}}{N_{exp}} \cdot 100 \%$	$N_{pl}$ – Number of plausible data points $N_{exp}$ – Total number of received data points
Consistency	$1 - \frac{\sigma_{\Delta x}}{\mu_{\Delta x} + \epsilon}$ (or) with/without ML-model	$\frac{N_{con}}{N_{exp}} \cdot 100 \%$	$\sigma_{\Delta x}$ – Standard deviation of consecutive differences ( $\Delta x_i = x_i - x_{i-1}$ ) $\mu_{\Delta x}$ – Mean of consecutive differences $\epsilon$ – Small constant (to avoid division by 0, e.g. $10^{-6}$ ) $N_{con}$ – Number of consistent data points $N_{exp}$ – Total number of expected data points
Precision	$1 - \frac{\sigma}{R}$	$\frac{N_{pr}}{N_{exp}} \cdot 100 \%$	$N_{pr}$ – Number of data points without noise $N_{exp}$ – Total number of expected data points $\sigma$ – Standard deviation of the measurements $R$ – Acceptable variation range

## 7 SUMMARY

Bridge monitoring is a key component of structural assessment to ensure safety and longevity. Despite its growing importance, monitoring is not yet a standardized procedure and is mostly implemented on a case-by-case basis. A structured approach can follow the recommendations of the DBV guidelines.

The sensor market is expanding rapidly, with increasingly intelligent and complex technologies for measuring temperature, material fatigue, deformation, and traffic loads. Innovations such as System-on-a-Chip (SoC) and edge computing, including Weigh-in-Motion (WIM) systems, enable greater automation of data collection but require systematic storage and analysis.

A precise data classification and standardization are essential for efficiently processing monitoring data and making it usable for digital twins or measurement-based verifications. Classification is based on positional reference (point, line or field measurements), time-based structure (continuous or

discontinuous data), and time reference (instantaneous values, averaging or advanced methods such as Rainflow counting or FFT analysis).

Beyond the actual measurement values, metadata and additional information play an essential role in correctly interpreting the collected data. Metadata consists of machine-readable values assigned to sensors and measurement systems, while metainformation includes structured documentation details. A clear assignment of responsibilities for collecting and managing this data is necessary to maintain a consistent data foundation.

The ANYTWIN data processing model integrates various sensor types, measurement durations, and data processing methods, including machine learning, into a structured eight-step process. It follows established data processing frameworks (CRISP-DM, SEMMA, Fayyad, DBV guidelines, Farrar) and ensures data quality through an iterative feedback loop.

The process begins with defining the monitoring objective, followed by system installation and data collection. Next, data

selection, preprocessing, and standardization ensure structured and high-quality input for data mining and analysis. Finally, the results are evaluated and interpreted to support structural assessments and maintenance decisions. This structured workflow enables continuous monitoring and reliable decision-making in structural health management.

A key aspect of data analysis is the evaluation of data quality using quality indicators, which are categorized into system level (availability, completeness, timeliness, synchronization) and sensor level (plausibility, consistency, precision). At the system level, data is assessed for availability, completeness, timeliness, and synchronization. At the sensor level, the focus is on evaluating the quality of individual measurement series, particularly in identifying measurement deviations and anomalies. To detect and quantify measurement anomalies and uncertainties, statistical methods such as filter functions, regression analyses, and standard deviations are applied. These methods enable a precise assessment of measurement data, contributing to improved data evaluation.

By storing these indicators as time series, they can be integrated into digital twins. Furthermore, they could be incorporated into measurement-based verifications by serving as a foundation for modified partial safety factors, considering uncertainties in measurement technology and data processing. While these approaches are promising, further research is required to enable their practical implementation in structural monitoring.

## ACKNOWLEDGMENTS

This paper presents the findings of the ANYTWIN research project, which is funded by the German Federal Ministry for Digital and Transport (BMDV) as part of the mFUND funding program (Funding Reference Number: 19FS2248A-F). We sincerely acknowledge this support, which has enabled the advancement of research and innovation in this field.

**ABSTRACT:** To effectively monitor engineering structures such as bridges, tunnels, and retaining walls, comprehensive knowledge of load-bearing behavior and load transmission mechanisms is essential. This knowledge allows for the assessment of its behavior and the identification of damage mechanisms. A thorough and clear documentation of regular inspection forms the foundation for this. It is important not only to capture damage patterns and visible defects but also to determine their origin and precise location. This information aids in the development of monitoring processes, the selection of measurement variables, and the implementation of monitoring technologies. The paper addresses the progress on how a documentation process of inspections is carried out to serve as a basis for a valid monitoring of such structures. Therefore, the use of digital models and a standardized description of damage in combination with a precise localization on the structure is described in the beginning. Such documentation provides valuable insights into load-bearing behavior and possible underlying damage mechanisms. Additionally, the development of suitable monitoring systems that serve as key parameters for structural inspection is demonstrated. The interaction and exchange of information between inspection and monitoring are emphasized, including clear visualizations and meaningful data overlays, to offer valuable benefits for building owners and inspection personnel.

**KEY WORDS:** Inspection, SHM, monitoring data, structural behavior.

### 1 INSPECTION OF CIVIL ENGINEERING STRUCTURES

Inspections are an essential part of the maintenance strategy for residential and industrial buildings (see [1] & [2]) as well as for infrastructure such as bridges and tunnels (see [3] & [4]). While the former is usually carried out by the building owner, the latter are part of the responsibilities of the owners of the infrastructure (road or railway) or those responsible for maintenance. Due to its geographical location in the center of Europe and its alpine topography, Austria places special demands on the routing of its road and railway network and the associated infrastructure. Therefore, a large number of engineering structures to secure cuts and slopes (see Figure 1), cross mountains and span valleys.

Figure 1. Gravity wall along the Semmering railway line.

The majority of the routes required for this purpose, especially along the high-level road network, were built between 1960 and 1980, while other structures (e.g. along the Semmering railway line [5]) are already more than 150 years in service.

Figure 2. Visual inspection method.

Aside from the erection and the ongoing maintenance, inspections, as shown in Figure 2, are essential to ensure the reliability of these structures and, consequently, their roadworthiness, usability and safety. The principal task lays in generally on a manual visual inspection, which includes the load-bearing and non-load-bearing components and structural elements required for safety.

### 1.1 Goals, methods and guidelines

In general, for inspection, a distinction can be made between ongoing tasks by internal personnel and inspection and testing by trained specialist personnel. These inspection activities are carried out periodically and usually conclude with a report. Thus, providing information on the state of preservation, includes necessary steps for maintenance and serves as the basis for subsequent testing and inspection intervals.

Planning documents are required as the basis of inspection to define the scope and provide the necessary structural and safety-related information, defining the tasks for the inspection personnel. Furthermore, these documents provide the basis for recording information of the on-site activity during the inspection process. Examples hereof are damaged areas, image numbers, changes compared to the forerun inspections or in general changes in the state of preservation.

Depending on the asset to be analysed, different guidelines and regulations apply in Austria. These are issued by the FSV and are to be regarded as the state of the art:

- Road bridges - RVS 13.03.11 [6];
- Anchored retaining walls - RVS 13.03.21 [7];
- Road tunnel - RVS 13.03.31 [8];
- Gantries - RVS 13.03.51 [9];
- Retaining structures - RVS 13.03.61 [10];
- Noise barriers - RVS 13.03.71 [11], and
- Trough - RVS 13.03.81 [12].

In general, manual and visual inspections are carried out, which are performed by the inspection personnel directly on site. Various smaller tools and instruments are used to carry out such activities on structures. Depending on the type of structure and asset, these range from cameras and plans to observation instruments (binocular or crack magnifier) and tools such as hammers and spanners.

Digital tools for carrying out a structural inspection are generally not defined. Only specifications for integrating the inspection results into corresponding databases are given. Furthermore, within the area of monitoring [13] topics such as IoT (Internet of Things) and, briefly, the necessary digitalisation of measurement and monitoring tasks and the management of data and results are addressed.

### 1.2 Damage and damage symptoms

In order to enable a diagnosis of the structure and the resulting statement on the state of preservation, it is necessary to record defects and damage continuously on the structure to be inspected. Some examples are given in Figure 3.

Due to the wide-ranging and interdisciplinary approach to civil engineering structures, it is difficult to provide a schematic collection of damage patterns and defects in such structures. However, the literature (see [14] to [17]) provides comprehensive descriptions and lists that can be used as a basis. In such a categorisation, a general distinction must be made between damage and defects relevant to load-bearing capacity and those relevant to durability.

A distinction can be made between structural, geotechnical and geological damage patterns. In addition to a differentiation, however, an interdisciplinary and interactive approach is required in order to recognise the underlying causes of the damage so these can be addressed during maintenance.

Figure 3. Examples for damages found during inspection of civil engineering structures; reinforcement corrosion and concrete spalling (top); shift and misalignment within a construction joint (center); erosion and unguided surface flow (bottom).

### 1.3 Climate change

Austria's topography, the dense road and railway network and the increasing average age of the infrastructure are a major challenge for long-term maintenance. In addition to the approximately 2,300 km of high-ranking road network and 5,000 km of railway lines, there are also around 125,000 km of lower-ranking road network [3]. In terms of motorways, there are around 250 km per million inhabitants, which means that the high-ranking road network is around 50 % larger than the EU average.

In addition to an increase in loads and traffic, climate change will also have a direct impact on structures as a perceptible manifestation of climate change. These are superimposed by geological and geotechnical effects such as increasing water

supply due to heavy rainfall events or the increase in natural hazards such as mass movements and rockfalls.

The effects of climate change can be summarised as ‘*long-term changes in temperature and weather patterns*’ Figure 1. Gravity wall along the Semmering railway line. Among other things, this will have an impact on road and railway infrastructure. These changed boundary conditions influence the durability of the infrastructure substance due to increased thermal and hydraulic stress and changed environmental conditions. At higher temperatures, the saturation vapour pressure of the atmosphere increases and more and more water vapour can be held in the air (+ 7% per 1°C). This intensifies the greenhouse effect and increases the risk of short-term extreme precipitation (see [18] & [19]). The intensity of these events can for example exceed the capacity of existing drainage systems, leading to both direct damage to the structure and indirect damage with respect to surface erosion and sediment transport. Increased extreme precipitation is also accompanied by an increasing risk of gravitational natural hazards such as rockfall, which, in addition to the direct risk in the area along the infrastructure, can also have a corresponding impact on the functionality of engineering structures due to an impact. [20]

The increase in damage patterns, damage intensity and defects in combination with the increasing age of structures and the rise in traffic and loads pose new challenges for those responsible for maintaining structures. In 2021, the European Commission drew up a technical guideline to ensure the climate compatibility of infrastructure [21], which defines that the primary goal must be to make ‘*infrastructure climate-neutral and climate-resilient*’.

#### 1.4 Digital inspection

In addition to the advantages that a digitalisation can offer, it is also important to adapt working methods to newly created possibilities in order to generate a corresponding increase in time and quality. Preparation by the inspection staff will remain essential, but the approach will take a different form. For the most part, the collection and collation of (meta) data will no longer be necessary and a stronger focus on existing issues and damage will be possible.

Figure 4. Using digital inspection tools to reduce workload and to improve information transfer.

However, it is not only the preparation that changes, the form of the inspection also changes when digital solutions are used. For example, due to standardisation and the use of existing inspection results, personnel will play a much stronger role as a controlling element. This results from the fact that a software-supported inspection specifies or can specify defects or damage and structures and thus provides a framework for recording in the field.

A number of benefits can be generated through the digitalisation of structural inspection. The biggest and usually most decisive point is the potential for savings in terms of on-site inspection time. In addition to the monetary savings, this can also result in shorter closure times, which could lead to massive improvements in route availability, especially if a total closure is required. In addition, software solutions using digital devices on site creates a standardised and less error-prone structural inspection, from which reports and documentations can be created with little effort or information and characteristic parameters can be further processed digitally. In addition, photorealistic 3D models (e.g. from photogrammetry) depict the current condition of a structure more comprehensively and allow a comparison between different inspection periods.

It should also be mentioned that structural inspections can provide the foundation for implementing structural health monitoring. Through the appropriate collection, evaluation, and interpretation of inspection results, it becomes possible, to have the fundamental information required for a structural health monitoring system readily available. Furthermore, based on the results of structural inspection and the analysis of findings over time, it is possible to determine whether the structure can remain in operation with monitoring, whether restrictions are necessary, or whether demolition, reconstruction, or strengthening are necessary.

In addition to these advantages, there are also disadvantages associated with a digitalisation measure - or generally a change and adaptation of existing processes. On the one hand, these relate to usability and the utilisation of digital solutions by users. However, this can be very easily remedied with an appropriate software solution (UX and UI design see Figure 4). On the other hand, the pervasive and sustainable use of digital solutions often requires adjustments to databases, data structures and standardisation. In Austria, there is largely a lack of specifications relating to the use of digital products for structural inspection of infrastructure. Nonetheless, a corresponding trend and a corresponding willingness to implement such solutions and procedures can currently be recognised among a number of structural owners and maintainers.

## 2 MONITORING OF CIVIL ENGINEERING STRUCTURES

An essential component of the safety assessment of civil engineering structures can be created by the systematic consideration of monitoring data. This can give an inclusive insight into the behaviour of the structure or the triggers responsible for damage or a change in the structures reliability.

However, in order to be able to utilise such information comprehensively, it is necessary to plan a monitoring system accordingly. The following briefly discusses possible measured variables, the timing of monitoring and the digitalisation of

existing measuring equipment. This serves to enable a holistic view between inspection and monitoring.

### 2.1 Behavior of the structure

The decisive factor when carrying out monitoring is the correct selection of the measured variable to be recorded. Due to the size and extent of engineering structures and the frequent interaction between the object and its surroundings, measurement data of the terrain is often the first choice. For example, data from satellite measurements or LIDAR measurements in the vicinity of the infrastructure can be used for this purpose. Such data offers information on areas that are otherwise difficult to access or overviews of the structure and the terrain, deformations can already be derived.

Monitoring is also usually carried out by attaching sensors or transducers. These are usually attached directly to the structure or to relevant component regions. A range of different measured variables [13] can be used to analyse the terrain, the structure or individual components. These are often also related to the requirements or statements from the structural inspection - such as questions regarding load-bearing behaviour or load transfer. In addition, the overall behaviour of the structure must be considered when selecting measured variables or generally when defining the monitoring concept.

Figure 5. State of preservation with respect to a measurand depending on the behavior of the structure.

In addition to the arrangement of the sensors, the time component must also be thought of when planning a monitoring system. This is related to the behaviour of the structure and can be seen schematically in Figure 5. This shows the change in a possible measured variable depending on the state of preservation of the structure. The greater the damage to the structure - i.e. the greater the decrease in the state of preservation - the greater the change in a possible measured variable used for monitoring.

The extent to which a measured variable increases until the structure fails is strongly influenced by the behaviour of the structure. While all structures should exhibit ductile behaviour, this may only be the case to a limited extent, especially in the

case of brittle structures. An example of this is the reduction in the load-bearing capacity of a concrete cross-section that is damaged by corrosion of the main reinforcement [22].

This aspect means that the possible, recordable and detectable measured variable of a value is defined accordingly by the behaviour of the structure. As a result, during the planning of a monitoring, it is necessary to estimate how large the possible, still available supply of a measured variable is and whether the quantity is still sufficient to enable meaningful and accurate monitoring.

### 2.2 Timing of measurement

The behaviour of a structure in relation to the measurable value also results in a temporal influence on the monitoring. Similar to the quantity of the measurand to be recorded, a brittle or ductile structure also has an effect on the time available until failure occurs. This is shown schematically in Figure 6.

Figure 6. Timely installation of a monitoring system with respect to the state of preservation depending on the behavior of the structure.

This shows that, depending on the behaviour of the structure or the effects of damage, there are different time periods that indicate a decrease in the state of preservation. This can have a considerable influence, particularly with regard to the implementation of monitoring as a measure following a structural inspection. If the time period is too short, only a limited statement can be made about the behaviour of the structure. Meaning that it is not possible to differentiate between temperature-related and damage-related behaviour of the structure. This in turn means that a planned monitoring can only make a small contribution to the structural inspection.

### 2.3 Digitalization of existing measurement equipment

When implementing monitoring concepts, classic approaches applicable to new structures or the monitoring method can only be used to a limited extent. The subsequent installation and calibration of sensors and monitoring equipment on existing structures is often only possible to a limited extent due to accessibility. A particular problem with existing structures is the unknown construction effects and the limited observation

time compared to the age of the structure. In particular, the assessment of load-bearing behaviour, load redistribution and the delimitation of seasonal effects therefore usually requires a combination with redundancy and an overdetermination of the measurement concept in order to correctly characterise the structure's behaviour. Another aspect of monitoring tasks on existing structures is the reactivation or digitalisation of existing measuring equipment.

The aim of monitoring must always be to create a valid database which, in combination with appropriate testing and inspection of the structure, can be used to identify the load-bearing behaviour and possible damage mechanisms of the structure. One innovative application example is the digitalisation of hydraulic force measuring devices on prestressed grouted anchors. The current anchor force (see [23]) is one of the main parameters of an anchored structure. As a rule, force measuring devices have to be installed during the prestressing process of the tendon, making a retrofitting of such a measuring device not often possible.

Figure 7. Time-period of a subsequently digitalized anchored load plate.

Digitising the measured value readings, as shown in Figure 7 and described in more detail in [24], enables permanent data recording and provision for existing force measuring systems. Temperature and seasonal anchor force changes and the resulting effects on the structure can be reliably recorded thanks to continuous recording. This makes it easier to interpret the measurement data and represents a significant improvement on the current practice of periodic and manual readings.

### 3 INTERLINK INSPECTION TO MONITORING

The previous chapters have attempted to provide a brief insight into the inspection and monitoring of engineering structures. These topics are usually directly linked, but are currently usually considered separately. While the inspection of the objects is carried out and documented regularly, monitoring is usually only used for structures that already show a deficit in their behavior or corresponding damage.

However, in order to be able to implement monitoring in a targeted manner, the content and results of inspection must be included. This can be seen schematically in the cycle in Figure 8. The cycle without monitoring refers to the classic inspection of a structure, in which the relevant data and information on the structure and its condition are collected in the course of an on-site activity in order to enable a subsequent assessment. This

usually takes place in a purely visual and manual manner. The data and information collected is therefore purely about damage patterns or changes in the state of preservation recognizable on the surface of the structure or its surroundings. If there is no major damage and no extensive changes in the behavior of the structure can be detected, the inspection process is completed for the period in question and no further activities are required.

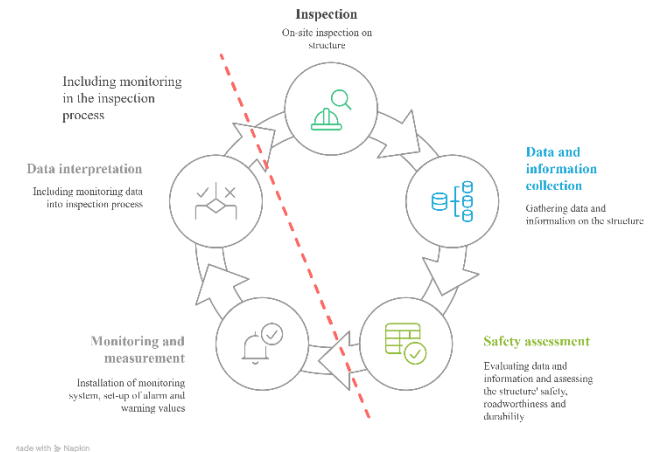

Figure 8. Schematic process of interlinking monitoring processes into the cycle of structural inspection.

The aim of the inspection is to be able to make a statement about the load-bearing behaviour of the structure and thus about its state of preservation. If this is not possible, special tests in the form of a material analysis or an in-depth inspection of the structure can be carried out. However, these often only provide information about the progression of damage (e.g. carbonation) or provide characteristic values for materials or components. A statement about the load-bearing behaviour of the structure and, for example, the interaction with the subsoil can only be given to a limited extent.

Monitoring of the structure can be used for this purpose. This can be used to make a statement about the behaviour of the structure by recording measured values and interpreting them accordingly. In relation to the building inspection or rather the assessment of the construction, a valid statement can be made about the load-bearing behaviour, load transfer mechanisms or, for example, a number-based assessment of the load and stress levels of components.

Figure 9. Ongoing circle on assessing data and information including asset management, maintenance and use phase.

If this relationship is now considered over the entire service life of a structure, it can be seen, as shown in Figure 9. Ongoing circle on assessing data and information including asset management, maintenance and use phase., that this results in a continuous process. Beginning after construction with a continuous recording and observation of the behaviour of the structure, which can be carried out either by inspection or supplemented by monitoring.

Based on this, the necessary processes are planned and implemented in the asset management in order to be able to carry out maintenance. Here, both smaller measures can be derived from the inspection (e.g. flushing the drainage) and larger measures (e.g. replacing the edge beam) can be implemented. The whole process is completed by a phase of utilisation which is not associated with any restrictions and in which the structure is in a sufficiently good condition to be used safely and reliably.

This brief and schematic illustration shows the possibilities in which the inspection of structures and their monitoring are linked. It also shows that monitoring is usually implemented as a measure or as a reaction to an inspection. It is therefore essential that the results are communicated and transferred to the monitoring of the structure in order to enable the two processes to interact and integrate with each other.

#### 4 EXAMPLE – ANCHORED STRUCTURES

The approach described in the previous chapter can be explained using a practical example. An anchored construction as shown in Figure 10, which has a height of 9.00 m and a total length of approx. 240 m. The wall was constructed in three stages, with individual concrete elements anchored by two anchors (diagonally). It is not possible to tell from existing planning documents whether there is a transverse force-locking connection between the elements in vertical and horizontal direction.

Figure 10. Segmented anchor wall.

In the course of an inspection of the wall, a number of damage patterns were identified, which primarily affect the durability of the entire structure as well as that of the concrete components. Two examples of this are given in Figure 11. These show two symbolically recorded cracks, which can be found in a similar way along the entire wall. The cracks have a width of 0.2 to 0.5 mm.

Some cracks are located in the area of the installed anchoring elements, as shown in the picture, while others are scattered across the entire surface of the wall. In general, the cracks are characterised by sintering and moss-like growth was also

visible, which indicates that the cracks have been present for some time.

No damage could be visually detected on the tensile elements of the structure (strand anchors), only slight signs of corrosion on the external components could be detected. In general, the structure was in an inconspicuous condition and only limited moisture damage, water leakage or other geological failure mechanisms could be found in the adjacent area.

Figure 11. Cracks along the concrete structure and adjacent to the anchors.

In general, this structure can be assumed to be in a good state of preservation, but there is a lack of information, particularly with regard to the anchorage, its function and the associated effects on the load-bearing behaviour. In order to obtain this information, special inspections [23] such as an endoscopic examination of the anchor head area and a lift-off check of the tension elements would be the first option. However, this is not possible on all structural anchors due to the non-liftable design of the tension elements, but it was possible to carry out subsequent digitisation on six structural anchors with existing force measuring equipment.

The monitoring data (Figure 7) shows that there is a clear correlation between the temperature and the anchor force, even over a longer period. This indicates that either the structure, the measuring device or both together exhibit temperature-

dependent behaviour. However, as there is no inexplicable change in the anchor forces, it can be assumed that there is no massive damage to the structure which is therefore behaving as it was designed intentionally.

Figure 12. Anchor wall, anchor head and scheme of monitoring positions and sensors.

Such investigations were possible because the structure already had force measurement equipment (see Figure 12) that could be included in the monitoring. Whether this takes the form of digitisation or continuous readings is merely a question of the desired accuracy or a resource-related one. If this had not been possible, a variety of other measurement systems would have been applicable, which are briefly described below:

Classical deformation monitoring, for example by attaching measuring points, could possibly provide a statement about the temperature-related behaviour of the structure. However, this only provides a limited possibility of deducing an increase in damage, as only a limited distinction can be made between temperature-related fluctuations and a change in deformation. In particular, only periodic recording of the wall (e.g. on a weekly or daily basis) and not recording the entire surface of the structure means that only very limited detailed information can be provided. Current approaches such as full-surface monitoring of the wall surface and the resulting derivation of overall deformations could provide a remedy here, but are not yet considered state of the art.

As there were no signs of extensive deformation of the object in the course of an inspection of the rear area of the structure, no major changes in the stresses on the structure due to earth or water pressures can be assumed. On the one hand, this would rule out a change in the above-mentioned structural deformations and, on the other hand, would also put geotechnical measuring equipment such as inclinometers or extensometers in their place as far as the detection of a change in the structural behaviour as a result of damage is concerned.

As a result, only measured values that consider the structure itself remain possible. As this is an existing structure, the installation of earth pressure cells or the determination of the change in strain in the reinforcement, for example, is only possible to a limited extent, at great expense and with a possible falsification of the structure's behaviour. Nevertheless, the cracks already encountered on the front of the structure, for example, would be suitable for monitoring. Particularly with regard to a possible load redistribution between the tension element, which could indicate damage to these, would possibly manifest itself in the crack pattern of the structural components. Monitoring of the cracks on the front side would be recognisable in the event of a significant change in the cutting forces resulting from an anchor failure or a reduction in the prestressing force. A similar approach can also be used for corrosion-damaged angular retaining walls [24], for example, to show a redistribution between individual reinforcement elements.

## 5 CONCLUSIONS & SUMMARY

The aim of this article is to highlight the similarities between structural inspection and monitoring. The duality of this topic must be considered, which makes a significant contribution to a comprehensive understanding of the behavior of damaged infrastructure structures, whereby a distinction can be made between structural, geotechnical and geological damage patterns. In addition to a differentiation, however, an interdisciplinary and interactive approach is also required in order to recognize the underlying causes of the damage so that these can be addressed in the course of maintenance if necessary.

On the one hand, the structural inspection and the resulting information on damage and damage processes form the basis for the planning and implementation of monitoring and the interpretation of monitoring data. On the other hand, monitoring can significantly improve the level of data and information on the behaviour of a structure. This is a great added value in the assessment of the structure, especially for structures in a poor condition, but also for objects with missing documentation.

The aim of this article is to highlight the similarities between structural inspection and monitoring. The duality of this topic must be considered, which makes a significant contribution to a comprehensive understanding of the behaviour of defective infrastructure structures, and the relationships presented here are intended to show that considerable added value can only be generated through interdisciplinary and targeted cooperation and the exchange of information in both structural testing and monitoring. Only in this way it is possible to obtain a comprehensive statement about structures and thus subsequently guarantee their safety and reliability. Only in this way can a sustainable, durable and resilient infrastructure be made possible, which, in addition to appropriate usability, also has a certain resistance to climate change-related effects, whereby a distinction can be made between structural, geotechnical and geological damage patterns. In addition to a differentiation, however, an interdisciplinary and interactive approach is also required in order to recognise the underlying causes of the damage so that these can be addressed in the course of maintenance if necessary.

**ABSTRACT:** This paper presents the remaining useful life (RUL) prediction problem in civil engineering applications using a hidden Markov regression model (HMRM), as a promising approach for model-based degradation. Unlike self-transition hidden Markov models for mass-produced components, where prior lifetime signals are available to estimate state information, the proposed HMRM formulates the conditional probability of RUL in terms of the estimated regressor parameters, after temporally fitting the damage model. The discrete property of state in HMRM makes it possible to handle heterogeneities in the degradation process. The HMRM can also synthesise multiple signals by adopting a decision-level fusion. An adaptive closed-form solution for RUL prediction is presented. The performance of HMRM is demonstrated on synthetic measurements and compared with a Bayesian extended Kalman filter (EKF) updating technique.

**KEY WORDS:** Hidden Markov chain; model-based degradation; remaining useful life prediction; damage model.

## 1 GENERAL GUIDELINES

The prediction of Remaining Useful Life (RUL) holds significant importance in both condition-based monitoring (CBM) and the formulation of maintenance strategies for structural components. RUL is defined as the time a structure has before reaching its design threshold, when it can no longer perform under its design function. In CBM, damage is characterised as a change in structural components due to the interaction between internal degradation and the working environment which adversely affects its current and future performance. The progression of damage is heterogeneous, and such heterogeneity can be due to *unit-to-unit variability* [1] of the material, *changing operational conditions* [2], or *periodic loading* [3].

Various damage models have been developed, ranging from empirical laws (such as Paris' laws) to continuum damage mechanics (CDM) methods [4], which requires stochastic-based approaches (such as Markov chain, Weiner processes) for predicting RUL [5]. However, these approaches suffer from parameter correlation. This study focuses on simple power and exponential laws suited in a hidden Markov chain, which, despite their simplicity, provide correlated, good curve fitting by: a linearised and automated regression segmentation and an adaptive parameter updates via a recursive Markov chain to improving accuracy. According to Si, et al. [5][6] hidden Markov models (HMMs) are suited for RUL prediction based on degradation state processes. HMM is composed of two state processes; an unobservable (hidden) Markov chain which accounts for the actual state of degradation such as fatigue at the grain level of a metallic component, and an observable process that interprets the monitoring information, for instance, crack width in a reinforced concrete beam.

Within a degradation process is multiple discrete-hidden states. Past studies [7][8] [9][10] focused on the transition probability matrix and state duration definition. They consider that these states can switch into each other under a predefined transition probability, which is specific to the lifetime datasets. Modelling degradation by this approach is limited to the Markov property

[11] which means that: a) the state at any given time step only depends on the previous state and not on any earlier states, b) and that shorter state durations are more likely than longer ones, i.e., state duration follows a geometric distribution. This can be a limitation for modelling real-world degradation processes. To remedy this weakness, hidden semi-Markov models (HSMM) have been proposed to explicitly model state duration distributions rather than assuming a geometric one [12][13]. Unfortunately, this improvement of modelling degradation in components with predefined transition probability and state duration does not extend to modelling the degradation processes on bespoke components that obeys damage laws.

To the best of the author's knowledge, this study frontier a premise of adopting a sequence of state in model-based degradation process. By this approach, the degradation process experiences a state switch at stages of damage triggered by the weighted state posterior distribution [14]. In addition, the proposed approach can handle multiple information of measured signals (i.e., multiple HMRM) earlier introduced in [13]. This improves the state identification since it captures the interacting factors of multiple signals, and reduces measurement noise uncertainty, leading to a more confident RUL prediction. The extended Kalman filter (EKF) is introduced in this study to recursively observe data in real-time, to compare with our inspection approach. As with HMM belonging to a finite-discrete set of states, the EKF is an optimal non-linear filter for finite-dimensional stochastic systems, for model-based analysis, where the states are continuous and described as parameters of the damage model [15].

Within the framework of modelling degradation presented in the paper, two case studies are considered: a fatigue crack growth process, and a multi-sensor beam degradation measurement. A decision-level fusion technique using fisher's weighted discriminant ratio [13] is considered to aggregate the multiple estimated parameters and predict the RUL.

## 2 HIDDEN MARKOV REGRESSION MODEL (HMRM)

This section provides the framework that captures the hidden state degradation processes.

### 2.1 HMRM Parameter estimation

The unobserved degradation processes  $u_t$  represent a sequence of  $K$  hidden states of data points, formulated at index time  $t$  in a particular state  $k$  as:

$$u_t = U_t \cdot \exp(\sigma_k^2 \dot{\varphi}), \quad (t=1, \dots, T) \quad (1)$$

where  $U_t$  represent the damage model that characterises the degradation process up till failure time  $T$ . To model the hidden Markov chain, we take the log-transform of equation 1 and put in matrix form as:

$$y_t = \log u_t = \mathbf{x}_t \boldsymbol{\beta}_k + \sigma_k^2 \dot{\varphi} \quad (2)$$

$y_t$  becomes degradation processes that follows a Gaussian distribution of mean  $\mathbf{x}_t \boldsymbol{\beta}_k$  and variance  $\sigma_k^2$ , the parameter vector  $\boldsymbol{\theta} = (\boldsymbol{\pi}, \mathbf{A}, \boldsymbol{\beta}_1, \dots, \boldsymbol{\beta}_K, \sigma_1^2, \dots, \sigma_K^2)$  defines the model of the degradation process.  $\dot{\varphi}$  is a random variable that follows the standard Gaussian distribution (zero mean and unit variance) representing an additive measurement noise with standard deviation  $\sigma_k$ .  $\mathbf{x}_t$  is the covariate vector at index time  $t$  that translates scatter due to environmental/operational conditions and  $\boldsymbol{\beta}_k$  is a  $\square^{2 \times 1}$  vector containing the regression coefficients. The hidden sequence  $\mathbf{k} = (1, \dots, K)$  is assumed to be a homogeneous Markov chain (as shown in Figure 1) of the first order and parameterised by an initial state distribution  $\boldsymbol{\pi}$  and a transition matrix  $\mathbf{A}$ .

Figure 1. Schematic representation of the actual degradation process over a sequence of hidden states (HS), from 1 to  $K$ .

As shown in Figure 1, the hidden state discretises the observation that is continuously measured, in a sequence. This sequence of discretization is irreversible since degradation process is progressive, except when a maintenance action is implemented. Figure 2 describes the probability of stay in a hidden state is defined by the transition probability  $A_{k,k}$  in the transition matrix  $\mathbf{A}$ . Hence,  $A_{k,k}$  determines whether the degradation process is either staying or moving to the next degradation stage.

Figure 2. Illustration of the possible sequence of transition path between hidden states.

The vector  $\boldsymbol{\theta}$  can be estimated using the limiting properties of consistency, and asymptotic normality of the so-called maximum likelihood method. Its efficiency is subject to a considerable number of data points, so the sample size is suitable for taking advantage of the limiting properties of the likelihood estimator. The log-likelihood is presented in the form:

$$\begin{aligned} L(\boldsymbol{\theta}^{(m)}) &= \log p(\mathbf{y}_1, \dots, \mathbf{y}_T; \boldsymbol{\theta}^{(m)}) \\ &= \log \sum_{\mathbf{k}} p(\tau_1; \boldsymbol{\pi}) \times \prod_{t=2}^T p(\tau_t | \tau_{t-1}; \mathbf{A}) \prod_{t=1}^T N(\mathbf{y}_t; \mathbf{x}_t \boldsymbol{\beta}_k, \sigma_k^2) \end{aligned} \quad (3)$$

The Baum-Welch algorithm is referred to as the expectation-maximisation (EM) algorithm [11][16], which performs a recursive iteration over E-M steps while updating estimated parameters that govern the regression model. The regressor mean is:

$$\begin{aligned} \hat{\boldsymbol{\beta}}_k^{(m+1)} &= \left[ \sum_{t=1}^T \mathbf{x}_t' \gamma_{tk}^{(m)} \mathbf{x}_t \right]^{-1} \sum_{t=1}^T \mathbf{x}_t' \gamma_{tk}^{(m)} \mathbf{y}_t \\ &= [\mathbf{X}' \mathbf{W}_k^{(m)} \mathbf{X}]^{-1} \mathbf{X}' \mathbf{W}_k^{(m)} \mathbf{Y} \end{aligned} \quad (4)$$

where

$$\mathbf{X} = [\mathbf{x}_1, \dots, \mathbf{x}_T]' \quad (5)$$

is the  $\square^{T \times 2}$  regression matrix and  $\mathbf{W}_k^{(m)}$  is a  $\square^{T \times T}$  diagonal matrix of weights whose diagonal elements represent the posterior probabilities  $(\gamma_{1k}^{(m)}, \dots, \gamma_{Tk}^{(m)})$ . On the other hand, the covariance matrices are updated as a weighted variant of the estimation of a Gaussian density with the polynomial mean  $\mathbf{x}_t \hat{\boldsymbol{\beta}}_k^{(m+1)}$ :

$$\begin{aligned} \hat{\sigma}_k^{2(m+1)} &= \frac{1}{\sum_{t=1}^T \gamma_{tk}^{(m)}} \sum_{t=1}^T \gamma_{tk}^{(m)} (\mathbf{y}_t - \mathbf{x}_t \hat{\boldsymbol{\beta}}_k^{(m+1)})' (\mathbf{y}_t - \mathbf{x}_t \hat{\boldsymbol{\beta}}_k^{(m+1)}) \\ &= \frac{1}{\sum_{t=1}^T \gamma_{tk}^{(m)}} (\mathbf{Y} - \mathbf{X} \hat{\boldsymbol{\beta}}_k^{(m+1)})' \mathbf{W}_k^{(m)} (\mathbf{Y} - \mathbf{X} \hat{\boldsymbol{\beta}}_k^{(m+1)}) \end{aligned} \quad (6)$$

### 2.2 Multiple HMRM (M-HMRM)

Regarding the case of multiple signals, the model can be expanded as a set of  $q$  time-series:

$$\mathbf{y}_j = \begin{cases} \mathbf{x}_i \boldsymbol{\beta}_{1k} + \sigma_{1k}^2 \dot{\mathbf{0}}_i \\ \mathbf{x}_i \boldsymbol{\beta}_{2k} + \sigma_{2k}^2 \dot{\mathbf{0}}_i \\ \vdots \\ \mathbf{x}_i \boldsymbol{\beta}_{qk} + \sigma_{qk}^2 \dot{\mathbf{0}}_i \end{cases}, \quad \forall j=1, \dots, q, \quad (7)$$

where the latent degradation state  $k$  simultaneously governs all of the univariate time series components. Having observed the multivariate degradation process with the M-HMRM in equation (7) and obtaining the estimated posterior distribution, the weighted discriminant type fusion technique [13] is used to re-define the regression parameters to a univariate process, and consequently the sampled distribution. The core concept of discriminant function analysis is to determine whether groups differ in terms of the mean of a variable, and then use that variable to predict which group the sample distribution might belong to. When dealing with a single variable, the final test to assess whether the underlying assumption of homogeneity of variance (i.e. homoscedasticity) distinguishes between groups is the  $F$ -test. This test is calculated by comparing the variance between groups to the pooled (average) variance within groups. If the variance between groups is significantly higher, it indicates significant differences in the prediction. The weighting process is influenced by the respective  $F$ -values. The  $F$ -value indicates how statistically significant a variable is in distinguishing between groups, reflecting its unique contribution to predicting group membership or fusion.

Here, the estimated covariance ( $\hat{\sigma}_k^2$ ) of the M-HMRM is a  $q \times q$  matrix. Since  $F$ -value is a measure of the extent to which a variable makes a unique contribution to the prediction of group membership, one can easily obtain the  $F$ -value of the different sensors from ( $\hat{\sigma}_k^2$ ) to be:

$$F_{jk} = \frac{\text{variance between groups}}{\text{variance within groups}} \quad (8)$$

The final fusion becomes a weighted linear combination, as follows:

$$\{\hat{\boldsymbol{\beta}}_k, \hat{\sigma}_k^2\} = \frac{\sum_{j=1}^q F_{jk} \{\hat{\boldsymbol{\beta}}_{jk}, \hat{\sigma}_{jk}^2\}}{\sum_j F_{jk}} \quad (9)$$

and the estimated bivariate coefficients are then integrated into the failure function. Integrating these coefficients into the degradation process facilitates the consideration of time-varying dynamics of systems, making it a preferred approach among researchers.

### 3 REMAINING USEFUL LIFE PREDICTION

Having established the single and multiple signal HMRM degradation process, in this section the PDF of the RUL of their underlying damage models are formulated using a derived closed-form expression. As stated in the previous sections, the degradation is modelled by a random process  $\{\hat{u}_k(\tau); \tau \leq 0\}$ , assumed Gaussian for simplicity. Under the concept of first hitting time (FHT), the conditional RUL ( $\hat{\ell}_k$ ) of the system on the observation  $\hat{u}_k(\tau)$  at degradation rate  $\tau$  of state  $k$  is defined as the time from the initial state of performance

degradation until the failure threshold ( $\lambda$ ) is reached for the first time, as:

$$\hat{\ell}_k = \inf \left\{ \tau : \hat{u}_k(\tau + \hat{\ell}) \geq \lambda \mid \hat{u}_k(\tau) < \lambda \right\} \quad (10)$$

A simple system architecture of the approach is presented in Figure 3. The HMRM parameters are obtained by sampling the observed data over the underlying state-based damage model

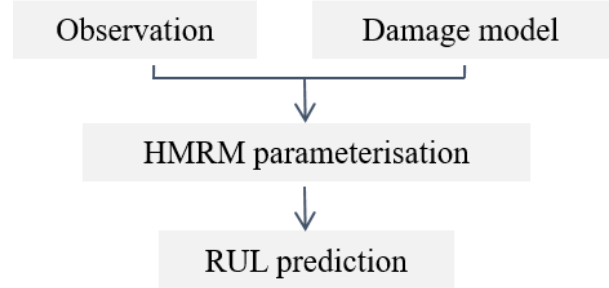

Figure 3. Remaining useful life flowchart.

#### 3.1 Power model

Consider that multiplicative measurement error in equation 1 can be approximated as  $\exp(\hat{\sigma}_k^2 \dot{\mathbf{0}}_\tau) \approx 1 + \hat{\sigma}_k^2 \dot{\mathbf{0}}_\tau$  and the variability in sampling the observation is very small, i.e.,  $(\hat{c}_k \tau^{\hat{b}_k} \hat{\sigma}_k^2 \sim \hat{\sigma}_k^2)$ , then the failure function becomes:

$$\hat{u}_k(\tau) = \hat{U}_k(\tau) + \hat{\sigma}_k^2 \dot{\mathbf{0}}_\tau = \hat{c}_k \tau^{\hat{b}_k} + \hat{\sigma}_k^2 \dot{\mathbf{0}}_\tau \quad (11)$$

$\tau$  controls switching between one degradation point  $u(\tau)$  and another across the  $K$  hidden states. From the log-linear transform,  $\mathbf{x}(\tau) = [1 \log \tau]$  and  $\hat{\boldsymbol{\beta}}_k = [\log \hat{c}_k \hat{b}_k]'$ . Since the FHT of the nonlinear degenerate model at the current rate  $\tau$  satisfies the inverse Gaussian distribution [17][18]. The degradation path upon hitting  $\lambda$  can be expressed as the PDF of the system RUL as:

$$f_T(\hat{\ell}_k \mid \hat{\theta}, \lambda) = \frac{\lambda - \hat{u}_k}{\sqrt{2\pi \hat{\ell}_k^3 (\hat{\sigma}_k^2 \hat{\ell}_k + \hat{\rho}_k)}} \times \exp \left[ -\frac{(\lambda - \hat{u}_k - \hat{c}_k \hat{\ell}_k^{\hat{b}_k})^2}{2 \hat{\ell}_k (\hat{\sigma}_k^2 \hat{\ell}_k + \hat{\rho}_k)} \right] \quad (12)$$

Where  $\hat{\rho}_k$  equal to one [19].

#### 3.2 Exponential model

Under the measurement error condition of log-normal distribution as assumed in the power model, the exponential failure function is presented as:

$$\hat{u}_k(\tau) = \hat{c}_k e^{\hat{b}_k \tau} + \hat{\sigma}_k^2 \dot{\mathbf{0}}_\tau \quad (13)$$

From the log-linear transform,  $\mathbf{x}(\tau) = [1 \tau]$  and  $\hat{\boldsymbol{\beta}}_k = [\log \hat{c}_k \hat{b}_k]'$ . The degradation path upon hitting  $\lambda$  can also be expressed in terms of the PDF of the system RUL:

$$f_T(\hat{\ell}_k | \hat{\theta}, \lambda) = \frac{\ln \lambda - \ln \hat{u}_k}{\sqrt{2\pi \hat{\ell}_k^3 (\hat{\sigma}_k^2 \hat{\ell}_k + \hat{\rho}_k)}} \times \exp \left[ -\frac{(\ln \lambda - \ln \hat{u}_k - \hat{b}_k \hat{\ell}_k)^2}{2 \hat{\ell}_k (\hat{\sigma}_k^2 \hat{\ell}_k + \hat{\rho}_k)} \right] \quad (14)$$

### 3.3 Performance error

The threshold  $\lambda$  is chosen based on expertise judgement. However, since this degradation dataset lacks historical data, as typical for bespoke components, the value of the last data point will be used as the threshold. In the second case study (for multiple sensor information), the mean of the signals' last data points is considered as the threshold.

Since the true internal states of degradation are not available, the number of states for the lifetime of either case is unknown. However, any chosen number of discrete states should be able to capture the degradation effects, encompassing material degradation, loading, environmental conditions and maintenance regimes. For prediction performance accuracy, we compute the root mean square error (RMSE) metric over each state  $k$  of the RUL, given as:

$$\text{RMSE} = \sqrt{\frac{1}{K} \sum_{k=1}^K (\ell_k - \hat{\ell}_k)^2} \quad (15)$$

where  $\ell_k$  and  $\hat{\ell}_k$  represents the actual and predicted RUL respectively.

## 4 FATIGUE CRACK GROWTH (FCG)

A FCG degradation process in a structural component has been simulated based on the Paris law of fracture mechanics described in [20], and the synthetic data is shown in Figure 4. The synthetic data will be used as the available data for the both models discussed in the previous section.

### 4.1 Results

Since RUL prediction solely depends on the available data, signals were continuously updated at every 25 cycles until failure. The advantage of this is to capture the heterogeneity of the degradation process. Typical for damage propagation in FCG, 2 and 3 state has been considered [21]. The parameter estimation procedure in section 2 and the PDF of RUL in section 3 is repeated recursively per inspection points.

The estimated PDF of RUL in terms of recursion in 2-state HMRM by power model is shown in Figure 5. At early stages of prediction (i.e., 25, 50 cycles), the prediction is dominated by uncertainty (high variance) due to limited degradation process, which does not clearly indicate the propagation trends. As failure approaches, the degradation process becomes more predictable and the variance shrinks. In addition, states switches is seen to adjust continuously as more data is introduced. However, the model seems to suffer a positive bias in predicting the RUL, as these models are conservative and obviously may not match the growth dynamics of Paris' law.

Figure 4. Fatigue crack length measurements  $u(n)$  versus magnitude of cycles  $n$ .

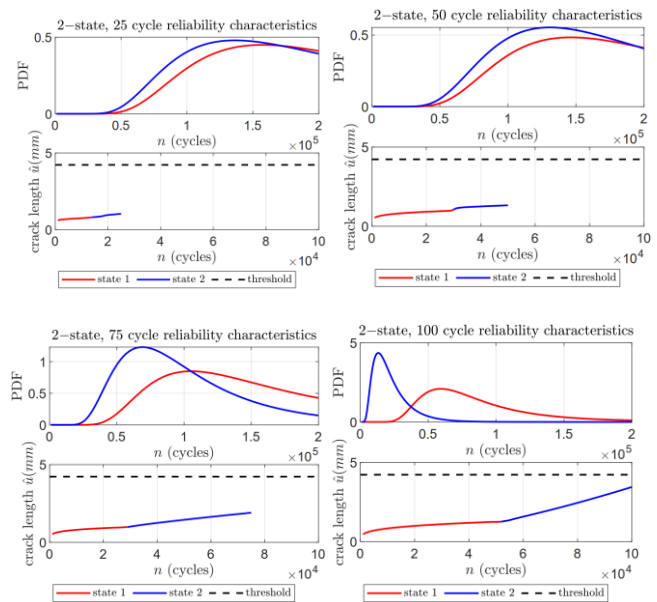

Figure 5. 2-state power HMRM reliability characteristics showing the predicted degenerate slope and the accompanying PDFs of RUL for real-time monitored information from the populated 25 initial cycles, updated by a populated 50, 75, and 100 cycle of monitored information.

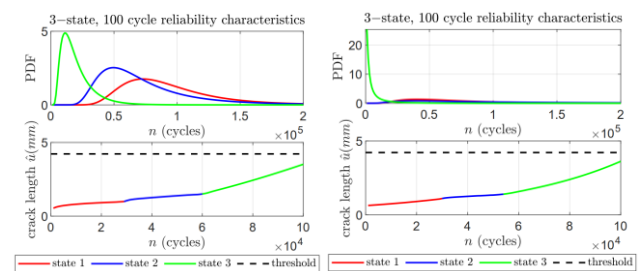

Figure 6. Reliability characteristics showing predicted degenerate slope and the accompanying PDFs of RUL for 100 cycles of monitored information in 3-state power (left) and exponential (right) HMRMs.

Figure 6 shows the complete (100 cycles of) predicted degenerate slope and the accompanying PDFs of RUL for 3-state HMRMs. It compares the prediction by power and exponential model. From the PDF plots, it shows that prediction from power model suffers more uncertainty than of the exponential model, especially at the late stage of damage propagation. This uncertainty is associated with the regressor parameter  $\hat{b}_k$ , which is gradual in the power model than in exponential model.

Figure 7 presents the RUL prediction based on the PDF of RUL plots. From the plot, it is observed that 2-state hidden states satisfy the heterogeneity in the datasets, and an additional state does not contribute to the dynamical distribution in the dataset. This is reasonable since FCG simulation is quasi-static, and rarely models the micro-cracks at grain levels. As time passes, it is shown that the predicted RUL converges towards the actual RUL in the absence of a prior degradation. The RUL distribution of the 2- state exponential model are observed to converge best than the power model. This is evident as the model follows damage accumulation scenario, which is a typical exponential. An EKF model based on the power model is also presented, for comparison. The EKF-power model converges to the true RUL better than 2-state power model. This is because, for an inspection routine with HMRM, the variance of estimating the regressor parameters over a sequence of observed data is higher than that of an EKF monitoring process. Along the true RUL is a 95% confidence interval.

Figure 7. RUL prediction versus magnitude of cycles.

Figure 8 shows the corresponding RMSE using equation (15). Since error is cumulative, the model's performance is conditioned on state's discretisation and its ability to effectively capture the heterogeneity due to any dynamic effects by the switch operation mechanism of HMRM. The cumulative RMSE for 2–3 states of power model are  $2.51 \times 10^4$  and  $1.50 \times 10^4$  cycles; of exponential model are  $3.12 \times 10^4$  and  $2.60 \times 10^4$  cycles. The RMSE of EKF is  $2.86 \times 10^4$  cycles.

Figure 8. RMSE performance accuracy.

## 5 STRUCTURAL BEAM DEGRADATION

The second case study presents the corrosion degradation problem of a structural beam (see Figure 9). Sensors are deployed at intervals across the beam length to monitor the degradation process. For this study, synthetic measurements of signals from [20] were also considered which obey the power model in equation 11, with assumed log-normal state distribution and normal multiplicative measurement error as detailed in the mentioned reference.

Figure 9. Multi-sensor condition monitoring scenario of a structural beam under progressive spatial varying damage accumulation, specific to the red "dotted" location.

Figure 10 illustrates the degradation distribution of the 10 sensor locations which were placed at 400mm sensor-sensor, numbered from left to right. Each degradation data point approximates the degradation level per year.

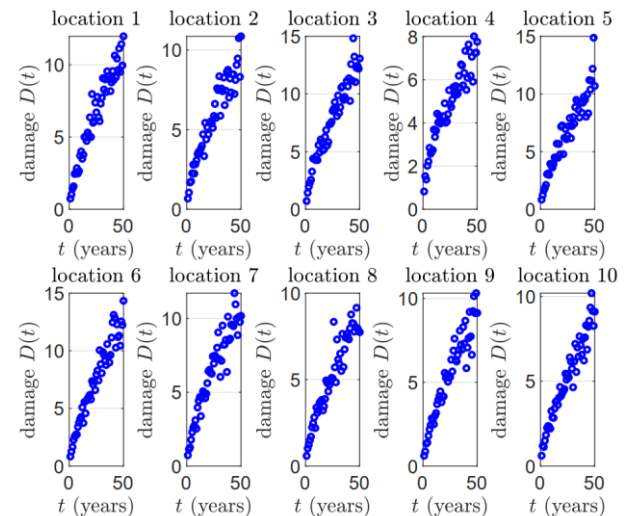

Figure 10. Synthetic sensor-based monitoring datasets of a structural beam subjected to damage accumulation. Observed dataset over the 10 sensor locations.

Figure 11. Combined distribution of the datasets.

As in the previous example, the sensor signals are inspected in 25 years' intervals until failure, when available, which was observed to be a minimum data points for a 2-state M-HMRM regression parameter estimation problem, according to the model. The same procedure of sequential updating of degraded sensor measurements applies to track the RUL change with time.

In Figure 11, the observed degradation in equation 7 is a  $t \times 10$  matrix for  $t$ -year cycle, which is used to estimate the degradation parameters by adopting the decision-level fusion in equation 9. A  $t \times 1$  predicted degenerate slope is obtained and the accompanying PDFs of RUL for 2 and 3-state M-HMRM are also obtained. The sensitivity of the concave degenerate slope is captured in the PDF distribution, in the hidden states, respectively. Whereas, a mean distribution of the  $j^{\text{th}}$  sensors is the assumed observation for the EKF.

Figure 11. Multi-Sensory monitoring of a structural beam based on 2-state (left) and 3-state(right) segmentation process.

Figure 12 describes the RUL prediction at different times and its corresponding prediction performance accuracy. The prediction performance is influenced by the number of states used per observed cycle. The result shows that the 3-state predicted RUL converges better towards the actual RUL, consequently posing a better confidence of RUL prediction. The RUL for The RMSE for the prediction performance accuracy of both models is also presented. Figure 13 shows the cumulative RMSE for 2 and 3 states to be 10.47 and 10.94 years which is twice more accurate, in absolute terms, than 20.09 years of EKF.

Figure 12. RUL prediction versus duration of degradation.

Figure 13. RMSE performance accuracy.

## LIMITATION IN PRACTICAL APPLICATION

The models discussed in this paper are generalized empirical power models to approximate self-accelerating crack growth behaviour and corrosion damage in a structural beam. While corrosion in reinforced concrete beam obey empirical power laws [22], crack growth may require differential or rate-based power laws, such in Paris or NASGRO equation [23], to capture multiple parameters (or uncertainties) which characterizes real-world systems. Crack growth phenomenon are influenced by multiple factors (or uncertainties) such as, material variability, environmental, and operational effects. Provided that these laws can be approximately linearised and adapted into hidden-state process to quantify these parameters or uncertainties, a closed form solution of it FHT to predict the remaining useful life distribution can be obtained. Although, the solution may not follow closely a similar trend as discussed in this paper, but the principle is the same.

## CONCLUSIONS

A framework to estimate the RUL of bespoke components was presented and illustrated on two examples. A regression-based hidden Markov model was proposed for degradation process prediction and two power failure functions were used to illustrate the state-dependent degradation scenarios for each problem. A case of multiple sensor measurements has also been presented.

Both cases presented address the situation where the system's prior lifetime dataset is unavailable, which makes it difficult to estimate RUL using traditional methods. The observations are modelled as sets of data that become available, and the parameters of the failure function are updated. Finally, the PDFs of RUL can be evaluated based on the re-estimated parameters of failure function, for each state. Compared to extended Kalman filter method, the model demonstrates its ability to estimate the RUL of a structural component in the absence of failure history.

**ABSTRACT:** Structural dynamical properties are vulnerable to the dynamic loads because such loads can change those parameters significantly. It is not possible to halt the aforementioned issue as dynamic loads are entirely unpredictable. The changes in stiffness, mass, and damping can lead to minor to serious damage scenarios depending on the level of changes of those parameters. Typically, the displacements trajectories of any systems are unknown, and if any other physical parameters e.g. damping is unknown that will form a nonlinear problem. Herein, to deal with the early mentioned problem a nonlinear observer namely the unscented Kalman filter (UKF) is employed. In conventional practice, the partial or full stiffness matrix are identified but identifying damping matrix is rare due to inherent complicity. Hence, this study has focused on the identification of the entire damping matrix by adopting the UKF. The outcome of study shows that UKF is capable of identifying damping coefficients quite accurately. This outcome can play a vital role in the area of structural health monitoring and control applications.

**KEY WORDS:** Structural Health Monitoring, Unscented Kalman Filter, Dynamic Loads, Damage.

## 1 INTRODUCTION

System identification is a process that helps to estimate any desire quantities e.g. stiffness based on measured sensory data and develop an underlying mathematical model of the dynamical system. Typically, the goal of the system identification is to develop a representative model that can render the true behavior of the dynamical system. Modern structures are getting complicated to monitor due to many underlying uncertainties such as their form, adaptation of state-of-art technologies e.g. sensors, dampers, monitoring tools. Therefore, monitoring such structures require proper tools, scheme and knowledge to deal with hidden uncertainties. For instance, in order to keep track on any changes real-time monitoring could be an option [1], [5], [13] and [14]. On the other hand, system identification might assist to understand the structure better as it might help to update the virtual or mathematical systems real-time or offline.

System identification (SI) is a shared topic in many areas of science and engineering e.g. mechanical/civil engineering, robotics, process engineering [15][16]. However, in case of civil engineering application still the use and application of SI is limited due to associated problems, for instance, models are very large compare to a robot or mechanical tool. Dealing with large model require serious attention as many variables are unknowns along with inputs. To deal with the numerous uncertainties, typically, from the measured data, stiffnesses are identified and feed to the control loop to adjust and update the model. Thereby, the updated model can render the true system behavior better contrary to doing no update. If the aforementioned process is done in real-time, optimal control performances can be expected.

Many works can be found those who tried various methods to identify different parameters of various type of structures e.g. buildings, bridges. Among them, a new type black-box by the use of extended Kalman filter (EKF) is studied for SI [4], a

neural network and dead-zone Kalman filter algorithm has been reported in [6], SI for time-varying system [7], autoregressive models based frequencies and damping ratio identification by [8], new forms of EKF for SI [9], SI for medical image processing application [10], SI using stochastic filter techniques [12]. The fundamental concept of the Kalman filter was proposed by Rudolf E. Kalman in 1960 [17]. Later, many have been proposed and developed different nonlinear filters such as EKF and UKF [11], [18] and [19] and their modified version.

It is mentioned early that stiffness are often identified for civil engineering application due to the simplicity in contrast to identifying damping. For instance, a detail theoretical formulation and an experimental validation of semi-active control problem along with stiffness matrix identification has been carried out in [14]. In the aforementioned study, author did not perform the identification of damping matrix individually or linked to any control problem. Because, damping coefficients are extremely sensitive to inputs and material properties as a result dealing with the control problem makes things troublesome or even could lead to an uncontrollable situation. Therefore, not many studies have been conducted in case of damping coefficients/matrices in combination with states due to the underlying complicity. More specifically, when both states and damping coefficients are unknown simultaneously, it leads to a nonlinear problem that requires a nonlinear observer to solve. The aforementioned problem has been focused in [20] to identify damping matrix where main consideration was to see the effect of initial covariance of the observer. Another work [3] has tried to identify damping via sensitivity enhanced method linked to Principal Component Analysis. A more detail issues linked to nonlinear damping identification has been reported in [2].

From above discussion it is clear that identification of damping itself leads to a complicated problem and it gets more

complicated when both sates and damping coefficients are unknown. To handle this issue, this study has focused into the identification of damping coefficients along with unknown states. A 15 degree-of-freedom (DOF) dynamical system is consider for the numerical implementations. The system identification task is performed by employing the unscented Kalman filter (UKF). The overall outcome shows that the UKF is capable of identifying damping coefficients quite accurately. As a result, the dynamical response (e.g. displacements) of the system shows excellent match with the response of the true system. Rest of the paper contains, problem description & formulation, results and discussion and finally a summary of the study.

## 2 PROBLEM DESCRIPTION & FORMULATION

The numerical investigations are conducted by adopting a 15 storied dynamical system. The dynamical system is considered to be model as lumped-mass-spring system as depicted in Figure 1. A sample free-body diagram of the top floor and a typical floor is shown in the early mentioned figure along with the full structure. Typically, equation of motion (EOM) is derived for each floor from the free-body diagram of the structure. As for example, an EOM has been derived for the 1<sup>st</sup> DOF as shown below,

$$m_1 \ddot{x}_1(t) + c_1 \dot{x}_1(t) + k_1 x_1(t) - c_1 [\dot{x}_2(t) - \dot{x}_1(t)] - k_1 [x_2(t) - x_1(t)] = -\ddot{u}_1(t) \quad (1)$$

$$m_1 \ddot{x}_1(t) + [c_1 + c_2] \dot{x}_1(t) - c_1 \dot{x}_2(t) + [k_1 + k_2] x_1(t) - k_1 x_2(t) = -\ddot{u}_1(t) \quad (2)$$

Later, all those equations of motion are combined into one single equation in matrix-vector form. And the dynamical model can be expressed in vector-matrix form as,

$$M\ddot{X}(t) + C\dot{X}(t) + KX(t) = -\beta\ddot{u}_g(t) \quad (3)$$

where M, C and K are the mass, damping and stiffness matrices with a size of  $15 \times 15$ ,  $\dot{X}$ ,  $\ddot{X}$  and  $\ddot{X}$  are the displacement, velocity, and acceleration vector those have a size of  $15 \times 1$ ,  $\ddot{u}_g$  is the input excitation,  $\beta$  controls input excitations location,  $t$  is the time vector.

Figure 1. The structure and sample free-body diagram of a typical floor and top floor.

It is quite common that the dynamical system further formulated by adopting the state space (SS) formulation technique. The SS formulation contains two main equations, they called, (i) the process equation in Eq. (2), and (ii) the observation equation in Eq. (3).

$$x_{k+1} = Ax_k + Bu_k \quad (4)$$

$$y_k = Cx_k + Du_k \quad (5)$$

where  $x$  is the states vector that has displacement and velocity,  $A$  is the state matrix,  $B$  represents the input matrix, it can be with single of multi inputs,  $D$  is the feedthrough matrix,  $C$  is output matrix,  $u$  contains input and control force (if any),  $y$  is the output vector.

Step ahead, the noise terms (both process and observation) are added to the SS formulation to deal with the observer. Typical, formulation of the UKF would look like,

$$x_{k+1} = f(x_k, v_k) \quad (6)$$

$$y_k = h(x_k, n_k) \quad (7)$$

where  $v_k$  represent process noise and  $n_k$  is the observation noise. The dynamical systems are described via  $f$  and  $h$  functions [18]-[19]. UKF propagates random variables using a specific statistical procedure known as the unscented transformation (UT). Due the aforementioned procedure UKF is derivative free, as a result it is faster than its counterpart EKF [18]. In short, a structured transformation, distributed equally around the mean (also known as the sigma points) that propagate through early mentioned complex nonlinear functions. The sigma points ( $\hat{x}_k$ ) are estimated as follows,  $\hat{x}_k = [\hat{x}_{k-1}, \hat{x}_{k-1} + \sqrt{(L + \lambda)P_{k-1}}, \hat{x}_{k-1} - \sqrt{(L + \lambda)P_{k-1}}]$ , where  $L$  is the dimension of the states and  $\lambda$  is a scaling factor. There are two main steps for the UKF, they are known as (i) the prediction Eq. (6) and (ii) the measurement update Eq. (7).

$$\hat{x}_{k|k-1} = f(\hat{x}_{k-1}, u_{k-1}) + w_{k-1} \quad (8)$$

$$\hat{y}_{k|k-1} = h(\hat{x}_{k|k-1}) + v_k \quad (9)$$

A simplified flow-chart of the UKF is depicted in Figure 2. The overall estimation is done recursively until the simulation ends.

Figure 2. Basic steps of the UKF.

The estimation steps of the UKF is given below with more detail:

(i) The initialization step (setting the states and covariance):

$$\hat{x}_0 = E[x_0], P_0 = E[(x_0 - \hat{x}_0)(x_0 - \hat{x}_0)^T]$$

$$\hat{x}_0^a = E[x^a] = [\hat{x}_0^a \ 0 \ 0]^T, P_0^a = E[(x_0^a - \hat{x}_0^a)(x_0^a - \hat{x}_0^a)^T]$$

(ii) The Sigma Points estimation:

$$\gamma_{k-1}^a = \left[ \hat{x}_{k-1}^a, \hat{x}_{k-1}^a + \sqrt{(L + \lambda)P_{k-1}^a}, \hat{x}_{k-1}^a - \sqrt{(L + \lambda)P_{k-1}^a} \right]$$

(iii) The prediction or time update:

$$\gamma_{k|k-1}^x = f[\gamma_{k-1}^x, \gamma_{k-1}^v]$$

$$\hat{x}_k^- = \sum_{i=0}^{2L} [w_i^m \gamma_{i,k|k-1}^x]$$

$$P_k^- = \sum_{i=0}^{2L} [w_i^c (\gamma_{i,k|k-1}^x - \hat{x}_k^-)(\gamma_{i,k|k-1}^x - \hat{x}_k^-)^T]$$

$$\tau_{k|k-1} = h[\gamma_{k|k-1}^x, \gamma_{k|k-1}^v]$$

$$\hat{y}_k^- = \sum_{i=0}^{2L} [w_i^m \tau_{i,k|k-1}]$$

(iii) The measurement update & correction:

$$P_{\bar{y}_k \bar{y}_k} = \sum_{i=0}^{2L} [w_i^c (\tau_{i,k|k-1} - \hat{y}_k^-)(\tau_{i,k|k-1} - \hat{y}_k^-)^T]$$

$$P_{x_k y_k} = \sum_{i=0}^{2L} [w_i^c (\gamma_{i,k|k-1}^x - \hat{x}_k^-)(\tau_{i,k|k-1} - \hat{y}_k^-)^T]$$

$$\hat{x}_k = \hat{x}_k^- + P_{x_k y_k} P_{\bar{y}_k \bar{y}_k}^{-1} [y_k - \hat{y}_k^-]$$

where  $P_x$  is the process noise covariance,  $P_y$  is the measurement noise covariance,  $w_i$  is the weight parameters [462].

### 3 RESULTS AND DISCUSSION

The numerical investigations are conducted by adopting a 15 degree of freedom (DOF) dynamical system. Therefore, the mass, damping and stiffness matrices size are  $15 \times 15$ , while, the mass matrix is assumed to be fully-diagonal. The mass is assumed to be equal in each floor and the weight of every floor is around  $60 \times 10^3$  Kg. And the stiffness components of each floor are considered  $65 \times 10^5$  N/m. The damping coefficients are estimated using eigenfrequencies and a damping ration of 2%. The main goal here is to identify all of the 15 damping coefficients. To do this, UKF is employed as nonlinear observer and the numerical investigations are conducted for 160 sec with a sampling rate of 200 Hz. The harmonic type input excitation

( $\ddot{a}_g = 1 \times \sin(16.5t)$ ) is used to excite the structure (see Figure 3). The harmonic type input load has been selected due to the simplicity of the nature of the load in contrary to complex type input e.g. earthquake.

Figure 3. Input excitation: full-time series (top), zoomed view (bottom).

The comparison of the original versus identified damping coefficients are presented in Figure 4, Figure 5, and Figure 6. More precisely, the damping coefficients are separated as  $c_1 - c_5$  in Figure 4,  $c_6 - c_{10}$  in Figure 5, and  $c_{11} - c_{15}$  in Figure 6, respectively. The aforementioned separation is done for better visualization purpose. Additionally, the values are normalized with respect to the top floor's value for the same reason as mentioned earlier.

Figure 4. Comparison of the original and identified damping coefficients [ $c_1 - c_5$ ].

It is observed that the accuracy of the estimated damping coefficients is in generally good. However, few parameters have struggled than their peers, it is due to the size of model's variables, meaning, more parameters lead to complex tuning process (e.g. noise level, initial covariances, etc.), similar issues have been reported by many [12], [20] and [21]. However, even after hard tuning still at the end accuracy may not be as expected because it is mentioned earlier that the accuracy is not depended on any single variable.

Figure 5. Comparison of the original and identified damping coefficients  $[c_6 - c_{10}]$ .

Figure 6. Comparison of the original and identified damping coefficients  $[c_{11} - c_{15}]$ .

There are many underlying uncertainties for parameters identification in general and it gets worse when it comes to damping. It is due to the nature of the damping itself and there are many influencing factors such as amplitudes of the inputs, initial covariances and noise. Additionally, the accuracy of the estimation/identification may change significantly if the sampling rate, duration of the simulation, initial states and covariances are not tuned properly. A summary of the identified damping coefficients is given in Table 1. Along with the early mentioned table a graphical representation of the data is shown in Figure 7. It should be noted that the normalized errors are estimated based on the last value at the end of the simulation. Hence for better understanding, Figure 4, Figure 5, and Figure 6 are recommended to see the whole time-series. As the parameters take some time to reach in stable or so-called steady-state condition hence errors are not isolation to a point of time of simulation (for example the identified value in the table).

Table 2. Summary of the identified damping coefficients.

Damping coefficients	Original	Identified*	Normalized Error (%)
$c_1$	1273.55	1665.95	0.016
$c_2$	3807.57	5017.11	0.048
$c_3$	6302.52	501131.164	19.78

$c_4$	8732.81	493153.22	19.36
$c_5$	11073.48	53097.78	1.68
$c_6$	13300.52	25630.01	0.49
$c_7$	15391.08	28422.90	0.52
$c_8$	17323.71	47258.82	1.19
$c_9$	19078.57	42974.68	0.95
$c_{10}$	20637.66	411245.85	15.61
$c_{11}$	21984.98	36596.87	0.58
$c_{12}$	23106.76	3977.92	0.76
$c_{13}$	23991.326	7640.00	0.65
$c_{14}$	24629.76	28217.52	0.14
$c_{15}$	25015.46	75434.76	2.01

\*absolute identified values belong to the end of the simulation

Further, the propagation of the uncertainties have evaluated and given as the root mean squared (RMS) and the standard deviations (STD), those values are estimated and illustrated in Figure 8 and Figure 9, respectively. Both the RMS values and STD shows that they are not constant and consistent throughout the simulation period. That also justify why the identified parameters may have different level of errors based-on at what point the parameters are considered.

Figure 7. Comparison of the original and identified damping coefficients and their errors  $[c_1 - c_{15}]$ .

Figure 8. Point-to-point error changes during the simulation period  $[c_1 - c_{15}]$ .

Figure 9. Standard deviation changes during the simulation period  $[c_1 - c_{15}]$ .

Furthermore, to understand the effect of the identified damping coefficients, the displacements trajectories of the 5<sup>th</sup>, 10<sup>th</sup> and 15<sup>th</sup> DOF is evaluated. The displacement of 5<sup>th</sup> floor is depicted in Figure 10, while Figure 11 has the 10<sup>th</sup> floor displacement and the 15<sup>th</sup> floor displacement is shown in Figure 12. All of the aforementioned figures have a full-time series (top sub figure) and a zoomed view (bottom sub figure). It can be observed that all of those figures show a very good accuracy in terms of rendering the original behavior of the system.

Figure 10. Original versus estimated displacement of the 5<sup>th</sup> floor.

Figure 11. Original versus estimated displacement of the 10<sup>th</sup> floor.

Figure 12. Original versus estimated displacement of the 15<sup>th</sup> floor.

Last but not least, the acceleration response of those early mentioned floors (e.g. 5<sup>th</sup>, 10<sup>th</sup> and 15<sup>th</sup>) has been evaluated and presented in Figure 13, Figure 14, and Figure 15, correspondingly. Similar to the earlier observation, it has been noticed that the estimated acceleration data render the original data quite accurately.

Figure 13. Original versus estimated acceleration of the 5<sup>th</sup> floor.

Figure 14. Original versus estimated acceleration of the 10<sup>th</sup> floor.

Figure 15. Original versus estimated acceleration of the top floor.

#### 4 CONCLUSION

This study investigates the possibility of identification full damping matrix of a 15 DOF system. The goal is achieved by adopting the UKF as an observer. The estimated parameter results show very good match with the original data. The displacement and acceleration comparison results confirm (due to their a very good match) that the identified damping coefficient are quite accurate. However, that doesn't mean that all 15 damping coefficients (e.g.  $c_1 - c_{15}$ ) are having same accuracy. UKF perform recursive estimation during the given time-span hence the error of the estimation is optimized by minimizing errors. In other words, the accuracy of the states (displacements and velocities) are not very much affected due to the individual damping coefficient accuracy. In a nutshell, the outcome of this study can be summarized that the investigated approach might be beneficial for structural health monitoring and vibration control applications as the states can be updated during the simulation in real-time.

**ABSTRACT:** Integrated Motion Measurement Systems (IMMSs) are multi-sensor systems, based on the principle of integrated navigation with inertial sensors as central components and an aiding by, e.g., GNSS receivers. IMMSs can be used to track elastic motions as additional degrees of freedom (DOFs) that capture the deformations of the object. To support the estimation of elastic properties, additional internal aiding measurements like strain gauges can be implemented. In addition to the raw sensor data, the elastic DOFs in the time and frequency domain are possible indicators to be used for Structural Health Monitoring (SHM).

With the increasing availability of low-cost micro-electro-mechanical systems (MEMSs), combined with their ease of implementation, applications in large sensor quantities become feasible. To validate and experimentally test such an integrated motion measurement, a test rig with a movable, flexible pendulum beam was designed, to represent an idealization of a mast, rotor blade, or aircraft wing.

In this study a short categorization of possible SHM applications for IMMSs is given, based on previous work and state-of-the-art SHM approaches. In this context, the principle of IMMS is explained with the experimental realization, validation, and the resulting modal characteristics of the elastic DOFs as potential indicators for SHM. Furthermore, the importance of strain gauges is investigated with methods to reduce their number by redundant sensors and restricted aiding.

**KEY WORDS:** Sensor fusion; Kalman filter; Inertial sensors; Complementary Sensors.

## 1 INTRODUCTION

Integrated motion measurement of flexible structures is the expansion of conventional integrated navigation systems, typically employing an inertial measurement unit (IMU) aided by GNSS (global navigation satellite system) [1-3]. In contrast to the classic approach, the object of interest is now developed from a simple rigid point with six degrees of freedom (DOFs, three for the position and three for the attitude) to an elastic body with extra DOFs, capturing elastic deformations. Furthermore, additional sensors are distributed on the structure, enabling this model extension. Such additional sensors are, on the one hand, inertial sensors like accelerometers or gyroscopes to expand the system input to accommodate the extra DOFs. On the other hand, further GNSS receivers, strain gauges, or other sensor types are feasible for aiding [4].

With the ongoing development and miniaturization of micro-electromechanical systems (MEMSs), such integrated motion measurement systems (IMMSs) can now be realized with cost-effective sensors. A test rig [5], as well as a hybrid sensor system [6] was developed to validate the principle of IMMS on a flexible beam. The test rig and beam were designed to resemble an aircraft wing, mast, or rotor blade of a wind turbine. The validation proved that such low-cost sensor systems are suitable for IMMS applications and can reliably estimate structural deformations [7]. Concluding, IMMSs for flexible structures allow a comprehensive movement determination of the object including the rigid body part as well as elastic deformation of the structure itself.

The validation [7] so far relied on the usage of a quantity of strain gauges being the same as the number of characteristic deformations introduced as additional DOFs. This means that

with rising complexity of the structure and increased number of relevant mode shapes, more strain gauges are needed to complete the system requirements. Despite dominant advantages like high sensitivity leading to a reliable aiding of the selected deformations, certain disadvantages would benefit a reduction of these sensors. Such disadvantages are i.e. a complex installation process as well as maintenance. Installing strain gauges can be a lengthy and complex task that demands skill and accuracy. It requires specialized knowledge to ensure that the gauges are attached, wired, and calibrated correctly. Furthermore, strain gauges are vulnerable to environmental factors and therefore need to be shielded adequately. All these factors can add to the overall complexity of the project [8]. In contrast to that, the application of IMUs and Time-of-Flight distance sensors (ToF) is relatively easy. In the present setup, both sensors are located on a circuit board and screwed to the structure [6]. It can be beneficial to reduce the usage of strain gauges in favor of low-cost, easy to apply sensors like IMUs, ToFs, or GNSS receivers for installation and maintenance reasons.

The additional estimation of deformations by a distributed sensor network puts IMMSs in the spotlight as a potential application for vibration-based structural health monitoring (SHM) at a global approach. Unlike local methods, where a dense sensor network is setup around a perimeter of expected damage, the behavior of the complete structure is evaluated for damage diagnosis [9]. An abundance of methods exists in this field, however, to the knowledge of the authors, no existing method utilizes the estimation of elastic deformations via kinematic considerations:

In state-of-the-art SHM applications, accelerometers are widely used as sensors and typical parameters for damage evaluation are modal parameters like natural frequencies and mode shapes. Often, the input or output signals are further processed by methods like Fast Fourier transform (FFT), or Wavelet transform (WT) [10]. While several methods combine IMU or accelerometer data with GNSS measurements [11-13], the sensor network or node is treated as a rigid body and in practice, the displacement of the monitored location is extracted for signal evaluation. On the other hand, applications with distributed sensors, mostly accelerometers without any aiding exist. For example, a network of low-cost MEMS accelerometers is applied in a bridge structure for displacement and vibration analysis [14]. In this case, modal parameters like frequencies, damping ratios and amplitudes are estimated based on the model of a damped harmonic oscillator. Subsequently, the mode shapes are extracted from the calculated amplitudes of the involved sensor locations and modes. In other applications, the overall deflection of a bridge [15] or wind turbine [16] is reconstructed based on the calculated rotation angles of distributed IMUs or accelerometers, gyroscopes, and magnetometers respectively. The latter method proposes to use the obtained deflection to assess the occurring stresses via a Finite Element (FE) simulation for SHM.

Furthermore, many papers suggest the usage of Operational Modal Analysis (OMA). Here, only the measurement data with unknown system excitation is used to obtain modal parameters of the observed structure. A commercial OMA tool is for example used to identify different damage scenarios of an open-source benchmark system with distributed accelerometers [17]. In other OMA applications, simulated accelerometer data of distributed sensors are used to extract mode shapes [18] or natural frequencies, mode shapes, and curvature mode shapes [19] for floating offshore wind turbines and wind turbine blades respectively. Damage detection can then be applied by assessing the change of mode shape after applying damages [19]. Alternatively, distributed strain sensors in the form of Fiber Bragg Gratings (FBGs) can be used for damage detection by identifying the change of eigenfrequencies, obtained from OMA on a wind turbine structure [20].

In another approach, damage assessment is done by Finite Element Model Updating for a laboratory bridge structure equipped with accelerometers [21]. Based on the measurements obtained, the mass, damping, and stiffness matrices of the FE simulation are updated to match the characteristics of the measurements. To conclude, there exist a variety of SHM methods and applications which could potentially be adapted to an IMMS, which aims at a more complementary, integrated use of different types of sensors.

Thus, in this study, a preliminary classification and outlook on potential SHM applications by IMMS is conducted. Furthermore, the reduction as well as replacement of strain gauges with different sensor types and aiding approaches is investigated. For that, Section 2 introduces the concept of IMMS of flexible structures, including the general system equations and the kinematic equations for accelerometers and gyroscopes as central components. Section 3 provides the application of such a system for a flexible beam, introducing unit deformations as characteristic elastic deformations and

aiding models of different sensor types. The test rig for experimental implementation as well as a summary of the conducted validation are presented subsequently. Based on this, the experimental approach of this study is presented in Section 4, followed by the presentation and discussion of the results in Section 5. A conclusion and outlook finalize the paper in Section 6.

## 2 INTEGRATED MOTION MEASUREMENTS OF FLEXIBLE STRUCTURES

The main task of IMMSs is to track the propagation with time of the motion state vector

$$\mathbf{x}(t) = [\mathbf{r}(t) \quad \dot{\mathbf{r}}(t) \quad \boldsymbol{\Theta}(t) \quad \dots]^T, \quad (1)$$

which holds the classical navigation parameters position  $\mathbf{r}$ , velocity  $\dot{\mathbf{r}}$ , and attitude  $\boldsymbol{\Theta}$ . The state vector is further expanded by additional DOFs reflecting elastic deformations, which will be derived within this section. Other typical parameters like sensor biases are excluded for a better overview [4]. The dynamic behavior of  $\mathbf{x}$  can be modelled by a nonlinear, kinematical model

$$\dot{\mathbf{x}} = \mathbf{f}(\mathbf{x}, \mathbf{u}) + \mathbf{G}\mathbf{w}, \quad (2)$$

driven by the input vector  $\mathbf{u}(t)$ . In the case of IMMSs, the input consists of accelerations and angular rates, measured by an array of inertial sensors. Additionally, the stochastic measurement noise  $\mathbf{w}(t)$  of the input is mapped to  $\dot{\mathbf{x}}$  via the noise matrix  $\mathbf{G}$ . Inherent errors like sensor noise and bias of the input  $\mathbf{u}$ , in combination with numerical integration leads to a rising error if the system state  $\mathbf{x}$  is calculated from Equation (2). To reduce this error and ensure observability of the system, regular correcting measurements are necessary which are represented by the aiding vector

$$\mathbf{y} = \mathbf{h}(\mathbf{x}, \mathbf{u}) + \mathbf{v}. \quad (3)$$

The aiding vector  $\mathbf{y}(t)$  comprises measurements, e.g. from GNSS receivers, which can be modeled according to the current system state  $\mathbf{x}$ , input  $\mathbf{u}$ , and their stochastic measurement noise  $\mathbf{v}(t)$  [1].

The IMMS combines the calculated system state from Equation (2) with the aiding Equation (3) to merge different sensor types by using the advantages of each sensor type against the disadvantages of the other sensors. This so-called sensor fusion, as well as solving the differential Equation (2) is accomplished by an extended Kalman Filter (EKF). The system architecture and signal flow of an EKF, which works according to the observer principle, is depicted in Figure 1 [22].

Figure 1. System architecture of IMMS. Adapted from Wagner and Wieneke [22].

The system state  $\mathbf{x}$  and therefore the aiding vector  $\mathbf{y}$  results from the accelerations and angular rates acting on the object,

which are measured by the input  $\mathbf{u}$ . Based on this input, an estimate of the system state  $\hat{\mathbf{x}}$  and measurement vector  $\hat{\mathbf{y}}$  is calculated. Conclusively, the difference between actual aiding measurements and their estimation  $\mathbf{y} - \hat{\mathbf{y}}$  is used to calculate an updated system state  $\hat{\mathbf{x}}$ .

### 2.1 Kinematic system model and input

To complete the state vector from Equation (1), to accommodate elastic deformations, and to give an overview of the involved input sensors within an IMMS, a simplified model of an aircraft fuselage with one wing as a beam is depicted in Figure 2.

Figure 2. Simplified aircraft model with exemplary input sensors. Adapted from Örtel [4].

The wing is sketched in its deformed (solid line) and undeformed (dashed line) state. In this case, measurements of the input vector  $\mathbf{u}$  are indicated as red arrows, which are comprised of the accelerations  $a_{D,\eta}$ ,  $a_{D,\zeta}$ , and the angular rate  $\omega_D$  obtained from an IMU in the center of the system  $D$ . Furthermore, additional peripheral accelerometers or gyroscopes at arbitrary positions  $j$  measure either the acceleration  $a_j$  or angular rate  $\omega_j$ . Instead of single-axis accelerometers or gyroscopes, complete IMUs can be installed as peripheral sensors, however, only one of the signals shown is mandatory for the presented system model. The relevant coordinate systems are indicated by dotted arrows, which are the inertial coordinate system  $(i\eta, i\zeta)$ , the body coordinate system  $(b\eta, b\zeta)$ , and the sensor coordinate system  $(s\eta, s\zeta)$ . Accelerations and angular rates are measured with respect to the inertial coordinate system, in either the body coordinate system (IMU in the center  $D$ ) or the sensor coordinate system (peripheral sensor in  $j$ ). The lever arm  $\ell_j$  is the distance between  $D$  and  $j$ . In the case of peripheral accelerometers, the kinematic equation of motion of  $j$  is

$$\ddot{\mathbf{r}}_j = \ddot{\mathbf{r}}_D + \ddot{\ell}_j + 2(\boldsymbol{\omega}_{bi} \times \dot{\ell}_j) + \dot{\boldsymbol{\omega}}_{bi} \times \ell_j + \boldsymbol{\omega}_{bi} \times (\boldsymbol{\omega}_{bi} \times \ell_j), \quad (4)$$

with  $\ddot{\mathbf{r}}_j$  comprising  $a_j$ , which is therefore directly measured by the peripheral accelerometer (the left superscript indicates the reference system for differentiation). Furthermore,  $\ddot{\mathbf{r}}_D$  holds the accelerations  $a_{D,\eta}$ ,  $a_{D,\zeta}$ , whereas  $\boldsymbol{\omega}_{bi}$  contains the angular rate  $\omega_D$ , meaning both vectors are readily available from the IMU measurements in  $D$ . With lack of low-cost angular acceleration sensors,  $\dot{\boldsymbol{\omega}}_{bi}$  is calculated via numerical differentiation of  $\boldsymbol{\omega}_{bi}$ . Considering peripheral gyroscopes, the kinematic equation of motion becomes

$$\boldsymbol{\omega}_j = \boldsymbol{\omega}_{bi} + \frac{d(\text{rot } \ell_j)}{dt}. \quad (5)$$

Here,  $\boldsymbol{\omega}_j$  is directly measured by the peripheral gyroscope with  $\omega_j$ . Both Equations (4) and (5) contain the unknown lever arm

$\ell_j$  and its first and second derivative ( $\dot{\ell}_j$  and  $\ddot{\ell}_j$ ) in the case of peripheral accelerometers [4].

As indicated in Figure 2, the lever arm  $\ell_j$  is modeled by a rigid part  $\bar{\mathbf{r}}_j$  on the undeformed wing plus a time-dependent, elastic part  $\Delta \ell_j(t)$ . Under the assumption of small deformations, the lever arm is modeled by a series approach

$$\ell_j = \bar{\mathbf{r}}_j + \Delta \ell_j(t) \approx \bar{\mathbf{r}}_j + \sum_{\chi=1}^{\Gamma} (b_{\chi}(t) \cdot \mathbf{s}_{\chi}(\bar{\mathbf{r}}_j)), \quad (6)$$

with a selected number  $\Gamma$  of time-dependent deformation variables  $b_{\chi}(t)$  as a coefficient to their associated shape functions  $\mathbf{s}_{\chi}(\bar{\mathbf{r}}_j)$ . The deformation variables act as additional DOFs and reflect the current amplitudes of the shape functions, which spatially represent the structural deformations. For the latter, it is assumed that  $\mathbf{s}_{\chi}(\bar{\mathbf{r}}_j)$  only have components in  $b\zeta$ -direction, which justifies the usage of single-axis sensors (more components require more sensor-axes). Additionally, the shape functions are defined in a way that they have the maximum displacement value of 1 at least at one point. Due to this definition, they will be referred to as unit deformations, of which two exemplary selections  $\mathbf{s}_1(\bar{\mathbf{r}}_j)$  and  $\mathbf{s}_2(\bar{\mathbf{r}}_j)$  are sketched in Figure 3. In this case the rigid part  $\bar{\mathbf{r}}_j$  of the lever arm is aligned with the  $\eta$ -axis of the body coordinate system.

Figure 3. Typical unit deformations. Adapted from Örtel [4].

As a result, the superposition of all selected unit deformations multiplied with their current amplitudes should reflect the total deformation of the structure. Consequently, the choice of type and number of unit deformations is essential for a proper approximation of the structure. It has been proven that the eigenmode shapes are a reasonable, but not mandatory choice for the unit deformations [4,7].

Based on Equation (6), the first and second derivative of  $\ell_j$  can be formulated with

$$\begin{aligned} \dot{\ell}_j &= \sum_{\chi=1}^{\Gamma} (\dot{b}_{\chi}(t) \cdot \mathbf{s}_{\chi}(\bar{\mathbf{r}}_j)) \\ \ddot{\ell}_j &= \sum_{\chi=1}^{\Gamma} (\ddot{b}_{\chi}(t) \cdot \mathbf{s}_{\chi}(\bar{\mathbf{r}}_j)) \end{aligned} \quad (7)$$

With the abbreviation  $\mathbf{s}_{\chi}(\bar{\mathbf{r}}_j) = \mathbf{s}_{\chi,j}$ , Equations (7) are substituted into (4), to deliver the set of Equations

$$\ddot{\mathbf{r}}_j(t) = f(i\ddot{\mathbf{r}}_1, \dots, i\ddot{\mathbf{r}}_v, \dots, i\ddot{\mathbf{r}}_D, \boldsymbol{\omega}_{bi}, \dot{b}_1, \dots, \dot{b}_{\Gamma}, b_1, \dots, b_{\Gamma}, \mathbf{s}_{1,1}, \dots, \mathbf{s}_{\Gamma,v}), \quad (8)$$

for  $\chi=1, \dots, \Gamma$  selected unit deformations and  $j=1, \dots, v$  peripheral accelerometers. Substituting Equation (6) into (5) yields

$$\dot{\mathbf{r}}_j(t) = f(\boldsymbol{\omega}_1, \dots, \boldsymbol{\omega}_v, \boldsymbol{\omega}_{bi}, \text{rot } \mathbf{s}_{1,1}, \dots, \text{rot } \mathbf{s}_{\Gamma,v}), \quad (9)$$

for  $\chi=1, \dots, \Gamma$  selected unit deformations and  $j=1, \dots, v$  peripheral gyroscopes [4].

Depending on the type of peripheral sensor being either accelerometer (acc) or gyroscope (gyro), the state vector from Equation (1) becomes

$$\mathbf{x}_{\text{acc}} = \begin{bmatrix} {}_i\mathbf{r}_D & {}_i\dot{\mathbf{r}}_D & \Theta & \mathbf{b} & \dot{\mathbf{b}} \end{bmatrix}^T \quad (10)$$

or  $\mathbf{x}_{\text{gyro}} = \begin{bmatrix} {}_i\mathbf{r}_D & {}_i\dot{\mathbf{r}}_D & \Theta & \mathbf{b} \end{bmatrix}^T$ ,

according to the general form of Equation (2). All selected deformation variables  $b_1, \dots, b_\Gamma$  and their derivatives are summarized in the vectors  $\mathbf{b}$  and  $\dot{\mathbf{b}}$  respectively. The system input becomes

$$\mathbf{u}_{\text{acc}} = \begin{bmatrix} a_{D,\eta} & a_{D,\zeta} & \omega_D & \dot{\omega}_D & \mathbf{a} \end{bmatrix}^T \quad (11)$$

or  $\mathbf{u}_{\text{gyro}} = \begin{bmatrix} a_{D,\eta} & a_{D,\zeta} & \omega_D & \boldsymbol{\omega} \end{bmatrix}^T$ ,

with  $\mathbf{a}$  and  $\boldsymbol{\omega}$  holding all measured peripheral accelerations  $a_1, \dots, a_\nu$  and angular rates  $\omega_1, \dots, \omega_\nu$ . To maintain the observability of the IMMS, the number of peripheral sensors must be equal or higher than the elastic DOFs  $\nu \geq \Gamma$ . A further condition is that the chosen unit deformations need to be linear independent, and the sensor positions must be chosen adequately [4].

## 2.2 Aiding equations and measurements

The aiding Equation (3) relates the actual aiding measurements  $\mathbf{y}$  to their estimate  $\hat{\mathbf{y}}$ , to correct the state estimate  $\hat{\mathbf{x}}$  according to Figure 1. To achieve that, the measurements need to be reconstructed from the system state, which corresponds to the right-hand side of Equation (3). Aiding equations can be divided into two principles, with applications in Section 3:

**External aiding:** The systems providing the measurements are independent and located outside of the object. A prominent example of such an aiding system are GNSSs. If the system, i.e. provides a position or distance reference of a point  $j$ , the measurement can be related with a function including the position, orientation, and the deformations [4].

**Internal aiding:** The measurement systems are located on the structure. Strain gauges, for example, provide data which can be related to the elastic DOFs only [4].

## 3 IMMS APPLICATION OF A FLEXIBLE BEAM

For experimental validation and application of IMMS of flexible structures, the simplified aircraft model from Figure 2 was reduced to a suspended, elastic pendulum as shown in Figure 4. This setup should abstract the aircraft fuselage and one wing as the pendulum bearing  $D$  and the pendulum itself. This representation also holds for a rotor or mast of a wind turbine and is therefore generally applicable. Considering technical limitations and the desired realization, all inertial sensors are applied in the form of a six-axis IMU measuring three accelerations and three angular rates. This means, that an IMU is placed in  $D$ , measuring  $a_{D,\eta}$ ,  $a_{D,\zeta}$ , and  $\omega_D$ , as well as in  $j_s$ , measuring  $a_{j_s}$  and  $\omega_{j_s}$ . As a result of restricted GNSS visibility due to an indoor test rig, Time-of-Flight distance sensors (ToF) are placed alongside the peripheral IMUs, measuring the distance  $\rho_j$  from the point  $j_\rho$  towards a reflector plane, placed at the known location  $d_{\text{ref}}$ . Internal aiding is provided via strain gauges, which are applied as a wheatstone full bridge, measuring the bending strain  $\varepsilon_j$  in the location  $j_\varepsilon$  close to the IMU. The setup is completed by a high

precision distance sensor, providing the displacement of the bearing  $\rho_D$ . The Pendulum is a steel sheet of the material DX51D+Z, with the dimension 4 m x 0.2 m x 0.002 m [5,7].

Figure 4. Experimental IMMS setup [7].

The state vector of the IMMS can be taken directly from Equation (10), with

$${}_i\mathbf{r}_D = \begin{bmatrix} d & h \end{bmatrix}^T, \quad \Theta = \phi \quad (12)$$

and  $h$  being the displacement of  $D$  in  $i\eta$ -direction. The input follows from Equation (11) without adjustments, including  $j_s = 1, \dots, \nu_s$  peripheral accelerometers or gyroscopes. Ultimately, the aiding vector becomes

$$\mathbf{y}_{\text{acc}} = \mathbf{y}_{\text{gyro}} = \begin{bmatrix} \rho_D & \dot{\rho}_D & \boldsymbol{\rho} & \boldsymbol{\varepsilon} \end{bmatrix}^T. \quad (13)$$

The vectors  $\boldsymbol{\rho}$  and  $\boldsymbol{\varepsilon}$  hold the data set of all measured distances  $\rho_1, \dots, \rho_\nu$  and bending strains  $\varepsilon_1, \dots, \varepsilon_\nu$  from  $j_\rho = 1, \dots, \nu_\rho$  utilized ToFs and  $j_\varepsilon = 1, \dots, \nu_\varepsilon$  strain gauges. The position measurement  $\rho_D$  contains the horizontal distance of the bearing  $\rho_D$  corresponding to  $d$  and a pseudo-measurement of 0 corresponding to  $h$  respectively. In the final application, not all available sensor signals are utilized, meaning that an IMU is used without the accompanying ToF or vice versa. Therefore a distinction between placement and number of the sensors at hand  $\nu_s$ ,  $\nu_\rho$ , and  $\nu_\varepsilon$  must be made.

### 3.1 Unit deformations

The unit deformations of the pendulum are acquired from the eigenmodes of the linearized structure. These were calculated with a Finite Element (FE) analysis in ANSYS®. As indicated in Figure 2 and 3, the unit deformations are relevant from the perspective of the object and therefore should be transformed into body coordinates. The first six transformed modes are plotted in Figure 5, where the first two modes of the structure have similar shape due to the transformation. As a result, these two modes are merged to a combimode, since their distinction by the system can not be guaranteed [4,7].

Consequently, the first six modes are represented by the first five unit deformations  $\Gamma = 1, \dots, 5$ , with the third mode corresponding to the second unit deformation, etc. The eigenfrequencies as well as the associated modes of each unit deformation are listed in Table 1.

Figure 5. First six transformed modes shapes [4,7].

Table 1. Allocation of eigenmodes to unit deformations with corresponding frequencies [7].

Unit def.	1	2	3	4	5
mode	1	2	3	4	5
$f_i$ [Hz]	0.302	0.860	1.909	3.492	5.262

### 3.2 Beam deflection, curvature, and aiding equations

To give insight into the applied aiding measurements and equations, a sketch of the randomly deformed pendulum is shown in Figure 6. Furthermore, an arbitrary point (or sensor)  $j$ , placed at position  $\ell_j$  on the undeformed wing with deformation  $\Delta\ell_j$  is highlighted. The sensor coordinate system  $s$  is rotated relative to the body system  $b$  by the angle  $\phi_{j, sb}$ , whereas  $b$  is rotated by  $\phi$  relative to the inertial system  $i$ .

Figure 6. Relation between the local rotation and gradient of the bending line.

Considering  $j = 1, \dots, \nu$  arbitrary peripheral points, the elastic deformation of the object at each location can be reconstructed with

$$\begin{bmatrix} \Delta\ell_1 \\ \vdots \\ \Delta\ell_\nu \end{bmatrix} = \begin{bmatrix} s_{1,1} & \dots & s_{1,\nu} \\ \vdots & \ddots & \vdots \\ s_{\nu,1} & \dots & s_{\nu,\nu} \end{bmatrix} \cdot \begin{bmatrix} b_1 \\ \vdots \\ b_\nu \end{bmatrix} = \mathbf{S} \cdot \mathbf{b} \quad (14)$$

and the matrix of unit deformations  $\mathbf{S}$ . With the angle  $\phi$  being permanently calculated as part of the state vector, the location of  $j$  in the inertial coordinate system is given by the transformation

$${}^i\mathbf{r}_j = \begin{bmatrix} {}^i\eta_j \\ {}^i\zeta_j - d \end{bmatrix} = \begin{bmatrix} \cos \phi & -\sin \phi \\ \sin \phi & \cos \phi \end{bmatrix} \cdot \begin{bmatrix} \ell_j \\ \Delta\ell_j \end{bmatrix} \quad (15)$$

for small deformations. Under the same condition, the rotation  $\phi_{j, sb}$  from the body to the sensor coordinate system can be approximated by the gradient of the bending line  $\alpha_j$ . Considering the rotation of  $b$  relative to  $i$ , the total rotation of  $s$  relative to  $i$  can be formulated with

$$\begin{bmatrix} \phi_1 \\ \vdots \\ \phi_\nu \end{bmatrix} \approx \phi + \begin{bmatrix} \alpha_1 \\ \vdots \\ \alpha_\nu \end{bmatrix} = \phi + \begin{bmatrix} s'_{1,1} & \dots & s'_{1,\nu} \\ \vdots & \ddots & \vdots \\ s'_{\nu,1} & \dots & s'_{\nu,\nu} \end{bmatrix} \cdot \begin{bmatrix} b_1 \\ \vdots \\ b_\nu \end{bmatrix} = \phi + \mathbf{S}' \cdot \mathbf{b} \quad (16)$$

and

$$\frac{\partial s_{\chi,j}}{\partial b_\eta} = s'_{\chi,j} \quad (17)$$

being the gradient of the unit deformations [4].

While the aiding measurements  $\mathbf{p}_D$  and  $\dot{\mathbf{p}}_D$  directly correspond to the system states  $\mathbf{r}_D$  and  $\dot{\mathbf{r}}_D$ , the remaining aiding measurements have to be viewed in detail:

ToFs: The distance  $\rho_j$  is measured perpendicular to the local sensor position as sketched in Figure 7. With the location of the sensor, calculated from Equation (15), and the rotation  $\phi_j$  from Equation (16), the distance measurement can be modeled by the function

$$\rho_j = \frac{d_{\text{ref}} - {}^i\zeta_j}{\cos \phi_j} = h(d, \phi, \mathbf{b}) \quad (18)$$

Figure 7. Distance measurement of peripheral ToF sensor.

Strain gauges: Considering the area moment of inertia and the moment of resistance, the bending strain of a rectangular beam of thickness  $h^*$  can be expressed for small deflections with

$$\begin{bmatrix} \varepsilon_1 \\ \vdots \\ \varepsilon_\nu \end{bmatrix} = -\frac{h^*}{2} \begin{bmatrix} s''_{1,1} & \dots & s''_{1,\nu} \\ \vdots & \ddots & \vdots \\ s''_{\nu,1} & \dots & s''_{\nu,\nu} \end{bmatrix} \cdot \begin{bmatrix} b_1 \\ \vdots \\ b_\nu \end{bmatrix} = \mathbf{S}'' \cdot \mathbf{b} = \mathbf{h}(\mathbf{b}) \quad (19)$$

for  $\nu_\varepsilon$  applied strain gauges.

### 3.3 Test rig

The implementation of the IMMS setup from Figure 4 is implemented by a test rig shown in the big picture of Figure 8. The movable pendulum 1 is suspended with a plain bearing 2 from a guidance rail 3. A reflector plane 4 for the ToFs completes the general structure. To impose movements  $d$  on the pendulum, a linear spindle actuator is mounted underneath the guidance rail and connected to the bearing suspension. The reproducible excitation of the system can then be used to provide comparability between different measurements and input for simulations [5].

The intended input and aiding measurements of Equations (11) and (13) are realized by a hybrid sensor system [6], developed for this application. The system consists of multiple interconnected printed circuit boards (PCBs) as shown in the small picture of Figure 8, which accommodate an IMU, a ToF, along with an analogue to digital converter (ADC) to connect the strain gauges. An additional PCB reads the measurements of the displacement sensor in the bearing. Controlled by a Master PCB, the measurement system provides simultaneous

measurements of the implemented sensor types at multiple, selectable positions.

Figure 8. Test rig (big picture) and PCB (small picture) with IMU 1b, ToF 2b and ADC 3b [5].

### 3.4 Validation results

For validation, a practicable and realistic displacement function for the actuator was created. The displacement consists of back-and-forth movements, superimposed by frequency components up to the fifth eigenfrequency of Table 1. The resulting displacement  $d(t)$  is plotted in Figure 9, including an initial resting phase of 60 s for initialization purposes. As comparison parameters, the horizontal displacement  $d$  of the bearing, the angular orientation  $\phi$ , and the pseudo-elastic deformation  $e$  were chosen, the latter being the joint-related deformation and calculated by  $\Delta\ell$  according to Equation (14) at the lower tip of the pendulum. To evaluate the IMMS, the FE model from Section 3.1 was simulated with the displacement input measured by  $\rho_D$ . To create a realistic scenario, an artificial white noise is added to  $\rho_D$ , which is in the order of magnitude of the sensor noise of the ToFs.

Figure 9. Displacement function  $d(t)$  [7].

It could be proven that for this excitation, the errors of attitude  $\Delta\phi$  and pseudo-elastic deformation  $\Delta e$  converge with four involved unit-deformations  $\Gamma=4$  and four peripheral sensors (accelerometers or gyroscopes)  $v_s = v_\rho = v_\varepsilon = 4$ . The position error  $\Delta d$  was insignificantly affected by the inclusion of the elastic DOFs. A comparison of the attitude  $\phi$  and pseudo-elastic deformation  $e$  is shown in Figure 10 for a time interval with relatively high dynamics. The simulated parameters (sim) are compared against the accelerometer (acc) and gyroscope (gyro) configuration of the converged case.

Despite time intervals with high dynamics, resulting in large deflections and other nonlinear effects, the results indicated that the IMMS delivers reliable estimates of the classical navigation parameters and the elastic deformation. A clear difference between the two sensor types in terms of the error values could not be determined, which can be explained by the relatively strong aiding of the deformation variables  $\mathbf{b}$  by the comparatively accurate strain gauges. This resulted in a convergence of the estimated deformation variables of both configurations towards the simulated values, as shown in

Figure 11. Furthermore, the plot shows that an excitation of four involved unit deformations from Table 1 could be registered, showing frequency components of the corresponding eigenfrequencies. Although higher unit deformations have less impact on the total deflection, their estimation in time and frequency domain can give valuable insight into the structural behaviour.

Figure 10. Attitude  $\phi$  and pseudo-elastic deformation  $e$  with nearly identical results for “acc” and “gyro”.

Figure 11. Deformation variables  $\mathbf{b}$  [7].

For the scenario at hand a sample rate of 200 Hz of the IMUs and strain gauges turned out reasonable, whereas the distance measurements were sampled with 33.33 Hz due to technical limitations.

### 3.5 Modal characteristics of deformation variables

In addition to the conducted validation, the modal characteristics of the deformation variables are shortly investigated in this Subsection, following the state-of-the-art criteria in SHM from Section 1. For that, the single-sided amplitude spectrum of the deformation variables of the time interval from Figure 11 are plotted in Figure 12 for the “acc” and “gyro” configurations. To obtain the amplitude spectrum, the according signals are processed via FFT with a Hamming window and zero-padding to smooth the results. The eigenfrequencies of Table 1 are highlighted with red dotted lines, whereas the eigenfrequencies of the according unit deformations are marked with red dashed lines.

While all amplitudes show distinctive peaks at their according frequencies, a coupling of the different mode shapes is clearly seen, especially for the fourth unit deformation. This can be explained by the multiple nonlinearities of the system, like the Coulomb-Friction in the bearing [7]. Furthermore, the displacement function of Figure 9 has components of the fourth eigenfrequency during the analyzed time interval, which explains the strong coupling of the fourth deformation variable. To minimize the nonlinearities, the bearing was fixed in a

purely simulative model, forcing the attitude  $\phi = 0$  at all times. Subsequently, the sensor data were obtained by the FE simulation with the same input of Figure 9. For a short overview of the fundamental changes by the linearization of the system, the deformation variables  $b_3$  and  $b_4$  are plotted in Figure 13 for the same selected time interval. Due to the system changes, a combimode according to Figure 5 is no longer necessary. Therefore the deformation variables  $b_3$  and  $b_4$  of Figure 13 correspond to  $b_2$  and  $b_3$  of Figure 11.

Figure 12. Single-sided amplitude spectrum of the deformation variables from Figure 11.

Figure 13. Deformation variables  $b_3$  and  $b_4$  for a simulated linearized system due to a fixed bearing ( $\phi = 0$ ).

Analogously, the single sided amplitude spectrum with the adapted eigenfrequencies is shown in Figure 14. Figures 13 and 14 show that a decoupling of the included deformation variables can be observed. This indicates that if the unit deformations are set according to the mode shapes of the structure, the deformation variables reflect the associated modal parameters of natural frequencies and modal damping. The prerequisite for this is, however, that the system is linear or at least linear during certain time intervals.

Figure 14. Single-sided amplitude spectrum of the deformation variables  $b_3$  and  $b_4$  from Figure 13.

#### 4 EXPERIMENTAL APPROACH

This part of the study follows the experimental validation of IMMS [7], which was recapped in Section 3.4, to assess the

importance of strain gauges. It is based on a pendulum equipped with 18 PCBs (holding IMUs and ToFs) and 12 strain gauge arrays (wheatstone full bridge), which were placed to investigate different configurations. According to each chosen sensor configuration, the optimal set of sensors is selected according to the method of Effective Independence [4,23] out of the available test beam. In analogy to the conducted validation, the system is excited by the displacement function of Figure 9. Furthermore, only configurations with four additional unit deformations  $\Gamma = 4$  are investigated. Due to the similarity of the results from Figure 10 and 12, the configuration with four unit deformations and four peripheral gyroscopes, strain gauges and ToFs (gyro:  $\nu_s = \nu_\rho = \nu_\varepsilon = 4$ ) serves as a new benchmark (bm) to compare and evaluate the acquired results. The comparative parameters are the attitude angle  $\phi$  of the bearing, the pseudo-elastic deformation  $e$ , as well as the deformation variables  $b_1, \dots, b_4$ . Of these, the error values are evaluated by calculating the root mean square error (RMSE) according to

$$\Delta x_{\text{rmse}} = \sqrt{\frac{1}{N} \sum_{i=1}^N (x_{\text{bm},i} - \hat{x}_i)^2} \quad (21)$$

for an arbitrary variable  $x$  with  $N$  samples. Again, the sample rate of the input vector and strain gauges (if used) is set to 200 Hz, while the ToFs and the linear distance sensor are set to 33.33 Hz as in Section 3.4.

To evaluate the importance of strain gauges, or more precisely the accurate aiding of the deformation variables in IMMS applications, the experimental procedure is divided into the following steps:

- Removing strain gauges:  
In the first step, an accelerometer and gyroscope configuration with four peripheral inertial sensors and ToFs (acc/gyro:  $\nu_s = \nu_\rho = 4$ ,  $\nu_\varepsilon = 0$ ) are compared against the benchmark.
- Extended aiding by redundant ToFs:  
To compensate for omitted strain gauges, configurations with varying number of peripheral ToFs  $\nu_\rho = 4, \dots, 13$  and redundant inertial sensors  $\nu_s = 4, 5$  are created.
- Aiding with reduced number of strain gauges:  
A reduced number of strain gauges  $\nu_\varepsilon = 1, 2, 3$  are employed. Even though measurement Equation (19) becomes underdetermined in this case, aiding can still be employed via the EKF. Based on the preceding results, a reduced set of deformation variables  $\mathbf{b}_{\varepsilon, \text{aided}}$  is aided by the strain gauges, leaving a remaining set of unaided deformation variables  $\mathbf{b}_{\varepsilon, \text{unaided}}$ . So, the strain gauges are selected in such a way that their placement is optimal with respect to  $\mathbf{b}_{\varepsilon, \text{aided}}$ . If the unaided deformation variables  $\mathbf{b}_{\varepsilon, \text{unaided}}$  are already accurately estimated by e.g. redundant ToFs, their contribution to the bending strain can be subtracted from Equation (19). Accordingly, the matrix  $\mathbf{S}_\varepsilon''$  is separated, resulting in the adapted aiding Equation

$$\boldsymbol{\varepsilon} - \mathbf{S}_{\varepsilon, \text{unaided}}'' \cdot \mathbf{b}_{\varepsilon, \text{unaided}} = \mathbf{S}_{\varepsilon, \text{aided}}'' \cdot \mathbf{b}_{\varepsilon, \text{aided}} = \mathbf{h}(\mathbf{b}_{\varepsilon, \text{aided}}) \quad (22)$$

Consequently, the left-hand side of Equation (22) is the adapted bending strain, associated to the aided deformation variables. The resulting configurations are supplemented by additional ToFs  $\nu_\rho = 4, \dots, 13$ .

Depending on the degree of observability and quality of aiding measurements, a careful filter tuning of the EKF can become a crucial task [24]. This applies especially to the cases of removed and reduced strain gauges. In these cases, the settings of the EKF are adapted in an appropriate range. However, by applying extensive filter tuning, the results can be further improved for any of the applied methods.

## 5 RESULTS

The results are presented in the order as they are introduced in Section 4. The configurations in the following subsections will be either with accelerometers (acc) or gyroscopes (gyro) as peripheral input sensors. If not specified otherwise, the number of peripheral sensors are set according to the case with removed strain gauges ( $\nu_s = \nu_\rho = 4$ ,  $\nu_\varepsilon = 0$ ).

### 5.1 Removing strain gauges

To demonstrate a general effect on the estimated system states by removing the direct aiding of the deformation variables, the estimates of attitude  $\phi$  and pseudo-elastic deformation  $e$  are displayed on the left side of Figure 15 for the whole time interval of excitation.

Figure 15. Estimated attitude  $\phi$  and pseudo-elastic deformation  $e$  (left), and overscaled beam deformation at  $t = 230$  s (right) for the acc and gyro configuration without strain gauges, compared to bm.

Both configurations show a gradual drift from the bm-values for both selected parameters in opposite directions, meaning that the attitude diverges contrary to the pseudo-elastic deformation. This behavior becomes apparent by visualizing the deformed, suspended beams at time  $t = 230$  s on the right side of Figure 15. The graph displays the three configurations including the bearing  $D$  indicated by the black circle. The deformations of the beam are overscaled to emphasize the occurring effect. Additionally, the positions of the involved ToFs are marked by dots on the deformed structures. The tangent lines on the beam origin is plotted by dash-dotted lines, visualizing the attitude  $\phi$  against an imaginary vertical line. Although the positions of the ToFs are accurate within the limits of their sensor error, the bending lines show a clear mismatch with respect to the benchmark. Without direct aiding of the elastic deformations and restricted accuracy of the ToFs, the aiding Equation (18) allows seemingly arbitrary combinations of  $\phi$  and  $\mathbf{b}$  to match the distance measurements. Ultimately, an overestimated attitude is compensated by an underestimated deformation.

In analogy to Figure 11, the deformation variables are plotted for the same time interval of high dynamics in Figure 16. The first deformation variable  $b_1$  is estimated accurately. This can be explained by its comparatively high amplitude, which can be resolved by the distance measurements. The deformation variables  $b_2$  to  $b_4$  display the observed drift, however in phases of high amplitude the estimations are partially corrected towards the bm values (especially  $b_2$  and  $b_3$ ). Furthermore, the gyro configuration displays a smoother and qualitatively more accurate representation of the deformation variables than the acc configuration.

Figure 16. Estimated deformation variables  $b$  for the acc and gyro configurations without strain gauges, compared to bm.

### 5.2 Aiding by redundant ToFs

To compensate for the effects displayed in Figures 13 and 14, varying number of ToFs  $\nu_\rho = 4, \dots, 13$  are employed in combination with  $\nu_s = 4, 5$ . The RMSE of  $\phi$  and  $e$  according to Equation (21) is plotted in Figure 17 for the new acc and gyro configurations. With one additional ToF  $\nu_\rho = 5$ , both error values for both sensor types can be reduced significantly. By further increasing  $\nu_\rho$  the errors can be further decreased, however both error values converge towards a limit. Redundant inertial sensors show no positive effect, which is why they will be dismissed for further evaluation.

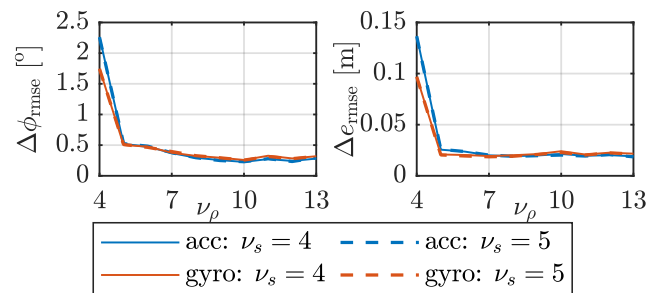

Figure 17. RMSE of the estimated attitude  $\phi$  and pseudo-elastic deformation  $e$  for the acc and gyro configuration with additional ToFs, compared to bm.

To show the reduced drift, the attitude  $\phi$  and pseudo-elastic deformation  $e$  for two exemplary acc and gyro configurations with  $\nu_\rho = 10$  is plotted in Figure 18 for the respective time interval. All cases display a satisfactory estimate, with the unwanted drift significantly reduced.

Accordingly, the deformation variables are displayed in Figure 19, analogously to Figure 16. While still displaying a reduced deviation,  $b_2$  to  $b_4$  are no longer shifted exclusively in

the negative direction. Again, the gyro configuration displays a superior behavior regarding the deformation variables.

Figure 18. Attitude  $\phi$  and pseudo-elastic deformation  $e$  for exemplary acc and gyro configurations with additional ToFs, compared to bm.

Figure 19. Estimated deformation variables  $b$  for the acc and gyro configurations with additional ToFs, compared to bm.

Overall, the negative effects of removing the direct aiding of the deformations can be significantly compensated (but not prevented by placing additional ToFs on the structure). This is because the aiding is carried out by Equation (18), which also involves deformation variables. However, the Equation is highly nonlinear, and the measurement accuracy and frequency are not sufficient to distinguish the low amplitudes of higher deformation variables. The higher accuracy of gyroscopes can be explained by the one-time integration of  $\mathbf{b}$  according to Equation (10) in comparison to the double integration of  $\ddot{\mathbf{b}}$  for accelerometers.

### 5.3 Aiding with reduced number of strain gauges

From Section 5.2 it becomes apparent that additional ToFs can not fully replace all removed strain gauges. However, it could be proven that the first deformation variable  $b_1$  is sufficiently aided by a system without strain gauges. Building on that, configurations with  $\nu_\epsilon = 1, 2, 3$  are created with the following specifications of Equation (22):

- $\nu_\epsilon = 1$ :  $\mathbf{b}_{\epsilon, \text{aided}} = [b_2 \ b_3 \ b_4]^T$ ,
- $\nu_\epsilon = 2$ :  $\mathbf{b}_{\epsilon, \text{aided}} = [b_3 \ b_4]^T$ ,
- $\nu_\epsilon = 3$ :  $\mathbf{b}_{\epsilon, \text{aided}} = [b_4]^T$ .

The selection is based on the observation that a set of aided variables equal to the number of the strain gauges used turned out to be beneficial. Nevertheless, aiding only one deformation variable was not feasible in the present setup.

In analogy to Figure 17, the RMSE of  $\phi$  and  $e$  are plotted in Figure 20 including the comparative values of the gyro configuration  $\nu_\rho = 10$  from the previous Section with a black, dash-dotted line. By employing at least one strain gauge, the

errors are comparable or better to the one achieved with additional ToFs. By increasing their number, the errors can be further decreased. Regarding the attitude and pseudo-elastic deformation, the gyro configurations with  $\nu_\epsilon = 2$  displays a superior behavior.

Figure 20. RMSE of the estimated attitude  $\phi$  and pseudo-elastic deformation  $e$  for the acc and gyro configuration with reduced number of strain gauges, compared to bm.

Assuming an adequate estimation of  $b_1$  and  $b_2$  according to the previous Sections, the RMSEs of  $b_3$  and  $b_4$  are further assessed in Figure 21. The errors decrease with increasing number of strain gauges, whereas the gyro configurations show superior characteristics for each number of strain gauges.

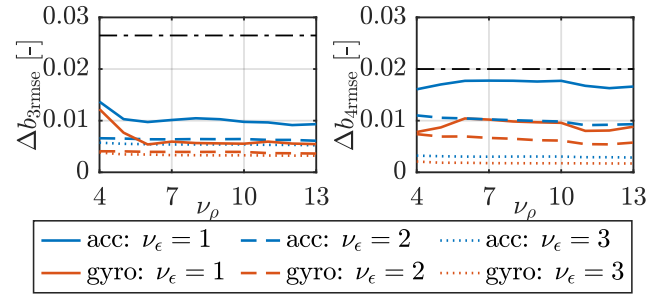

Figure 21. RMSE of the estimated deformation variables  $b_3$  and  $b_4$  for the acc and gyro configuration with reduced number of strain gauges, compared to bm.

The results suggest that a configuration with gyros and one strain gauge is comparable to accelerometers with two strain gauges and the same number of ToFs. Thus, the estimation of  $b_3$  and  $b_4$  for two corresponding configurations (acc:  $\nu_\epsilon = 2$ ,  $\nu_\rho = 10$ , gyro:  $\nu_\epsilon = 1$ ,  $\nu_\rho = 10$ ) is plotted in Figure 22 for the selected time interval. Despite comparable RMSE values, the estimation of the gyro configuration approaches the bm values significantly better.

Figure 22. Estimated deformation variables  $b_3$  and  $b_4$  for the acc and gyro configurations with reduced number of strain gauges.

Concerning redundant ToFs and a reduced number of strain gauges, an attitude error of around  $\Delta\phi \approx 0.3^\circ$  corresponds to a

deflection of roughly  $\Delta e \approx 0.02\text{m}$ , which matches the error values of Figures 15 and 18. This error is within the limit of accuracy of the measurements and modelling errors. The gain in accuracy of the deformation variables is the result of their direct aiding through Equation 22. Nevertheless, the attitude and total deflection can not be further improved. Although the error  $\Delta b_{i,\text{rmse}}$  is roughly the same according to Figure 21 for the inspected case in Figure 22, the latter shows a superior performance of the gyro configuration. This can be achieved, even with fewer strain gauges than the accelerometer case.

## 6 CONCLUSIONS

In this study, IMMS are presented as a comprehensive tool for determining rigid and elastic movements of a wide range of possible structures. In addition to a general categorization within possible SHM applications, the reduction of high-maintenance sensors like strain gauges was investigated.

This study showed that the direct aiding of the deformation variables is crucial for a precise estimation of the state variables. It could be shown that redundant position aiding via distance sensors can not fully compensate for a loss of strain sensors, but the negative effects could be largely reduced. However, a reduction in strain gauges is feasible without an essential loss in accuracy. This can be achieved by aiding larger deformations with the available distance sensors and small deformations by the accurate remaining strain gauges.

With respect to the deformation variables, it could be shown that modal parameters are represented within the time and frequency domain. Even for a nonlinear system, the deformation variables show distinctive frequency peaks at their corresponding eigenfrequencies of the linearization. A linear simulated system holds the potential to estimate the modal amplitudes in the time domain during operation. With current SHM approaches using modal parameters like eigenfrequencies, mode shapes, or damping ratios, the estimation of the deformation variables in time and frequency domain are potential parameters to be analyzed. Eigenfrequencies could thus be extracted from the frequency, while the modal damping ratio could be extracted from the time domain. Both time and frequency domain of the deformation variables could also serve as an input for Finite Element Model Updating to localize simulated damage mechanisms. Additionally, the estimated deformation and curvature of the structure can indicate changes in the mode shapes due to damage. Furthermore, the precise movement analysis can give insight into loads and strains during operation and can therefore be included in the estimation of the remaining service life. In conclusion, this study could show the existing potential of IMMS for SHM.

Next steps will apply artificial “damages” in the form of additional masses or stiffeners to the test beam. Subsequently, the influence of these structural changes on the behavior of the deformation variables in time and frequency domain will be analyzed according to the presented state-of-the-art methods in SHM. Further steps could replicate the linearized system with a fixed bearing and a sensitivity analysis regarding sensor requirements like accuracy and noise in combination with quantity. Ultimately, the benefit of IMMS in relation to state-of-the-art methods needs to be proven experimentally.

**ABSTRACT:** Solving structural dynamic equations is crucial for evaluating the reliability and safety of civil infrastructures such as bridges, airport runways and railways under various loads. Currently, the Neural Operator (NO) shows great potential in solving structural dynamic equations under various excitations and boundary conditions without retraining and are capable of zero-shot learning. However, there has been a dearth of research into providing prediction errors and explicit uncertainty quantification of the operator-learned model for computing structural responses in different data regimes. This research aims to approximate the solution operator of structural dynamic equations with uncertainty quantification. Deep evidential learning is introduced to establish the Evidential Neural Operator (ENO) and the epistemic uncertainty of structural responses can be obtained. An illustrative example is given in this paper, which shows that the E-NO model can effectively identify the well-prediction condition and the worse-prediction condition. This work can provide an end-to-end framework for building surrogate models of real-world structures, which can rapidly compute structural responses with uncertainty.

**KEYWORDS:** Structural Dynamics; Uncertainty Quantification; Evidential Deep Learning; Neural Operator.

## 1 INTRODUCTION

The uncertainty analysis of structural systems is the key to ensuring the safety and reliability of structural design. The conventional physical model-based method can analyze the uncertainty of the forward computation under random material parameters, geometric dimensions or external excitation through the probabilistic or non-probabilistic framework [1]. Probabilistic uncertainty analysis methods such as Monte Carlo simulation [2], [3], stochastic finite element method [4], [5], etc., statistically sample uncertainty propagation on uncertainty parameters by calculating models or conducting experiments. Non-probabilistic methods such as interval analysis [6], [7] and fuzzy theory [8], [9], which are different from probabilistic methods, are suitable for analyzing the epistemic uncertainty caused by a lack of knowledge in the absence of deterministic prior information. The above methods are versatile and flexible in the form of the model, but the calculation cost would greatly increase to conduct the uncertainty analysis of large-scale and high-dimensional structures.

With the breakthrough of deep learning technology, neural operators [10], [11] can effectively learn the global mapping relationship of complex systems, especially for the cross-resolution solution of high-dimensional and nonlinear problems, which reduces the computational cost compared with traditional physical modeling methods. Chawit et al. established the vehicle-bridge interactive neural operator as a surrogate model of the bridge structure, which can more accurately predict the structural response under different structural damage fields than the traditional finite element model [12]. Ding et al. solved the coupled differential equations of structural dynamics based on the physics-informed neural operator (PINO-CDE). Also, PINO-CDE provides a higher resolution for uncertain propagation tasks, which takes less

than a quarter of the computing time compared to the probability density evolution method [13].

However, the neural operator mapping process is nonlinear and non-intuitive. The results are affected by multiple sources of uncertainty, such as aleatoric uncertainty and epistemic uncertainty [14], [15]. Most of the existing studies focus on the probability distribution of the output results of neural operators, but it is difficult to distinguish the sources of quantitative uncertainty. This fuzziness may lead to misjudgment in practical engineering based on computing results. While deep evidential learning provides a feasible path for aleatoric and epistemic uncertainty qualification of regression problems [16]. Therefore, how to integrate deep evidential learning and neural operators to build an efficient and interpretable computational uncertainty framework for dynamic structures is worth exploring.

In this work, we propose an evidential neural operator, extending evidential deep learning to a more flexible and complex neural network like the Fourier neural operator. For parametric structural dynamic systems with stochastic structural parameters and load excitation, ENO can quantitatively distinguish aleatoric uncertainty and epistemic uncertainty in the forward computation without retraining. The multi-task regularizer is introduced in ENO to improve adaptability to high-dimensional scenarios and complex structural systems, by flexibly controlling the weights of regularizer. A single-degree-of-freedom system is provided as a numerical example to verify the accuracy of uncertainty estimation and quantization distinction.

## 2 THEORETICAL BASIS

### 2.1 Fourier Neural Operator

Fourier Neural Operator (FNO) can capture high-frequency characteristics of dynamic systems by Fast Fourier Transform

and spectrum convolution operation and is suitable for solving structural vibration differential equations to simulate the dynamic behavior of structural systems.

Besides, performing convolution in Fourier space greatly reduces the computational complexity. For a single hidden layer (1), the Fourier neural operator utilize the kernel-integral operator, extend deep neural networks to infinite dimensions:

$$(N_l V)(x) = \sigma(A_l V(x) + B_l(x) + \int_D K_l(x, y) V(y) dy) \quad (1)$$

Due to,

$$K_l(x, y) = K_l(x - y) \quad (2)$$

$$\int_D K_l(x - y) V(y) dy = K_l \times V \quad (3)$$

Using the Fourier transform result in (4):

$$K_l \times V = f^{-1}(f(K) \cdot f(V)) \quad (4)$$

Hence, the computational complexity can be reduced from  $O(N^2)$  to  $O(N \log(N))$ . FNO shows great potential for fast and accurate computation of oscillatory differential equations.

## 2.2 Evidential Neural Operator

The sources of uncertainty can be divided into aleatoric uncertainty and epistemic uncertainty. Evidential theory assumes that the prediction target  $Z_i$  can be independently sampled from the Gaussian distribution. Then, a probabilistic estimate of its mean and variance is required.

The normal-inverse-gamma (NIG) prior distribution is introduced in evidential regression [16]. The mean  $\mu$  is assumed to follow a Gaussian distribution, and the variance  $\sigma$  is assumed to follow an inverse gamma distribution. By marginalizing  $\mu$  and  $\sigma$ , the model evidence can be expressed as a Student-t distribution (5):

$$p(z_i | \theta) = St(z_i; \gamma, \frac{(1+\tau)\beta}{\tau\alpha}, 2\alpha) \quad (5)$$

where  $\theta$  represents the combination of parameters of the NIG distribution.  $\gamma$  represents the expectation of the mean  $\mu$ .  $\tau$  is the precision parameter of the Gaussian distribution.  $\alpha$  and  $\beta$  are the shape parameters of the inverse gamma distribution.

Combining the high-dimensional computing capability of FNO and the ability of NIG high-order distribution for capturing data diversity and uncertainty. The evidential neural operator is proposed to convert the model output into four parameters of NIG distribution. The loss function (6) of the evidential neural operator is designed for uncertainty sources, which can be divided into two parts: negative log-likelihood loss and evidence regularizer.

$$\mathcal{L}_{ENO} = \mathcal{L}_{NLL} + \sum_{i=1}^n \lambda_i \mathcal{L}_{REGi} \quad (6)$$

where,

$$\mathcal{L}_{NLL} = \frac{1}{2} \log\left(\frac{\pi}{\tau}\right) - \alpha \log(\phi) + \left(\alpha + \frac{1}{2}\right) \log((z_i - \gamma)^2 \tau + \phi) + \log\left(\frac{\Gamma(\alpha)}{\Gamma(\alpha + \frac{1}{2})}\right)$$

$$\mathcal{L}_{REGi} = |z_i - \gamma| \cdot (2\tau + \alpha)$$

where,  $\phi = 2\beta(2\tau + \alpha)$ .  $n$  represents the number of regularizers for different outputs.

In this work, ENO adds multi-task regularization to ensure that each task has independent error and evidence constraints, and can better adapt to multi-task learning and complex scenarios by flexibly controlling regularization weights. The data normalization module is incorporated into the training process to normalize and denormalize the dataset to address the potential training instability and gradient explosions arising from differences in the scale of output variables.

## 3 ILLUSTRATIVE EXAMPLE

For validating the effectiveness of ENO, a single degree of freedom random vibration equation (7) with harmonic excitation is used as an example to solve the forward uncertainty of response prediction:

$$M\ddot{u} + C\dot{u} + Ku = A \sin(wt) \quad (7)$$

where,  $M$  is mass,  $M = 1\text{kg}$ .  $C$  is damping and  $K$  is stiffness.  $A$  represents amplitude and  $w$  represents the frequency of the harmonic force.  $u$ ,  $\dot{u}$ ,  $\ddot{u}$  represent the displacement, velocity, and acceleration, respectively.

$K$ ,  $A$ , and  $w$  are randomly sampled with a uniform distribution. The sampling interval of stiffness is  $[200, 300]$  N/m. The sampling interval of amplitude and frequency are  $[50, 100]$  N and  $[10, 45]$  rad/s, respectively. The probability density surface diagrams of three stochastic variables are shown in Figure 1. The Newmark- $\beta$  integral algorithm is used to solve equation (7) and generate the datasets. The proportions of the training set, verification set and test set are 70%, 20% and 10%, respectively. The network parameters, such as convolutional layer depth  $D_{\text{conv}}$ , convolutional layer width  $W_{\text{conv}}$ , fully connected layer depth  $D_{\text{fc}}$  and width  $W_{\text{fc}}$  of FNO were optimized by using the Bayesian optimization algorithm. The optimal network parameters were determined as follows:  $D_{\text{conv}}=4$ ,  $W_{\text{conv}}=32$ ,  $D_{\text{fc}}=3$ , and  $W_{\text{fc}}=64$ .

The ENO model is implemented in PyTorch and the Fourier modes of spectral convolution layers are 26. The weight parameters of the loss item are:  $\lambda_1 = 1$ ,  $\lambda_2 = 2$ ,  $\lambda_3 = 2$ . The total number of epochs is 300 and the Adam optimizer was used with a learning rate of  $10^{-3}$ .

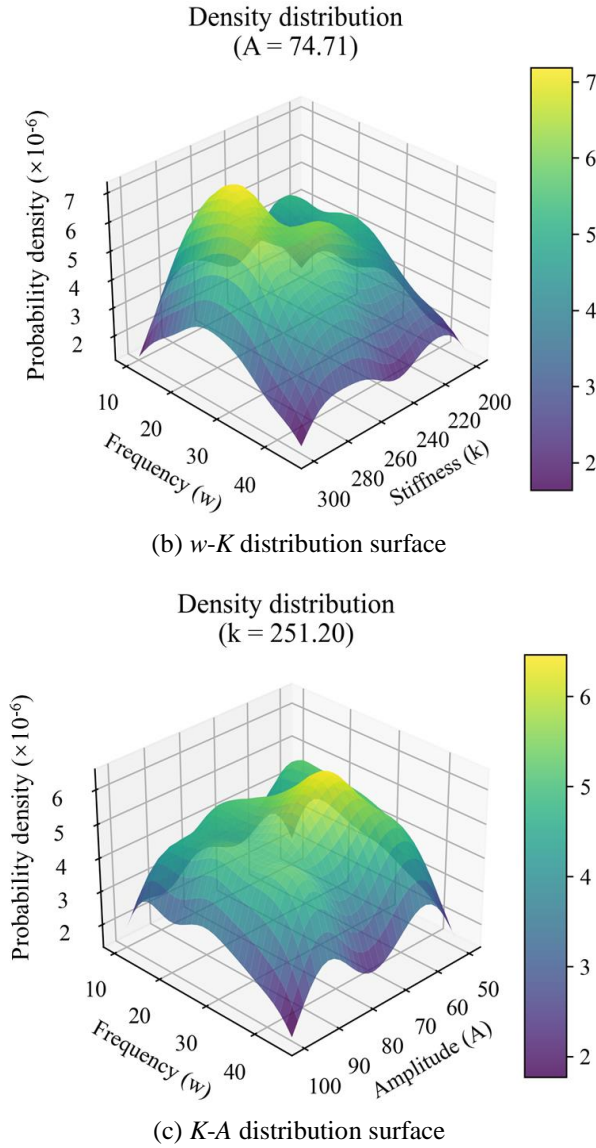

Figure 1. Probability density surfaces of stochastic variables.

The ENO model is validated against the state-of-the-art Deep Ensemble model presented in [17]. The baseline model is also embedded in the FNO framework (FNO-DE) to conduct ablation experiments, and the network parameters are consistent with those adopted by ENO. FNO-DE consists of five independently trained models with identical architecture but different random initializations. The evaluation metrics applied Root Mean Square Error (RMSE), Empirical Coverage Probability (ECP) and Pearson Correlation Coefficient ( $R_{pr}$ ). RMSE can evaluate the error level between the predicted mean and the ground truth. ECP monitors the proportion of samples falling into the predicted confidence interval to the total number of samples. In this work, 95% confidence is considered, and the ideal value of ECP should be close to 0.95. Besides, the Pearson Correlation Coefficient can evaluate the correlation between prediction error and uncertainty.

#### 4 RESULTS AND DISCUSSION

For solving the single-degree-of-freedom vibration equation, the ENO model performance was first tested by sampling test sets in the interval. The outputs of displacement, velocity and

acceleration responses and their corresponding uncertainties are shown in Figure 2. Due to the high cognition level of the tested model within the interval, it can be seen that the aleatoric and epistemic uncertainty are both small, which are lower than  $10^1$ .

(a) Uncertainty prediction of the displacement

(b) Uncertainty prediction of the velocity

(c) Uncertainty prediction of the acceleration

Figure 2. Uncertainty prediction in the distribution (ENO).

The out-of-distribution test evaluates the zero-shot learning ability and generalization of the ENO model. The results of out-of-interval testing are shown in Figure 3. The epistemic

uncertainty of the model has increased by 20~40%, compared with that in distribution testing. And the epistemic uncertainty is always greater than the aleatoric uncertainty of the raw data, due to no extra noise added in the dataset for this illustrative case.

(a) Uncertainty prediction of the displacement

(b) Uncertainty prediction of the velocity

(c) Uncertainty prediction of the acceleration

Figure 3. Uncertainty prediction out of distribution (ENO).

The performance comparison between the ENO model and the FNO-DE model is shown in Table 1. The ENO model can achieve higher fitting accuracy than the FNO-DE model. The RMSE of ENO is less than that of FNO-DE, especially when

ENO is tested out of distribution. ENO has better generalization performance. In terms of uncertainty prediction, FNO-DE remains competitive in in-distribution testing, and the empirical coverage probability of both ENO and FNO-DE is relatively close to the nominal values. However, the uncertainty estimated by ENO shows a stronger correlation with prediction errors ( $R_{pr} \sim 0.86$ ) in interpreting out-of-domain data.

Table 1. Compared the metrics of ENO and FNO-DE models.

In distribution			Out of distribution		
Metrics	ENO	FNO-DE	Metrics	ENO	FNO-DE
RMSE	<b>0.35</b>	0.38	RMSE	<b>2.22</b>	2.41
ECP	<b>1.0</b>	1.0	ECP	<b>1.0</b>	0.82
$R_{pr}$	0.70	<b>0.79</b>	$R_{pr}$	<b>0.86</b>	0.67

## 5 CONCLUSION

In this paper, a novel evidential neural operator is proposed, which cooperates with the basic principle of deep evidential learning and the high-dimensional nonlinear mapping capability of the Fourier neural operator. ENO provides a scientific machine learning framework for the uncertainty quantification for the forward computation of structural vibration equations. This work solves the vibration equation of a single degree of freedom as a numerical example, indicating that the model has higher epistemic uncertainty when tested outside the interval. Compared to the evaluating metrics with the art-of-state ensemble model, the ENO shows superior uncertainty calibration and fitting accuracy in out-of-domain testing. Future works would consider the effect of data noise on the uncertainty qualification and expand the ENO to a more complex structural system.

## APPENDIX: PREDICTION RESULTS OF FNO-DE

### A-1: Test results of FNO-DE within the interval

The test results of the baseline model (FNO-DE) within the sampling interval are also shown in Figure 4. The predicted responses are generally consistent with the ground truth, indicating the FNO-DE can capture the dynamic change trend of the displacement and its derivative. The regions with large uncertainties are mainly concentrated at the boundaries of time, such as around  $t = 0$  and  $t \approx 0.5$ , while the uncertainty distribution is narrow within the time interval. This demonstrates that the FNO-DE model is quite sensitive and can not comply well with the boundary conditions.

(a) Uncertainty prediction of the displacement

(b) Uncertainty prediction of the velocity

(c) Uncertainty prediction of the acceleration

Figure 4. Uncertainty prediction in the distribution (FNO-DE).

#### A-2: Test results of FNO-DE out of the interval

Outside the sampling interval (Figure 5), the deviation between the model prediction results and the Ground Truth increases, while the uncertainty region (green shadow) expands significantly, especially around the time period  $t = 0.4$  s, where the confidence interval of displacement  $u(t)$  increases from about  $\pm 0.1$  m to  $\pm 0.2$  m. This shows that the prediction confidence of FNO-DE for unseen data is greatly reduced.

(a) Uncertainty prediction of the displacement

(b) Uncertainty prediction of the velocity

(c) Uncertainty prediction of the acceleration

Figure 5. Uncertainty prediction out of the distribution (FNO-DE).

**ABSTRACT:** Describing the damage initiation and development of engineering structures during strong dynamic loadings such as earthquake is one of the most important topics in structural condition monitoring and identification. Structural nonlinear restoring force (NRF) can not only directly describe the initiation and development process of nonlinear behavior of the structure during strong dynamic loadings but also can be used to evaluate the energy dissipation of structural members or substructures. However, it is hard to measure structural dynamic responses at all degree of freedoms (DOFs) of a structure in practice, and to model the NRF with an accurate parametric mathematical model in advance due to the variability and individuality of structural materials and types. In this study, a Chebyshev polynomial model as a nonparametric model is employed to model the NRF of a structure and structural stiffness, damping, mass and NRF are identified based on the extended Kalman particle filter (EKPF) algorithm by using acceleration measurements at limited DOFs during the known external excitation. Then, two multi-degree-of-freedom (MDOF) numerical models equipped with different types of magnetorheological (MR) dampers are used as numerical examples to validate the performance of the proposed approach. Identified results show that the proposed method is effective for identifying the nonlinear MDOF structures with different nonlinearity with limited noise-polluted acceleration measurements.

**KEY WORDS:** Nonlinear restoring force; Extended Kalman particle filter; nonparametric identification; Chebyshev polynomial; MR damper.

## 1 INTRODUCTION

During the service of engineering structures, when subjected to severe loads, the structural characteristics may change abruptly or gradually, resulting in stiffness deterioration and increased damping. The problem of precisely detecting parameter changes has piqued civil engineering researchers' interest. Understanding changing structural parameters is crucial for designing, maintaining, and reinforcing structures, as well as selecting post-disaster rescue routes. When civil engineering structures are subjected to extraordinarily significant external excitations, such as earthquakes on buildings or heavy cars on bridges, they frequently exhibit nonlinear behavior.

Identification of structural parameters and nonlinear restoring force (NRF) of nonlinear structural systems using partial acceleration measurements from structural health monitoring (SHM) is crucial for structural condition assessment and damage identification[1, 2]. In the past decades, many researchers have developed many parameters and NRF identification methods of nonlinear system. It is difficult to measure the acceleration responses of all degrees of freedom in practical engineering, some methods based on Kalman filter (KF)[3, 4], extended Kalman filter (EKF)[5, 6], unscented Kalman filter (UKF) [7-9], and particle filter (PF) [10, 11] were proposed to tackle the problem. However, conventional methods are only suitable for nonlinear hysteresis model parameters that are known. Due to the diversity and individuality of nonlinear behaviors, it is crucial to propose a general nonparametric identification method for nonlinear behaviors that does not rely on nonlinear hysteresis models.

The idea of nonparametric identification of nonlinear behavior was first proposed by Masri and his collaborators[12,

13]. Based on the equivalent linear theory and least squares method, identified methods of the structural nonlinear restoring force were proposed by Xu et al. [14, 15] using external excitation and complete dynamic response information and verified the feasibility of the proposed method through dynamic test data of a multi-degree-of-freedom shear frame model equipped with a magnetorheological (MR) damper. Xu and his cooperators proposed nonparametric identification method of the NRF in the presence of the known or unknown input, where the NRF was expressed using different polynomial models[16-19]. Some researchers regarded the nonlinear restoring force as an unknown virtual input, proposing different NRF identification methods[20-22]. The effectiveness of the proposed method was verified by numerical simulation and experiment. However, as far as the author knows, there is no extended Kalman particle filter (EKPF) method that is suitable for nonparametric identification of structural nonlinear behavior under non-Gaussian measurement noise without the need of the known parametric model of nonlinear behavior.

Since the standard PF algorithm takes the transition probability of the system state as the importance density function, it does not use the updated observations. Therefore, the generated particle samples are concentrated at the tail of the posterior probability distribution, resulting in a large randomness in the selection of particles, which affects the filtering results. When there is a peak in the likelihood distribution, the prediction state is distributed at the tail of the likelihood distribution, which has a particularly serious impact on the filtering accuracy. The EKPF uses EKF as the posterior probability density function, which solves the problem of particle degradation in PF algorithm and improves the filtering

accuracy. For the EKF part of EKPF, when Kalman filter is applied in practice, model error, noise error and calculation error may cause the prediction error covariance matrix and gain matrix to weaken the modified state estimation with the increase of iteration times, which leads to filter divergence. Therefore, the fading memory filtering (MF) technology can be used for EKF to increase the proportion of new data, reduced the proportion of old data and the negative impact of old data on filtering [16].

In this paper, a model-free identification method for structural parameters and nonlinear restoring force under limited acceleration observation is proposed by using EKPF algorithm. Based on the equivalent linear theory and EKPF algorithm, the structural parameters, unknown dynamic response measurements and nonlinear locations are identified under limited acceleration observations. Based on the identification value, the Chebyshev polynomial model is used to characterize the nonlinear restoring force of the structure, and the nonparametric identification of the NRF is realized. To verify the feasibility of the proposed method, two four-degree-of-freedom shear frame models are established, and MR dampers with different numbers and different parameter models are introduced to simulate the nonlinear behavior of shear frame structures. Considering the influence of measurement noise in the observed acceleration signal, the structural stiffness, damping coefficient, mass, unknown dynamic response and NRF are identified. The feasibility of the proposed method is verified by comparing the identification results with the real values.

## 2 EXTENDED KALMAN PARTICLE FILTERING ALGORITHM

### 2.1 The state-space equation

In general, the nonlinear dynamic system of structures in civil engineering can be described as,

$$\begin{cases} \mathbf{x}_k = f(\mathbf{x}_{k-1}) + \mathbf{r}_{k-1} \\ \mathbf{y}_k = h(\mathbf{x}_k) + \mathbf{v}_k \end{cases} \quad (1)$$

where, the function  $f(\square)$  and  $h(\square)$  represent the state transition function and the measurement model function of the system respectively.  $k$  is the number of time steps,  $\mathbf{x}_k$  is the state value of step  $k$ ,  $\mathbf{y}_k$  is the observation value of step  $k$ ,  $\mathbf{r}_k$  is the process noise of step  $k$ ,  $\mathbf{v}_k$  is the observation noise of step  $k$ . Equation (1) describes the recursive relationship between the structural state vector and the structural response over time.

### 2.2 Bayesian theorem and Monte Carlo simulation

For the state space equation assumed by the formula (1), let  $\mathbf{x}_{0:k} = \{\mathbf{x}_0, \mathbf{x}_1, \dots, \mathbf{x}_k\}$ ,  $\mathbf{y}_{1:k} = \{\mathbf{y}_1, \mathbf{y}_2, \dots, \mathbf{y}_k\}$ , and given  $\mathbf{x}_{0:k}$ , when the measurement sequence  $\mathbf{y}_k$  is independent of each other, the prediction and update can be written recursively by the Bayesian formula,

$$p(\mathbf{x}_k | \mathbf{y}_{1:k-1}) = \int p(\mathbf{x}_k | \mathbf{x}_{k-1}) p(\mathbf{x}_{k-1} | \mathbf{y}_{1:k-1}) d\mathbf{x}_{k-1} \quad (2)$$

$$p(\mathbf{x}_k | \mathbf{y}_{1:k}) = \frac{p(\mathbf{y}_k | \mathbf{x}_k) p(\mathbf{x}_k | \mathbf{y}_{1:k-1})}{\int p(\mathbf{y}_k | \mathbf{x}_k) p(\mathbf{x}_k | \mathbf{y}_{1:k-1}) d\mathbf{x}_k} \quad (3)$$

For nonlinear models, the above analytical formulas are often unable to be obtained, and it is also very difficult to solve them

integrally. Therefore, the Monte Carlo simulation is considered to realize the recursion of Bayesian filter. The Monte Carlo simulation regards the problem to be solved as a random variable. By establishing a probability model and sampling a large number of samples, the integral value is regarded as the mathematical expectation of the random variable, and then the problem to be solved is estimated. That is to say, for the integrand  $f(x)$ , it can be decomposed into the product of the state variable  $g(x)$  and its probability density function  $p(x)$ , then the integral of  $f(x)$  can be regarded as the mathematical expectation of  $g(x)$ .

### 2.3 The sequential importance sampling

According to the Monte Carlo simulation, if we can sample from the posterior probability density function  $p(\mathbf{x}_{0:k} | \mathbf{y}_{1:k})$

and get the sample set  $\{\mathbf{x}_{0:k}^{(i)}, \omega_k^{(i)}\}_{i=1}^N$ , then  $p(\mathbf{x}_{0:k} | \mathbf{y}_{1:k})$  can be approximated by the sum of discrete samples, that is, the approximate solution formula of  $g(\mathbf{x}_{0:k})$  can be written as,

$$E(g(\mathbf{x}_{0:k})) = \sum_{i=1}^N \omega_k^{(i)} g(\mathbf{x}_{0:k}^{(i)}) \quad (4)$$

However, in practice, it is very difficult to extract samples from the posterior probability distribution. Therefore, the importance sampling method is introduced to extract samples from the importance density function  $q(\mathbf{x}_k^{(i)} | \mathbf{x}_{k-1}^{(i)}, \mathbf{y}_k)$ . Then the mathematical expectation of  $g(x)$  can be written as,

$$\begin{aligned} E[g(\mathbf{x}_{0:k})] &= \int g(\mathbf{x}_{0:k}) \frac{p(\mathbf{x}_{0:k} | \mathbf{y}_{1:k})}{q(\mathbf{x}_{0:k} | \mathbf{y}_{1:k})} q(\mathbf{x}_{0:k} | \mathbf{y}_{1:k}) d\mathbf{x}_{0:k} \\ &= \sum_{i=1}^N \hat{\omega}_k^{(i)} g(\mathbf{x}_{0:k}^{(i)}) \end{aligned} \quad (5)$$

where  $\hat{\omega}_k^{(i)}$  is the normalized weight, which can be written as,

$$\hat{\omega}_k^{(i)} = \frac{\omega_k^{(i)}}{\sum_{j=1}^N \omega_k^{(j)}} \quad (6)$$

For the weight  $\omega_k^{(i)}$  of each particle, it can be recursively expressed as,

$$\begin{aligned} \omega_k^{(i)} &= \omega_{k-1}^{(i)} \frac{p(\mathbf{x}_{0:k} | \mathbf{y}_{1:k})}{q(\mathbf{x}_{0:k} | \mathbf{y}_{1:k})} \\ &= \omega_{k-1}^{(i)} \frac{p(\mathbf{y}_k | \mathbf{x}_k^{(i)}) p(\mathbf{x}_k^{(i)} | \mathbf{x}_{k-1}^{(i)})}{q(\mathbf{x}_k^{(i)} | \mathbf{x}_{k-1}^{(i)}, \mathbf{y}_k)} \end{aligned} \quad (7)$$

Accordingly, the implementation steps of the PF algorithm are as follows,

(1) By sampling from the known prior probability distribution  $p(\mathbf{x}_0)$ , the initial sample  $\{\mathbf{x}_{0:k}^{(i)}, \omega_k^{(i)}\}_{i=1}^N$  is obtained, where  $\{\omega_k^{(i)}\}_{i=1}^N = 1/N$ .

(2) A new particle set  $\{\mathbf{x}_k^{(i)}\}_{i=1}^N$  is obtained by sampling from the importance density function  $q(\mathbf{x}_k | \mathbf{x}_{k-1}^{(i)}, \mathbf{y}_k)$ .

(3) Calculating the weight of each particle according to Equation (7).

$$(4) \text{ Normalized weights, } \left\{ \hat{\omega}_k^{(i)} = \omega_k^{(i)} / \sum_{j=1}^N \omega_k^{(j)} \right\}_{i=1}^N.$$

(5)  $k=k+1$ , and return to step (1) to continue the iteration.

#### 2.4 Resampling

Because the variance of the particle weight increases with time, the particle degradation in the basic PF is inevitable. After multiple iterations, most of the particle weights are so small that they can be ignored, while the weights of individual particles are too concentrated. To improve this situation, the resampling method is used to discard the particles with small weights, copy the particles with large weights and make them have equal weights, so as to reduce the phenomenon of particle degradation. The system resampling method is adopted to avoid particle degradation in this paper.

#### 2.5 EKF importance sampling density

At time  $k$ , according to the new observation, the EKF algorithm is used to calculate the particle mean estimation  $\bar{\mathbf{x}}_k^i$  and variance estimation  $\hat{\mathbf{P}}_k^{(i)}$ , and then the particles are extracted from the approximate Gaussian distribution  $N(\bar{\mathbf{x}}_k^{(i)}, \hat{\mathbf{P}}_k^{(i)})$ . This method of using EKF to generate importance density function is called EKPF. For a state vector  $\mathbf{X}(t)$ , the specific algorithm is as follows,

(1) The initial particle samples are obtained by sampling from the known prior probability distribution.

(2) The initial particles are updated by EKF,

$$\tilde{\mathbf{x}}_{k+1|k}^{(i)} = \mathbf{f}(\hat{\mathbf{x}}_{k|k}^{(i)}, 0) \quad (8)$$

$$\mathbf{P}_{k+1|k}^{(i)} = \Phi_{k+1|k}^{(i)} \mathbf{P}_{k|k}^{(i)} (\Phi_{k+1|k}^{(i)})^T \quad (9)$$

$$\mathbf{K}_{k+1}^{(i)} = \mathbf{P}_{k+1|k}^{(i)} (\mathbf{H}_{k+1}^{(i)})^T \left( \mathbf{H}_{k+1}^{(i)} \mathbf{P}_{k+1|k}^{(i)} (\mathbf{H}_{k+1}^{(i)})^T + \mathbf{R}_{k+1} \right)^{-1} \quad (10)$$

$$\hat{\mathbf{x}}_{k+1|k+1}^{(i)} = \tilde{\mathbf{x}}_{k+1|k}^{(i)} + \mathbf{K}_{k+1}^{(i)} \left[ \mathbf{y}_{k+1} - \mathbf{h}(\hat{\mathbf{x}}_{k+1|k}^{(i)}, 0) \right] \quad (11)$$

$$\mathbf{P}_{k+1|k+1}^{(i)} = (\mathbf{I} - \mathbf{K}_{k+1}^{(i)} \mathbf{H}_{k+1}^{(i)}) \mathbf{P}_{k+1|k}^{(i)} \quad (12)$$

where  $\Phi_{k+1|k}^{(i)}$  is the state transition matrix,  $\mathbf{H}_{k+1}^{(i)}$  is the observation coefficient matrix, there are,

$$\Phi_{k+1|k}^{(i)} = \frac{\partial \mathbf{f}_k(\mathbf{X}_k^{(i)}, \mathbf{y}_k)}{\partial \mathbf{x}_k^{(i)}} \bigg|_{\mathbf{x}_k^{(i)} = \hat{\mathbf{x}}_{k|k}^{(i)}} \quad (13)$$

$$\mathbf{H}_{k+1}^{(i)} = \frac{\partial \mathbf{h}_k(\mathbf{x}_{k+1|k}^{(i)}, 0)}{\partial \mathbf{x}_k^{(i)}} \bigg|_{\mathbf{x}_k^{(i)} = \hat{\mathbf{x}}_{k+1|k}^{(i)}} \quad (14)$$

Considering the cause of filtering divergence and the infinite growth of Kalman filter memory, the data error at the previous moment will cause the error covariance matrix  $\mathbf{P}$  and the gain matrix  $\mathbf{K}$  to lose the ability to correct the state estimation with the iteration, resulting in filtering divergence. To increase the weight of new data and relatively weaken the influence of old data, a fading factor is introduced to reduce the negative impact of old data on filtering estimation. The formula (9) is modified as follows,

$$\mathbf{P}_{k+1|k}^{(i)} = \Phi_{k+1|k}^{(i)} \mathbf{P}_{k|k}^{(i)} (\Phi_{k+1|k}^{(i)})^T S \quad (15)$$

Among them, the forgetting factor  $\lambda = 1/S$ , the literature suggests  $0.95 < \lambda < 1.0$ , then the weighted weight of the fading memory is  $1.0 < S < 1.05$ .

(3) Complete the sequential importance sampling with reference to Section 2.3.

(4) Complete system resampling with reference to Section 2.4.

### 3 PARAMETER-FREE RESTORING FORCE IDENTIFICATION METHOD BASED ON EKPF AND CHEBYSHEV POLYNOMIAL

#### 3.1 The equivalent linearization theory

For a multi-degree-of-freedom nonlinear dynamic system, the equation of motion can be written as,

$$\mathbf{M}\ddot{\mathbf{x}}(t) + \mathbf{K}\mathbf{x}(t) + \mathbf{C}\dot{\mathbf{x}}(t) + \mathbf{f}_{non}(t) = \mathbf{f}(t) \quad (16)$$

In the formula,  $\mathbf{M}$ ,  $\mathbf{K}$  and  $\mathbf{C}$  are the mass, stiffness and damping matrices of the system respectively.  $\ddot{\mathbf{x}}(t)$ ,  $\mathbf{x}(t)$  and  $\dot{\mathbf{x}}(t)$  are the acceleration, displacement and velocity vectors respectively.  $\mathbf{f}_{non}(t)$  is the nonlinear restoring force vector provided by the nonlinear element, and  $\mathbf{f}(t)$  is the excitation vector the system.

The dynamic equation of the equivalent linear system is,

$$\mathbf{M}_E \ddot{\mathbf{x}}(t) + \mathbf{C}_E \dot{\mathbf{x}}(t) + \mathbf{K}_E \mathbf{x}(t) = \mathbf{f}(t) \quad (17)$$

where  $\mathbf{M}_E$ ,  $\mathbf{C}_E$  and  $\mathbf{K}_E$  represent the equivalent linear mass, equivalent linear damping and equivalent linear stiffness, respectively. Since the structural mass does not change during the nonlinear development process,  $\mathbf{M}_E$  can be regarded as the identification value of the mass, that is, and  $\mathbf{M}$  is numerically equal  $\mathbf{M}_E$ . The nonlinear restoring force of the structure in the equation (17) will be reflected in the parameters  $\mathbf{C}_E$  and  $\mathbf{K}_E$  of the equivalent linear system, which is,

$$\mathbf{R}_{non}(t) = \mathbf{C}_E \dot{\mathbf{x}}(t) + \mathbf{K}_E \mathbf{x}(t) \quad (18)$$

#### 3.2 Model-free nonlinear restoring force representation based on Chebyshev polynomial

The Chebyshev polynomial is one of the most important function sets in mathematics. Any continuous function can be represented by a set of orthogonal function sequences on  $[-1, 1]$ , the expression is as shown in the literature[16].

Therefore, the restoring force of the nonlinear element between the two degrees of freedom of the structure can be expressed by a set of relative velocity and relative displacement between the stories,

$$\mathbf{R}_{i,i-1}^{non}(t) \approx \sum_{a=0}^A \sum_{b=0}^B c_{i,i-1,a,b}^{non} C_a(v'_{i,i-1}) C_b(s'_{i,i-1}) \quad (19)$$

where  $\mathbf{R}_{i,i-1}^{non}(t)$  denotes the NRF of the nonlinear member between the  $i$ -th and  $(i-1)$ -th degrees of freedom of the system, and  $c_{i,i-1,a,b}^{non}$  denotes the coefficient of the Chebyshev polynomial.  $C_a(v'_{i,i-1})$  and  $C_b(s'_{i,i-1})$  are Chebyshev polynomials.  $A$  and  $B$  are integers, and their values are related to the degree of nonlinearity of the structure. In this paper,

A+B=4.  $v'_{i,i-1}$  and  $s'_{i,i-1}$  denote the relative velocity and relative displacement between the  $i$ -th and  $i-1$ th degrees of the normalized system, respectively.

$$v'_{i,i-1} = \frac{v_{i,i-1} - \min(v_{i,i-1})}{\max(v_{i,i-1}) - \min(v_{i,i-1})} \quad (19)$$

$$s'_{i,i-1} = \frac{s_{i,i-1} - \min(s_{i,i-1})}{\max(s_{i,i-1}) - \min(s_{i,i-1})} \quad (20)$$

Among them,  $v_{i,i-1}$  and  $s_{i,i-1}$  are the relative velocity and relative displacement between the layers of the structure before normalization.

From Eqs. (17) and (18), the motion equation of the  $i$ -th DOF of the structure can be discretized as,

$$m_i \ddot{x}_i + \sum_{a=0}^A \sum_{b=0}^B c_{i,i-1,a,b}^{\text{non}} v_{i,i-1}^a s_{i,i-1}^b + \sum_{a=0}^A \sum_{b=0}^B c_{i,i-1,a,b}^{\text{non}} v_{i,i+1}^a s_{i,i+1}^b = f_i(t) \quad (21)$$

Therefore, the nonlinear member is introduced into the structure. After the complete structural parameters and dynamic response are obtained by the EKPF method, the Legendre polynomial coefficients are identified by the least square method, and the total nonlinear restoring force  $R_{\text{non}}(t)$  of the structure can be calculated. Finally, according to Eqs. (16) to (18), the damping force provided by the nonlinear member can be inversely derived.

## 4 NUMERICAL VERIFICATION

### 4.1 Example 1

To verify the effectiveness of the proposed method, numerical simulations are carried out to validate the four-degree-of-freedom shear-type frame with MR damper as an example. The nonlinear behavior of the structure is simulated by introducing the MR damper in the four-story concentrated mass shear-type frame shown in Figure 1. The mass of each layer of the structure  $m_i=150\text{kg}$ , the inter-story stiffness  $k_i=2.0 \times 10^5 \text{N/m}$ , and the damping coefficient  $c_i=160 \text{N} \cdot \text{s/m}$ , where  $i=1, 2, 3, 4$ . A horizontal external excitation  $f(t)$  with an action time of 2s is applied to the third story, and the time profile is shown in Figure 2. The structural response is obtained by the fourth-order Runge-Kutta method with a time step of 0.001s.

Figure 1. Nonlinear model equipped with MR dampers  
Define the structure state vector as,

$$X(t) = [x_1, x_2, x_3, x_4, \dot{x}_1, \dot{x}_2, \dot{x}_3, \dot{x}_4, k_{E1}, k_{E2}, k_{E3}, k_{E4}, c_{E1}, c_{E2}, c_{E3}, c_{E4}, m_{E1}, m_{E2}, m_{E3}, m_{E4}]^T \quad (22)$$

The MR damper introduced in the structure is a Bingham model with a damping force that satisfies the relation,

$$F_{\text{non}}^{\text{Bh}} = f_c^{\text{Bh}} \cdot \text{sgn}(v, v_{i,i-1}) + C_0^{\text{Bh}} \cdot v_{i,i-1} + f_0^{\text{Bh}} \quad (23)$$

where  $F_{\text{non}}^{\text{Bh}}$  is the damping force provided by the Bingham model,  $f_c^{\text{Bh}} = 20 \text{N}$ ,  $C_0^{\text{Bh}} = 600 \text{N} \cdot \text{s/m}$  and  $f_0^{\text{Bh}} = 0$  are model coefficients. The damping force calculated from Eq. (23) is accurately calculated by the mathematical relation equation and thus can be used as the theoretical damping force of the structure to evaluate the identified value.

Figure 2. External excitation force time history

The setting range of the initial parameters of the structure is estimated based on the real parameters of the structure, and the number of particles is set to 20000, the initial value of the stiffness of each floor is  $130 \text{kN/m} \sim 210 \text{kN/m}$ , the initial value of the damping coefficient is  $0 \text{kN} \cdot \text{s} \cdot \text{m}^{-1} \sim 1000 \text{kN} \cdot \text{s} \cdot \text{m}^{-1}$ , and the initial value of the mass is  $100 \text{kg} \sim 160 \text{kg}$ . In fact, due to the use of EKF as the importance function for sampling, the identified range of particles after EKF update can exceed the setting range of initial parameters. Assuming that the acceleration of the second story of the structure cannot be measured, only the accelerations of the first, third and fourth stories of the structure are observed, and 5% non-Gaussian noise is added to the observations.

Taking the mean value of the last step in each iteration as the parameter identification result, the structural stiffness, damping, and mass are identified using EKPF, the convergence process of the equivalent linear parameter is shown in Figure 3. Figure 3(a) gives the convergence process of the identified equivalent stiffness of each story of the structure. It can be seen that from Figure 3(b) the equivalent damping identification value of the first to the third stories tends to the true value, but the identified value of the fourth story identifies with the other stories in the completely opposite direction, which can be judged that the structure has undergone a nonlinear behavior in the fourth story, which is also consistent with the actual installation of the damper. The convergence result of mass identification is shown in Figure 3(c), which can accurately converge to the actual value, which also shows that the nonlinear behavior of the structure does not affect the mass of the structure after it occurs. Table 1 and Table 2 give the identified results of the mass and the equivalent stiffness and equivalent damping, respectively. It can be seen from Table 1 that the identified result of the structural mass is better, and the error of each story is less than 1%. The equivalent linear parameters have also achieved good identification results.

Table1. Identified mass results

Mass	Identified [kg]	Actual [kg]	Error [%]
$m_1$	148.85	150	0.77
$m_2$	150.26		0.17
$m_3$	149.85		0.10
$m_4$	149.71		0.19

(b) Equivalent linear damping

(c) Equivalent linear mass

Figure 3. Structural parameter convergence process

Table2. Identified equivalent stiffness and damping results

Parameter	Identified	Actual
$k_{E1}$ (kN/m)	200	200
$k_{E2}$ (kN/m)	198	200
$k_{E3}$ (kN/m)	200	200
$k_{E4}$ (kN/m)	201	200
$c_{E1}$ (kN·s·m <sup>-1</sup> )	0.13	0.16
$c_{E2}$ (kN·s·m <sup>-1</sup> )	0.16	0.16
$c_{E3}$ (kN·s·m <sup>-1</sup> )	0.17	0.16
$c_{E4}$ (kN·s·m <sup>-1</sup> )	<b>0.86</b>	0.16

Figures 4 and 5 show the comparison between the identified results and the actual values of the displacement and velocity response of each story of the structure, and Figure 6 shows the comparison between the identified values and the true values of the unobserved acceleration of the 2nd story of the structure. The identified results of displacement, velocity and acceleration of the second story are in good agreement with the true values.

Figure 4. Identified structural displacement responses

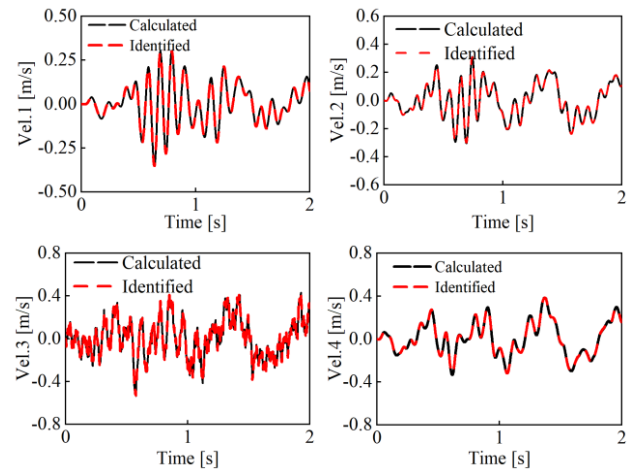

Figure 5. Identified structural velocity responses

Figure 6. Identified structural acceleration responses on second floor

Based on the identified structural parameters, displacement and velocity responses, the NRF of the 4th floor of the structure can be further obtained using the least squares algorithm in a nonparametric manner, and the results of the comparison between the identified and the true values of the NRF of the 4th floor of are shown in Figure 7.

Figure 7. Identified MR damper force

The identified results of the unknown acceleration and NRF are quantified by the root mean square error (RMSE)[23], which are calculated to be 0.12m/s<sup>2</sup> and 12.59N for the acceleration of on the 2<sup>nd</sup> floor and NRF, respectively.

#### 4.2 Example 2

Considering the actual situation that the structure may have multiple damages under strong dynamic loading, in order to verify the generality of the proposed algorithm, MR dampers are introduced in the first and fourth stories of the structure, and horizontal external excitation is applied to the second floor, and the nonlinear structural model and the external excitation are shown in Figure 8 and Figure 9, respectively.

Figure 8. Four-story shear frame model with MR dampers

Figure 9. External excitation force time history

Distinguishing from the Bingham model in Example 1, the two MR dampers in this example use the modified Dahl model with the expression,

$$F_{non}^{Dh} = K_0^{Dh} s_{i,i-1} + C_0^{Dh} v_{i,i-1} + F_0^{Dh} Z + f_0^{Dh} \quad (24)$$

$$\dot{Z} = \sigma v_{i,i-1} (1 - Z \operatorname{sgn}(v_{i,i-1})) \quad (25)$$

where  $F_{non}^{Dh}$  is the damping force provided by the Dahl model,  $K_0^{Dh} = 30 \text{ N/m}$ ,  $C_0^{Dh} = 600 \text{ N}\cdot\text{s/m}$ ,  $F_0^{Dh} = 35 \text{ N}$ ,  $\sigma = 500 \text{ s/m}$  and  $f_0^{Dh} = 0$ ,  $f_0^{Dh} = 0$ ,  $C_0^{Dh}$ ,  $F_0^{Dh}$  and  $\sigma$  are model coefficients, and  $Z$  is the dimensionless hysteresis.

The settings of the initial parameters and the structural true values in Example 2 are the same as those in Example 1, and the identified process of the equivalent linear stiffness, damping and mass is given below. From Figure 10 the structural stiffness, damping, and mass parameters of the other floors converge to the actual value of the structure, except for the equivalent damping values of the first and fourth floors in Figure 10(b), which deviate from the actual value, and according to which it can be shown that the structure undergoes nonlinear behavior in the first and fourth floors. The identified results of the mass, the equivalent linear stiffness and damping are shown in Tables 3 and 4, respectively. The identified results of the parameters have small errors.

(a) Equivalent linear stiffness

(b) Equivalent linear damping

(c) Equivalent linear mass

Table 3. Identified mass results

Mass	Identified [kg]	Actual [kg]	Error [%]
$m_1$	147.70	150	1.53
$m_2$	150.48		0.32
$m_3$	149.01		0.66
$m_4$	150.13		0.09

Table 4. Identified equivalent stiffness and damping results

Parameter	Identified	Actual
$k_{E1}$ (kN/m)	197	200
$k_{E2}$ (kN/m)	199	200
$k_{E3}$ (kN/m)	200	200
$k_{E4}$ (kN/m)	201	200
$c_{E1}$ (kN·s·m <sup>-1</sup> )	<b>0.96</b>	0.16
$c_{E2}$ (kN·s·m <sup>-1</sup> )	0.16	0.16
$c_{E3}$ (kN·s·m <sup>-1</sup> )	0.15	0.16
$c_{E4}$ (kN·s·m <sup>-1</sup> )	<b>0.95</b>	0.16

Figures 11 and 12 show the comparison of the identified results of displacement and velocity response of the nonlinear structure respectively, it can be found that the dynamic response of the structure in all floors are identified with good results.

Figure 11. Identified structural displacement responses

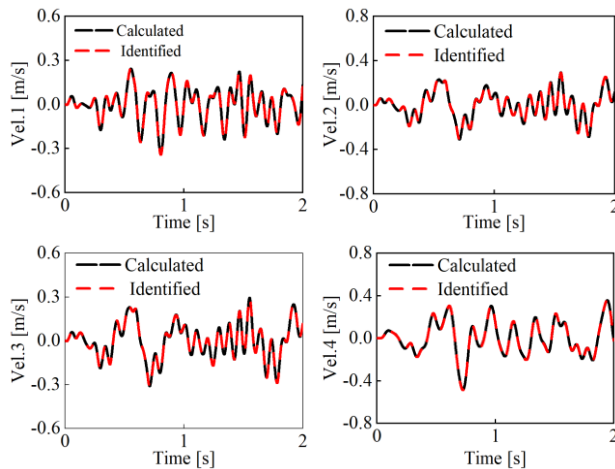

Figure 12. Identified structural velocity responses

The same as in Example 1, based on the parameters and responses identified by the structure, the NRFs between the first and fourth floors can be identified, as shown in Figure 13. The RMSE of the identified acceleration value of the second floor is  $0.30\text{m/s}^2$ , the RMSE of the identified value of NRF of the first floor is  $14.43\text{ N}$ , the RMSE of the identified value of NRF of the fourth floor is  $11.46\text{ N}$ . It can be seen in Figure 13 that the identified values of the first and the fourth floors of the damping force are in good agreement with the real values, which indicates that the proposed algorithm is not only able to effectively identify the nonlinear behavior of the structure at a single unknown location under strong dynamic loading, but also applies to the case of a nonlinear system where multiple nonlinear locations are unknown.

## 5 CONCLUSIONS

In this paper, based on the EKPF algorithm and equivalent linear theory, the structural parameters and nonlinear locations are identified under limited acceleration observations, and a model-free identification of structural NRF is proposed based on Chebyshev polynomial.

Numerical simulations of a four-degree-of-freedom concentrated mass nonlinear shear frame model were performed. In two examples, different numbers and models of MR dampers (Bingham model vs. Dahl model) are sequentially introduced to the structure to simulate different nonlinear behaviors for different numbers and locations. Considering the effect of measurement noise and changing the location of horizontal external excitation application, the structural stiffness, damping, mass parameters, and the inter-story NRF at the arrangement of MR dampers are identified with limited observations of the acceleration response, and the validity and applicability of the proposed methodology are verified by comparing the identified values with the theoretical values.

The method proposed in this paper is general in that it does not need to utilize a parametric model of the NRF of the structure in the identified process. The identified NRF under strong dynamic loads such as earthquakes is an intuitive description of the hysteretic performance of the structure, and through the restoring force characteristics at different moments, it can reflect the occurrence and development of the damage of the structure or sub-structure at different moments in the process of dynamic loading, and can be used for the quantitative description of the energy dissipation of the structural components in the process of the loading. The method proposed in this paper is of great significance for damage localization, quantitative assessment and post-disaster structural performance evaluation of structures subjected to dynamic loads such as earthquakes.

**ABSTRACT:** As climate change leads to increasing temperatures around the globe, rail track buckling has become an increasing concern for rail operators. This paper provides an overview of the key outcomes from a four-year research program that sought to explore the use of distributed fibre optic sensors (DFOS), analytical modeling, and artificial intelligence techniques to aid in track buckling assessment and detection. Lab tests and field monitoring data were used to develop and evaluate two DFOS systems, one for short length dynamic buckling assessment due to train passage and the other for long length thermal buckling assessment. The data from each system was used to develop models for the detection of buckling using different techniques depending on the quality of the initial data and the required output. Finite element model (FEM) updating and statistical FEMs were explored to predict buckling response based on measurements at service loads. Beam on elastic spring models were used to estimate the influence of train passage on buckling capacity while Gaussian process regression (GPR) techniques provided insights into buckling indicators at the field sites.

**KEY WORDS:** Distributed fibre optic sensing; Rail track buckling; Lab tests; Field monitoring; Data-based modelling.

## 1 INTRODUCTION

Continuous welded rail (CWR) is used in most modern rail networks because of the enhanced ride quality it provides as well as reducing noise and wear on the rails. However, the removal of joints along the rail means that there is no room for the rail to expand when its temperature changes relative to the rail neutral temperature (RNT) resulting in the development of a state of self-stress within the rail. If the temperature increases to a critical value, the lateral load resistance system of the rail track, consisting of ballast, ties, and fasteners, can no longer provide adequate support and the rail track buckles laterally [1,2]. The critical temperature can change over the operational life of the rail network as deterioration lowers this buckling temperature and proper maintenance increases it [1,3].

Analytical models exist to account for buckling during the design stage [1,4] however there are a number of challenges with using these models for the assessment of in-service buckling such as variations in geometry and support conditions that are present in existing rail tracks. Numerical simulations can provide more accurate estimates of track behaviour since they can account for variations in geometry and support conditions with length [2,5]. But obtaining the measurements required to develop accurate models in the field is time consuming and expensive.

Structural health monitoring techniques represent a potentially useful approach for either detecting rail track issues directly or acquiring the data required to develop more accurate models. Researchers have previously explored the use of a variety of sensors to detect rail track issues such as strain gauges [6], accelerometers [7], ultrasonic and laser vibrometers [8,9], and digital image correlation [10]. The challenge with many of these techniques is that they only provide a local measurement of rail behaviour whereas buckling can occur anywhere along the length of the rail.

A potential solution to this challenge is the use of distributed fibre optic sensors (DFOS). For strain sensing, research has focused on the use of Rayleigh based systems when high-resolution (gauges lengths less than 1 mm are possible) and high-accuracy measurements (up to  $\pm 1$  microstrain at the fiber core for Rayleigh based systems) are required [11]. And Brillouin based systems when lower resolution (gauge lengths of 50 mm) and lower accuracy ( $\pm 15$  microstrain) [12] is an acceptable trade-off to achieve longer sensing lengths (100 m per channel for Rayleigh-based systems [11] versus up to 25 km and more for Brillouin-based systems [12]). Most of the current research using DFOS for rail applications has focused on the response of the rail due to vehicle loading [13,14]. Initial studies have been conducted on short lengths of rail to measure thermal strain due to free expansion using Brillouin Optical Time Domain Analysis (BOTDA) [15,16] as well as to measure strains due to thermal stress in the lab and the field [16].

The goal of the research campaign described in this paper was to evaluate the viability of using DFOS for the assessment of rail track buckling. The objective of this paper is to provide an overview of the entire research campaign starting with lab-based thermal buckling experiments that were used to update finite element models (FEM) as well as to explore the use of statistical FEM (StatFEM) with distributed sensing data for the first time. Three field tests were also undertaken on a tangent track and a curved track section in Ontario, Canada to acquire first of their kind data sets and to explore the use of DFOS data to inform improved models of rail track buckling.

## 2 LAB TESTING

### 2.1 Introduction

Before undertaking field tests, the first phase of this research involved a series of small-scale lab-based experiments to

explore the use of both Optical Frequency Domain Reflectometry (OFDR), and BOTDA measurements for assessing rail track buckling. The rails were subjected to both mechanical and thermal loading to induce buckling in the rail.

## 2.2 Specimens

An ASCE 5.95 kg/m (12 lbs/yd) mining rail specimen with the length of 3,048 mm (Hammer Steel Products, Canada) was used, as buckling of the member could be induced within the available lab constraints. The specimen had a specified elastic modulus ( $E$ ) of 207 GPa, cross-sectional area ( $A$ ) of 761 mm<sup>2</sup>, and coefficient of thermal expansion ( $\alpha$ ) of  $11.6 \times 10^{-6} / ^\circ\text{C}$ . The second moment of area was 53,000 mm<sup>4</sup> about the weak axis ( $I_y$ ) and 229,000 mm<sup>4</sup> about the strong axis ( $I_x$ ). The specimen was instrumented with eight nylon-coated single mode strain measurement optical fibres (F1 – F8) to measure the surface strain and a temperature measurement fibre to measure the distributed temperature as illustrated in Fig. 1. Further details about the specimens are provided in [17,18].

Figure 1. Lab buckling test specimen (in mm). (a) rail cross-section dimensions, (b) fibre locations on cross-section, (c) longitudinal dimensions and fibre layout.

## 2.3 Test setup

As shown in Figure 2, the testing frame consisted of two steel plates that were connected to four threaded rods using nuts. Two types of tests were conducted: (1) buckling due to applied load from an actuator with three different lateral support conditions and (2) thermal buckling caused by restraining axial elongation due to changes in temperature.

Figure 2(a) shows the schematic frame setup for the applied load buckling with no lateral restraint (NS) and thermal buckling tests. In the applied load tests with lateral restraint, the lateral restraint was provided by springs with a stiffness of 32.7 N/mm, and a maximum compressible length of 30.2 mm. Figure 2(b) illustrates the test setup for the applied load tests with one spring placed at the mid-length test, and Figure 2(c) shows the applied tests with two springs placed at 1/3 and 2/3 of the rail length, respectively, where weak-axis buckling occurs in the vertical direction.

For the thermal buckling tests, the rail temperature was adjusted by changing the temperature within a climate chamber where the specimen was placed. The steel frame experienced similar thermal expansion/contraction as the rail due to a temperature increase/decrease ( $\Delta T$ ), so to keep the length of the rail constant (e.g. full axial restraint), an axial load was applied to the rail to ensure the net axial displacement of the rail was 0 mm. For all tests, the axial load was applied by a hydraulic jack

with a capacity of 1010 kN and measured using a load cell with a 222 kN capacity. The actuator, supports, and the specimen could not be aligned perfectly, and axial loads with different eccentricities occurred in all tests. A linear potentiometer (LP) was placed at the mid-length of the rail to measure the lateral deflection during the test. The strain was measured using a LUNA ODISI 6104 analyzer (LUNA Innovation, USA) for the OFDR tests and an NBX-6050A Brillouin Optical Time Domain Analysis (BOTDA) analyzer (Neubrex, Japan) for the BOTDA tests.

Figure 2. Lab buckling test setup. (a) no lateral restraint, (b) one spring, (c) two springs.

## 2.4 Results

The lab experiments were used to evaluate the potential for using DFOS measurements to assess buckling. Because 8 fibres were placed around the rail cross-section (see Figure 1), it was possible to define a fitted strain plane using the measurements at each point along the length of the rail as seen in Figure 3.

Figure 3. Strain measurements from 8 fibres on the rail forming a strain plane enabling calculation of axial strain and strong and weak axis curvature.

The strain plane seen in Figure 3 can be used to calculate the axial strain and weak and strong axis curvatures in the rail. The curvatures can then be numerically integrated twice to obtain a lateral deflection profile along the rail. One of the key conclusions from this part of the research was that both OFDR and BOTDA sensor systems could be used to measure the response of the rail using the strain plane approach although OFDR provided more accurate measurements, especially of the lateral restraint force provided by the springs [18]. While measurements of axial strain and displacement can be used as

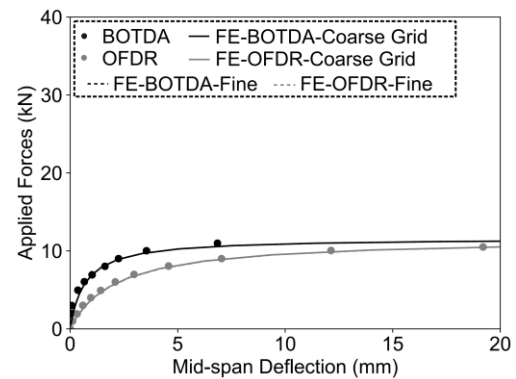

thresholds for assessing the impact of buckling, to provide predictions of future behaviour, a numerical model based on the experimental data is required as discussed in the next sections. Further details about the lab-based experimental campaigns can be found in [17,18].

### 2.5 Finite element model updating

One challenge with using monitoring data to estimate the ultimate limit state behaviours of a structure is that the data is usually recorded at service loads. In this investigation DFOS data captured at service loads (i.e., applied loads and temperatures that were 50% of ultimate) were used to update finite element models to estimate the buckling capacity. A commercially available finite element analysis (FEA) program (i.e., Abaqus) was used to model the tests. The 3.048 m long slender member was modelled with 30 three-noded beam elements (B32), with the same cross-sectional and material properties as the rail. Connector elements with one degree of freedom perpendicular to the member were used to model the spring supports and were given one of two stiffnesses: (i) the manufacturer specified value (i.e., 32.7 N/mm) or (ii) the stiffness calculated from the DFOS measurement derived reaction force divided by the DFOS measurement derived displacement at the support location for each test [18]. Three steps of analyses were undertaken: 1. a linear buckling analysis to obtain the initial deflected shape, 2. a static general analysis considering geometric nonlinearity to determine the value of the mid-span imperfection and the end eccentricities through model updating and, 3. a static risk analysis to develop the buckling load-displacement response. Two approaches were taken to step 2: (a) a coarse grid and (b) a fine grid analysis. In the coarse grid analysis, the initial eccentricity parameters (at the supports and at midspan) were varied over a range of  $\pm 2.0$  mm with an increment of 0.5 mm and the optimum analysis was chosen based on the computed root mean square error (RMSE) between the modelled curvature values and the measured curvature values. In the fine grid analysis, each of the optimal eccentricity values from the coarse grid analysis were varied over a range of  $\pm 0.5$  mm with an increment 0.1 mm resulting in 1331 analyses.

Figure 4 presents the load-deflection responses from the finite element model updating investigation for (a) the NS tests and (b) the OS tests. Also plotted in the figure are the measured load and displacement at each load stage. Figure 4(a) shows the results from the tests using both the OFDR and BOTDA sensing systems. The difference in behaviour between the OFDR and BOTDA tests is not a function of the measurement systems but is due to the different axial load eccentricities present in each test. The results from the fine and coarse grid approaches plot on top of each other suggesting either approach to estimating the impact of eccentricities on the tests results is acceptable. Overall, the finite element model updated using the service load data was able to capture the ultimate behaviour of the rail accurately. In Figure 4(b) it can be seen that using the manufacturer or estimated spring stiffness provides the same result for the OFDR system. This is because the higher spatial resolution and accuracy of this system compared to the BOTDA allows for localized behaviour, such as lateral supports, to be resolved more accurately. Using the manufacturer's spring stiffness along with the BOTDA data at service loads enables the updated FEM to capture the full

behaviour. Though the estimated spring stiffness model is not as accurate, it is still conservative.

(a) No lateral restraint tests comparing BOTDA and OFDR data to FE models using Coarse and Fine Grid approach

(b) One spring restraint tests comparing BOTDA and OFDR data to FE models using both the Manufacturer and Estimated spring stiffness, K, from the data

Figure 4. FE model updating results compared to measured response from applied load tests.

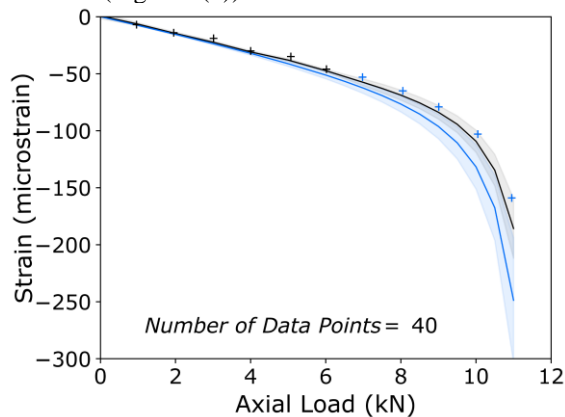

### 2.6 Statistical FEM model

The previous section highlighted that DFOS data could be used to support FEM updating but one limitation of the approach is that depending on the number of structural parameters to be optimized and the complexity of the model, model updating can have a high computational cost associated with finding the structural parameters that provide the optimum fit to the data. A second limitation is that traditional model updating assumes the model perfectly represents the true structural response whereas in reality the model always involves assumptions and idealization of the actual system (e.g., materials, boundary conditions, loading, etc.). To address these two limitations, a second FEM updating investigation was undertaken, exploring the use of the Statistical FEM (StatFEM) with distributed sensor data for the first time [19]. The basis of the StatFEM approach is that the measured structure response is composed of the true structure response and errors due to sensor measurement noise that have a known statistical distribution. The true structural response is assumed to be a combination of the FEM structural response and the model-reality mismatch due to model idealization and assumptions. The same approach was taken whereby data acquired at service

loads was used to update the model that was then used to predict ultimate capacity. In this investigation, polynomial chaos expansion (PCE) was investigated as an approach to generate the FE probability distribution prior to updating as opposed to the more traditional Monte Carlo simulation. This resulted in order of magnitude improvements in computation time from 16 hours and 40 minutes to 9 minutes with a less than 1% reduction in accuracy.

Figure 5 shows the strain versus load relationship for an (a) OFDR tests and (b) a BOTDA test for when 40 data points along the rail length (i.e.  $n_y = 40$ ) were used. It can be seen that the initial FE probability distribution overestimated the strain at a given load in the nonlinear range but that the StatFEM prediction of the ultimate limit state response incorporating the DFOS data collected in the service load range shows an excellent visual agreement with the measured ultimate limit state structural response. The model updated using the OFDR measurements (Figure 5(a)) demonstrates an excellent fit to the data over the entire measurement range and the error range (the grey shaded area) is smaller than the model updated using BOTDA data (Figure 5(b)).

(a) OFDR measurements

(b) BOTDA measurements

Figure 5. Strain versus load relationship where the blue line and shaded area represents the FE prediction, the black line and shaded area represent the StatFEM prediction, and the discrete points are measured strain.

The number of data points used to update the model was also found to play an important role in terms of prediction accuracy and the size of the error envelope. This shows the benefit of

using DFOS for FEM updating as the number of points enable much higher prediction accuracy. Further details on the use of DFOS with the StatFEM can be found in [19].

### 3 FIELD MONITORING

#### 3.1 Introduction

Having demonstrated the potential to use DFOS for monitoring of thermal buckling and development of robust numerical models using controlled lab-based experiments, the next phase of the research involved three separate field investigations to evaluate the use of DFOS to monitor rail track buckling in the field: (i) short term dynamic monitoring, (ii) long-term thermal monitoring and assessment of tangent track, and (iii) long-term thermal monitoring and assessment of curved track.

#### 3.2 Site installations

The site installations were similar in that three nylon-coated strain measurement fibres with a diameter of 0.9 mm were installed at the various heights in the cross section as illustrated in Figure 7 so that the strain plane in Figure 3 could be measured. The two long-term monitoring installations were similar with the major difference being one was on a tangent track and the other was on a curved track. In both cases, a 20 m long 8 mm diameter temperature fibre and 4 thermocouples were also installed on the rail as shown in Figure 7 to capture thermal effects. The long-term fibre optic data was acquired using an NBX-6050A Brillouin Optical Time Domain Analysis (BOTDA) analyzer with readings being taken every 30 minutes over the course of one month [20]. For the short-term dynamic monitoring, the installed fibre length was 9 m (as opposed to the 20 m shown in Figure 7) so that the data could be acquired at a rate of 13 Hz using a LUNA ODISI 6104 analyzer [21].

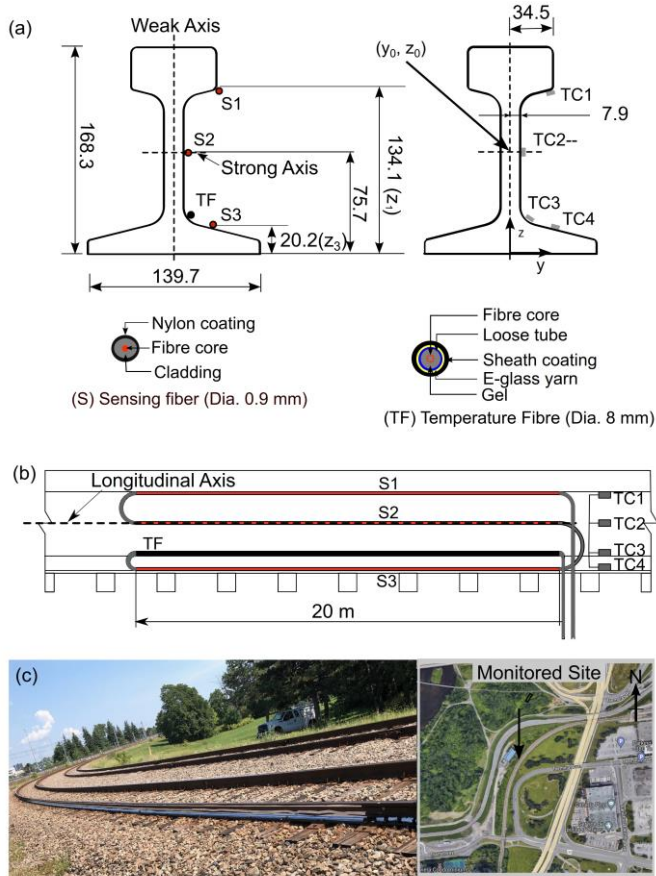

Figure 7. Field monitoring installation on curved track. Strain (S) and temperature fibre (TF), and thermocouple (TC) locations on (a) cross-section (in mm) and (b) rail length, and (c) site layout and location.

### 3.3 Impact of temperature and train passage

One of the key findings from the installation on the tangent track was that solar gain had an impact on rail strain measurements. Figure 8 shows the difference in temperature measurements from the thermocouples at various points on the rail cross-section relative to the location of the temperature fibre (TC3). It can be seen that at night (between midnight and 8 am in Figure 8) the difference in temperature measurements is less than 1°C and is within the noise of the thermocouple measurements. During the day this difference can be as high as approximately 2°C and depends on the position of the sun relative to the rail as well as the amount of cloud cover. The impact of this temperature difference is three-fold. First, it challenges the conventional assumption of constant temperature in the rail cross-section often used in buckling assessment. Second, the strain measurements from the fibres must be compensated for temperature with the correction factor being approximately 20 microstrain/°C for the BOTDA system [16]. Third, this differential temperature can cause rail bending if the rail is not adequately restrained, which could increase the likelihood of rail track buckling.

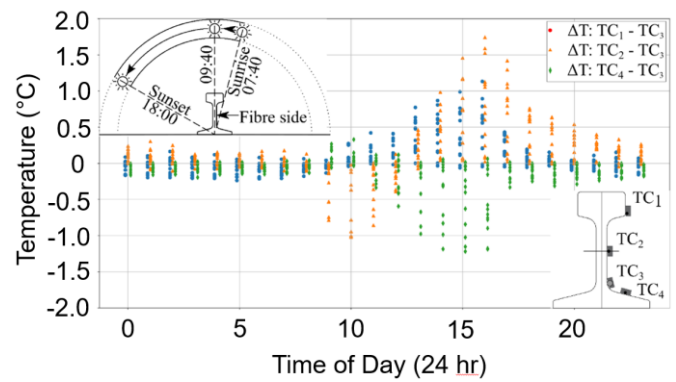

Figure 8. Difference in rail temperature at 4 different locations on the rail cross-section with time of day.

A second issue that affects the accuracy of long-term monitoring data is the passage of trains. Figure 9 shows three sets of consecutive measurements taken at the curved track site taken before any trains passed, after the position of Train 1, and after the passage of Train 2 at a constant temperature.

Figure 9. Effect of train passage on DFOS measurements at the curved rail site. (a) Curvature and (b) Axial Strain

One can see from Figure 9 that both the curvature and the axial strain are impacted by the passage of a train. While this might not be the case for a track that was properly restrained against lateral and longitudinal movement, previous research has demonstrated that rail tracks supported by wooden ties and gravel ballast can experience longitudinal movement and thus changes in axial strain due to the passage of trains [22]. Thus, when monitoring and assessing rail tracks for buckling using DFOS, temperature effects due to solar gain and the passage of trains are important issues that must be carefully addressed. In the case of thermal effects, a potentially straightforward solution is to use combined strain and thermal measurement fibres at all three measurement heights along the rail.

### 3.4 Dynamic thermal buckling models

Dynamic buckling occurs when the train wheel loads acting on the rail track cause a section of the track to lift off the ties and

become laterally unsupported. If that section of rail track is already prone to buckling due to being on a curve, having a small amount of misalignment along its length, or both then railway buckling can occur at lower temperatures than static thermal buckling.

DFOS measurements were taken with the OFDR analyser along a section of curved track as a passenger train travelled over the instrumented section. Because strains were measured at multiple heights on the rail, the curvature profile along the instrumented section could be derived. A beam on elastic foundation (BOEF) model, where the rail is modelled as a beam with the same flexural stiffness (EI) as the rail and the foundation is modelled as a series of elastic springs, was then created. The curvature pattern was then used to update the BOEF model to estimate the track modulus by adjusting the spring stiffness until the measured rail curvature matched the model beam curvature, which resulted in a track modulus of 13.6 MPa in this case.

To predict the dynamic buckling temperature, a finite element model was constructed in ABAQUS using two-noded beam elements. Two types of connector elements were used in the FE model to simulate the interaction between the rail track and the rail ties as well as between the ties and the ballast, respectively. The track modulus that affects the rail lifting-off behavior under train loading was derived from the DFOS measurements as noted above and the rest of the structural parameters that affect static thermal buckling behavior were obtained from the literature [21]. The FE modelling was conducted in two stages. First, a static nonlinear analysis was conducted to get the railway lift-off response under train loading. Afterwards, the impact of railway lift-off response on the lateral resistance provided by the ballast to the railway system was inputted into the railway FE model to simulate the railway dynamic buckling. A misalignment in the rail of either 20 mm or 34 mm was modelled and then an increasing temperature was applied to the model to determine the temperature increase above the rail neutral temperature versus lateral displacement response as seen in Figure 10. Further details of the model can be found in [21].

From Figure 10 it can be seen that the passenger cars had no impact on the buckling behaviour as the dynamic buckling curve for the passenger cars plots on top of the static thermal buckling curve. This was because the rail passenger cars were not heavy enough to cause the rail to lift off the ties and reduce the lateral resistance. The locomotives, on the other hand, were heavy enough to cause the track between trucks of the locomotive to lift off the ties. As a result, the temperature to cause thermal buckling while a locomotive is passing was found to be lower than the static case. By comparing Figures 10(a) and 10(b) one can also see that rail misalignment impacts both the static and dynamic buckling temperature where larger misalignments lead to lower critical buckling temperatures as would be expected. The combined effect of dynamic buckling and misalignment can be significant since in this case the critical temperature increase to cause buckling went from 42.6°C with a 20 mm misalignment and no train loading to 35.3°C with a 34 mm misalignment and locomotive loading.

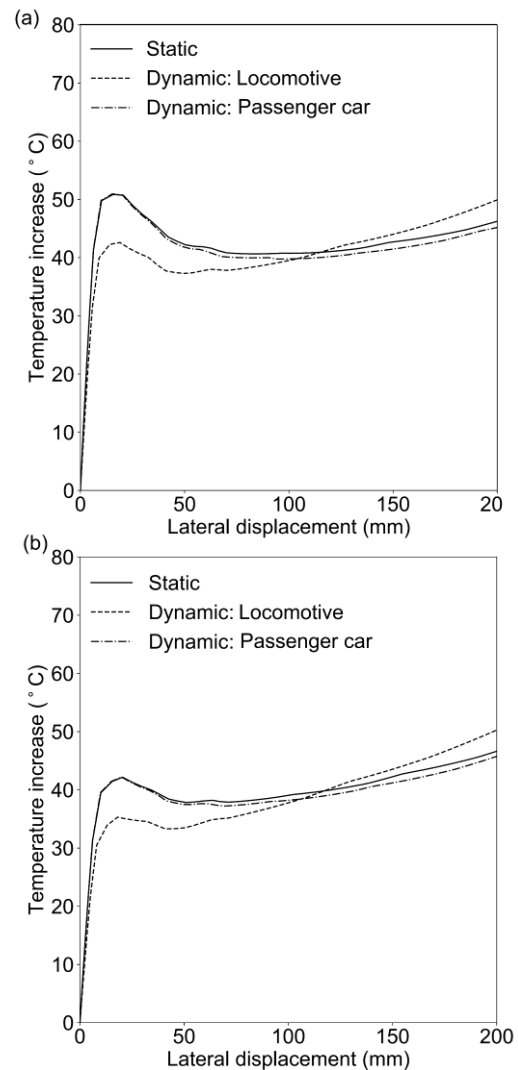

Figure 10. Static versus dynamic buckling response for monitored section of track. (a) 20 mm misalignment, (b) 34 mm misalignment

### 3.5 Data-driven thermal buckling models

In many infrastructure monitoring applications, the system being monitored is too complex to be accurately captured by a physics-based model. Such is the case for many rail buckling applications where the likelihood of buckling is a function of a complex system that involves interaction between the environment and a physical system with spatial varying geometric and material properties. As noted earlier in the paper, the position of the sun and cloud conditions affect the rail temperature and due to the lack of perfect rail restraint (e.g., due to gaps between the restraint plates and the rail) the rail experiences changes in the stress-state due to the passage of trains. Other issues such as variable support stiffness and rail track alignment further complicate the situation and make it essentially impossible to develop a comprehensive physics-based model.

One potential solution to this is to use a data-driven modelling approach. DFOS produces thousands of data points along the length of the rail to capture the spatial variability in both strain and temperature and allows for scans to be taken multiple times a day over the course of weeks to help resolve

the temporal variability. Gaussian process regression is a data-regression technique that allows for the uncertainty of the model to be calculated. The first step in the process is to select an appropriate kernel which defines the function and the relationships between variables. In the current work a Matern32 + linear kernel was selected based on a comparison of 12 different kernels to determine which one best fit the data. Each of the 12 models was trained using the first two weeks of data from the curved track monitoring site and then were used to predict the data from the last two weeks of monitoring.

Two different GPR models were developed: Model 1 defined a relationship between the axial strain and curvature along the rail and the input variables of rail surface temperature and location. Model 2 also considered train passage and non-uniform rail surface temperature as noise components that could impact the results based on the observations presented earlier. Figure 11 presents the GPR model results for axial strain versus temperature where the blue line represents the most likely relationship proposed by both models. The dark blue shaded region in the figure is the range of potential relationships according to Model 1 while the light blue region is the range of potential solutions for Model 2. It should be noted that the associated uncertainty for each model represents the range of potential models and should not be confused with other potential sources of error such as measurement error. If enough training data was available, it would be possible to have a GPR model with no uncertainty, but the actual measurements might not lie on the curve due to measurement noise. More details about the development of the models can be found in [20].

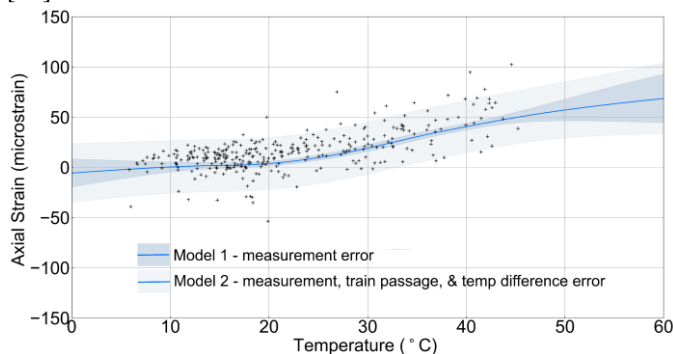

Figure 11. GPR model of the relationship between axial strain and temperature with and without consideration of train passage and differential rail temperature effects.

From Figure 11 it can be seen that the uncertainty band for Model 1 is smaller than for Model 2, due to the added potential uncertainty due to train passage and temperature variation around the cross-section of the rail. The uncertainty is also higher when the temperature is below approximately 7°C and above 45°C due to lack of training data in these regions. This presents a challenge as rail operators are most concerned about the behaviour above 40°C but there is inherently going to be less or even no training data at these critical temperature levels. Another important thing to note about Figure 11 is that many of the measured points do not match the proposed relationship or in some cases do not even fall within the uncertainty bounds. One reason for this is measurement error but there is another more fundamental issue and that is for this system there is more than one state of stress that can occur at a given temperature.

Because of variables such as gaps between the rail and the supports, train passage, and differential rail temperatures, the rail can actually take on a variety of positions at a given temperature. As such, a limitation of using GPR for systems such as these is that they are not accurately described by a closed-form solution. However, they do provide rail operators with guidance as to the overall relationship.

### 3.6 Future Work and Scalability

The initial results suggest that DFOS show promise as a rail track thermal buckling detection tool. However, three major issues still need to be addressed: (i) installation, (ii) improved thermal compensation, (iii) and automated detection. In terms of the installation, in a parallel study the research team developed a prototype robotic system that could install the fibre optic cables at various heights on the rail section an order of magnitude faster than human installers with improved placement accuracy. In the current work, temperature was only measured along the rail at one location on the cross-section, which meant that temperatures at other locations must be inferred from the single fibre optic measurement and thermocouple measurements. However, there are commercially available fibres that combine strain and temperature measurement fibres in a single housing that could be used to improve the temperature compensation. Finally, while the current research has shown that data driven techniques can be used to assist in modelling rail behaviour, further work is required to develop models and detection techniques that can be used by rail operators to automatically detect and provide warnings of thermal rail track buckling.

## 4 CONCLUSIONS

This paper presented the key findings from a four-year investigation into the use of distributed fibre optic sensing (DFOS) to support the monitoring and assessment of rail tracks that are susceptible to thermal buckling. The key conclusions include:

1. Installing three DFOS strain sensing fibres on the cross-section of the rail allows a strain plane at every sensor location along the length to be derived. Axial strain, and weak and strong axis curvature can then be determined and the curvature can be numerically integrated to obtain displacement along the length of the rail.
2. DFOS data can be used to update finite element models that are capable of predicting the ultimate response even when model updating is based on data acquired at service loads. Additionally, DFOS data can be used with the StatFEM to provide not only more accurate models but also error bounds associated with sensor noise.
3. The change in strains due to the passage of trains and due to variable heating of the rail cross-section due to solar effects are two of the challenges associated with using DFOS results for the assessment and modeling of buckling behaviour.
4. Dynamic DFOS measurements can be used with a beam on elastic foundation (BOEF) model to estimate the deflected shape of the rail and the track modulus. The deflected shape and track modulus can then be used in an FE model of the rail track to estimate the impact of vehicle load on the dynamic thermal buckling behaviour.

5. Data-driven models such as Gaussian process regression (GPR) offer a potential approach for developing models in situations where a physics-based model is intractable. However, if the system does not have a unique solution at a given temperature, e.g., due to poorly constrained degrees of freedom from gaps between the rail and sleepers, the GPR model may not capture this behaviour but can still serve as a guide for rail network managers.

## ACKNOWLEDGMENTS

This project was supported in part by collaborative research funding from the National Research Council of Canada's Artificial Intelligence for Logistics Program, and the Natural Sciences and Engineering Research Council of Canada. The authors would also like to acknowledge the support of Paul Montgomery and Andrew MacDonald from City of Ottawa in providing temporary access for placing the BOTDA analyzer, Paul Charbachi from VIA Rail Canada Inc., in assisting with coordinating field tests, and Heshan Fernando from Queen's University for assisting with the field tests. And finally the support of Fehmi Cirak of the University of Cambridge and Eky Febrianto of the University of Glasgow for their assistance with the StatFEM portion of the research.

**ABSTRACT:** Distributed acoustic sensing (DAS) has emerged as a powerful technology for monitoring the health and integrity of civil and geotechnical infrastructure. This technology leverages existing fiber-optic cables as dense arrays of vibration sensors, enabling continuous, real-time monitoring over long distances. This abstract summarizes recent research advancements in applying DAS to various infrastructure monitoring challenges. We first provide a brief overview of the DAS technology and its working principles. Subsequently, we present several case studies demonstrating the versatility of DAS. These include: (1) monitoring and identifying geohazards, such as landslides and rockfalls, that threaten the stability of linear infrastructure; (2) detecting disturbance events, including drilling and excavation activities, near a high-speed railway tunnel; (3) identifying wire breaks in prestressed concrete cylinder pipes for early warning of potential failures; (4) measuring flow rates and detecting illicit flows in urban underground pipelines for improved water management; and (5) integrating DAS with deep learning for traffic monitoring, providing insights into traffic dynamics and patterns, particularly during the COVID-19 pandemic. These examples highlight the potential of DAS as a cost-effective and comprehensive solution for enhancing the safety, resilience, and operational efficiency of critical infrastructure.

**KEY WORDS:** Distributed acoustic sensing (DAS); Infrastructure monitoring; Geotechnical hazards; Artificial intelligence; Fiber optic sensing

## 1 INTRODUCTION

Civil and geotechnical infrastructure faces escalating risks from geohazards, structural degradation, and operational challenges. Traditional monitoring methods often suffer from sparse spatial coverage, high deployment costs, or limited real-time capabilities. Distributed acoustic sensing (DAS) revolutionizes infrastructure health monitoring by repurposing optical fibers as ultra-dense vibration sensor arrays [1, 2]. Through precise analysis of Rayleigh backscattered (RBS) phase changes, DAS achieves meter-scale spatial resolution over tens of km ranges, enabling simultaneous strain rate measurement across thousands of sensing channels [3, 4].

Recent advances integrate DAS with artificial intelligence to address critical applications: geohazard early warning (e.g., landslides), tunnel integrity protection, prestressed pipeline diagnostics, urban water management, and intelligent traffic systems. This work demonstrates DAS's dual capability as both physical sensor network and AI-driven data platform, providing cost-effective solutions for infrastructure resilience. Case studies validate its adaptability across energy, transportation, and water sectors, highlighting its transformative potential in smart city ecosystems.

## 2 DAS MEASUREMENT PRINCIPLE

A DAS system consists of an interrogator unit (IU) and a sensing fiber. The IU injects a continuous pulsed laser into the fiber and detects the RBS phase changes over specified gauge lengths (Figure 1). These scattering are caused by refractive index variations in the fiber. For the same pulsed (along the fast axis), the phase delay  $\Phi$  of the RBS between two points of the gauge length is:

$$\Phi = \frac{4\pi n L_g}{\lambda} \quad (1)$$

where  $n$  is the refractive index of the optical fiber,  $L_g$  is the gauge length, and  $\lambda$  is the wavelength of the incident laser.

Figure 1. Schematic of DAS measurement principle.

Between adjacent pulse (along the slow axis), the change in phase delay  $\Delta\Phi$  over a gauge length is linearly correlated with axial strain rate  $\dot{\epsilon}_{xx}$ , following:

$$\dot{\epsilon}_{xx}(x, t) = \frac{\lambda f_s}{4\pi n L_g \psi} \Delta\Phi \quad (2)$$

where  $x$  and  $t$  determine the spatial and temporal information of the phase delay change,  $f_s$  is the sampling rate of the DAS IU, and  $\psi$  is the Pockels coefficient.

Commonly available commercial DAS IU offers a range of gauge length from 1 to 20 m, with channel spacing capable of reaching below 1 m and a sensing range that can extend up to 50 km. During DAS measurement, the sensing fiber is divided into dense sensing units based on the chosen gauge length. This approach enables each sensing unit to measure the axial strain rate of the fiber induced by vibration signals.

For the case studies described in this work, we utilized an OVLINK MS-DAS2000II DAS IU. This interrogator is based on the principle of phase-sensitive optical time-domain reflectometry ( $\Phi$ -OTDR), which allows for the high-sensitivity detection of dynamic strain events along the sensing fiber.

### 3 CASE STUDIES

#### 3.1 Automated rockfall classification

DAS enables continuous seismic monitoring, offering valuable insights into critical infrastructure hazards like rockfalls (Figure 2). However, automated real-time classification of extensive DAS datasets remains challenging. We developed an accurate and interpretable random forest classifier that achieved over 98.4% precision, recall, and F1-score in differentiating windowed DAS signals of rockfall events and various interferences (Figure 3) [5]. Rigorous training and validation on field-collected data leveraged waveform and spectral features for robust rockfall identification. Hyperparameter optimization further improved classification, reaching 99.3% accuracy through cross-validation. Importantly, the model generalized well to unlabeled test data, demonstrating its resilience for real-world deployment. This near real-time solution transforms distributed fiber networks into comprehensive seismic monitoring systems, unlocking their potential to enhance safety and resilience of critical infrastructure worldwide.

Figure 2. Conceptual overview of DAS for rockfall event monitoring along linear infrastructure.

Figure 3. Confusion matrices comparing Random Forest classification performance for window lengths of (a) 2 s, (b) 4 s, (c) 6 s, and (d) 8 s. Five classes are shown: rockfall (1), pedestrian walking (2), hammering (3), truck driving (4), and background noise (5).

#### 3.2 Automatic identification of diverse tunnel threats

As the backbone of modern urban underground traffic space, tunnels are increasingly threatened by natural disasters and anthropogenic activities. Current tunnel surveillance systems often rely on labor-intensive surveys or techniques that only target specific tunnel events. We present an automated tunnel monitoring system that integrates DAS technology with ensemble learning (Figure 4) [6]. We develop a fiber-optic vibroacoustic dataset of tunnel disturbance events and embed vibroscope data into a common feature space capable of describing diverse tunnel threats. On the scale of seconds, our anomaly detection pipeline and data-driven stacking ensemble learning model enable automatically identifying nine types of anomalous events with high accuracy. The efficacy of this intelligent monitoring system is demonstrated through its application in a real-world tunnel (Figure 5a), where it successfully detected a low-energy but dangerous water leakage event (Figure 5b). The highly generalizable machine learning model, combined with a universal feature set and advanced sensing technology, offers a promising solution for the autonomous monitoring of tunnels and other underground spaces.

identified in the Beijing–Xiong'an Intercity Railway tunnel during a monitoring campaign.

### 3.3 Identifying wire breaks in prestressed concrete cylinder pipes

The inspection of broken wires in prestressed concrete cylinder pipes is crucial for ensuring the safety and reliability of the pipeline. Traditional point detection techniques always require labor-intensive periodic inspections and cannot be deployed along the entire pipeline, significantly limiting the development of the industry. Hence, there is an urgent need for more advanced and intelligent sensors that can achieve 100% coverage and provide sufficient accuracy assurance. Figure 6 presents an overview of the PCCP wire breaking test site. We develop a DAS-based automated monitoring system to accurately classify the rupture of prestressed wires (Figure 7) [7]. First, a computer vision approach is employed to primarily screen out potential vibrational signals from DAS array images. Then, a pre-trained support vector machine model is used to classify the vibrations as either wire breakages or non-wire breakages (Figure 8). This model's performance surpassed other classification strategies, achieving 99.62% accuracy, 99.41% precision, 98.82% recall, and 99.12% F1-score in a side-to-side comparison. Our innovative workflow provides a comprehensive solution for detecting broken wires and offers guidance for the application of artificial intelligence-based DAS to complex vibration systems with limited training data.

Figure 6. PCCP wire breaking test site; photos show the wires in a circular recess, DAS interrogation unit used, water pressure monitoring gauge within the PCCP, and optical fibers coupled to the outer wall of the pipe.

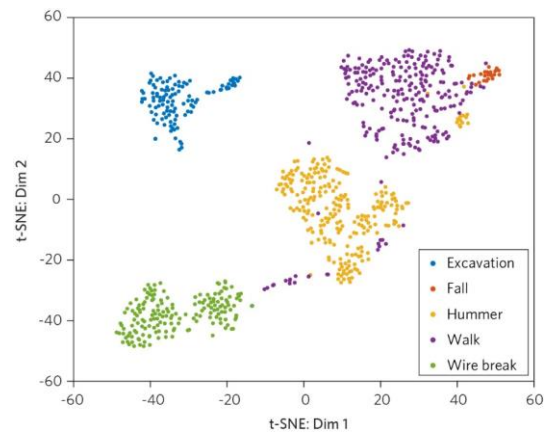

Figure 8. t-SNE is used to reduce the feature dimensionality from 15 to 2 dimensions for purpose of visualization. Five kinds of events are embedded in the same feature space, in which different types are distinguished with different colors.

### 3.4 Detecting illicit flows in urban underground pipelines

Wastewater discharge from outfall pipes can significantly impact river water quality and aquatic ecosystems. Effective outfall monitoring is critical for controlling pollution and protecting public health. We demonstrate a novel DAS approach for detecting wastewater discharge events from outfall pipes located along rivers [8]. Controlled field experiments were conducted in an industrial park river to systematically evaluate DAS performance (Figure 9). DAS detects vibrational signals imparted to suspended fiber-optic cables by turbulent wastewater flows, predominantly within 10–30 Hz, enabling continuous monitoring along entire river lengths. Vibrational power analysis locates outfalls with meter-level accuracy, while time–frequency techniques discern discharge timing and characteristics (Figure 10). Cable type and outfall–fiber separation influence on detection capability was assessed. Thermoplastic-jacketed cables optimized detection through enhanced vibrational coupling. Vibrational energy decreased exponentially with separation, highlighting benefits of proximal deployment for sensitivity. However, detection range scales with discharge flow rate. Frequency centroid proved a robust feature with potential for automated discharge identification. Overall, DAS enables high spatiotemporal resolution monitoring to pinpoint concealed outfalls minimally invasively. This positions DAS as a promising tool supporting improved water governance through early pollution warnings and rapid source localization via outfall vibrational signatures emanating across river networks.

(c) Power spectral density (PSD) comparison of the discharge signal, wave noise, and system noise. (d) Outfall location identified by calculating vibration power (10–30 Hz) along the cable.

### 3.5 Enhanced traffic monitoring

Traffic monitoring provides crucial data for intelligent transportation systems (ITS) but traditional sensors are expensive to deploy and maintain at scale. A field experiment was conducted using a section of telecommunications fiber-optic cable co-trenched with a natural gas pipeline in Yudu County, Ganzhou City, Jiangxi Province (Figure 11). We explore DAS using existing fiber-optic infrastructure as a cost-effective solution for traffic monitoring [9]. While DAS offers advantages, vehicle detection signals are susceptible to noise. To address this, we propose a novel approach combining DAS with deep learning object detection using YOLOv8. Pre-processed and labeled DAS data collected over two weeks on a highway during a COVID-19 lockdown were used to train the YOLOv8 network, achieving 92% classification accuracy. Applying the trained model revealed detailed hourly traffic patterns and vehicle compositions (Figures 12 and 13), demonstrating the potential of DAS for robust and cost-effective ITS. These findings highlight the effectiveness of combining DAS and deep learning for noise mitigation in traffic monitoring and provide valuable insights into traffic dynamics during the pandemic.

## 4 CONCLUSIONS

This overview demonstrates the transformative potential of DAS as a unified monitoring solution for heterogeneous infrastructure systems. Across geohazard monitoring, structural integrity assessment, and urban network management applications, DAS consistently proves its capacity to convert standard optical fibers into high-resolution vibration sensor arrays. By synergizing Rayleigh backscattering physics with machine learning architectures, the technology overcomes traditional trade-offs between spatial granularity, coverage range, and operational scalability.

The case studies reveal two paradigm-shifting attributes: First, DAS inherently operates as a cyber-physical transducer, simultaneously capturing mechanical wavefields and feeding AI-driven digital twins. Second, its compatibility with existing fiber networks enables rapid deployment at marginal cost, particularly advantageous for linear assets like pipelines and tunnels. While signal interpretation remains context-dependent, emerging standardization frameworks for DAS data annotation are reducing domain adaptation barriers.

As cities prioritize infrastructure resilience, DAS emerges as a strategic tool for converged monitoring of above-ground and subsurface environments. Future implementations could expand its use in decarbonization initiatives, such as CO<sub>2</sub> storage integrity verification and smart grid dynamics tracking. By bridging physical infrastructure with computational analytics, this technology redefines the boundaries of structural health monitoring in the era of ubiquitous connectivity.

## ACKNOWLEDGMENTS

The authors extend their sincere gratitude to all past and present members of Nanjing University's DAS research team whose intellectual contributions and persistent efforts shaped the ideas and projects described in this work. Particular appreciation goes to colleagues who participated in multi-year collaborations that made this decade-long research journey possible. This research was supported by the National Natural Science Foundation of China through grants 42107153 and 42030701, and the Young Elite Scientists Sponsorship Program of the China Association for Science and Technology through grant YESS20200304.

**ABSTRACT:** 60s economic boom led to spread construction of large transport infrastructures. Many of these steel reinforced concrete structures attain their end of lifespans on this and next decade. With no major renewing plan, repairing and retrofitting are explored alternatives. A good example is Milano's ring-road viaduct; while already repaired and its concrete deck enlarged, SHM begins nowadays. **Monitoring of thermal and mechanical induced strain, static and dynamic, brings access to permanent strain, thermal expansion, eigenmodes of each single road span and better understanding of the whole structure dynamic behavior.** Three trucks moving at 30 km/h load dynamically the enlarged deck, while real traffic is used for modal analysis. Often, this kind of comprehensive monitoring requires combining various measurement technologies, making their installation time-consuming and expensive. Thus, the number of sensors may be undercut, and measurement campaigns duration reduced, which may result in poorer monitoring results and mismatching between experimental results and model's ones. FEBUS SHM solutions based on DAS (Distributed Acoustic Sensing), DSS (Distributed Strain Sensing) and DTS (Distributed Temperature Sensing) provide quick instrumentation and easy monitoring. With long-range devices to address tens of km of infrastructure instrumented in a row, up to 400 kHz continuous monitoring, state-of-the-art DAS repeatability threshold of only 2 picoStrain/SquareRoot(Freq), FEBUS DFOS (Distributed Fiber Optics Sensing) solutions brings values for every node of the structure, remote monitoring and mastered opex and capex.

**KEY WORDS:** SHM; DFOS; DAS; Bridge monitoring; Dynamic strain monitoring; Fiber Optics instrumentation.

## 1 INTRODUCTION

DFOS begins to play a major role in SHM due to its outstanding combination of huge number of sensing points, sensitivity, repeatability, and easiness of very large instrumentation. In the past, DAS (Distributed Acoustic Sensing based on Rayleigh Backscattering in fiber optics) has been used to assess the dynamic behavior of a structure, while DSS/DTS (Distributed Strain Sensing / Distributed Temperature Sensing both based on Brillouin backscattering in fiber optics) focused on quasi-static strain and temperature monitoring.

The collapses of widely used infrastructures like the Morandi Bridge in Genoa and the Florida International University Pedestrian Bridge have highlighted the need of implementing monitoring strategies to prevent such disasters. These failures are often attributed to design flaws, material deficiencies, overloading, or insufficient maintenance. Following the Morandi bridge collapse, a substantial number of infrastructures were flagged for close inspection. DFOS monitoring can play a major role in detecting anomalies and raising early alerts to infrastructure operators and owners before collapses occur. Indeed, traditional point sensors have limitations, especially in urban environments with complex needs, stacked infrastructures and embedded networks [1 - 7]. When addressing Operative Modal Analysis, we can benefit from high sensitivity of DAS, and different kind of active and passive sources can be used. Indeed, Ambient vibration recordings provide valuable dynamic information on structural behavior. These vibrations stem from various sources such as traffic on the deck and ambient anthropogenic noise, including external traffic, construction activities, and industrial

operations, as well as natural elements like wind and earthquakes. They enable the estimation of dynamic parameters related to structural properties and serve as a valuable tool for monitoring structural condition [8 - 12].

This study shows how FEBUS Optics' DAS technology can be used for both dynamic (OMA) and quasi-static strain monitoring of an enlarged steel reinforced concrete bridge, which is a high-traffic viaduct.

Figure 1. Two in-parallel motorway steel reinforced concrete viaduct. Yellow lines show extended deck interface.

Indeed, the sensed structure is Milano's Ring-road, having a 12 km concrete viaduct with new bridge held by their own piles have been built parallel to each original viaduct and the road-

slabs have been joined together through steel bars (Figure 1, Figure 2).

Figure 2. Transversal section. Extended deck in yellow frame

This viaduct is facing several issues and challenges. It is suffering from corrosion on its exposed rebars at several locations, not fully successful repair works, heavy traffic, and interferences with other infrastructures and buildings that complicate the attempts of structural retrofitting to improve safety and durability.

This study covers the first tests done with the initially instrumented parts of the viaduct and brought significant results to improve the understanding of the behavior of the structure, allowing to check the viability of the instrumentation for the entire viaduct, validating the numerical models, and highlighting the importance of monitoring and control of the structure to the asset operator (confidential).

## 2 METHODS

### 2.1 DAS. Distributed Acoustic Sensing

DFOS technologies rely on one of the three backscattering effects which are Rayleigh, Brillouin and Raman. The DAS (Distributed Acoustic Sensing based on Rayleigh backscattering technology) record high-frequency laser pulses sent into the fiber, analyzing backscattered light to detect heterogeneities along the cable.

Rayleigh backscattering, caused by defects in the fiber, is repetitive along its length and changes when the fiber is disturbed by external events. These changes grant access of physical parameters variations like vibrations coming from a leakage being energetic enough to propagate its related noise around. The optical phase shift between two positions along the fiber is related to the longitudinal strain using equation 1 below. Key acquisition parameters include fiber length, pulse rate frequency, spatial and temporal sampling intervals, and gauge length (GL).

$$\varepsilon_{yy} = \frac{\lambda \cdot d\theta}{4\pi \cdot n \cdot GL \cdot \xi} \quad (1)$$

Where  $\varepsilon_{yy}$  is the longitudinal strain,  $\lambda$  is the optical wavelength,  $d\theta$  is the phase shift,  $n$  is the optical fiber index and  $\xi$  is a correction factor.

As briefly introduced above, the optical principle of operation is based on the Rayleigh backscattering of a light pulse propagating through the fiber. As it progresses, a tiny fraction of the laser pulse is continuously returned to the interrogator by random heterogeneities present in the fiber. An acoustic interaction at one point of the fiber will alter this process allowing its detection and location by time of flight of light (Figure 3).

Figure 3. Principle of measurement via DFOS.

The information is contained in the optical phase of the received signal requiring interferometric detection. As the pulse propagates very quickly, the fiber can be repeatedly interrogated by sending a series of pulses, thus allowing to solve in frequency of acoustic vibrations (Figure 4) [13 – 17].

Figure 4. Distributed acoustic measurements. Filtered signal Bandpass @465Hz (Width 20Hz)

The achieved acoustic bandwidth can range from a few Hz to a few tens of kHz, the upper limit being a function of the length of the fiber used (the longer the fiber is, the longer the pulse will travel through the fiber and the lower the cut-off frequency is). This device performs highest state-of-the-art sensitivity,

which is an advantage but can also be a disadvantage by being subject to noise acoustic environment. Real-time digital processing of the data is required to extract the signals of interest, as well as correctly applying the technology and instrumenting in the right manner the structure to be sensed. [18]

Figure 5. Fast Fourier Transform representation of Rayleigh, Brillouin and Raman backscattering [19]

## 2.2 Experimental Setup. Dynamic loading of the viaduct

Given the fact that the evolution of elastic modulus because of material ageing was not characterized and not having preliminary results from previous measurements at the beginning of this test campaign, one of the main challenges was to mobilize heavy enough loads to ensure the entire structure would strain as theoretically expected. To do so, up to three trucks were used to bend each span. The principle was very simple, each span was statically and dynamically strained by three trucks moving on single file at 30 km/h (Figure 6). Live tests were done overnight to be able to use these heavy trucks for loading.

Figure 6. Principle of dynamic bending of viaduct's span.

Strain rate was measured by DAS. Both strain rate and dynamic strain were real-time plotted onsite. Indeed, time-integrated strain rate brings strain without need of classic DSS (Distributed Strain Sensing based on Brillouin). This use of Rayleigh backscattering technology (DAS) combines the best state-of-the-art repeatability of FEBUS A1 (DAS), the capability of measuring quasi-static strain and high frequency (up to 400 kHz) strain all along the sensing fiber optic cable which would be complex to match using Brillouin technology (DSS/DTS) going up to around 100Hz nowadays.

## 2.3 Sensors. Fiber Optic sensing cables

Three different fiber optic sensing cables were tested for this study.

- Strain sensing - Tight-buffered cable with steel reinforcement. Deemed the robust cable.
- Strain sensing - Tight-buffered cable without steel reinforcement. Lighter and less rigid providing more sensitivity but less protection.
- Temperature sensing - Loose tube cable. Essential to understand the thermal expansion of the viaduct. Not presented on this publication.

While choosing a robust (tensile, bending and torsion resistant) make sense for high demanding deployments, the downside is that cable reinforcements increase stiffness which tends to reduce sensitivity of the cable. That's why the second strain sensing tight-buffered cable without steel reinforcement is selected (Figure 7).

Additionally, temperature sensing loose tube cable is used for both assess the thermal behavior of the viaduct, typically sensing the temperature evolutions between day and night as well as seasons ones. This was used for a classic temperature compensation with other Brillouin interrogator used on the study but out of the scope of this paper.

## 2.4 Instrumentation

Different approaches were discussed during preparation phases. Indeed, one of the difficulties were to find a cost-effective method to instrument the entire viaduct in a durable and sensitive way. It is important to note that the instrumentation is done beneath the viaduct deck, under its bottom, so gravity is pulling down the whole cable/glue until fully cured. Prior the bonding, point-by-point attachments allow to place the cable at right position until the glue is spread and cured.

All the cables were bonded using three different glues:

- Fast crosslinking (*curing*) - Resin PPPO (2,5-diphenyl-p-phenylene oxide). Combining tenacity and vacuum effect to increase quick adherence (bonding strength).
- Strong - Thixotropic Polyurethane (undisclosed formulation). Extremely rigid after crosslinking. Specially designed for structural gluing.
- Medium Strong - Thixotropic Polyurethane (undisclosed formulation). Less rigid and quicker on crosslinking than the second one. Specially designed for structural gluing.

Fast curing adhesive is used for the first part of the instrumentation. Despite the use of temporary tape, uncured state viscosity remains too low and not perfectly fully suited to bottom instrumentation. Main goal was to deem if coupling is severely impacted by the type of Strong and Medium Strong adhesives (Figure 7).

Figure 7. Sensors and Instrumentation.

Figure 7 shows the sensing fibers instrumentation in a single loop, so the full line is interrogated using only one channel. It is important to note during data interpretation that each cable passes three times through the same spatial point. This way, each truck will be seen three times.

### 3 RESULTS

#### 3.1 Strain Rate monitoring

The results are presented on a 3-axis diagram typically called inverted waterfall. Time on vertical axis (sooner time close to zero), distance on horizontal axis and magnitude of strain Rate on colour scale on the right side (Figure 8).

The bending of the viaduct is properly captured. As expected, the tension relative strain (positive, red) appears first then replaced by compression (negative, blue) as truck goes away from each sensing point. This is coherent with a bended deck sensed on its bottom (Figure 6).

Figure 8. Longitudinal axis Strain Rate. Comparison of three different adhesives and two first instrumented spans.

It is noted the three trucks are equally captured. Indeed, three consecutive positive and negative loadings (related to (tension and compression respectively) are plotted. Furthermore, the amount of strain is the same, meaning the three trucks weigh the same. Since the loads are moving at constant speed, both tension and compression strain rate follow constat slope. Trucks are moving in the same direction and sense; the wavy shape is due to the sensing fiber loop instrumentation (Figure 7). Both spans respond qualitatively and quantitatively in the same way. The same slope and same amount of strain rate around  $\pm 1500$  nm/m/s. It is important to highlight the units (nanometers/meter/second) to understand the slight straining of the viaduct deck.

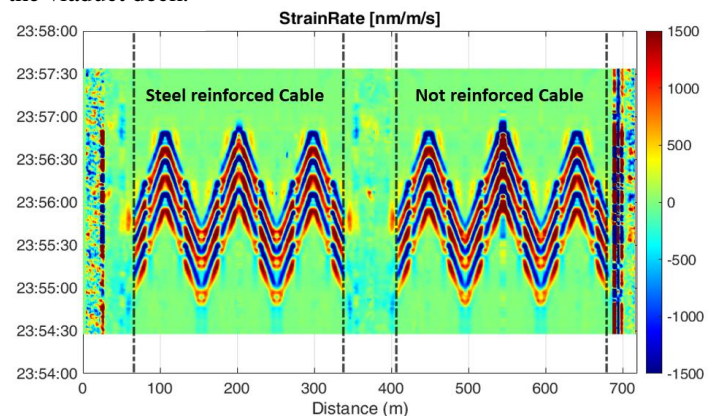

Figure 9. Longitudinal axis Strain Rate. Comparison of Steel reinforced and not reinforced cable.

Then, the adhesive and bonding are assessed. It is shown that all three adhesives show the same response. Indeed, there are no significant differences on the intensity of the strain rate which points to a similar coupling structure-sensors, leading *in fine* to a similar sensitivity. The same conclusion for the comparison between steel reinforced cable and not reinforced one, having similar sensitivity (Figure 9).

#### 3.2 Strain monitoring

From previous results, strain rate expressed in nm/m/s - typical dimension and units of vibration on DAS measurements - many useful information can be inferred.

Dynamic strain rate can be time integrated to obtain strain, expressed on  $\mu\text{m/m}$ . In this case, typical integration time is 1ms but can be adjusted thanks to the capabilities of FEBUS A1 (DAS) to modify all its measurement parameters like pulse rate frequency (number of laser pulses emitted per time) and time resolution.

Figure 10. Longitudinal axis strain from time integrated strain rate

In the graph above (Figure 10), the strain is plotted in function of time (left axis) and distance (bottom axis), while intensity of the strain is represented by the color scale on the right. To enhance the result, only two first spans with strong glue are plotted. From 105 m to 155 m.

It is important to note the trucks are travelling from far distance to closer one, more precisely started on 155 m and go to 105 m, while the time is increasing on the left axis, so the trucks' movements is seen as diagonal from bottom right corner of the graph to the upper left corner.

It is observed in the figure above (Figure 10) the same patterns of positive and negative strain for each truck pass, as seen with strain rate. In contrast of strain rate results exploitation, we can note that the first span is reaching up to 100  $\mu\text{m/m}$  on tensile and -60  $\mu\text{m/m}$  on compression, while the second span is less strained on tensile, going up to 80 only  $\mu\text{m/m}$ , and the same compression strain of -60  $\mu\text{m/m}$ .

To go further in the quantification, we can see the pass of the trucks two and three on second span seemed to load 20  $\mu\text{m/m}$  more than the pass of the first truck.

### 3.3 Displacement monitoring

It is important to note that one the main aim of this study was to quantify the positive longitudinal displacement of the span because of the bending. To do so, a space integration was done at a particular point, where the strain was related to tensile, so positive. The region of this point is represented by the orange rectangle between 110 m and 115 m (Figure 10).

#### Longitudinal axis displacement

Figure 11. Longitudinal axis displacement from space integrated strain

In the graph above (Figure 11), we can see the result of the space integration of the strain rate, which is the longitudinal axis displacement created by the bending of the span. The length of integration was 1m, which can be tuned as wished with FEBUS A1. Thus, it is observed the amount of displacement is 80  $\mu\text{m/m}$  on first span. This matches the expectations from numerical modelling as confirmed by the technical direction of CaemATE Srl, the entity tasked of the mechanical modelling of the bridge for this study.

### 3.4 Modal analysis with DAS

FEBUS A1 DAS was applied for monitoring of strain rate, strain and displacement but also for its more common use, modal analysis. The same cable and interrogator were suited for this kind of acquisition, and the real traffic at a high load time of the day (rush hour) was used. This is widely used and bring plenty of acoustic signals. Since the sensitivity of DAS is very high, it is preferable to plot results at one single point but other FFT-based 3D representations allow to get info from the entire line at once. In this case, the choice is to represent time on left axis while the frequency is on the bottom axis, while color represents the signal energy, thus amplitude of the vibration (Figure 12).

### Modal Analysis of the viaduct

Figure 12. Vibrations from real traffic, frequency in function of time for a particular point

From previous information, the frequencies can be represented for a particular point and time, thus the amplitude of the vibration in function of the frequency, as shown on the figure below (Figure 13). In the aim of comparison of different states, two instants are plotted, on red the steady state to see the ambient noise when no vehicle on the instrumented spans, and blue for high intensity signals from traffic on the instrumented spans.

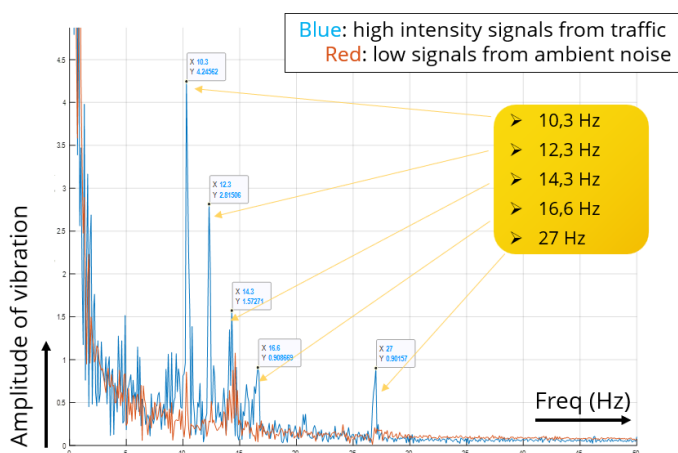

Figure 13. Modal frequencies of the viaduct

Up to five modal frequencies are detected clearly, between 10,3 Hz and 27 Hz.

It is important to note that this is plotted for one single point, thus one node identified previously on FFT over distance, but it is possible to do the same analysis for all the nodes of the structure, that are sensed simultaneously thanks to the properties of Distributed Acoustic Sensing, and its long range and fine resolution measuring capabilities.

## 4 DISCUSSION

It has been shown that DAS technology can be applied to both dynamic and quasi-static acquisitions addressing OMA and strain measurements with the same sensor (Fiber Optics) and DAS interrogator (FEBUS A1). Live data production - time and space integration - allowed to go from strain rate to strain and displacement during the acquisitions and check the quality of results and the coherence with the numerical models.

While this is mathematically well known, the application of this methodology to DAS acquisitions is a novelty that unlocks new applications of DAS in the context of SHM and Civil Engineering as well as other potential uses on sectors like Oil & Gas and Geophysics, for static and dynamic assessment of pipelines and ground movement for instance. Indeed, thanks to the capabilities of FEBUS A1, all measurement parameters can be easily modified to suit to the infrastructure length and acquisition demands.

Besides, one of the main advantages of Modal analysis of DAS monitoring is the possibility to combine high sensitivity and decide the position of nodes after instrumentation, allowing to overcome the difficulties of predicting the nodes of the vibration modes, and deciding the right positions to locate traditional point sensors without knowing how the structure behaves dynamically. For the selected position, 5 modal frequencies were located spectrally and quantified in terms of amplitude of vibration.

The measurements were achieved with all the combinations of cable and adhesive in the scope, two different cables, steel reinforced and not reinforced, and three different glues. Indeed, all cables and glues tested shown good properties in terms of coupling and sensitivity for the intended goal of longitudinal axis displacement and Modal Analysis.

**ABSTRACT:** Real-time monitoring and accurate localization of pipeline leaks are crucial for pipeline safety. Conventional methods often fail to detect micro-leaks and face issues such as low positioning accuracy, high false alarm rates, and inability to monitor long distances. This study proposes two innovative leakage monitoring methods based on distributed temperature sensing (DTS) and distributed strain sensing (DSS). The first method utilizes evaporation-induced relative humidity measurement. By measuring the temperature of DTS fiber optic cables wrapped in gauze, real-time detection and localization of leaks in pipelines carrying ambient-temperature liquids can be achieved. A significant temperature drop at the leakage location allows precise identification of micro-leaks. The second method employs fiber optic cables with water-swelling blocking yarns for localized strain sensing, combined with Optical Frequency Domain Reflectometry (OFDR). At the leakage location, the strain of the sensing fiber significantly decreases, providing a distinct signal for detection. Indoor experiments confirmed the feasibility of both methods, demonstrating their ability to achieve real-time monitoring and precise localization of micro-leaks. These methods offer novel solutions for addressing pipeline leakage challenges.

**KEY WORDS:** Micro-Leakage; Distributed Fiber Optic Sensing; Distributed Temperature Sensing; Distributed Strain Sensing.

## 1 INTRODUCTION

Pipeline transportation is a widely adopted technology for conveying fluids such as gases and liquids. In recent years, it has developed rapidly and has been extensively applied in sectors such as energy, municipal infrastructure, and water conservancy due to its advantages of high transport capacity, small land footprint, short construction cycles, and low operational costs. As one of the five major modes of modern transportation—alongside rail, road, waterway, and air—pipeline systems have become the predominant solution for transporting water, oil, and gas across land, playing a critical role in national economic development and public safety [1,2].

However, as pipelines age, they become increasingly vulnerable to damage caused by thermal expansion and contraction, fatigue, corrosion, foundation settlement, or accidental excavation. These factors frequently lead to failures such as rupture or leakage, resulting in significant resource loss and economic damage. Consequently, real-time monitoring and accurate localization of pipeline leakage are essential to ensuring safe operation, protecting public assets, and maintaining system reliability [2].

Conventional leakage detection methods—such as the negative pressure wave, mass balance, ground-penetrating radar (GPR), capacitive sensing, electromagnetic reflection, and acoustic emission (AE)—have been widely utilized, but each presents notable limitations. While some offer advantages like fast response or low cost, they often suffer from poor localization accuracy, high false alarm rates, limited sensitivity to small or slow leaks, and an inability to monitor over long distances. For example, the negative pressure wave method is effective only for large and sudden leaks; the mass balance method lacks precise localization capability; and GPR and AE techniques are heavily dependent on operator expertise and are

sensitive to environmental noise. These drawbacks significantly restrict their applicability in large-scale or complex pipeline systems.

In this context, distributed fiber optic sensing (DFOS) has emerged as a promising alternative, offering numerous advantages such as corrosion resistance, compact structure, high sensitivity, immunity to electromagnetic interference, and long-term operational stability [3]. By monitoring physical parameters such as temperature, strain, or vibration, DFOS enables distributed and real-time leak detection with high spatial resolution.

Among DFOS techniques, temperature-based methods have been most extensively studied. For instance, Vogel et al. [4] employed Distributed Temperature Sensing (DTS) to detect pipeline leaks by identifying abnormal temperature variations, a method that has since gained widespread adoption. Wang et al. [5] applied Brillouin Optical Time-Domain Reflectometry (BOTDR) for temperature-based leak detection and investigated how different installation methods influence sensing performance. However, these approaches typically rely on a significant temperature difference between the leaking fluid and the surrounding environment. To address this issue, some researchers have introduced active heating of the fiber to enhance detection sensitivity [6], though this introduces safety concerns in environments containing flammable gases. Commercial systems such as Omnisens DiTeST, which utilize both Brillouin and Raman scattering to monitor temperature and strain, can detect large-scale leaks but usually require the leakage volume to exceed 0.01% of the total flow to be identified [7].

Additional innovations include MacLean's polymer-embedded fiber design, which swells upon contact with leak fluids and causes signal attenuation detectable via Optical

Time-Domain Reflectometry (OTDR) [8]. While effective, this design is single-use and must be replaced after each leak event. Similarly, Jia et al. adopted Brillouin Optical Time-Domain Analysis (BOTDA)-based strain sensors, which exhibited significant accuracy degradation and poor reusability after leakage exposure. Interferometric methods such as Sagnac or Mach-Zehnder configurations offer high sensitivity but require complex signal processing. Moreover, Stajanca et al. [9] applied Distributed Acoustic Sensing (DAS) based on Rayleigh scattering to detect vibrations from gas leaks, but the method was highly susceptible to environmental noise, had low localization accuracy, and consumed large amounts of optical fiber.

Despite these advancements, current DFOS-based technologies still face three main challenges:

(1) limited ability to detect ambient-temperature liquid leaks without external heating;

(2) low sensitivity to small or slow leakage events, resulting in potential missed detections; and

(3) dependence on non-reusable sensing materials, such as polymer coatings that degrade upon fluid exposure.

To address these limitations, this study proposes two novel DFOS-based methods for micro-leakage monitoring in tunnel pipelines. The first method utilizes evaporation-induced humidity sensing, in which a gauze-wrapped DTS fiber detects localized temperature drops caused by water evaporation at leak points. The second method employs Optical Frequency Domain Reflectometry (OFDR)-based strain sensing, using fiber optic cables integrated with water-swelling blocking yarns that exhibit measurable strain changes upon contact with leaking fluid.

## 2 MATERIALS AND METHODS

### 2.1 Pipeline Leakage Sensing Principle Based on EETS-DTS

Distributed Temperature Sensing (DTS) technology measures temperature along an optical fiber by exploiting the temperature-dependent intensity ratio between Stokes and anti-Stokes components of Raman backscattered light. When a pump pulse is launched into the fiber by a DTS laser source, photon-molecule interactions generate backscattered Raman signals at two distinct frequencies—Stokes and anti-Stokes. The Stokes signal intensity is largely temperature-independent, while the anti-Stokes intensity is strongly temperature-sensitive, increasing with local fiber temperature.

The DTS interrogator calculates the temperature at each point by computing the intensity ratio of the anti-Stokes to Stokes signals and locates the scattering position using the round-trip travel time of the light pulse. The temperature  $T$  can be expressed as follows:

$$R(T) = \frac{I_F}{I_S} = \left(\frac{\nu_F}{\nu_S}\right)^4 e^{\frac{-h\nu}{KT}} \quad (1)$$

where  $R(T)$  is the temperature function,  $I_F$  is the anti-Stokes light intensity,  $I_S$  is the Stokes light intensity,  $\nu_S$  is the central frequency of the Stokes component,  $\nu_F$  is the central frequency of the anti-Stokes component,  $c$  is the speed of light in vacuum,  $\nu$  is the Raman shift,  $K$  is the Boltzmann constant,  $h$  is the Planck constant, and  $T$  is the absolute temperature.

The distance from the laser input to the scattering point can be determined by:

$$X = \frac{cT}{(2n)} \quad (2)$$

where  $X$  is the distance,  $v$  is the speed of light in vacuum,  $t$  the travel time of the light and  $n$  is the refractive index of the fiber. By combining Equations (1) and (2), the temperature at any point along the fiber can be measured in a distributed manner.

Figure 1. Principle of distributed temperature sensing (DTS) technology.

In unsaturated air, evaporation can occur at any temperature. When leakage occurs in a pipeline, the leaked liquid may come into contact with the sensing cable. However, conventional temperature-sensing cables have smooth outer surfaces, which inhibit significant evaporation, leading to minimal temperature drop. To enhance detection sensitivity, Sun et al. [10] proposed wrapping the fiber with porous gauze, which increases water absorption and promotes evaporation.

The proposed Evaporation-Enhanced Temperature Sensing DTS (EETS-DTS) method involves deploying a gauze-wrapped DTS cable beneath the pipeline. The gauze absorbs leaking water and facilitates capillary spreading due to its high porosity and large surface area. This promotes enhanced evaporation, resulting in a localized temperature decrease at the leak site, which is detected by the DTS system. Over time, a thermal equilibrium is reached between the heat loss due to evaporation and the heat supplied by ambient air, causing the gauze temperature to stabilize at a value lower than the surrounding dry areas.

For ambient-temperature water leakage, the temperature difference  $\Delta T$  between dry and wet cables can be estimated using the World Meteorological Organization (WMO) psychrometric formula:

$$\Delta T = T_1 - T_2 = \frac{e_w(t_2) - U/100 \cdot e_w(t_1)}{AP} \quad (3)$$

where  $e_w(T_1)$  and  $e_w(T_2)$  are the saturated vapor pressures corresponding to the dry and wet cable temperatures,  $U$  is the relative humidity (%RH),  $A$  is the psychrometric coefficient (related to air velocity and sensor design), and  $P$  is the atmospheric pressure (MPa). Hence, the temperature difference is mainly influenced by humidity and ventilation conditions.

Figure 2. Schematic of the EETS-DTS leakage detection principle.

The DTS cable used in this study (model NZS-DTS-C09) has an outer diameter of 5 mm and consists of five structural layers: a tight-buffered optical fiber, spiral steel armor, Kevlar yarn, braided metal mesh, and a protective outer sheath (Figure 3). The spiral armor and braided mesh provide mechanical protection, the Kevlar layer enhances tensile strength, and the outer sheath offers good thermal conductivity and flame resistance. The cable operates reliably within a temperature range of  $-20^{\circ}\text{C}$  to  $85^{\circ}\text{C}$ .

Temperature data are collected using a DTS interrogator (model NZS-DTS-A03), manufactured by Suzhou Nanzee Sensing Technology Co., which provides high-resolution distributed temperature profiling along the fiber. The key specifications of the device are listed in Table 1.

(b)

Figure 3. Structure of the DTS temperature-sensing cable: (a) Schematic diagram; (b) Physical photograph.

Table 1. Specifications of the DTS interrogator.

Parameter type	Value
Measurement range (km)	1~16
Temperature range ( $^{\circ}\text{C}$ )	$-40\sim 120$
Fiber type	Multimode 62.5/125 or 50/125
Temperature accuracy ( $^{\circ}\text{C}$ )	$\pm 0.3$
Temperature resolution ( $^{\circ}\text{C}$ )	0.1
Response time (s)	2 s/channel
Spatial resolution (m)	0.5~3
Number of channels	4
Fiber connector type	FC/APC
Communication interface	USB / RS232 / Ethernet
Power supply	DC19V

## 2.2 Pipeline Leakage Sensing Principle Based on OFDR

Optical Frequency Domain Reflectometry (OFDR) is a high-resolution sensing technique based on frequency-swept continuous wave interferometry (FMCW). It employs a laser source with linear wavelength sweep combined with heterodyne detection. The optical signal is split into two arms: a reference arm and a signal arm. Due to differences in optical path lengths, the Rayleigh backscattered signal from the sensing fiber interferes with the reference signal, producing a beat frequency that is directly proportional to the scattering position. By applying a Fast Fourier Transform (FFT) to the interference signal, a spatially resolved Rayleigh scattering profile can be obtained.

Rayleigh scattering originates from random microscopic fluctuations in the refractive index of the fiber. Froggatt and Moore modeled these variations as a weak random Bragg grating. When external strain is applied to the fiber, the local spectrum of the Rayleigh scattering shifts. The magnitude of this spectral shift is linearly proportional to the applied strain. By comparing the shifted spectrum with a reference state, the strain distribution along the fiber can be quantified with high spatial resolution.

Figure 4. Measurement principle of OFDR.

Building upon the high-resolution strain measurement capability of OFDR, this study proposes a novel strain-sensing cable that incorporates water-swelling yarns into a fixed-point sensing structure. These yarns are made of polyester filaments coated with super-absorbent polymers (SAPs) and are commonly used as water-blocking fillers in optical cables. The SAPs contain abundant hydrophilic functional groups and a moderately cross-linked polymer network, enabling them to absorb water up to hundreds or even thousands of times their own weight. Once hydrated, the yarns expand into a hydrogel, maintaining structure under pressure and remaining functional under thermal cycling.

Figure 5. Schematic of pipeline leakage detection using OFDR and water-swelling yarns.

In the proposed sensing cable, the fiber is pre-tensioned between discrete fixed points. Upon contact with leaked liquid, the SAP yarns rapidly swell, reducing the tensile force acting between anchor points. This localized strain reduction is accurately captured by the OFDR system, allowing for precise leakage detection. The cable features a four-layer construction, consisting of: a 0.9 mm tight-buffered strain-sensing fiber, a spiral armored tube, water-swelling yarn, and an outer braided mesh (Figure 6).

Figure 7. Structure of the strain-sensing cable with water-swelling yarns: (a) Schematic diagram; (b) Physical photograph.

The cable is fixed at 1-meter intervals, creating a structure with discrete sensing segments. The outer mesh ensures that the yarn remains in place during operation. The yarn itself consists of two components: a super-absorbent polymer (e.g., polyacrylate), which swells when exposed to water, and reinforcement fibers (e.g., nylon or polyester), which improve tensile strength and elongation properties. The key specifications of the water-swelling yarn and the OFDR interrogator (model OSI-S) are presented in Tables 3 and 4, respectively.

Table 3. Performance parameters of water-swelling yarn.

Property	Value
Yarn linear density (dtex)	3330
Basis weight (m/kg)	3000
Breaking strength (N)	≥100
Elongation (%)	15
Swelling rate (ml/g in 1st minute)	≥60
Long-term thermal swelling (150 °C, 24 h, ml/g)	≥65
Instant thermal swelling (230 °C, 10 min, ml/g)	≥65
Moisture content (150 °C, 1 min)	9

Table 4. Specifications of OSI-S OFDR interrogator.

Type	Specification
Portable enclosure dimensions (mm)	280×250×164
Portable enclosure weight (kg)	4.5
Spatial resolution (mm)	1-100
Maximum sampling resolution (mm)	1
Temperature accuracy (°C)	±0.1
Temperature repeatability (°C)	≤0.1
Measurement range (m)	100

### 3 RESULT

#### 3.1 EETS-DTS Monitoring

Based on the spatial resolution of the DTS system, the length of gauze wrapping on the EETS cable was set to 1.8 meters. To simulate leakage, a 2-meter-long PVC pipe with an inner diameter of 75 mm and a leakage hole at the bottom was used. The fiber optic cable was secured directly beneath the pipe using plastic zip ties. Before the experiment, the water inside the pipe was left to stand for 24 hours to allow its temperature to reach equilibrium with ambient conditions.

During the test, the PVC pipe was maintained in a fully filled state. A dual-probe PT100 thermometer was employed to continuously monitor and record both the water temperature inside the pipe and the ambient air temperature. As humidity can significantly influence evaporative cooling, a digital hygrometer was placed near the pipe to record ambient relative humidity throughout the experiment.

The DTS temperature-sensing cable was connected to a temperature calibration box, which in turn was linked to the DTS interrogator, enabling real-time acquisition of the distributed temperature profile along the fiber. The complete experimental setup is shown in Figure 8.

Figure 8. Photograph of the experimental setup.

Figure 9 presents the temperature variation trends at different positions along the bare DTS cable wrapped with gauze. The observed behavior is consistent with that of the sheathed cable: the temperature at each point decreases over time, and the closer a point is to the leakage location (located at 6.02 m), the greater the temperature drop. Furthermore, the temperature distribution is approximately symmetrical about the leakage point.

Figure 9. Temperature variation trends at different positions along the bare DTS temperature-sensing cable.

However, in contrast to the sheathed condition, where temperatures eventually stabilized, the bare cable setup exhibited a continuous temperature decrease over time, without reaching equilibrium. This indicates that the evaporative heat loss exceeded the heat replenishment from the surrounding environment, suggesting that a dynamic thermal balance was not achieved during the experiment. One possible explanation is that, in this configuration, the gauze was directly wrapped onto a copper mesh, enhancing the fluid contact efficiency and promoting stronger evaporation, which resulted in sustained cooling.

Figure 10 illustrates the temperature distribution profiles along the bare cable at different time intervals. Similar to the sheathed condition, the temperature profile forms a characteristic “arch-shaped” curve, indicating that the temperature is lowest near the leakage point at any given time. However, compared with the sheathed cable, the bare cable exhibits a sharper temperature gradient, with a maximum temperature difference of 2.8 °C observed at 3600 seconds.

Figure 10. Temperature distribution along the bare DTS sensing cable at 3600 s.

These results indicate that the protective sheath has a noticeable effect on the EETS-DTS leakage detection performance. The bare cable yields clearer monitoring results, suggesting improved sensitivity. Therefore, the following sections focus on analyzing influencing factors for the bare EETS-DTS configuration.

### 3.2 OFDR-Based Monitoring

In this experiment, a peristaltic pump was employed to control the leakage rate, and both ends of the strain-sensing optical fiber cable—embedded with water-swelling yarns—were fixed in place. The leak outlet of the pump was precisely aligned with the sensing section of the cable. The selected leakage rate was 70 mL/min. The OFDR interrogator was connected to capture wavelength shift data corresponding to strain variations. The experimental setup is shown in Figure 11.

Figure 11. Experimental setup for OFDR-based leakage monitoring.

The measured strain distribution along the fiber is shown in Figure 12. Upon leakage, the strain recorded by the OFDR

system dropped sharply and then stabilized. Throughout the leakage process, the strain-affected segment—defined by a significant drop in measured strain—spanned from 3.36 m to 4.36 m. In contrast, the rest of the cable exhibited minimal strain change, resulting in a distinct step-like pattern in the strain profile.

Figure 12. Strain magnitude measured by the fixed-point strain-sensing cable with water-swelling yarns.

To further analyze strain behavior, two points were selected: one located within the strain-drop region and the other outside it. Their strain variation over time is compared in Figure 13. It is evident that the strain at the leakage point decreased rapidly at first, followed by a gradual stabilization, while the unaffected region maintained a stable strain level throughout. The time required for the strain to stabilize was approximately 100 minutes.

Figure 13. Strain variation over time at the leakage point of the strain-sensing cable with water-swelling yarns.

## 4 DISCUSSION

### 4.1 Applicability Analysis

This study presents two pipeline leakage monitoring methods: one based on evaporation-induced humidity sensing using DTS, and the other based on strain sensing using Optical Frequency Domain Reflectometry (OFDR) combined with water-swelling yarns. Both methods are suitable for detecting ambient-temperature liquid leaks in environments where the pipeline is exposed to air, such as underground utility corridors and aboveground pipelines. However, they are not applicable to

buried pipelines, where direct air contact is absent, and evaporation or swelling may be inhibited.

The current work focuses on leakage scenarios involving water as the leaking medium. The effectiveness of these methods for other fluid types (e.g., oils, chemicals) requires further study, as variations in fluid properties may affect evaporation behavior or interaction with swelling materials.

The first method, based on evaporation sensing (EETS-DTS), is generally applicable in a wide range of environments and performs especially well in conditions with low humidity and high airflow, which enhance evaporation and generate more distinct temperature differences. In high-humidity environments, however, evaporation may be limited or suppressed, leading to reduced sensitivity or loss of functionality.

The second method, based on OFDR strain sensing with water-swelling yarns, demonstrates broader applicability. It is insensitive to environmental variables such as humidity and wind speed and exhibits high sensitivity, enabling the detection of small-scale or micro-leaks with better reliability.

#### 4.2 Practical Application Analysis

Both methods offer distributed monitoring capabilities for pipeline leakage and are particularly advantageous for detecting small-volume, ambient-temperature liquid leaks. They are well-suited for underground utility corridors and open-air pipelines, where sensing cables can be conveniently installed beneath the pipelines.

The EETS-DTS method supports long-distance distributed measurement, but it offers relatively low measurement accuracy. In practical scenarios, elevated ambient humidity may cause natural temperature fluctuations, leading to false positives. Additionally, in harsh environments—such as acidic, dusty, or corrosive conditions—the gauze layer may degrade or fail over time, compromising the monitoring performance. For long-term or demanding applications, regular gauze replacement is recommended to ensure reliability.

The fixed-point strain-sensing cable embedded with water-swelling yarns also enables distributed leakage detection. However, given that standard OFDR systems are limited to approximately 100 meters, it is advisable to adopt alternative demodulation technologies such as Brillouin Optical Domain Frequency Analysis (BODFA) or Brillouin Optical Time-Domain Reflectometry (BOTDR) for longer-distance applications.

In practical deployment, a hybrid monitoring strategy is recommended: (1) Use the EETS-DTS method in well-ventilated, low-humidity environments to take advantage of its evaporation-based sensitivity. (2) In environments where the EETS-DTS method is inapplicable or limited, deploy the strain-sensing cable with water-swelling yarns to ensure continued leakage detection.

## 5 CONCLUSION

This study proposed and experimentally validated two novel pipeline leakage monitoring methods based on distributed fiber optic sensing (DFOS): an evaporation-enhanced temperature sensing method using DTS (EETS-DTS), and a fixed-point strain sensing method using OFDR combined with water-swelling yarns. Both approaches demonstrated effective

capabilities for detecting small-scale leaks of ambient-temperature liquids in tunnel or aboveground pipeline environments.

The EETS-DTS method leverages gauze-wrapped optical fibers to amplify evaporation-induced temperature differences, enabling distributed leak localization with a relatively simple setup. It is particularly effective in low-humidity, well-ventilated environments. The OFDR-based strain sensing method utilizes the swelling behavior of specially embedded yarns to detect leakage-induced strain changes with high resolution and sensitivity, and is less affected by environmental variables.

Laboratory experiments confirmed the feasibility and reliability of both methods. The EETS-DTS technique offers advantages in long-range monitoring, while the OFDR-based method provides high accuracy in micro-leak detection. A hybrid deployment strategy is recommended to combine the strengths of both approaches for broader practical applicability.

Overall, the proposed methods provide promising and complementary solutions for pipeline leakage monitoring, offering new perspectives for enhancing infrastructure safety and maintenance in complex pipeline networks.

**ABSTRACT:** Recent developments in digital technology make it possible to create interactive 3D models for structural analysis in a user-friendly software environment. In addition, the technology for creating 3D models of real structures using point cloud data for various users is also developing rapidly. Such rapid change may raise concerns about a developing gap between traditional structural mechanics education based on beam theory and the modern structural analysis scheme. However, if it becomes possible to efficiently perform structural analysis by recreating structures in cyberspace without special skills, it will be beneficial to cultivate a sense of structural mechanics for beginners. In this study, we investigated the feasibility and simplicity of constructing a point cloud-based structural analysis model to capture the general trend of deformation and stress in a structure. Specifically, we constructed a point cloud model from photographs of an approximately 2m long steel plate girder bridge using the SfM technique, meshing the model, and assembled a solid FE model using only general functions of packaged software without any special operations for model modification. We compared the strain in the constructed model under static loading with the actual measured values for the bridge. The model properly calculated the deflection shape, and it will help learners understand structural mechanics.

**KEY WORDS:** Structure from Motion, Point cloud model, Structural mechanics.

### 1 INTRODUCTION

Our predecessors have taught us that the history of structural mechanics is a repeated process of observing phenomena through experimentation, and then formulating and systematising them [1], [2]. Today, students can learn about systematised structural mechanics efficiently. In exchange for these fruits, many students are passive and just learn how to solve problems.

On the other hand, recent developments in structural analysis software have made it possible to precisely analyse structures' deformation and stress distribution with complicated shapes and materials. In addition, it has become possible to model even existing structures easily using point cloud technology[3]. Researches have been conducted on utilising point cloud data for structural analysis. However, they require advanced or complex procedures developed by each researcher[4], [5]. We have yet to fully benefit from them in structural engineering. Bridging the gap between cutting-edge structural analysis technology and traditional structural mechanics education or feeding back the latest technology to the learning of beginners will increase the attractiveness of this engineering area.

The authors investigated the technique of constructing precise structural models of actual structures from point cloud models using SfM (Structure from Motion) or photogrammetry techniques. We have also developed a method for converting point cloud models into 3D FE models that can be used for structural analysis. Through this research, it has become possible to model the damaged actual structures with a certain degree of precision and to evaluate the stress of damaged members. On the other hand, modelling point clouds into appropriate shapes of FE models requires a relatively

complicated procedure, and fine-tuning of parameters is also necessary individually. The precise evaluation of structural performance with automated procedures from point cloud data is the ambitious goal; however, even if the analytical accuracy is somewhat limited, more straightforward procedures will enhance the possibility of structural mechanics.

In this study, we investigated the feasibility and simplicity of constructing a point cloud-based structural analysis model to capture the general trend of deformation and stress in a structure. Specifically, we constructed a point cloud model from photographs of an approximately 2m long steel plate girder bridge using the SfM technique, meshing the model, and assembled a solid FE model using only general functions of packaged software without any special operations for model modification. We compared the strain in the constructed model under static loading with the actual measured values for the bridge.

### 2 FE MODEL FROM POINT CLOUD

#### 2.1 A model bridge and point cloud model

A simple steel girder bridge, an out-of-service railway bridge located on a test bed consisting of two main girders made of rolled I-shaped steel[4], was subject to study. The length of the girder is 2.4 m, and the total width of the bridge is 1.1 m. The steel surface was generally rusted, but there was no significant reduction in thickness. A damaged state was prepared by grinding a 200×68.5 mm area on the top surface of the lower flange at the mid-span of one girder.

The static loading experiment was conducted by placing steel plates on top of the main girders to create a two-point loading

condition as shown in Figure 1. The loading weight is 80 kN. Strain gauges measured strain at the mid-span of girders. The point cloud model of the bridge was constructed using SfM. A SONY  $\alpha 6500$  digital camera captured 2,969 images from around the bridge. The vertical and horizontal overlap rates were set to 80% or more. The Agisoft's Metashape (ver1.6.5.11249) loaded captured images and constructed a tie point cloud with high accuracy. Then, a point cloud model was constructed at medium quality and high-depth filter settings. Figure 2 shows the point cloud model of the bridge. There were no missing points in the entire point cloud. Table 1 shows the plate thickness of the damaged bridge at the center cross-section of the span. The average error was 1.1 mm, and the model was generally accurate. The reduction in plate thickness of the damaged area was also modeled.

## 2.2 Conversion method into FE model

Because the number of points in the point cloud model was enormous, a voxel grid was set on the point cloud, and a voxel downsampling was applied to create nodes. The grid size, which was set to 9mm or 18mm in this study, corresponds to the mesh size of the FE model. The centroid of the point cloud within the grid was then calculated as the node of the FE model.

The girders were divided into web and flanges using the maximum and minimum z-coordinates of the web. The maximum and minimum values were calculated by using the normal vector for each point.

To create a cross-section, align only the x-coordinate value of each point along the component's axis to the same plane. An outline of a section was created along the component's axis. The shape of the outline was controlled by a shrink factor determined by trial and error for each component.

Figure 3 shows the concept of element generation. A 2D Delaunay triangulation was first performed on each cross-sectional outline, dividing the 2D region into triangles using an arbitrarily set group of nodes. Next, the process of generating solid elements was applied to all cross-sections where 2D Delaunay triangulation was performed. For each triangular element on the  $S_n$  cross-section, the closest point on the  $S_{n+1}$  cross-section was found, and triangular solid elements were formed by connecting these points. Lastly, the web and flanges were reconnected using a similar way of generating the solid elements of each component.

The elements and node information were exported to a NAS file and then imported into the structural analysis software Midas NFX. The constructed FE model of the damaged bridge, which is called Model A, will be shown in Figure 4. The analytical result will be discussed in Chapter 4.

## 3 A SIMPLE METHOD FOR POINT CLOUD BASED FEM

The recent development of image processing technologies and laser ranging technologies have brought about several options to obtain point cloud models of structures. If more straightforward procedures can be utilized to construct the FE model from the point cloud model, structural analyses will be much more user-friendly for non-professional users. Therefore, the authors explored a method to compose an FE model using only general software without original codes. The proposed steps are as follows:

Figure 1. Static loading experiment.

Figure 2. A point cloud model of a simple girder bridge.

Table 1. Plate thickness (mm).

		Real	P.C. model
Upper flange (G1)		20.0	19.6 (-0.4)
Web (G1)		15.0	13.1 (-1.9)
Lower flange (G1)	outside	15.0	12.6 (-2.4)
	inside	10.0	10. (+0.4)
Upper flange (G2)		20.0	19.7 (-0.3)
Web (G2)		15.0	12.2 (-2.8)
Lower flange (G2)		20.0	20.1 (+0.1)

Figure 3. Concept of elements generation.

- I. Loading the point cloud data by scanning and meshing software for point cloud data.

In this study, Autodesk ReCap Pro loaded the same point cloud data in the previous chapter. Downsampling is also conducted in the software to 25% of the original point cloud model.

- II. The meshing of the point cloud model

Convert the point cloud to a mesh using the scan-to-mesh service from ReCap with the medium-quality setting.

- III. Converting the meshed data into a 3D object

Recap Photo converts the meshed data to 3D object data in an FBX format. The target face count is decimated by 90%.

- IV. Transformation of the mesh body into a solid body

Autodesk Fusion opens the FBX file and closes the mesh. The mesh body has mass and volume, and then the mesh body is converted into a solid body with the facet option.

The constructed FE model of the bridge, which is called Model B, will be shown in Figure 5, and the analytical result will also be discussed in Chapter 4.

#### 4 LINEAR STATIC LOADING ANALYSES

Linear static analysis is conducted for the constructed 2 FE models; Model A was originally developed by the authors [4], and Model B was the proposed simple model in this study. The boundary conditions in the FE models were applied to the points on the underside of the sole plate, assuming the simple support condition. For the loading conditions, vertical downward loads of 80 kN in total acted at 4 points 400 mm away from the midspan to the support. In Model A, distributed load acted on nodes within the experimental loaded area. On the other hand, 4 concentrated loads were applied in Model B because the size of the automated generated mesh was not uniform and was larger than that of Model A. Commercial software Midas NFX for Model A and Fusion for Model B calculated the stress and deformation of the model.

Figure 4 and Figure 5 show the longitudinal bending stress distribution and the enlarged deformation in Models A and B, respectively. Both figures show that stress distribution and deformation indicate positive bending in the structure.

In the damaged area of Model A, tensile stress increases due to the introduction of damage at the midspan of the lower flange, and compressive stress predominates in the loaded area. The error in the experimental result was about 6% for the nodal longitudinal stress at the damaged point.

On the other hand, the stress value of Model B is generally half of the stress of Model A. The thickness of plates was generally identical to the point cloud model and the actual structure in both FE models. However, the web plates of Model B have some thick parts due to rivets of connection and the roughness of the paint, and they may cause the reduction of stress. The error in the calculated stress is caused by such mesh configuration of Model B because both models are generated from the same point cloud data. Additionally, due to the low density of nodal points, a local torsional deformation occurs in the upper flange because of the eccentric loading at the upper flange, which was not observed in the experiment.

Figure 4. The analytical result of Model A.

Figure 5. The analytical result of Model B.

#### 5 CONCLUSION

The authors have developed the construction method of the FE model from point cloud models. Because straightforward procedures will enhance the possibility of structural mechanics, we investigated the feasibility and simplicity of constructing a point cloud-based structural analysis model using only general functions of packaged software without any special operations for model modification. From the analytical results of a 2m long steel girder bridge, the global tendency of deformation and stress of the structure could be obtained, although the precision of calculated stress needs to be improved. The reproducibility and stability of composing mesh and solid are also subjects to be improved. However, future developments of this technique will provide a powerful tool for learners in structural mechanics and motivate the development of innovative construction design and effective maintenance methods.

**ABSTRACT:** This study presents a structural shape monitoring system combining Real-Time Kinematic (RTK) technology with an Unmanned Aerial Vehicle (UAV) for georeferencing without Ground Control Points (GCPs). Traditional GCP-based methods, though accurate, require substantial field efforts, limiting efficiency. This approach employs RTK-enabled UAVs for direct georeferencing, achieving sub-2 cm positioning accuracy. Experiments involved detecting shape changes using a target structure with attached brick shapes of varying depths (8 mm, 20 mm, 44 mm, and 84 mm). Successful detection was achieved for depths of 20 mm or greater, with limitations for smaller depths due to sensor and resolution constraints. Depth and volume estimation errors, initially 11% and 3%, were reduced to 6% and 1% through point cloud registration, improving alignment and geometric accuracy. The study also identified challenges like occlusions and patternless surfaces, which impacted reconstruction quality. These findings highlight the system's potential to enhance structural health monitoring, offering an efficient, scalable solution for infrastructure inspections, with applications in civil engineering and beyond.

**KEY WORDS:** Structural health monitoring, Real-time kinematic positioning, Point cloud, Unmanned aerial vehicle, Photogrammetry, Change detection, Structure from motion, Civil engineering

## 1 INTRODUCTION

Recently, the integration of unmanned aerial vehicles (UAVs) with photogrammetry technology has been widely utilized across various fields. For example, it is used for large-scale 3D mapping of extensive areas such as terrain, forests, and coastal regions, as well as for the 3D mapping of individual objects such as buildings, bridges, and roads. Additionally, it is employed for monitoring construction progress and detecting deformations in roads, landslides, and ground subsidence. UAV-based photogrammetry has potential applications in structural health monitoring by detecting changes in structural geometry.

Traditional UAV-based photogrammetry lacks scale and orientation information, which has conventionally been compensated for by using ground control points (GCPs) to generate 3D models. Since the point cloud is aligned to a real-world coordinate system based on GCPs, the process requires installing GCPs around the target area and measuring their precise coordinates.

However, the use of GCPs is time-consuming and costly, which can hinder the efficiency of UAV-based photogrammetry. Additionally, in areas with difficult access, such as valleys and rivers, deploying GCPs can be challenging. To address this issue, recent advancements have enabled georeferencing without GCPs by utilizing UAVs equipped with Real-Time Kinematic (RTK) receivers (Figure 1: RTK UAV). UAVs equipped with RTK receivers have been reported to achieve terrain mapping accuracy of 2–10 cm without GCPs, making them suitable for various applications over extensive terrains [1-2]

In this study, structural health monitoring was conducted using a UAV equipped with RTK technology without the need for GCPs. The contribution of this research lies in the quantitative evaluation of monitoring accuracy in terms of the positional accuracy of the point cloud and the sensitivity to detecting structural deformations.

## 2 METHODOLOGY

### 2.1 Photogrammetry

Photogrammetry consists of Structure from Motion and Multi-View Stereo to reconstruct 3D structures from overlapping, unoriented, and uncalibrated images, producing sparse and dense 3D point clouds. Structure from Motion involves the simultaneous reconstruction of the unknown three-dimensional scene structure, as well as the estimation of camera positions and orientations, based on a given set of feature correspondences [3]. After successfully recovering the intrinsic and extrinsic parameters of the camera in the Structure from Motion process, Multi-View Stereo is employed to create a 3D densified reconstruction [4].

Figure. 1 RTK UAV

## 2.2 Georeferencing

Georeferencing is the process of aligning and scaling a generated 3D model to a real-world coordinate system. There are two approaches to georeferencing: rigid registration and non-rigid registration [5]. Rigid registration is applied after Structure from Motion, modifying the reconstructed point cloud to align with the RTK-surveyed coordinates of GCPs on the ground or GNSS-geotagged data from UAV-captured photos. Non-rigid registration, also known as adaptive registration, introduces a more dynamic approach. It utilises pose priors—the RTK-geotagged data in the UAV-captured photos—as flexible constraints during the Structure from Motion Bundle Adjustment phase.

## 3 EXPERIMENTS

The target structure is shown in Figure 2. A flight path was generated as a double-grid trajectory for 3D photogrammetry using the built-in app on the UAV's remote controller and deployed in all the survey cases.

Figure. 2 Target structure

Structure from Motion (SfM) and multi-view stereo processing were performed using Pix4Dmapper v4.56, as shown in Figure 3. These processes were employed to generate a dense point cloud representation of the target structure based on UAV-acquired images.

Figure 3. Target structure (Point cloud)

Figure 4 presents the comparison of two point clouds of the target structure acquired at different time intervals using the

Cloud-to-Cloud (C2C) absolute distance measurement in millimetres. This method quantifies the geometric differences between the two datasets by calculating the shortest distances between corresponding points in the point clouds. The resulting C2C distance values indicate structural deformations or displacements over time, allowing for an assessment of changes in the target structure's shape and stability.

Figure 4. C2C absolute distance (mm)

## 4 CONCLUSION

This study evaluated the feasibility of using an RTK-equipped UAV with GCP-free georeferencing for structural shape monitoring. The results demonstrated that the generated point clouds achieved centimeter-level accuracy, with positioning differences of less than 2 cm compared to RTK rover measurements. The method successfully detected variations in brick depths down to 20 mm at a UAV altitude of 15 m, though it failed at 8 mm, suggesting that close-up images could improve detection but would introduce higher operational complexity. Point cloud registration was found to enhance alignment, reducing depth and volume estimation errors from 3% and 4% to 1% each. However, patternless surfaces and occlusions negatively impacted reconstruction accuracy, highlighting the need to consider such factors for effective structural shape monitoring.

**ABSTRACT:** To support safe operation of monorail systems, periodic track inspections for line maintenance and structural inspections of the concrete girders and steel beamway that form the track are necessary, and efficient inspections and highly accurate inspection results are required. Since conventional inspections centered on manual measurement and visual inspection, there were issues in terms of the safety risk associated with work in high places and work efficiency. Furthermore, in visual inspections, it was not possible to gain an adequate understanding of deterioration over time due to the difficulty of quantitative evaluation. This paper presents an example of a non-contact inspection technique in which industrial area cameras, laser displacement sensor and a high-speed 2D laser profiler were installed on the inspection vehicle, and track displacement, visible deterioration trolley wire wear are measured while the vehicle is traveling. Although inspection work at the work site had required half a year with the conventional technique, the introduction of this technique shortened the inspection time to only 4 days, realizing improved efficiency and reducing the man-power required in site work. Future goals include sustainable infrastructure maintenance and improvement of track safety through efforts in trend analysis of the progress of deterioration based on an expanded range of inspection items and analysis of various types of accumulated data.

**KEY WORDS:** Structural Condition Assessment; Performance Evaluation; Laser Scanning; Non-Destructive Testing; Infrastructure Monitoring.

## 1 INTRODUCTION

### 1.1 Background and Issues of Monorail Inspection

Monorails are widely used as a key part of transportation infrastructure in urban areas and tourist destinations. Figure 1 shows a photograph of a monorail train traveling along the track beam above automobile street traffic. In proper maintenance management of this track structure, appropriate maintenance (line maintenance) is demanded from the viewpoints of safe operation and long service life. However, several issues arise in inspections of monorail systems.

Investigations of equipment degradation by conventional manual work center on judgments based on the experience and subjectivity of the inspection worker. However, in inspection work, objective and quantitative assessments are required for numerical management of the track condition. Manual inspection work is also extremely time- and labor-intensive, and securing work safety is also an issue because work is frequently performed in high places or at night. Although automation and digitization utilizing laser measurement and image analysis techniques have been promoted in recent years, techniques adapted to the structures and environmental conditions peculiar to monorails have not been adequately established[1][2][3].

### 1.2 Purpose and Significance of this Paper

In the current state of monorail inspections, the 3 issues of “Efficiency,” “Quantifiable Results” and “Safety” may be mentioned.

To solve these problems, this paper proposes a non-contact inspection technique utilizing industrial area cameras and laser displacement sensor. In addition to a very substantial reduction in work time achieved by mounting sensors on an inspection vehicle and performing measurements during vehicle travel,

the quantifiable results of the inspection results is also improved by quantification and visualization of the measured data. Cracks and other surface damage are detected using image analysis with the cameras, and displacement of the track beam and wear of the trolley wire are captured with high accuracy by analyzing the data acquired by the laser displacement sensor as point cloud data. Higher efficiency and improved safety in inspection work and more advanced maintenance management can be expected by introduction of this technique.

Figure 1. Photograph of a monorail

## 2 VISUAL AND MANUAL INSPECTION TECHNIQUES AND THEIR ISSUES

Since the track structures of monorail systems are subject to progressive deterioration in the forms of rail displacement and beamway deformation when used repeatedly day after day, railway operators are legally required to conduct periodic inspections and perform appropriate maintenance management. In particular, since monorails play a key role in urban transportation, securing their safety is an extremely important social obligation. However, the current inspection methods still

depend on visual inspections and manual work, and higher efficiency and more advanced methods are needed.

## 2.1 Conventional Inspection Techniques by Close Visual Inspection

In conventional inspections of monorails, the inspectors checked the structures directly, and the general method was judgment of abnormalities based on Close Visual Inspection. Concretely, inspectors conducted a “Visual Inspection” for structural deterioration by visually checking the structure surface for cracks, peeling, discoloration, etc., and “Track Displacement Measurement,” in which deviations in the height and levelness of the travel surface and misalignment of joints between beam segments and the gap between the beam segments were measured. The inspection items are shown in Table 1 and Table 2, and photographs of the conventional techniques used in rail displacement measurements are shown in Figure 2.

Table 1. Inspection items in Visual Inspections

Inspection equipment
PC track beams (including beam underside surface), steel track beams, lower part of steel beams, cross beams, PC track beam bearings, joint devices, signs, track circuit boundary markers
Inspection items
Cracks and other damage (fissures, etc.)
Paint peeling and deterioration (corrosion)
Paint peeling/corrosion of bearings (PC beams, steel beams)
Paint peeling/deterioration of lower part of steel beams and cross beams (except flange parts)
Other abnormalities (damage of resin mortar, presence/absence of damping materials, looseness of bearing anchor bolts and nuts, confirmation of signs and boundary markers)

Table 2. Inspection items in Track Displacement Measurements

Inspection equipment	
Position of expansion joints of PC/steel track beams (including branch beams, median lines and pullup lines)	
Inspection item	Content of inspection
Partial longitudinal level irregularity measurement	Measure changes in height of track beam
Partial horizontal alignment irregularity measurement	Evaluate linearity of track beam, and detect horizontal bending
Cross level irregularity measurement	Measure levelness (inclination) of beam
Vertical/horizontal misalignment measurement	Measure vertical level difference in joints and horizontal differences in the level of girder joints
Joint gap measurement	Measure gap between beams at beam joints

Figure 2. Conventional inspection techniques

## 2.2 Issues Related to Efficiency, Quantifiable Results and Safety

### 2.2.1 Issues related to efficiency

Many of the target sections of monorail inspections have been in service for more than 25 years, and since many lines were also constructed in the same period, demand for inspections and repairs is tending to increase. Because the target section in this paper has a total constructed length is 28.6 km and contains a large amount of infrastructure, enormous amounts of time and labor when an inspection is conducted. Thus, it is necessary to reduce the work load on inspection workers. However, a single inspection by the conventional method requires as much as several months, and securing speed (high efficiency) is an issue.

### 2.2.2 Issues related to quantifiable results

Partial deterioration of the track beam with age has already been confirmed from the inspection results, and further progress of deterioration is also expected in the future. Because inspection workers judge abnormalities by visual inspection and manual work, a large part of the conventional inspection method depends on the individual experience and senses of the inspectors. For example, when measuring the width of cracks, there are variations in the results depending on the measurement position and angle, and in some cases, there are differences in the evaluation depending on the inspector, even when inspecting the same damage. Since it is difficult to check for deterioration of facilities over the wide inspection area by a single standard, securing quantifiable results is an issue.

### 2.2.3 Issues related to safety

Because the track beam of monorails is generally installed in an elevated location, inspection worker must use a high-lift work vehicle or scaffolding to conduct inspections. Inspections

are frequently carried out at night, which increases the possibility of accidents due to fatigue or decreased concentration. Because this work involves a risk of falling or contact accidents, securing work safety is an issue.

### 3 PROPOSED NON-CONTACT INSPECTION TECHNIQUE

#### 3.1 Necessity of Digital Measurement Technique

In recent years, infrastructure inspections using non-contact measurement technologies have been widely adopted, and more accurate and efficient inspections are expected to be possible by utilizing laser measurement and image analysis techniques. This can achieve improved worker safety and labor-saving in inspection work. In addition, it can also contribute to predictions of long-term deterioration and sustainable infrastructure maintenance by accumulating and analyzing data.

This paper introduces a non-contact inspection technique utilizing laser displacement sensor and industrial area cameras and describes its effectiveness. The laser displacement sensor enable quantitative evaluations of the displacement of structures and wear of trolley wires. Highly accurate image analysis, without depending on visual inspection, is possible by using the industrial area cameras in combination with the laser displacement sensor. Although it was difficult to accumulate numerical data in conventional visual inspections, the proposed technique enables precise measurement and evaluation of visible deterioration and wear with high quantifiable results by combined use of the industrial area cameras and laser displacement sensor.

#### 3.2 Outline of the Technique and Sensor Configuration

As described in this paper, a non-contact measurement technique was constructed in order to gain a highly accurate understanding of the condition of the track beamway and the trolley wires of monorails and quantitatively evaluate the current condition of deterioration.

In this technique, sensors were mounted on a monorail inspection vehicle, and data are acquired while the vehicle was traveling. The main sensors and their inspection items were industrial area cameras (visible deterioration, joint gap measurement), laser displacement sensor (for longitudinal level irregularities, horizontal alignment irregularities and vertical and horizontal misalignment of joints) and a high-speed 2D laser profiler (for trolley wire wear).

The sensor installation arrangement was designed to extract the maximum possible measurement accuracy. The cameras were installed on the front of the vehicle, and photography was performed with a total of 16 units so as to cover the entire surface of the track girder, including the beamway, side surfaces, under beam area, bearing parts and track beamway substructure. The laser displacement sensor were installed at equal intervals under the vehicle and capture information on the distance to the beamway. A high-speed 2D laser profiler was also installed on the vehicle underbelly to capture information on wear of the trolley wire. Introduction of the cameras, lasers and various other sensor makes it possible to collect data continuously, and achieves more comprehensive deformation analysis than is possible with conventional spot measurements. The images of the installation positions of the industrial area

cameras and image of installation of the laser displacement sensor are shown in Figure 3 and Figure 4, respectively, and photographs of the installed sensor are shown in Figure 5.

Figure 3. Image of installation positions of industrial area cameras

Figure 4. Image of installation positions of laser displacement sensor

Figure 5. Photographs of site installation condition

### 3.3 Visual Inspection by Industrial Area Cameras

#### 3.3.1 Camera installation method and arrangement

In visual inspections for facility deterioration, industrial area cameras are employed to capture surface cracks and paint degradation. Compared to line scan cameras, area cameras offer greater flexibility in installation and imaging conditions, as they can capture full-frame images in a single exposure without requiring continuous motion of the object. A total of 16 compact area scan cameras with 2.35 megapixel resolution and a framerate (fps: frames per second) of 30 fps are used. A dedicated camera frame was designed to enable photography with the same quality from positions equidistant from the object of photography. An appropriate lighting arrangement and photographing distance for extraction of cracks with a width of 0.2 mm were planned. The cameras used to photograph the running surface and side surfaces of the beamway were arranged directly facing those objects, and the cameras used to photograph the bearings and underside of the steel beamway were arranged to photograph those objects from an oblique angle. Arranging the cameras so there is an overlap in the camera angle of view of the beam side surfaces enables sure data acquisition, with no gaps between the photographs of each image. Since it would be difficult to photograph the underside surface of the girder directly from within the vehicle limit width, a method of photographing images reflected by a mirror was adopted. Table 3 shows the specification of the cameras mounted on the vehicle.

Table 3. Specification of high-resolution cameras

Product name	GO-2400C-PMCL
Appearance	
Standard	1936 x 1216 px
Sensor	1CMOS
Sensor size	1/1.2 type
External dimensions	29 x 29 x 41.5 mm
Weight	46 g

#### 3.3.2 Issues in photography and countermeasures

Since photography while the vehicle traveling is affected by vehicle vibration and shaking, the shutter speed of the cameras used in this technique was set to 1/4 000 s. This made it possible to minimize the effect of blurring caused by vibration and shaking. On the other hand, if this setting is used, the images will be dark because the short exposure time limits the light available when photographing an image. In order to acquire high quality image data even in dark areas, multiple LED lights were arranged so as that the entire surface of the girder received an appropriate, uniform amount of light.

#### 3.4 Track Displacement Measurement by Laser displacement sensor

Track displacement, including unevenness, level differences, and inclination, is measured using a total of 14 laser

displacement sensors, each capable of high-precision, single-point distance measurements that enable the detection of subtle structural shifts. Since the sampling frequency is 2 000 Hz, measurement at a pitch of about 2 mm in the travel direction at a travel speed of 15 km/h. The spacing of the laser displacement sensor was adjusted to 400 mm, which is the median value of the measurement range, and were installed so as to enable capture of displacement of the upper limit value ( $\pm 100$  mm). The specification of the laser displacement sensor is shown in Table 4.

Table 4. Specification of laser displacement sensor

Product name	LK-G405
Appearance	
Measurement range	300 to 500 mm
Wavelength	655 nm (visible light) Laser class: 3Ror2
Sampling period	20 to 1 000 $\mu$ s
Protection structure	IP67 (IEC60529)
External dimensions	3.6 x 10.8 x 8.5 cm
Weight	Approx. 380 g (including cord)

#### 3.5 Trolley Wire Wear Inspection

To investigate wear of the trolley wire located on the side face of the beamway, a high-speed 2D laser profiler is used to perform continuous scanning of cross-sectional shapes, enabling precise visualization and quantification of wear, misalignment, and other geometric anomalies. As in the case of the above-mentioned laser displacement sensor, because the sampling frequency is 2 000 Hz, measurement at a pitch of approximately 2 mm in the travel direction is possible, assuming a travel speed of 15 Km/h. Since it is necessary to grasp the complete image of the trolley wire when investigating wear, the high-speed 2D laser profiler was installed so that the entire trolley wire can be scanned from a position directly facing the wire. The specification of the high-speed 2D laser profiler is shown in Table 5.

Table 5. Specification of high-speed 2D laser profiler

Product name	LJ-V7300
Appearance	
Measurement range	155 to 445 mm
Wavelength	405nm (visible light) Laser class: 2
Sampling period	Max. 16 $\mu$ s
Protection structure	IP67 (IEC60529)
External dimensions	5.7 x 17.3 x 8.8 cm
Weight	Approx. 1 000 g

## 4 ANALYSIS OF MEASURED DATA

### 4.1 Preparation of Composite Image and Investigation of Visible deterioration

After geometric correction, magnification correction and color correction, the images captured by the industrial area camera are composed as continuous composite images. Geometric correction is a type of correction processing in which images that contain distortion and deformation are adjusted to produce orthorectified images with an accurate shape and positional relationship. Creating composite images makes it possible to check each of the girders and beams of the track over a wide range, and at the same time, understand their actual positional relationships. Figure 6 shows composite images of the beamway running surface and side surface.

Damage is extracted using the crack drawing support software “k-TRACE” (Figure 7), which was developed by this company (KRC: Keisoku Research Consultants Co.)[4][5]. When the inspector clicks the line of a crack with the mouse, k-TRACE analyzes the shading of the color around the line joining the clicked points and automatically outputs the shape and width of the crack. Application of this tool is not limited to cracks, as the software can also extract the positions of peeling, water leaks and free lime at the same time. This processing makes it possible to obtain a comprehensive understanding of the exact position and scale of the damage from images, without going to the site, thereby securing “Safety” and “Quantifiable Results.”

Figure 6. Composite images of beamway (top: running surface, middle: side surface, bottom: underside of girder)

Figure 7. “k-TRACE”: crack drawing support software

### 4.2 Joint Gap Measurements

For joint gap measurements, analysis is performed based on the photographed images. An image showing the joint part in the center is extracted from multiple images, and the width of the joint gap is calculated from the number of pixels at the gap position in the image. The calculated joint gap is standard value are then compared, and the locations of joints where the gap exceeds the control standard value are extracted. A photograph of the joint gap image is shown in Figure 8.

Figure 8. Position of joint gap measurement

### 4.3 Partial Longitudinal Level Irregularity Measurement

Displacement of the height of the beamway running surface (partial longitudinal level irregularity) is measured by using 3 laser displacement sensor (A, B, C) installed at 1 m intervals in the travel direction. The partial longitudinal height displacement  $h_d$  is calculated as the difference between the average distance measured by the first and last units  $(A+C)/2$  and the distance measured by the center unit B. The calculated values are arranged for each beamway segment, and locations that exceed the control standard value are extracted. An image of the height calculation method is shown in Figure 9.

Figure 9. Image of height value calculation

#### 4.4 Partial Horizontal Alignment Irregularity Measurement

Similarly to the partial longitudinal level irregularity measurement method, lateral deviations of the beam side are measured by 3 laser displacement sensor installed at equal distances in the travel direction. The data calculation method is also similar to that used in partial longitudinal level calculations. The waveform obtained in a horizontal alignment irregularity measurement is shown in Figure 10.

Figure 10. Waveform in horizontal alignment irregularity measurement

#### 4.5 Cross Level Irregularity (Inclination) Measurement

The inclination (cross level) of the beamway is measured by using an inclinometer and laser displacement meter. If the beam and the vehicle are parallel, the cross level  $\theta$  can be measured using only the inclinometer, but there will be a slight variation in the inclination. Therefore, displacement is measured by using laser displacement sensor installed on the guideway and the stability surface of the beamway side surface to correct for the difference in inclination, and the difference in the inclinations of the track beamway and the vehicle is obtained from the respective measured values of  $a$  and  $b$  and positional relationship  $l$  between the displacement meters. Since the measured values of the inclinometer are also affected by centrifugal force, the cross level  $\theta$  of the beam can be calculated by adding a corrected value  $\Delta\theta_c$ , which is calculated based on the beam linearity and speed values. An image of the relationship of the inclinometer and the beam side surface and the numerical expression are shown in Figure 11.

Figure 11. Relationship of inclinometer and beam side surface

#### 4.6 Vertical and Horizontal Misalignment Measurement

Vertical misalignment and horizontal misalignment are measured at beamway joints (total of 6 positions of the running surface, guideway and stability surface) using laser displacement sensor. The amount of displacement is calculated from height of the fingerplate surface measured before and after passing the joint, and the vertical and horizontal misalignment of each joint is evaluated. Figure 12 shows a position diagram of the laser displacement sensor when measuring vertical and horizontal misalignment, and Figure 13 shows the waveform of vertical misalignment measurement results.

Figure 12. Position diagram of laser displacement sensor for vertical and horizontal misalignment

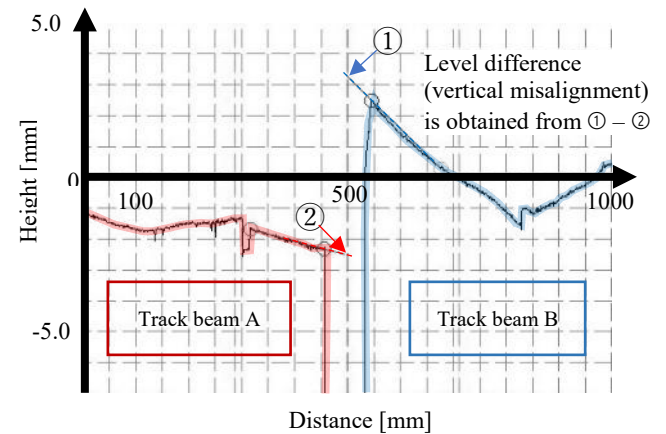

Figure 13. Result of vertical/horizontal misalignment measurement

#### 4.7 Trolley Wire Wear Measurement

In wear inspections, the cross-sectional shape of the trolley wire is measured using a high-speed 2D laser profiler, the result is compared with the design cross section, and the wear amount  $\Delta W$  is calculated. Here,  $\Delta W$  is the difference between the design value of the trolley wire thickness  $W_{design}$  and the measured thickness of the remaining part of the wire  $W_{meas}$ . The thickness of the remaining part  $W_{meas}$  is calculated by acquiring point information on 1 point (point A) at the tip, which is the wear zone of the trolley wire, and 2 corner points (points B and C) of the metal part where wear has not occurred, and calculating  $W_{meas}$  from the relationships of distances  $a$ ,  $b$  and  $c$  between the each of these points and the laser displacement meter.

Using the high-speed 2D laser profiler enables more complete, quantitative wear measurement than is possible by

conventional manual measurement. It is also possible to analyze the trend of wear progress and carry out systematic trolley wire maintenance and exchanges by accumulating measurement results over the long term. Figure 14 shows an image of the trolley wire and wear and the numerical expression for the wear calculation. Figure 15 shows the data used to create the composite waveform of the high-speed 2D laser profiler.

Figure 14. Image of trolley wire and wear

Figure 15. Point cloud composed using scan data from the 2D laser profiler

## 5 DISCUSSION

### 5.1 Improvement of Work Efficiency

With the proposed method, site working time was shortened from half a year by the conventional method to only 4 days because many types of measured data can be collected at one time while travelling. This shortening of site working time not only improves work efficiency, but also contributes to improved safety. On the other hand, the load of office work, such as processing and analysis of acquired data, is large, so efforts for improvement for reduction of the volume of work are necessary. Nevertheless, digitization of inspection results has lightened the work involved in arranging and managing measurement results and improved the convenience of data use.

### 5.2 Improvement of Quantifiable Results

By using the proposed technique, measured results with quantifiable results based on numerical values, and evaluations of damage based on those results, have become possible by using industrial area cameras and laser displacement sensor. In detection of cracks, semi-automatic measurement of the width and length of the damage is possible by utilizing image analysis, and quantitative comparison with past data is now easy. In measurements of track displacement, measurement results and evaluations with high quantifiable results have also become possible by using laser displacement sensor.

### 5.3 Improvement of Safety

With the proposed technique, it is no longer necessary for workers to enter dangerous areas because the sensors are mounted on the inspection vehicle and measurements are carried out while the vehicle is traveling. The use of non-contact sensors rather than contact-type measurement methods has not only reduced the loads on structures during measurements, but has also realized stable measurement.

## 6 CONCLUSION AND FUTURE OUTLOOK

### 6.1 Conclusion

The proposed technique is a system in which sensors are mounted on an inspection vehicle, and track displacement and visible deterioration are measured while the vehicle is traveling. Cracks and other surface damage are detected by utilizing image analysis of images acquired with industrial area cameras, and displacement of the track beamway is measured with laser displacement sensor. Highly precise evaluation of trolley wire wear has also become possible by applying an analysis technique utilizing point cloud data. Although conventional site inspection work had required half a year, the application of these techniques has shortened the site work time to only 4 days, realizing improved work efficiency and a reduction of the work load. Improved safety could also be secured by shortening the site work time of workers.

By using the industrial area cameras, creation of composite images, understanding the overall deterioration of facilities, and comparison of deterioration between two time periods have become easy, and in measurements of track displacement, it is

now possible to obtain measurement results with high quantifiable results as a result of the acquisition of high-accuracy data using the laser displacement sensor and establishment of methods for calculating the amounts of various types of displacement using that data. Likewise, in measurements of trolley wire wear, quantitative evaluation of the amount of wear has become possible by a technique using a high-speed 2D laser profiler. Based on the above, in comparison with conventional inspections, it can be said that improvement of the reproducibility of inspection results, understanding of changes over time and quantitative evaluations are now possible.

## 6.2 Future Outlook

The introduction of the proposed technique has realized high efficiency and improved quantifiable results in inspection work. However, we intend to address the following issues in order to develop more advanced techniques and enable long-term operation.

### 6.2.1 Reduction of the data processing load and automation

With the proposed technique, on-site measurements can be completed in significantly less time compared to conventional methods. However, the analysis of the acquired images and point cloud data still requires a certain amount of processing time. In particular, damage detection and evaluation by image analysis involve work that requires specialized knowledge. Therefore, the introduction of AI technologies is expected to improve the efficiency of post-processing and reduce reliance on expert interpretation.

- AI automation of image analysis:  
Analysis time can be shortened and variations in accuracy can be reduced by automatic recognition and classification of cracks and other damage by machine learning. We will also study a system for diagnosis and evaluation of structures from damage extracted for each girder/beam.

### 6.2.2 Further expansion of range of application

Although this technique has been applied mainly to evaluations of displacement and damage of the track beamway and trolley wire wear, application to other inspection items should also be studied in the future.

- Deployment to various structures on the track:  
The aim here is to realize comprehensive infrastructure monitoring by expanding the objects to inspections to include bridges on the track, peripheral equipment, stations, etc.
- Selection of the optimum sensor technologies:  
In addition to the existing image and laser technologies, LiDAR, thermal infrared camera technology, etc. will also be studied in order to establish a multifaceted deterioration detection technique.

### 6.2.3 Confirmation of linkage of individual inspection items

Causal relationships also seem to exist between respective inspection items such as longitudinal levelness, horizontal levelness, misalignment, etc. These will be utilized for

appropriate line maintenance by clarifying their relationships based on accumulated data.

### 6.2.4 Prediction of long-term deterioration risk

In the future, the establishment of a technology for predicting the future deterioration of structures by using accumulated data will be demanded.

- Creation of risk assessment model:  
Based on acquired data, a technique for assessing the rate of progress of deterioration and the range of its effects, and quantitatively judging the priority of repairs and maintenance, will be developed.
- Deterioration prediction using risk assessment model:  
Based on the risk assessment model, the progress of displacement and wear of the track beamway and trolley wire will be predicted to optimize maintenance management plans.

In the future, we promote higher efficiency and more advanced techniques by solving these issues, with the aim of realizing more sustainable and precise infrastructure maintenance management.

**ABSTRACT:** The Structure from Motion/Multi-View Stereo (SfM/MVS) technique, which enables reconstruction of the three-dimensional shape of an object based on multi-view images, is a useful technique for inspection of infrastructure such as bridges in order to gain a comprehensive understanding of the state of damage. However, in SfM/MVS, the camera position and three-dimensional coordinates of the object are estimated based on feature points in images, making it difficult to apply this technique to steel structures, which have fewer feature points on surface textures due to coating. This paper presents a case in which SfM/MVS was successfully applied to a steel structure, specifically a steel bridge, by substituting the incomplete polygon model constructed in the conventional SfM/MVS process with a current-state CIM model created from existing drawings and point cloud data acquired with a terrestrial 3D laser scanner.

**KEY WORDS:** SfM/MVS; Terrestrial Laser Scanner; Point Cloud; Steel Bridge; Inspection; BIM/CIM.

## 1 INTRODUCTION

At present, aging of bridges in service and a shortage of inspection engineers have become problems in Japan [1], heightening the need for higher efficiency and labor-saving in bridge inspections. In this situation, preparation and wide use of Guidelines for Use of New Technologies [2], Delivery Manual for 3-Dimensional Deliverables [3] and other regulations are being promoted for image instrumentation technologies, including the Structure from Motion/Multi-View Stereo (SfM/MVS) technique [4], [5], which enables reconstruction of the three-dimensional shape of an object structure from images to gain an understanding of the state of damage, etc.

This study focuses on steel bridges as one type of bridge. As in other types of bridges, the problems associated with aging have also become apparent in steel bridges, as seen damage by corrosion of the steel materials [6]. However, it is sometimes difficult to apply the SfM/MVS technique to steel bridges since steel materials have fewer feature points, which are necessary for image processing, due to the uniform surface texture formed by coating film, and in such cases, reconstruction of the three-dimensional shape may be incomplete.

This paper examines the applicability of the SfM/MVS technique to steel bridges by using a method that utilizes a current-state CIM model (current-state CIM). This model was constructed by correcting existing drawings based on the current-state point cloud data (TLS point cloud) measured with terrestrial 3D laser scanners (TLS).

## 2 USE OF SfM/MVS AND POINT CLOUD DATA

### 2.1 Overview of SfM/MVS

SfM/MVS is a technique in which the three-dimensional geometry of an object is reconstructed from an image sequence (multi-view images) of the object by estimating the camera position and posture and the three-dimensional coordinates of the object by calculations based on feature points. Figure 1 is an image diagram of the reconstruction of a three-dimensional shape by SfM/MVS.

“Feature points” refer to points on the object appearing in the image that can be identified based on differences in color, brightness, etc., allowing its position to be determined. By detecting corresponding feature points between images, it becomes possible to estimate the relative camera position and posture with respect to the target structure, as well as the three-dimensional coordinates of each point. In general, the less uniform the surface texture of a structure, the greater the number of points detected as feature points. Accordingly, SfM/MVS technology can be effectively applied to structures with non-uniform surface textures and abundant feature points, such as concrete bridges.

### 2.2 Flow of Processing in SfM/MVS

The following describes the process of reconstructing the three-dimensional shape of an object by SfM/MVS and determining the three-dimensional location, size and other features of damage of the object structure. First, the point cloud data of the object structure is obtained by estimating the position and posture of the camera and the three-dimensional coordinates of the object structure based on the feature points described above. Next, a polygon model composed of surfaces is constructed based on the point cloud data, and a textured polygon model is obtained by applying textures sourced from photographic images onto the surface of that model. After this, it is possible to confirm the two-dimensional damage position and size by outputting orthoimages based on the textured polygon model. Figure 2 shows the general processing flow of SfM/MVS, including image acquisition.

Figure 1. An image diagram of a three-dimensional shape reconstruction by SfM/MVS

Figure 2. General Processing Flow for Applying SfM/MVS

### 2.3 Objects with Few Feature Points

The importance of feature points in SfM/MVS is as described above. However, when a paint film or other coating has been applied to the surface of the steel materials of a steel bridge, etc., the surface texture becomes uniform. This results in fewer points being detectable as feature points, making it difficult to apply SfM/MVS using general methods. Figure 3 shows a comparison of the detection status of corresponding feature points between objects with surface textures of varying uniformity. In the case of non-uniform surface texture, corresponding points are distributed across the entire surface. On the other hand, in the case of uniform surface texture, it is confirmed that corresponding points are not detected, except in distinctive areas such as corroded parts. Furthermore some manuals for general software products used in computational processing by SfM/MVS also recommend avoiding objects with a uniform texture or luster [7].

Figure 4 shows an example of constructing a point cloud data from SfM/MVS technique, targeting a steel bridge. In this example, there were many areas where the surface texture is uniform, and there were also areas where it was not possible to acquire a point cloud of the object structure at members that intrinsically have a flat surface due to the inadequate number of feature points. The inaccuracies in the shape of the polygon model and the improper placement of textures make it difficult to record the condition of damage of the entire object.

Figure 5 shows the processing flow for the problem that occur when SfM/MVS processing by the general technique is applied to an object with a uniform surface texture due to coating film.

Figure 3. Comparison of the detection status of corresponding feature points

Figure 4. Point cloud where gaps occurred

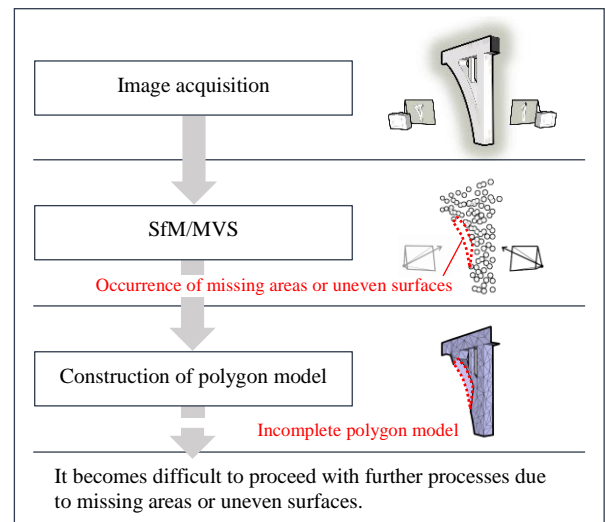

Figure 5. Problems in processing flow of SfM/MVS

### 2.4 SfM/MVS Combined with Measured Point Cloud Data

To solved the problems in application of SfM/MVS to steel bridges with few feature points, this paper examines a technique in which the object is measured with TLS, and the acquired measured point cloud data are used.

In this method, positions and posture of cameras, along with three-dimensional coordinates within the possible range, are first estimated using the conventional SfM/MVS approach.

Then, instead of the polygon model used in conventional methods, the current-state CIM, which reproduces the current shape of the object based on TLS point cloud and existing drawings, is utilized. Texture is projected onto this current-state CIM using camera images as sources, enabling the construction of textured models and orthoimages. Furthermore, even the incomplete polygon models created through conventional methods are used as a reference data for aligning the current-state CIM. UAV is employed for image acquisition, and during the SfM/MVS phase, GNSS data obtained during image acquisition is also used for analysis. This method is referred to as "SfM/MVS combined with TLS point cloud" and the processing flow is shown in Figure 6.

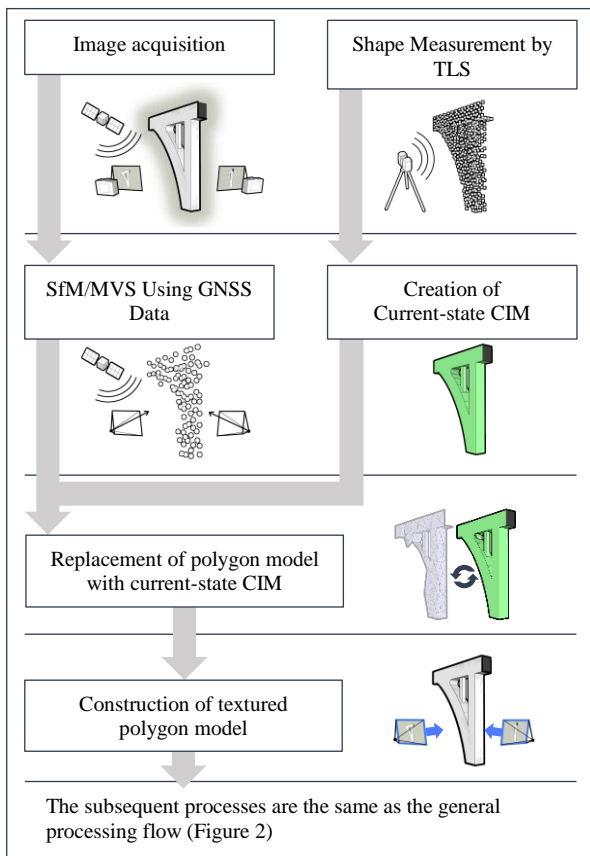

Figure 6. Processing flow of SfM/MVS combined with TLS point cloud

### 3 EXAMPLE OF APPLICATION TO AN ACTUAL STEEL BRIDGE

This chapter presents an example in which the proposed technique, SfM/MVS combined with TLS point cloud, was applied to an actual steel bridge. This verification is an attempt to apply SfM/MVS in work for investigation of the condition of corrosion and others of the steel materials of the object bridge.

#### 3.1 Overview of Steel Bridge

The object bridge is a bridge with a total length of 651 meters, in which the main bridge section is a mid-height-deck arch Lohse structure as shown in Figure 7. The object range of the inspection was the steel parts between piers P5 and P8, as

shown in Figure 8. The bridge is constructed over the sea, and the distance between the revetments on the origin and terminus sides is approximately 450 meters. Owing to the water depth directly under the bridge between piers P5 and P7, it was impossible to enter this area on foot, but the area between piers P7 and P8 could be entered on foot at low tide. The specifications of the bridge are shown in Table 1. As can be seen in Figure 9, the steel materials in this object range have a uniform surface texture due to paint film.

Figure 7. Object bridge

### 3.2 Equipment Used

Image acquisition was performed using two types of UAVs with an attached camera. A Matrice 300 RTK was mainly used, and a compact Skydio was used in some places. Table 2 shows the specifications of the UAVs and the attached cameras.

To acquire measured point cloud data on the current state of the object bridge, measurements were carried out with TLS. Two types were used in the measurements, a medium-range Focus S-350 (FARO) and a long-range SX10 (Trimble). Table 3 shows the specifications of the instruments

The software used in image analyzing by SfM/MVS was Metashape Professional (Agisoft).

Unit weight	4.2 kg	7.5 kg

### 3.3 Condition of Measurement

The condition of image acquisition by UAV is shown in Figure 10. To prevent UAV crash accidents, the UAVs were not flown directly over the bridge, and images were acquired from positions where visual confirmation of the UAV by the operator was possible. In acquiring the images of the underside of the girders between P7 and P8, we entered the riverbed area of P7 during low tide, and used the compact Skydio UAV to photograph the structure due to the limited space under the girders. To prevent image blurring, the shutter speed was set to approximately 1/1 000 s during photography, and continuous images were taken at intervals after adjusting the focus. The purpose of this work was to understand the positions and surface areas of corroded areas. Image acquisition was performed at a resolution of approximately 3 mm/pixel with a 45 megapixel camera (8 192 x 5 460 pixels), as this is adequate resolution for confirming corrosion and image processing, and SfM/MVS can be performed more easily with a wider field of view per image. Image acquisition by UAV was conducted over a 4-day period, and a total of 10 232 images were captured. Figure 11 shows the cross-sectional positions of image acquisition.

Figure 12 shows the condition of shape measurement of the object bridge by TLS. The Focus S-350 was used in measurements on the bridge. The inner surface shapes of the arch ribs and suspension members were measured. Additionally, given that the distance between the revetments at the bridge origin and terminus sides of the bridge is approximately 450 meters, the entire side elevation of the bridge was measured using the SX10 laser scanner, which enables long-distance measurement from both revetments. Figure 13 shows the measurements positions of the two TLS.

Figure 12. Condition of measurements by TLS (left: from revetment, right: on bridge)

Figure 13. Positions of measurements by TLS (Created using aerial photographs (by the Geospatial Information Authority of Japan))

### 3.4 Measurement Results

The TLS point cloud of entire bridge shape is shown in Figure 14. By precisely aligning the point cloud data measured from the various positions, the point cloud data representing the entire bridge shape were obtained.

Figure 14. TLS point cloud of entire bridge shape

### 3.5 Creation of Current-state CIM Based on TLS Point Cloud

When the TLS point cloud was superimposed on existing drawings data, as shown in Figure 15, deviations were observed in the lateral shape of the arch rib members. Therefore, the linear data of existing drawings were corrected in accordance with the geometry of the TLS point cloud. The condition of correction of the drawing data is shown in Figure 16.

Next, based on the corrected drawing data, a current-state CIM of the bridge was created. The condition of creation of this current-state CIM is shown in Figure 17. The required level of performance for reproducing CIM models, based on their intended use, is defined as "Level of Detail (LOD)" in the Guidelines for Introduction of CIM [8], [9] issued by Japan's Ministry of Land, Infrastructure, Transport and Tourism. Excerpts of the definitions of each specified level of detail are shown in Table 4. In the range where point cloud data were acquired for steel materials, an LOD of approximately 300 was used, as it was possible to understand the external shape. However, in the range where point cloud data could not be acquired, for example, on the underside of girders, modelling was performed using LODs of 200 to 300, referring to the data in existing drawings, etc. The created current-state CIM created is shown in Figure 18.

Figure 15. Overlay of measured cloud point data and drawing data

Figure 16. Correction of drawing data

Figure 17. Creation of current-state CIM

Table 4. Definitions of levels of detail (LOD)

LOD	Common definition
100	Model showing the position of the object by symbols, lines or simple shapes.
200	Model with sufficient detail to understand the structural type. Cuts and fills are represented by standard transects, or in sufficient detail to sweep the standard transects of each structure in the general drawing in the object range.
300	Model accurately representing the external geometry of the object, with the exception of ancillary works and other detailed structures and the structure of connecting parts.
400	In addition to the requirements of LOD 300, accurate modeling is performed, including ancillary works, connecting structures and other detailed structures and the arrangement of reinforcing materials.
500	Model representing the actual geometry of the object.

Figure 18. Created current-state CIM

### 3.6 SfM/MVS combined with TLS point cloud Application Process and Results

First, sparse point cloud data of the object bridge were obtained using location information from the GNSS data of UAV-captured images and camera posture information derived from SfM analysis. The results are shown in Figure 19.

Subsequently, for the dense point cloud data obtained through MVS analysis, a color map was created based on the number of depth maps used to generate each point cloud, as shown in Figure 20. A depth map is data that indicates the distance from the camera to each pixel in an image, and it is generally determined that the more depth maps used in the point cloud generation process, the higher the reliability of the

point cloud data. The number of point cloud for each confidence level is shown in Table 5. As shown in Figure 20, while a large number of depth maps were used in some areas, a decrease in the number of depth maps used was observed near areas with missing point cloud.

In the following step, in order to create textures based on camera images and construct a textured polygon model for the created current-state CIM, the current-state CIM and the cameras must be in the correct positional relationship. Therefore, to align the current-state CIM, a polygon model was first created based on the point cloud obtained through conventional SfM/MVS. As shown in Figure 21, although this model itself was an incomplete polygon model with missing areas and unevenness in originally flat sections, the point cloud derived from SfM/MVS with a confidence level of 10 or higher were superimposed on the TLS point cloud, and their differences were examined, as shown in Figure 22 and Table 6. As a result, 57.34% of the point cloud fell within a difference of 0.15 m and was distributed across the entire bridge. Note that 27.86% of the point cloud showed a difference of 0.3 m or more, which is thought to be primarily due to differences calculated at the lower parts of the girders where sufficient measurement using TLS was not possible.

Based on these results, the overall shape of the bridge and areas with high confidence were deemed to have a sufficient level of precision to serve as data indicating the positional relationship between the bridge and the camera. Therefore, the constructed incomplete polygon model was used as a reference for aligning the current-state CIM.

Subsequently, the aligned current-state CIM was imported into the SfM/MVS software, enabling the creation of an accurate textured polygon model. Figure 23 shows the data of the SfM/MVS application process using the current-state CIM, and Figure 24 shows the textured model created by this process. In addition to being able to confirm damage such as corrosion on the textured model, it became possible to output orthoimages, as shown in Figure 25, and accurately record the location, size, and other details of the damage by overlaying the orthoimages with drawings. Furthermore, the visualization of damaged areas using the 3D model enabled desk-based assessments of deterioration, as shown in Figure 26.

Figure 26. Example of a damage map created based on orthoimages

### 3.7 Issues

Four points may be mentioned as issues in the SfM/MVS combined technique using measured point cloud data described in this paper: i), Increase in costs associated with the construction of the current-state CIM, ii) Accuracy and level of detail of the current-state CIM, iii) Accuracy of alignment of the current-state CIM and camera positions and iv) Applicability of SfM/MVS to more difficult cases.

i) Cost incurred in construction of the current-state CIM

Compared to conventional SfM/MVS, the measurement of point cloud data aimed at understanding the current-state shape, the modification of drawing data to match the actual shape, and the creation of the current-state CIM lead to an increase in costs and workflow. It is necessary to plan accordingly to ensure efficient and sufficient data acquisition, based on the purpose of applying SfM/MVS techniques. This involves selecting appropriate equipment, preparing a measurement plan, and

considering factors such as the level of detail (LOD) of the 3D model, as described later.

ii) Accuracy and level of detail of the current-state CIM

The current-state CIM prepared in the proposed method will contain errors due to measurement accuracy, accuracy during model preparation and the setting of LOD. As the error in shape estimation increases, the accuracy of the positional relationship of the model and the cameras will decrease, leading to decreased quality of the textures to be projected. In actuality, even in the case described in this paper, it was confirmed that due to the difficulty in capturing detailed geometry using TLS, the quality of textures decreased in parts on the underside of the girders, where the level of detail of the current-state CIM was low, compared to other areas.

iii) Accuracy of alignment of the current-state CIM and camera positions

The point cloud obtained through conventional SfM/MVS processing was confirmed to be usable as reference data for alignment based on comparative verification with the TLS point cloud. Using the constructed incomplete polygon model as a reference, the alignment between the current-state CIM and the camera was performed. On the other hand, to ensure the accuracy and reproducibility of alignment, it is desirable to manage coordinates on public coordinate systems. This can be achieved by setting up multiple ground control points during UAV imaging and TLS measurements, and performing processes such as aligning the control points placed on the current-state CIM based on the TLS point cloud with the control point coordinates calculated by SfM/MVS.

iv) Applicability of SfM/MVS to more difficult cases

In the example described in this case, it was possible to estimate the camera positions by applying conventional SfM/MVS and perform polygon modeling, although incomplete. The factors in this successful result are thought to include the fact that image acquisition was performed by setting the angle of view to capture a wide range in photography by the UAVs, and corroded parts and fine irregularities on members could be detected and used as feature points. Thus, there is a possibility that the technique described in this paper may be inadequate for steel bridges and other structures with uniform surface textures or flat shapes over larger areas. Therefore, going forward, it will be necessary to consider combining SfM/MVS with other 3D model acquisition techniques, including improvements to the methods discussed in this paper.

## 4 CONCLUSION

As a technique for applying SfM/MVS to steel bridges, in which the steel materials have a uniform surface texture as a result of coating film, this paper examined a processing flow for projecting textures from camera images on a current-state CIM model based on measured point cloud data obtained with terrestrial 3D laser scanners. The technique was also verified at an actual bridge. Although the quality of textures differed depending on the accuracy and level of detail (LOD) of the current-state CIM model, the possibility of constructing a textured model and orthoimages with sufficient quality to identify overall damage could be confirmed.

On the other hand, various issues for application of the SfM/MVS technique verified in this paper may be mentioned.

These include the cost of creating the current-state CIM model, the accuracy and LOD of the model, the accuracy of alignment, and the applicability of the proposed technique to more difficult object structures. To overcome these problems, it will be necessary to plan methods corresponding to the purpose of applying SfM/MVS, the geometry of the object structure, and the surrounding environment. In the case described in this paper, the current-state CIM model was prepared based on existing drawings and the measured point cloud data of the current shape of the structure. In the future, the application of BIM/CIM, which has been actively promoted in recent years, may make it possible to substitute the current-state CIM with BIM/CIM models constructed at stages prior to inspections.

As future work on SfM/MVS application techniques, the authors intend to improve the accuracy and expand the range of application of the SfM/MVS technique, and study approaches for realizing higher efficiency and labor-saving in bridge inspections of steel bridges.

**ABSTRACT:** Finite element analysis (FEA) is widely used to evaluate civil structures' performance. To consider detected structural anomalies due to damage in FEA, it is required to represent the anomalous areas in the original finite element (FE) model and update the mesh configuration. This study proposes an approach for updating the shell-element FE models of thin-walled structures with anomalous areas by the point cloud data (PCD)-based CV method, focusing on surface planar anomalies. In this approach, the Iterative Closest Point (ICP) algorithm was used for the alignment of the point cloud with the FE model. The Density-Based Spatial Clustering of Applications with Noise (DBSCAN) on HSV values of PCD was used to extract points of anomalies. The anomalous region is denoted as its boundary points detected by the Alpha-shape algorithm. Constrained Delaunay Triangulation (CDT) generates the new meshes over a constrained area based on points related to anomalies. An experimental study was conducted for validation using a steel plate structure with various stickers attached to simulate the anomalies. The proposed CV-based FE model updating method was validated by comparing the PCD-based updated model and the manually updated model in terms of geometric and analytical accuracy. Most of the corresponding anomalous regions in the two models show a high degree of consistency, except for some areas affected by the low quality of the PCD, which, however, do not have a significant impact on the FEA results. With the same thickness reduction of anomalies, the analysis results indicate that there is only a minimal error between the two models. The proposed method is feasible as a substitute for manual rebuilding, facilitating the automation of the FE model updating with anomalies.

## 1 INTRODUCTION

Since civil infrastructures, such as buildings, bridges, dams, and tunnels, in many countries have been in service for extended periods, various damage accumulated through aging in these in-service structures seriously threatens their safety. The damage assessment for aging structures is critical, considering the infrastructure's crucial role in supporting the quality of life and the economy.

Residual capacity assessment, based on simulation with finite element analysis (FEA), is one of the most widely used methods for evaluating damage to in-service structures. Computer vision (CV) techniques based on point cloud data (PCD) enable the identification and representation of real structural anomalies in computational models. However, current PCD-based modeling studies primarily focus on geometric reconstruction, while relatively limited attention has been given to their applicability in structural analysis. Moreover, there are far more studies related to mass solid structures such as concrete than shell structures like steel [1], [2], [3], [4], [5].

Considering that the PCD-based method of extracting anomalies can greatly facilitate the subsequent damage assessment based on numerical simulation, the purpose of this research is to propose a method for extracting anomalous information from the point cloud and incorporating it into the finite element (FE) model for analysis.

## 2 EXPERIMENT

This research conducted a full-scale steel structural mock-up test to simulate the actual inspection process of anomalies in steel structures. Shell element FEA was used to assess the structure's performance. The results of the manually built

model served as a reference to validate the proposed CV-based modeling method. The specific setup of the specimen and FEA will be elaborated on as follows.

The specimen was set up in this experiment as shown in Figure 1. It is based on a combined structure, consisting of three orthogonal SS400 steel plates welded together, with dimensions of 400 mm in height, 180 mm in length, and 180 mm in width. The thickness of all plates is 9 mm.

On the surface of the specimen, stickers of different shapes, sizes, and colors are arranged in various locations to indicate anomalies.

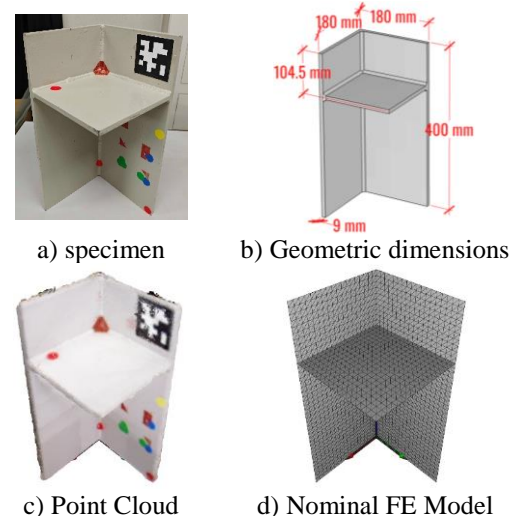

Figure 1. Setup and source data of specimen.

In this paper, A standard static analysis was conducted on the model using the commercial FEA software Abaqus. The reference model is manually imprinted with the outline lines of

anomalous regions in the geometric model, and the mesh generator tool included with the software is used to generate shell element (S3) meshes. Meanwhile, the test model is automatically remeshed based on the existing nominal FE model. The re-meshing is only executed within the local region specified by the proposed method. To introduce an observable amount of load capacity reduction, a uniform shell thickness of 3 mm is used in the anomalous regions for both models, representing a corrosion depth of 6 mm.

### 3 METHOD

We propose a PCD-based, CV-driven approach for updating the shell finite element model with anomalous information on the structure. This approach comprises three tiers.

The Perception Tier extracts geometry, features, and anomalous information from structures using point cloud data and establishes correlations between this information. The PCD of the steel structure was registered to the mesh through two steps: coarse (PCA) and fine (ICP) alignment. A clustering method that combines the Density-Based Spatial Clustering of Applications with Noise (DBSCAN) algorithm and the Support Vector Machine (SVM) was implemented to extract anomaly-related points based on the color information of points.

The Anomaly Description Tier processes anomalous information in the point cloud, extracting features to represent the anomalous area. We utilize the Alpha-shape algorithm for boundary detection. For a single anomalous area that may distribute across multiple planes, the points are further separated into corresponding planes by joint lines, allowing boundary detection to be conducted on each subset.

The Re-meshing Tier performs local mesh regeneration of the target area based on the feature extracted by the previous tier. The Constrained Delaunay Triangulation (CDT) algorithm is used to generate new meshes within the original edge lines of the remeshing region.

### 4 RESULTS

The original model, manually updated model, and PCD-updated model are shown in Figure 2.

Figure 2. Results of the updated FE model

The locations of anomalous regions in the PCD-based updated model are generally consistent with those in the manually updated model.

Figure 3 presents the load-displacement curves at the loading point for the three models during the loading process.

Figure 3. Load-displacement curve

### 5 CONCLUSION

This study proposed a method that utilizes PCD-based CV techniques to extract anomalous information from the structure and update it into an existing FE model. This paper focuses on surface anomalies commonly encountered in structures modeled by shell elements. The meshes corresponding to anomaly are locally updated based on geometric and color information contained in the point cloud.

The PCD-updated FE model was validated at the analytical level using a manually updated model created according to the design as the criterion. The following conclusions were drawn:

1. The PCD-updated model accurately captures the changes in the global distribution of stress and reduction in ultimate load capacity caused by anomalies in nonlinear analysis. Its results are in good agreement with those of the manually updated model, with a difference of less than 1% in the ultimate strength reduction.

2. The local stress distribution in the anomalous areas of the PCD-updated model is highly consistent with that of the manually updated model. However, due to limited detail in the extracted boundaries of anomalous regions, its local stress concentration effects do not perfectly match those of the manually updated model. Nevertheless, the level of accuracy is sufficient for evaluating structural load-bearing capacity.

**ABSTRACT:** Quantification of friction demands is a major task in management of road infrastructures. The use of pavement texture measurement in friction assessment offers the potential for describing road frictional characteristic in a non-contact manner. However, surface macrotexture profiles tested by stationary measurements and high-speed laser systems provide limited range of texture information at high frequency scales. To achieve adequate outdoor road surface reconstruction at ultra-high resolution and low cost, this research develops a synthetic environment for ground truth reference and efficient generation of data and experiment. To illustrate the approach, a photo-realistic computer graphics model of asphalt pavement surface is produced and virtually scanned using candidate image acquisition plans. Then, in-depth quality assessment of the corresponding 3D point cloud reconstruction models is performed. In this way, suggest use of a close-range photogrammetric pavement surface scan method using Structure-from-Motion (SfM) technology and its requirements for friction-oriented texture quantification in terms of spatial resolution, camera movement, and illumination configuration is put forth. The effectiveness of the synthetic environment and the optimized experiment setup is demonstrated through a field survey on three roads. Finally, the obtained point cloud datasets are used in texture feature characterization and friction number prediction modeling processes.

**KEY WORDS:** Synthetic environment; Structure-from-Motion; Pavement texture measurements; Infrastructure friction performance.

## 1 INTRODUCTION

Pavement skid resistance is one of the most important properties among other highway surface characteristics. Demand for engineering interventions to restore friction of the aging and deteriorating highway network has been increased through years. Period assessment of pavement friction performance at the tire-road interaction has a pivotal role in developing the inventory of the condition of infrastructures at the highway network level. Current means of tire friction measurement devices and processes need calibration and harmonization for quality assurance. The use of pavement texture measurement in friction prediction offers the potential for describing highway frictional characteristic in a non-contact manner. To this end, such practices need to identify a comprehensive list of pavement macrotexture and microtexture attributes which contribute to friction. Both stationary measurements and high-speed laser systems are employed for sufficient reconstruction of macrotexture surface profiles [1]. However, a lower bound of microtexture wavelengths that relate to pavement skid resistance is not standardized. Furthermore, not all high frequency scales of microtexture are measurable. Criteria for sufficient spatial sampling rate and quality quantification of a pavement microtexture measurement approach, which includes all useful scales, is still vague [2].

In this paper, camera-based sensing of highway surface texture, using Structure-from-Motion (SfM) technique, is suggested for outdoor practices of high-resolution reconstruction of surface topography. In order to make fully use of the advantages provided by SfM technique while at the same time quantify and overcome limitations observed in previous studies, the investigation qualify SfM pipelines for pavement

texture measurements with three main contributions: (1) in-depth quantitative studies of the texture measurement accuracy influenced by the photogrammetric capturing quality of highway surfaces at high frequency scales; (2) comprehensive list of 3D texture characteristics contributing to the texture-friction correlation; (3) suggest use of an experimental setup using commercial off-the-shelf camera and its requirements for sufficient pavement texture quantification in terms of spatial resolution, camera movement, and illumination configuration is put forth. The works aims to optimize the use of outdoor photogrammetry techniques to friction-oriented road surface assessment, particularly for sufficient characterization of surface texture at micro-scales.

## 2 PAVEMENT SYNTHETIC ENVIRONMENT

Development of a synthetic test environment for close-range image acquisition of pavement surface topography is important for the proposed investigation for two main reasons:

1. Ground truth measurement: Evaluation of the SfM surface reconstruction quality in terms of texture characterization requires a well-defined ground truth model as the target reference. More often, camera-based approaches rely on a comparison to model from another costly technique such as a laser texture scanner or a microscopy. Therefore, the quality of such a comparison is limited by inevitable uncertainty in the reference model. Practices to mitigate this drawback include replication molding of the target surface and the use of 3D-print target objects [3]. In an approach using synthetic environment, the surface topography ground truth data is available. The

accuracy and quality of a SfM reconstructed surface digital elevation model (DEM) can be quantified using a direct comparison to the ground truth displacement map of the synthetic texture model. Subsequently, the pavement texture measurement performance from a photogrammetric survey can be optimized based on the observed variation in comparison results.

2. Efficient data generation and experiment: In the submillimetre, and micrometer range, quality of a photogrammetric surface reconstruction can be affected not only by the environmental and apparatus setups, but also by local characteristic variations of a target surface texture. Conducting a quantitative study of these factors in the field is time and cost consuming. In contrast, SfM surveys using images rendered in the synthetic environment can efficiently cover a wide variety of system configurations at any time without labor-intensive and site-sensitive field surveys.

A synthetic environment has been developed to test and quantify all influential factors regarding pavement macrotexture and microtexture measurements in a generalizable manner. To bring the close-range photogrammetric setup into the outdoor field environment, the image acquisition strategy should be developed, tested, and optimized for an efficient and robust performance.

Blender software is used to implement the synthetic modeling steps introduced herein. To extend the synthetic environment to a generalizable one, the high-resolution surface geometric details are modeled with a variation of texture characteristics using the Blender-Python API (Blender, 2024). The developed environment is used to produce survey images “captured” by a virtual micro-four thirds camera using different ground sampling distance (GSD). The resolution of each simulated image is  $4592 \times 3448$ , in which each pixel has a size of  $3.77 \mu\text{m}$ . This section describes the detail of each created texture model and the steps to develop the synthetic setup for pavement close-range photogrammetric texture measurement. First, a mesh of each solid object in the environment is created to represent the 3D geometric details of the target structure. Then, multiple texture maps and settings are imported to control base color, roughness, and shading effects of the object surfaces. Third, a simplified surrounding scene is configured, and a camera-light pair is positioned facing down at a determined height. Finally, a group of simulated images rendered from predetermined viewpoints are produced. An overview of the development is depicted in Figure 1.

Figure 1. Framework for the synthetic approach of pavement texture photogrammetry.

## 2.1 Synthetic Data Generation

The synthetic environment developed in this research consists of a  $100 \text{ mm} \times 75 \text{ mm}$  patch of surface texture with four edges enclosed by a  $10 \text{ mm}$  wide rectangular control frame.

A solid object of control frame was generated in the synthetic environment. A cardboard thickness of  $3.175 \text{ mm}$  ( $1/16 \text{ in.}$ ) was selected to ensure flatness of reference surface for surveys in the field. The frame has a rectangular shape, and its inner and outer dimensions are  $100 \text{ mm} \times 75 \text{ mm}$  and  $120 \text{ mm} \times 95 \text{ mm}$ . The  $10 \text{ mm}$  width of four edges is selected so that the entire inner scanning area can be captured with at least two images (high overlapping). With a printed paper texture projected on the control frame top surface, a total of 40 reference marks of  $5 \text{ mm}$  diameter are horizontally distributed on the edges of the enclosed target scanning area. The edge distribution approach of ground control points (GCPs) is followed to have an optimized mapping accuracy [4] and to avoid texture occlusion. Previous studies have observed that the addition of a few vertically distributed GCPs can decrease the vertical reprojection error of a UAV surface mapping without influencing the planimetric accuracies [4], [5]. Therefore, additional heights ( $1/32 \text{ in.}$ ,  $1/16 \text{ in.}$ ,  $3/32 \text{ in.}$ ,  $1/8 \text{ in.}$ ) are added to four of the 40 edge marks so that they can be utilized as vertical GCPs.

A photogrammetry-based asphalt material downloaded from an public database [6] was adapted to generate a realistic pavement texture at a ultra-high level of resolution in the synthetic environment. The original data has a color map, a roughness map, a normal map, and a displacement map, each was represented by a  $16\text{K}$  image of  $1.2 \text{ m} \times 1.2 \text{ m}$  area. Several data processing steps were developed to the texture maps so that realistic ground truth textures with a variation of statistical characteristics can be tested in the synthetic environment.

1. The original maps have a resolution of  $186.4 \text{ p/mm}^2$ , equivalent to a pixel size of  $73.2 \mu\text{m}$ . Each of the three texture maps was refined to have an ultra-high resolution of  $1.68 \text{ Kp/mm}^2$  ( $24.41 \mu\text{m}$  pixel size) using bicubic interpolation. The 3D surface developed from a refined texture mesh has a smooth mesh geometry in the simulated images, in which unexpected edge artifacts in the high-frequency domain become invisible to the virtual camera pixels. Figure 2 shows a  $5 \text{ cm} \times 5 \text{ cm}$  patch of the surface color map before and after the interpolation. While increasing the synthetic surface smoothness enables a more realistic modeling of structure, it significantly increases the required computational power and time. The increased resolution of  $1.68 \text{ Kp/mm}^2$  in the geometry modeling of ground truth surfaces is selected to offer a tradeoff between model reality and tedious work. As a result, the ground truth power spectrum density (PSD) has a nominal high cutoff wavevector of:

$$\frac{2\pi}{\lambda_{min}} = \frac{2\pi}{4.882 \times 10^{-5} \text{ m}} = 1.287 \times 10^5 \text{ m}^{-1} \quad (1)$$

Figure 2. 5cm x 5cm patch of the asphalt texture model: original (left) and refined (right).

2. To enable real world applications of the system configuration with performance tested in synthetic simulations, the synthetic asphalt was scaled to have a middle level of average macrotexture MPD equal 0.83 mm. In this way, the target pavement shows realistic amplitude asperities over a large frequency range.

Using the Blender-Python API [7], gridded vertices, and triangulated faces of a mesh with displaced vertical coordinates is first created to represent the ground truth geometry of each synthetic pavement. Then, the generated 3D mesh is textured using a principle BSDF node in Blender, in which the base color and the light reflection roughness of the mesh surface are controlled and rendered using a physically based approach.

## 2.2 Rendering Synthetic Images

The length of the abstract is limited to 15 lines. The abstract should be self-contained and it must not refer to the other parts of the paper (such as the list of references). After the synthetic textured mesh of a pavement surface is created, an image acquisition plan including illumination condition and camera viewpoints is needed for optimization of tradeoff between spatial resolution and time/cost efficiency.

**Optics.** The critical parameters of a commercial off-the-shelf camera optics that influence the GSD of captured images on the target surface are: (a) the minimum focus distance, which is the closest capturing distance the camera can focus; (b) the depth of field (DoF), which is the vertical variability limit the survey can digitize. The reference project developed in the synthetic environment uses a virtual 4K camera of 30 mm focal length capturing at a height as low as 80-mm.

Macro camera lenses with a 1:1 or higher magnification ratio are widely used in applications of close-range photogrammetry [8]. The magnification ratio is the relationship of the size of a focused object in reality and the size of its reprojection on the camera image sensor. For a camera with pre-determined pixel size, a lens with higher magnification ratio enables capturing of images at a higher resolution. However, macro lenses exhibit a limited DoF without a time tedious process of focus stacking. According to the size of image sensor, most commercial off-the-shelf cameras can be categorized into three types: micro-four thirds (17.3 mm x 13 mm), APS-C (about 23 mm x 15 mm), and full frame (36 mm x 24 mm). Figure 3 compares the three types of cameras and the relationship between GSD and DoF. The focal lengths are selected for individual camera type, so that they achieve same level of image GSD at an equivalent object (focus) distance. Although large image sensor size cameras feature superior performance in cases that require low-

light (small aperture) and/or high-ISO settings, they result in shallower DoF assuming equivalent effective focal length. At a lateral resolution level of 10  $\mu\text{m}$ , the three cameras produce DoF results of 4.44 mm, 3.12 mm, and 2.03 mm, respectively. Therefore, micro-four thirds camera type is selected in both the synthetic environment and the field experiments to achieve sufficient DoF with cost efficiency.

Figure 3. Depth of field (DoF) relationship with GSD for three camera types at a 60 mm equivalent effective focal length.

To capture full range of surface texture amplitudes in a targeting pavement, a DoF greater than the texture maximum height ( $S_z$ ) is preferred. Most asphalt pavements have an MPD of less than 2 mm. Thus, a minimum GSD of 10  $\mu\text{m}$  is selected for all configurations of image acquisition tested in the synthetic environment.

**Scanning Area and GSD.** The ground sampling distance (GSD) of captured images is a standard metric for the resulted spatial resolution of reconstructed point cloud, as it is the measured distance between two consecutive pixel centers on the ground. The determination of GSD depends on various factors including the camera focal length, the sensor pixel size, and the object distance (Figure 4a). A camera with fixed focal length captured at a higher height can result in larger GSD and lower spatial resolution (Figure 4b) compared to a closer range of photo capturing (Figure 4c). Ideally, a GSD is expected to be smaller than the smallest roughness horizontal scale to enable measurement of surface irregularities at the highest frequencies. However, the apparatus cost can be exponentially increased to have an image sensor with smaller pixel size and a macro camera lens that allows higher magnification ratio captured at a longer distance. While the synthetic environment is an effective tool enabling the use of simulated images “captured” by a virtual camera of any specifications at any distance, inevitable constraints on a low-cost field survey configuration should be taken into consideration.

Figure 4. Determination of GSD (a), Large GSD – Low spatial resolution (b), and Small GSD – High spatial resolution (c).

Another factor that can affect the selection of GSD in a photogrammetric survey is the dimensions of target scanning area. A single 4K digital image can only capture about 16 mm in width if a  $4\ \mu\text{m}$  of GSD is used. Therefore, numerous numbers of images will be required for a single pavement texture 3D scan. This requirement can lead to tedious image acquisition work as well as long image processing time. Figure 5 shows the variation of the required number of images with GSD for a  $3.77\ \mu\text{m}$  pixel size 4K camera capturing a  $120\text{mm} \times 95\text{mm}$  surface area. The calculated number of required images include auxiliary images captured from multiple heights to ensure consistent mosaicking of partial scans. In the resolution range of  $10\ \mu\text{m}$  or smaller, the required number of images per survey is increased exponentially as GSD decreases. The minimum tested GSD of  $10\ \mu\text{m}$  enables not only enough DoF, but also reasonable image acquisition time. As the computational power grows and the cost per pixel decreases through time [9], the observed limitations can become negligible for future implementations.

Figure 5. Required number of images with GSD for 4K camera scanning  $120\text{mm} \times 95\text{mm}$  area.

**Scene and Lighting.** The primary goal of lighting configuration is highlights while at the same time provide shadowless illumination. As discussed before, a camera with focus stacking technique may be needed if the aperture optimized for exposure provides insufficient DoF. In the proposed approach, fixed settings of F-stop ( $f/22$ ) and ISO 200 are selected for deeper DoF and smaller visibility of noise. As the target object is partially insulated from the environmental

illumination through set-ups including the surrounding control frame, close apparatus, and a very small aperture, a specific light source in conjunction with the sunlight is used towards proper exposure. In Figure 6, three images are rendered at 105 mm camera height with different energy settings of the added point light source. Therefore, proper adjustments of the light power output with object distance changes are required to prevent irreversible loss of data in the dynamic range.

Figure 6. Synthetic rendered images of asphalt pavement texture with histogram at different light settings: (left) under exposed, (middle) proper exposure, and (right) over exposed.

Finally, a complete synthetic scene of pavement background and morning sunlight was used in image rendering processes. A 600mW power of diffused point light source moves along with the virtual camera is used to ensure shadowless and even imaging. In field studies, the shadow introduced by an imaging apparatus capturing at a close distance can be removed using a ring light installed around the camera lens. Figure 7 shows the rendered scene including a target object placed on the ground, a virtual camera facing down, and a diffused point light with pre-adjusted power output. Camera specifications and illumination configurations are set according to optimization of trade-off between cost, time, and resolution discussed in the above sections.

Figure 7. Scene and lighting configuration in synthetic environment.

**Camera Motion.** Images captured from numerous prescribed viewpoints are used in SfM technique to estimate the relative camera positions through feature matching, which is the start of triangulation processes. Both quantity and quality of the acquired images can greatly influence the feature detection performance. Following the principle of full coverage with high overlapping, two main strategies of shooting scenarios are widely used to obtain high quality of surface scanning: circular camera motion around the object, or viewpoints in a Cartesian lattice [8]. The former is preferred when the size of a single image footprint is greater than the target scanning area, whereas the latter is good for wider

surface scanning. A minimum net scan area width of 100 mm is required for measurements of pavement macrotexture MPD. Therefore, one standard 4K image cannot fully cover a scanning area of the required size at a GSD smaller than 25  $\mu\text{m}$ . However, the lowest wavelength of pavement roughness in rubber friction theory can be as small as a few micrometers [10]. This approach follows the Cartesian approach to avoid illumination artifacts and to achieve a lateral resolution as small as 10  $\mu\text{m}$ . In addition, a few auxiliary images captured at larger heights are collected so that the overall reconstructed surface structure is consistent through small partial scans.

The accuracy of 3D reconstruction outputs and their performance in texture characterization are tested at multiple levels of GSD: 10  $\mu\text{m}$ , 13  $\mu\text{m}$ , 15  $\mu\text{m}$ , and 38  $\mu\text{m}$  in the developed synthetic environment. As shown in Figure 8, a Cartesian approach is used in the first three image acquisition plans as it allows closer object distance for smaller GSD. The strategy of circular camera motion around the target, at a 22.5° rotation interval, is also tested for comparison. The number of images used in the texturing of the reconstructed surface in four different image acquisition plans are 80, 35, 20, and 13, respectively. At least 80% image overlap is employed in all four plans since photogrammetry in a close-range scenario requires larger overlapping of images [11].

Figure 8. Image acquisition plans simulated in the synthetic environment tested at different GSD: (a) 10  $\mu\text{m}$ , (b) 13  $\mu\text{m}$ , (c) 15  $\mu\text{m}$ , and (d) 38  $\mu\text{m}$ .

### 2.3 Photogrammetric Process and 3D Reconstruction

All simulated images for each system configuration of pavement characteristics and camera viewpoints are imported in ContextCapture software [12] carrying out a photogrammetric process. The entire process includes three major stages: feature tracking, sparse reconstruction, and dense point cloud reconstruction.

First, the evenly distributed ground control points (GCPs) are detected in the images, either manually or automatically. An aerotriangulation process started from estimating the photogroup intrinsic and extrinsic properties. Taking into

account the world coordinates of GCPs for georeferencing, the aerotriangulation detects and tracks matched features in the overlapped area of consecutive images. As a result, numerous automated tie points are detected and an estimation of camera properties is provided. Figure 9 shows an example of 4,412 tie points detected in one image “captured” at a GSD of 13  $\mu\text{m}$  with a root mean square (RMS) reprojection error of 0.5 pixel. Enough tie points with sub-pixel parallaxes matched in the images is a good indicator of high precision in feature tracking.

Figure 9. Example of 4,412 tie points detected in one rendered image by ContextCapture.

Next, the correspondence found between all tie points at the previous stage still contain errors and the camera pose estimates will be further refined in sparse reconstruction. At this stage, a bundle adjustment of camera internal and external parameters is employed for robust estimation. Taking advantage of redundancy in large number of detected tie points, this step estimates the geometry of the scene and obtains a sparse point cloud with robustness. Figure 10 shows the output of the sparse reconstruction stage of an asphalt surface texture modeled in the synthetic environment. The pavement model has an average MPD of 1 mm and was scanned at a GSD of 10  $\mu\text{m}$ . The control frame on the edges is only used to provide GCPs and will not be included in the reconstruction of dense point cloud. This stage marks the end of SfM technique applications.

Figure 10. Sparse point cloud reconstruction output example.

The proposed photogrammetry approach requires a 3D reconstruction result of dense point cloud with a resolution equal or close to the determined GSD. Therefore, Multi-View Stereo is implemented to increase the point cloud density and reconstruct the 3D model with voxel color texturing according to stereo images of the scene captured with overlapping across different viewpoints. In both synthetic and laboratory

environments, the camera motion can be controlled precisely with accurate positioning data. However, to simulate the outdoor scenario that camera positions are not available to be used as initial estimate of camera extrinsic parameters. In the proposed method, the scene coordinate system of a developed output 3D reconstruction was initialized using at least three arbitrary GCPs of choice instead. Figure 11 compares the top view of a synthetic asphalt surface in Blender and its 3D reconstruction model produced by ContextCapture at a spatial resolution of 10  $\mu\text{m}$ . The original pavement model on the left is a mesh containing 1,567,362 vertices and 3,129,672 triangular faces. Due to the limited computational power (32Gb memory), the resulting resolution of the model is set as 24.41  $\mu\text{m}$ . Compared to the model ground truth, the 3D reconstruction on the right provides a top view picture with higher resolution. Although the two structures have different voxel resolutions, limited differences among the measurement of pavement texture parameters should be observed for a good photogrammetric texture reconstruction.

Figure 11. Synthetic asphalt pavement surface (left) and its 3D reconstruction with 10  $\mu\text{m}$  spatial resolution (right).

### 3 DATA QUANTIFICATION AND EVALUATION

The quality of each photogrammetric survey can be assessed by quantifying the difference between ground truth and 3D reconstruction and its Digital Elevation Model (DEM).

#### 3.1 3D Reconstruction Model Quality

Regardless of asperities in the surface topography, the modeling quality of a 3D reconstruction depends on the image acquisition plan, illumination, and camera intrinsic and extrinsic properties. Table 1 compares quality of 3D reconstruction outputs developed using different image acquisition plans. The density of the reconstructed point cloud remains uniform throughout the entire scanning area when a Cartesian approach is selected. Therefore, the resulted point cloud resolution of each Cartesian output is at the same level of the pre-determined image GSD (10  $\mu\text{m}$ , 13  $\mu\text{m}$ , and 15  $\mu\text{m}$ , respectively). However, if a circular camera motion is selected, the resulted point cloud will be distributed at a range of resolution because of the inclined orientation of camera viewpoints. In this case, a sampling rate equal to the highest resolution (37  $\mu\text{m}$ ) or one pixel size (38  $\mu\text{m}$ ) will be used in the creation of surface DEM model even if smaller resolution values were observed in partial areas.

Generally, a large number of tie points per image with a sub-pixel parallax for images used in the aerotriangulation process is desired for high quality 3D reconstruction. The automated tie points detected in each image of the circular camera motion model (GSD=38  $\mu\text{m}$ ) is significantly decreased compared to results from the Cartesian approaches. A reason of this change is that the target surface was not covering the whole

image footprint when the camera was capturing the entire object with a rotation in Z direction. An RMS reprojection error of less than one pixel size is observed for all four outputs, indicating that a satisfied precision in camera pose estimations can be obtained at various levels of point cloud resolution. As shown in Table 1, the average uncertainties found in estimation of image poses are less than 0.01 mm in all directions for three models with a  $\text{GSD} \leq 15 \mu\text{m}$ . For the model with 38  $\mu\text{m}$  of GSD, the observed image pose uncertainties are also less than one pixel size for quality assurance. For all four model outputs, the image uncertainty in the Z direction is smaller than ones in the two horizontal directions, as the camera was moving mostly in the X and Y directions.

Table 1. Quality summary of 3D construction at different GSD levels in image acquisition/

Point Cloud Resolution Range	Median Tie Points per Image	RMS Tie Points Reprojection Error
0.0099 mm – 0.01 mm	4,541	0.55 pixels
0.013 mm	5,395	0.5 pixels
0.015 mm	6,025	0.5 pixels
0.028 mm – 0.037 mm	1,263	0.68 pixels

#### 3.2 Digital Elevation Model Quality

Measurements of pavement texture only concern the height or elevation values of a target surface. Instead of conducting a direct comparison between voxels in two 3D structures, the 3D dense point cloud output of photogrammetry model will be rasterized to provide a surface DEM at one pixel sampling rate in MATLAB. The output map contains generalized height information of the input point cloud based on a local binning algorithm. As the GSD (one pixel size in mm) was selected as the fixed resolution of the grid element along X and Y axes, a few missing values are inevitable in the computed DEM and will be filled with linear interpolation. The corresponding percentage of the unfilled grids in DEM of the models with different grid resolutions are 0.099% (10  $\mu\text{m}$  resolution), 0.1% (13  $\mu\text{m}$  resolution), 0.15% (15  $\mu\text{m}$  resolution), and 0.00056% (38  $\mu\text{m}$  resolution) respectively. The number of unfilled grids in all four DEMs are neglectable compared to the matrix sizes. And the DEM of each 3D point cloud will be compared with the original displacement map of the synthetic asphalt pavement in terms of both residual errors and texture characteristics measurements. A visual comparison of the displacement (height) ground truth and the created model DEMs are displayed in Figure 12. According to the DEM surface plots, most of the height asperities of the structure are accurately scanned into the models. However, one deep pit was lost with a decreased absolute height in its 3D scans. The possible reason for this false is that occlusion happened when the optical paths were detecting the target point in valley.

Figure 12. 3D surface plot comparison of surface ground truth (a) and DEMs of four 3D reconstructions of the synthetic pavement at different resolutions: 10  $\mu\text{m}$  (b), 13  $\mu\text{m}$  (c), 15  $\mu\text{m}$  (d), and 38  $\mu\text{m}$  (e).

Before comparing individual values in the ground truth matrix and the computed DEM of a 3D point cloud reconstruction, a spatial referencing process is needed to align the two matrices with different grid sizes. Then, the size of the matrix with a larger resolution is increased using linear interpolation. Finally, the residual errors of each DEM using the identical world coordinates are collected. Figure 13 shows the residual distribution of the DEMs compared to the ground truth. The shapes of residual histograms are close to normal distributions with zero means. It is observed that the RMS of all the residual distributions is within single digits of pixels. The general quality of a surface DEM is not improving with a decreased resolution. And the model sampled at 38  $\mu\text{m}$  resolution provides the highest quality because a tilt camera view helped in preventing the occlusion issue. However, a high DEM general quality only means that the texture roughness in the range of wavelengths greater than  $2 \times$  resolution was reconstructed accurately. The height asperity data in higher frequency ranges of the original structure was lost.

Figure 13. Residual distributions of DEMs of four 3D reconstructions of the synthetic pavement at different resolutions: 10  $\mu\text{m}$  (a), 13  $\mu\text{m}$  (b), 15  $\mu\text{m}$  (c), and 38  $\mu\text{m}$  (d).

After the spatial referenced comparison, the quality of a DEM needs to be further evaluated in terms of the characterization of pavement macrotexture and microtexture. To this end, a Butterworth filter was applied to both the pavement ground truth and the reconstruction DEMs to get: (iii) total texture roughness with wavelengths less than 50 mm, (ii) macrotexture with wavelengths within [0.5 50] mm, and (iii) microtexture with wavelengths  $\leq 0.5$  mm. Figure 14 illustrates the filtering process and its effects on the synthetic pavement

ground truth. As shown in Figure 14d, the original synthetic pavement contains waviness with wavelengths greater than 50 mm and it will be filtered out before the texture characterization processes.

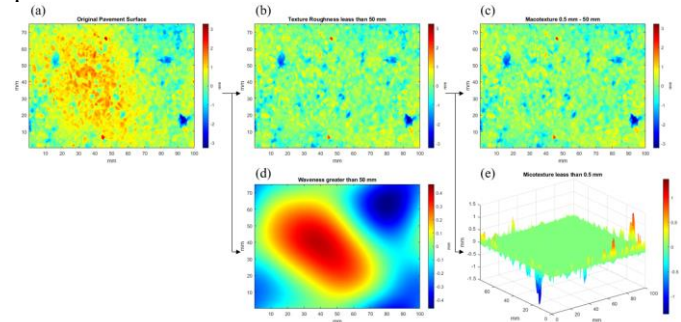

Figure 14. Butterworth filtering results on the synthetic pavement texture: (a) original surface; (b) total texture roughness; (c) macrotexture; (d) removed waviness; (e) microtexture.

### 3.3 Texture Characterization Quality

In this section, the macrotexture MPD and 3D areal parameters in total texture roughness measured from the 3D reconstructions will be evaluated.

First, the standard MPD is calculated from macrotexture of both the ground truth and the DEMs. Since different numbers of MPD measurements will be collected from data with different resolutions, the averaged MPD and the RMS MPD value will be compared as metrics. Since all four 3D reconstructions were sampled at a resolution much smaller than the microtexture lower bound wavelength (0.5 mm), the MPD measurements of DEMs are all accurate with small differences observed in the averages ( $<3.1\%$ ) and the RMS ( $<3\%$ ) compared to the ground truth, as shown in Table 2.

Table 2. Evaluation of the photogrammetric macrotexture MPD measurements.

Resolution	Average MPD		RMS MPD	
	mm	Diff (%)	mm	Diff (%)
<b>Ground Truth</b>	0.8305	-	0.8498	-
<b>0.01 mm</b>	0.8343	0.4596	0.8548	0.5910
<b>0.013 mm</b>	0.8048	-3.0875	0.8244	-2.9851
<b>0.015 mm</b>	0.8413	1.2991	0.8626	1.5069

Two pavements with the same macrotexture and microtexture amplitudes, e.g. MPD, can have different friction levels. A variety of supplemental variables have been used to represent the texture-friction correlation with improved performance. 3D areal parameters has been playing a significant role in tribological studies [13]. Adapted from the ISO 25178-3 [14] standard, a list of statistical quantitative texture measurements is used for comprehensive characterization of a 3D surface topography. Specifically, in total of 26 3D areal texture parameters were calculated across five categories: seven height parameters (arithmetic mean height  $Sa$ , RMS height  $Sq$ , minimum peak height  $Sv$ , maximum peak height  $Sp$ , skewness  $Ssk$ , and kurtosis  $Sku$ ), two hybrid parameters (root mean square gradient  $Sdq$  and developed interfacial area ratio  $Sdr$ ), three spatial parameters (autocorrelation length  $Sal$ , texture aspect ratio  $Str$ , and the texture direction in rad  $Std$ ), five

feature parameters (the density of peaks  $Spd$ , arithmetic mean peak curvature  $Spc$ , five-point peak height  $S_{5p}$ , five-point pit height,  $S_{5p}$ , and ten-point surface height,  $S_{10z}$ ), and nine functional parameters (peak material volume  $Vmp$ , core material volume  $Vmc$ , core void volume  $Vvc$ , dales void volume  $Vvv$ , peak extreme height  $Sxp$ , surface section difference  $Sdc$ , reduced peak height  $Spk$ , core height  $Sk$ , and reduced dale height  $Svk$ ).

The measurements of all seven height parameters were robust among four 3D models. The differences between the 3D measurements and the ground truth are less than 5%.

The two hybrid parameters are both good indicators of texture roughness in general. As  $Sdq$  increases, the surface is inclined steeply. The surface becomes more rough when the  $Sdr$  value increases. All three 3D models with a resolution smaller than the ground truth resolution (24.4  $\mu m$ ) provide good measurements of the hybrid parameters. However, significant errors (>10% difference) are observed for the model that has a larger resolution (38  $\mu m$ ).

Spatial parameters measure the surface horizontally. Therefore, the accuracy of 3D measurements varies depending on the influence of surface isotropy in the high frequency range. The strongest surface orientation was not accurately detected in the two 3D models of higher resolution (15  $\mu m$ , 38  $\mu m$ ).

Due to the sensitive nature of feature parameters, the difference observed between the ground truth and the 3D measurements in this category are large. Among the four 3D reconstructions, the circular camera motion model with a resolution of 0.038 mm has the best performance in feature parameters measurements. The reason is that a tilt camera orientation can help in capturing the actual value of points with the largest global peaks and pits heights. However, there is a trade-off between the sampling resolution and camera orientation. Therefore, feature parameters will not be used in the friction prediction modeling process utilizing the field texture measurements.

Most of the nine functional parameters are measured accurately in the four 3D models. Some error in  $Vmp$  measurement were observed in two models with the smallest resolutions (10- $\mu m$  and 13  $\mu m$ ). A possible reason is that redundant volume of extreme peaks are sampled in the two models as the result of linear interpolation. The significant differences in  $Spk$  and  $Sxp$  measurements for the 3D model with 15  $\mu m$  indicate that this model failed to scan some peak height values.

#### 4 FIELD EXPERIMENT

A low-cost commercial off-the-shelf camera (Lumix GX850) with a micro-four thirds 4K image sensor (4592×3448) installed with a macro lens is utilized in the field capturing images of pavement surface texture. The selected macro lens has a fixed focal length of 30 mm and a minimum focus distance of 105 mm (equivalent to a minimum working distance of about 22 mm). To minimize shake and achieve a spatial resolution of the order of tenth of micrometer, the camera was mounted on a tripod with a working height as low as 55 mm. In addition, a 180 mm rail nodal slider is fitted on the tripod to ensure consistent overlapping between consecutive images. Although the macro lens allows a maximum magnification ratio of 1:1, a smaller magnification (1/3) is selected to allow

larger DoF at f/22 aperture. The target three track roads have previous MPD measurements fall in the range of 0.1 mm – 2 mm. Therefore, a DoF of 5.63-mm should be sufficient to capture the asperities in amplitudes. As tested in the synthetic environment, a battery powered ring light is added to compensate for the low environmental lighting resulted from the shallow aperture.

A LTS measurement pair for each photogrammetric texture scans was recorded for initial validation purposes of field MPD measurements. The LTS Model 9200 by Ames scans enables selected number of 100 mm length 2D texture profiles at a horizontal resolution of 0.015 mm. The device needs approximately 15 minutes to complete 50 scans of profiles over a scan area of 107.95 mm by 72.01 mm.

Figure 15 shows all the apparatus utilized in field texture measurements as well as the LTS used for validation purposes. The total cost of all equipment listed in Figure 15b is less than \$1000. Specifications of the photogrammetry device used for field texture scan are listed in Table 3.

Figure 15. Apparatus of field texture scans: (a) LTS model 9200, (b) 4K camera, macro lens, tripod, slider, and ring light.

Table 3. Summarized specifications of texture scan using LTS and photogrammetry.

SfM-based Photogrammetry	
Total scan area	100 mm × 75 mm
Resolution	0.011 mm in X, Y, Z directions
Pixel Size	3.77 $\mu m$
Image Sensor Size	17.3 mm × 13 mm (4592×3448)
Aperture	f/22
ISO	200
Focal Length/GSD	30 mm/0.011 mm

Field data collection of pavement friction and texture was conducted on three track roads in Spring 2024. As shown in Figure 16, the research and development division of INDOT has three track pavements with distinct MPD levels: two hot-mix asphalt (HMA) pavements at the left and middle lanes, and one slick concrete pavement on the right. For each road, two longitudinal sections (each about 65 feet long) along with three locations: the left wheel-path, the center line, and the right wheel-path were selected as individual test locations. The three transversal locations are assumed to have different levels of traffic polishing. Consequently, the difference observed in friction data gathered from the three locations within each road will explain the influence of traffic polishing on road wet friction performance. On the other hand, two longitudinal sections for each road were selected for data argumentation,

assuming that the pavement surface texture in real world is not homogenous in real-world scenarios.

Figure 16. The test fields: three track roads in INDOT. Each road includes two longitudinal sections (left) and three transversal locations (right).

After texture data collection, a LWST was employed to obtain the pavement friction number (FN) at two vehicle speed levels with multiple repetitions. In total of 130 LWST measurements were completed in three days, and the test temperature of pavement varies between 45°F to 112°F.

The residual errors of GCPs during the reconstruction of the field surfaces increases compared to the synthetic test results. One important reason is the additional uncertainties caused by calibration of a real-world camera with lens distortion. To verify the method reliability in the field, a comparison of macrotexture MPD measurement distributions between the proposed photogrammetric method and its LTS counterpart is employed. Since the measurement sampling rates and locations in the transversal direction varies, two sample T tests are employed to compare the average MPD in the distributions provided by the two methods. All 41 tests failed to reject the null hypothesis that MPD measured by photogrammetry and LTS are from populations with equal means at a 5% significance level.

The R-square value of 0.7672 indicates that limited information in the road friction performance can be explained by the standard macrotexture MPD solely. Therefore, three alternative models are trained: stepwise linear regression, neural network (NN) model, and regression ensemble model (random forest). The optimized regression ensemble model contains 47 learners of all 25 predictors. And the model achieves better goodness-of-fit compared with both the stepwise linear model and the NN. As shown in Table 4, a R-squared (Test) of 0.98 is obtained. The RMSE (Test) has been reduced to 3.36, and the MAE (Test) is only 2.55. It is worth noting that the MAE statistic (mean absolute error) is less sensitive to outliers compared to RMSE and MSE.

Table 4. Performance of three texture-based FN prediction models.

Model	RMSE (Valid)	R-squared (Valid)	RMSE (Test)	R-squared (Test)
Stepwise LR	4.853	0.960	4.995	0.956
Neural Network	5.318	0.952	4.796	0.959
Ensemble	3.549	0.978	3.361	0.980

As discussed in the synthetic simulations, a selection of small image GSD leads to high spatial resolution in the 3D photogrammetric pavement texture reconstruction.

Consequently, the measurement quality of texture roughness characteristics is also changed with the sampling rate. The comparison results of an asphalt pavement surface scanned at multiple image GSD in the synthetic environment suggest that a DEM developed using the proposed 3D reconstruction method with a GSD/resolution of 0.011 mm – 0.013 mm can provide reliable measurements of 23 distinct texture parameters, as long as the maximum imaging DoF is sufficient for feature capturing of extreme peaks and pits. However, the highest frequency of pavement microtexture is undefined. Therefore, the minimum spatial resolution in surface texture scan required for reliable prediction of pavement friction performance is still debated.

The original 3D reconstruction of 41 field texture photogrammetric scans will be down sampled at a scale of 0.5 multiple times. Next, texture DEMs of the down sampled point cloud data are developed, among which there are five distinct resolution levels: 0.022 mm, 0.044 mm, 0.088 mm, 0.176 mm, and 0.352 mm. The 22 areal texture parameters are measured using the down sampled texture DEMs. The original speed, pavement temperature, and macrotexture MPD are kept as they were not affected by the down sampling process. Finally, new observations with changed values in 22 texture predictors are collected.

The optimal regression ensemble model is used to predict FN using the six test groups of data observations. The prediction performance in terms of resolution changes is measured using the test RMSE and R-squared values. High R-squared values are observed in test results of all five samples, indicating that most of the pavement performance can be explained by pavement macrotexture. However, the RMSE between predicted FN using input of 25 predictors and the true FN provided by a LWST increases as the spatial resolution in texture 3D scan increases. Therefore, the texture asperities at micro-scales have contributed to the friction performance of a pavement surface. According to the increasing rates of test RMSE shown in Figure 17, it is suggested that the spatial resolution of a comprehensive 3D texture scan for friction prediction should be smaller than 0.1 mm at the least.

Figure 17. Relationship between the Model performance and spatial resolution in texture scans.

## 5 CONCLUSION

This paper develops a prototype of image-based pavement texture measurement for friction prediction in a non-contact manner. Towards the goal of data quality assurance, a synthetic environment is developed before field implementation. The

survey simulations evaluate sensitivities in texture measurements arising from different experimental designs and testing feature configurations. The minimum condition for optimized 3D surface reconstruction of pavement surface is discussed. Finally, a field experiment investigates the characterization of surface texture at different scales and their contribution to pavement friction performance.

## ACKNOWLEDGMENTS

The authors would like to thank Michael Sanders of INDOT for his input and technical guidance in the field road friction experiments.

**ABSTRACT:** For efficient maintenance and repair, 3D modeling of bridges for converting analytical models and visualizing deformation locations is being advanced. Instead of manually creating models from drawings and ledgers, automating model generation from point cloud data, capable of capturing as-is geometry quickly and widely, can improve efficiency. Generating 3D modeling of bridges from point cloud data requires segmenting each member, but dynamically setting thresholds for shape features and positional relationships is challenging due to point density and missing points. While deep learning can dynamically set thresholds, in the case of point cloud data, it is impractical to prepare sufficient training data, and the number of inputting points is inadequate for setting appropriate thresholds. Therefore, this research focuses on two aspects: most bridges consist of members with swept cross sections along longitudinal direction, and deep learning classification methods for 2D images are highly developed. The aim is to segment members based on deep learning on 2D cross-sectional point cloud data obtained by slicing along longitudinal direction. This reduces the number of inputting points and increases training data. Additionally, fine cross sections enable segmentation close to 3D. The multiple patterns of learning methods, training data processing, and procedures of segmentations are compared to identifying highly accurate segmentation methods.

**KEY WORDS:** Point cloud; Deep learning; Segmentation; Cross section; Steel truss bridge.

## 1 INTRODUCTION

A vast number of existing bridges are rapidly aging. Since it is not practical to rebuild all of them at the same time, strategic renewal through life cycle extension is required. To extend the life cycle of bridges, 3D models of bridges are created. These models can be converted numerical analysis models [1] and can visualize deformations [2]. However, in cases of old bridges, as-build drawings are often unavailable. In addition, conditions of bridges inevitably changed since its construction due to various factors. Therefore, it is necessary to construct 3D model based on dimensions data instead of relying on drawings, but manual measurement is time-consuming and prone to various human errors.

Therefore, a method to efficiently create 3D models from point cloud data, capable of capturing as-is 3D geometry as a set of points quickly and widely, has begun to attract attention. It can make a significant contribution to efficiency. Qin et al. [3] sliced the point cloud data of a PC box girder bridge vertically from the ground and used the density of each obtained point cloud as a threshold to divide the superstructure and substructure for Building Information Modeling (BIM). Schatz et al. [4] semi-automatically divided the point cloud data of a PC box girder bridge into substructure, girders, bearing pavement, drainage facilities, etc. based on template matching, and created an Industry Foundation Classes (IFC) model. The authors [5] performed Finite Element Method (FEM) modeling of a steel truss bridge by segmenting a fine section along a longitudinal direction and dividing the point cloud of the section based on Euclidean distance. The segmentation and component determination processes in these papers are a mixture of manual processing based on human visual judgment and automatic processing based on threshold values such as

shape features and positional relationships. In general, it is not easy to set the threshold dynamically in automatic processing because of the effects of point density, missing points, and other factors. In recent years, deep learning has attracted attention as a method for dynamically setting threshold values, and there are several cases where it has been applied to point cloud data processing [6, 7]. However, when targeting large-scale bridges with a wide variety of geometries, the classification is roughly divided into upper and lower structures, and the lack of training data and the number of input points are insufficient.

Therefore, this research focuses on the characteristics of bridges, which generally have many structures with swept cross sections of each member along a longitudinal direction, and the fact that classification methods for 2D images are relatively well-developed. In this research, point cloud data of 2D cross sections sliced along the longitudinal direction is used to classify members using deep learning. The number of input points can be reduced, and the number of training data can be increased by inputting point cloud data of cross sections. In addition, a finer cross-sectional view leads to an almost 3D segmentation. The optimal learning method, processing procedures, and multiple proposed patterns are compared and validated, and a highly accurate segmentation method is considered.

## 2 STRUCTURE OF THE MODEL

### 2.1 Literatures about segmentation by using deep learning

Deep learning-based image classification and segmentation often uses Convolutional Neural Network (CNN), which obtains features by convolving surrounding pixel features. If the number of pixels is reduced by convolution, the

segmentation results are restored to the original number of pixels by increasing the number of pixels based on the convolved features again. Typical models include U-Net [8], which performs domain segmentation at the pixel level; Feature Pyramid Networks (FPNs) [9] which combine high-resolution and low-resolution features to exploit multi-scale information; DeepLap v3+ [10] which applies convolution with different expansion rates in parallel. As an example of member segmentation of point cloud data of bridges, Saovana et al. [11] implemented segmentation of point cloud data by segmenting photographs of bridges from multiple viewpoints into members using U-Net and then projecting the results onto the point cloud data generated by Structure from Motion (SfM). The results are then projected onto the point cloud data generated by SfM to implement point cloud data segmentation.

On the other hand, point cloud data differs from images in that pixels are not arranged in a regular and continuous manner, the same shape and color data can be obtained even if the order of the points is changed, and the three-dimensional coordinates provide a large degree of freedom. To cope with these problems, a transformation matrix is obtained from the features and applied to control the posture, and MaxPooling is applied to eliminate the effect of reordering. The segmentation of point cloud data is similar to that of a CNN. Typical models include PointNet [12], PointNet++ [13], and Dynamic Graph CNN (DGCNN) [14]. PointNet does not perform convolution to obtain features for all input points. PointNet++, an advanced version of PointNet, reduces the number of points and obtains features from the points in the neighborhood of the point, which is similar to the convolution process. DGCNN also obtains features from neighboring points, but the number of points does not change at any layer.

## 2.2 Structure of the deep learning model in this research

Since the aforementioned PointNet++ [13] and DGCNN [14] are candidates for deep learning models in this research, the details of these model configurations are described in this section.

The model structure of PointNet++ is shown in Figure 1. First,  $c_1$  is obtained by randomly sampling  $n_1$  points from the cross-sectional point set  $c_0$ . Next, a point  $p_{c_1}$  in  $c_1$  is used to search  $k_1$  neighbor points within  $r_1$ , and then vectors from  $p_{c_1}$  to the neighbor points as feature values. The obtained feature values are convolved by using Conv1d, BatchNormize and Relu function. This process is repeated 4 times to obtain a set of cross-sectional points  $c_1$ ,  $c_2$ ,  $c_3$ , and  $c_4$  reduced by random sampling and the features associated with  $c_4$ . After that, 3 neighbor points from  $c_3$  to  $c_4$ , are detected and their feature values are convolved by using Conv1d, BatchNormize and Relu function. This process is repeated until the  $c_0$  features are updated, and finally they are convolved with the classified features and output as random variables by applying the Logsoftmax function.

The model structure of DGCNN is shown in Figure 2. In PointNet++, the neighbor points were obtained based on the position coordinates, but in DGCNN, the  $k_n$  neighbor points are obtained based on all the feature values changed by convolution, not limited to the position coordinates, and the vector from the reference point to the neighbor points and the original feature values are integrated and convolved. The

Figure 1. Model structure of PointNet++.

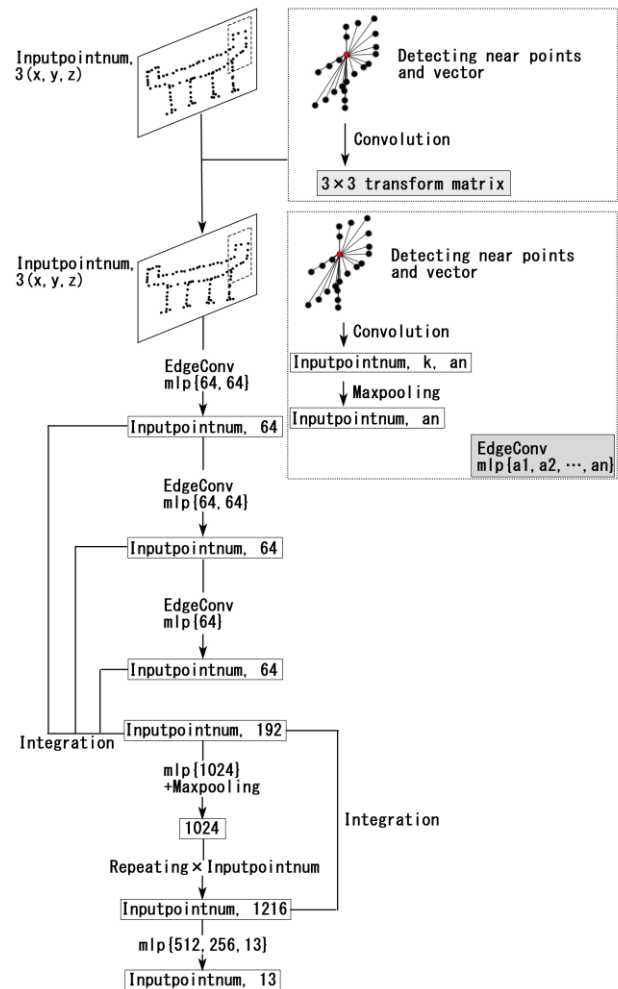

Figure 2. Model structure of DGCNN.

number of input points does not change in either layer, but the xyz coordinates also change due to convolution. After repeating this process 3 times, the feature values obtained in each step are integrated. Next, MaxPooling is applied, and replicated for the number of input points. Finally, after several convolutions, the number of classified features is obtained and output as a random variable by applying the Logsoftmax function. Although the paper [14] describes a categorical vector that provides labels for each input data as additional information, it is not used in this research.

### 3 PREPARING DATA FOR DEEP LEARNING

#### 3.1 Case study

A two-span continuous through-type truss bridge in Aichi Prefecture, Japan, is the case study. A photograph of the bridge is shown in Figure 3. The bridge length is 136.9m with a span length of 2@67.9m. A full width is 14.3 m with sidewalks on both sides. The effective width of the roadway is 7.5 m and that of the sidewalk is 2.0 m without widening. A slab thickness is 200 mm with a pavement of 80 mm thickness (roadway) and of 30 mm thickness (sidewalk). In addition, the bridge is straight and has a symmetric cross slope. A general bridge drawing is shown in Figure 4. The members to be segmented are "Upper chord", "Lower chord", "Brace (tensile)", "Brace (compression)", "Main girder", "Cross beam", "Upper lateral bracing", "Lower lateral bracing", "Sway bracing", "Gate", "Handrail", "Mounted components", and "Slab".

#### 3.2 Generating point cloud data from 3D CAD data

The 3D CAD data was manually created based on the drawings of the bridge shown in Section 3.1. Furthermore, for each 3D CAD component, point cloud data is obtained by randomly sampling points on its surface. In this case, noise and missing points are not generated. In addition, a uniform density (1 [pts./cm<sup>2</sup>] in this case) was set for all members in order to avoid extreme bias in density. It is also possible to assign to each point the normal vector of the plane from which it was generated as a parameter. The generated point cloud data is shown in Figure 5. Each point in the point cloud data has a label number that corresponds to only one of the 13 types of components mentioned above, and the colors of the points in the figure correspond to the labels of the components (Figure 6). The total number of points was 64,016,718.

#### 3.3 Creating cross sectional point clouds

The following shows the flow of the method for acquiring cross-sectional point clouds.

First, the line that corresponds to a longitudinal direction is determined. Since the bridge in this research has straight linear and the width is not widened, a line passing through the centroid of the point cloud data and having the direction of the first principal component vector obtained by principal component analysis is defined as the "longitudinal direction line".

Next, the point **p** is shifted pitch (0.1[m] in this case) from the starting point of the longitudinal direction line, and the plane that contains **p** and is perpendicular to the line along the longitudinal direction line is defined as the "cutting plane". Points within *d* (0.05 [m] in this case) of the cutting plane are detected, and these points are projected onto the cutting plane.

(a) Side view

(b) Bottom view

Figure 3. Pictures of the case study bridge.

(a) Front, Top, Bottom view

(b) Cross sectional diagram

Figure 4. General bridge diagram (Unit: mm).

This process is repeated until **p** reaches the end point (Figure 7).

From the point cloud data described in Section 3.2, 695 cross-sectional point clouds were created. Examples are shown in Figure 8. The position of the braces differs depending on the cross section, and those irregular cross sections such as cross beams and sway bracings, are also included.

#### 3.4 Normalization process for deep learning

When training a cross-sectional point cloud, the coordinate system is modified. Define a local coordinate system for the cutting plane as shown in Figure 7. The cutting plane is the xy-coordinate plane of the local coordinate system. The world

midpoint between min. and max  $x$ -coordinates and  $y$ -coordinates as shown in Figure 7. In order to prevent overlearning, the  $x$ -coordinate is flipped with respect to the  $y$ -axis with a probability of 50%.

## 4 IMPLEMENTATIONS AND DISCUSSIONS

### 4.1 Overview

In this chapter, several cases are implemented and discussed using training data described in Chapter 3 and test data obtained

from the actual steel truss bridge by the stationary laser scanner. The implementation environment is shown in Table 1, and the common parameters used for verifying multiple cases are listed in Table 2. The number of input points and the batch size must fit in the GPU's memory. If this limit is exceeded, computation is offloaded to the main memory, significantly increasing computation time. In addition, the batch size must be 2 or greater due to the use of BatchNormalize function as explained in Section 2.2. The number of training samples is 10,336, calculated by dividing the total number of points in the cross-sectional point cloud by the number of input points.

The implementation cases are organized in Table 3. During training, validation is included in each epoch. No fixed distinction is made between training and validation data; instead, 8,000 samples are randomly selected from the 10,336 available for each epoch. The Intersection over Union (IoU) for each member in the cases is shown in Figure 9. The values shown represent the results from the epoch in which the average IoU across all members was the highest. Computation times for each case are summarized in Table 4.

#### 4.2 Point cloud for using the implementation

In this section, the measured point cloud data of the actual bridge without member labels is mentioned. It is used for the test of the trained model. The point cloud data (1,065,353,413 points, Figure 10) measured with a stationary laser scanner Leica RTC360 (resolution: 3mm@10m, accuracy: 1.9mm@10m) from 27 locations on the underpass and road surface of one span of the bridge described in Section 3.1. 5,000 cross-sectional point clouds are created as the validation data by slicing at regular intervals (0.02 [m] in this case) along the longitudinal direction. Note that although this point cloud data contains color information, it is not used because there is no color information in the training data. Normals were obtained by calculating them with the Point Cloud Library [15], a point cloud data processing library. The normalization described in Section 3.4 is also applied to this cross-sectional point cloud.

#### 4.3 Comparing PointNet++ or DGCNN

First, the effectiveness of PointNet++ and DGCNN in segmenting point cloud data of cross sections sliced along the longitudinal direction is evaluated. The construction of model is shown in Figure 1 and Figure 2. As shown in the results of the application to the point cloud data presented in Section 4.2 (Figure 11 and Figure 12), PointNet++ was more accurate in the test. Although DGCNN resulted in a higher IoU and faster computation time during training, there were many places where other members were misidentified as the main girders in the test. PointNet++ was able to distinguish between two types of cross-sections of the braces with high accuracy, although in some cases the slabs were misidentified as the cross beams in areas where the data quality was low due to limitations of the measurement environment. This is likely due to the fact that DGCNN have over-trained the training data. In addition, it seems that PointNet++ is more versatile in handling 2D point cloud data with image-like features, as its behavior more closely resembles the convolution process used in image-based deep learning. For generality, PointNet++ is used in the subsequent validations, although it takes more time.

#### 4.4 Comparing sampling methods as input data

The number of input points is 6144, but the number of cross-sectional point clouds is approximately 50,000 to 100,000 points. Therefore, sampling is required. Here, two types of sampling "block partitioning" and "random sampling" are selected and compared the accuracy. For block partitioning, one point is randomly selected from the cross-sectional point cloud, from which points within a 5 m block around it are extracted and sampled so that the total number of points is 6144. In addition, the coordinates that origin is at the center of the block are calculated and added as new features. Random sampling was performed by randomly selecting 6144 points from the entire cross-sectional point cloud and  $x$  and  $y$  coordinates are adjusted so that a distance to the farthest point from the origin point is 1. As shown in the test results (Figure 13), block partitioning is able to detect the slabs without misidentifying them even in areas where the quality of the measurement data is low, but the accuracy of other members such as the braces and the cross beams is low.

#### 4.5 Comparing presence or absence of scale normalization

According to Section 4.4, since block partitioning without scale normalization has a higher detection rate of the slabs, the additional case without scale normalization with random sampling is implemented. As shown in the test results (Figure 14), the accuracy of the slab segmentation was improved, but the accuracy of the braces was significantly reduced. The second span, where segmentation accuracy is low, was not originally intended to be measured. However, it was partially captured during scanning of the adjacent first span. As a result, the point cloud data is of poor quality, with low density and many missing points. Although it is necessary to develop a learning model that can be applied to point cloud data of low measurement quality as a future challenge, this paper concludes that random sampling and scale normalization are effective for segmentation accuracy in high measurement quality areas.

#### 4.6 Comparing presence or absence of normal vector

In the previous explanations, only  $xyz$  coordinates were used for the input point cloud data, but the case with additional normal vector was also verified. As shown in the test results (Figure 15), the reason for the poor results in the case where normals were added is that, as shown in Figure 16, normals were generated even where the laser scanner would not have been irradiated if generated from 3DCAD, which may have caused a discrepancy between the training data and the test data. Although it is useful to develop a sampling tool that simulates a laser scanner, it is more effective to create a learning model that does not use normal vector, considering the efficiency of training data generation.

#### 4.7 Adjusting weights for loss calculation

The equation for the CrossEntropyLoss function is shown below:

$$Loss = \sum_{n=1}^N -w_{yn} x_{n,y_n} \quad (1)$$

The loss is calculated each member and they are sum up.  $N$  is the number of points and  $x_{n,y_n}$  is a random variable in the output data. In the previous cases,  $w_{yn}$  was set to 1 for all members, but in this case, it is adjusted for each member. This

Figure 10. The point cloud data measured with a stationary laser scanner

Figure 11. Result of case A: PointNet++.

parameter is used to prevent bias in the accuracy of the classification depending on the size of the member that is

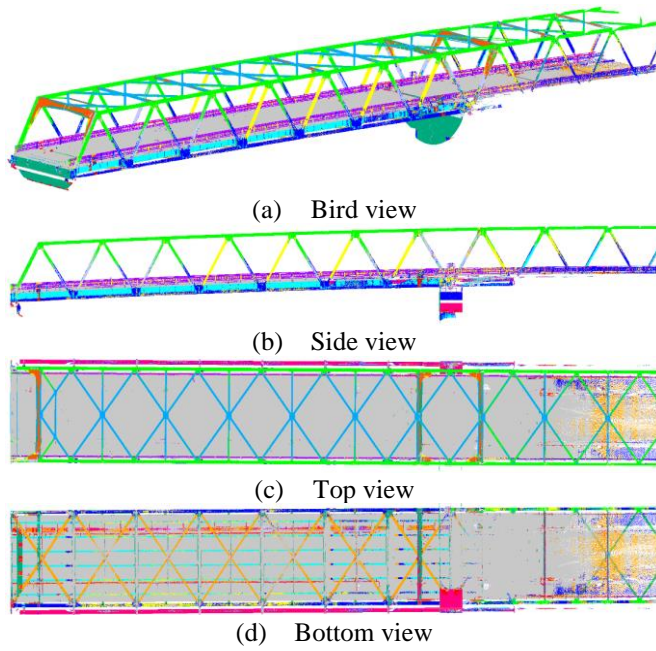

Figure 13. Result of case C: block partitioning.

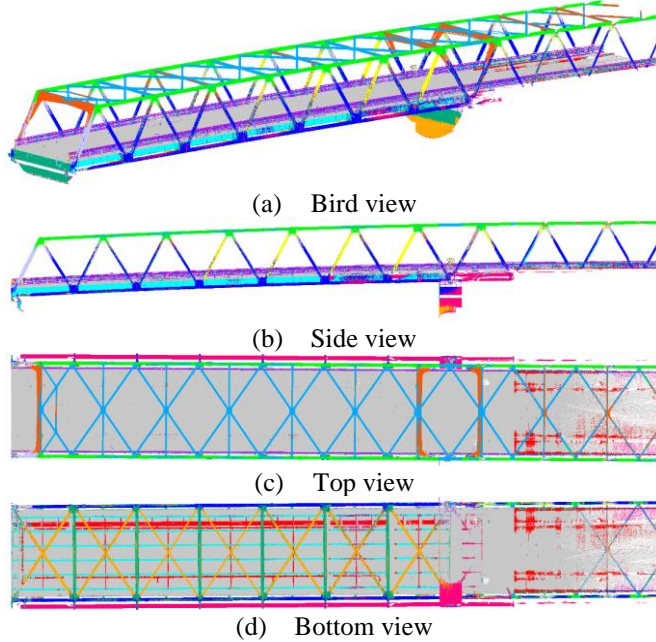

Figure 14. Result of case D: without scale normalization.

number of points. So, in this case,  $w_{yn}$  is set inversely proportional to the number of points in each member (Table 5). As shown in the test results (Figure 17), the outcomes were generally similar to the case in which all weights were set to 1. However, the segmentation accuracy for the braces was slightly lower. This is believed to be due to the increased weight assigned to members that appear in only a small number of cross-sectional point clouds, such as the gates and the sway bracings, which in turn reduces the accuracy for other members that appear in most cross-sectional point clouds. Therefore, it is more effective to set all weights to 1 without adjusting the weights between members.

## 5 CONCLUSION

In this research, as a method for segmenting point cloud data of bridges into members using deep learning, using point cloud data of 2D cross sections sliced along the longitudinal direction. Several patterns are proposed and compared for validation to identify a highly accurate segmentation method.

Through the implementation of several cases, it was confirmed that the following settings were effective when point cloud data obtained by pseudo-sampling the surface of a 3D

Table 5. The weights inversely proportional to points.

UC	1.76	MG	1.19	SW	2.99	SI	1.00

Figure 17. Result of case F: adjusting weights for loss.

model was used as training data and point cloud data obtained by measuring the same bridge with a laser scanner was used as test data:

- The learning model type PointNet++ is expected to be more versatile because of its higher segmentation accuracy of the test data.
- When the number of input points was reduced to about 5-10% of the total number of points, random sampling was more accurate and faster.
- To increase versatility, it was more effective to apply scale normalization at the time of training model input.
- Normal vectors can cause discrepancies between training data and test data depending on the calculation method, so care must be taken when generating them.
- Weight adjustments during the calculation of the loss function for each member did not have a significant effect.

As future work, training on multiple types of bridges (not limited to steel truss bridges) and performing segmentation across various bridge types is necessary, since the training and test data in this research are from the same bridge, although generated by different methods. In addition, since the bridges covered in this paper have straight liner and no width widening, it is desirable to conduct verification on bridges with curved liners or varying widths.

**ABSTRACT:** The mid-span closure segment assembly of a cable-stayed bridge after cantilever construction traditionally relies on using a total station to measure the longitudinal distances of key control points to determine the closure trimming length. This approach neglects the rotation of the cantilever section, reduces the inherently three-dimensional (3D) assembly problem to a one-dimensional (1D) longitudinal assembly. To overcome this limitation, this paper presents a 3D virtual pre-assembly method for the closure segment based on point clouds captured from a single station. An efficient and accurate two-stage registration method based on 2D image matching and 3D visibility simulation was developed to align incomplete measured point clouds with the design model. The estimated poses of the two cantilever ends were used for the virtual assembly of the closure segment. An optimization model for 5-DOF geometric information of the closure segment was established and calibrated using a particle swarm optimization. The proposed method was validated during the construction monitoring of a large-span railway cable-stayed bridge, demonstrating its reliability and practical effectiveness.

**KEY WORDS:** Virtual Assembly, Laser Scanning, Point Cloud Registration

## 1 INTRODUCTION

Cable-stayed bridge closure marks the moment when two independent cantilevers become a single, continuous load-carrying system. To achieve the desired stress redistribution and deck profile, engineers must monitor the closure joint during the 48 h immediately preceding installation, capturing temperature-induced movements and determining the match-cut length of the closure segment with millimetre-level precision. Traditional construction monitoring relies on total-station surveys of a handful of control points on each cantilever tip to estimate the longitudinal gap. Although well established, this point-wise procedure is labour-intensive, prone to human error, and often too slow for modern fast-track schedules. Terrestrial laser scanning (TLS), by contrast, can acquire a dense, full-field 3-D point cloud of the entire closure region in a single scan, providing sub-centimetre accuracy and a far more comprehensive geometric record.

Over the past decade, researchers have explored TLS-enabled “virtual pre-assembly” workflows in bridge construction, focusing on reducing geometric deviations and optimizing prefabricated component assembly. Zhou et al. [1] proposed the virtual trial assembly method for prefabricated steel components in scenarios like bridge construction. It integrates high-precision point cloud registration, reverse BIM construction, and finite element analysis to accurately predict geometric shapes and stress states in prefabricated components. Li et al. [2] developed an automatic modeling approach for creating as-built prefabricated component models from laser-scanned data, specifically for virtual trial assembly. Liu et al. [3] develops an automated virtual trial assembly framework for large and complex steel members, integrating terrestrial laser scanning and BIM to improve geometric accuracy, streamline assembly point extraction, and enable precise geometric quality inspection of bending and torsional deviations. Zhang et al. [4] introduced an automated virtual trial assembly framework for

large steel members with bolted connections, leveraging multiscale point cloud fusion to achieve submillimeter precision in feature extraction, registration, and assembly deviation analysis. Li et al. [5] proposed a virtual pre-assembly method utilizing 3D laser scanning technology to predict alignment of large-span segmental precast assembled concrete cable-stayed bridges under stress-free conditions, effectively shortening construction time, reducing complexity, and enhancing precision in the assembly process.

Despite the progress achieved in prior studies, significant challenges still remain. First, current fit-up calculations seldom account for the local downward deflection of the free cantilever tips under self-weight, thermal gradients, or wind loads, leading to non-vertical end faces at the time of measurement. Second, by collapsing millions of points into a few targets, valuable shape information is discarded. To address these gaps, this study introduces a 3D virtual-assembly method for cable-stayed-bridge closure that capitalises on high-resolution TLS. After all segments except the closure slab are erected, a TLS survey simultaneously captures the full geometry and relative pose of the two cantilever ends. A particle-swarm-optimisation-based virtual assembly routine then searches the point-cloud pair for the closure segment length and installation attitude that minimise global deck discontinuities. The method was validated during the closure of a cable-stayed bridge in Zhejiang Province, China, where it delivered rapid, centimetre-level predictions that aligned with field measurements. Ultimately, the goal is to leverage complete 3-D geometry and relative pose information to predict—before any on-site cutting—the optimal closure-segment length and pose, thereby streamlining cable-stayed bridge completion and enhancing construction quality control.

## 2 METHODOLOGIES

Traditional closure practice measures only the longitudinal gap between the two cantilever tips and match-cuts the segment vertically, reducing a fundamentally 3-D structural-assembly problem to a 1-D splice. Because this approach ignores the true pose of the cantilever end sections (rotations and offsets), it struggles to meet today's mm-level accuracy requirements.

To overcome these limitations, we develop a point-cloud-driven virtual pre-assembly workflow consisting of three core stages (Figure 1).

In the first stage, each cantilever tip is scanned in situ, yielding dense but incomplete point clouds that capture deck edges. A synthetic point cloud generated from the as-designed numerical model is then rigidly aligned to the measured data via an iterative closest-point procedure, producing a 3D transformation matrix that maps design space to the bridge's physical coordinate frame. This registration not only reconciles deviations due to construction tolerances but also embeds the design geometry in the same reference frame as the field measurements.

The second stage performs virtual pre-assembly. The meshed design models of the two cantilever tips are transformed with the previously obtained matrix and imported into a physics-aware simulation environment. A particle-swarm-optimization solver searches the six-degree-of-freedom space to minimize the surface misfit between opposing tips, rapidly converging to a sub-mm pose match. Because the algorithm explores both translational and rotational degrees of freedom concurrently, it reveals subtle misalignments that would otherwise remain undetected under one-dimensional gap measurements.

In the final stage, the optimized virtual pose is used to derive the manufacturing and installation parameters of the closure segment. After correcting for construction-stage temperature effects, the workflow outputs the optimal match-cut length, the required bevel angle of the end faces, and the spatial orientation necessary for installation. These data provide fabricators with precise cutting instructions and give field crews an accurate set-out for lifting and welding, thus shortening decision cycles while ensuring that closure is achieved within the stringent tolerances demanded by fast-track bridge construction.

Figure 1. Flowchart of the proposed method for closure segment cutting calculation.

## 3 FIELD TEST ON A CABLE-STAYED BRIDGE

The proposed virtual-assembly workflow was validated on a cable-stayed bridge crossing on the Fuchun River in Hangzhou,

Zhejiang Province, China. The structure features a mixed-height, H-shaped pylon arrangement and a hybrid steel–concrete deck. Span configuration proceeds from the west abutment as 62.395 m + 97 m + 300 m + 46 m + 30 m, giving an overall length of 535.395 m. The downstream pylon rises 141.5 m above foundation level, whereas the upstream pylon is 92 m high (see Figure 2).

The 300 m main span employs a composite section in which a U-shaped steel box girder is integrally connected to a cast-in-place concrete deck slab, yielding both bending stiffness and fatigue durability. Construction of this span followed the free-cantilever method: modular box-girder segments were symmetrically erected from each pylon, forming two outward-growing cantilevers. When the remaining gap diminished to less than a single segment, a closure unit was installed using the thermal-expansion technique to create a continuous load path. The segments immediately adjacent to the closure piece are labelled MG15 on the south-east cantilever and MD09 on the north-west cantilever. This full-scale construction scenario offered a realistic test bed for examining the accuracy and efficiency of the TLS-driven virtual pre-assembly method under field conditions.

Figure 2. Tested bridge for closure in construction

A RIEGL VZ-400i terrestrial laser scanner was deployed to acquire high-density point clouds of the opposing cantilever tips. The instrument offers a ranging window of 0.5 – 800 m and a single-shot accuracy of  $\pm 5$  mm; for this test the pulse-repetition frequency was set to 1.2 MHz, while the full 360° horizontal and 100° vertical fields of view were enabled. To maximize coverage of the local cross-section, the scanner was rigidly mounted 1.6 m above the deck on the outboard edge of segment MD09 and levelled with its optical axis parallel to the bridge centerline. From this vantage, a single sweep captured the entire end face of the MD09 tip together with the mating surface of segment MG15 across the closure gap, yielding a unified dataset that preserves both geometry and relative pose for subsequent virtual pre-assembly processing.

Figure 3 depicts a representative time step of the raw point-cloud data. Because each sweep originates from a single scanner station, the TLS captures only the outward-facing portions of the two cantilever tips; one tip is almost complete, whereas the opposite tip contains only a narrow chord of the full cross-section. To isolate the geometric cues most relevant for alignment, the cloud is first segmented by fitting a best-fit plane to the deck-edge points of each tip and then retaining the points within a narrow band around that plane. The result shown in Figure 4 is a pair of sparsely sampled, partially visible cross-sections that serve as registration targets.

Figure 3. Raw point cloud of the cable-stayed bridge captured with the TLS.

Figure 4. Filtered cantilever-tip cross-section extracted from the TLS data.

Iterative closest point (ICP) requires a reasonably accurate initial transform to avoid convergence to local minima. It is challenge to deal with the two targets share only limited overlap. To generate a robust starting estimate, the extracted cross-sections are orthogonally projected onto an image plane and converted to binary occupancy maps. A phase-correlation matcher is then applied to the two images, yielding translational shifts and in-plane rotations with sub-pixel precision; these parameters are back-projected into 3D space to construct the initial rigid-body transform.

Directly registering the measured cloud to the full design model is computationally inefficient and prone to bias because large portions of the as-designed surface are invisible in a single scan. We therefore employ a ray-casting routine to generate a virtual scan of the design model that mimics the scanner's actual position and field of view. The synthetic cloud retains only those facets that would be visible to the TLS under identical conditions, producing a down-sampled "design-congruent" dataset whose completeness closely matches that of the field measurement. ICP is then executed between the real and virtual point clouds, with the phase-correlation transform as its initialization. After registration, the measurements of control point distances were extracted from the TLS data and compared with those obtained from the total station. As shown in Figure 5, the distance errors for all 17 control points are within 10 mm.

Figure 5. Comparison of control point distance measurements at cantilever beam ends using total station and TLS.

Once the spatial poses of the two cantilever tips have been fixed, the search for the best installation strategy can be formulated as a stand-alone optimization problem. A closure

segment of ample stock length is first inserted between the tips in a nominal configuration that deliberately intersects both end faces. Because high-quality welding demands near-perfect geometric agreement at each splice plane, we evaluate every candidate pose by the overlap area—the common surface shared by the closure-segment end face and its mating cantilever section.

To automate the search, we couple the point-cloud pose information with the 3D CAD model of the closure segment and cast the task as a 5-DOF optimization: three translational components and two rotational angles around the local horizontal axes. The remaining rotation about the longitudinal axis is fixed to maintain deck camber continuity. A PSO scheme explores the 5-DOF space, beginning from a physically reasonable initial guess derived from the measured gap and the nominal bridge geometry. During each PSO iteration the algorithm updates the candidate pose, clips the closure segment to the planes of the two cantilever tips, and computes the resulting overlap areas. The fitness function is defined as the negative sum of these areas.

Convergence of the swarm yields the pose that maximizes simultaneous overlap at both interfaces. From the converged configuration the algorithm extracts two quantities required for fabrication and erection: (i) the match-cut length, obtained by measuring the distance between the optimally aligned splice planes, and (ii) the six-parameter installation pose, which prescribes the precise translation and orientation of the trimmed closure segment in the bridge's global coordinate frame. In this way, the virtual pre-assembly routine provides construction crews with a complete, data-driven specification for manufacturing and installing the closure element.

## 4 CONCLUSIONS

This study presented a point-cloud-driven, 3D virtual-assembly method for cable-stayed-bridge closure that resolves the intrinsic shortcomings of one-dimensional match-cutting practices. By combining high-precision TLS acquisition, rigid registration of design geometry, and a particle-swarm-optimized pose-matching procedure, the workflow delivers sub-mm estimates of the closure gap and end-face attitude. Field trials conducted on the 300 m main span of the cable-stayed bridge verified the method's effectiveness.

**ABSTRACT:** Terrestrial laser scanning (TLS) is commonly used to capture 3D point cloud data of the environment. In this article we demonstrate that TLS data can also be used to measure long-term and daily deformations of bridges. On one hand full dome laser scanning is used to determine the deformations of entire bridge pillars whereas scanning total stations are well suited to capture segments and profiles of bridge pillars. We highlight that an accurate point cloud registration and appropriate processing algorithms are crucial to reliably determine deformations in the millimeter range. The capabilities of our approach are demonstrated on two large highway bridges where the bending of bridge beams due to temperature changes and one side sun illumination are investigated.

**KEY WORDS:** Terrestrial laser scanning, bridge monitoring, structural health monitoring

## 1 INTRODUCTION

Many large highway bridges in Europe were built in the 1960s and 70s. While the lifetime of these bridges was designed to be up to 100 years, reality shows that lots of bridges do not meet this expectation. One of the reasons is the increased load due to the rapid increase of traffic volume within the last decades (Figure 1 [1]).

As the replacement of the respective structures will take several years, aging objects need to be kept in service in the meantime. To ensure safe operation during this period, monitoring measures are often taken to obtain crucial data for decision making, e.g. prioritize structural measures, restrict traffic or similar.

One way to gather reliable data of bridges is to capture geometric changes of the structures. A geometric change can either be induced by loading of the bridge, by changing environmental conditions or by damages. Deformations can be measured with traditional geodetic sensors such as Robotic Total Stations (RTS), where one or multiple discrete points are measured and the absolute coordinates are determined in 3 dimensions with high accuracy. Another possibility is to capture multiple point clouds with Terrestrial Laser Scanners (TLS) over time. The different point clouds can be compared to each other and deformations can be computed throughout the entire object.

With these kind of remote sensors, not only static deformations can be captured but also dynamic changes during the pass of a load over a bridge. Modern RTS can track individual prisms with 20 Hz [2] and many TLS can also be operated in profile mode. The Profile Laser Scanner (PLS), works just as an TLS, but the rotation of the standing axes is suppressed. Therefore, the profile is measured multiple times per second and the relative deformations can be captured dynamically in 2D [3]. When using an RTS dynamically, the instrument stays with observing just one prism at the time but can take angle and

distance measurements with up to 20 Hz and therefore capture the dynamic 3D deformation of this prism. A study about the performance of both of the methods as well as Profile Laser Scanners can be found in [2] and [4]. Additionally, some modern RTS have also a scanning feature included. These so called Multi Stations (MS) have a slower scanning speed than conventional TLS and therefore are not well suited for full dome scanning but well applicable for scanning defined sections of a scene, e.g. a tunnel face or bridge pillars.

Figure 1. Exemplary trend of good transportation at the Brenner pass for Railway and road transportation from 1960 – 2022, translated to English after [1].

While dynamic measurements are mostly done to assess the deformations of structures due to dynamic loading, e.g. overpass of a truck or other dynamic excitation, static measurements are used to either determine the deformations

during static load tests or to observe changes due to environmental effects such as temperature or structural changes. One important criterion for the comparison of multi-epoch data is the registration of point cloud data to obtain reliable results. This is challenging as bridges do not always offer stable areas to connect multiple scan epochs.

In this paper we demonstrate that it is possible to compare multiple scanning epochs that are taken over several days with a scanning total station, as well as point cloud data captured by a classical TLS with target-based registration over a longer period of time on a real-life bridge object. This work focuses on the deformation of the bridge pillars. The deformation of the bridge decks e.g. during load tests are discussed in [2], [4] and [5].

## 2 BRIDGE OBJECTS

### 2.1 Aurachbrücke

The Aurachbrücke, is the highest bridge of the A1 Westautobahn in Austria, located between Linz and Salzburg. The observed bridge is a temporary building for the time of the replacement of the old bridge. The bridge is a concrete box girder structure with 5 spans and a total length of 420 m.

### 2.2 Gschnitztalbrücke

Situated in Steinach am Brenner in Tyrol, the Gschnitztalbrücke (Figure 2) is part of the most frequented alp passage in Europe, the Brenner highway. The bridge consists of 7 spans with a total length of 560 m. The deck is curved with an arch radius of about 600 m. The steel-concrete composite bridge was built as a continuous beam in the 1960s for two lanes in each direction.

## 3 MEASUREMENT SETUP

### 3.1 Aurachbrücke

The measurements at the Aurachbrücke were taken within 48 hours from 06.09.2024 to 08.09.2024 with a Leica MS60 RTS with scanning function. Every 15 minutes the following sequence of measurements was performed: First multiple prisms were measured within 3 sets of combined angle and distance measurements. Afterwards, parts of the pillars 3 and 4 were scanned, see Figure 3. The scans included areas pointing along and across the bridge's direction. This setup creates the possibility to derive the 3D bending line of the pillars. In this paper, only pillar 3 is considered.

Additionally, IoT tilt sensors were mounted on top of every pillar for long term monitoring. The measurement rate of these sensors was also set to 15 minutes. Hence, three different data types (3D prism coordinates, point clouds, tilt readings) are available for comparison.

### 3.2 Gschnitztalbrücke

At the Gschnitztalbrücke in Tyrol, TLS and RTS measurements are taken epoch-wise 4 times a year. The measurements are taken at night from 10 p.m. onward to avoid truck traffic affecting the measurements. In Figure 2 the setup with the laser scanner in span 7 and the setup of the static total station is shown. A Leica RTC360 was used as TLS. This instrument performs full dome scans and hence the captured 3D point cloud includes the whole bottom side of the girders as well as the pillar and end abutment of the bridge. The measurement time is about two and a half minutes per scan for the highest scanning resolution (without pictures). The RTS takes

Figure 2. Overview at the Gschnitztalbrücke with span 6 & 7.

The measurement setup shows the prisms at the spans, as well as the RTS position and the TLS position.

In the 1980s an additional third lane was built in each direction due to upcoming traffic. One of the 7 spans is observed via TLS and RTS.

measurements of the prisms sequentially. Not only the prisms on the bridge are measured, but also control points are included in the measurements.

Figure 3. Setup of the RTS at Aurachbrücke.

The scanning areas can be seen in light yellow, as well as the measured prisms mounted at the pillars (red circles)

## 4 DATA ASSESSMENT

### 4.1 Aurachbrücke

The Leica MS60 is capable of not only measuring single points sequentially, but also capturing point clouds. Compared to a real TLS, the scanning speed is rather slow, but the advantage of the scanning total station is, that specific Regions of Interest (RoI) can be chosen which are scanned. This reduces the scanning time, and the definition of the scans can be used multiple times, so a time series of scans can be captured. All these measurements are triggered externally by a laptop using a python script and Leica GeoCom for communication. Combining the scanning function with classical point-wise measurements, the following data is available for every epoch (15 minutes):

- 3 sets of all prism points
- 1 scan of each of the two pillars 3 & 4

The scan resolution is about 5 cm in horizontal and 5 cm in vertical direction. To compute the deformations of the pillar, horizontal bands of 0.5m are cut from the point cloud along the Z-component for the longitudinal and cross section of the pillar. The points within each band are then averaged for every 5 cm in height and a moving average filter is applied to the remaining vector with a size of 0.2 m. To eliminate stationing errors, the bottom part (1 m) of the pillar is supposed to be fixed, so the mean value of the lowest meter is subtracted from every epoch. As reference epoch serves the first captured epoch on 06.09.2024 at around 20:00.

For the sequentially measured object points a free stationing is computed for every epoch and the polar points are derived from there. The coordinates can be transformed into along and across direction of the bridge to compare the results of both methods. A bending line can also be calculated, assuming, that the bending originates from the temperature differences of both sides of the pillar which is calculated by

$$\Delta T = \frac{d \cdot 2 \cdot B}{\alpha_T \cdot H^2} \quad (1)$$

whereas  $d$  is the displacement,  $B$  is described as the width of the pillar,  $\alpha_T$  is the temperature expansion coefficient of the material and  $H$  the height of the pillar. The biggest temperature differences are calculated to be less than 3 K.

Also, for the tilt sensor data, a theoretical bending line is calculated to be compared to the captured point cloud and pointwise prism data.

### 4.2 Gschnitztalbrücke

The scans at the Gschnitztalbrücke were taken at night with the Leica RTC360 while no heavy traffic was passing the bridge. Hence the load free state of the bridge was captured and only environmental effects are affecting the structure. The registration of the point clouds was target based, whereby four targets were setup and their positions determined via RTS measurements. Different approaches to register deformed point clouds are available and investigated by many researchers, one of the latest examples is stated in [6].

In this case the comparison of the point clouds of the pillars was done using a Cloud to Cloud (C2C) comparison directed to the surface plane of the examined pillar. So, it is possible to show the deformation of the pillar over the entire surface. Comparisons with the RTS data are not shown in this work but can be seen in [5]. Other state of the art methods of comparing point clouds are described in [7].

## 5 RESULTS

### 5.1 Aurachbrücke

The results of the 48 hours measurement reveal interesting significant temperature dependent deformations. The behavior of the pillar can be followed for every 15 minutes over 2 full days.

Figure 4. Deformation of Pillar 3 in longitudinal and cross direction for the epoch 07.09.2024 12:00 compared to the first captured epoch (06.09.2024 20:00)

In Figure 4, one epoch captured at noon is shown relatively to the first epoch measured in the evening. In longitudinal direction, the bending of the pillar is clearly visible and matches well the calculated theoretical bending line that is derived by the prism on top of the pillar.

Looking at the cross direction, the prism on the top as well as the scanning data do not show significant deformations at the height of the pillar. However, a strong deformation is noticeable at the height of about 10 to 15 m. The source of this anomaly was not clearly found, but it seems unlikely that the pillar deforms that way. Yet, looking at the waterfall Figures 5 and 6, it can be seen, that the apparent deformation occurs in both directions at the same time of day in the same height of the pillar. This indicates, that the deformations may occur due to a combination of angle of incident of the sun and the angle of impact of the laser distance measurement by the RTS.

Also, it can be seen in Figure 5 that the bending in longitudinal direction rises beginning on top of the pillar and grows with time over the day and peaks at about midday. After the deformation is widely dismantled, a short deformation in the other direction can be seen on the second day at around 16:00. But this coincides also with the described anomaly and therefore is not considered real deformation but rather a problem with the laser distance measurement due to the surface of the pillar.

The peak of bending on midday is explainable by the East-West alignment of the bridge which implies that the pillars are illuminated from one side before and from the other side after midday.

To further validate the quality of the point cloud acquisition, a band of 1 m is cut from the top of the point cloud and averaged for every epoch. This timeseries can be directly

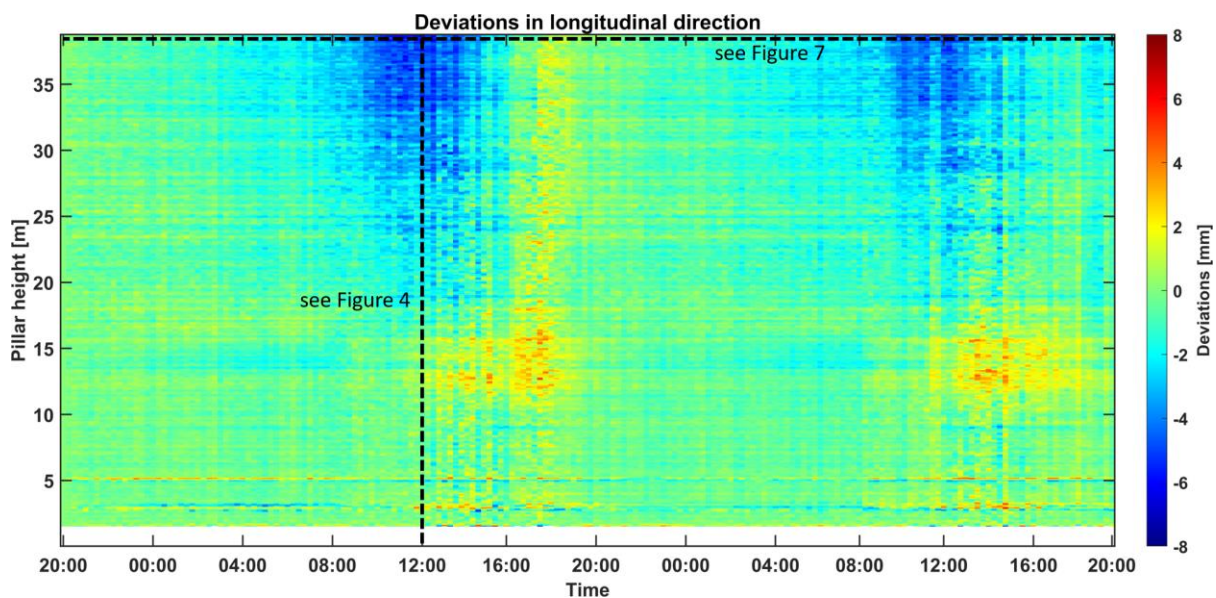

Figure 5. Deformations of pillar 3 in length direction of all measured epochs.

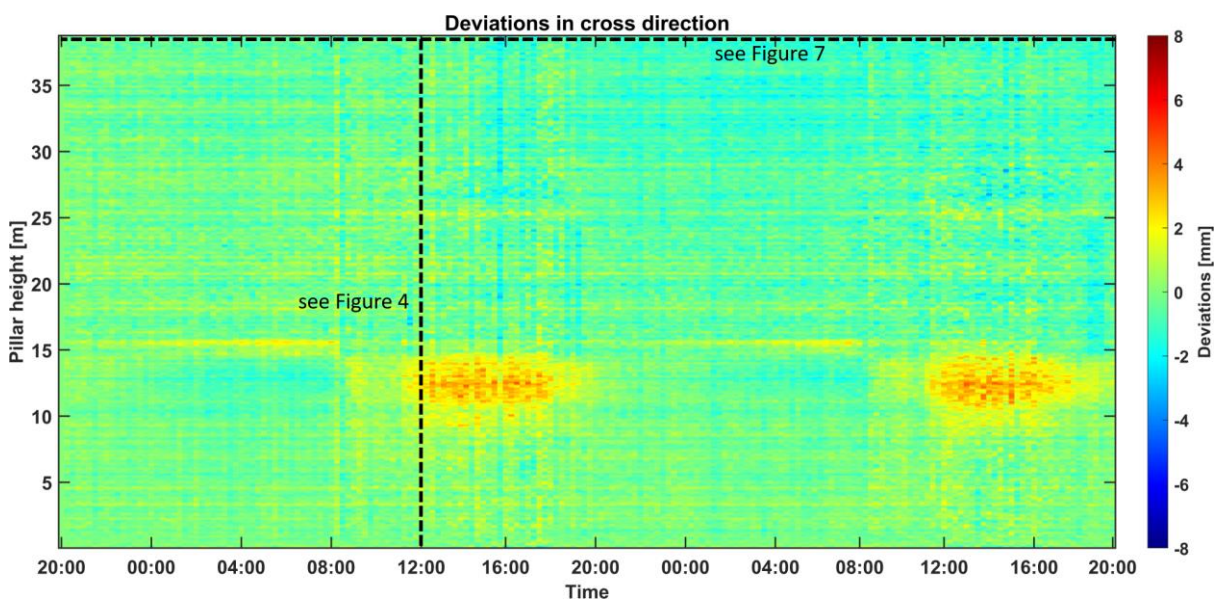

Figure 6. Deformations of pillar 3 in cross direction of all measured epochs.

compared with the time series of the prism on top and bottom of the pillar, but also with the calculated displacement by the tilt sensor data assuming a temperature induced bending. These results for both, longitudinal and cross direction can be seen together with the temperature and global radiation during the experiment in Figure 7. The measurement of global radiation is disturbed by the bridge's shadow that is casted onto the radiation sensor from 08:30 to 10:30 for both days. The missing parts are interpolated in Figure 7 (bottom).

The timeline of the prism at the bottom of the pillar shows deformations of less than 0.5 mm in both directions, which could be assumed as stable. The prism on top of the pillar shows a deformation over the day up to 6 mm with its minima at 12:00 at midday. The same deformation with small variations is also captured by the tilt sensor in longitudinal direction. In cross direction, the tilt sensor obviously captures deformations that are not recorded by any other sensor and may be caused by internal temperature dependent effects of the sensor itself but needs further investigation.

The calculated deformation of the point cloud data shows a higher noise than the other sensors in both directions. Nevertheless, the deformation derived from TLS fits well with the measured deformations using the RTS and the prism.

In cross direction, no clear diurnal variation can be seen, except for the tilt sensor. As the pillar is significantly wider in cross direction than in longitudinal direction, this seems to be plausible. Also, no force due to bridge expansion can act onto the pillar in cross direction, whereas the fixed bearing at the pillar may cause additional longitudinal deformations.

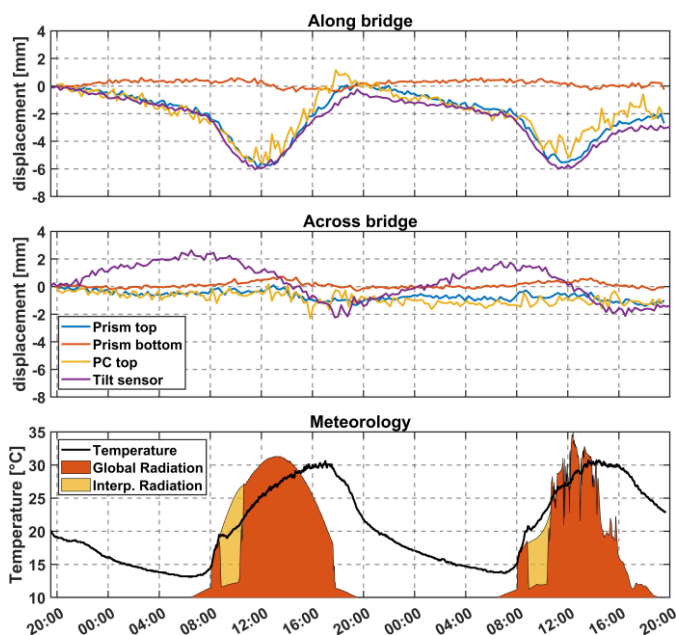

Figure 7. Deformation of the top part of the point cloud (PC), the prism on top and bottom and calculated deformation of tilt sensor on top in length direction (top figure), cross direction (central figure), and the temperature and global radiation during the experiment, while shadow is casted onto the sensor the global radiation is interpolated (bottom figure)

## 5.2 Gschnitztalbrücke

At the Gschnitztalbrücke multiple measurement epochs were taken, and two of them are shown here. While the comparison of pillar deformations at the Aurachbrücke was motivated by the behavior of the pillar due to one sided sun illumination over a rather short time and high measurement frequency, the concern at the Gschnitztalbrücke is the thermal expansion of the bridge deck and transfer of this deformation to the pillars. Usually the bearings between pillar and girder should absorb this deformation, but as long-term tilt measurements indicated, the bearings do not take the full deformation that is expected by thermal expansion.

In Figure 8, the deformations in plane direction of the pillar can be seen for the spring (2023/05) and summer (2023/08) epochs. The temperature difference between the epochs was only 1°C. Assuming a free thermal deformation of the bridge, and the length of 210 m to the zero point of thermal expansion, the deformation of the girder should sum up to 2.5 mm at the position of the pillar. Figure 8 shows deformations of up to 10 mm and therefore rather bigger deformations than expected.

Looking at the second epoch that is examined in Figure 9, the measured deformations are way bigger with up to 25 mm. The temperature difference on the other hand is 7°C compared to the reference epoch which results in a theoretical deformation of 17.5 mm. So, also in the second epoch, the deformation is way bigger than expected. The shape of deformation can also be seen in the figure and leads from the bottom left to the top right.

Figure 8. C2C comparison of pillar 6 seen from the end abutment below span 7 of reference epoch 2023/05 and the following epoch of 2023/08

Figure 9. C2C comparison of pillar 6 seen from the end abutment below span 7 of reference epoch 2023/05 and epoch of 2023/11

While both epochs overshoot the expected deformation, the differences of the epoch can also be considered. The temperature difference is 6°C, and therefore a deformation of about 15 mm is expected. Taking the maximum values, which occur on top of the pillar, of 10 mm of the first epoch and 25 mm of the second epoch into account, the relative deformation adds up to 15 mm which is exactly the expected value between the epochs. The offset to the reference epoch has to be investigated further on as its source cannot be determined yet.

The results of the Gschnitztalbrücke show the potential of gathering valid data of the behavior of the structure and verifying the idea of nonconforming bearing transmission over a long period of time.

## 6 CONCLUSIONS & OUTLOOK

Conventional geodetic monitoring of bridges delivers deformation data only at a few distinct points. With modern laser scanners entire bridge decks and pillars can be observed and a tilting of a pillar can be well distinguished from bending.

The required point clouds can either be captured with full dome laser scanners or scanning total stations. Depending on the given situation the right type of instrument has to be chosen. Although a full dome laser scanner is much faster than a total station, the distance measurement noise is usually higher. Measurements to individual prisms with an RTS still deliver highest accuracy, see Table 1 and true 3D displacements [8].

Table 1. Performance of RTS measurements on prisms [9] and scanning of TLS RTC360 [10]

Instrument	Angle accuracy	Distance Accuracy
MS60 prism measurement	1"	1 mm + 1.5ppm
RTC360	18"	1 mm + 10 ppm

Furthermore, a scanning total station can register point clouds with a high accuracy by using RTS setup functionalities like free stationing.

Overall both techniques help to gain a better understanding of the overall behavior of large civil structures without the need to physically access the measurement location to install sensors on the structure.

## ACKNOWLEDGMENTS

We want to acknowledge the support of the Austrian Highway Agency (ASFINAG), for the possibility of performing a load test and taking measurement at their bridges.

**ABSTRACT:** This study proposes a novel non-contact electromagnetic (EM) sensing system tailored to detect magnetic flux density changes associated with prestressed tendons embedded in concrete structures. The research emphasizes the optimization of sensor head geometry and coil configurations, including single, multi-solenoid, and Halbach array arrangements, to enhance external magnetic field detection at distances representative of real structural applications. Analytical formulations based on closed-form magnetic field equations were validated through finite element analysis (FEA) using ANSYS Maxwell. Results confirm that concentric Halbach-arrayed multi-solenoids outperform conventional configurations in delivering high-density magnetic fields beyond structural surfaces, particularly at target distances up to 30 cm. The verified modeling framework supports further development toward practical integration into structural health monitoring (SHM) systems.

**KEY WORDS:** External Magnetization; Tensile Force Estimation; Magnetic Sensor; Simulation;

## 1 INTRODUCTION

The long-term structural integrity of prestressed concrete (PSC) systems relies heavily on the performance and health of internal tendons, which bear the majority of tensile stresses in such structures. Over time, factors such as corrosion, overloading, or construction defects can compromise the tendon condition, potentially leading to severe degradation or even catastrophic failure of bridges, buildings, or other critical infrastructure. Accurate and efficient detection of tendon degradation is thus essential for ensuring public safety, extending structural service life, and reducing maintenance costs.

Conventional non-destructive testing (NDT) methods—such as ground-penetrating radar, ultrasonic testing, and magnetic flux leakage (MFL)—have shown limitations in terms of resolution, access requirements, or signal penetration through dense concrete media. Many existing approaches require contact or partial exposure of the internal tendon system, making them invasive, time-consuming, and impractical for routine inspection in large-scale infrastructure. In particular, methods that rely on internal access or cutting into protective sheaths can inadvertently introduce new vulnerabilities into the structure or disrupt service operations [1][2].

To overcome these limitations, recent research has shifted toward the development of non-contact electromagnetic (EM) sensing technologies capable of detecting magnetic field variations induced by internal steel tendons through external measurements. These techniques leverage the principle that magnetization induced in ferromagnetic tendons (such as carbon steel wires) generates measurable magnetic flux that extends beyond the concrete surface. However, accurately detecting and analyzing such flux from the outside remains challenging, especially at distances exceeding several centimeters from the embedded tendon.

This study proposes a new design and modeling approach for an external, non-contact EM sensor system specifically engineered to detect magnetic flux leakage fields generated by

prestressed tendons embedded in concrete. Central to this investigation is the optimization of the sensor head geometry, solenoid coil configuration, and magnetization arrangement to maximize field sensitivity and directional control. Theoretical modeling is performed using closed-form solutions based on vector potentials and elliptic integrals, while simulation validation is conducted through finite element analysis (FEA) using ANSYS Maxwell [3].

## 2 DERIVATION OF EXTERNAL MAGNETIC FIELD FOR NON-CONTACT EM SENSOR DESIGN FOR EXTERNAL SECTIONS

### 2.1 External Magnetization Trends by Sensor Head Geometry

Sensor head designs with varying top diameters (0.3 mm to 50 mm) were modeled in ANSYS Maxwell. The diameter of the upper surface was changed from 0.3 to 50 mm and finite element analysis was performed using ANSYS Maxwell software.

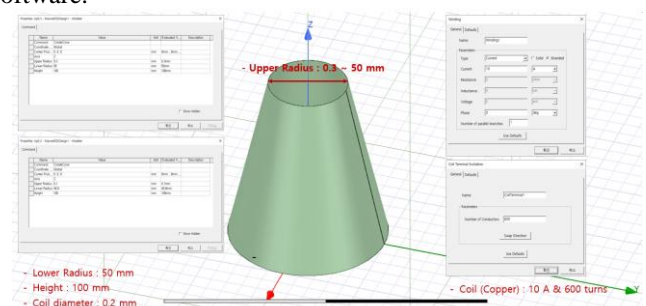

Figure 1. Modeling of sensor head

Figure 2. Magnetization according to the shape of head

As the upper radius of the cylindrical sensor increases, the magnetic field concentration effect at the upper part decreases, but the magnetic field dispersion effect into the external space increases.

A finite element analysis was performed on the space of 300 mm above and below the sensor head, and a graph of external magnetization by distance was obtained.

Figure 3. External magnetization according to distance by sensor head type

## 2.2 Generating an external magnetic field using multiple solenoids

The magnetization trend at heights of 10 cm, 20 cm, and 30 cm outside the solenoid was analyzed by changing the diameter of the solenoid (100 mm, 150 mm, and 300 mm) in the same area along the x-axis and y-axis.

Figure 4. Magnetization degree at heights of 10 cm, 20 cm, and 30 cm for each solenoid diameter

In order to determine the optimal solenoid arrangement with the strongest magnetic flux density in the same area, various coil arrangements were analyzed. As a result, it was confirmed that the arrangement of three concentric circles showed the strongest magnetic flux density at a position of 30 cm.

Figure 5. Magnetization degree at heights of 10 cm, 20 cm, and 30 cm for a solenoid arrangement with concentric circles

## 3 CONCLUSION

This study presented a comprehensive approach for designing, modeling, and validating a non-contact electromagnetic (EM) sensor system for external magnetic field detection, aimed at assessing the integrity of prestressed tendons embedded in concrete structures. Through the combination of theoretical modeling and finite element analysis (FEA), the work systematically explored the influence of sensor head geometry, solenoid arrangement, and coil dimensions on the resulting external magnetization performance.

In the early stages, parametric simulations were conducted to evaluate how varying the sensor head's upper surface diameter affects magnetic field distribution. The results revealed a trade-off between field concentration at the sensor surface and its dispersion into external space, and consequently, a cylindrical head with identical top and bottom diameters was selected as the optimal geometry for external flux detection.

Further investigation into solenoid coil diameter demonstrated that larger diameters yield significantly higher external flux densities. In particular, concentric arrangements of solenoids with increasing diameters (100 mm, 200 mm, and 300 mm) achieved approximately double the magnetization at a 30 cm height compared to a single solenoid of equivalent maximum diameter. These results support the use of concentric, multi-sized solenoid configurations for enhanced long-range sensing. Overall, the study has successfully established a robust design methodology for non-contact EM sensing tailored to the constraints of structural health monitoring in concrete infrastructures. The integration of analytical theory with numerical simulation provides a solid foundation for practical implementation. Future work will focus on experimental prototyping, performance evaluation in real structural environments, and integration with data acquisition and diagnostic systems to enable autonomous, continuous health monitoring of critical infrastructure components.

**ABSTRACT:** Ground Penetrating Radar (GPR) is commonly used for internal inspection of concrete structures. However, the fixed design parameters of commercial GPR limit adaptability for specific inspection conditions and integration with emerging technologies. This study presents the development of a Stepped-Frequency Continuous Wave (SFCW) radar for concrete structure assessment, based on numerical simulations and experimental validation. Parametric analysis was performed to evaluate the influence of frequency bandwidth, antenna spacing, synthetic aperture length, and beamwidth on imaging performance, particularly in detecting embedded reinforcing bars. B-scan data were generated and processed using Delay and Sum Algorithm (DSA) for an image focusing, and image resolution was evaluated in both azimuth and range directions. Based on the simulation results, an SFCW radar prototype was built, and its performance was assessed through tests on reinforced concrete specimens. The experimental results confirmed the system's capability to detect internal targets. The findings suggest that the proposed radar system offers improved flexibility and adaptability for concrete inspection compared to conventional commercial GPR.

**KEY WORDS:** Nondestructive Estimation; SFCW Radar; GPR; Image Focusing; Concrete Structure Inspection.

## 1 INTRODUCTION

In recent decades, the deterioration of civil infrastructure has become a growing issue in many countries. In addition, extreme climate events have introduced loading and environmental conditions that were not considered during the original design and construction phases. Under such conditions, accurate structural condition assessment and maintenance technologies are essential. For reinforced concrete structures, identifying internal features such as voids and rebar structure is necessary for reliable performance evaluation. Currently, Ground Penetrating Radar (GPR) is widely used for internal inspection of concrete structures [1, 2, 3, 4, 5]

GPR can be categorized into impulse-type and stepped-frequency continuous wave (SFCW) type depending on the signal transmission method [1]. Impulse-type GPR transmits short-duration electromagnetic pulses, while SFCW GPR transmits continuous waves by sweeping the frequency in discrete steps. SFCW has advantages in terms of signal-to-noise ratio and penetration depth [6], and is also used for concrete inspection applications [7, 8, 9, 10]

The image quality of GPR data depends on various radar design parameters such as waveform, frequency bandwidth, antenna characteristics, and scanning distance (synthetic aperture). These parameters affect the azimuth (scan direction) and range (depth direction) resolution and the overall imaging performance [6, 11]. However, most commercial GPRs have fixed configurations in terms of frequency range, antenna spacing, and polarization, which limits the ability to optimize inspections for specific applications. Additionally, integrating GPR with technologies such as drones or multi-channel antenna arrays is restricted. Therefore, it is necessary to develop a customizable radar platform for concrete inspection.

This study develops an SFCW radar for internal imaging of concrete structures through numerical simulations and experimental validation. The effects of key design parameters - frequency bandwidth, antenna spacing, synthetic aperture length, and beamwidth - on imaging quality were analyzed using simulation. Based on the results, a SFCW radar system was constructed and its performance was evaluated through experimental tests on reinforced concrete specimens.

## 2 DESIGN OF SFCW RADAR FOR CONCRETE SCAN

### 2.1 SFCW Radar

An SFCW radar transmits continuous waves while incrementally increasing the frequency from a minimum frequency ( $f_{min}$ ) to a maximum frequency ( $f_{max}$ ) at fixed intervals  $\Delta f$ , as expressed in Equation (1) [6]:

$$s_{tx,i}(t) = A_i \cos(2\pi f_i t + \phi_i) \quad (1)$$

Here,  $s_{tx,i}(t)$ ,  $f_i$ ,  $A_i$ , and  $\phi_i$  represent the  $i$ -th transmitted wave, its frequency, amplitude, and phase, respectively, and  $t$  is time. The received signal is a delayed version of the transmitted signal, with a round-trip delay ( $\tau$ ) due to the wave propagating to and from the target, as shown in Equation (2):

$$s_{rx,i}(t) = B_i \cos(2\pi f_i(t - \tau) + \phi_i) \quad (2)$$

In this equation,  $s_{rx,i}(t)$  is the received signal corresponding to the  $i$ -th transmission (A-scan),  $B_i$  is the attenuated amplitude. Due to spherical spreading and material attenuation,  $B_i$  is typically proportional to  $(\Delta t/\tau)^2$ .  $\Delta t$  is the time step between A-scans. The radar module demodulates the received signal into a baseband signal in frequency domain as in Equation (3):

$$S_{f,i} = (\Delta t/\tau)^2 C_i \exp(-j2\pi f_i \tau) \quad (3)$$

Here,  $C_i$  is a coefficient related to the amplitude and assumed to be 1. The time domain response is then obtained by applying the inverse Fourier transform to the frequency domain signal:

$$s_{t,m} = \mathcal{FFT}(S_f)_m \quad (4)$$

where  $m$  denotes the scan position. Performing this calculation across all scan positions yields the B-scan data.

## 2.2 GPR Image Focusing

To obtain focused images, image processing is applied to the acquired B-scan data. In this study, the Delay and Sum Algorithm (DSA) was used for image focusing [12]. The focused image  $g(x_i, z_j)$  is calculated as:

$$g(x_i, z_j) = \frac{1}{M} \sum_{m \in C_x} s_{t,m}(\tau)$$

where  $(x_i, z_i)$  denotes the azimuth and range coordinates of an image pixel,  $m$  is the number of A-scan positions,  $C_x$  is the set of A-scan positions.

To analyze the design parameters of SFCW radar for concrete inspection, a simulation was performed as illustrated in Figure 1. Two reinforcing bars were embedded 50 mm deep in concrete with a center-to-center spacing of 50 mm. This spacing was chosen based on the maximum aggregate size and typical cover thickness. The relative permittivity of concrete was assumed to be 10 [13], and the rebars were modeled as point targets.

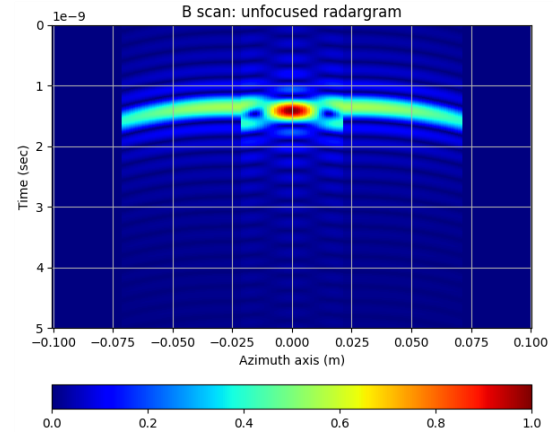

Figure 1. Numerical simulation model (unit: mm)

The frequency bandwidth used in the simulation was set to 1–5 GHz, based on typical GPR configurations for concrete inspection [7]. The transmitting and receiving antennas were placed on the surface of the concrete with a defined spacing, and moved horizontally with 1 mm step intervals to simulate scanning. The antenna was assumed to have a beamwidth ( $\theta$ ), and signals outside this angle were ignored for simplicity.

Figure 2(a) shows a representative B-scan image generated through the simulation ( $d_{ant} = 80$  mm,  $\theta = 120^\circ$ ). The amplitude values were normalized to a range of 0 to 1. The time interval was set to 5 ps, and the total time window was determined to be 20 ns based on the 50 MHz frequency step. Only the reflections from the rebars were considered, and surface reflections and direct waves were excluded, assuming that background removal would eliminate these components [14]. Background removal was performed by averaging the B-

scan data along the scan direction and subtracting it from the original signal.

Figure 2(b) shows the focused image obtained by applying DSA to the B-scan in Figure 2(a), also normalized from 0 to 1. The image shows a strong reflection at the rebar locations, with decreasing amplitude as the distance from the rebar increases, indicating that the imaging and focusing were successful.

Figure 2. Simulation results

Figure 3 shows the reflection amplitude in dB scale along a cross-section including the rebars, and the  $-3$  dB resolution was measured in both azimuth and range directions [15].

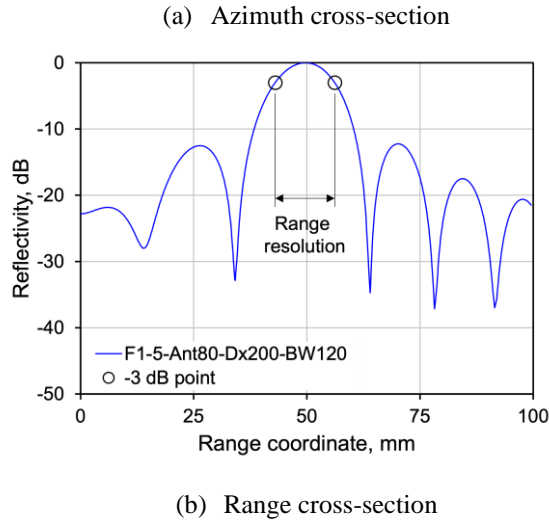

Figure 3. Distribution of reflectivity at rebar cross section

### 2.3 SFCW Radar Design Parameters

Based on the numerical simulations, several design parameters for SFCW radar in concrete scanning were considered. First, wide frequency bandwidth is required, and higher frequency components are preferred unless significantly attenuated. Vivaldi antennas, commonly used in wideband applications, can be applied [16]. However, electromagnetic attenuation in concrete increases with frequency [17], so optimal bandwidth selection should consider this trade-off.

Second, a smaller antenna spacing improves resolution, but mutual coupling effects must be considered. The simulation did not account for these effects, but in practice, closely spaced antennas may interfere with each other's radiation patterns and impedance [18,19]. Therefore, antenna spacing should be minimized without causing mutual coupling.

## 3 SFCW RADAR DEVELOPMENT AND VALIDATION

### 3.1 Radar Configuration

A vector network analyzer (VNA) is a device used to evaluate the frequency domain performance of RF components by sweeping a wide frequency range. When combined with appropriate antennas, it can function as an SFCW radar. In this study, the UVNA-63, the educational VNA by Mini-Circuits, was used as the SFCW radar module (Figure 4).

Figure 4. UVNA-63 (<https://www.minicircuits.com>)

The device provides a maximum output power of 0 dBm and operates in the frequency range from 0.1 to 6 GHz, which covers the frequency range of typical commercial GPRs [8, 9, 10]. The maximum receive input level is 10 dBm.

For transmission and reception, a wideband Vivaldi antenna (113 × 150 mm) was used (<https://www.craeca.com/antenna>).

Figure 5. Preliminary test for antenna spacing

As shown in Figure 5, the antenna was mounted on a 2D motorized scanning frame that enables C-scan acquisition. The horizontal scan range was set to 1150 mm to secure a sufficient synthetic aperture length. This configuration ensures that concrete members located 100 mm away can be scanned up to approximately 1.2 m in depth. The antennas were oriented so that the scan direction aligned with the H-plane, which typically has a wider beamwidth. The antenna used in this study had a reduced beamwidth at higher frequencies, indicating the need for further development of antennas that maintain beamwidth across the full frequency range.

A preliminary experiment was conducted to determine the appropriate antenna spacing using two D16 rebars (SD400 grade) placed 40 mm apart in air, as shown in Figure 5. The antennas were spaced at 9, 50, and 88 mm during horizontal B-scan. The rebars were positioned 165 mm away from the antenna tips and fixed using Styrofoam, which has a relative permittivity of approximately 1.04 [20], making it nearly equivalent to air and minimally affecting the measurement. Electromagnetic absorbers were placed around the rebars to minimize environmental reflections.

The transmission bandwidth was set to 1–5 GHz based on antenna performance, with 50 MHz frequency steps. The transmit power was 0 dBm. A-scan data were acquired at 2 mm intervals over a scan distance of 600 mm. To enhance high-frequency components in the measured data, an amplification process was applied as defined in Equation (6), where R was empirically set to 1000:

$$S_{\text{enhanced},i} = S_{f,i} \exp \left[ \ln R \frac{f_i - f_{\min}}{f_{\max} - f_{\min}} \right] \quad (6)$$

Here,  $S_{\text{enhanced},i}$  is the amplified signal at frequency  $f_i$ , and  $f_{\min}$  and  $f_{\max}$  are the minimum and maximum frequencies, respectively.

The B-scan data were processed with background removal and DSA for image focusing. Figure 6 shows the experimental results. The white circles indicate the positions of the rebars.

Unlike the simulation results, lower resolution was observed when the antennas were placed too close together. At 9 mm spacing, the two rebars could not be distinguished. When the spacing was increased to 88 mm, the rebars were clearly resolved. This result indicates that at least 88 mm of antenna separation is required to suppress mutual coupling effects.

Figure 6. Preliminary test results

### 3.2 Validation Test

To validate the developed SFCW radar, an experiment was conducted using a reinforced concrete specimen. Figure 7 shows the geometry of the specimen. The concrete block measured  $160 \times 200 \times 260$  mm and included six D16 rebars (SD400) embedded in two layers. The vertical spacing between the two layers was 50 mm, and the horizontal spacing between rebars in the same layer was 50 mm and 70 mm. The compressive strength of the concrete was 30 MPa, a typical value for structural applications. The antenna spacing was set

to 100 mm to avoid mutual coupling effects. The scan length was 1000 mm with 2 mm measurement intervals. The standoff distance between the antenna and the specimen surface was 100 mm. The same high-frequency amplification process used in the preliminary test was applied to the acquired data.

Figure 7. Concrete test specimen (unit: mm)

Figure 8. Verification test setup

Figure 8 shows the experimental setup. To minimize environmental interference, only the concrete specimen was placed in the direction of wave propagation. The scan was performed on the surface with a concrete cover of 42 mm. The transmit frequency range was set from 0.1 to 6 GHz in 50 MHz steps, and the transmit power was 0 dBm.

The acquired B-scan data were processed using background removal and DSA. Figure 9(a) shows the time-domain B-scan after high-frequency amplification and background removal. A strong surface reflection was observed due to the large area of the concrete surface, exceeding the strength of the rebar reflections. DSA was applied with a relative permittivity of 7 for concrete. Refraction at the air-concrete interface was accounted for using Snell's law. Figure 9(b) shows the focused image in dB scale for the scan area (260 mm in azimuth, 160 mm in range). Strong reflections were observed at the positions of the front-layer rebars, and three distinct rebar signatures were clearly identified. The positions in both range and azimuth directions matched the actual locations of the rebars. These results confirm that the developed radar can detect and localize rebars located 50 mm deep in concrete.

However, the rebars in the rear layer were not detected in the focused image. This is attributed to signal attenuation during propagation and interference from surface and front-layer reflections. Since the rear-layer signal becomes weaker and is partially masked by stronger reflections, detection is more difficult. To address this, future research is required on signal compensation techniques, clutter removal methods, and

antenna design that enhances high-frequency transmission for deeper penetration.

(a) B-scan data

(b) Focused image

Figure 9. Verification of test result

## 4 CONCLUSION

This study conducted numerical simulations and experimental tests to develop an SFCW radar system for internal inspection of concrete structures. The following conclusions were drawn:

1. To analyze the effects of SFCW radar design parameters on image quality, simulations and image focusing were performed using rebar-embedded concrete models. The results identified five key design parameters for an SFCW radar in concrete scanning:

(1) A wide frequency bandwidth is required, and higher frequency components should be used as long as attenuation is acceptable.

(2) The antenna spacing should be minimized without introducing mutual coupling effects.

(3) The synthetic aperture length should exceed the expected rebar spacing and target area.

(4) A larger antenna beamwidth improves resolution; therefore, the antenna should be oriented such that the scan direction aligns with the plane having a wider beam.

(5) Amplifying high-frequency components while maintaining overall bandwidth improves azimuth resolution without degrading range resolution.

2. An SFCW radar system was developed using a vector network analyzer. Ultra-wideband Vivaldi antennas were employed. Preliminary tests were conducted on exposed rebar with varying antenna spacing. The results showed that mutual coupling effects were avoided when the spacing was 88 mm or more.

3. A validation experiment was conducted on a reinforced concrete specimen using the developed radar. The focused image showed strong reflections at the locations of the front-layer rebars, and three rebars were clearly detected. This confirmed the radar's ability to identify and localize rebars embedded 50 mm deep in concrete. However, the rear-layer rebars were not detected due to signal attenuation and masking by front-layer reflections. To address this, further research is needed on signal compensation, clutter suppression, and antenna design for improved high-frequency transmission.

The developed SFCW radar offers greater flexibility than commercial systems, as its configuration can be freely modified by the user. This advantage makes it suitable for structure-specific inspection applications, integration with emerging technologies such as UAVs, multi-channel antenna arrays, and the development of new NDT techniques. With continued development, the proposed system has the potential to outperform existing commercial GPRs in terms of performance and applicability.

# A Novel System Identification-Based Method for Rebar Radius Estimation in Radar SAR-Based Non-Destructive Testing

Kwang-Yeun Park, Joo-Hyung Lee, Changbin Joh

KOREA INSTITUTE of CIVIL ENGINEERING and BUILDING TECHNOLOGY, Korea, Republic of (South Korea)  
email: kypark@kict.re.kr, leejoohyung@kict.re.kr, cjoh@kict.re.kr

**ABSTRACT:** Non-destructive testing of reinforced concrete commonly utilizes electromagnetic waves, such as radar, to obtain internal structural information. When probing around rebars using electromagnetic equipment, hyperbolic-shaped images are often generated. Typically, image focusing techniques, including Hyperbolic Summation, Kirchoff Migration, Phase-shift Migration, Omega-k Migration, and Back-projection-based Focusing, which are based on Synthetic Aperture Radar (SAR) algorithms, are applied to analyze these hyperbolic images. However, these conventional methods cannot accurately determine the size of rebars and face limitations when inspecting doubly reinforced concrete due to shadow regions created by surface-layer rebars, which obscure the internal rebars. To address these challenges, this study proposes a novel approach that analyzes hyperbolic images based not on the image itself, but on the information related to wave propagation distances. In this method, the rebar cross-section is assumed to be a circle with an arbitrary radius, and a hyperbolic equation is established accordingly. The radius is determined by solving the equation using a system identification (SI)-based approach that minimizes the error between the measured hyperbola and the theoretical one. As with many conventional SI techniques, this problem is highly ill-posed, requiring the introduction of regularization methods to stabilize the solution.

**KEY WORDS:** System Identification (SI), Rebar Radius Estimation, Non-Destructive Testing (NDT), Radar SAR Imaging, Regularization Techniques.

## 1 INTRODUCTION

When non-destructive testing is performed on reinforced concrete using radar equipment, the result appears in a hyperbola as shown in Figure 1. Such hyperbola images can be processed using methods such as hyperbolic summation, Kirchoff migration, phase-shift migration, Omega-k migration, or back-projection-based focusing [1-5], or analyzed empirically to determine the position and size of the rebar. These methods are very useful for identifying the overall internal structure of concrete. They make it possible to detect the presence of materials other than concrete (e.g., rebar or voids) inside the concrete and to estimate their approximate size. However, only a relative size can be inferred; the exact size of the object remains unknown. While it is fairly easy to detect a missing rebar—omitted either by mistake or wrongdoing during construction—it is difficult to confirm whether a rebar with a smaller cross-sectional area than required was used. It is also challenging to verify significant reductions in effective cross-sectional area due to severe corrosion. Moreover, in cases such as double-layered reinforcement, shadowed areas may appear, making analysis difficult.

Figure 1. Hyperbola seen in a B-scan when rebar is present in concrete

To compensate for these shortcomings of image focusing methods, this study aims to develop an algorithm that determines the size of the rebar by analyzing the hyperbola seen in B-scan images—strictly speaking, this curve is not a perfect hyperbola but one that closely resembles it, and is commonly referred to as such.

## 2 PROBLEM DEFINITION AND SOLUTION

### 2.1 Definition of “Hyperbola”

When rebar is present inside concrete, a B-scan taken on a plane parallel to the rebar’s cross-section shows a hyperbola, as in Figure 1. If it is assumed that the rebar has a perfectly circular cross-section and that the transmitting and receiving antennas are located at the same position (mono-static), the principle behind the formation of this hyperbola can be explained by Figure 2.

In Figure 2, the gray area represents concrete and the white area represents the rebar. The variables  $r_r$ ,  $T$  and  $\bar{T}$  correspond to the rebar radius, the distance from the transmitter/receiver antenna to the surface of the rebar, and the rebar-related information actually recorded by the transmitter/receiver antenna in the B-scan, respectively.

Because the transmitter/receiver antenna transmits electromagnetic waves in all directions and receives waves from all directions, it only knows the time difference between transmission and reception; it does not know which direction the wave traveled. At each position of the antenna, the signal strength is recorded over time and plotted with the vertical axis as time (or distance) and the horizontal axis as the antenna’s location. By displaying signal intensity as color, one obtains a B-scan similar to Figure 1. Conventionally, the time axis in a

Figure 2. Principle behind hyperbola formation in the B-scan when rebar is present in concrete

B-scan represents half the round-trip time of the wave, effectively the one-way travel time. When the dielectric constant is known and assumed constant, this time can easily be converted into distance. For simplicity, the discussion here assumes the vertical axis represents the one-way travel distance of the electromagnetic wave.

In Figure 1, a hyperbola commonly appears in the B-scan. This hyperbola can be idealized by the red curve in Figure 2. For instance, when the transmitter/receiver antenna is located at the inverted triangle in Figure 2, the electromagnetic wave emitted by the transmitter reflects off the rebar and then returns to the receiver. Because the angle of reflection equals the angle of incidence, only the wave that follows the normal vector of the (assumed circular) rebar cross-section can return to the receiver. Therefore, the wave travels a distance of  $T$  to reach the rebar, reflects, and then travels the same distance  $T$  to reach the receiver. In the B-scan (Figure 1), the reflected signal from the rebar appears at a vertical distance of  $T$  beneath the antenna's position. If this vertical distance is denoted by  $\bar{T}$ , then in an ideal situation with no external interference and no measurement error,  $\bar{T}$  should be equal to  $T$ . The term  $T$  is the distance from the rebar center to the antenna minus the rebar radius; using Figure 3, it can be expressed as follows:

$$T(x, r_x, r_y, r_r) = \sqrt{(r_x - x)^2 + r_y^2} - r_r \quad (1)$$

Here,  $x$ ,  $r_x$ , and  $r_y$  denote the antenna's horizontal position, the rebar center's horizontal coordinate, and its vertical

Figure 3. Travel distance of the electromagnetic wave upon reflection

coordinate, respectively. In Equation (1), if the rebar radius  $r_r$  is set to zero—in other words, if the cross-section of the material embedded in the concrete is assumed to be a point—the curve becomes a perfect hyperbola. It is for this reason that the curves in Figures 1 and 2 are commonly referred to as “hyperbolas.”

## 2.2 Estimation of the Rebar Radius in the Form of an Inverse Analysis

As explained above, in an ideal situation without any measurement error,  $T = \bar{T}$  holds in Figure 2. By substituting three pairs of  $(x, \bar{T})$  into Equation (1) and solve the simultaneous equations, the rebar radius  $r_r$  can be found. However, because actual measurements are subject to various errors, the measured  $\bar{T}$  inevitably includes some error. As a result, the value of  $r_r$  obtained using only three pairs of  $(x, \bar{T})$  can be extremely sensitive to even slight errors.

To reduce such errors, Multiple  $(x, \bar{T})$  pairs is used to solve an inverse problem defined by the following optimization equation:

$$\min_{r_x, r_y, r_r} \frac{1}{2} \int_A \|\bar{T} - T(x, r_x, r_y, r_r)\|_2^2 dx \quad (2)$$

In this equation, the integration domain  $A$  covers all  $x$  values where measurements were made. Discretizing this integral yield:

$$\min_{r_x, r_y, r_r} \frac{1}{2} \sum_{\text{for all } n} (\bar{T}_n - T(x_n, r_x, r_y, r_r))^2 \quad (3)$$

$\bar{T}_n$  and  $x_n$  denote the  $n$ -th measured  $(x, \bar{T})$  pair. Although Equations (2) or (3) can be solved by various methods, because the gradient vector and the Hessian matrix can be derived analytically, Newton's method provides an efficient way to obtain a solution.

## 3 NUMERICAL EXAMPLE

### 3.1 General Rebar Example

To analyze the error sensitivity of the proposed method, a numerical example was employed to verify Equation (3). In general, non-destructive testing equipment that uses electromagnetic waves discretizes the signals received by the receiver antenna. As shown in Figure 1, because only discrete points on the hyperbola can be recorded, the actual measurement cannot produce a smooth curve; instead, it is represented by quantized (or gridded) points. Such quantization becomes a significant source of error when using Equation (1) to fit to the measurement points for solving Equation (3). Various other errors that inevitably occur during the measurement process also contribute substantially to the instability of Equation (3).

To verify the stability against these errors, a numerical example was created using Equation (1), and then Equation (3) was solved using Newton's method to obtain a solution. The details of the example are as follows:

- Rebar radius: 12 mm

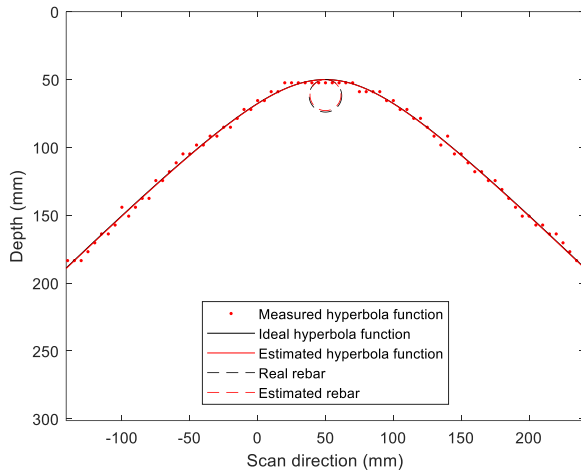

Figure 4. General rebar example and the resulting estimation of the rebar radius

- Concrete cover: 50 mm
- Rebar spacing: 50 mm
- Spatial sampling frequency: once per 5 mm
- Time sampling frequency: 20.48 GHz
- Relative permittivity of concrete: 5

It was assumed that the measuring device is Proceq's GP8800 [6]. The horizontal axis was discretized based on the number of scans per unit distance, and the vertical axis was discretized based on the temporal sampling rate and the relative permittivity. Up to 3% uniformly distributed white noise was added to the hyperbola generated by Equation (1), and the data were placed at the nearest discretized (grid) point.

Figure 4 shows the results of this example. The black dashed line indicates the actual rebar cross-section, and the black solid line represents the hyperbola derived from Equation (1). After adding white noise and mapping it onto the discretized grid, the red points appear in a stepwise manner rather than forming a smooth curve. It can also be observed that some points are distributed discontinuously because of the white noise.

Using the  $(x, \bar{T})$  pairs of these red points to solve Equation (3), the rebar radius was estimated to be 12.229 mm. The rebar radius and center location obtained from the estimation are plotted as a red dashed line in Figure 4, showing a good match with the actual location and radius.

### 3.2 Double-Layered Rebar Example

When the rebar is double-layered, as shown in Figure 5, information about the rebar behind the front one is obscured. Figure 5(a) shows the B-scan image, and Figure 5(b) illustrates a schematic representation. The obscured region is where the curve undergoes the most significant change, and thus contains the greatest amount of information. If a typical image-focusing post-processing method is applied to this image, almost no meaningful information about the rebar can be extracted. However, by employing the proposed inverse hyperbola analysis method, the rebar radius can still be estimated in such cases. The same conditions as the previous example were used, with the concrete cover doubled and a shadow region created extending five times the rebar radius from its center. As shown

Figure 5. Double-layered rebar as seen via B-scan: (a) B-scan and (b) Schematic

Figure 6. Simulation example of double-layered rebar and the resulting rebar radius estimation

in Figure 6, this setup is similar to the previous example but lacks measurement points near the rebar. By solving Equation (3), the rebar radius was estimated to be 13.42 mm. Although the accuracy is lower compared to the earlier example, it still represents a reasonably good estimation of the rebar radius

## 4 CONCLUSION

- An inverse-analysis-based method for estimating the rebar radius is proposed, which utilizes the hyperbolas observed in B-scans. By treating the rebar center coordinates and radius as unknown variables and formulating an optimization problem that minimizes the least-squares error, it becomes possible to determine the precise size of rebar cross sections—information that is difficult to obtain using conventional image-focusing techniques.
- The proposed rebar radius estimation method was verified through numerical examples. In a scenario with a typical rebar arrangement, the method accurately estimated the

rebar radius. It also performed well for the multi-layered rebar

- By presenting an inverse analysis approach for explicitly estimating the rebar radius, the proposed method overcomes limitations of existing non-destructive testing techniques. It can be effectively applied to detailed analyses of internal concrete structures. With ongoing research to refine  $(x, \bar{T})$  pair extraction and address numerical instabilities, even higher levels of accuracy can be expected in the future.

**ABSTRACT:** Concrete structures are at several stages of deterioration across the world. The presence of chloride ions salts as in the case of marine infrastructure or due to the application of de-icing salts, can further aggravate the rate of deterioration. Inspections of large concrete structures are predominantly undertaken through visual inspections. Detailed inspections are undertaken using piezo-generated ultrasonics. These inspections can be time and resource-intensive as the piezo devices need to contact the structure during measurements and their energy outputs are limited. Rapid inspections of large civil engineering structures would require a non-contact, high-energy source means of measurement. In our approach, we used a high-energy pulsed laser for excitation and an acoustic microphone for reception towards monitoring concrete structures. Defects in concrete like debonding and honeycombing, were simulated in the concrete specimens. The pulsed laser was used to excite the concrete specimen and the resultant waves generated due to this excitation were measured using focused cardioid microphones. The characteristic features in a typical waveform were first identified in pristine specimen. Subsequently, features corresponding to defects are extracted from the acquired signals using the signals from the pristine signal as a reference. The variations in these features were localised and their veracity was associated with the embedded defects in the specimen. As a result, the location and the nature of the defect were inferred. Thus, through this work, a framework for using pulsed lasers and microphones for non-contact non-destructive detection of defects in concrete is demonstrated.

**KEY WORDS:** Concrete structures, Pulsed laser, acoustic microphone, non-contact Condition monitoring, damage detection.

## 1 INTRODUCTION

Australia has a road network of about 14,500 km of National highways and 265,000 km of major local roads. These roads are supported by 53,000 bridges which are predominantly made of concrete [1]. According to the National State of the Asset Report in 2024, councils across Australia have concrete bridges, buildings and stormwater drains worth \$66.5bn that are in poor condition, function and capacity [2].

Traditionally, built infrastructure assets have been inspected visually, depending on the expertise of the inspectors. These assets are predominantly inspected visually which is tedious, unreliable, and expensive. Moreover, asset owners find it difficult to allocate resources for their monitoring and maintenance. So, sensors can be embedded into the assets to improve reliability in reporting their condition. Fibre optic sensors have been embedded in concrete structural assets to measure strains and sense deterioration in them [3]. As these fibres are predominantly glass fibres, they are susceptible to deterioration due to alkali attack from the concrete. Ensuring the longer durability of these sensors is a challenge [4]. Radio Frequency Identification (RFID) sensors have been embedded in concrete assets to detect changes in humidity and temperature in assets [5]. However, RFID devices are a passive means of monitoring, requiring the sensors to be embedded during the construction phase of assets.

Ultrasonic sensors generate waves that travel through the asset and interact with any emanating deterioration in it. Ultrasonic sensors can be embedded in concrete, and the condition of the concrete asset is discerned through the recorded travelling waves [6]. However, they can deteriorate over time and are prone to vandalism, making them unreliable. Moreover, these sensors must be pre-embedded in the assets before the inception of any deterioration. Mobile sensors can be used to alleviate the shortfalls in embedded sensing [7].

Image analysis and its synergistic association with computer vision have also been attempted for mobile sensing of concrete assets [8]. However, using this method, sub-surface deteriorations in the assets cannot be detected until they emerge to the surface. Mobile piezo sensors are commonly used for the generation and reception of ultrasonic waves for condition monitoring. They have been used to detect corrosion in rebars [9] and subsequently when they are embedded in concrete [10]. Field instruments that can provide scans of concrete are now available. The compact modular design of these ultrasonic scanners makes them convenient for surface-based operations [11]. The data obtained from these scanning devices can be coupled with advanced imaging algorithms to understand hidden rebars [12], incipient corrosion and debonding [13]. However, the scanning area is rather limited (around 300 mm square). Moreover, it is a manual and contact device. Thus, generating ultrasonic scans for concrete assets using mobile piezo sensors can be time and labour-intensive with contact between the sensors and the asset imperative.

In Impact Echo (IE), the surface of the concrete asset being tested is impacted with a solenoid-based metallic impactor, and the response is measured using an accelerometer. Lower frequency waves are typically used in this inspection to develop rapid scans in concrete assets [14]. These waves can also be monitored by using an array of acoustic microphones on a mobile platform [15]. The limited energy of the impactor and high attenuation of waves in concrete restrict the inspection range of this method. This impactor can be replaced with a high-energy pulsed Laser to generate high-energy pulses for rapid inspections of large concrete assets.

The range of inspections can be extended by using a high-energy pulsed laser for excitation. A pulsed laser imparts high-energy laser pulses on the substrate being monitored, making them ideal for sub-surface inspections. The energy from the

Laser pulse ablates the substrate being monitored and subsequently generates waves in the substrate [16]. These generated waves can be monitored using a range of air-coupled sensors such as acoustic microphones and Laser Vibrometers [17,18]. The laser-generated waves, when received non-contact, would help improve the inspection capabilities for large concrete assets.

In this paper, we explore the capabilities of a non-contact pulsed laser-microphone system for inspecting large concrete assets. The results and discussion of the experimental works are presented in the subsequent sections of this paper. The embedded defects in the specimens simulate some of the common defects in concrete structures.

## 2 METHODOLOGY

### 2.1 Experimental setup

In the present scheme of experiments, an Nd-YAG pulsed laser was used to excite the concrete specimen. This pulsed laser, NL303 HT, was made by Ekspla and can operate at two wavelengths 1064 and 532 nm. In the present scheme, the Laser was operated predominantly at 1064 nm with a pulse duration

causes the generation of travelling mechanical stress waves in the material. A portion of the generated stress waves leaks into the air surrounding the concrete while the other part propagates in the concrete. In the present testing regime, the pulsed Laser is operated at a lower energy such that the pulsed laser, upon impact, results in an ablative region on concrete about 1 mm in diameter. The depth of penetration of this ablative region is on a sub-millimetre scale. This laser ablation results in the generation of stress waves in concrete. Visual observations reveal that the geometry of the ablation marks on concrete was of the order of some air voids which occur in concrete while it sets. Moreover, the imparted energy of the Laser wasn't of the order to cause any severance to the structure. Moreover, this approach doesn't involve the extraction of a core from the concrete specimen. Thus, as the inspection method is relatively void of destruction to the specimen, this approach is considered a non-destructive test for assessing concrete.

The stress wave propagation in concrete interacts with any defects in concrete in its travel path. Based on the differences in acoustic impedances of the defect and the surrounding concrete, a portion of the travelling wave gets reflected towards the free surface of the concrete, causing vibrations in the air

Figure 1 Experimental setup

of 3-6ns where the pulse was Gaussian in shape. The pulse repetition rate of this laser was 10 Hz. The maximum energy output from this laser was 800mJ. The waves generated from the laser impact were measured using a microphone and amplifier system. A representation of the experimental setup is shown in Figure 1. A matched pair of Røde Compact Cardioid ½'' condenser microphones was used as an air-coupled receiver. The received signals were amplified using a Yamaha MG06 mixer. The amplified signals were digitised using a Picoscope 2000 series modular oscilloscope, and subsequently, the digitised data was stored as .csv files on a personal computer. During the experiments, the specimens were securely placed on the measurement table on a positioner assisted by a guide. The Nd-YAG pulsed Laser was operated at 1064nm wavelength for excitation at an energy output of 480mJ. The microphones were placed on a rigid support and secured to the measurement table using screws as needed. An average of 32 signals is used for measurements made at any acquisition location.

As the Pulsed Laser impacts concrete, the temperature at the impact location rises to a few tens of thousands of degrees. The severe increase in temperature causes melting and ablation of material locally. As the ablation and molten material front moves ahead, it interacts with the surrounding material. This

surrounding the concrete. The vibrations in the air caused by the laser impact and subsequent reflections from embedded defects in the air surrounding the concrete are measured by acoustic microphones. The vibrations received at the microphones are digitised and amplified as required.

### 2.2 Specimen details

In this experiment, concrete specimens were cast for testing. All specimens were of the dimension 500 x 250 x 100 mm. Each specimen has two steel bars of 10 mm diameter embedded in it. The concrete specimens were prepared with a mix design by weight as shown in Table 1.

Table 1: Concrete Mix Design

Constituent	Cement	Fine aggregate	Coarse aggregate	w/c ratio
Ratio	1	1.44	2.32	0.5

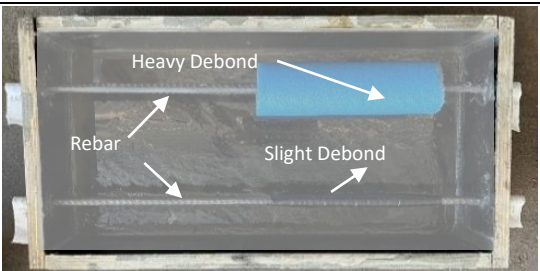

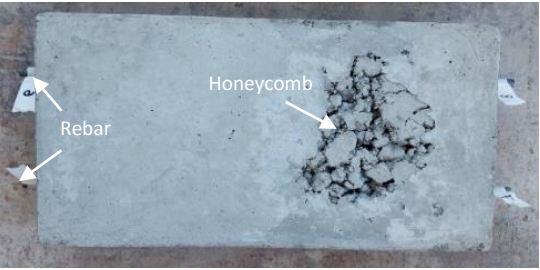

The nominal size of the coarse aggregate used was 10mm. The prepared moulds were filled in three layers, and a table vibrator was used to remove any air voids formed during casting of the specimen. After casting, the specimens were cured for 28 days in a water bath. Along with the specimen mentioned below,

cylinders of the specimen were also cast to test the cylinder compression test of the mix. The average compression strength of concrete obtained from this mix was 48.2 MPa. Table 2 demonstrates the details of the specimens used in the present study. In specimen D1, two types of debonds were created on the embedded rebars. One debond was created using a polystyrene foam wrap around the bar, representing severe debonding, and the other by wrapping several layers of insulation tape around the bar, representing slight debonding. In specimen H1, a region of honeycombing was simulated. This was created by placing aggregates of larger diameter mixed with cement without vibration in the mould and letting it set for one day before casting. Subsequently, the measurement points were marked on the specimen at distances of 50 mm. The microphones were placed 70 mm from the surface of the specimen for all measurements. As the Laser impacts on the specimen, due to ablation a travelling mechanical stress wave gets generated and is received by the microphones. The first arrival times of these waves are noted as the Time of Arrival (*ToA*). The *ToA* of the first positive peak was calculated using Equation 1.

$$ToA = \frac{d_a}{v} \quad (1)$$

Here  $d_a$  is the aerial distance between the microphone and the laser impact on the concrete specimen, and  $v$  is the velocity of sound in air. The specimens presented in Table 2 will now be tested, and the results will be reported in the subsequent sections of this paper.

### 3 RESULTS AND DISCUSSIONS

#### 3.1 Specimen D1

On specimen D1, the pulsed laser was applied, and measurements were subsequently taken on three lines, namely A, B and C series. The measurement points were marked on the specimen at distances of 50 mm as shown in Figure 2. The

microphones were placed 70 mm from the surface of the specimen for all measurements. The distance between the point of laser impact and measurement using the microphone was set to 100mm. The impact and measurement locations were chosen such that they span undamaged and locations with embedded damage in the specimen. In the present study, the pulsed laser and microphone were placed on the same side of the concrete specimen while undertaking measurements. Thus, all measurements were taken in the reflection mode, where reflected waves were monitored.

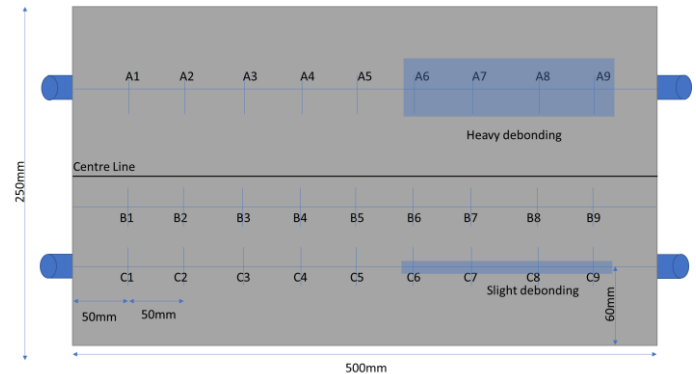

Figure 2: Specimen D1 with simulated debonding

Typical measurements from the laser-microphone acquisition setup are presented in Figure 3. This measurement is called A-Scan. Along line B, to develop an overview of the specimen condition, the laser was imparted at B8, B7, B6 etc., and the corresponding measurements were received by Microphones at positions B6, B5, B4, etc., ensuring a 100mm distance between the transmission and measurement points in the specimen. In Figure 2, the measurements' nomenclature is chosen so that it denotes the location of laser impact and microphone placement during measurements. The measurement, LaserB7\_MicB5, represents the measurement taken with a pulsed laser impacting at B7 and a microphone at B5. In Figure 3, the presented measurements denote the pristine location of the specimen. From here forth, this nomenclature will be followed for nomenclature. In these measurements presented in Figure 3, the first peak was observed between 0.3 and 0.4 ms. *ToA* of the first positive peak was calculated using Equation 1. Here, *ToA* accounts for the arrival of the Rayleigh wave to the microphone due to Laser impact on concrete.

Figure 3 Repeatability of measurements

During the experiments, the Laser is aimed at a horizontal distance of 100 mm from the microphone on the concrete. The microphone is placed at a vertical distance of 70 mm from the concrete surface. For this configuration, the value of  $d_a$  was 122.06 mm. The value of  $v$  was assumed to be 343 m/s at a temperature of 25°C. Thus, the  $ToA$  was 0.35 ms as per Equation 1. As the Laser impacts the concrete surface, a stress wave is generated in the concrete due to its ablation. Upon impact, a stress wave travels in the air as well as in the concrete. The travelling stress waves in concrete have a higher velocity. The stress wave in concrete travels through the specimen and reflects from the concrete-air interface at the bottom of the specimen. The difference in acoustic impedance between concrete and air results in the generation of this reflected wave. The reflected wave now reaches the level where the laser had initially impacted. Subsequently, the reflected wave leaks into the air and reaches the microphone. The expected arrival time of this reflection is around 0.7 ms. The presence of any defects in concrete would result in a mismatch of acoustic impedances between the concrete and the defect. This acoustic impedance difference would result in the generation of a subsequent reflected wave. As the source of the reflected waves would lie before the bottom of the specimen, the reflection from embedded defects would occur before the arrival of the reflection peak. Thus, the first arrival and the arrival of the reflected peak would be considered as two markers in the measured signals. Further investigations will be undertaken to explore reflection signatures from defects in the subsequent sections.

The characteristic of this peak corresponding to the first arrival remains unchanged over the measurement undertaken on line B. Between 0.4 and 0.7 ms, several other reflections are observed. This corresponds to the arrival of the reflected waves in the specimen. Similarities in the character of the signal were observed across several measurements along line B, as presented in Figure 3. As the signals remain relatively unchanged across several locations on the specimen, the repeatability in measurements using the laser-microphone system is ascertained. Now, the variations in measurements over locations of embedded debonds will be explored to understand the capabilities of this technique for the detection of embedded damages.

Subsequently, measurements were undertaken on specimen D1 in a similar configuration. The laser-microphone measurements were taken over Lines A and C over the two rebars embedded in the specimen. Over these measurement lines, two different types of debonding were simulated. During casting, heavy debonding was simulated along line A by embedding a concentric low-density polyethylene foam of about 10 mm thickness over the rebar. Along line B, four layers of regular insulation tape were used to create the slight debonding case. The observed variation in measurements corresponding to the locations of defects is presented in Figures 4 and 5.

As observed in Figures 4 and 5, the measurements taken along lines A and C in principle have similar characteristics between 0.3 and 0.4 ms as those observed earlier over line B. This initial peak, corresponding to the arrival of Rayleigh waves, can be observed at 0.4 ms. They correspond to the measurements acquired over the simulated heavy debond and slight debond

regions are presented. In the measurements along line A, the signal amplitude varies between 0.5 and 0.7 ms in regions with the presence of an embedded heavy defect. Figure 4 shows the variation in the amplitudes in measurement LaserA6\_MicA8 in the heavy debond region over the measurement LaserA2\_MicA4. This variation is caused by the acoustic impedance introduced by the heavy *debond*.

Figure 4 Measurements over simulated heavy debonding

On line C, a significantly different variation in the phase of the signal between 0.6 and 0.7 ms was observed. In the mentioned time interval, the measurement LaserC8\_MicC6, which is directly over the slight debond region, has a significantly different signature as compared to the pristine region in measurement LaserC3\_MicC1, as observed in Figure 5. This variation was on account of the change in acoustic impedance caused by the simulated slight debond that was embedded in the specimen. The variations in amplitude and phase as reflected in the signal characteristics due to the embedded effects were thus observed.

Figure 5 Measurements over simulated slight debonding

Thus, considerable changes in the waveform were observed in the specimen corresponding to the presence of embedded damages in the specimen. These changes in the waveform need to be identified and subsequently used to understand and classify the nature of damage in the specimens.

### 3.2 Specimen H1

The methodology discussed for specimen D1 will now be tried for specimen H1. Measurements are undertaken on lines A and C on this specimen as presented in Figure 6. In Figures 7 and

8, measurements taken along the lines B and C on the specimen are presented.

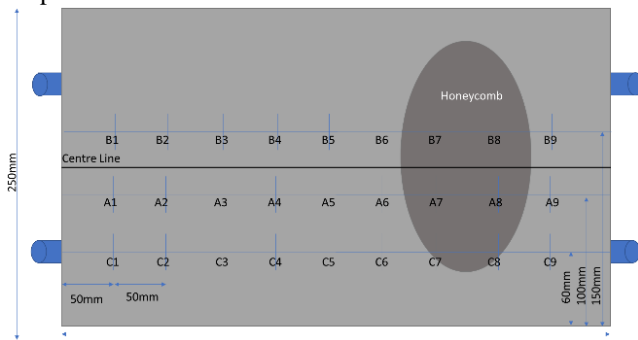

Figure 6 Specimen H1 with simulated honeycombing

The arrival time of the first peak across all measurements in this specimen is consistent with those observed in specimen D1. However, there is a considerable variation in the phase and magnitude of the signal after the first arrival between 0.4 and 0.8 ms. Along the line B, in the measurement LaserB6\_MicB8, there is a sharp rise in the amplitude and considerable variation in the phase of the signal compared to measurements at LaserB1\_MicB3. The increased difference in acoustic impedance due to air voids in the honeycomb around the LaserB6\_MicB8 points resulted in this variation in the signal. The variations in the signal between 0.4 and 0.7ms warrant further investigation to uncover details about hidden defects in the specimen (Figure 7).

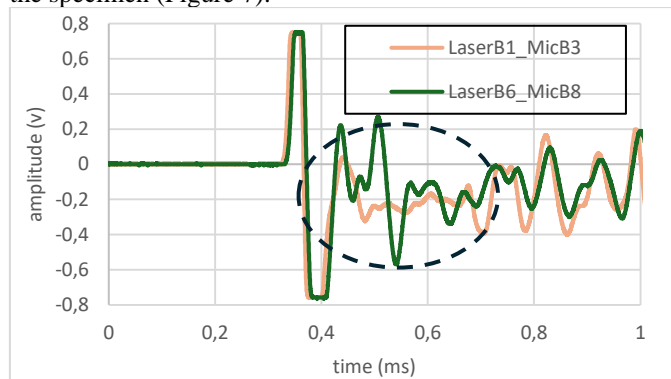

Figure 7 Signals in specimen H1 over the line B

In measurements along line C, the extent of variation in the signals is slightly lower compared to the ones over line B. In Figure 8, a variation in measurement over honeycomb, LaserC8\_MicC6, between 0.4 and 0.7ms over measurement LaserC3\_MicC1 can be observed. This trend is expected, and a plausible explanation surrounding this trend is the presence of line C further away from the core of the honeycomb. However, this variation is to be classified, and its extent is associated with the veracity of the damage in the specimen.

Figure 8 Signals in specimen H1 over the line C

### 3.3 Classification of defects

To further understand and classify the variations in the acquired signals due to embedded damages. The acquired signals are compared with the measurements at the pristine region. A Condition Index ( $CI$ ) is proposed to compare the signals acquired at various locations in the specimens. Though there are several approaches to compare two vectors, the proposed approaches are used for its simplicity and ease of computation. To undertake this comparison, the signals in the comparison are considered vectors. The vectors are unitised by dividing them by their magnitude. The process of unitising a vector is presented in Equation 2 by considering the example of a pristine signal. Here  $V_p$  is the signal and  $V_{pu}$  is its corresponding unitised vector.

$$V_{pu} = \frac{V_p}{\|V_p\|} \quad (2)$$

Subsequently, unitised vectors of measurements from other damage locations are also developed. Using scalar products, the similarities of the developed vectors are evaluated. The scalar product of these vectors is presented in Equation 3. The scalar product is captured in a parameter  $CI$ .

$$CI = V_{pu} \cdot V_{du} \quad (3)$$

Here  $V_{du}$  represents the unitised vector from an A-Scan acquired over a defect. This is compared with the  $V_{pu}$  calculated over the pristine region.

The outcome of Equation 3 is  $\cos \theta$ , where  $\theta$  represents the angle of the two unitised vectors. If  $CI = 1$ , the corresponding  $\theta$  between the vectors is 0, which implies the vectors are identical to each other. As the value of  $\theta$  increases, the value of  $CI$  decreases. Thus, the value of  $CI$  indicates the difference between the signal at a location with the pristine signals. Now,  $CI$  at several locations will be compared with the pristine signal to understand its association with the location of damage in the specimens.

To undertake the comparison, an average of three measurements recorded at LaserB5\_MicB3 on specimen D1 over line B was utilised and as  $V_{pu}$  as per Equation 2. Subsequently, three other pristine locations on this specimen were considered as  $V_{du}$  and their  $CI$ s calculated as per Equation 3. In Table 3, a comparison of  $CI$  values at various locations in the pristine region is presented. These values are very close to each other, indicating that the time signals are like each other.

Table 3 CI over the line C for pristine condition

Location	CI
Pristine1	0.993458
Pristine2	0.986087
Pristine3	0.990595

As the reliability of measurements was observed earlier over the pristine location, an average of the three measurements recorded at the pristine region will now be used as a reference pristine signal. The variation in *CI* at the damage will now be explored to understand the sensitivity of the proposed approach in detecting damage. This will be compared against the measurements taken over the defect regions. As seen in Table 4, a low *CI* value was observed at the debond region. This variation occurred because of the variation in the acquired signal due to the acoustic impedance difference between the surrounding concrete and the simulated debond in specimen D1. This variation in acoustic impedance causes the incident wave to reflect, thus the variation in the wave signature. The magnitude of *CI* further reduces over the honeycomb region in specimen H1. The air present in the simulated honeycomb results in further variation in acoustic impedance and thus a further decrease in *CI* value.

Table 4 Variation in signal similarities at various locations

Location	CI
Heavy debond	-0.08175
Slight debond	-0.08782
Honeycomb1	0.050011
Honeycomb2	0.001647

The veracity of the proposed methodology in detecting hidden damages in concrete is thus established. Further investigations are now underway to explore the capabilities of the proposed method to evaluate the veracity of this method in deciphering defects at various depths from the surface. This will be extended to detecting progressive deterioration. Monitoring long-term durability due to the actions of corrosion and freezing-thawing will be explored.

#### 4 FREQUENCY RESPONSE

To understand the variation in A-Scans due to defects, the acquired time signals will now be explored to understand the frequency content in them. The frequency content in the signal was developed through the Fast Fourier Transform algorithm implemented using the ‘fft’ function in MATLAB software [19]. The frequency content of signals is presented in Figure 9. A high-pass filter with a cut-off set at 2 kHz was used on the frequency response to remove any ambient vibrations in the signal. The frequency response of the pristine sample was compared with that of the defect cases discussed earlier. It can

be observed that the signal has considerable signal strength between 6 and 15 kHz across all measured signals. The magnitude of the frequency spectra across all the damage cases is higher than the pristine case. Moreover, there is an increase in the magnitudes of lower frequency components, particularly between 6 and 12 kHz and a damping down of frequencies higher than that range. This indicates a change in the vibration characteristic of the specimen. To explore the trends in the frequency responses, regions of interest will be identified, and the frequency content in the regions will be explored. Further information can be inferred from the inclusion of information about the phase spectra of the acquired signal.

Figure 9 Frequency responses of A-Scan signals

#### 5 CONCLUSIONS

In this paper, we present a novel pulsed-laser microphone system to monitor deterioration in concrete. In this method, high-energy pulses are used to generate acoustic waves and microphones are used for reception. The efficacy of this non-contact, non-destructive method for monitoring hidden deterioration in concrete is explored in this study. The following are the key conclusions:

- In this study, the generation of acoustic elastic waves in concrete using a Pulsed Laser and their reception using an acoustic microphone was established.
- The variation in acoustic wave pressure due to laser impact was received by the microphone and digitised into an electrical signal.
- The signals were acquired on two specimens with embedded defects like simulated debonding and honeycombing.
- The variation of signals in the pristine region and the defects was identified.
- A Condition Index (*CI*) was developed to qualify the variation of signals due to the presence of defects.
- The efficacy of using a pulsed laser–acoustic microphone system in detecting embedded defects was established.

**ABSTRACT:** Real-time monitoring of road infrastructure is crucial in addressing the challenges posed by the increasing volume of vehicles and the need for timely maintenance to manage structural aging. Traditional Weight-in-Motion (WIM) systems provide accurate measurements of vehicle load, axle configurations, and speed but are costly to install and require road closures, hindering widespread deployment. This study introduces an innovative method for estimating traffic load by repurposing acceleration-based Structural Health Monitoring (SHM) systems integrated with an AI powered vision system which enables to classify vehicles, estimate their weight, speed and finally assess traffic load over time with a scalable and cheaper solution. Vehicles have been classified into three macro classes: cars, lightweight trucks and heavy trucks. A comparative analysis has been performed between load estimation using only the AI-powered vision system, based on YOLO object detection, and an enhanced approach that integrates acceleration data. The combined method demonstrated significantly improved accuracy in weight estimation. The methodology was tested on an highway viaduct and the results validated by using a reference WIM system. The findings underscore the potential of this integrated approach to provide cost-effective and scalable solutions for traffic load estimation and structural health assessment.

**KEY WORDS:** SHM; Weight in motion; Road traffic monitoring; Sensor fusion

## 1 INTRODUCTION

In recent decades, highway infrastructure has been subjected to escalating stress due to the combined impacts of increasing traffic volumes and the aging of structural components. Transportation networks, which serve as vital conduits for economic activity and goods distribution, are facing growing demands. A major driver of this strain is the rapid expansion of road-based freight transport, fueled by the rising demand for efficient and adaptable logistics. In Europe, for instance, road freight accounted for more than 75% of all inland freight transport in 2023, with heavy-duty vehicles (HDVs) playing a central role in long-haul logistics and supply chains [1]. Bridges and viaducts are particularly susceptible to the combined effects of increased loading and structural aging. These assets often endure long service durations, facing environmental wear, and intensified mechanical stresses. Among the various contributors to their deterioration (e.g. material fatigue, environmental factors, seismic forces and inadequate maintenance) overloading by HDVs stands out as one of the most widespread and damaging. Numerous studies have identified overloading as a critical factor in both the progressive degradation and sudden failure of bridge structures across different contexts and typologies [2, 3].

Given this context, the need for effective and continuous traffic monitoring systems has become increasingly urgent. In particular, identifying and quantifying the load contribution from heavy vehicles is critical for estimating cumulative damage, supporting load rating decisions, and optimizing maintenance schedules. Traditional static weighing stations, while accurate, are inefficient for large-scale deployment due to their reliance on vehicle stops, high operational costs. Consequently, Weigh-In-Motion (WIM) systems have

emerged as a valuable alternative, capable of measuring axle loads, gross vehicle weight (GVW), and vehicle classification in real time without interrupting traffic flow [4]

WIM systems are generally classified into two main categories: Pavement-based WIM (P-WIM) and Bridge-based WIM (B-WIM). P-WIM systems involve the installation of strain or piezoelectric sensors within the roadway surface to directly record the forces exerted by passing axles. While effective in certain applications, these systems require a high installation cost and frequent maintenance and recalibration due to their direct exposure to traffic and weather. In contrast, B-WIM systems leverage the dynamic or static responses of bridge structures to estimate vehicle weights typically using strain, displacement, or acceleration sensors. This approach is advantageous as it utilizes existing infrastructure, minimizes road surface interventions, and offers spatial scalability over the entire highway network [5].

The concept of B-WIM was first introduced by Moses in 1979, where an inverse problem formulation was used to estimate axle weights based on strain measurements recorded during vehicle crossings [6]. This methodology laid the foundation for modern B-WIM systems and has since been refined through the integration of improved sensing hardware, robust signal processing algorithms, and advanced calibration procedures [7]. Strain-based B-WIM systems are currently the most widely adopted, offering high accuracy for vehicle weight estimation under controlled conditions. However, they still face limitations related to temperature sensitivity, sensor drift, and

Figure 1: Viaduct schema and accelerometer position.

the need for detailed knowledge of bridge geometry and boundary conditions.

More recently, research has explored the use of acceleration-based B-WIM systems as a low-cost and scalable alternative. These systems utilize MEMS (Micro Electro-Mechanical System) accelerometers to measure bridge vibrations induced by vehicle crossings. Their non-intrusive nature and ease of deployment make them attractive for widespread monitoring applications. Nevertheless, acceleration-based systems introduce new challenges, particularly related to signal variability caused by vehicle dynamics, road roughness and environmental noise [8]. Despite these challenges, several promising studies have demonstrated the feasibility of such approaches. For instance, Sekiya et al. [9] deployed MEMS accelerometers on a steel bridge and demonstrated the potential to estimate GVW and axle positions from a single vehicle crossing. A follow-up study [10] extended this investigation to a year-long deployment, highlighting the need for temperature compensation and advanced data filtering techniques to ensure accuracy.

Further developments in the field have explored hybrid and data-driven methods. O'Brien et al. [11] used statistical analysis of acceleration signals to jointly estimate vehicle weight and assess bridge integrity. While effective for GVW estimation, the method struggled to resolve axle weights and spacings. Wang et al. [12] addressed some of these limitations by integrating vision-based systems with acceleration data to enhance vehicle detection and classification capabilities. The incorporation of transfer learning also demonstrated improved generalization across different bridge types.

These advancements underscore the growing interest in low-cost, scalable, and intelligent structural health monitoring systems. The evolution of WIM technologies, particularly B-WIM systems enhanced by MEMS sensors and machine learning algorithms, opens new possibilities for real-time infrastructure assessment. However, significant challenges remain in terms of robustness, environmental adaptability, and the reliable estimation of axle-level loads. As urban infrastructure continues to age and traffic volumes increase, the development of resilient and accurate WIM systems becomes

not only desirable but essential for the future of bridge

Figure 2: Piezoelectric accelerometers (Acc\_1 and Acc\_2) positioned on the viaduct spans.

maintenance and safety.

This study aims to demonstrate the feasibility of estimating highway traffic loads by utilizing existing structural monitoring systems installed on viaducts, offering a cost-effective alternative to conventional, high-cost systems such as P-WIM technologies. The proposed methodology integrates vision-based systems for vehicle detection and classification with acceleration data acquired using accelerometers positioned on the bridge spans of the viaduct. The effectiveness of this approach is illustrated through a case study involving an operational highway viaduct located in Italy (schematized in Figure 1) where a reference P-WIM system is present as a reference for the vehicle weight.

In this work, sensitive data regarding highway traffic and viaduct accelerations were used; therefore, the actual acceleration values will be masked in the figures, and no

Figure 3: Vehicle detection when it crosses the P-WIM system (left) and while it crosses the first viaduct span (right).

absolute values will appear in the text. This does not affect the validity of the results.

## 2 MATERIALS AND METHODS

The viaduct features a simply supported beam configuration and consists of six spans. This study focuses on the first three spans, each measuring 21 meters, as they correspond to the direction of traffic flow. The primary structural components are made of conventional reinforced concrete, while the decks and pier caps are constructed using pre-stressed reinforced concrete to enhance load-bearing capacity and durability. Overhangs are located at piers 5 and 6, supporting the adjacent suspended spans through Gerber saddles, which facilitate simple support articulation and allow for structural continuity. The entire structure is founded on direct foundation systems.

The monitoring setup implemented on the viaduct includes three PCB 393A03 piezoelectric IEPE accelerometers positioned on the first three spans of the viaduct (see Figure 1 and Figure 2). The use of multiple accelerometers enables vehicle speed estimation by correlating the time delays between the signals captured by the sensors. Furthermore, it allows for a comparative analysis of acceleration responses at mid-span locations (Acc\_0 and Acc\_2), where the dynamic amplification of structural response is more significant and near the joint (Acc\_1), where vehicle impacts contribution on the acceleration data. Data acquisition was performed synchronously using a National Instruments CompactDAQ system (model cDAQ-9172 equipped with NI 9230 boards) with a sampling frequency of 1000 Samples/s.

For vehicle detection and classification, a vision system comprising a Sony Handycam HDR-CX405 camera was installed above the tunnel exit, providing a clear field of view of the traffic flow immediately following the tunnel (as shown in Figure 3). To establish a ground-truth reference, a P-WIM system located upstream of the viaduct was used. Given the absence of highway exits along between the P-WIM system and the viaduct, it was ensured that all vehicles recorded by the P-WIM system subsequently traversed the viaduct under investigation. To account for potential overtaking between the two locations, an auxiliary camera installed at the P-WIM site was used to reorder vehicles and ensure accurate matching with the viaduct observations.

The reference data provided by the P-WIM system included detailed vehicle information, such as speed, length, lane position, axle count and spacing, individual axle loads, gross vehicle weight (GVW), and vehicle classification based on the ASTM E1318-09 standard [13]. The vehicle flow was sparse

enough to ensure that only one vehicle crossed at a time, simplifying the analysis and reducing the complexity associated with multi-vehicle events. The dataset analyzed comprises a total of 96 vehicles that traversed the viaduct during the time period in which all monitoring systems were simultaneously acquiring data. Approximately 90% of the recorded vehicles were two-axle vehicles, with an average GVW of around 2 tonnes. This category includes not only passenger cars, but also vans, light trucks, and motorcycles. The remaining 10% consisted of heavier vehicles with three, four, or five axles, corresponding primarily to trucks, with an average GVW of approximately 20 tonnes. Regarding vehicle speed estimation, it was derived by correlating the data from the accelerometers with the output from the vision system. The velocity measurements provided by the P-WIM system could not be considered a reliable reference, as the system is located upstream of the viaduct and vehicle speeds may vary along the intervening highway segments.

### 2.1 Vision-based vehicle detection and speed estimation

Vehicle detection and classification within the region of interest were performed using a Python-based application that integrates OpenCV with a pre-trained object detection algorithm. Each video frame was processed to identify and localize vehicles using the YOLOv3 (You Only Look Once [14]) model, trained on the COCO dataset [15], which enables vehicle classification in only four classes: car, motorbike, bus, and truck. To achieve more stable classification and refine detections, post-processing was performed by applying a confidence threshold and non-maximum suppression. A tracking algorithm was then employed to assign persistent IDs to detected vehicles across consecutive frames by comparing the centroids of bounding boxes. This enabled consistent object identification throughout the video. Vehicle counting was carried out by monitoring object trajectories across a user-defined detection zone delimited by three virtual lines. When an object centroid crossed the designated thresholds, it was counted and classified accordingly (see Figure 3 (right)).

Given the relevance of vehicle speed as a parameter, a method for its estimation was also implemented. During video processing, the frame numbers at which each vehicle entered and exited the detection area is recorded. By combining this information with the known frame rate and the estimated physical distance ( $\Delta s$ ) between the entry and exit lines, the vehicle speed ( $v_{ID}$ ) was approximated using the following relation:

$$v_{ID} = \frac{\Delta s \times fps}{frame_1 - frame_0} \quad (1)$$

where  $frame_0$  and  $frame_1$  denote the frame indices corresponding to the vehicle entry and exit points, respectively, and  $fps$  (frame per second) corresponds to 50 for the camera used. The accuracy of this estimate depends on factors such as camera placement, resolution, and perspective distortion. Several limitations in the detection and classification process were addressed. First, the object class assigned by YOLOv3 may vary across frames, leading to misclassification. To

Figure 5: Average spectrum for heavy vehicles and light vehicles during their passage over the accelerometer Acc\_0.

mitigate this, all class labels assigned to an object during its passage were stored, and the most frequently assigned class (mode) was used as the final classification. Second, incomplete or intermittent detections, often due to low confidence scores, could cause the same vehicle to be assigned to different IDs, affecting both vehicle counting and speed estimation. To address this, the ID matching process was extended to compare across both temporary detection lists, improving continuity in object tracking. However, if a vehicle was detected only in the latter part of the detection zone, the estimated speed would be significantly overestimated. To prevent this, the system recorded the initial detection point for each object and suppressed speed calculations for vehicles detected too late in the zone, where time-distance correlation becomes unreliable.

## 2.2 Acceleration-based vehicle detection and speed estimation

This section focuses on vibration analysis using accelerometer data, aiming to correlate sensor-derived information with data obtained from video recordings. Specifically, the analysis addresses two objectives: (i) the identification of light and heavy vehicles using time-domain features extracted from acceleration signals, and (ii) the estimation of vehicle speed through the synchronization of signals from three accelerometers, followed by comparison with speed estimates derived from the vision-based system.

By analyzing the time histories from raw accelerometer data (see Figure 4), vehicle pass-by events were initially identified by observing distinct signal peaks. A representative segment of the vibration data, collected during one of the experimental campaigns, illustrates this concept. To improve detection clarity, a moving Root Mean Square (RMS) function was applied to the signal. The RMS provides a measure of signal energy over a defined time window and is particularly useful for distinguishing between light and heavy vehicles, as heavier vehicles are expected to induce greater energy in the structure. However, fixed thresholds for vehicle classification cannot be determined a priori, as they depend on the specific structure and sensor placement.

Frequency domain analysis (see Figure 5) reveals that the primary distinction between light and heavy vehicles lies in the low-frequency range, specifically below 50 Hz. Based on this observation, the signal energy within this band, quantified using the RMS of the band-pass filtered signal (5–50 Hz), was selected as the key feature for vehicle classification.

Vehicle speed can be estimated also correlating signals from different accelerometers, based on their spatial position and the time taken by a vehicle to traverse the corresponding distance. Several methods can be used to estimate the time lag between two signals; in this case, the cross-correlation method was used, which computes the time lag between two signals considering the well-known correlation function:

$$\text{Corr}(\tau) = \int_0^T a_{en}(t) a_{ex}(t + \tau) dt \quad (2)$$

where  $a_{en}(t)$  and  $a_{ex}(t)$  represent the signals from entry and exit sensors, respectively, and  $\tau$  denotes the time shift. The correlation was applied either directly to the moving RMS of the signal or to the envelope of the signal. These two acceleration-based methods will be compared to the vision-based estimates in the results section to evaluate their performance.

## 3 RESULTS

This section presents the results of the study, beginning with the comparison of speed estimations comparison between the two systems and subsequently discussing the outcomes of vehicle classification between light and heavy vehicles.

Although vehicle speed estimation is not the primary focus of this study, it remains a valuable parameter, as the velocity at which a load travels over a viaduct can significantly influence the dynamic response of the structure. Moreover, since speed is also estimated by P-WIM systems, utilizing existing infrastructure such as cameras or accelerometers for speed estimation can enhance the spatial coverage of traffic monitoring. This approach has the potential to provide a more comprehensive mapping of vehicle speeds across the highway network, contributing to a more accurate assessment of moving loads on the structure.

The comparison between the acceleration-based and vision-based vehicle speed estimation methods is summarized in Table 1.

Table 1. Vehicle speed estimation comparison between acceleration-based and vision-based methods.

Method	$\Delta < 20 \frac{\text{km}}{\text{h}}$	$\Delta \geq 20 \frac{\text{km}}{\text{h}}$
<b>Moving RMS</b>	91.7%	8.3%
<b>Envelope</b>	82.5%	17.5%

Both the Moving RMS and the Envelope methods have been used for speed estimation from the acceleration based system. The parameter  $\Delta$  represents the absolute difference in speed estimates between the two systems. Results are categorized based on whether this difference is less than or greater than 20 km/h. The Moving RMS method exhibited a high level of agreement, with 91.7 % of the estimates falling within a  $\Delta < 20$

Figure 6: RMS value of the acceleration in the time window when the vehicle passes by the accelerometer Acc\_0.

Figure 7: RMS value of the acceleration in the time window when the vehicle passes by the accelerometer Acc\_1.

km/h and only 8.3 % exceeding this threshold. Similarly, the Envelope method showed that 82.5 % of estimates were within the acceptable margin, while 17.5 % exceeded it. These findings suggest that both acceleration-based techniques, particularly the Moving RMS approach, demonstrate promising accuracy and consistency when compared with the vision-based system.

#### 4 CONCLUSION AND FURTHER DEVELOPMENT

This study presents a preliminary investigation into the feasibility of leveraging existing monitoring systems - , specifically, accelerometers installed on viaducts and highway surveillance cameras - to estimate traffic loads acting on highway infrastructure.

Although not the primary objective, traffic load estimation is highly relevant for informing maintenance strategies, forecasting potential structural damage and design new infrastructure.

Currently, P-WIM systems serve this purpose but are often associated with high installation and maintenance costs. As an alternative, the proposed methodology offers a low-cost, albeit less precise, approach by estimating vehicle loading by identifying the number of heavy vehicles (>10 tons) traversing the viaduct. A reference P-WIM system was used as ground truth for weight calibration, enabling a daily estimate of total traffic-induced load, potentially useful in design or assessment contexts where knowledge of acting loads is required.

Results demonstrate that employing an intelligent vision-based system (e.g. using pre-trained deep learning object detection models), can distinguish between light and heavy vehicles. However, intermediate vehicle categories (e.g., vans, minibuses, RVs) are occasionally misclassified. One inherent limitation is the high variability in heavy vehicle weights depending on loading conditions, making it challenging to detect overloading or estimate precise weight using classification alone. In this regard, the inclusion of structural acceleration data improves classification accuracy, as the energy transferred by the vehicle, expressed through the root mean square (RMS) of the acceleration signal, provides an additional informative metric for estimating vehicle mass.

Furthermore, the study compares vehicle speed estimates derived from both systems. By correlating signals from three accelerometers and cross-referencing them with visual detections, the comparison shows that in 90% of cases, the speed difference between the two methods is below 20 km/h, suggesting consistency and potential for dual-system validation.

Despite its promising results, the study faces several limitations that define avenues for future research. Most notably, the dataset includes only 239 vehicles, limiting the use of more sophisticated data-driven algorithms that could enhance load estimation using richer input features beyond RMS. Expanding the dataset would enable the exploration of machine learning models trained directly on raw acceleration signals.

Concerning vision-based algorithms, having a bigger dataset would allow model retraining with more vehicle classes specifically tailored for this application, enabling a more precise weight estimation. Additionally, while the present study analyzes the two systems separately, future work should consider integrating their outputs into a unified model, enabling sensor fusion to enhance overall system robustness and accuracy.

**ABSTRACT:** With the rapid development of sensor technologies and computational methodologies, real-time structural health monitoring (SHM) has gained significant attention in the field of civil engineering. Infrastructures, such as long-span bridges and dams, are often equipped with diverse sensor arrays to enable continuous monitoring of their structural conditions. However, conventional SHM typically require extended data collection periods post-sensor installation, which can delay their practical applications. To address this challenge, this study introduces a novel methodology termed information transferring with dimensional expansion, which leverages transfer learning principles to enhance anomaly detection capabilities in newly instrumented structures. By referencing datasets from similar existing infrastructures, this approach mitigates the dependency on extensive initial data while ensuring reliable anomaly detection. Validation through a case study on a long-span bridge in Republic of Korea demonstrates the method's efficiency and accuracy, highlighting its potential to revolutionize SHM practices by enabling immediate operationalization upon sensor deployment. This research contributes to advancing SHM systems, emphasizing scalability and adaptability for diverse structural applications.

**KEY WORDS:** Structural Health Monitoring; Transfer Learning; Anomaly Detection; Gaussian Process Regression.

## 1 INTRODUCTION

As sensor technology and computational capabilities have advanced, interest in structural condition monitoring has been steadily growing. In particular, there has been a noticeable shift toward real-time monitoring of infrastructures, such as long-span bridges and dams, utilizing a wide array of sensors including accelerometers, strain gauges, inclinometers, anemometers, thermometers, piezometers, and water level gauges. Consequently, the development of techniques capable of identifying structural anomalies based on sensor data has become important.

Previous studies have proposed various methods for detecting structural anomalies. For instance, Lee et al. (2018) dynamically adjusts anomaly detection criteria by considering environmental conditions' seasonal and daily variations [1]. Lee et al. (2019) integrates information from finite element simulations to build anomaly detection models of structures under construction [2]. Lee et al. (2022) explored the evaluation of railway bridge deflections under high-speed train loads to identify behavioral irregularities [3]. However, a common limitation of these methods is their reliance on extensive data collection before deployment, making them less viable for immediate application following sensor installation.

To address this challenge, our study seeks to develop an anomaly detection model for newly constructed structures by leveraging data from similar existing ones. We adopt the concept of transfer learning [4], enabling knowledge transfer

from previously monitored structures to new monitoring applications.

## 2 METHOD

To develop an anomaly detection model for structural condition monitoring, an information transfer approach with a dimensional expansion can be introduced. Traditional methods require extensive data collection before deployment, while the proposed approach aims to leverage data from existing structures with similar characteristics to enhance anomaly detection in newly instrumented structures. The methodology consists of the following steps:

- **Data collection:** This process involves acquiring data using sensors, such as accelerometers. A crucial aspect of this step is securing pre-existing sensor data from structural members and physical quantities similar to those of the newly installed target.
- **Dimensional expansion:** To address the issue of scale differences in data from different sensors, an additional feature via one-hot encoding is introduced, distinguishing data classes while maintaining comparability. For example, when temperature and response data are collected from two different sensors, the input dimension can be expanded, as shown in Figure 1, distinguishing between different sources of data.
- **Transfer learning implementation:** Instead of training separate models for each dataset, a unified *super-model*

that incorporates knowledge from well-established datasets which fine-tuning for new dataset is constructed.

- Probabilistic anomaly detection: A probabilistic anomaly detection model to identify deviations in structural behavior is constructed using Gaussian process regression, which is non-parametric Bayesian regression methods.

AS-IS		TO-BE

Figure 1. Dimensional expansion via one-hot encoding

### 3 RESULTS

The approach was validated using real-world bridge monitoring sensors: two accelerometers installed on the cables of an operational cable-stayed bridge. One accelerometer had been measuring data for two weeks in advance, while the other began recording approximately two weeks later, leaving only one day of available data for anomaly detection model construction. The acceleration measurements from the two sensors differed in scale by approximately 2 cm/s<sup>2</sup>. The objective was to detect anomalies in the sensor data over the subsequent 10-day period (Figure 2).

Figure 2. Dataset utilized to validate the approach

First, Figure 3 presents the anomaly detection results obtained using only one day of data without applying transfer learning. Although the 10-day prediction period corresponds to a normal state with no actual anomalies, the model incorrectly identifies multiple data points as anomalies. In contrast, Figure 4, which applies the proposed approach, successfully distinguished the normal state, even though the model was built with limited data from a newly installed sensor. This demonstrates that the proposed approach enables the construction and deployment of an anomaly detection model from the early stages of sensor installation.

Figure 3. Anomaly detection without transferring information

Figure 4. Anomaly detection with transferring information

### 4 CONCLUSION

This study demonstrates the effectiveness of a transfer learning-based approach for structural anomaly detection in newly monitored structures. Traditional anomaly detection methods require a substantial data collection period before deployment, limiting their immediate applicability. To address this challenge, leveraging pre-existing sensor data from similar structural members can be considered to enhance anomaly detection for sensors with limited initial data.

The results show that models built using only one day of data without transfer learning tend to misclassify normal conditions as anomalies. In contrast, the proposed method effectively distinguishes normal states, even when applied to a newly installed sensor. This confirms that transfer learning can improve anomaly detection accuracy from the early stages of sensor deployment.

**ABSTRACT:** Structural health monitoring (SHM) plays a crucial role in ensuring the safety and longevity of critical infrastructure, such as bridges. SHM refers to continuous, sensor-based, and automated monitoring that complements traditional inspection methods by providing real-time data on structural performance. This paper proposes an unsupervised machine learning approach to SHM using vibration data, aiming to address the challenges of data scarcity and the difficulty of collecting labelled damage examples. The methodology combines statistical and spectral feature extraction with an Isolation Forest anomaly detection model, trained solely on healthy data to identify potential damage. The feature extraction process includes key metrics such as root mean square, entropy, and spectral centroid, which capture both time-domain and frequency-domain characteristics of the vibration signals. The Isolation Forest model is trained on these features to distinguish between normal and anomalous patterns, making it well-suited for applications where labelled damage data is unavailable. Results from FE simulation show high accuracy (95.5%), precision (91.75%), and recall (100%), demonstrating the effectiveness of the method in distinguishing damage from healthy states. The proposed approach provides a scalable and data-efficient solution for real-time damage detection in civil infrastructure, with significant potential for deployment in large-scale monitoring systems. Future work will focus on experimental validation and improving the model's robustness in real-world conditions.

**KEY WORDS:** Structural Health Monitoring; Unsupervised Learning; Anomaly Detection; Vibration Data; Isolation Forest; Damage Detection; Bridges; Machine Learning; Feature Extraction; Real-Time Monitoring

## 1 INTRODUCTION

Structural health monitoring (SHM) is an essential aspect of maintaining the safety and integrity of civil infrastructure, particularly for critical structures like bridges. With the ageing of infrastructure, globally and increasing demands on transportation networks, the need for efficient, real-time monitoring systems has never been more pressing. SHM refers to continuous, sensor-based, automated monitoring that complements traditional inspection methods by providing real-time data on structural performance. This allows engineers to prioritise inspections and, in some cases, reduce their frequency, especially for hard-to-access structures such as long-span bridges or offshore platforms.

Machine learning-based approaches represent a more contemporary method for processing SHM data and developing models that enhance damage detection. These methods can improve both the speed and accuracy of detection and complement established techniques like system identification that are commonly used for real-time monitoring. Structural responses, such as acceleration, displacement and strain, provide quantitative measures of how a structure reacts to applied loads. Among machine learning approaches, unsupervised anomaly detection has gained interest for its ability to function without requiring labelled damage data. This is especially useful in civil infrastructure applications, where collecting labelled examples of damage is costly, time-consuming, and often impractical.

Unsupervised learning approaches are particularly advantageous in SHM applications where only healthy baseline data are available, as they do not require labelled damage examples for training. While unsupervised methods broadly include clustering and dimensionality reduction techniques, this study specifically adopts an anomaly detection approach trained solely on healthy data. This is especially relevant in large-scale infrastructure where controlled damage scenarios are infeasible [1]. Accelerometers, widely used for collecting vibration-based data in SHM, are valued for their simplicity, cost-effectiveness, and ability to capture overall structural response. Despite limitations such as temperature sensitivity and noise, they remain a preferred choice for large-scale deployment. While other sensors, such as Fibre Bragg Grating (FBG), can detect localised damage with higher precision, they require complex installation and costly equipment [2].

Soltani et al, provided a comprehensive review of machine learning techniques for SHM, highlighting the increasing use of unsupervised methods such as Principal Component Analysis (PCA), Isolation Forest, and autoencoders [3]. Their study emphasised the importance of real-time, data-driven monitoring frameworks in situations where model-based or supervised methods are limited by the lack of labelled damage data. Fernandez-Navamuel and Magalhães proposed an ensemble method that combines PCA and autoencoders for feature extraction and damage detection in bridge vibration data [4]. Their hybrid approach improved sensitivity to structural changes while maintaining robustness in noisy environments, making it suitable for long-term monitoring

applications. Boccagna, Bottini, Petracca, and Amelio also supported hybrid techniques by combining convolutional autoencoders with PCA and Isolation Forest to detect anomalies in railway bridge vibration data [5]. Their results demonstrated the potential of integrating deep learning and traditional unsupervised methods to detect complex structural changes in simulated datasets. This work further reinforces the value of hybrid models, particularly where conventional techniques may struggle to capture subtle anomalies. Recent work by Toufigh and Ranjbar explored a deep autoencoder–Isolation Forest framework for detecting damage in concrete structures using ultrasonic vibration responses [6]. Their method integrated automatic feature extraction with unsupervised anomaly detection, offering an efficient and scalable solution without the need for labelled damage data. Similarly, Bayane, Leander, and Karoumi developed an unsupervised SHM pipeline using vibration-based features and anomaly detection techniques to monitor bridges [7]. Their results illustrated the practicality of using data-driven methods for real-time monitoring, especially in preventing costly maintenance or failure events.

In contrast to these studies, the model developed in this paper focuses on vibration data from bridge structures, particularly using statistical and spectral feature extraction methods (e.g., RMS, entropy), combined with the Isolation Forest algorithm trained exclusively on healthy data. The novelty of this approach lies in its use of a sliding window technique to segment the signal, enabling localised anomaly detection over time. This is especially valuable for identifying slowly progressing damage, such as cracking or fatigue, which may not be visible in global features. Additionally, the implementation of a consecutive anomaly rule ensures that damage is only flagged when anomalies persist across multiple windows, which increases robustness against transient noise and false positives. Together, these design choices make the system well-suited for large-scale, real-time SHM applications where computational efficiency and scalability are essential.

In this study, a finite element (FE) model of a simply supported beam was developed to simulate the dynamic response under both healthy and damaged conditions. A moving load was applied to reflect real-world traffic scenarios, and acceleration data were collected at mid-span. The time-series signals were segmented using a sliding window, and statistical and spectral features were extracted. These were used to train an unsupervised Isolation Forest model, aiming to detect structural damage based solely on deviations from the healthy baseline vibration signature.

## 2 METHODOLOGY

### 2.1 Simulation Setup

The finite element model represents a simply supported beam subjected to a moving load, as illustrated in Figure 1. This configuration is used to emulate bridge structures, where the

pinned–roller boundary condition provides a simplified yet effective representation of real-world support systems [8]. To ensure the accuracy of the model and to validate the results, the initial simulation setup was based on the approach outlined in [8]. Specifically, the model was first validated by replicating their results, ensuring that the acceleration of the mid-span of the beam matched their findings before proceeding to select the range of velocities and forces for further simulations.

The beam is discretised into ten elements, with damage introduced in a single element for selected cases[8]. In the validation setup, the damaged element is positioned at 35% of the beam's total span from the left support.

In this study, damage was introduced by locally reducing the stiffness of a single finite element in the beam by 20 per cent. The damage location remained static across all damaged simulations and was fixed at 35 per cent of the beam span from the left support, following the setup used in Mousavi and Holloway [8]. This fixed location was chosen to allow consistent comparison of model predictions across simulations and to simplify the initial sensitivity analysis. The reduction in stiffness was chosen to represent a moderate-to-severe degradation, such as advanced cracking or corrosion. While 20 per cent is a relatively large value, it was selected to ensure the damage signal was sufficiently distinct to validate the effectiveness of the detection method. Future work will explore smaller reductions and varying damage locations to assess the model's robustness in detecting more subtle or distributed damage scenarios.

Figure 1. The schematic of the simply supported beam with a moving load

A total of 200 dynamic simulations were conducted to evaluate the beam's acceleration under varying loading conditions—100 with undamaged beams and 100 with damage applied. For each simulation, the magnitude of the vertical force and the moving velocity were randomly selected within specified ranges, using uniform random sampling. The vertical force was chosen randomly between 5000 N and 15000 N, and the velocity was selected between 13 m/s and 25 m/s. This approach introduces variability in the system, ensuring that a range of realistic vehicle loading conditions is tested.

Material properties for the beam were based on structural steel, assuming linear elastic behaviour. To simulate structural degradation, damage was introduced by locally reducing the stiffness of a single element. This modelling approach is used

in the literature to represent localised damage within a linear elastic framework [9]–[11].

Huner, Irsel, Bekar, and Szala demonstrate that explicit solvers provide advantages over implicit methods in both computational efficiency and accuracy when dealing with transient impact loads [12]. An explicit solver (LS-DYNA) was used to perform the simulations, selected for its effectiveness in modelling highly dynamic and nonlinear systems.

All simulations were sampled at a frequency of 1000 Hz, ensuring high-resolution capture of the system's dynamic response. The main modelling parameters are listed in Table 1.

Table 1. System Parameters for the SHM model.

Quantity	Value
Modulus of elasticity	200 GPa
Density	7800 kg/m <sup>3</sup>
Poisson's ratio	0.3
Beam length (L)	20 m
Cross-section width (w)	0.2 m
Cross-section depth (h)	0.2 m
Sampling frequency	1000 Hz
Load range (F)	5000 – 15000 N
Velocity range (V)	13 – 25 m/s
Number of simulations	200 (100 damaged, 100 undamaged)

## 2.2 Anomaly Detection with Isolation Forest

An unsupervised anomaly detection framework was developed to identify structural damage from acceleration time-series data obtained from simulations of both healthy and damaged beam conditions. The overall procedure is summarised in Figure 2, which presents a flowchart of the anomaly detection pipeline. Although each simulation lasts only 1.54 seconds at the lowest velocity (13 m/s), the signals were concatenated across 100 healthy and 100 damaged runs to emulate continuous traffic loading. The resulting dataset was divided into overlapping windows of two seconds, with 50% overlap. This approach enables the system to track localised signal variations while preserving frequency content and computational efficiency.

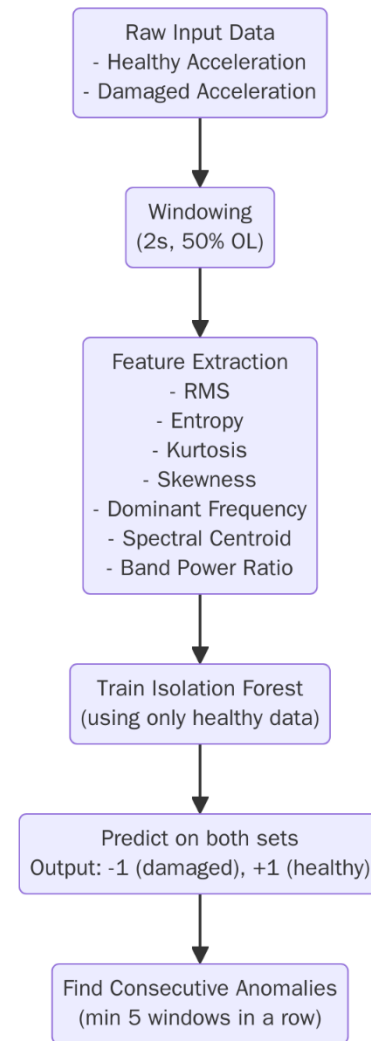

Figure 2. Flowchart of the anomaly detection model.

This configuration was selected to balance temporal and frequency resolution and improve the model's sensitivity to dynamic structural changes. While smaller window sizes were considered, they reduced the effectiveness of frequency-domain features and increased susceptibility to noise. The adopted strategy aligns with recent studies in structural health monitoring that use similar windowing to support reliable anomaly detection. An example of the sliding window approach used to segment the time-series data is illustrated in Figure 3.

Figure 3. Sliding windows illustration

For each window, a set of statistical and spectral features was extracted to characterise the dynamic response. The features used in this study include root mean square (RMS), entropy, kurtosis, skewness, dominant frequency, spectral centroid, and band power ratio. These features were selected for their proven utility in vibration-based structural health monitoring and are supported by recent benchmark studies.

An Isolation Forest model was trained exclusively on the healthy feature set to establish a baseline for normal structural behaviour. This algorithm builds an ensemble of binary trees (isolation trees), each of which recursively partitions the data space using randomly selected features and split values. The key idea is that anomalies differ sufficiently from the bulk of the data to be isolated more quickly. For any input vector  $x$ , the anomaly score is computed as:

$$s(x, n) = 2^{-\frac{E(h(x))}{c(n)}}$$

where:

- $h(x)$  is the path length, that is, the number of splits required to isolate the data point within a tree.
- $E(h(x))$  represents the average path length of  $x$  across all trees in the forest.
- $c(n)$  is the expected average path length in a binary search tree built from  $n$  samples. It is approximated by:

$$c(n) = 2H(n-1) - \frac{2(n-1)}{n}$$

Here,  $H(i)$  is the  $i$ th harmonic number, approximated by  $\ln(i) + \gamma$ , with  $\gamma \approx 0.5772$  being the Euler–Mascheroni constant. Data points with short path lengths (i.e. those isolated quickly) receive anomaly scores close to 1, indicating a higher likelihood of being anomalous. Normal points, which are harder to isolate, tend to have longer path lengths and receive scores closer to 0.

In this study, the IsolationForest implementation from the scikit-learn library (v1.6) was used. The number of trees (`n_estimators`) was set to 100 to ensure a stable estimation of anomaly scores. The `random_state` was fixed at 42 to ensure reproducibility. The `contamination` parameter, which estimates the expected proportion of anomalies in the dataset, was tuned to 0.085 based on preliminary experiments. This value provided a good balance between capturing true positives and minimising false detections.

After training on the healthy data, the model was applied to both healthy and damaged datasets. The `.predict()` method classified each window as either normal (+1) or anomalous (−1), depending on whether its anomaly score exceeded the threshold determined by the `contamination` setting. To enhance reliability, only groups of five or more consecutive anomalous windows were treated as an indication of structural damage. This post-processing step helped reduce the risk of false positives caused by transient fluctuations or signal noise, ensuring that only sustained deviations from the healthy baseline were flagged as damage.

Once trained, the model was used to classify both healthy and damaged windows as either inliers (labelled +1) or anomalies (labelled −1). To enhance the robustness of the classification and reduce false positives, a post-processing step was applied whereby only groups of five or more consecutive anomalous windows were considered indicative of actual damage. This thresholding logic aligns with practices in unsupervised SHM where transient anomalies or noise could otherwise trigger misleading alerts [17].

This decision was motivated by the observation that isolated anomalous predictions frequently arose due to short-lived signal fluctuations or imperfect feature generalisation. By requiring a minimum streak of five consecutive anomalies, the model avoids false alarms while still being sensitive to sustained deviations caused by damage. Additionally, the simulation data were not shuffled during concatenation. Instead, the 100 healthy simulations were placed first, followed by 100 damaged ones, ensuring a continuous transition from undamaged to damaged conditions in the time series. This ordering reflects a realistic monitoring scenario in which damage develops after a prolonged healthy period and also allows for visual and algorithmic evaluation of detection accuracy at the transition point.

### 3 RESULTS

The system's performance was evaluated using accuracy, precision, recall and F1-score metrics, with the confusion matrix providing a summary of classification outcomes. Results

The performance of the anomaly detection framework was evaluated using both visual comparison of signals and quantitative metrics derived from classification results.

Figure 4 shows a side-by-side comparison of raw acceleration data from the damaged and undamaged simulations. It is evident that the damaged signal (red) exhibits a higher density of peaks and more abrupt variations in magnitude than the undamaged signal (blue). This variation highlights the physical impact of stiffness reduction on dynamic response.

Figure 4. (a) Time-series comparison of acceleration signals between damaged and undamaged beams at mid-span from 101 to 103 seconds under a 10,000 N moving load at 15 m/s.

(b) Kernel density estimate of full signal distributions, showing increased spread in the damaged case.

Figure 5 illustrates the point of transition between healthy and damaged data in the concatenated signal, where the black dashed line marks the onset of damage. This figure does not represent a change in damage location, but rather demonstrates the model's ability to correctly identify the onset of anomalous behaviour. The Isolation Forest model successfully distinguishes between the two conditions, with no false

Figure 5. Mid-span acceleration response under moving load for healthy and 20% stiffness-reduced beam. Dashed line marks detected damage.

The confusion matrix in Figure 6 provides a quantitative view of the model's predictive accuracy. Out of 945 damaged windows, all were correctly identified, yielding a recall of 1.000. Meanwhile, 860 out of 945 healthy windows were correctly classified, producing a precision of 0.917. The overall accuracy of the model was 0.955, and the F1 score was 0.957, indicating a strong balance between precision and recall.

Figure 6. Confusion matrix for SHM anomaly detection.

Table 2. Anomaly detection performance metrics.

Metric	Value
Accuracy	0.955
Precision	0.917
Recall	1.000
F1 Score	0.957
True Positives (TP)	945
True Negatives (TN)	860
False Positives (FP)	85
False Negatives (FN)	0

These results, summarised in Table 2, demonstrate that the proposed combination of statistical and spectral features with an unsupervised Isolation Forest algorithm is effective in identifying structural damage using only healthy training data. The perfect recall of 1.000 confirms the model's ability to detect all instances of damage under the simulated conditions. While this result is promising, it may also reflect the relatively distinct nature of the simulated damage (a 20% stiffness reduction), which provides a clear contrast to the healthy baseline. In real-world scenarios, where damage may be more subtle or masked by noise, recall performance may vary. Nonetheless, achieving full sensitivity in this setup is an important step toward validating the model's potential for practical SHM applications.

The absence of false negatives indicates that the selected features, including root mean square, kurtosis and spectral centroid, are sensitive enough to detect changes in the mid-span acceleration response associated with damage. Permutation feature importance analysis in Figure 7 supports this, showing that RMS had the greatest influence on the model's predictions, while entropy, kurtosis and skewness contributed less. This highlights the importance of signal energy in distinguishing damaged from undamaged states and suggests that the model relied primarily on RMS to detect anomalies.

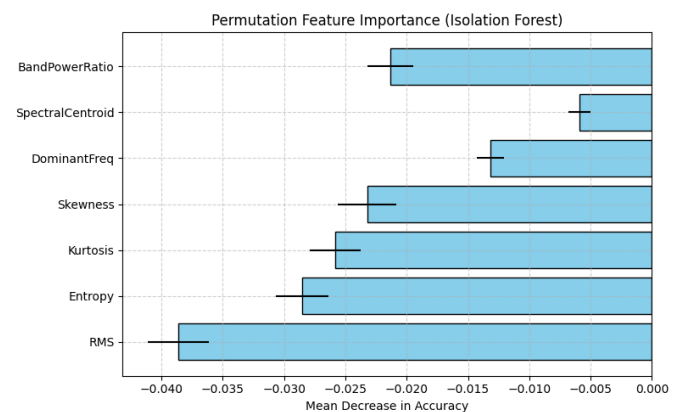

Figure 7. Permutation feature importance showing the relative contribution of all features to the Isolation Forest model's anomaly detection performance.

However, the presence of 85 false positives, reflected in a precision of 0.917, suggests that some healthy windows exhibited irregular but non-damaging patterns. These anomalies may be due to transient structural behaviours, elevated loads, or complex vibration modes that were not well represented in the training data.

This result reflects a trade-off between sensitivity and specificity. In structural monitoring applications, prioritising recall is often preferred, as missing damage poses a greater risk than raising a false alarm. The high F1 score of 0.957 supports the strength of this balance. Nevertheless, repeated false positives may reduce user trust in the system and increase inspection costs. To address this, further work is needed to

investigate the nature of these misclassifications and explore feature refinement or adaptive thresholding strategies that can improve specificity without compromising detection accuracy.

The simulations used in this study were designed to represent realistic bridge conditions, based on established finite element modelling techniques reported in structural health monitoring literature. A simply supported beam was subjected to a moving load, with force and velocity ranges chosen to reflect typical vehicle traffic scenarios. By randomly sampling these parameters across simulations, the model captures a level of variability comparable to that seen in practice. However, while the simulations reproduce essential structural behaviours, certain complexities that exist in real-world monitoring, such as sensor noise, thermal drift, and environmental changes, were not included. Although the method performs well in this controlled environment, additional validation using experimental or field data is needed to confirm its applicability in real conditions.

In this study, damage was introduced by reducing the stiffness of a single element in the finite element model by 20%. This level of degradation represents a significant structural change, such as might result from cracking or corrosion. The resulting increase in vibration energy was clearly detectable in the acceleration signal, particularly at the beam's mid-span. While the model achieved full sensitivity to this level of damage, its performance with smaller changes remains to be assessed. Reductions in stiffness of 5%-10%, for example, may produce more subtle variations in the signal, making them harder to distinguish from normal fluctuations. Future work will investigate how sensitive the model is to such smaller degradations and how well it performs under more realistic conditions that include noise and environmental variation.

All results presented in this study are based solely on finite element simulations. While these simulations provide a controlled and repeatable environment for evaluating the proposed method, they do not capture the full complexity of real-world monitoring scenarios. It is well known that vibration-based damage detection techniques often face challenges in practical applications due to noise, environmental variability, temperature effects, and operational conditions. These factors can introduce variability that may obscure subtle signs of damage or increase the rate of false positives.

We acknowledge this as a limitation of the current study and plan to address it in future work. Specifically, we aim to validate the approach using real-world sensor data collected from instrumented laboratory-scale bridge models or in situ field deployments. This would involve applying accelerometers to physical structures subjected to controlled damage and comparing the model's predictions against ground truth. Such validation is essential for assessing the robustness and transferability of the proposed method and would provide critical insights into how it performs under realistic operating conditions.

#### 4 CONCLUSION

This study set out to develop and evaluate an unsupervised machine learning framework for structural health monitoring (SHM), with the specific aim of detecting damage using only vibration data from healthy structural conditions. The motivation was to address the limitations of supervised approaches that rely on labelled damage data, which is often unavailable or impractical to collect in real-world scenarios.

The proposed method combined lightweight time-domain and frequency-domain features with an Isolation Forest anomaly detection model, further enhanced by a consecutive anomaly rule to reduce false positives. The approach was tested on simulated acceleration data from both healthy and damaged beam configurations. Results showed that the model achieved high detection accuracy, with perfect recall and no false negatives, indicating strong sensitivity to damage. Precision and F1 scores also demonstrated the model's ability to reliably distinguish between normal and abnormal structural behaviour, despite being trained exclusively on healthy data.

These findings confirm the method's suitability for low-cost, real-time deployment on civil infrastructure, particularly in settings where computational resources and data availability are constrained. Although this study relied on simulated data, it provides a solid foundation for future experimental validation using real-world sensor inputs. Further refinement may focus on improving robustness to environmental variability and exploring hybrid models to enhance detection performance.

**ABSTRACT:** Structural health monitoring is essential for ensuring the safety, reliability, and longevity of infrastructural assets. However, conventional monitoring measurements face significant challenges, such as being labor-intensive, costly, and time-consuming. In recent years, the rise of machine learning and deep learning has data analysis frameworks, offering a promising solution to these challenges. Despite this, developing reliable and robust approaches that generalize well to unseen scenarios often requires large amounts of training data. This presents a challenge, mainly with regulatory constraints and difficulties in collecting data, particularly for rare events. To address the issue of data scarcity, this study proposes a generative data augmentation approach using a Wasserstein Generative Adversarial Network (WGAN). This approach generates high-quality short-time Fourier transform (STFT) spectrograms, which are transformed into image-like data, from in-situ acceleration signals for model training. The collected signals, recorded from real-world bridges during various events such as hammering, drilling, environmental noise, and, most importantly, the rare event of wire breakage in prestressed concrete bridges, are processed and fed into the WGAN model to synthesize additional data. This improves the diversity and robustness of training datasets. Evaluation of the generated spectrograms using various performance metrics, such as Structural Similarity Index Measure, Peak Signal-to-Noise Ratio, and Fréchet Inception Distance, demonstrates that the proposed method offers a scalable and cost-effective solution for enhancing the training dataset, particularly in scenarios where event data is sparse, such as prestressing wire breakage.

## 1 INTRODUCTION

Bridges are critical infrastructures for transportation and economic development, but are increasingly vulnerable to deterioration caused by aging, traffic loads, and environmental impacts [1]. Structural Health Monitoring (SHM) is essential for the early detection of damage, as highlighted by failures such as the Reale Viaduct and Fossano Bridge collapses in Italy [2, 3]. However, conventional SHM methods, such as visual inspections, are often costly, labor-intensive, and ineffective at detecting subtle or internal damage. Although sensor-based methods offer improvements, they generate complex and noisy data, making manual analysis difficult [4]. As a result, recent advances in Machine Learning (ML) and Deep Learning (DL) have emerged as promising approaches, demonstrating strong performance across various domains, including structural damage detection [5, 6]. Nevertheless, real-world implementation of these methods still faces challenges, particularly data scarcity and class imbalance, which are especially essential for rare events like wire breakage, an internal form of structural damage that is difficult to capture.

Data augmentation (DA) techniques have been proposed to address these issues, but conventional methods like Mixup and time-shifting are insufficient for replicating the complexity of real-world events. In this study, Generative Adversarial Networks (GANs) are proposed as a powerful solution for generating realistic synthetic data. Prior work, mainly in speech and audio generation, has demonstrated the effectiveness of spectral-domain representations, such as STFT spectrograms, for improving generative models. However, applications of GANs in SHM, particularly for STFT-based augmentation, remain limited.

To address this gap, this study utilized Wasserstein GAN using gradient penalty (WGAN-GP), a GAN model designed to generate single-channel STFT spectrograms specifically for SHM applications. Unlike traditional three-channel approaches, the single-channel input maintains the spectral information of structural vibration signals. This study also

provides a unique real-world dataset from two operational bridges in Italy, offering realistic and challenging data for model training and validation. By enhancing dataset diversity and improving model robustness, the proposed approach aims to tackle key SHM challenges, advancing scalable, adaptive, and reliable monitoring frameworks. The methodology, experimental setup, evaluation strategies, and detailed analysis are presented to support future developments and replication steps.

## 2 METHODS

### 2.1 Generative Adversarial Networks

GANs are a type of generative model that learns patterns in data and generates new samples that resemble the original dataset [7]. GANs consist of two neural networks, competing in a zero-sum game: the generators, which create the synthetic data, and the discriminator, which distinguishes between the real and generated data (Figure 1). The generator aims to minimize the discriminator's ability to differentiate between real and fake samples, while the discriminator tries to maximize its ability to classify data correctly.

GANs' training can be challenging due to issues like mode collapse and gradient instability. To address this challenge, Wasserstein GAN (WGAN) was introduced [8]. In this approach, the Wasserstein distance (Earth Mover's distance) was utilized to measure the difference between the real and generated data. The WGAN replaces the discriminator with a critic network, which provides more stable gradients, avoiding the problem of vanishing gradients in traditional GANs.

To further improve training stability, WGAN with gradient penalty (WGAN-GP) was introduced [9], which added a gradient penalty in the loss function. This term makes the critic's gradient more stable and smooth and improves convergence. The WGAN-GP loss functions are:

$$L_D = \frac{1}{N} \sum_{n=1}^N [d(g(z_n)) - d(x_n)] + \lambda \cdot E[(|\nabla d(\hat{x})|_2 - 1)^2]$$

In this equation  $d(x_n)$  and  $d(g(z_n))$  are the critic's outputs for real and generated images, respectively.  $N$  is the batch size and  $\lambda$  is controlling the strength of the gradient penalty.

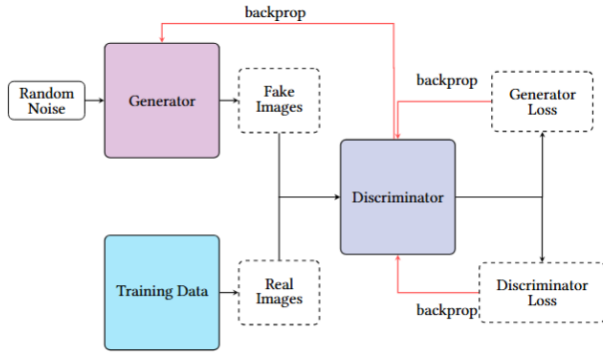

Figure 1. Overview of Generative Adversarial Networks.

## 2.2 Evaluation Metrics

### 2.2.1 Structural Similarity Index Measure (SSIM)

SSIM evaluates the similarity between two images by considering structural information, such as luminance, contrast, and structure. The SSIM score ranges from 0 to 1, with 1 being perfect similarity [10].

$$SSIM = \left( \frac{2\mu_x\mu_y + c_1}{\mu_x^2 + \mu_y^2 + c_1} \right) \cdot \left( \frac{2\sigma_x\sigma_y + c_2}{\sigma_x^2 + \sigma_y^2 + c_2} \right) \cdot \left( \frac{\sigma_{xy} + c_3}{\sigma_x\sigma_y + c_3} \right)$$

In this equation,  $x$  and  $y$  are image patches.  $\mu_x$  and  $\mu_y$  are the mean intensities of the image  $x$  and  $y$ .  $\sigma_x$  and  $\sigma_y$  are the standard deviations and  $\sigma_{xy}$  is the covariance, and  $c$  is the constant value to prevent division by zero.

### 2.2.2 Peak Signal-to-Noise Ratio (PSNR)

PSNR measures the similarity between two images by comparing the maximum pixel value to the noise in the image. Higher PSNR value indicates better quality [11].

$$PSNR(R, G) = 10 \log_{10} \left( \frac{MAX_I^2}{MSE} \right)$$

$R$  and  $G$  refer to the real and generated images, respectively.  $MAX_I$  is the maximum possible pixel value (set to +1 in this study due to normalization), and  $MSE$  is the mean squared error between the real and generated images.

### 2.2.3 Fréchet Inception Score (FID)

FID measures the distance between the feature distributions of real and generated images [12]. A lower FID score indicates better image quality.

$$FID = \|\mu_r - \mu_g\|^2 + Tr(\Sigma_r + \Sigma_g - 2(\Sigma_r \Sigma_g)^{\frac{1}{2}})$$

$\mu_r$  and  $\mu_g$  are the mean feature vectors of the real and generated images, respectively.  $\Sigma_r$  and  $\Sigma_g$  are the covariance matrices of the real and generated images.  $Tr$  refers to the trace of the matrix, which is the sum of its diagonal elements.

## 2.3 Acquisition Setup and Data Collection

The experimental framework was conducted on two post-tensioned concrete bridges in Italy, Le Pastena and Cerqueta. The data collection phase was performed during the deconstruction and maintenance phase with a collaboration between Politecnico di Torino and Strada dei Parchi S.p.A. Due to the bridges' height and limited access, a Mobile Elevated Work Platform (MEWP) was used for instrumentation setup. The wire cutting process, performed on twisted tendons, was carried out using an electric trimmer in a controlled setup after the prestressing tendons were exposed.

The primary dataset was acquired using two accelerometers (Model 805M1, DSPM Industria srl), placed 4.5 meters from the cutting point on the sides of the beams. This setup was chosen to ensure the signal could be reliably recorded, considering the effects of signal attenuation and dispersion along the propagation path. These propagation effects can influence the measured acceleration signals and, consequently, the generated spectrograms. These accelerometers recorded structural vibrations during wire cutting, with a high sampling rate of 96 kHz and a frequency response of 0.4 to 12 kHz. In addition to the rare event of wire breakage signals, other vibrational events such as hammering, electric trimmer, and traffic were captured. This comprehensive dataset ensures the development of a robust model for generating sound events and further development of more generalized automated systems (Figure 2).

Figure 2. Sensor positions on La Patenda Bridge.

## 2.4 Experiments

### 2.4.1 Feature Extraction

The dataset used in this study comprises four signal classes: wire breakage (202 samples), hammering (264 samples), electric trimmer (459 samples), and traffic (415 samples). As it is evident, there is a class imbalance, with critical events like wire breakage being underrepresented, which may affect model performance. The signals were captured at a sampling frequency of 96 kHz, with each signal having 1000 samples over 0.0104 seconds (Figure 2). To ensure consistency and reduce bias from varying amplitudes, all signals were normalized before further processing.

Figure 3. Time-domain representation of the wire breakage acceleration signal (units: m/s<sup>2</sup>).

This study uses Short-Time Fourier Transform (STFT) for feature extraction from in-situ acceleration signals to analyze event patterns. STFT transforms signals from the time domain to the two-dimensional time-frequency domain, keeping both temporal and spectral information. One important parameter in STFT analysis is the window size selection, which can affect the trade-off between time and frequency resolution. Smaller window sizes (e.g., 64) offer high time resolution but low frequency resolution, while larger windows (e.g., 512) provide better frequency resolution but less temporal precision. In this study, the optimal balance was achieved using window sizes of 128 and 256 (Figure 3). The extracted STFT spectrograms were used as single-channel images for model training, optimizing feature extraction and computational efficiency for event detection and structural health monitoring applications.

Figure 4. STFT spectrogram of a wire breakage signal. The x-axis represents time (seconds), the y-axis represents frequency (Hz).

### 2.4.2 Model Developments

The WGAN-GP was implemented as one of the most successful models for image generation. It improves on the standard GAN and WGAN models by using the Wasserstein loss function and adding a gradient penalty. The generator starts with a latent noise vector of size 100, a typical setting in GAN studies. This vector is reshaped into small feature maps and upsampled through transposed convolutional layers to generate spectrogram-like images. In this study, the generator consists of four transposed convolutional layers with kernel sizes of 5×5 and strides of 2, progressively reducing the feature map depth from 512 to 256, 128, and 64 before producing the final spectrogram. To ensure stable training and avoid vanishing or exploding gradients, batch normalization is applied after each layer. Leaky ReLU activation is used throughout the layers to add non-linearity, except in the final layer, where a tanh activation function normalizes the output values to the range [-1, 1].

The critic, unlike the discriminator, does not classify samples as real or fake; instead, it assigns real-valued scores to samples, helping to approximate the Wasserstein distance between real and generated data. The critic consists of several 2D convolutional layers, which progressively reduce the spatial dimensions of the input, followed by batch normalization and Leaky ReLU activations to improve learning stability. To enforce the Lipschitz constraint, a gradient penalty term with a coefficient of  $\lambda=12$  is added to the loss function. The selection of hyperparameters search space was based on a combination of recommendations from GAN literature and preliminary tuning experiments on dataset to achieve stable and high-quality spectrogram generation. The summary of hyperparameter selection for this model is in Table 1.

Table 1. Hyperparameter Selection for WGAN-GP Model

Parameter	Value	Search Space
Learning Rate (Generator)	$2 \times 10^{-5}$	$2 \times 10^{-5}$ to $2 \times 10^{-5}$
Learning Rate (Critic)	$2 \times 10^{-6}$	$2 \times 10^{-5}$ to $2 \times 10^{-5}$
Batch Size	16	16 to 64
Epochs	1500	1000 to 5000
Optimizer	Nadam	Nadam, Adam, RMSProp
Gradient Penalty Coefficient	12	1 to 25
Activation Function (Generator)	Leaky ReLU, Tanh	Leaky ReLU, ELU, Tanh
Activation Function (Critic)	Leaky ReLU	Leaky ReLU, ELU, Tanh
Generator Layers	4 Transposed Convolutions	3 to 8
Critic Layers	5 Convolutions	3 to 8
Kernel Size	5x5	3x3 to 5x5

To assess the performance of WGAN-GP and the quality of generated images, the model was evaluated using multiple metrics, including SSIM, PSNR, and FID. The results are shown in Table 2 for both window sizes of 128 and 256, which enable the determination of the effect of window sizes in generating STFT-based images.

Table 2. Performance Metrics of WGAN-GP

Metrics	Class	Window Size:128	Window Size:256
SSIM	Breakage	<b>0.367</b>	0.180
	Trimmer	0.342	<b>0.403</b>
	Hammer	0.208	0.232
	Traffic	0.170	0.186
PSNR	Breakage	13.409	11.972

	Trimmer	<b>13.424</b>	<b>13.621</b>
	Hammer	10.520	11.289
	Traffic	11.374	12.020
FID	Breakage	0.219	0.331
	Trimmer	<b>0.173</b>	0.270
	Hammer	0.221	<b>0.194</b>
	Traffic	0.179	0.237

For SSIM, WGAN-GP achieved the highest value for the Trimmer event at window size 256 (0.403), indicating better structural similarity compared to the other events. It is notable that for the breakage event at a window size of 128, the score dropped from 0.367 to 0.18, which suggests that the model is not able to preserve the pattern of more complex signals, such as wire breakage. For Hammer and Traffic events, the SSIM values were relatively lower, indicating that WGAN-GP had difficulty maintaining high structural similarity for these types of events across both window sizes.

In terms of PSNR, which measures image clarity and noise levels, the best performance was obtained for the Trimmer event with a PSNR of 13.424 at window size 128 and 13.621 at window size 256, indicating that WGAN-GP generated spectrograms with minimal distortion for this event. However, the Breakage event exhibited lower PSNR scores, particularly at window size 256 (11.972), highlighting a reduction in image quality for events with more intricate features. Hammer and Traffic events also showed similar trends, with Traffic performing better at window size 256 (12.020). For reference, higher PSNR values indicate greater similarity, with values above 20 generally considered good for images; however, in the context of generated spectrograms, PSNR values are typically lower, and values above 10 are commonly reported as acceptable in the literature for synthetic data with complex structures.

The FID metric, which evaluates the similarity between real and generated data distributions, showed that WGAN-GP performed well for the Trimmer event at window size 128 (FID of 0.173). However, it struggled with Breakage and Hammer, with higher FID scores indicating that the generated spectrograms deviated more from real data. Overall, Traffic also showed relatively low FID values at both window sizes, indicating good model performance for simpler events.

Figure 5. STFT Spectrogram images (window size 128) of wire breakage signal (Left) Real Sample, (Right) Generated by WGAN-GP. The x-axis represents time (seconds), the y-axis represents frequency (Hz).

In summary, WGAN-GP demonstrated strengths in generating synthetic spectrograms for certain events like

Trimmer and Traffic, especially at window size 128. However, the model faced challenges in generating high-quality spectrograms for more complex events such as Breakage and Hammer, particularly at larger window sizes. These results highlight the need for further development and utilization of GAN models to better capture fine spectral features and improve consistency across different types of events.

## 2.5 Conclusion and Future Developments

This study demonstrated the potential of GAN-based data augmentation in the context of structural health monitoring using STFT spectrograms from in-situ acceleration signals. The model showed promising performance, particularly for Trimmer and Traffic events. However, it is important to note that WGAN-GP showed some limitations in generating more complex STFT patterns, such as those associated with Wire Breakage events.

To further improve the model, future work will focus on addressing these limitations by refining and customizing the architecture. Additionally, integrating more advanced models, such as sequential models and attention mechanisms, which are robust for time-series data, will be explored to enhance the model's ability to capture intricate temporal dependencies and improve the generation of complex event patterns. Furthermore, future studies will systematically evaluate the impact of GAN-generated data on downstream event classification and detection models to better quantify the practical benefits of data augmentation for structural health monitoring.

**ABSTRACT:** Achieving both energy efficiency and high triggering accuracy is a critical multi-objective optimization challenge in Structural Health Monitoring (SHM), particularly for power-constrained wireless edge devices deployed in dynamic environments. Traditional empirical and static-threshold-based methods often struggle to simultaneously have low miss trigger and false trigger rate and lack adaptability to varying environmental and operational conditions. This study proposes a multi-stage adaptive triggering strategy built upon a Feedback Control (FC) framework, driven by Bayesian Optimization (BO) as the optimization engine, and accelerated by Digital Twin (DT) for data augmentation and Neural Networks (NN) for real-time contextual understanding and robust inference. The strategy dynamically refines triggering thresholds based on simulated insights and partial observations, enabling rapid adaptation and generalization across scenarios. Experimental validation through simulations and onboard deployments demonstrates that the proposed method improves F-beta performance by over 30% compared to conventional empirical methods. This approach provides a promising pathway toward intelligent, energy-efficient, and sustainable SHM sensing through fast feedback, reduced deployment cost, and minimized missed critical events.

**KEY WORDS:** Trigger Sensing, Energy-efficiency, Adaptive Sensing, Feedback Control, Bayesian Optimization, Structural Health Monitoring

## 1 INTRODUCTION

In Structural Health Monitoring (SHM) systems, triggering mechanisms are essential for determining when edge sensor nodes should initiate data acquisition to capture transient structural responses during events of interest [1]. In real-world deployments with limited energy resources, triggering directly affects both responsiveness and long-term system sustainability. A mechanism that is both energy-efficient and accurate allows the system to capture meaningful data while minimizing power consumption [2]. When continuous high-rate sampling is infeasible, intelligent triggering becomes critical for reliable and autonomous monitoring.

Conventional methods typically rely on fixed thresholds or handcrafted rules based on prior knowledge [3]. While easy to implement and low in computational cost, they lack adaptability. Triggering parameters (e.g., threshold and duration) set during deployment often remain static, making it difficult to respond to changes in structural behavior or environmental conditions. In practical deployments, these parameters are often conservatively configured to minimize the risk of missing events of interest. This conservative strategy prioritizes recall at the expense of precision, which, although effective in reducing missed detections, often leads to an increased rate of false triggers [1].

Practical SHM deployments present several challenges that complicate the design of effective triggering mechanisms. Structural events are typically rare, limiting the amount of available data and making it difficult to establish reliable patterns for triggering. The occurrence of events is also highly imbalanced, with most data corresponding to normal or inactive states, which biases learning-based methods and complicates threshold design. In addition, due to energy constraints, sensors

operate in low-power sentinel modes and only acquire data when a triggering condition is met. As a result, only responses associated with triggered events are recorded, leading to partial observability, where only a subset of structural behaviors is accessible for analysis [4]. These factors collectively call for a triggering mechanism that is adaptive, context-aware, and lightweight, while also possessing the capability to predict and infer unobserved structural responses.

To address these challenges, this study proposes a multi-stage adaptive triggering strategy primarily built upon a Feedback Control (FC) framework [5], which integrates a digital twin (DT) [6], onboard neural networks (NN) [7] [8], and Bayesian optimization (BO) [9]. FC enables the continuous refinement of triggering behavior through performance-driven feedback; BO operates as an optimization engine that seeks the global optimum and guides trigger parameters toward rapid convergence; DT facilitates data augmentation by simulating real deployment environments; NN provides real-time contextual awareness and accurate prediction, even under partial observability. This integration empowers the triggering system to adaptively and efficiently search for the optimal trigger parameters under uncertain event conditions.

The proposed strategy is validated upon a setup mimicking real-world deployment, showing clear advantages over empirical baselines. Specifically, it achieves over 30% improvement in  $F_\beta$  score, enhancing event detection without increasing unnecessary energy use. These findings demonstrate the effectiveness of the proposed strategy in simultaneously optimizing detection accuracy and energy efficiency, and further underscore the potential of integrating closed-loop control, Bayesian optimization, and digital twin to enable

adaptive and intelligent triggering in real-world SHM deployments.

## 2 SMART ADAPTIVE TRIGGERING

### 2.1 Basic triggering mechanism and baseline strategy

An example of a typical trigger sensing mechanism is the one implemented in Xnode [2], which combines a low-power, low-resolution sensor with a high-power, high-resolution sensor, as illustrated in Figure 1 and Table 1. The low-power sensor, such as the ADXL362 [10], is responsible for continuously monitoring motion and detecting events of interest based on predefined thresholds and durations. When the signal amplitude exceeds the configured threshold for a specified duration, an event of interest is deemed to have occurred, as shown in Figure 1. At this point, the low-power sensor activates the high-power sensor, transitioning the system from sentinel mode to working mode to capture detailed event data. This fundamental triggering mechanism forms the basis of the smart adaptive triggering strategy proposed in this study.

Table 1. Xnode sensor energy consumption.

Mode \ Sensor	ADXL362 (12 bit)	LIS344 (24 bit)
Sentinel Mode	Working 270nA	Sleeping 1uA
Working Mode	Sleeping 10nA	Working 680uA

Figure 1. Xnode trigger sensing mechanism.

In SHM practice, the application of basic triggering mechanisms is typically accompanied by parameter configuration using empirical approaches. Engineers often perform preliminary sensing to gain insights into the target structure or environment, and subsequently configure the triggering parameters (i.e., threshold and duration) manually in a conservative manner to ensure low miss trigger rate [2]. This empirically tuned method also serves as the baseline for comparison in subsequent sections.

### 2.2 Feedback control powered by Bayesian optimization

As stated in the introduction, the goal of the triggering mechanism is to minimize missed triggers while keeping the false trigger rate at an acceptably low level, which constitutes a multi-objective optimization problem in its mathematical nature. To facilitate the analysis, the  $F_\beta$  score is introduced to

quantitatively and comprehensively evaluate the performance of the triggering mechanism, as defined in Equation (1). Note that with the use of  $F_\beta$ , the original multi-objective problem is transformed into a single-objective optimization problem, where the parameter  $\beta$  controls the relative weighting between missed and false triggers. In SHM context, usually more weight should be put on recall, which means  $\beta$  should be configured greater than 1. For situations where precision is more important than recall, e.g., false triggering can be quite costly,  $\beta$  should be smaller than 1.

$$F_\beta = (1 + \beta^2) \frac{\text{Precision} \cdot \text{Recall}}{\beta^2 \cdot \text{Precision} + \text{Recall}} \quad (1)$$

Based on the analysis presented in the introduction, smart adaptive triggering centers on two key questions: what are the optimal triggering parameters, and how they can be efficiently approached during system operation. The first question represents an optimization problem, while the second constitutes a control problem. A major limitation of most existing triggering mechanisms lies in their lack of adaptivity, which can be effectively addressed through a feedback loop. As illustrated in Figure 2(a), the triggering mechanism outputs a performance metric to the optimizer, which in turn determines the next parameter configuration to explore based on historical observations. To comply with modern control theory [5], the closed loop can be expressed as Figure 2(b). Figure 2(b) depicts the formal structure of feedback control, comprising four main components: the environment, the system, the estimator, and the controller. In the context of trigger-based SHM, the environment refers to the structural responses that sensors aim to observe. The system corresponds to the triggering mechanism itself, as shown in Figure 1. The estimator is responsible for monitoring or estimating the performance of the triggering mechanism, specifically, the  $F_\beta$  score in this study. The controller, in turn, utilizes iterative feedback to search for the optimal parameter configuration and to devise strategies for efficiently approaching the optimal values. In short, feedback control serves as a backbone to integrate necessary tools to provide adaptivity for triggering parameter fine-tuning.

Figure 2. Feedback control framework for triggering parameter optimization: (a) optimization loop; (b) feedback control form.

At the core of the feedback control architecture is the controller, which governs the adaptation process through parameter adjustment. While various tools can be used to implement the controller, the choice must be carefully tailored to the characteristics of the target problem. In the case of trigger-based SHM, the controller takes the  $F_\beta$  score as input and outputs the triggering threshold and duration. However, there is no explicit analytical expression linking the input to the output, making it a black-box optimization problem. Moreover, each feedback iteration requires calculating the  $F_\beta$  score based on many events, resulting in considerable computational cost, in addition to the overhead of observation and estimation. Given these considerations, Bayesian optimization [9] is adopted as the controller due to its demonstrated effectiveness in solving black-box problems and its ability to efficiently converge toward the global optimum.

The algorithmic framework of BO is presented in Algorithm 1. As illustrated, the optimization process is driven by the observation dataset  $\mathcal{D}$ , which comprises input–output pairs, where the inputs are the triggering parameters, and the outputs are the corresponding  $F_\beta$  scores. The process begins with an initial sampling phase to obtain a preliminary understanding of the input–output relationship. Subsequently, the optimization proceeds iteratively, with each iteration updating the surrogate model  $\mathcal{M}$  and expanding the dataset with new evaluations. Typically based on Gaussian Process Regression (GPR), the surrogate model provides a non-parametric, probabilistic estimate of the objective function, offering both the predicted mean and associated uncertainty for any given input. This probabilistic nature enables GPR to model complex, non-linear relationships with relatively few samples, while maintaining analytical tractability and useful mathematical properties such as differentiability. To balance exploration of uncertain regions and exploitation of promising areas, an acquisition function  $\mathcal{S}$  is employed to determine the most informative point  $x_i$ . Common acquisition functions include Expected Improvement (EI), Probability of Improvement (PI), and Upper Confidence Bound (UCB), each offering a different strategy for leveraging the predictive mean and variance to guide sampling. Herein, UCB is used for simplicity. After evaluating the objective function to obtain the corresponding output  $y_i$ , the dataset  $\mathcal{D}$  is updated. Finally, the input  $\hat{x}$  associated with the best observed output in  $\mathcal{D}$  is selected as the optimum.

#### Algorithm 1 Bayesian Optimization Algorithm Framework

**Input:** Search space  $\mathcal{X}$ , objective function  $f$ , surrogate model  $\mathcal{M}$ , acquisition function  $\mathcal{S}$

**Output:** Dataset  $\mathcal{D}$  (set of sampled points and their evaluations)

Initialize dataset:  $\mathcal{D} \leftarrow \text{InitSamples}(f, \mathcal{X})$

**for**  $i = |\mathcal{D}|$  to  $T$  **do**

Fit the model:  $p(y|x, \mathcal{D}) \leftarrow \text{FitModel}(\mathcal{M}, \mathcal{D})$

Select next point:  $x_i \leftarrow \arg \max_{x \in \mathcal{X}} \mathcal{S}(x, p(y|x, \mathcal{D}))$

Evaluate objective function:  $y_i \leftarrow f(x_i)$

Update dataset:  $\mathcal{D} \leftarrow \mathcal{D} \cup \{(x_i, y_i)\}$

**end for**

Pick the best from  $\mathcal{D}$  as optimum:  $\hat{x} \leftarrow \arg \max_{(x,y) \in \mathcal{D}} y$

After introducing the algorithmic details, it becomes evident that the surrogate model  $\mathcal{M}$  plays a central role in addressing the black-box nature of the problem by providing a reliable approximation of the true input–output relationship along with favorable mathematical properties. Meanwhile, the acquisition function  $\mathcal{S}$  serves as the foundation for efficient convergence toward the global optimum, as it guides the search process in a principled manner rather than relying on random exploration.

As can be inferred by Algo. 1, the computational efforts required for BO for the following edge deployment is mainly determined by the size of observation dataset  $\mathcal{D}$ , and each sample in this dataset is only a pair of triggering parameters and performance metric, meaning it can be easily operated on edge devices.

### 2.3 Digital twin for data augmentation

Feedback control is a powerful tool to address the lack of adaptivity; however, it falls short in tackling another critical challenge—data scarcity, imbalance, and uncertainty. Digital twin technology offers a promising solution to augment data for a variety of purposes, such as simulation, optimization, and neural network training. To effectively construct a digital twin for trigger-based sensing for SHM, it is essential to accurately simulate both the structural response and the triggering mechanism. Specifically, this involves modeling the excitation–structure–response chain as well as the threshold–duration-based triggering logic, as shown in Figure 3.

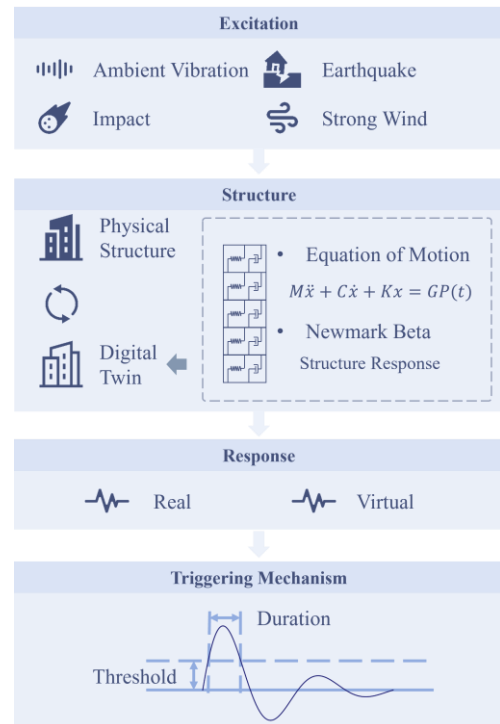

Figure 3. Digital twin for excitation-structure-response flow and triggering mechanism.

Excitation simulation is the first step in structural response modeling. To support the study, several common types of events are considered, including ambient vibrations, earthquakes, impacts, and strong winds. Each event type can be

generated using either external databases or simulation techniques. Ambient vibrations are typically modeled using Gaussian white noise, while earthquakes can be synthesized by superimposing harmonic waves based on a given spectrum. Impacts are represented as impulsive loads, and strong winds can be simulated using autoregressive models combined with time modulation.

Structure modeling is another crucial step in response simulation, achieved by formulating the equation of motion, as shown in Equation (2). In this equation,  $M, C, K$  represent the mass, damping, and stiffness matrices, respectively.  $G$  denotes the force allocation matrix, and  $P(t)$  represents the external force vector at time  $t$ . Equation (2) thus serves as a digital twin of the target structure to be monitored. Following structural modeling is the simulation of structural responses, which involves calculating the displacement, velocity, and acceleration of each degree of freedom in the constructed digital twin. A widely used and reliable numerical method for this purpose is the Newmark-beta method [11], which provides accurate structural response simulation.

$$M\ddot{x} + C\dot{x} + Kx = GP(t) \quad (2)$$

In addition to structural responses, the basic triggering mechanism must also be simulated to complete the digital twin, with implementation details provided in Algorithm 2. With a comprehensive digital twin that includes both the structural model and the triggering logic, data can be flexibly manipulated for various purposes, such as simulation, optimization, neural network training, and more.

---

**Algorithm 2** Triggering Mechanism

---

**Input:** signal value  $s$ , threshold  $\tau$ , duration  $d$

**Output:** trigger flag  $T$  (binary: 1 for trigger, 0 for no trigger; initialized as 0)

**Internal Variable:** counter  $c$  (initialized as 0, used to track consecutive time steps)

For each time step  $t$ :

if  $|s| \geq \tau$  then

Increment counter:  $c \leftarrow c + 1$

if  $c \geq d$  then

Set trigger flag:  $T \leftarrow 1$

Reset counter:  $c \leftarrow 0$

end if

else

Reset counter:  $c \leftarrow 0$

Set trigger flag:  $T \leftarrow 0$

end if

---

#### 2.4 Lightweight neural networks for onboard inference

Feedback from the triggering mechanism is essential for achieving adaptivity; however, its effectiveness is often hindered by challenges in real-world deployment. As shown in Equation (1), the computation of the  $F_\beta$  score relies on both precision and recall, each of which faces practical difficulties. Specifically, precision depends on the identification of true positives and false positives. In the absence of human intervention, ground truth labels for captured signals are typically unavailable, making it impossible to determine whether a triggered signal corresponds to an actual event of

interest. This uncertainty undermines the ability to accurately evaluate performance metrics such as precision and, consequently, the  $F_\beta$  score. The situation is even more challenging for recall, which relies on identifying both true positives and false negatives as shown in Equation (4). Estimating false negatives necessitates knowledge of missed events of interest—information that is inherently inaccessible in trigger-based sensing systems. These limitations present fundamental barriers to autonomous online adjustment of triggering parameters, underscoring the importance of developing effective solutions.

$$precision = \frac{TP}{TP+FP} \quad (3)$$

$$recall = \frac{TP}{TP+FN} \quad (4)$$

Edge intelligence, which integrates lightweight onboard computation with AI, offers a promising pathway for achieving online fine-tuning on edge devices, particularly for problems beyond the reach of traditional approaches. To address the issue of precision, the absence of ground truth can be mitigated by deploying an onboard AI classifier to infer signal labels. Similarly, for recall, an AI-based estimator can be employed to directly approximate the recall value, thereby facilitating more accurate performance evaluation. Most importantly, the onboard AI enables autonomous feedback generation without the need for human intervention, thereby streamlining operations and advancing full system automation. To meet the requirements of edge deployment, these neural networks should prioritize lightweight architecture and high computational efficiency.

Table 2. NN parameters summary.

Parameter Type	CNN	DNN
Total Parameters	142 (572.00 B)	209 (836.00 B)
Trainable Parameters	44 (176.00 B)	209 (836.00 B)
Non-trainable Param.	8 (32.000 B)	0 (0.00 B)
Optimizer Parameter	90 (364.00 B)	0 (0.00 B)

To effectively classify time series data, a 1D Convolutional Neural Network (CNN) combined with feature engineering is employed. Given an input signal of 6000 samples, the data is first transformed from the time domain to the frequency domain using the Fast Fourier Transform (FFT). Both time- and frequency-domain signals are then downsampled to 64 samples each. The resulting vectors are concatenated into a 128-dimensional feature vector, which serves as the input to a lightweight CNN classifier. Details of the network size and architecture are provided in Table 2 and Table 3, respectively. The training curves and classification results are presented in Figure 4.

Table 3. CNN classifier architecture.

Layer	Output Shape	Para. Number
Input Layer	128	0
Conv1D	128	16
BatchNorm	128	16
ReLU	128	0
GlobalAvgPooling	4	0
Dense	4	20

Table 4. DNN Recall estimator architecture.

Layer	Output Shape	Para. Number
Dense	16	64
Dense	8	136
Dense	1	9

Since false negatives cannot be directly observed in trigger-based sensing, a Dense Neural Network (DNN) is introduced to estimate recall based on noise level, trigger threshold, and duration. Utilizing the dataset generated from the digital twin, the DNN is trained to predict recall under various noise conditions and triggering configurations. The network size is detailed in Table 2, the architecture is provided in Table 4, and the training curves are shown in Figure 4. With both the CNN classifier and the DNN recall estimator trained, the feedback loop is fully established, completing the final component of the closed-loop control system.

Figure 4. NN training curves: (a) CNN classifier (b) DNN estimator.

### 3 STAGED DEPLOYMENT

Despite the many advantages of edge intelligence, its most prominent inherent limitation lies in the constrained onboard resources, which restrict the efficiency of triggering parameter optimization. In the previous section, a feedback control approach was introduced for iterative optimization of triggering parameters. To further accelerate this process, a staged

deployment strategy is proposed, comprising a pre-deployment optimization stage and an onboard fine-tuning stage. The second stage inherits insights obtained during the first, allowing only lightweight fine-tuning on the device and thus minimizing computational overhead.

Figure 5 illustrates the concept of this staged optimization strategy. Both stages are built upon the same feedback control framework. The key differences lie in two components: the environment component, which refers to the excitation-structure-response flow, and the estimator component, which is responsible for providing performance metrics. In Stage I, the environment is simulated using a digital twin. Although the structural responses are not real, this fully controlled setting provides complete knowledge of all events, enabling accurate performance evaluation. In Stage II, the environment becomes real and uncertain. Since ground truth labels are unavailable, recall cannot be directly computed. To overcome this limitation, onboard neural networks including the CNN classifier and the DNN-based recall estimator are employed to complete the closed-loop feedback control. It is important to note that in the trigger sensing setup, the DT model is not required to be of high fidelity, as its primary role is to generate synthetic data for training the classification model.

Figure 5. Staged deployment strategy: (a) pre-deployment optimization (b) onboard fine-tuning.

## 4 VALIDATION AND RESULTS

### 4.1 Dataset generation

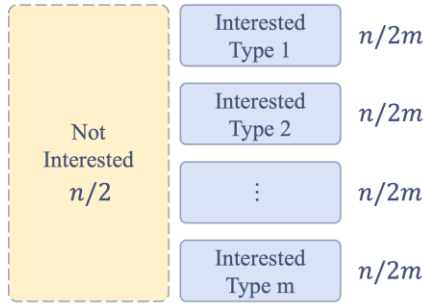

Figure 6. Dataset generation.

As previously discussed, the uncertainty of data distribution in real-world deployment makes it unsuitable for reliable evaluation of triggering mechanism performance. To enable consistent and controlled assessment, a synthetic dataset with a predefined distribution was constructed, as illustrated in Figure 6. Let  $n$  denote the total number of event samples, and  $m$  represent the number of event types considered as events of interest. Events of no interest, represented by ambient vibration in this context, account for half of the dataset ( $n/2$  samples), while the remaining half is evenly divided among the  $m$  types of events of interest. In this study,  $n$  is set as 1200 for validation. For ambient vibration signals, data is generated using a Gaussian distribution with a mean of zero and a standard deviation derived from real-world ambient data. This approach aims to closely approximate actual deployment conditions.

In this evaluation setup, three types of events are defined as events of interest: earthquake, impact, and strong wind, resulting in  $m = 3$  and  $n/6$  samples for each type. These signals are synthesized using a uniform distribution based on peak value ranges, allowing for diverse intensity levels within each event type. This structured and realistic data generation strategy ensures a balanced and reproducible dataset, enabling consistent evaluation of triggering mechanisms across a wide range of simulated scenarios.

### 4.2 Host Devices and Implementation Procedures

According to the proposed staged deployment strategy, the first stage focuses on preliminary optimization of triggering parameters using the digital twin in a resource-rich environment, such as a personal computer or workstation. The second stage is dedicated to real-time fine-tuning in real-world conditions on resource-constrained edge devices. To emulate this setup in the evaluation, Stage I was carried out on a personal computer, while Stage II was implemented on LiftNode, a low-cost microcontroller-based AIoT sensor node developed by the Laboratory of Intelligent Infrastructure at Nanyang Technological University. More specifically, the implementation is based on a dedicated middleware named TinySHM, which is currently under active development and features a hierarchical structure of basic utilities (e.g., time management, communication), mathematical operations, signal processing, and AI support (accelerated by ESP-DL library [12]). The specifications of the host devices, including main frequency and RAM capacity, are summarized in Table 5.

Table 5. Host devices specifications.

Layer	Main Freq.	RAM
PC	2.50 GHz	32 GB
LiftNode-ESP32	480 MHz	8 MB

Figure 7. The main control board of LiftNode-ESP32.

ESP32 features the capability for Wi-Fi Connection designed for IoT applications. By combining onboard SD card module for large volume data storage and IoT capabilities, the proposed framework can achieve large dataset storage via Internet streaming and record-by-record onboard processing within limited onboard memory. In short, the implementation adopted a ‘more time for less space’ strategy, using longer time consumption to address the limits of restrained onboard resources. This is reasonable, as the appearance of interested events can be sparse during monitoring, leaving enough time for edge device to process. Besides, the event records are only used to provide classification label, the core part for adaptive optimization is BO, which only focuses on the observation dataset  $\mathcal{D}$ , simply data pairs of trigger parameters (threshold and duration) and performance metric ( $F_\beta$ ). Usually, it requires hundreds or thousands interested events to update the observation dataset  $\mathcal{D}$  once, which means low demand for computational capability on edge devices.

In this research, each record was formulated to 1 min long, assuming most events will not exceed this duration. Theoretically, even the time history data is longer than 1 min, the onboard NN can still easily provide the type of events using partial data, showing the robustness of the proposed framework design. For each triggered and recorded event, the host device determined its type, and update the counting variable. Only when there are enough number of events recorded, the host machine will conduct BO for triggering parameter updating.

### 4.3 Results

The detailed configurations for the optimization process is listed in Table 6, and the optimization process is recorded and visualized in Figure 8 and Figure 9. As illustrated in Figure 8, red dots represent Stage I optimization results and blue dots represent Stage II results. To accelerate convergence, a bonus factor of 1.1 is applied to the final  $F_\beta$  score for iterations where both precision and recall exceed 90%. The final results including the baseline approach and breakdown results of stage I and II are presented in Table 9.

Table 6. Validation configurations.

Parameter	Description	Value
noise std	ambient vibration	$2.92 \sim 3.57 \times 10^{-3} \text{ g}$
EQ peak val.	earthquake	$0.1 \sim 3.0 \text{ g}$
IP peak val.	impact	$0.1 \sim 3.0 \text{ g}$
SW peak val.	wind (x noise std)	$1.5 \sim 2.5$
beta	beta in Eq (1)	5
IniNum	# initial observation	15

IterNum1	# iteration in stage I	50
IterNum2	# iteration in stage II	20
bonus factor	for $p > 0.9$ & $r > 0.9$	1.1
$\tau_{lb}$	threshold lower bound	0
$\tau_{ub}$	threshold upper bound	0.01706
$d_{lb}$	duration lower bound	2
$d_{ub}$	duration upper bound	10

Figure 8. Optimization result overview.

Table 7. Validation results.

Item	F-beta	Precision	Recall
Baseline	0.8025	50%	100%
Stage I	1.0808	96.33%	98.37%
Stage II	1.0511	92.54%	95.72%

As shown in Figure 9 and Table 7, the baseline method, marked in black, reflects a conservative conventional configuration. While it achieves high recall, this comes at the cost of significantly reduced precision, resulting in a high false trigger rate. In contrast, the proposed staged optimization framework effectively addresses this limitation. Several key observations can be drawn from the results.

**Superior Performance of SATM.** The proposed SATM framework demonstrates clear advantages over the conventional approach, achieving  $F_\beta$  scores of 1.0808 during pre-deployment optimization and 1.0511 during onboard optimization, significantly outperforming the baseline score of 0.8025. These results highlight the effectiveness of SATM in optimizing triggering parameters for SHM applications.

**Strong Synthetic-to-Real Transferability.** The similarity between data distributions in the pre-deployment phase (based on the digital twin) and the real-world onboard phase indicates strong transferability of the optimization strategy. Although some deviations are observed due to inherent differences between synthetic and real data, such discrepancies are expected to decrease as real-world data continues to accumulate over time.

**Highly optimized energy-efficiency ratio.** For long-term, battery-powered monitoring, a trigger-based scheme is significantly more energy-efficient than always-on or duty-cycled approaches. By adaptively optimizing the triggering parameters, the overall performance can be quantitatively

evaluated using a dedicated performance metric. Depending on the initial parameter settings, energy consumption may decrease if the parameters are overly strict, or increase if they are too loose. However, one thing remains consistent: the energy-efficiency ratio improves, as reflected by the performance metric.

Figure 9. Optimization results: (a) top view, (b) front view, (c) side view.

**Efficiency of the Surrogate Model.** The surrogate model, trained within the digital twin environment, significantly enhances the efficiency of onboard fine-tuning. It enables the optimization process to converge in fewer iterations compared to the initial stage, achieving rapid progression toward high-quality configurations and yielding improved average performance during real-world deployment.

**Balanced Exploration and Exploitation.** The two-stage deployment strategy effectively balances the trade-off between exploration and exploitation. The first stage emphasizes exploration, exhibiting greater variability in performance metrics to thoroughly investigate the parameter space. In contrast, the second stage focuses on refining configurations based on prior knowledge, resulting in stable and robust system performance.

## 5 CONCLUSION

This study introduces a smart adaptive triggering mechanism that seamlessly combines feedback control, digital twin modeling, and Bayesian optimization. It is specifically designed to tackle key challenges such as limited adaptivity, multi-objective optimization, unknown event distributions, lack of ground truth, partial observability, and high data acquisition costs. SATM is structured around four core components: the environment, the system, the estimator, and the controller. The mechanism functions through two sequential phases: an initial pre-optimization phase utilizing a digital twin to identify a strong baseline configuration, followed by an onboard fine-tuning phase that adapts parameters under real-world deployment conditions. Evaluations confirm that SATM achieves substantial improvements in triggering performance, delivering approximately a 30% increase in the  $F_\beta$  score compared to traditional approaches. These results underscore the promise of SATM in enabling automatic, adaptive parameter tuning for trigger-based sensing systems across various application domains. In future, the proposed method will be used for long term monitoring uses and incorporate more types of events, e.g., structure failure.

**ABSTRACT:** Monitoring the structural integrity of civil infrastructures, such as bridges and viaducts is crucial, as non-visible damage like post-tensioned wire breaks can lead to catastrophic failures, endangering public safety. In this study, we simulate post-tensioned wire breaks by generating controlled mechanical impacts using a sclerometer. These impacts are applied at varying distances from optical fibers cables attached to the tendons of two different structures. A novel detection framework is developed using distributed acoustic sensing (DAS) technology to identify post-tensioned wire breaks in a suspension and a concrete bridge while effectively distinguishing between vehicular noise, environmental noise, and actual wire break events. For suspension bridges, a spectrogram-based template matching approach is implemented, leveraging sub-band selection and image-based analysis to enhance sensitivity to break events while suppressing false positives from environmental noise. In concrete bridges, a deep learning-based convolutional neural network (CNN) model achieves 96% classification accuracy, outperforming traditional methods in detecting wire breaks with high precision. These approaches provide a real-time, reliable solution for structural health monitoring, offering significant advancements in distinguishing critical break events from background interference, improving bridge safety and maintenance strategies.

**KEY WORDS:** Distributed acoustic sensors, Distributed optical fiber sensors, Structural Health Monitoring, Bridge monitoring

## 1 INTRODUCTION

Bridge maintenance is crucial for infrastructure management, directly impacting public safety and economic stability. Among the key components of bridge structures, post-tensioned cables are essential for enhancing load-bearing capacity and ensuring structural integrity [1]. These high-strength steel tendons, tensioned after concrete curing, play a pivotal role in suspension and concrete bridges. However, wire breaks in post-tensioned systems present a serious risk to structural stability, potentially causing catastrophic failures [2]. Such failures have led to costly repairs and tragic accidents, emphasizing the need for advanced monitoring and detection methods.

Traditional detection methods for wire breaks include techniques such as visual inspections, electromagnetic testing, and strain gauges. While these approaches have served as the foundation for bridge maintenance, they have limitations. Visual inspections are subjective and often miss hidden defects, while electromagnetic testing is hindered by accessibility challenges and the need for specialized equipment [3]. Strain gauges, although effective in measuring tension, lack comprehensive coverage, particularly in inaccessible areas [4]. These limitations highlight the need for real-time, reliable systems for continuous monitoring of bridge infrastructure.

The detection of post-tensioned wire breaks has been investigated using Fiber Bragg Grating (FBG) sensors and acoustic emission (AE) techniques, both crucial for ensuring the structural integrity of bridges and wind turbines. FBG sensors, which are point-based, detect wire breaks by monitoring changes in natural frequency [5], while AE methods, utilizing piezoelectric transducers, capture signals associated with wire fractures [6]. Despite their effectiveness, these approaches face challenges in distinguishing wire break

signals from background noise. In contrast, Distributed Acoustic Sensing (DAS) technology presents a promising alternative by converting optical fibers into dense arrays of vibration sensors. DAS sensors offer continuous spatial coverage and capture spatiotemporal patterns, significantly enhancing the detection of wire breaks within noisy environments, particularly in large-scale structures. Additionally, DAS systems enable the tracking of event propagation along the entire length of the optical fiber, a capability absent in point sensors, which are limited to detecting localized signals and cannot monitor the full progression of an event.

DAS technology has emerged as an innovative technology that utilizes fiber optic cables to detect vibrations, enabling real-time data collection and analysis [7]. DAS technology, leveraging optical fibers, is currently used in various applications such as infrastructure monitoring [8], seismic data acquisition[9], security[10], and environmental research[11]. While DAS is typically employed for monitoring natural frequencies in Structural Health Monitoring (SHM)[12], this paper explores its use for detecting potential wire breaks in infrastructure. This technology addresses the shortcomings of traditional methods by providing reliable, continuous monitoring of the entire bridge, allowing for early detection and timely intervention to prevent minor issues from escalating into major problems.

Simulating wire breakages under controlled conditions is essential for thoroughly testing and calibrating the DAS system for detecting such failures. Field testing with actual wire breaks in post-tensioned tendons is inherently challenging and impractical, as it requires the intentional damage of structural elements, which is not a feasible approach for testing.

Controlled impact testing has been widely used in structural health monitoring to simulate damage events in prestressed concrete [13], as well as for detecting wire breakages in post-tensioned structures [14]. These methodologies substantiate the use of impact-induced stress waves as a reliable proxy for wire break simulations, enabling repeatable testing without causing irreversible structural damage. To generate these controlled impacts, a sclerometer was utilized, as it is a well-established industry method for producing stress waves that replicate those associated with actual wire failures.

The evolution of detection algorithms for post-tensioned wire breaks using DAS has been driven by the need for efficient and accurate monitoring. Traditional, labor-intensive methods have been replaced by automated systems that employ artificial intelligence, machine learning, and advanced signal processing for real-time detection, even in challenging environments. Although DAS has proven effective in controlled settings, it faces challenges such as external noise and unpredictable conditions [15]. As an example, in railway systems, DAS techniques like gradient analysis and convolution have been used for rail break detection but can struggle with varying track conditions or interference [16].

Machine learning algorithms, such as support vector machines and neural networks, have improved detection accuracy but rely on large, labeled datasets, limiting their effectiveness in dynamic environments [17]. DAS systems have been explored as a promising solution to overcome these limitations in detecting wire breaks in prestressed concrete pipes. For instance, one study introduced a DAS system combined with a pre-trained support vector machine model, achieving 99.62% accuracy in classifying vibrational signals, thus automating the detection process and improving pipeline safety [18]. Another research applied DAS to detect wire breaks by analyzing key parameters, such as zero-crossing rate and short-time energy, which allowed for precise identification and location of acoustic signals generated by wire breaks in large experimental pipelines [19]. While both studies demonstrate the effectiveness of DAS in wire break detection, they do not address other potential causes of structural failure or the influence of environmental factors and external noise, which may limit the accuracy of these systems in practical, real-world settings.

This study proposes a novel approach for detecting post-tensioned wire breaks in bridges using DAS technology. By strategically installing fiber optic cables along post-tensioned tendons, it enables continuous real-time monitoring and advanced signal processing to identify acoustic anomalies indicative of cable failures. This innovative methodology enhances bridge safety, reliability, and maintenance by addressing the limitations of current detection methods. The findings from this research demonstrate the potential of DAS to revolutionize structural health monitoring, offering a more efficient and cost-effective solution for premature failure detection and long-term infrastructure resilience.

## 2 INSTALLATION AND SETUP

An UTS-AS1000 DAS interrogator from Uptech Sensing was employed at two locations: a suspension bridge in Bear Mountain and a viaduct in Florida, both in the United States. A single-sensing optical fiber was used, and measurements were

recorded with different fiber installations. The two sites were chosen to evaluate the DAS system's performance in different structural environments.

### 2.1 Installation at Suspension Bridge

First, in the Bear Mountain suspension bridge installation, the optical fiber was structurally bonded to one of the suspension cables using epoxy resin, enabling distributed acoustic sensing along the cable. A schematic representation of the installation is provided in Figure 1, where the monitored cable is highlighted in red.

Figure 1: Schematic of the optical fiber (red line) installed at Bear Mountain bridge.

Figure 2: (a) Suspension bridge with fiber optics from Type 1 (red) and Type 2 (yellow), placed within 1 cm of each other. (b) Fiber arrangement in Type 1 (red) and Type 2 (yellow) cables with color-coded segments indicating their function.

Two fiber optic cables from different manufacturers were installed in the structure: one from Prysmian (Type 1) and one from Solifos (Type 2), both of them containing several fibers for strain sensing (tight fibers in the cable) and for temperature sensing (loose fibers). The fiber was glued to a suspension cable of the Bear Mountain metal bridge by means of an epoxy

resin. These two fibers, strain and temperature, are widely used in industry when measuring with distributed strain and temperature sensors (DTSS), being the first tight bonded, thus sensitive to temperature and mechanical deformations, while the latter loosely bonded, therefore only much less affected by strain variations. However, for DAS sensing, both fibers will detect the acoustic events, since the sensitivity is highly increased with respect to a DTSS, but it is expected to have higher attenuation levels in loose fibers (temperature) rather than in tight fibers (strain).

The schematic representation of the cable installed in the structure is shown in Figure 2(a). Type 1 is highlighted in red, while Type 2 is highlighted in yellow. The Type 1 cable contains three fibers—two temperature-sensitive and one strain-sensitive. The Type 2 cable contains six fibers—four temperature-sensitive and two strain-sensitive. Together, they form a total of nine segments, each of the 60-m-long. The figure drawn is scaled for a better representation of the scenario.

A 540 m composite fiber was formed by fusion-splicing the nine 60 m fiber segments in series. The purpose of creating this composite fiber was to investigate the impact of different fiber couplings on the measurements obtained by the DAS sensor, with the goal of determining whether significant differences in the results could be observed. The splicing at the different ends of fibers A and B is shown in Figure 2(b), with each fiber represented by a distinct color for clarity. In Type 1, the temperature-sensitive fibers are shown in blue and orange, while the strain-sensitive fiber is in green. In Type 2, the temperature-sensitive fibers are represented in purple, gray, red, and blue. The strain-sensitive fibers in Type 2 are shown in pink and black. The figure drawn is scaled for a better representation of the scenario.

After creating the 540 m composite fiber, two distinct cables, each incorporating two different fiber types, were employed to evaluate the performance of both the cables and the optical fibers. The fiber-cable combinations were assessed to evaluate their impact on the system's ability to minimize false positives, improving the reliability of event detection.

## 2.2 Installation at Concrete Bridge

Next, the interrogator was deployed at the Roosevelt Viaduct in Stuart, Florida, a major highway, where measurements were taken at the second location. It has a twin parallel drawbridge, one for northbound traffic and the other for southbound traffic. The interrogator was connected to a previously installed fiber for DTSS measurements in a road bridge in Florida. The sensing optical fiber is affixed to one of the tendons using an industrial-grade adhesive, ensuring strong coupling for effective vibration and acoustic sensing. This configuration enables the detection of structural responses to environmental and vehicular loads, facilitating distributed acoustic sensing along the bridge.

The optical fiber was installed inside the structure of the Roosevelt Viaduct, with its placement highlighted in red in both images in Figure 3: In Figure 3(a), the exterior of the viaduct is shown for reference, providing context for the installation. In Figure 3(b), the fiber was visibly integrated within the interior, demonstrating its positioning for structural monitoring. This setup was designed to optimize the detection, ensuring effective internal assessment of the viaduct's condition. Additionally, the impacts were generated at different

distances from the fiber to evaluate the influence of the distance of the impact from the fiber on the detection performance.

(a)

(b)

Figure 3: Optical fiber installation at Roosevelt Viaduct: (a) Exterior perspective from the structure, (b) Interior placement within the structure. Installed fiber is highlighted in red.

Suspension bridges like the Bear Mountain metal bridge rely on cable-supported flexibility, allowing vibrations to dissipate through tensioned cables and the deck, resulting in distributed and oscillatory wave propagation. In contrast, concrete bridges such as the Roosevelt in Florida, with their rigid structural elements, transmit vibrations more directly through the solid slab and supporting components, leading to localized wave reflections and attenuation. This fundamental difference affects how vibrations propagate through each type of bridge[20]. This distinction in vibration behavior underscores the need for tailored monitoring approaches for each bridge type. With this understanding in mind, the impacts on both structures are approached differently.

## 3 WIRE BREAK DETECTION

### 3.1 Experimental Design

As introduced before, a controlled approach was employed, utilizing a sclerometer to generate impact events, simulating the sound and vibrations generated by a post-tensioned cable break, at varying distances from an optical fiber sensing cable affixed to the tendons of two distinct structures. The study analyzed the DAS system's response to controlled impacts to assess its ability to detect, characterize, and locate potential tendon failures in real-world conditions, while minimizing the possible false cases generated due to other events that might produce similar sound patterns.

On one hand, the DAS sensor is configured with a spatial resolution of 2m, a gauge length of 2m, and an acquisition frequency of 2 kHz, monitoring a 540-meter-long optical fiber cable on the suspension bridge installation. On the other hand, for the concrete bridge tests, the system used spatial resolution and gauge length of 3m, with the same acquisition frequency of 2 kHz, to monitor a 3.5-kilometer-long optical fiber.

In the suspension bridge configuration, impact events were generated using a sclerometer to replicate the characteristic waveforms of wire breakage. These impacts were delivered at varying angles relative to the suspension cable axis, enabling the investigation of strike orientation on the propagation of acoustic signals through the structure. As depicted in Figure 4, the monitoring optical fiber, highlighted in red, was positioned along the cable to capture the resulting waveforms. A series of tests was conducted under controlled conditions, with the impact responses systematically recorded for each test. The waveform of the sclerometer hits were obtained for angles of 0°, 45° and 90° with respect to the position of the monitoring fiber. The resulting data were organized into a comprehensive dataset, facilitating further analysis of signal variations as a function of impact direction and intensity.

Figure 4: Fiber optic scheme (red line) in suspension cable and sclerometer strike angle diagram relative to the position of the monitoring optical fiber.

For the concrete bridge, impact events were generated at two carefully selected locations to assess the system's sensitivity to structural vibrations. As shown in Figure 5, the sensing fiber highlighted in red was positioned in the concrete slab to capture the resulting waveforms. The first set of impacts was applied at the midpoint of the 19th span, directly on the ground, to simulate the propagation of vibrations through the bridge deck. The second set of impacts was introduced on the ceiling, generating acoustic waves that traversed the upper structural elements. The impact events were generated at varying distances from fiber (0.7112m, 1.4224m, 2.032m, 3.3528m) in both cases. The resulting data were organized into a comprehensive dataset, facilitating further analysis of signal variations as a function of impact direction and intensity.

Figure 5: Fiber optic scheme (red line) in concrete slab and sclerometer strike diagram relative to the position of the monitoring optical fiber in the bridge.

## 3.2 Data Analysis

### 3.2.1 Data Analysis on Suspension Bridge

Data analysis plays a crucial role in monitoring suspension bridges, enabling the assessment of structural integrity and the identification of potential issues. Nine fiber segments were used to monitor the same region, arranged one after the other in parallel. This configuration results in repeated measurements, with the hit observed across all nine segments. The fiber runs from A to B, as shown in the Figure 2(a) and Figure 2(b).

In this study, the sclerometer hits were obtained for angles of 0°, 45°, and 90° with respect to the position of the monitoring fiber. The waveform of the sclerometer hits was recorded at an angle of 0° relative to the position of the monitoring fiber. Figure 6 presents the first two segments, where the x-axis range from 20 to 80 meters corresponds to the first fiber segment, and the range from 80 to 140 meters represents the second fiber segment. Signal amplitudes are represented by the color scale previously shown, where negative values (down to -2.0 a.u) are indicated by blue hues and positive values (up to 2.0 a.u) are depicted in red, with near-zero values shown in white. All the waterfall plots were generated using this fixed amplitude limit to ensure consistent visual comparison across different events. Distinct diagonal and vertical patterns can be observed in the data distribution.

Two segments monitor the same zone of the suspension cable, and the sclerometer hit was clearly visible in both, characterized by the diagonal pattern. This pattern was attributed to the propagation of the hit made at 0° angle respect to the structure, captured as the disturbance moves through the fiber. Notably, the second segment exhibits a reversed version of the pattern seen in the first segment, which results from the light in the second segment traveling in the opposite direction compared to the first, producing a mirror image of the hit's propagation.

Figure 6: Waterfall data from two segments with the hits from the sclerometer.

Additionally, a fainter hit was observed closer to time 100ms, which was produced by the rebound of the sclerometer hit. It is important to note that whenever a hit is produced, it is usually followed by several rebounds, resulting in the consistent visibility of the secondary, fainter hit. Noise was also observed around the 80-meter mark as a vertical pattern, at the end of cable B, shown in Figure 2(a), is highly susceptible to wind exposure. This noise was not observed at end A, as this portion of the bridge was less affected by winds compared to the other end.

A waterfall diagram containing a sclerometer stroke for the entire length of the fiber is shown in Figure 7. Diagonals with opposite slopes were observed, which were repeated along the

spatial axis (x-axis) and were found to correspond to the acoustic signals acquired by the nine optical fiber segments connected in series. Additionally, multiple diagonals over time (y-axis) were identified, representing replicas of the blow that had been generated by the sclerometer.

When comparing the signals acquired from the center of each optical fiber region, it was evident that the strain fibers labeled as "c," "h," and "i" demonstrated the highest sensitivity. This was observed through both temporal and spatial replications, as each of these fibers consistently detected three replicates of the same event at different time intervals and locations. The repeated detection at multiple spatial points and across various times indicates that these fibers were particularly responsive to the transient events, highlighting their effectiveness in capturing the signal. In contrast, the temperature fibers had demonstrated variable sensitivity; fiber "d" had been able to detect the third replication slightly, whereas fibers "a," "b," "e," and "f" had not exhibited such detection capabilities. The consistency of the replicated patterns was observed to indicate a high degree of repeatability in the impact response of the sclerometer. This observation was found to highlight the reliability of strain-sensitive fibers in capturing high-frequency acoustic signals. Moreover, the periodic nature of the detected hits was noted, further reinforcing the consistency of the acquired signals. The temporal waveform at the center of each optical fiber region is presented in Figure 8.

Figure 7: Waterfall diagram showing a sclerometer stroke hits obtained for angles of 0° acquired by the DAS sensor.

Figure 8: Waveforms at different spatial positions of the monitoring fiber. The spatial positions correspond to those indicated in Figure 7.

The comparison of the performance across the nine segments highlighted distinct differences between fiber types, but no significant differences between cable types. As seen in Figure 8, the strain fibers exhibited a pronounced detection pattern, while the temperature fibers showed a more subtle response. This difference is due to the tight bonding of strain fibers, which makes them highly sensitive to vibrations but also more prone to noise. In contrast, temperature fibers, with their loose bonding, produced less noise but were less effective at detecting vibrations. Therefore, the choice of fiber should depend on the specific application, with strain fibers ideal for high-sensitivity detection and temperature fibers better suited for scenarios where noise reduction is a priority. Additionally, as shown in Figure 7, the detection patterns were consistent across different cables when the same fiber type was used, indicating that cable type had a negligible impact on the overall detection performance.

A similar analysis was conducted for impact angles of 45° and 90° with respect to the cable, revealing variations in the acquired waveforms. At 90°, as shown in Figure 9. The amplitude of the diagonals was observed to be lower than at 0°, and the temporal replicas of the signal could no longer be detected. The corresponding temporal waveform at the center of each optical fiber region, depicted in Figure 10, indicated that the amplitude of the impacts was comparable to background noise, making detection challenging without spatial information.

Figure 9: Waterfall diagram showing a sclerometer stroke hits obtained for angles of 90° acquired by the DAS sensor.

Figure 10: Waveforms at different spatial positions of the monitoring fiber. The spatial positions correspond to those indicated in Figure 9.

For the 45° impact, the amplitude of the diagonals, which represents the signal strength along the diagonal axis of the data, as shown in Figure 11, was found to be similar to that of the 0° impact but greater than that of the 90° impact. While temporal replicas were still visible, they appeared significantly attenuated. The temporal waveform at the center of each optical fiber region, presented in Figure 12, demonstrates that the amplitude of the initial impact was distinguishable from noise, whereas the replicas became indistinguishable. These findings indicate that while monitoring fiber effectively captured acoustic events at different impact angles, the detectability of replicated signals was highly dependent on impact orientation, with attenuation effects becoming more pronounced at higher angles.

Figure 11: Waterfall diagram showing a sclerometer stroke hits obtained for angles of 45° acquired by the DAS sensor.

Figure 12: Waveforms at different spatial positions of the monitoring fiber. The spatial positions correspond to those indicated in Figure 11.

The monitoring composite fiber effectively captured acoustic events from different impact angles, although performance depended heavily on the impact orientation. Attenuation effects increased at higher angles, a phenomenon that field experts link to air gaps between the structure and cables at certain orientations, likely caused by installation flaws. Orientations where fibers were closer together experienced less gap interference, resulting in better event detection. This sensitivity profile indicates that high-energy events like tendon ruptures, especially in well-coupled areas, would produce strong, easily detectable signals similar to sclerometer impacts recorded

outside poor coupling zones. These findings strengthen the system's potential for reliably detecting critical structural events, boosting confidence in its monitoring ability for vital infrastructure.

### 3.2.2 Data Analysis on the Concrete Bridge

In the context of monitoring concrete bridges, data analysis plays a crucial role in assessing integrity and detecting potential issues. For this analysis, data were recorded from hits generated by a sclerometer, simulating events such as wire breaks. Unlike suspension bridges, where the fiber installation allows for repetition across multiple segments, the configuration of fibers in concrete bridges is unique, meaning repetition of patterns across segments is not expected. A typical hit pattern detected by the interrogator is shown in Figure 13. The pattern clearly shows a hit detected across multiple spatial points, with surface waves propagating from the point of impact to adjacent locations. This wave distribution aids in detecting the event at various points, crucial for assessing the damage's extent.

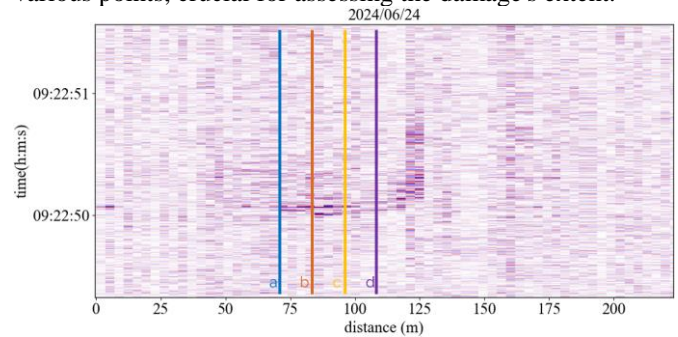

Figure 13: Waterfall diagram showing a sclerometer stroke acquired by the DAS sensor.

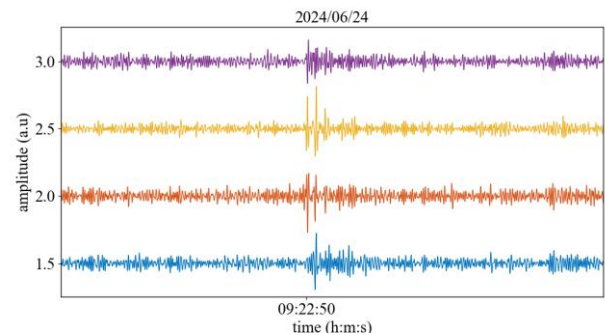

Figure 14: Waveforms at different spatial positions of the monitoring fiber. The spatial positions correspond to those in Figure 13.

A detailed analysis of the acquired signals was conducted, and the temporal waveform at points "a" to "d" was presented in Figure 14. The hits were distinctly observed, and the duration of each blow was measured at approximately the same time 09:22:50. Furthermore, variations in amplitude across different spatial points were identified, suggesting differences in their sensitivity and signal attenuation. The time-domain characteristics of the acquired signals were analyzed, revealing that certain spatial points were more effective at detecting transient events due to their proximity to the point of impact and the propagation of surface waves. It was observed that signals from these locations exhibited stronger and clearer responses. Optimizing fiber selection and positioning could enhance detection accuracy by placing fibers at strategic

locations where the signal propagation is most pronounced, thereby capturing more relevant data.

Figure 15: Waveforms at central positions of the fiber monitoring for different hitting lengths from the fiber.

The impacts from the sclerometer at the different distances from the fiber were taken, and the mid spatial point is chosen from all the impacts, and their temporal evolution is shown in Figure 15. The decrease in hit amplitude with increasing depth from the sensor is primarily due to the fundamental principles of seismic wave propagation in concrete. As acoustic waves travel through the slab, their energy disperses, leading to geometric attenuation. Additionally, material absorption within the concrete causes further energy loss. Scattering effects due to variations in the concrete's composition and microstructural heterogeneities also contribute to signal attenuation. These combined factors naturally result in a reduction in amplitude as the distance from the source increases.

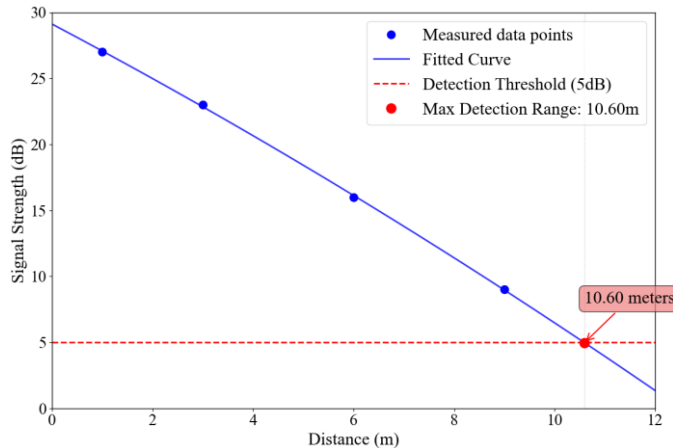

Figure 16 Maximum detection range estimation for tendon break monitoring.

To quantify the effective detection range for tendon break monitoring, the exponential attenuation relationship observed in Figure 15 was extrapolated using curve fitting analysis. The measured signal decay follows  $y = ae^{-bx} + c$ , with amplitudes decreasing from 27 dB at 1 m to 9 dB at 9 m due to geometric spreading, material absorption, and scattering effects in concrete. A minimum detection threshold of 5 dB was established to ensure reliable discrimination of tendon break signals from background noise. The fitted model, as shown in Figure 16 predicts a maximum effective detection range of 10.6 meters, beyond which the combined effects of wave

propagation losses render tendon break detection unreliable. This analysis provides essential parameters for determining sensor spacing in structural health monitoring systems, ensuring complete coverage for the early detection of prestressing tendon failures in concrete bridges.

In conclusion, this analysis highlights the influence of the distance between the sclerometer hits and the fiber on the amplitude of the detected signals. The decrease in hit amplitude with increasing distance is attributed to seismic wave propagation, material absorption, and scattering effects within the concrete. To enhance the sensitivity and reliability of the monitoring system, it is recommended that the sensing fiber be placed closer to the structure, allowing for more accurate detection of breaks and better signal capture.

### 3.3 Detection Algorithm

#### 3.3.1 Detection Algorithm for Suspension Bridges

The hits from the suspension and concrete bridge were clearly observed in the data, with the temporal traces from the relevant spatial points carefully explored to study the generated impacts. These impacts were analyzed in detail to understand their characteristics and temporal evolution. This was used effectively in designing the detection algorithm for the two structures.

As for the suspension bridge, in this study, a spectrogram-based method was proposed, utilizing only a single fiber segment. A spectrogram-based template matching approach was employed for the suspension bridge to detect transient events in time series data across multiple sensor channels. This method was chosen for its ability to detect transient events across multiple optical fiber segments by leveraging spectrogram-based template matching. The use of multiple optical fiber segments enhances the spatial robustness of the detection, reducing the likelihood of false positives and ensuring reliable identification of events. Additionally, the repetition of results across various fiber segments provides strong validation for detected events, reinforcing the reliability of the method. This approach is preferred over machine learning as it offers a clear, interpretable process that directly correlates spectral energy variations with event detection, without the complexity and data dependency often associated with machine learning models.

The methodology consisted of sequential steps, beginning with spectrogram computation. Given a time series  $x(t)$ , its time-frequency representation was obtained using the short-time Fourier transform (STFT), producing a spectrogram  $S(f, t)$ , where  $f$  represented frequency and  $t$  represented time. For the spectrogram computation, a window length of 256 samples and an overlap of 248 samples were used. This transformation enabled the localization of spectral energy variations over time, forming the basis for subsequent feature extraction.

To enhance sensitivity to specific frequency components, sub-band selection was performed by isolating predefined frequency ranges from the spectrogram. Two sub-bands were defined for analysis: Sub-band 1 ranged from 90 to 180 Hz, and Sub-band 2 ranged from 350 to 440 Hz. This process yielded refined sub-band spectrograms  $S'(f, t)$ , where only the relevant spectral components were retained. Each extracted sub-band spectrogram was then treated as an image  $I(f, t)$  in which pixel

intensities corresponded to spectral power. This conversion facilitated the application of image-processing techniques for event characterization.

The core of the detection methodology involved template matching, in which a predefined temporal template was convolved with  $I(f, t)$  to identify characteristic signal patterns. The template was designed with three consecutive time slots, where the first and third slots were assigned a weight of -1, and the central slot was assigned a weight of 1. This structure enhanced contrast by emphasizing transient spectral changes while suppressing background variations. The template extended across the entire frequency sub-band, ensuring comprehensive coverage of the targeted spectral range. Through convolution, a response function was obtained that highlighted localized temporal variations indicative of hits.

Figure 17: Detection of the hits in the suspension bridge.

To ensure spatial robustness, the template matching procedure was applied independently across multiple fiber sensor locations, generating a three-dimensional response matrix  $M(c, t)$  where  $c$  represented the sensor channel and  $t$  denoted time. Each entry in  $M(c, t)$  corresponded to the template matching response at a given location and time. A hit was considered when multiple sensor channels exhibited a significant response simultaneously, thereby reducing the likelihood of false positives caused by localized noise or isolated fluctuations. A thresholding operation was applied to  $M(c, t)$  to identify significant activations, ensuring that only strong and spatially correlated events were retained. The detection results are presented in Figure 17, where the significant activations identified through the thresholding operation are distinctly visualized across the sensor channels. The algorithm successfully identified the sclerometer impact points, which are highlighted in pale blue within the figure.

Despite the use of a single segment, minimal false-positive rates were achieved. The analysis was conducted exclusively on this segment, demonstrating the effectiveness of the proposed approach in reducing false positives. These results highlight the spatial and temporal correlations of the detected hits, demonstrating the effectiveness of the method in identifying true events while minimizing false positives. The figure provides a comprehensive overview of the detected impacts within the given time frame and sensor locations. By integrating sub-band selection, image-based template matching, and distributed sensor analysis, the approach provided a scalable and robust solution for detecting transient events in DAS applications. High sensitivity to localized perturbations was achieved while mitigating false positives, making the methodology well-suited for health monitoring and real-time monitoring for the suspension bridge.

### 3.3.2 Detection Algorithm for Concrete Bridges

This study presents a deep learning-based approach for detecting wire breaks in concrete bridges utilizing Convolutional Neural Networks (CNNs). Unlike suspension bridges, which benefit from repetition across multiple segments, allowing for template matching, concrete bridges lack this repeatability in optical fiber segments, necessitating a different method. Machine learning is preferred over traditional techniques because it can automatically learn complex patterns, eliminating the need for manual feature extraction. CNNs are ideal for this task as they efficiently learn complex patterns and features from data, making them highly effective for detecting wire breaks in concrete bridges.

The dataset consists of positive images showing a pattern from hits and negative images of patterns from vehicles and other patterns that are not hits. To generate a more robust dataset for training, a Generative Adversarial Network (GAN) was utilized for data augmentation, as it generated realistic synthetic data that enhanced the training dataset. GAN-based data augmentation techniques were employed here to create additional images, ensuring a larger and more diverse set of training data. The images were preprocessed and resized for uniformity, and the dataset was split into training and testing sets. Positive images were labeled as 1, and negative images as 0. This ensured the model could effectively learn to distinguish between the two classes.

The CNN architecture consists of five fully connected convolutional layers, each followed by a max pooling layer, which reduces the spatial dimensions while retaining key patterns. The number of filters increases progressively with the layers, to capture both low- and high-level features. The extracted feature maps are then flattened and passed through a fully connected layer, followed by a single neuron with a sigmoid activation to classify the images into two categories: breaks (1) or not possible breaks (0).

The training process and the model's learning progression are illustrated in Figure 18, which presents both training and validation loss trends throughout 15 epochs. Two side-by-side plots are shown: the left plot depicts a consistent decrease in loss values for both the training and validation datasets, while the right plot demonstrates an increase in accuracy metrics, which plateaued around 95%. The model was trained efficiently, and convergence was achieved with minimal overfitting, as indicated by the close alignment between validation and training performance throughout the training period.

Figure 18 Training and validation loss curves over 16 epochs.

Post training, the model's performance was evaluated on the test set, where predictions were converted into binary labels. Standard evaluation metrics, including accuracy, precision, recall, and F1-score, were calculated. Performance metrics and the confusion matrix are presented in Table 1 and the classification report is presented in Table 2, offering a detailed overview of the model's effectiveness. Confidence scores and entropy were also calculated to measure the model's certainty in its predictions.

Table 1 Confusion Matrix

	Predicted Negative	Predicted Positive
True Negative	673	19
True Positive	18	313

Table 2 Classification Metrics

Type of Perturbation	Precision	Recall	F-score
Negative	0.97	0.97	0.97
Positive	0.94	0.95	0.94

The predicted labels were visually compared with true labels on a subset of test images to assess the model's accuracy. Based on the results obtained, the proposed deep learning-based model demonstrates robust performance in detecting wire breaks in concrete bridges. The model achieved an overall accuracy of 96%, as evidenced by the confusion matrix and classification report. Visual comparisons of predicted and true labels for a subset of test images highlighted the model's strengths in correctly identifying wire breaks, while also revealing some misclassifications that can be improved. These insights are crucial for refining the model and enhancing its performance. This method's potential to advance structural health monitoring, particularly in the context of bridge inspections, underscores its importance in improving the safety and maintenance of infrastructure.

#### 4 CONCLUSION

A comprehensive method was developed for detecting post-tensioned wire breaks in both suspension and concrete bridges using DAS. By tailoring techniques to each bridge type, the approach enabled real-time monitoring and effective detection, classification, and localization of cable break events. These advancements offer valuable applications in improving the safety and maintenance of critical infrastructure.

In the suspension bridge, the monitoring fiber captured acoustic events at various impact angles; however, signal detectability was strongly influenced by orientation. The comparison of performance across different segments revealed distinct differences between fiber types, though no significant differences were observed between cable types. The strain fibers exhibited a pronounced detection pattern, while temperature fibers showed a more subtle response. Based on these findings, a spectrogram-based template matching approach was developed, incorporating sub-band selection and

image-based matching. This method enabled accurate detection while maintaining low false positive rates, even when relying on a single fiber segment. Therefore, the choice of fiber should depend on the specific application, with strain fibers ideal for high-sensitivity detection and temperature fibers more appropriate for environments requiring minimal noise.

For the concrete bridge, a decrease in signal amplitude was observed as the distance from the fiber increased. This emphasized the need to place the fiber close to the structural surface. A CNN achieved 96% classification accuracy, outperforming traditional methods in both precision and false positive reduction. Data augmentation using a GAN further improved model generalization by creating a diverse training dataset.

These tailored methodologies provide effective, real-time monitoring strategies for both bridge types. Future efforts should focus on integrating the proposed techniques to improve system accuracy and adaptability in complex environments, and on exploring additional data augmentation strategies to further enhance model robustness.

**ABSTRACT:** Prestressed concrete bridges are designed to limit cracking. Aging can lead to prestressing steel fractures with strain changes without visible cracks. To detect and locate fractures, long-term monitoring with distributed fiber optic sensors in combination with acoustic emission sensing is useful. This study focuses on fiber optic sensing based on Rayleigh backscattering. A long-term monitoring system was installed to ensure the service of two prestressed concrete bridges in Munich. Their prestressing steel is at risk of stress corrosion cracking. For reliable operation of the fiber optical measurements, tests were carried out both in the lab and in the field to investigate the measurement signal in conditions that are as isolated as possible. On the bridges data is collected at three-month intervals starting in 2021. Furthermore, strain changes caused by temperature fluctuations and traffic loads were captured. Moreover, valuable insights are being gained in a long-term operation. The investigations show that long-term fiber optical strain measurements are useful to assess the structural behaviour of existing prestressed bridges over several years and can ensure safety of structures.

**KEY WORDS:** SHMII-13; prestressed bridges, DFOS, stress corrosion cracking.

## 1 INTRODUCTION

The first standards and regulations for prestressing steel in Germany were developed after 1945 [1]. The first decades of the use of prestressing steel were the source of many structural problems in prestressed bridges. Due to the lack of knowledge at that time, some deficiencies can still be found in existing bridges today. One such material defect is the susceptibility of prestressing steel to stress corrosion cracking. This can lead to brittle failure of the steel without plastic deformation and subsequent collapse of the component without warning. Recently stress corrosion cracking led to the component failure of the Carola Bridge in Germany [2]. In this case, cracks were observed years before failure, but the existing crack widths were below the standard limits [3]. Acoustic emission (AE) monitoring is proposed for the remaining bridge components [4].

In Munich, a monitoring system with AE has been in operation since 2021 on two bridges with prestressing steel sensitive to stress corrosion cracking. Additionally, distributed fiber optical sensors (DFOS) are in usage for crack detection. On these bridges, DFOS can also be used to monitor structural behaviour. This application of DFOS for structural behaviour monitoring has been carried out in many cases. [5], [6], [7] and [8] are just a few examples. This case study provides some insights into the laboratory and field tests and shows selected results from the past years.

## 2 MONITORING KREUZHOF BRIDGES

German bridges with stress corrosion cracking sensitive steel must be reassessed according to the guideline HA SpRK [9]. This guideline recommends the numerical verification of sufficient warning behaviour as crack-before-failure. For both "Kreuzhof" bridges, the crack-before-failure criterion could not be verified in every section. But even in areas with sufficient warning behaviour, an object-related inspection instruction must be defined.

The bridges were built in 1967 and span a four-lane road. They are three-span slab bridges with longitudinal tubular voids and span lengths of about 20.5 m – 29.0 m – 20.5 m. The concrete slabs are prestressed by the bonded post-tensioning system according to the approval of the company "Polensky und Zöllner". There is a minimum of two and a maximum of six post-tensioning tendons in each web between these hollow bodies. Figure 1 shows the longitudinal and the cross-sectional profiles of bridge "BW40/45".

Acoustic emission sensors have been installed for direct detection of steel fractures. They are measuring continuously since 2021. The local and global structural response to fractures is measured as strain changes along the length of the bridge.

Longitudinal Section

Cross-Section

Figure 1. longitudinal and cross-section of the bridge „Kreuzhof“ BW40/45

Data is collected three to four times a year using BRUSens V9 distributed fiber optical sensors. Rayleigh backscattering technology is used with the ODiSI instrument manufactured by Luna Innovations Incorporated. The DFOS are applied in a groove milled into the structure and are located in every second web on the bottom of the slabs. In addition, 1.5 years of data acquisition was carried out using different sensor technologies for object-specific traffic load determination (B-WIM system). More details can be found in [10] and [11].

### 3 VERIFICATION OF STRAIN MEASUREMENTS

For verification of the measurements tests were performed in the laboratory using the same type of sensor. The BRUSens V9 is a layered sensor with an outer PA sheath, a stainless steel tube and a multilayer buffer to the optical fiber. In order to simulate the strain transfer from the host material to the sensor core in an equivalent way, the sensor was applied to a concrete specimen using the same method. The aim of these tests was to investigate conditions that were as isolated as possible. This was achieved by applying pure compressive, tensile or temperature loads, generating a specific crack width and performing a long-term test under constant conditions. In addition, different sensors with the same and different measurement principles were used for each test to validate the reliability of the strain signal.

Test loads were also applied to the bridges by trucks at the beginning of the monitoring and repeated after six months. The tests were carried out to assess structural behaviour and to analyse environmental effects on the measured data. For in-field verification, it was possible to compare the DFOS results with those from the B-WIM strain gauges.

### 4 RESULTS AND DISCUSSION

Laboratory tests show reliable results for compressive and tensile strains in the uncracked concrete. When cracks appear, due to the sensors layers a slippage can occur. In this case the crack width can no longer be determined exactly. Various studies have also analysed the measurement signal at crack opening with different sensors, i.e. [5], [12], [13], [14]. The appearance of a crack manifests itself always as a strain peak, even in the case of slippage. In prestressed structures already new formed small cracks are first signs of a deterioration.

If a test specimen is subjected to a constant temperature load, the DFOS BRUSens V9 will record the thermal expansion of the inner stainless steel jacket layer. In addition, the strain profile scatters over the sensor length with increasing temperature difference. In the tests, a value between  $15$  und  $19 \times 10^{-6}/K$  was determined for the thermal expansion coefficient of the sensor, whereby the average value is  $16 \times 10^{-6}/K$  according to the manufacturer Solifos AG [15].

Strain measurements on the bridges show that only very small strain changes of less than  $30 \mu m/m$  ( $0.03 \%$ ) occur when two trucks with a maximum vehicle weight of 42 tonnes are loaded. This means that the measurement signal from light vehicles such as cars is masked by the DFOS measurement noise. On both bridges no cracks have been detected since the start of monitoring.

In contrast, strain changes due to temperature variations are particularly pronounced. Figure 2 presents selected results from the mid-span of the 'Kreuzhof' bridges. The raw data taken on

twelve different days since November 2021 are shown. When these results are compared with the theoretical strain change at the given temperature, the same influence of thermal expansion on the data as in the laboratory results is observed. Furthermore, strain peaks in Figure 2 have a dominance of approx.  $200 \mu m/m$  ( $0.20 \%$ ). In laboratory tests, such peaks are an indication of the presence of a crack. A visual inspection of the bridge revealed an offset in the concrete surface in the location of the peak. This concrete offset results in a longitudinal offset of the sensor, which means that linear strain transmission between the concrete and the glass fibre core is not possible. When comparing all measurements over several years, the strain peaks appear in the same location. Provided a single measurement signal is referenced to a measurement taken at a similar temperature, no more pronounced strain peaks are visible. The conclusion is that no new strain change has occurred at these locations. In a theoretical case of a possible prestressing steel fracture, a local peak would appear that could be distinguished from the temperature.

Figure 2. Raw data of the results and the corresponding temperature in the mid-span of bridge BW40/45 from November 2021 to June 2024

### 5 CONCLUSION

The long-term monitoring on the "Kreuzhof" bridges in Munich, employing acoustic emission sensors and distributed fiber optic sensors (DFOS), does guarantee a safe operation of the bridge service. Laboratory tests have been crucial in understanding the limitations and reliability of the DFOS measurements, particularly in the presence of cracking and temperature variations. While with in field tests object specific limitations are discovered.

The City of Munich decided to replace the bridges due to the risk of stress corrosion cracking in the prestressing steel and a future tram line which will pass under these bridges. In January 2025 destructive structural tests were carried out shortly before the partial dismantling to validate the monitoring system. The first results will be generated in the middle of the year 2025.

### ACKNOWLEDGMENTS

The authors would like to thank the Department of Civil Structures of the City of Munich for the project assignment and the pleasant cooperation.

**ABSTRACT:** Stress corrosion cracking (SCC) of prestressing steel represents a critical threat to the long-term safety and serviceability of aging bridge infrastructure. This phenomenon occurs within the cross-section and leads to the initiation and propagation of cracks, ultimately causing the rupture of the prestressing wires, which may ultimately result in sudden bridge failure. This underscores the need for reliable monitoring solutions. Traditional non-destructive testing techniques, while valuable, often lack high-resolution capabilities. In contrast, Distributed Fiber Optic Sensing (DFOS) has emerged as a transformative approach, offering high-resolution, continuous monitoring of strain distribution and crack development in concrete structures. This study demonstrates the practical application of DFOS technology for detecting and quantifying crack propagation in operational bridge structures affected by the risk of active SCC. By considering field investigations on four infrastructure projects the research evaluates DFOS performance for structures vulnerable to SCC. The paper demonstrates the technology's capability to monitor crack dynamics under operational conditions as anomalies in the crack pattern may indicate early symptoms of structural damage caused by SCC. By bridging knowledge gaps in the application of DFOS for infrastructure safety, the study advances the role of fiber optic sensing in addressing SCC challenges, ultimately contributing to the development of more resilient and sustainable bridge monitoring systems.

**KEY WORDS:** DFOS, distributed fiber optic sensing, stress corrosion cracking, bridge monitoring, SHM, structural health monitoring.

## 1 INTRODUCTION

### 1.1 Background and motivation

Stress corrosion cracking (SCC) is a critical degradation mechanism in prestressed concrete bridges. This phenomenon involves the initiation and gradual propagation of cracks in prestressing wires inside the cross-section, often remaining undetectable by conventional methods in early stages. As the process advances, stress concentrations may lead to surface cracking in prestressed elements. Progressive SCC results in sequential wire rupture, reducing structural capacity and potentially leading to sudden failure. This form of corrosion is particularly insidious due to its delayed manifestation and the absence of external indicators, making early detection extremely difficult. Numerous historical cases have shown that even well-constructed bridges can suffer unexpected failures due to SCC, emphasizing its relevance for long-term structural integrity [1]. As many existing bridges age and are subjected to increasing traffic loads, the risk posed by SCC continues to grow. Conventional inspection techniques often fail to capture early signs of SCC, prompting the need for advanced, reliable monitoring methods. Therefore, the development and implementation of modern evaluation and monitoring strategies are essential to ensure the safety and longevity of critical infrastructure.

### 1.2 Scope and objectives of the article

This paper focuses on the application of Distributed Fiber Optic Sensing (DFOS) in the monitoring of structures

susceptible to SCC, with examples of identifying structural response to loading, crack detection, and evaluation of crack width changes. The article also outlines the advantages of DFOS over conventional inspection methods, emphasizing its ability to provide continuous, high-resolution, and little-invasive monitoring.

## 2 FUNDAMENTALS OF STRESS CORROSION CRACKING IN BRIDGES

### 2.1 Mechanisms of SCC in prestressing steel

The phenomenon of SCC refers to the chemical and/or electrochemical corrosion of a material under the simultaneous influence of static tensile stress. Two primary types of SCC in steel can be distinguished: anodic and cathodic corrosion [2]. Anodic corrosion involves the decomposition of material at the surface through an electrolytic reaction. Cracks form deep inside the crystal structure and are not visible from the outside. In contrast, cathodic corrosion occurs when free hydrogen atoms penetrate the metal's crystal structure. As hydrogen molecules form, they cause internal expansion, which leads to crack initiation along the grain boundaries.

Microscopic corrosion scars are usually the points of crack initiation. Scanning electron microscope (SEM) studies have shown that microcracks begin at weak points in the grain structure and grow into a honeycomb-like pattern [2]. The visible signs of stress corrosion manifest as numerous microcracks, perpendicular to the axis of the prestressing strand, starting at the surface and progressing inward —

see Fig. 1. What makes SCC particularly dangerous is progression without visible deformation of the structure or expansive corrosion products, meaning failure often happens suddenly due to brittle fracture of the prestressing steel.

In Germany, high-strength steels with tensile strengths above 1700 N/mm<sup>2</sup>, used primarily in the 1960s and 1970s, are considered particularly susceptible to SCC. This includes steel types such as Neptun St 145/160 (FRG), Sigma St 145/160 (FRG), and Henningsdorf St 140/160 (GDR) [3].

Figure 1. Inspection of the prestressing strand taken from the Carola Bridge (Dresden): a) microcracks visible by fluorescent magnetic particle method, b) longitudinal section [4]

## 2.2 Impact of SCC on structural integrity and service life

Several failures of well-designed and properly built structures have been linked to SCC. A prominent example is the partial collapse of a production hall in Mannheim in 1989, after 28 years of use. Investigations revealed that the primary cause was the loss of flexural capacity in the roof girders due to SCC. Despite proper grouting and maintained alkalinity, the prestressing wires showed numerous microcracks characteristic of SCC. Similar damage occurred in Mühlacker in 1992, where only rapid intervention prevented a collapse. Even with completely filled ducts, SCC-induced cracking was found in the prestressing steel. In some cases, such as the collapse of the Berlin Kongresshalle in 1980, SCC acted as an additional factor accelerating degradation, alongside moisture and chlorides.

Recent events underline the ongoing relevance of SCC: In September 2024, a 100-meter section of the Carola Bridge in Dresden collapsed due to severely corroded and fractured steel tendons [4]. The collapse caused major infrastructure and traffic disruptions in the city. Demolition of the remaining structure is currently planned. Similarly, in November 2024, the Elbe Bridge in Bad Schandau was immediately closed after inspections revealed longitudinal cracks in prestressed elements (particularly in the lower arch). The closure caused significant local transport disruptions, with temporary ferry services established. At the beginning of April 2025, load tests of the bridge were conducted. The collected results, including strain measurements using DFOS, were used to calibrate the computational model. Based on the performed analysis, authorities decided to temporarily reopen the bridge for use, with a restriction on the maximum allowed vehicle weight.

It is estimated that in Germany, there are at least 500 [5], [3] or even 1000 bridges [6] still in service that contain prestressing steel susceptible to SCC. Due to the considerable

costs and potential socio-economic consequences, it is essential to take actions aimed at extending the service life of these structures while maintaining an appropriate level of safety and considering the economic and environmental impacts.

## 2.3 Limitations of conventional monitoring technologies

Conventional monitoring methods have notable limitations in detecting and observing SCC. Visual inspection, though widely used, is time-consuming, costly, and limited to surface-level damage. Moreover, the reproducibility is limited due to the high dependency of crack localization on the observer's perception, as well as on environmental conditions at the time of inspection, such as temperature and humidity. It cannot detect microcracks or subsurface flaws, which often form due to localized stress concentrations – such as those caused by ruptured prestressing tendons [7].

Non-destructive testing methods like ultrasonic or radiographic testing offer deeper insight but still struggle with early-stage SCC, particularly in inaccessible areas or complex geometries [8]. These methods require skilled operation, offer limited scanning depth, and are significantly affected by the density of reinforcement. Early-stage SCC, which typically begins as microscopic damage below the surface, can avoid being detected until it becomes critical. Conventional techniques lack sensitivity to local stress concentrations, which are critical indicators of potential SCC initiation [9].

## 3 DISTRIBUTED FIBER OPTIC SENSING (DFOS) FOR STRUCTURAL MONITORING

### 3.1 Principles and advantages of DFOS

DFOS systems utilize the Rayleigh, Brillouin, or Raman scattering mechanisms in optical fibers to measure strain, temperature, or vibration continuously along the fiber length [10], [11]. Optical fibers serve both as the sensing element and the transmission medium, making them ideal for long-range, distributed measurements without the need for discrete sensors. Depending on the chosen scattering principle and instrumentation (e.g., OFDR, BOTDA), high spatial resolution (down to the millimeter scale) and varying sensing ranges (from 100 m to over 80 km) can be achieved [12].

The DFOS technology offers the following advantages:

- Provides high-resolution structural monitoring over time and along the full length of the sensor [13].
- Enables early detection of the cracks in reinforced and prestressed concrete structures, with the sensitivity allowing to detect even microcracks with very small widths [14].
- DFOS can be integrated into digital twin models and automated data analysis pipelines, supporting predictive maintenance and real-time infrastructure assessment [15].

### 3.2 Application of DFOS in crack detection and strain monitoring

Distributed Fiber Optic Sensing (DFOS) enable continuous, high-resolution strain measurements that are particularly effective for detecting cracks and evaluating their width changes in reinforced and prestressed concrete structures. Cracks are identified by localized strain peaks in the profile, which are analyzed based on parameters such as prominence, height, and width. The key challenge lies in

distinguishing these from peaks caused by noise or local deformation accumulations, which do not necessarily indicate cracks [16]. Crack detection is based on the algorithms employing a topographic approach, with peak height and prominence serving as key parameters. They quantify how distinctly a peak stands out from its surrounding strain environment. The careful selection of these parameters is critical: if set too high, adjacent cracks may be mistakenly interpreted as a single, broader crack, while if set too low, insignificant microcracks may be falsely detected, leading to overestimated number of cracks and underestimated widths of the real cracks at the same time. Additional parameters such as minimum peak width are employed to further filter out noise and ensure that only meaningful strain concentrations are considered.

The width of an identified crack is calculated as the integral of the strain distribution between local minima, which define the boundary of the strain peak – see Fig. 2. In reinforced concrete members, the tension stiffening effect reduces the apparent crack width, what is included by adjusting the area under the strain distribution curve according to the following equation

$$w_{cr,i} = \int_{x_{cr,i}-l_{t,i}^-}^{x_{cr,i}+l_{t,i}^+} \varepsilon(x) - \varepsilon^{TS}(x) dx \quad (1)$$

where:

- $x_{cr,i}$  – position of the crack,
- $l_{t,i}^-$  – distance to the preceding local minimum,
- $l_{t,i}^+$  – distance to the following local minimum,
- $\varepsilon(x)$  – measured strain,
- $\varepsilon^{TS}(x)$  – strain resulting from tension stiffening effect.

Practically, the effect of tension stiffening is accounted for in crack width calculations by subtracting the shaded regions, representing the contribution of concrete, from the total area under the strain distribution curve. These regions are typically approximated as triangular zones with peak values located at midpoints between adjacent cracks.

Figure 2. Parameters included in crack detection and estimation of crack width

The presented approach allows for accurate quantification of width changes as small as 0.02–0.05 mm [17]. Herbers et al. [18], [19] demonstrated that Rayleigh-based DFOS systems can reliably identify cracks across different fiber types and installation methods, achieving results

comparable to those obtained using high-resolution digital image correlation (DIC) techniques.

In addition to crack monitoring, DFOS is also effective in identifying prestressing wire or tendon failures. Abrupt strain changes – such as localized jumps or sudden deviations in gradient – are key indicators of tendon breakage events and can be detected with high spatial resolution [20]. Such events can be detected using DFOS, which is particularly well-suited for periodic measurements. To enhance diagnostic capabilities, it might be advantageous to integrate DFOS with complementary, continuous monitoring techniques such as Acoustic Emission (AE). In this configuration, AE signals can serve as event-based triggers, initiating high-resolution DFOS measurements to enable accurate spatial localization of damage. As DFOS provides a thorough strain distribution along the length of the sensor, it allows also to determine the anchorage length of prestressing tendons based on strain measurements along the tendon axis after cutting [21]. Furthermore, DFOS facilitates the creation of digital crack maps and enables the tracking of strain development under load and temperature fluctuations. These features support automated condition assessment, early damage detection, and risk-informed maintenance strategies [22].

### 3.3 DFOS Performance in Detecting Crack Initiation and Propagation

The initiation of cracking in concrete is typically associated with a localized strain concentration, which DFOS detects as a sharp and narrow strain peak along the fiber path. These peaks emerge even before visible cracking occurs and serve as early indicators of damage accumulation. Once cracks are initiated, DFOS allows for real-time tracking of their propagation. Lemcherreq et al. [23] applied DFOS under monotonic and cyclic loading, demonstrating that cyclic strain accumulation is directly correlated with the development of microcracks and that bond shear stresses progressively redistribute toward the unloaded end with an increasing number of load cycles. Importantly, the repeated loading (1 000 000 load cycles) did not impair the quality or reliability of the DFOS measurements throughout the test.

Based on the study by Broth and Hoult [24], it can be concluded that after 3 600 load cycles, strain profiles still captured distinct peaks at crack locations, with strain gradients evolving due to stress redistribution. Crack breathing was clearly visible in the strain signals across load cycles. The sensors enabled the recording of a gradual increase in strain peaks during successive loading cycles, particularly in deep beams, which suggested the widening of previously formed cracks. Initially, the strain values at crack locations reached approximately 1400–1500 μm/m, increasing to nearly 2000 μm/m by the final cycle of the test.

The DFOS system described by Galkovski et al. [25] achieved a measurement resolution of up to 10 μm/m (0.001%), allowing for detection of early-stage microcracking. Strain peaks exceeding 12 000 μm/m (1.2 %) were measured at crack locations—well above the steel yield strain (~2 000 μm/m), indicating DFOS capability to track yielding and post-yield bond behavior.

### 3.4 Limitations and Challenges

The application of DFOS in SHM of prestressed concrete structures susceptible to SCC offers comprehensive strain analysis. Conducting measurements that enable the acquisition of data essential for a reliable and unequivocal analysis necessitates careful consideration of the following aspect:

- interference from overlapping strains within the intensively cracked areas affected by superimposed long-term strains (from creep, shrinkage, or thermal gradients), complicating damage localization and potentially masking SCC-related events [26];
- proper choice of the sensor-adhesive combination and measurement settings are crucial for reliable measurement results and good quality data [19].
- quality of the installation – successful application of DFOS relies on the proper sensor installation. Adhesive selection, groove preparation, and embedding quality significantly influence data accuracy. Unsuitable adhesives or rough interfaces can introduce artificial strain peaks or suppress real ones [27];
- data interpretation – measurements, above all the 24/7 monitoring processes, produce large datasets requiring robust post-processing algorithms to distinguish true damage signs from noise, thermal effects, or adhesive degradation. Misinterpretation may lead to false alarms or overlooked damage [28], [29];
- sensor length affecting data quality – with longer sensors, optical device constraints lead to reduced spatial resolution and sampling rate [19]. This decline in performance is accompanied by increased measurement noise, which may obscure or distort strain events associated with SCC. In practical terms, a compromise must be made between coverage area and data fidelity, depending on the selected DFOS interrogation technology [11].

## 4 FIELD INVESTIGATIONS ON REAL INFRASTRUCTURE ASSETS

In the following section case studies demonstrating the application of DFOS for monitoring bridge structures susceptible to SCC are presented. The focus is on real-world infrastructure where DFOS enables early detection of microcracks, evaluation of changes in crack widths, and assessment of structural behavior under operational loading.

### 4.1 Considerations for DFOS Deployment at Bridge Structures

The installation of DFOS systems in existing bridge structures requires meticulous engineering, application-specific adaptation, and access to specialized equipment. Sensor routes must be defined with precision, targeting critical zones such as anchorage areas, webs, soffits, and coupling joints [30] – regions particularly vulnerable to hidden damage or prestressing wire fracture. For installations in existing structures reference measurements (“zero measurements”), ideally under constant loading conditions (no traffic), are used to initialize monitoring cycles and enable tracking of structural evolution over time.

The fiber optic sensors are typically bonded to prepared surfaces using adhesives. While exact details vary, the standard approach includes marking sensor paths, cutting grooves, and embedding the sensors with injection mortars, ensuring robust

strain transfer from the measured substrate to the sensor core. These operations are carried out with specialized cutting and cleaning tools. Due to the location of sensors on the underside of structural elements, auxiliary access equipment, such as scaffoldings, under-bridge platforms, or telescopic lifts, is often necessary – see Fig. 3.

Figure 3. Examples of the special equipment for sensor installation: a) lifting platform, b) under-bridge inspection device

Furthermore, proper choice of the sensors used is crucial for meeting the demands of the monitoring purpose – for high-resolution crack assessment, monolithic fiber optic sensors provide the best results, while their consistent and rigid geometry ensures more direct strain transfer. This is essential for accurately capturing sharp strain gradients near cracks [19]. Environmental durability and system reliability are ensured not only by using robust sensors, but also by routing fiber leads in protective conduits and terminating them in sealed cabinets. Additionally, to distinguish mechanical strain from temperature-induced effects, several thermal compensation methods are employed in practice [31]. Temperature influence strain measurements through changes in the refractive index (which represents the dominant effect on the results) and the thermal expansion of the fiber. One approach involves interrogators based on Raman backscattering, which is sensitive to thermal effects only. Alternatively, two interrogators (e.g., Rayleigh and Brillouin) can be used on the same fiber, allowing for precise measurements but requiring laboratory calibration. Mechanically decoupled reference fibers, typically embedded in gel, may be affected by friction and are generally more suitable for shorter measurement sections. The simplest and most cost-effective, though less precise, solution involves pointwise temperature measurements using conventional resistance temperature sensors embedded in structural members – particularly suitable for applications with minimal temperature gradients. In such cases, compensation is performed by subtracting the strain resulting from the known temperature change.

In the following sections, four examples of monitoring bridges at risk of SCC using DFOS technology are presented. In all reported implementations, monolithic sensors EpsilonSensor Ø3 mm (manufacturer: Nerve-Sensors) were installed. These sensors featured single-mode (SM 9/125) optical fibers and an external braid that additionally enhanced adhesion. Measurements were carried out using Rayleigh backscattering technique, with a spatial resolution of either 1.3 mm or 2.6 mm, depending on the total sensor length. Thermal compensation was achieved based on discrete temperature measurements. These measurements accounted for the previously discussed effect of the temperature change and the associated thermally induced strain changes.

#### 4.2 Asset 1: Königsbrücker Str. Bridge in Dresden

The bridge at Königsbrücker Straße in Dresden, constructed in 1979, crosses railway infrastructure and consists of three structurally independent units: one for tram traffic and two for road traffic. Due to the use of Hennigsdorf's prestressing steel a dedicated structural health monitoring (SHM) system based on DFOS and AE combination was deployed to ensure continued structural safety and detect early signs of deterioration [32]. Fiber optic sensors were installed along the full length of each superstructure, embedded into grooves on the bottom surface and bonded with high-performance mortar, enabling high-resolution, distributed strain and crack monitoring – see Fig. 4. Measurements are being conducted since November 2023, including an initial zero measurement and further follow-up measurements under varying seasonal and operational conditions.

Figure 4. Installation of the optic sensor on the bottom surface of the girder

Across all monitored spans, the DFOS system consistently detected multiple microcracks, with crack width variations typically below 0.05–0.07 mm and strain peaks occasionally exceeding 1000–1600  $\mu\text{m}/\text{m}$  – see Fig. 5.

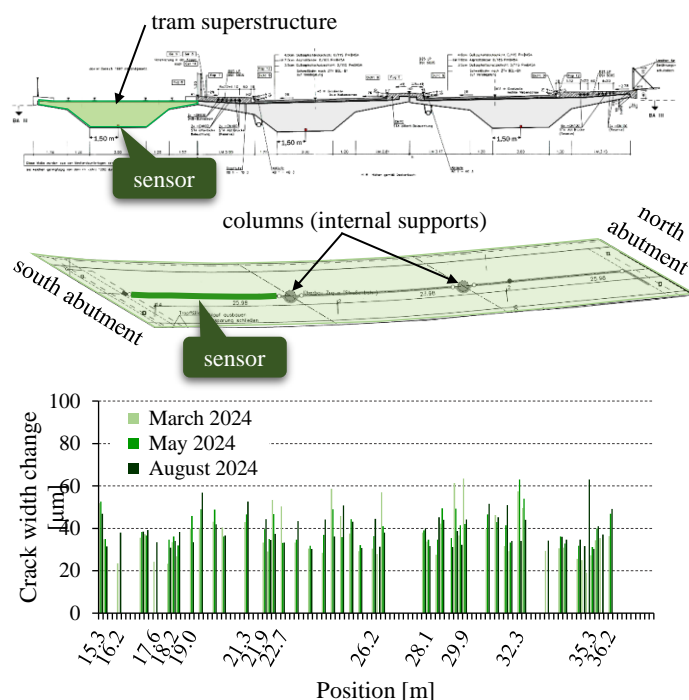

Figure 5. Comparison of the crack width change within the first span of the tram superstructure

In the latest, following measurement, only minimal crack width changes were noted compared to the previous measurements, suggesting no SCC-induced damage and confirming structural stability. The DFOS monitoring proved highly effective in characterizing microcrack evolution in SCC-susceptible girders and offers non-intrusive solution for long-term condition monitoring.

#### 4.3 Asset 2: Road bridge in Waren (Müritz)

The bridge on federal road B192 over the railway line in Waren (Müritz) is a continuous three-span structure consisting of two separate overpasses. Due to the use of high-strength prestressing steel prone to hydrogen-induced SCC, continuous monitoring has been in place since 2014. Long-term inclinometer measurements indicated a successive reduction in structural stiffness, suggesting progressive structural degradation, due to SCC.

In preparation for an upcoming replacement of the bridge, the south span - temporarily carrying all traffic – was equipped with a DFOS system to monitor potential crack propagation. Two sensor lines (10.5 m and 11 m) were installed on the underside of the deck to detect strain changes and localize microcracks in the mid-span section. Initial load tests in April 2024 with a 50-ton truck showed only minor strain changes (0–50  $\mu\text{m}/\text{m}$ ) and microcrack width changes below 0.01 mm, with no macroscopic damage detected – see Fig. 6. A second load test in October 2024 confirmed these results, with strain peaks up to 80  $\mu\text{m}/\text{m}$  and similar minimal crack width variations. The structural response remained consistent between both tests, and all observed strains were reversible after unloading.

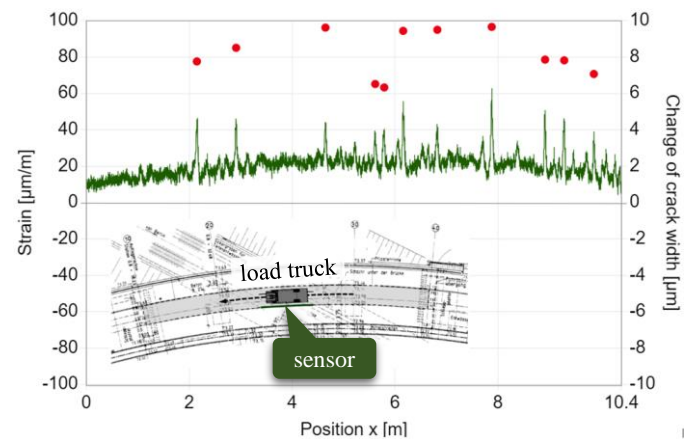

Figure 6. Strains (blue line) and change in microcrack (red points) resulting from truck load

Due to the results of long-term measurements, facing doubts about the condition and safety of the structure, it was decided to demolish and replace both spans, with the detonation of the north span scheduled for January 2025. Since the south span must carry all traffic during the construction period, DFOS measurements and load testing were carried out to assess whether the explosion on the north span had caused any damage to the south span and to ensure its safety for continued use. To this end, load testing was conducted using a 50-ton heavy-duty truck. Figure 7 presents the change in strains along the sensor segment at the mid-span, induced by the passage of

the test vehicle. A gradual increase in strains is evident along the monitored length. Distinct strain peaks correspond to the locations of pre-existing cracks. Under loading, local strain peaks of up to 40  $\mu\text{m/m}$  were recorded, while in the sections between the cracks, the strain values remained approximately constant at around 20  $\mu\text{m/m}$ .

Figure 7. Strain change resulting from the passage of a test truck with distinct microcrack opening

DFOS measurements enabled the identification of crack locations at the very beginning of the loading test, even before the test vehicle reached the center of the monitored span. Strain development was most pronounced at the crack locations, with the progressive formation of peaks clearly visible. Due to the considerable stiffness of the structure, the variation in the microcracks, calculated according to the methodology described in Section 3.2, was minimal and did not exceed 0.01 mm.

The DFOS measurements, conducted before and after the controlled demolition confirmed no anomalies or damage to the monitored bridge segment. The consistent, low, and fully reversible strain values provide clear evidence that the structural integrity was not compromised by the blast or load tests.

#### 4.4 Asset 3: Bridge BW55b in Döbeln

The B169 bridge near Döbeln (BW55b), built in 1966, is a prestressed concrete structure consisting of two hollow box girders connected by a concrete deck, spanning approximately 67 m with a total width of 16 m [33]. The bridge forms part of a vital route connecting the A4 and A14 motorways and remains structurally safe but is classified as highly susceptible to SCC due to the use of prestressing steel made from over 200 fine wires per tendon. Instead of replacing the bridge, the Saxon State Authority for Road Construction and Transport (LASuV) implemented an advanced SHM strategy to prolong its service life. This included the installation of DFOS on the undersides of the four longitudinal box girder webs, in total around 100 m of sensing length. The sensors were installed in grooves and bonded using high-performance injection mortar – see Fig. 8.

The follow-up measurement performed under regular traffic revealed strain changes with peak values typically below 150  $\mu\text{m/m}$ , and extremely small variations of crack widths – generally not exceeding 0.01 mm. Several local strain peaks were detected, suggesting the presence of microcracks, but no signs of active or progressive damage were observed. Temporary changes during vehicle crossings indicated reversible crack width variations between 5 and 20  $\mu\text{m}$ , which

immediately returned to previous state after the load passed, demonstrating the high stiffness and resilience of the structure. All measurements were temperature-compensated, and sensor performance remained stable. No anomalies indicating structural issues were identified. The purpose of the long-term DFOS monitoring supported by AE is the continuous assessment of the structure's condition, ensuring safe operation without the need for costly replacement.

Figure 8. Layout of the sensors on the surface of hollow box

#### 4.5 Asset 4: Budapest Str. Bridge in Dresden

The Budapest Straße Bridge in Dresden, built between 1963 and 1968, is a critical urban infrastructure linking the city center with the southern districts. The 850-meter-long structure spans the main rail yard of Dresden Central Station, tram lines, and the Ammonstraße, and is composed of multiple monolithically constructed prestressed concrete sections. Its overpasses were constructed with longitudinal post-tensioning using oil-tempered Henningsdorf's prestressing steel, a material highly susceptible to hydrogen-induced SCC. Cracks between 0.1 and 0.5 mm wide (Fig. 9a) and visible rust staining (Fig. 9b) have raised concerns about latent internal damage.

Figure 9. Visible damages: a) cracks with extensive widths, b) rust staining and displacement within coupling joint

To address the concerns and ensure long-term traffic safety without the necessity of a premature reconstruction, a comprehensive SHM system based on DFOS and acoustic emission is being installed – see Fig. 10. Around 880 meters of sensors are glued into the grooves along the underside of overpasses a and c. The system is designed to detect microcracks, localize strain peaks, and monitor changes over time under thermal and traffic-induced loading. Strain measurements are complemented by distributed temperature

fiber optic sensors, using Raman backscattering, to ensure reliable thermal compensation for longer sections. The main goals include detecting potential wires breakage, tracking crack formation near coupling joints, and providing high-resolution insights into the bridge's response to operational and environmental loads.

Figure 10. Localization of the sensors on the internal segment of the superstructure

The sensors are divided into 14 segments, each covering up to three spans, with data acquisition performed periodically using optical interrogators. This quasi-continuous monitoring allows localization of crack activity across the entire length of both overpasses. Although the installation in the existing structure obviously does not allow to monitor structural health from the “hour zero”, DFOS enables ongoing evaluation of crack development and possible early signs of structural deterioration starting directly after the installation.

## 5 DISCUSSION

### 5.1 Comparison with Traditional Monitoring Methods

DFOS offers several advantages over conventional monitoring methods such as strain gauges, vibrating wire sensors, and visual inspections. Unlike these techniques, DFOS enables continuous, high-resolution strain measurements over long sensor paths.

In a study on the Black River Bridge in Ontario, DFOS successfully identified localized cracking and strain concentrations – insights that were missed by traditional gauges spaced every meter. It also detected unintended semi-rigid restraint conditions at supports, demonstrating its ability to capture unexpected behavior [34]. DFOS strain resolution (typically 1–5  $\mu\text{m/m}$ ) is comparable or superior to that of foil strain gauges (5–10  $\mu\text{m/m}$ ), while covering thousands of data points simultaneously. In the project described in [35], discrete sensors were replaced by more than 1500 m of fiber optic sensors, with each individual sensor providing approximately 38 400 measurement points.

Compared to visual inspection, DFOS provides objective, quantitative detection of crack formation and width changes. With strain change exceeding 50  $\mu\text{m/m}$ , it can identify cracks smaller than 0.05 mm, well below the threshold of unaided visual assessment [20], [36]. Additionally, sensors can be embedded into structural components like tendons and rebar, enabling long-term monitoring of prestressing forces and

internal damage progression – tasks that are difficult or impossible with surface-mounted sensors or manual inspection.

### 5.2 Interpretation of Long-Term Structural Behavior including thermal compensation

DFOS enables precise interpretation of long-term structural behavior by continuously capturing strain distributions and tracking crack evolution under both mechanical loading and environmental influences. Based on DFOS measurements carried out by the authors on actual bridges during in-service operation, over several years of continuous monitoring, following findings can be pointed out. At the Königsbrücker Straße bridge in Dresden, fiber optic sensors recorded mechanical strain responses caused by tram and road traffic, with peak strain values near supports and midspans. These strain concentrations corresponded to microcrack openings predominantly between 0.01–0.05 mm. Changes in crack width over time indicated stable structural behavior under service loads. In the bridge on the road B192 over the railway in Waren, strain peaks of 50–100  $\mu\text{m/m}$  were recorded during staged loading under increasing traffic, allowing localization of microcracks with widths estimated around 0.02–0.05 mm. In both projects, thermal effects were observed as restrained strain patterns uniformly distributed along the spans, depending on exposure and structural response (imposed strains).

Thermal compensation is essential to distinguish thermal effects from mechanical responses. Rayleigh and Brillouin backscattering are sensitive to temperature-induced changes in the fiber, what needs to be considered in evaluation of mechanical strain readings [37]. Including the findings presented in [31], a temperature change of 1 K results in an additional strain of approximately 20  $\mu\text{m/m}$  in monolithic sensors embedded in concrete structures. To address this, multiple solutions can be utilized for dedicated temperature measurements, allowing separation of thermal and mechanical effects and thus enabling accurate compensation and interpretation of structural behavior over time [38]. For real use cases the most practical approaches to thermal compensation include utilizing distributed temperature measurements with Raman backscattering or even local spot temperature sensors.

### 5.3 Enhancing Predictive Maintenance Strategies

The integration of DFOS into SHM systems offers multiple advantages. One effective strategy is the use of hybrid monitoring systems, where DFOS is combined with technologies such as acoustic emission sensors. An example of such implementations is Kreuzhof bridge in Munich, where real-time detection of wire breaks via AE was supplemented by spatially distributed strain monitoring via DFOS, significantly improving damage assessment reliability [39].

Beyond external installations, DFOS can also be integrated directly into structural elements such as prestressing tendons or reinforcement cages. This embedded approach enables continuous internal monitoring of strain and prestressing forces, providing detailed insights from the initial loading stages through the entire service life of the structure. A practical demonstration of this concept was presented in a study on a prestressed concrete bridge girder, where fiber optic sensor was installed during fabrication to successfully

monitor strain development and crack formation under service and ultimate loads [40].

In addition, DFOS systems can be linked to digital twin platforms, enabling real-time data to support predictive maintenance, condition-based inspections, and system-wide risk assessments. This form of integration advances infrastructure monitoring from traditional inspection cycles toward proactive, data-driven management [15].

## 6 FUTURE RESEARCH DIRECTIONS

Despite significant progress in the deployment of DFOS for SHM, several open research questions remain, particularly addressed to:

- early-stage and automated SCC detection – future studies should explore enhanced DFOS signal interpretation methods, such as high-frequency dynamic strain analysis or modal-based decomposition, to identify signatures associated with early-stage wire degradation; the development of automated algorithms for the classification and localization of SCC-induced damage, based on DFOS strain gradients, could streamline monitoring and reduce the reliance on manual data interpretation; techniques such as anomaly detection, pattern recognition, and signal filtering are promising directions for algorithmic refinement.
- integration with predictive modelling – coupling DFOS data with finite element models and machine learning-based predictive tools would enable dynamic risk assessment by correlating measured strain patterns with probabilistic failure modes.

One of the most promising directions for the advancement of detecting tendon breakages is distributed acoustic sensing (DAS) technology. While distributed strain sensing excels in measuring quasi-static and low-frequency strain distributions with high spatial resolution, DAS extends the functionality of the same optical fiber network by enabling detection of dynamic, high-frequency acoustic signals along the entire fiber length. Mechanical disturbances, such as microcracking, prestress wire rupture, or acoustic emissions, alter the backscattering pattern, allowing the system to localize and characterize the source of dynamic events in real time. This makes DAS particularly suitable for detecting sudden or progressive failure mechanisms, including wire breakages or energy release events associated with SCC [41]. However, the use of this technology still requires extensive research to determine the effective detection range around the optic sensor – i.e., the distance between the event and the sensor at which the event can be reliably detected. Further studies are needed to establish the optimal application pattern and to develop automated methods for data analysis.

Combining DSS and DAS in a hybrid sensing system can significantly enhance the sensitivity, reliability, and redundancy of SHM strategies. For instance, a wire rupture may first be identified as a sharp acoustic signal via DAS and subsequently confirmed and quantified by correlated local strain changes registered by DSS. This fusion of datasets might support cross-validation, improve false positive rejection, and enable automated alert systems for infrastructure operators.

## 7 CONCLUSIONS

The application of distributed fiber optic sensing in the structural health monitoring of bridges vulnerable to stress corrosion cracking demonstrates clear advantages over traditional inspection and sensing methods. DFOS provides continuous, high-resolution strain data capable of detecting early-stage microcracks, quantifying crack width changes, and localizing damage with high spatial precision. The case studies presented confirm the efficacy of DFOS in operational environments, with successful deployment across multiple bridge structures. Monitoring results revealed that even microcrack width changes (typically below 0.01 mm) could be captured, and strain peaks were localized precisely at pre-existing damage sites. Multiple real-world case studies have shown that DFOS systems can effectively monitor the evolution of cracks under operational conditions, offering valuable insights into the structural integrity and residual service life of aging infrastructure. The ability to detect reversible strain patterns and correlate them with loading events supports informed decision-making regarding the continued safe use of SCC-affected structures.

The integration of DFOS with other sensing technologies, such as acoustic emission, further enhances damage detection capabilities and supports predictive maintenance strategies. While there are still challenges, such as sensor installation complexities and the need for robust data processing algorithms, the DFOS technology can be perceived as a transformative tool in advancing resilient, data-driven infrastructure monitoring practices.

## ACKNOWLEDGMENTS

This paper presents some of the results of the research project FOSSure - Faseroptische Sensoren zur sicheren Zustandsbewertung von Massivbrücken (Fiber Optic Sensors for the Reliable Structural Health Assessment of Concrete Bridges), funded by the Federal Ministry of Transport and Digital Infrastructure, Germany, within the innovation program mFUND (funding reference: 01FV2075C, 01FV2075A). The authors sincerely thank the funding agency for their support.

**ABSTRACT:** Existing prestressed concrete bridges without minimum shear or flexural reinforcement are at increased risk of sudden failure, even if they appear undamaged. To prevent such a sudden failure surface mounted Distributed Fiber Optical Sensors (DFOS) can detect local strain changes prior to cracking and visible damage. Failure mechanism analysis, laboratory tests and numerical simulations are used to identify relevant strain indicators. These strain changes could be detected by DFOS even if the failure location is not known exactly in advance. From these results, limits for a universal monitoring concept could be derived considering the individual failure mechanisms and the limitations of the sensor system.

**KEY WORDS:** SHMII-13; distributed fiber optical sensors; existing prestressed bridges; shear failure; brittle failure; monitoring.

## 1 INTRODUCTION

Existing prestressed concrete bridges often no longer meet current safety standards, even though they were originally designed and constructed in accordance with the standards in force at the time, and show no visible damage. Particularly critical are structures lacking minimum shear or flexural reinforcement, where sudden failure without sufficient prior warning can occur [1].

Reassessments of such structures according to the German Reassessment Guidelines and their supplements increasingly reveal structural deficiencies [2][3]. Some of these affect shear capacity, transverse reinforcement between flanges and web, and the structures bending robustness. Due to these deficiencies, early indications of failure become less likely or may not occur at all when conducting structural inspections in accordance with current German standards (e.g., DIN 1076 [4]) [1].

A further challenge is the accurate measurement of local strain changes in existing structures, where irregular surface conditions, structural tolerances and limited accessibility significantly affect the reliable application of both established and innovative monitoring methods.

To ensure the long-term structural safety of this existing structures, it is essential to develop and implement tailored monitoring strategies. This requires the development of practical principles that provide engineering consultants, clients and inspection authorities with a sound basis for decision making.

## 2 FAILURE MECHANISM

The absence of minimum reinforcement or corrosion damage, especially stress corrosion cracking in prestressing steel, can lead to brittle, unannounced failures in prestressed concrete bridges.

Figure 1 Applied DFOS on the Hammelburg bridge girder web, taken from [6]

## 2.1 Shear

Previous test programs have shown that, despite low shear reinforcement, redistribution in the tension chord can result in a certain increase in shear capacity [5]. In contrast, shear tests at the Hammelburg bridge revealed early failure after initial cracking due to pre-damaged and unfavourably oriented tendons, as well as smooth reinforcement bars [6]. Figure 1 shows the girder web of the Hammelburg bridge after the shear test.

## 2.2 Bending Robustness

Significant problems on prestressed structures with a lack of flexural reinforcement became apparent with increasing operational experience. In Germany the introduction of robustness reinforcement was consequently introduced in 1995 [7]. In bridges that were built before this time, calculative proof of sufficient warning behavior as a crack before structural failure is not always given. Moreover, even with proven sufficient warning behavior, the implementation of condition monitoring is required to prevent sudden failure [8].

## 3 SURFACE MOUNTED DFOS ON PRESTRESSED CONCRETE BRIDGES

Fiber optical measurement technology based on Rayleigh backscattering offers advantages on prestressed concrete structures. As there is generally little or no tensile stress in the cross-section of existing prestressed concrete bridges, there is less likelihood of significant cracking. Nevertheless, it is possible to follow the stress under temporary loading and thus detect cracks that may have been overstressed by the prestressing. Strain changes are detected continuously and with high spatial resolution up to 0.65 mm along a bonded fiber optical sensor with lengths exceeding 100 m.

The application of DFOS on the surface of existing structures faces many challenges. Uneven adhesive layer thicknesses, rough formwork surfaces, and positional inaccuracies due to construction tolerances are just a few, which have to be considered in the data evaluation. Discontinuities in the adhesive or surface irregularities can lead to strain peaks in the signal, but these can be validated through visual inspections [9].

The early detection of localized strain changes long before the appearance of visible cracks enables innovative condition monitoring strategies, which can significantly extend the service life of existing structures and support more efficient and economical maintenance planning.

## 4 ACTUAL RESEARCH

The current research at the Chair of Concrete and Masonry Structures at the Technical University of Munich includes numerical simulations to identify strain fields associated with failure mechanisms. Various damage scenarios are analyzed to map critical strain zones for shear and flexural failure. The results serve as the basis for defining expected measurement quantities and developing robust sensor layouts.

Parallel experimental investigations are conducted. In small-scale tests different sensor-adhesive combinations, application techniques, and environmental influences are compared. Particular attention is given to overhead applications and the detection of strains over irregular surfaces. Long-term tests

examine the effects of temperature cycles and potential creep phenomena within the sensor.

Building upon these results, current research focuses on the development of a monitoring concept for prestressed concrete bridges with static and structural deficiencies. The study emphasizes the identification of suitable sensors, application methods, sensor placement, and the definition of meaningful measurement intervals. The outcomes are intended to provide consulting engineers, clients, and inspection authorities with a solid basis for developing and implementing individually adapted monitoring strategies.

Large-scale tests on prestressed concrete girders will be carried out based on the numerical and experimental results. The focus of these tests lies on the application of a developed monitoring concept to detect the initial signs of a shear or flexural failure described in chapter 2. The load cycles are designed to induce microcracking and pre-damage, which, although not visibly detectable after unloading, can still be measured by DFOS.

The outcomings should lead to a comprehensive guideline for the use of DFOS on existing prestressed bridges. It will include recommendations for sensor layouts, suitable adhesive and application techniques, and methods for determining appropriate measurement intervals. The guideline also provides information on installation requirements and data interpretation. Validation will be carried out on two bridges with different types of structural deficiencies: one suffering from shear capacity issues and another from missing robustness reinforcement combined with susceptibility to stress corrosion cracking.

## 5 CONCLUSION

Effective use of DFOS on bridges has already been demonstrated by several studies, i.e. [10][11][12][13]. This shows that the general and widespread use of this sensor technology can be useful for extending service life of existing bridges. Therefore, limits can be developed for a universal monitoring concept for prestressed concrete bridges with known deficiencies using DFOS. Therefore, reliable sensor layouts for typical failure mechanisms and recommendations for the selection of suitable sensor and adhesive combinations have to be analyzed. Moreover, the development of methodological approaches for defining measurement intervals, considering damage probabilities and degradation processes have to be considered.

Through practical validation, the feasibility of the developed concepts will be demonstrated. Thus, the project contributes significantly to the sustainable maintenance of existing prestressed concrete bridges and the extension of their service life.

**ABSTRACT:** In recent years, Distributed Strain Sensing (DSS), utilizing optical frequency domain reflectometry of Rayleigh backscatter, has gained significant prominence in the realm of Bridge Structural Health Monitoring (BSHM). Its key advantage is its ability to provide continuous strain monitoring with high spatial resolution (0.65 mm) and an accuracy of up to 1  $\mu\text{m/m}$ . This capability facilitates the monitoring of deformations and defects, as well as precise crack detection, the assessment of crack width and others.

However, publications on DSS based on Rayleigh backscattering often report local effects that are not linked to disturbances caused by the measurement principle, such as noise or anomalies in strain readings. These effects can complicate the evaluation of DSS data, particularly concerning crack detection and width measurement, as well as tasks like detecting tension wire breakages. There have been theories, suggesting that these local effects may stem from micro-cracks or inhomogeneities within the concrete matrix, yet further investigations into this phenomenon are lacking.

Within this paper the phenomenon of local effects, henceforth referred to as the *concrete signature*, has been investigated on multiple time scales during. The analysis utilizes data from the openLAB research bridge in Bautzen, Germany. Possible reasons for the development and behavior of *concrete signature* are discussed, along with the challenges and opportunities associated with addressing it.

**KEY WORDS:** Concrete Signature, Distributed Fiber Optic Sensing, Distributed Strain Sensing, Bridge Structural Health Monitoring.

## 1 INTRODUCTION

Distributed fiber optic sensing (DFOS) has emerged as a pivotal technology in the realm of structural health monitoring (SHM) in recent years. The applications of DFOS can be broadly classified into three primary categories: distributed temperature sensing (DTS), distributed acoustic sensing (DAS), and distributed strain sensing (DSS). All these applications exploit backscatter effects arising from inhomogeneities within optical fibers. The principal types of backscatter effects include Raman, Brillouin, and Rayleigh backscattering [1, 2].

Within the scope of SHM of concrete structures, DSS has gained considerable attention, as it offers continuous strain measurements in structures, a significant advantage over traditional measurement systems such as strain gauges or inductive transducers [3]. DSS utilizing Rayleigh backscattering (optical frequency domain reflectometry) achieves a high spatial resolution of up to 0.65 mm with an accuracy of 1  $\mu\text{m/m}$  [4], albeit with a sensing range constrained to approx. 100 m [5]. Therefore, its principal applications lie in the evaluation of failures, damages and local effects in concrete structures, particularly in the realms of crack detection and crack width calculation [6, 7].

Crack detection with DSS is predicated on peak identification, while the subsequent quantification of crack width relies on minima or midpoint approaches to ascertain the influence length of the crack to find out the borders for linear integration. Hence, it is important to distinguish clearly

between peaks and minima attributable to cracks and those arising from other factors present in DSS readings [6, 7].

However, literature regarding DSS based on Rayleigh backscattering in concrete structures frequently reports local effects that do not correlate with disturbances originating from the measurement principle, such as noise or strain reading anomalies [8-11]. These local effects, subsequently referred to as the *concrete signature*, appear to evolve over time, maintaining a consistent position, thereby complicating the interpretation of DSS readings, particularly concerning crack detection and crack width evaluation, as well as for the identification of tension wire breakages [12].

Given that current publications on DSS employing Rayleigh backscattering predominantly rely on laboratory assessments or short-term field trials, this paper aims to investigate the phenomenon of evolving *concrete signature* in DSS readings over various time scales. To achieve this objective, DSS data from the openLAB research bridge in Bautzen, Germany, are analyzed [13, 14]. A picture of the openLAB research bridge is given in Figure 1.

The DSS dataset analyzed encompasses the production of precast elements, the installation phase, and the operational phase of the bridge, extending over a total sensor length of 1.5 km [13]. For the purposes of this analysis, a single beam will be selected to examine the development of the *concrete signature* along with the potential underlying factors and their implications. Ultimately, the study will elucidate the impact of *concrete signature* on DSS reading evaluation and its potential significance.

Figure 1. OpenLAB research bridge in Bautzen, Germany (Stefan Göschel)

## 2 CONCRETE SIGNATURE

Although *concrete signature* is recognizable in the majority of publications [12, 15, 16], only a few commented it briefly [8-11, 17]. For instance, Richter et al. highlighted the emergence of local effects that are not associated with disturbances in the measurement system [9]. Becks et al. reported fluctuations of up to 200  $\mu\text{m/m}$  in DSS readings from sensors adhered to the concrete surface, attributing these variations to local strain changes within inhomogeneous concrete [8]. Weisbrich et al. provided a similar explanation, conducting laboratory tests with concrete specimens that had Ormocer coated sensors glued to the surface, to reinforcement, and embedded in the concrete matrix [11]. They indicated that "inhomogeneities and imprecision of the concrete" could account for fluctuations in DSS readings observed during their tests [11]. Additionally, Sieńko et al. reported on micro-cracks resulting from thermal shrinkage during the concrete hardening process in laboratory tests, which correspond in size to the phenomena described by Becks et al. [8, 10]. Despite these effects being identified and illustrated in diagrams across numerous publications, there has yet to be a thorough investigation into their underlying causes and behaviors.

## 3 METHODOLOGY

To investigate the development and properties of *concrete signature* over various time scales, DSS readings from a fiber optic sensor placed in a 15 m prestressed bridge beam of the openLAB research bridge in Bautzen, Germany have been analyzed. The beam FT1.1 features a T-shaped cross-section and is prestressed. The beam is made from C20/25 standard

concrete using granite and quartzite aggregates, with a maximum aggregate size of 16 mm.

The fiber optic sensor analyzed is an EpsilonSensor, 3 mm, ripped from Nerve-Sensors [18], where the fiber itself is embedded within a monolithic core out of polyester fibers and epoxide. It is situated at the bottom of the beam within the concrete matrix and is securely fixed to the stirrups using cable ties. The sensor was interrogated by an ODiSi6100 system from Luna Inc. [5], utilizing a gage pitch of 1.3 mm.

Figure 2 and Figure 3 are showing the placement of the sensor within beam FT1.1. Figure 2 illustrates the sensor placement within the beam FT1.1 at openLAB, while Figure 3 is a picture of the fiber optic sensor (red) within the reinforcement cage during the production of FT1.1.

Figure 2. Sensor placement of the fiber optic sensor at beam FT1.1 in span 1 of the openLAB in Bautzen, Germany.

Figure 3. EpsilonSensor 3 mm ripped with the reinforcement cage of FT1.1 in span 1 of the openLAB in Bautzen, Germany.

In addition to DSS readings, temperature measurements with Gaia 200 of Maturix [19] using thermocouples type K inside the concrete took place during hydration. Later, during

prestressing and operation, the concrete temperature was measured using Testo 176T4 [20] with thermocouples of type K at five points inside the beam. In the operational phase, a combi-sensor continuously measuring air temperature and air humidity was installed next to the beam.

The DSS readings have not been compensated for temperature variations, either regarding optical or material effects. Compensation for material effects entails addressing the thermal expansion of both the sensor materials and the host material. In the case of concrete as the host material, this is typically accomplished by utilizing the overall thermal expansion coefficient of concrete [16]. For optical effects, temperature compensation related to changes in refractive index is achieved by applying the temperature calibration constant of the fiber and calculating the spectral shift based on the temperature difference [21]. Given that only gradual temperature changes occur within concrete elements, neither effect significantly impacts the local, distinctive manifestation of the *concrete signature*.

The analysis involved varying the DSS readings tare to examine the redevelopment of the concrete signature across different time scales and for comparisons. Thereby, tare defines the point where the DSS reading was set to zero line again.

#### 4 RESULTS

During the time scales under consideration, the global stress in the beam is changing several 100  $\mu\text{m}/\text{m}$  due to temperature changes, load, creep, and shrinkage. However, the focus of this study is the development of the local *concrete signature*. Thus, a representative segment of 2 meters from the DSS readings, collected at specific timestamps, is presented to elucidate the data. The diagram areas delineate a section of 200  $\mu\text{m}/\text{m}$ , visualized through a grid structured in increments of 50  $\mu\text{m}/\text{m}$ . The orientation of the readings was selected based on the mean value located at the midpoint of the y-axis to effectively showcase the manifestation of the *concrete signature*.

The investigation initiates with the first 24 hours of the hydration phase of concrete, aiming to analyze the initial development of the *concrete signature*. For that the DSS readings have been referenced to the beginning of the hardening.

Figure 4 depicts the evolution of the *concrete signature* throughout hydration. The timestamp 0 hours signifies the beginning of the hardening process and the tare for the following DSS readings; consequently, the DSS reading establishes a baseline of zero. After 2 hours, initial fluctuations are observed, although the DSS readings remain relatively smooth. After 6 hours, a pronounced signature emerges, exhibiting an increasing trend until 12 hours, ultimately reaching a value range around the mean of approx.  $\pm 80 \mu\text{m}/\text{m}$  and a standard deviation of approx. 22.6  $\mu\text{m}/\text{m}$ . Thereafter, the signature exhibits a decreasing trend until the concluding DSS reading at 24 hours with a value range of  $\pm 75 \mu\text{m}/\text{m}$  and a standard deviation of 20.4  $\mu\text{m}/\text{m}$ . Notably, significant peaks are apparent between 2 hours and 6 hours, with DSS readings at 24 hours remaining considerably elevated.

Figure 4. Distributed strain sensing readings during the first 24 hours of hydration.

During the hydration, a notable increase in the temperature of the concrete was observed, reaching a maximum temperature differential of 22.5 K relative to the tare readings at 0 hours. Figure 5 shows the temperature development during the hydration process as well as the temperature difference  $\Delta T$  for the selected DSS readings to the tare reading at 0 hours.

Figure 5. Temperature measurements during hydration.

The prestressing process was subsequently analyzed with respect to the tare prior to hydration and the tare prior to prestressing. This included assessments prior prestressing the tendon, after partial prestressing the tendon in subsequent bonding 33 % and after prestressing strands in immediate bonding at a concrete age of 5 days. Followed by DSS readings after full prestressing of the tendon 100 % in subsequent bonding at concrete age of 15 days.

Figure 6 illustrates the evolution of the *concrete signature* throughout the prestressing process. The red lines represent the DSS readings with tare before hydration, while the blue lines indicate the DSS readings with tare before partial prestress, marked by the zero line at the timestamp just prior prestressing. Regardless of the tare used, the *concrete signature* in both DSS readings shows an increase and noticeable similarities.

A comparison of DSS readings across the different tares reveals that primary features consistently re-emerge during the prestressing process, also after taring prior to prestressing. Specifically, the *concrete signature* with tare before hydration reaches a maximum value range according to the mean of  $\pm 69 \mu\text{m/m}$  and a standard deviation of  $22.1 \mu\text{m/m}$ , whereas the *concrete signature* with tare before prestressing reaches a maximum value range around the mean of  $\pm 31 \mu\text{m/m}$  and a standard deviation of  $11.8 \mu\text{m/m}$ .

During the prestressing process, the concrete temperature changed less than 1 K. Compared to the tare before hydration the temperature changed approx.  $-4.9 \text{ K}$ .

Figure 6. Distributed strain sensing readings during prestressing process (red: DSS readings with tare before hydration, blue: DSS readings with tare before partial prestress).

Finally, the *concrete signature* was assessed over one year with no traffic load during the DSS readings. The tare is established after finishing construction at the beginning of the operation phase (0 Months). Figure 7 illustrates the evolvement of the *concrete signature* during the operation. It is noteworthy that the *concrete signature* is already significantly redeveloped after three months. The increasing trend of the strain values from the left to the right side of the diagram in each DSS reading is due to the bending moment in the beam bearing on the columns. To quantify the *concrete signature* despite the bending effects, a sliding mean with a window of 380 (approximately 0.5 m at a gage pitch of 1.3 mm) was applied (Figure 7 dashed line). This approach yields a maximum value range of the concrete signature around the sliding mean of approximately  $\pm 29 \mu\text{m/m}$  at six months and a maximum standard deviation of  $8.1 \mu\text{m/m}$  at 12 months.

After two months, distinct patterns of regular increases and decreases, occurring approx. every 15 cm, become apparent and are clearly noticeable after six months.

Figure 7. Distributed strain sensing readings during one year of operation.

During the operation, the beam was exposed to environmental conditions, resulting in permanent changes in air temperature and humidity. Concrete temperature, air temperature and air humidity changes regarding the tare measurement at 0 months are presented in Table 1.

Table 1. Temperatures and humidity changes during the selected DSS readings regarding to the tare at 0 months.

DSS reading	$\Delta T_c$ [K]	$\Delta T_a$ [K]	$\Delta rH_a$ [%]
0 months	0	0	0
2 months	+11.4	+17.0	+12.37
6 months	+10.5	+19.6	+6.81
12 months	-3.6	-1.54	+56.01

## 5 DISCUSSION

It has been demonstrated that the *concrete signature* begins to develop during the hydration process, with certain features remaining consistent over time. In the chosen DSS readings the most prominent signature occurs at 12 hours, which correlates with the highest temperature reached, leading to relation between the *concrete signature* and the temperature behavior of the concrete matrix. The temperature expansion coefficients of the various components of the concrete matrix—such as granite, quartzite, and cement stone—differ substantially (as shown in Table 2), thus the distinct expansions of these materials could be recorded by the sensor.

Table 2. Thermal expansion coefficients [22].

Component	Coefficient of thermal expansion $\alpha T$ [-]
Granite, Quarzporphyr	$7.4 \times 10^{-6}$
Basalt, Diorite, Gabbro	$6.5 \times 10^{-6}$
Quartz sand/gravel	$11.0 \times 10^{-6}$
Quartzite	$11.8 \times 10^{-6}$
Cement matrix (min)	$10.0 \times 10^{-6}$
Cement matrix (max)	$23.0 \times 10^{-6}$

A temperature increase of 19.4 K, like for the 12 hours DSS reading, induces a temperature strain of approx.  $140 \mu\text{m/m}$  for granite, about  $130 \mu\text{m/m}$  for basalt, and around  $200 \mu\text{m/m}$  for liquid cement. This results in strain variations of up to  $65 \mu\text{m/m}$ , close to the variation visible in the DSS reading at 12 hours. However, it is important to note that the thermal expansion coefficient of the cement matrix increases during hydration and decreases with diminishing humidity [22]. Additionally, throughout the hydration process, the modulus of elasticity, concrete strength, and, as a result, creep behavior exhibit continuous variations [23], which may also affect the signature.

The decrease of the signature at 24 hours might be due to the cooling as well as relaxation effects. The peaks observed after cooling can be attributed to the shrinkage of the cement matrix in relation to the aggregates. The more prominent peaks may be indicative of micro-cracks formed as a result of this shrinkage, as described by Sieńko et al. [10]. However, the regular spatial appearance of these peaks suggests the influence of structural elements such as stirrups or cable ties used for sensor fixation may also contribute.

During the prestressing process temperature remains almost constant. However, even after taring before prestressing, the *concrete signature* begins to redevelop. This suggests that the concrete signature is also influenced by load changes, leading to creeping effects. The creep behavior in concrete is affected by the Young's modulus, which varies based on age, aggregate size and shape, its deformation characteristics, and the ratio of cement paste or mortar to aggregates [23]. Considering the use of two aggregate types with differing shapes, sizes, and deformation characteristics, variations in their respective Young's moduli are expected. These differences can significantly influence their creep behavior, potentially affecting the DSS readings.

Similarly, the *concrete signature* continues to redevelop during the operational phase even after taring in the beginning. In this phase, all the potential influencing factors previously mentioned are at play. Environmental changes, such as fluctuations in temperature and humidity, contribute to swelling, shrinking, and thermal expansion. Additionally, there are creeping effects resulting from the prestressing and the dead weight of both the beam and the cast-in-place concrete slab.

The interaction of these effects, combined with the heterogeneous nature of the concrete matrix, leads to a continuous change in the *concrete signature*. Noteworthy is, that the maximum value range of concrete signature apparently increases with the concrete temperature. Additionally, the most significant fluctuations in the *concrete signature*, as indicated by the highest standard deviation, occur at an elevated relative air humidity level, which serves as an indicator of increased

moisture in the concrete. However, due to the multitude of simultaneous effects, it is challenging to isolate and quantify the impact of each individual factor on the *concrete signature*.

The observed regular increases and decreases every 14 to 15 cm in certain sections may be attributed to the placement of stirrups, which are distributed approximately every 15 cm in the corresponding section of the beam. It is important to note that the concrete analyzed here is still relatively young (with the last DSS reading taken at an age of 19 months), which may result in greater fluctuations in the *concrete signature* due to more pronounced creeping effects in younger concrete.

Conceivable would also be that there are also effects from the reaction of the sensor coating itself. Fluctuations in the concrete moisture and concrete temperature can lead to expansion effects in the material, which can be transferred to the fiber. This effect is for example used for polyimide-coated fibers in order to measure humidity [24]. However, for coating out of polyester fibers and epoxide these effects can be neglected, since epoxide (epoxy glue) is used to insulate fibers from the surrounding moisture [24].

Regardless of the specific time episode being analyzed, the manifestation of the *concrete signature* is always dependent on the selected tare. While the tare does alter the resulting *concrete signature* itself - such as the position of the peaks - it does influence the prominence (e.g. the height of the peaks), as illustrated in the prestressing process. This distinction is crucial during data evaluation, as an appropriately chosen tare can enhance the *concrete signature* for analysis or diminish it to isolate other factors under scrutiny, such as tension wire breakages. However, the ability to reduce the *concrete signature* in this manner is contingent upon DSS readings taken in temporal proximity to the effect being analyzed, given that the *concrete signature*, at least in the evaluated DSS readings, tends to redevelop rapidly.

## 6 CONCLUDING REMARKS

It has been shown that *concrete signature* develops over various time episodes, ranging from several hours to several months. Potential environmental factors influencing this phenomenon include temperature, humidity, and load, which can lead to thermal expansion, shrinkage, swelling, and creep, as well as localized disturbances from structural elements like cable ties or reinforcement. Additionally, it is crucial to consider factors intrinsic to the concrete matrix, particularly the differing responses of aggregates and the cementitious matrix to these environmental influences. The age of the concrete itself may also play a significant role, since creeping and shrinkage depend on concrete maturity.

In this study, *concrete signature* achieved a maximum value range of  $\pm 75 \mu\text{m/m}$ , which considerably affects crack detection and width calculation, as peak detection and minima approaches may not work accurately. Moreover, identifying micro-cracks or instances of tension wire breakage may prove challenging, as these phenomena produce effects smaller than those associated with *concrete signature*. Consequently, the priority will be to develop effective compensation methods to ensure the reliability of data from digital signature systems (DSS).

However, gaining insights into the causes and influences on *concrete signature* could provide a better understanding of

concrete behavior related to load, creep, shrinkage, and thermal expansion. This understanding would facilitate more accurate assessments of structural behavior, for instance, by refining calculations pertaining to creep effects as outlined in EC2. Moreover, *concrete signature* may present opportunities for quality assessment during production through the examination of material inhomogeneities like gravel nests.

To gain a deeper understanding of the causes and factors influencing *concrete signature* in DSS readings, systematic testing is currently underway. Initial experiments are designed to isolate these impact factors and observe the resulting responses of the concrete matrix at the meso-level. Building on this knowledge, compensation methods and knowledge extraction techniques can subsequently be developed and evaluated in field tests.

## ACKNOWLEDGMENTS

This paper outlines findings from the research projects FOSsure (Fiber optic sensors for reliable condition assessment of solid bridges) and IDA-KI (Automated evaluation of monitoring data from infrastructure structures) funded by the Federal Ministry for Digital and Transport, Germany, within the innovation program mFUND (funding references: 19FS2075B and 19FS2013C).

Additionally, it outlines findings from the Return (Multi-risk science for resilient communities under a changing climate) This Foundation, with headquarters in Corso Umberto I, 40 80138 Napoli (NA), is founded by National Resilience and Recovery Plan (NRRP).

## ABSTRACT

Current climate protection goals are driving research toward large-scale structural health monitoring solutions for critical, long-lifespan infrastructure, alongside the usage of low CO<sub>2</sub> emission materials. In this work, we present an innovative approach that combines both aspects: the use of continuous basalt fibers assembled into sustainable reinforcement structures, and low-cost measurement systems for integrated long-term condition monitoring, specifically applied to tunnel segment monitoring. As a proof-of-concept for the integration of sensor elements into basalt reinforced concrete structures, we utilized stranded steel wire to create custom strain gauge sensors for integrated strain measurements, paired with a custom-designed resistive bridge-based measurement system to evaluate the feasibility of enabling low-cost condition monitoring. Mechanical tests were conducted on basalt-reinforced concrete specimens under both tensile and compressive loading. The results indicate that the system can measure even low strain values for the sensor-enhanced structures down to approximately 5  $\mu\text{m/m}$  and a standard deviation of 2.1  $\mu\text{m/m}$ , achieving a sensing performance close to state-of-the-art measurement systems and externally applied standard strain gauges. The study demonstrates the potential for cost-effective condition monitoring of individual tunnel segments with sustainable basalt reinforcement. Further optimizations of the system are anticipated in future projects.

**KEY WORDS:** Structural health monitoring; Strain measurements; Integrated stress monitoring; Crack detection; Basalt fiber reinforcement; Tunnel segment monitoring; Segmental lining element; Measurement system design; Low-cost electronics.

## 1 INTRODUCTION

The expansion of the European infrastructure network and the growth of international metropolises are increasing the need for major road and railway construction projects. Tunnelling and bridge construction are essential in this context. At the same time, the focus is shifting to climate protection and ambitious international targets. According to the Climate Act, the EU is committed to reducing net greenhouse gas emissions by 55% by 2030 and becoming climate-neutral by 2050 [1].

The construction and building sector is responsible for 38% of global CO<sub>2</sub> emissions and harbors great potential for innovation [2]. Cement production alone contributes 3.3% to Austria's and 4.5% to global emissions [3][4].

Structural steel in reinforced concrete is approx. 3 to 5 times more CO<sub>2</sub>-intensive per ton. According to a study on the Brenner Base Tunnel, one ton of structural steel emits 1,980 kg of CO<sub>2</sub>, while cement emits 576-622 kg of CO<sub>2</sub> per ton [5][6]. In segmental lining elements, concrete can contain approximately 150 kilograms of steel per cubic meter. The production of 150 kilograms of steel emits nearly the same amount of carbon dioxide as the cubic meter of concrete surrounding it. Consequently, a low-CO<sub>2</sub> material as an alternative to steel reinforcement offers great sustainability potential.

Due to these challenges, ongoing research projects are investigating the use of basalt fibers as a sustainable alternative for concrete reinforcement. The key advantages include significantly lower production intensity and CO<sub>2</sub> emissions compared to steel, as well as high corrosion resistance. Other beneficial properties include higher tensile strength than steel,

low weight, and fire resistance. Additionally, basalt reinforcement exhibits electrically insulating characteristics, resulting in longer lifespans of basalt-reinforced materials [7].

While the application of basalt fibers is also being researched in the form of macrofibers, this study considers continuous fibers with diameters of  $17 \mu\text{m} \pm 1 \mu\text{m}$  [8] bundled into multifilament yarns. These fibers can resemble structural steel in the form of Basalt fiber-reinforced polymer (BFRP) rebars or be woven into grid-like structures. Due to their processability, they can also be woven into 3D structures and precisely manufactured to meet specific load-bearing requirements. To maintain the stability of the reinforcement structure and ensure the stress distribution among the individual filaments within the bundle, they are impregnated with resin [9].

The manufacturing method allows for the processing of various fiber materials, leading to the concept of integrating a sensing fiber for strain measurements. The precise placement of fibers during the process enables the defined integration of measurement sensors, ideally within a fully automated manufacturing setup. The process combines sustainable and corrosion-resistant basalt fiber reinforcement with an efficient method for structural health monitoring. This offers significant potential in saving CO<sub>2</sub> emissions, particularly relevant in tunneling, where the required structural service life often exceeds 100 years [10].

The production of reinforcement structures using basalt fibers is considered to be particularly advantageous for prefabricated construction [7], placing the focus of our investigations on segmental lining elements. By equipping each

segment with an integrated, low-cost measurement device, continuous structural health monitoring could be extended beyond individual rings to cover the entire tunnel, enabling comprehensive long-term condition assessment. Building on this approach, we have extended our research to include the development of a cost-effective measurement system. Figure 1 shows the conceptual sketch of the combined basalt reinforcement and integrated strain gauges in a tunnel segment.

Figure 1. Segmental lining element ring and a conceptual sketch of the basalt reinforcement with integrated strain gauges in a tunnel segment.

The sensor's measuring length can be tailored to accommodate the desired spatial resolution and range. The strain sensor's integration into the reinforcement windings ensures precise measurement along the axis of maximum force, resulting in optimal measurement signals. An overlapping sensor configuration with varying measuring lengths is being evaluated for localized crack detection.

## 2 STATE OF THE ART METHODS

Current methods for ensuring structural safety and functional maintenance of tunnels rely on regular inspections. A distinction is made between destructive methods, core drilling, and non-destructive methods for condition monitoring.

The Austrian Federal Railways (ÖBB), for example, governs these inspections by the RW 06.01.02 regulations [11], focusing on crack formations in the tunnel linings. Tunnel scanners are used to create high-resolution images of the inner shell surface. Despite ongoing artificial intelligence integration, the process remains labor-intensive due to specialized equipment and manual evaluation [12][13].

In addition to condition assessments conducted through inspections, systems for continuous long-term monitoring (LTM) and structural health monitoring (SHM) are also employed. One focus is geotechnical monitoring, for which instrumentation, typically comprising extensometers, pressure cells, and convergence systems [14], are strategically installed in areas where geologically unstable zones, such as fault zones and swelling rock formations, are anticipated. The systems can be installed deep within the surrounding rock mass, extending behind the structural construction, in order to record data from the unaffected or stable rock formations.

To monitor the stress state of concrete structures, measurement systems are commonly embedded within the concrete matrix. These systems are typically attached to the reinforcement to ensure precise positioning, or alternatively,

they are mounted to separate structural elements, particularly in the case of unreinforced concrete. The two most common systems for SHM in tunnelling are based on strain gauges (SG) and distributed fiber optic sensing (DFOS). Both sensor types are applied in cast-in-place concrete, such as inner linings, as well as in precast elements, such as tunnel segments.

Vibrating wire sensors provide accurate measurement of strain and, consequently, allow for analytical prediction of stress within the tunnel lining. However, they are limited in their strain length, often below 250 mm. Therefore, they only provide localized data from a few selected points. Furthermore, data is manually collected on-site from individual measurement boxes, which often require road enclosures.

The more recent advancement in SHM with DFOS offers several benefits over SGs. One fiber optic cable enables multiple measurement points within the structural component, making it an ideal system for crack detection [15]. Additionally, data transmission can be performed over long distances without significant loss, allowing the measurement analysis to be conducted outside the tunnel. However, DFOS systems require careful installation and protective measures to ensure durability. To enhance robustness, they are often encased in a thick protective layer, compromising flexibility and being subject to strain incompatibilities with the material to be monitored. The complex setup and costly instrumentation are key reasons for the installation at only few locations [16].

An innovative alternative to conventional monitoring methods involves using carbon fiber reinforcement not only for structural support but also as a sensor [17]. Although carbon fibers offer greater durability and tensile strength, they are far less favorable than basalt fibers in terms of CO<sub>2</sub> emissions during production, production costs and handling during installation [7].

The presented disadvantages of the existing solutions speak in favor of the approach pursued in this work of a sensor system that can be fully and automatically integrated into the basalt reinforcement structure. This cost-efficient approach enables continuous SHM not only of sections, but the entire tunnel. A holistic SHM system is essential for detecting overstressing early, thereby enhancing safety, minimizing downtime of infrastructure, and reducing overall maintenance costs [12]. Particularly relevant for infrastructures such as tunnels with a projected and required long service life.

## 3 METHODOLOGY

Current state-of-the-art metrology solutions to measure strain on tunnel segments, like DFOS, offer precise measurement data and can, therefore, reliably monitor the few segments in which they are integrated. With this approach, the condition of other segments can only be estimated. Reliable condition monitoring of the whole tunnel system, however, depends on the condition monitoring of each segment. Therefore, more cost-effective and simpler solutions must be used. The following sections cover metrology, and the electronics used for this goal.

The Methodology section is divided into several subsections. It begins with the sensor conceptualization and the description of the hand-patterned steel wire strain gauge used in the devices under test. Next, the construction of the test device is discussed, including the design of the specimen. Following this, the

subsequent subsection describes the design of the custom electronic measurement system and the theoretical measurement principle behind the approach. In the final subsection, the test procedures that were conducted are explained.

### 3.1 Sensor Concept

Readily available strain gauges suitable for condition monitoring of tunnel segments are expensive and challenging to mount automated and securely on reinforcement or concrete surfaces. Additionally, the precise location and orientation of the strain gauges may become uncertain if they shift during the concrete pour. A more practical approach would involve integrating the strain gauges into the construction of the concrete reinforcement. One potential method involves integrating a resistance wire into the basalt reinforcement fabrication at predefined areas of interest and measuring the reinforcement's strain at those locations. This process can be automated using existing robots, simplifying the integration process. Prototype devices discussed in this work are equipped with hand-wound strain gauges glued to the basalt reinforcement. In future production processes, the resistance wire would be integrated between individual strands of the prefabricated basalt reinforcement of a concrete segment.

Accompanying electronics would need to be attached during this process. After concrete pouring and electronic verification, the segment would be ready for mounting inside a tunnel.

Because the anticipated operation duration is several years to decades, common issues such as creep and sensor degradation can affect long-term strain measurements. This may lead to false-positive or false-negative alerts regarding damage in the tunnel segment. These factors are a significant focus of our research and pose major concerns for the design and development of our condition monitoring system.

In this work, a stranded steel wire with 90 strands and a diameter of 14  $\mu\text{m}$  per strand is used. Electrical insulation between each winding is guaranteed due to the careful forming of meanders by hand. The specific resistance is approximately 70  $\Omega/\text{m}$ . 1.74 meters of wire are used, which results in 120  $\Omega$  resistance, accommodating standard bridge measurement systems.

The steel wire exhibits a gauge factor  $k$  of approximately 2, a typical value for metal strain gauges [18][19]. The gauge factor relation  $k$  is defined by

$$k = \frac{\Delta R/R_0}{\Delta l/l_0} = \frac{\Delta R/R_0}{\epsilon} \approx 2. \quad (1)$$

In the given equation the gauge factor  $k$  is defined as the ratio of the relative change in electrical resistance  $\Delta R/R_0$  to the technical strain  $\epsilon$ . The strain  $\epsilon$  is given by the relative elongation, where  $\Delta l$  is the change in length and  $l_0$  is the initial length. Similarly,  $\Delta R$  denotes the change in electrical resistance, while  $R_0$  is the initial resistance of approximately 120  $\Omega$ .

For clarity, relevant values of the steel wire material are presented in Table 1, the wire is a Bekinox® VN-fiber 14.1.9 from Bekaert [20]. The stainless-steel fiber bundle was chosen as the sensor material due to its corrosion resistance and the fact that the strands are not twisted. The individual strands are held together by a limited number of wrapped polyester filaments.

Table 1. Test strain gauge properties. [20]

Steel fiber: Bekaert Bekinox® VN-fiber 14.1.9			
Diameter	Strands	$\Omega/\text{m}$	k-factor
14 $\mu\text{m}$	90	70	2

Before concrete pouring and after curing, a digital multimeter was used to measure the wire's resistance and ensure proper installation and electrical connection.

### 3.2 Test Device Construction

Prior to the concrete tests, tensile tests using PET film were conducted to validate the measurement concept. The steel wire was mounted to a PET film strip over an approximate gauge length of 120 mm with seven meanders, using an epoxy adhesive. To verify the measurements, an additional reference strain gauge with the same length was attached adjacent. The promising results obtained justified further investigations in the context of the intended application on basalt reinforcements.

In the subsequent tests, the steel wire was attached by hand to the basalt rods using epoxy. Two types of reinforcement were used: basalt rebars with a diameter of 8 mm [21] and custom-manufactured basalt rods. The latter consisted of a total of 16 basalt fibers, each with a linear density of 2400 tex [8], bundled together. The 16-fiber configuration closely approximates the cross-sectional area of the basalt rebar and is intended to resemble the future application of fully automated placement of continuous basalt fibers into 3D reinforcement structures.

Figure 2 shows the steel wire strain gauge conceptual drawing and a BFRP rebar with the steel wire attached to the surface with epoxy, after a destructive compressive test.

Figure 2. Steel wire strain gauge conceptual drawing and implementation on basalt-reinforced polymer rebar after destructive compressive test.

Due to the small test geometry, multiple meanders were required. After the test, pieces of concrete were additionally detached for inspection of the steel wire.

Two test arrangements were designed for both basalt materials, with only one basalt rod in the center of each specimen, to investigate the suitability of the test strain gauge applied to basalt reinforcement inside concrete elements. The designs were developed to account for the different directions of applied force or load, specifically in both tension and compression directions. Both concrete specimen designs are cylindrical with only one reinforcing basalt rod in the center. The dimensions of both designs can be viewed in Figure 3. PVC pipes were used as molds for the concreting process. The concrete mix of both designs was similar to typical formulations used in precast elements for tunnel construction.

Figure 3. Specimen geometry for tensile (left) and compressive tests (right) with measuring length (in mm) and strain gauge (blue) on basalt reinforcement element.

The concrete mix design originates from the corresponding specification for precast tunnel segments but was adapted to suit the test specimen size. Specifically, aggregate fractions exceeding 8 mm were excluded and their mass proportions were redistributed among the other grain sizes. The cement used was CEM I 42.5 R-SR, and Dynamon NRG 1010 NK was employed as the superplasticizer and accelerator. Due to the slender design, the concrete was poured in layers with intermittent short compaction cycles on a vibrating table to minimize the formation of large pore spaces. Additionally, unreinforced specimens were produced for each mixing batch to determine the uniaxial compressive strength (UCS).

After demolding the tensile specimens, they were further modified by a 3 mm wide and 8 mm deep notch, achieved through four cuts with a stone saw, to ensure the formation of a central crack during the destructive tensile test. The central crack formation enables comparability of the strain gauges, as cracks near the fixtures, for instance, could occur outside the shorter measurement range of the reference strain gauge.

Due to the required length of the resistive sensor element of approximately 1.74 m to achieve a resistance of approximately

120  $\Omega$ , suitable for the commercially available bridge measurement devices, the steel wire test strain gauge had to be arranged in a meander pattern, resulting in varying effective gauge lengths between the tensile and compression tests. As a reference, a commercial strain gauge from the company Althen BV was applied to the outer surface of the concrete specimen after demolding. Two reference strain gauge types for concrete, mortar, and rock materials were applied: PL-120-11-3LJCT-F and PL-60-11-3LJCT-F. Both types feature a three-wire parallel vinyl cable configuration in a three-wire quarter-bridge setup [22]. The reference strain gauges were mounted on the surface with a 120 mm measuring length on the tensile and 60 mm on the compressive specimens, intended for the comparison of the inner strain on the basalt reinforcement to the strain on the outer concrete surface.

The specific steel wire gauge lengths and the required number of meanders for each test configuration was adjusted to the specimen length. For the tensile test setup, the measuring length was set to 214 mm with 4 meanders on the basalt reinforcement. The shorter compressive tests required 9 meanders of steel wire over the measuring length of 95 mm.

### 3.3 Electronic Design

The strain gauges' resistance is commonly not directly measured but rather utilized in a resistance measurement bridge. Therefore, a quarter bridge measurement to determine the strain of the specimen under test using the approximated strain relation presented in Equation (2) was used:

$$\varepsilon \approx \frac{4 \cdot V_d}{k \cdot V_0} \quad (2)$$

Here,  $V_d$  represents the amplified differential voltage of the two bridge arms,  $k$  is the gauge factor of the strain gauge, and  $V_0$  denotes the excitation voltage applied to the Wheatstone bridge.

As state-of-the-art measurement tools prove to be impractical for large-scale tunnel condition monitoring, a complementary, low-power, and compact electronic measurement system approach is being tested throughout the measurements. The block diagram of the developed prototype electronics is presented in Figure 4.

Figure 4. Block diagram of the developed measurement system. The device under test is employed in a quarter bridge. The ADS1261 IC measures the bridge voltage  $V_d$  and supplies the bridge with its internal voltage reference. An Arduino Uno R4 Minima reads the digitized data. Additionally, the Arduino exports its data to a PC for data storage.

The primary focus of this design is the sensor front-end section. This part is responsible for analog-to-digital conversion, amplification, filtering, and transmission of the digitized measured bridge voltage  $V_d$ . Furthermore, the resistance bridge must be supplied either by a current for absolute resistance changes or a voltage source for relative resistance changes. In addition to signal conditioning, the sensor front-end must

communicate with a microcontroller to transmit the measurement data to a PC for further signal processing. Given the significance of various key parameters, such as offset drift, linearity, potential supply outputs, the number of analog inputs, the number of samples per second, the possible integrated circuit (IC) supply ranges, package sizes, and recommended applications, the sensor front-end ADS1261 [23] (Texas Instruments, Inc.) was selected as the preferred choice. This sensor front-end incorporates a precision 40 kSPS Delta Sigma analog-to-digital converter ( $\Delta\Sigma$ -ADC), along with a programmable gain amplifier (PGA), an internal precision voltage reference, and an internal current source for bridge applications. Furthermore, the ADS1261 provides programmable registers to configure sampling rates, 4-wire or 6-wire measurements, current or voltage-driven bridge supply, PGA gain, filter modes, and read-only registers for data transmission over the serial peripheral interface (SPI). For the initial prototype, an Arduino Uno R4 Minima [24] (Arduino, Inc.) was used to read-in the digitized bridge level data. For this purpose, an algorithm to configure the ADS1261 registers for a predefined operating mode and a voltage-driven bridge circuit was developed. It then read the incoming data and displayed it on the Arduino's serial monitor for further storage and processing.

Figure 5. Developed Arduino shield incorporating the ADS1261 bridge front-end, screw terminals, and an OLED display for data visualization and debugging.

Furthermore, a printed circuit board (PCB) was designed and constructed. It integrates the ADS1261, connectors for the steel fiber strain gauge, and an OLED screen for data visualization, as shown in Figure 5. The printed circuit board was designed to fit seamlessly onto the Arduino pins, facilitating a direct connection. Such boards are commonly referred to as shields.

The strain gauge connection was realized with screw terminals as seen in light green and will be replaced by soldered connections in future revisions for a smaller contact resistance. These terminals form one half of the measurement bridge. This

approach enabled adaptation for every strain gauge resistance within certain linearity boundaries. Given a specific strain gauge resistance, either two strain gauges can be connected to form a temperature-compensating half bridge, or a resistor with an equal no strain resistance can be connected to the second terminal to form a quarter bridge circuit.

### 3.4 Test Configurations

Building on the success of previous proof-of-concept measurements that involved creating a test strain gauge by attaching a steel wire to a plastic foil for tension tests, handcrafted concrete test devices are used for the following evaluations. These devices are equipped with handcrafted meander-shaped strain gauges and serve as preparatory tools for future tests involving real segmental lining elements.

Figure 6 depicts the setup comprising the devices under test for tensile and compressive tests in the test stand, including the load cell in the tensile test arrangement, and the mechanical measurement connections that can be applied as tensile force or compression force by a servo-hydraulic actuator.

Figure 6. Test setup with the device under test mounted securely for tensile and compressive tests. Inside the device a steel fiber strain gauge is used. On the outside of the device, a standard strain gauge is installed. The load cell measures the applied force.

During measurements, the test stand applies and records force and travel distance in the longitudinal direction of the device under test. This force induces elongation or compression in the device and the strain gauges. Consequently, the strain gauges' resistances are anticipated to change. As a result, the strain/force relation can be quantified and visualized. As the resistance of the strain gauge also fluctuates in response to temperature, air pressure, magnetic field, and electromagnetic radiation changes, all of these factors were held constant to the extent practicable.

After constructing the devices under test and allowing a curing time of seven days, realistic test conditions were assumed. Special clamps to hold the devices, which are equipped with elastic rubber bands at the clamp edges were

used to ensure equal pressure around the circumference of each device. Once the devices were mounted in the clamps, the connection wires to the measuring devices were connected. At this stage, a small amount of pre-tension or pre-compression was applied to ensure that the test stand can directly apply force during movement without any forceless travel.

Due to a limited number of test devices resulting from the tedious manufacturing process, several measurements using non-destructive forces with half of the expected maximum force before failure were conducted. This approach allowed us to measure strain with multiple setups before any devices were destroyed. The testing control paradigm varied between the two test setups. The compression test was conducted in force-controlled mode with a linear increase in applied force over time. In contrast, the tensile test was performed in distance-controlled mode by linearly increasing the distance between the mounting positions of the device under test, due to easier test stand programming.

As the final step of a measurement session, a destructive test was conducted. During destructive tests, the applied force exceeded the load-bearing capacity of the concrete, leading to the formation of cracks. In the case of the displacement-controlled tensile test, the applied force drops rapidly after the expected initial crack in the pre-notched specimen center. Further cracks form along the length of the specimen. Depending on the arrangement, different reactions occur at the inner and outer measuring areas.

Table 2. Relevant specimen and test parameters.

	Tensile	Compressive
Number of samples	6	3
Number of tests	25	13
Nondestructive force (kN)	1.5	45
Destructive force (kN)	4	120

The experimental test program on the steel wire strain gauge with basalt fiber-reinforcement materials is structured into tensile and compressive tests as presented in Table 2. The

number of tests includes the number of repeated non-destructive variants and the final destructive ones for each test sample. Estimates of nondestructive and destructive loads are based on the results of tests with unreinforced concrete specimens.

## 4 RESULTS

Out of many test measurements, selected results based on their significance are presented in this section. Both for tensile and compressive tests on the reinforced concrete test objects, we present comparisons between the measurement signals recorded by a Quantum MX1615B [25] (HBK, Inc.) measurement system and the custom bridge measurement system. We organized the setups such that each strain gauge was measured with each measurement device, but for sequential and separate measurements. For instance, the inner strain gauge was connected to the MX1615B, and the outer strain gauge to the custom electronics during one non-destructive test. In the subsequent non-destructive test, we switch the connections. This method allows qualitative comparison of the results obtained by the MX1615B device and the results obtained by the custom electronics.

Using its accompanying software tool, we set a low-pass filter using a 4th-order Bessel filter, with a cutoff frequency of 10 Hz at a measurement rate of 50 Hz, for the Quantum MX1615B measurements.

For all signals recorded by the measurement systems, zero-phase digital filtering in the signal post-processing using Matlab's `filtfilt()` function was applied. In this case, an FIR low-pass filter with a cutoff frequency of 2 Hz and a length of 101 was implemented. This approach ensures no phase delays of different frequency components of the measurement signal.

### 4.1 Tensile tests

Based on previous test measurements conducted with unreinforced concrete test specimens, non-destructive tensile tests were performed with estimated tensile forces below 1.5 kN, less than half of the expected maximum load, as stated in Table 2. Given the relatively small forces, only minor strains

Figure 7. Two non-destructive tensile tests with an in-built hand-made strain gauge in green, measured with the custom-made electronics (left) and with the MX1615B (right). The applied tensile force is shown in blue.

of less than  $50 \mu\text{m/m}$  were anticipated, which was reflected by the executed measurements. Figure 7 shows two measurements of different test measurements using the same device under test for a qualitative comparison between the custom measurement system and the MX1615B. Each plot illustrates the tensile force resulting from uniform cylinder motion in blue and the low-pass filtered measurement signal from the measurement systems connected to the inner steel wire strain gauge in green. In the left plot, the measurement signal of the custom electronics is shown. On the right side, the measurement signal from the MX1615B instrument. Both measurement signals were digitally filtered with the aforementioned FIR low-pass filter with a filter length of 101 and a cut-off frequency of 2 Hz. As one can observe, at these strain values, even the reference measurement system MX1615B has significant signal variations.

Most non-destructive tensile tests were conducted over a duration exceeding 60 seconds, as the test stand exhibited a slow but consistent movement. It is evident from Figure 7 that the reduction of the tensile force signal precedes the end of the load sequence. The tests concluded at this point, and the force was set to zero manually after a few seconds, shown with the dashed blue line. The minor strain relaxation detected, prior to the manual movement, was observed in all tensile tests and is most likely attributable to displacements of the elastic rubber bands within the clamping device.

During destructive tensile tests, cracks in the concrete appeared, resulting in sudden force drops and elongation rises. Figure 8 shows this behavior in a comparable range for both, inner and outer strain gauges. As the force, due to the steadily moving test stand, increases, the device under test experiences more and more mechanical stress. At a certain point, the concrete rips and gives way for a relative movement between the concrete and the basalt reinforcement. This results in an overall elongation of the system, which is measured by the applied strain gauges, shown in Figure 8. During destructive tests, several cracks occur. For a more detailed insight into the destructive strain measurements, only one is shown here.

Figure 8. Concrete ripping apart during a destructive tensile test. The applied test stand force, shown in blue, drops due to the formation of a crack. The outer reference strain gauge in dashed green, and the inner steel wire strain gauge (green line) show the feasibility of crack detection. Both measurement signals were recorded with the MX1615B.

#### 4.2 Compression tests

Due to concrete's high compressive strength and previous unreinforced compression tests, a linearly increasing compression force of up to 60 kN was applied for non-destructive test measurements, again less than half of the expected maximum load, as stated in Table 2. Given the significantly higher forces during this measurement session, correspondingly greater changes in the signals were expected to be observed.

Figure 9 illustrates, similar to Figure 7, two separate compressive test measurements with the inner steel wire strain gauge. The compressive force is shown in blue, and the measurement signals from the custom electronics on the left and the MX1615B on the right are shown in green. Both strain signals were again filtered using the FIR low-pass filter with filter length 101 and a cut-off frequency of 2 Hz.

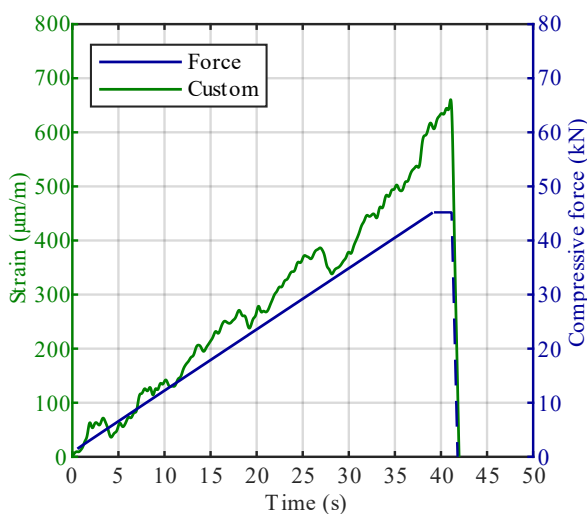

Figure 9. Two non-destructive compressive tests with an in-built hand-made strain gauge in green, measured with the custom-made electronics (left) and with the MX1615B (right). The applied compressive force is shown in blue.

Once again, the load was held at a specific point before manually setting it to zero after a few seconds, shown with the dashed blue line. The fluctuations in the strain measurement signals are believed to be a result of relative movement between the individual components of the composite material.

#### 4.3 Evaluation of Noise

During all tests, the Quantum MX1615B (accuracy class 0.1, linearity deviation 0.05) was used alongside the PL-120-11-3LJCT-F and PL-60-11-3LJCT-F strain gauges, which have a gain factor of  $2.1 \pm 1\%$ . According to the datasheet, the Quantum MX1615B produces less than  $0.6 \mu\text{V/V}$  noise at  $25^\circ\text{C}$  with a 5 V excitation.

In comparison, the ADS1261, used in the custom system, exhibits 30 nVRMS noise (gain 128, 20 SPS) and a linearity of 2 ppm. The stranded steel wire used in the setup is assumed to have a gain factor of 2. Throughout the tests, temperature and humidity were maintained constant, as the test stand is located in a sub-terrain basement. These factors lead to the standard deviations of the detrended measurement signals, as shown in Table 3.

Table 3. Standard deviations obtained from the reference Quantum MX1615B and the custom measurement system, both for tensile and compressive tests after low-pass filtering.

Standard deviations	Tensile ( $\mu\text{m/m}$ )	Compressive ( $\mu\text{m/m}$ )
MX1615B	0.769	0.563
Custom system	1.49	2.07

As is visible, after low-pass filtering, the standard deviations are in the same order of magnitude.

## 5 CONCLUSION

Our measurements aimed to demonstrate the feasibility of in-built strain gauges into the basalt reinforcement for future automated production processes.

Based on prior tests, tensile as well as compressive tests were conducted, using hand-patterned steel wire strain gauges mounted on basalt reinforcement to measure the device under test's elongation and compression. Both compressive and tensile tests showed promising results. Relative movement between the basalt reinforcement and the concrete is the same for wounded basalt fibers as well as basalt rebar. Furthermore, the adhesion between the hand-patterned strain gauge and the basalt rebar holds and the strain gauges endure the harsh concrete environment without failure, as seen in Figure 2.

These are promising findings for further development of automated basalt reinforcement construction. Additionally, it shows that the adhesion between the reinforcement and the concrete has to be improved in future revisions, giving valuable insight into the dynamic behavior of the compound material.

Our low-cost, custom-made, first prototype measurement device reaches acceptable sensitivity close to the range of the Quantum MX1615B measurement system. As a result, we demonstrated the viability of our low-cost, structural health monitoring concept, feasible for the instrumentation of a whole tunnel.

Future revisions of the electronics anticipate the replacement of the Arduino with an industrial-grade microcontroller, further reduction of component sizes, and the removal of the OLED screen for low-power operations within tunnel segments. Additionally, all metrics for improvement, concerning an integrated solution of both the electronics and sensors for the application in concrete elements, including temperature compensation actions, are being considered. These include half-bridge configurations, degradation compensation, and software measures to counteract false-positive and false-negative readings.

Moving forward, we anticipate further tests including bending beam tests as a precursor to tests on real tunnel segments due to more representative conditions of standard segment test scenarios. Furthermore, in the long term, we propose test arrangements with multiple measurement systems in segments, forming a tunnel ring, for real-world test environments.

# Wind Input and Acceleration & Displacement Outputs Monitoring System for High-Guyed Masts in ROSEHIPS Project

Miaomin Wang<sup>1</sup>, Duncan Gould<sup>2</sup>, Richard Stafford<sup>1</sup>, Ki-Young Koo<sup>1</sup>, James Brownjohn<sup>1</sup>

<sup>1</sup>University of Exeter, UK

<sup>2</sup>Arqiva Limited, UK

**ABSTRACT:** This paper presents a battery-operated wireless long-term response measurement system for high-guyed masts in the UK, as a part of ROSEHIPS project. The monitoring system aims to capture wind speed and direction as input and 3D accelerations and 3D displacements as outputs for a target period of three months. GNSS (Global Navigation Satellite System) based time-synchronisation methods were used in all subsystems for accelerometer, anemometer, and Computer Vision based cameras. Epson E-M352 sensors were used to measure triaxial accelerations with extreme accuracy 0.2 $\mu$ g/ÖHz at multiple points along the height of the mast, together with an anemometer. Low-power consumption features of ESP32 microprocessor unit was utilized to achieve a longer battery life. To remotely monitor its 3D displacement, a wireless stereo vision system was developed using Raspberry Pi. The displacement is measured in the image plane of each camera, and the data is then uploaded to the cloud for 3D reconstruction. The measurement accuracy was validated through an outdoor test, where the two cameras were approximately 100 meters apart, and the target was located about 200 meters from both cameras. The results showed a measurement error of approximately 1 mm. The time synchronisation between the accelerometer and the stereo vision system was also evaluated. By using the system to track an accelerometer mounted on a cantilever, the time-sync error was found to be less than 1 ms.

**KEY WORDS:** Structural Health Monitoring, Wireless Sensor, Accelerometer, Stereo Vision, Anemometer.

## 1 INTRODUCTION

High-guyed masts are critical infrastructure for telecommunications and broadcasting, yet their slender designs make them vulnerable to environmental loads, particularly wind-induced vibrations [1].

Effective monitoring of these structures is essential to ensure safety and reliability [2]. Traditional wired systems face challenges including high installation costs, power supply limitations, and maintenance difficulties. Wireless, battery-operated systems offer an attractive solution, providing flexibility and ease of installation.

This paper presents a wireless long-term monitoring system developed as part of the ROSEHIPS project, specifically targeting high-guyed masts. It integrates Epson E-M352 accelerometers for accurate acceleration measurements, an anemometer for wind monitoring, and a Raspberry Pi-based stereo vision system for remote displacement tracking. GNSS-based synchronization [3] ensures precise timing across all sensors.

## 2 WIRELESS INPUT-OUTPUT MONITORING SYSTEM

### 2.1 Accelerometer

Figure 1. Accelerometer node

The accelerometer node consists of a M5Stack Core2 MPU based on esp32, a GNSS module, an accelerometer module for an Epson M-A352 sensor, and a battery module. M5Stack provides a convenient modular design, which an additional feature can be added a module layer stacked below the MPU. Light sleep was employed in esp32 to save power-consumption.

### 2.2 Stereo vision system

The wireless stereo vision system comprises two identical nodes (left and right), each equipped with a SONY IMX296 camera and lens, a Raspberry Pi 4B computer, a GNSS board and antenna, and a 4G communication module. The camera in each node is triggered by its Raspberry Pi via a jumper cable. To achieve synchronous image capture, both nodes use pulse-per-second (PPS) signals from the GNSS modules; upon receiving these PPS signals, the Raspberry Pi generates a synchronised 10 Hz trigger signal for the cameras.

First, the two nodes are positioned, and their geometric relationship is accurately determined using a GPS-RTK system for later 3D reconstruction. Users set an identical start time for both nodes, initiating synchronised 10 Hz image capture upon receiving the PPS signals. A measurement target is selected from the initial images of each node, ensuring the same target is tracked by both nodes. Each node independently measures the target's 2D displacement, and the data is uploaded to AWS. Finally, the 3D displacement is calculated in AWS using triangulation based on the uploaded 2D measurements and the known geometric relationship between the cameras

### 2.3 Anemometer

Anemometer used was a GILL 1350 ultrasonic anemometer, which measures wind speed and direction up to 10 Hz.

### 3 SYNCHRONISATION VALIDATION

#### 3.1 Setup

The time synchronisation between the accelerometers and the stereo vision system was validated. Three accelerometers (named ACC1, ACC2, and ACC3) were mounted on a cantilever beam. Two camera nodes (named CV1 and CV2) were placed 0.62 m from the structure, as shown in Figure 2. The validation consisted of three subtests: (1) synchronisation error between accelerometers, (2) synchronisation error between camera nodes, and (3) synchronisation error between accelerometers and cameras.

Figure 2. Experiment setup.

#### 3.2 Results

##### (1) Synchronisation error between accelerometers

The structure was manually excited, and the accelerometers recorded the structural acceleration. Figure 2(a) shows the measurement results, and Figure 2(b) shows a zoomed view. If the sensors were perfectly synchronised, the measured data from all three sensors should have no phase lag. The observed phase lags were considered as synchronisation errors. The synchronisation error was 40  $\mu$ s between ACC1 and ACC2, and 11  $\mu$ s between ACC1 and ACC3.

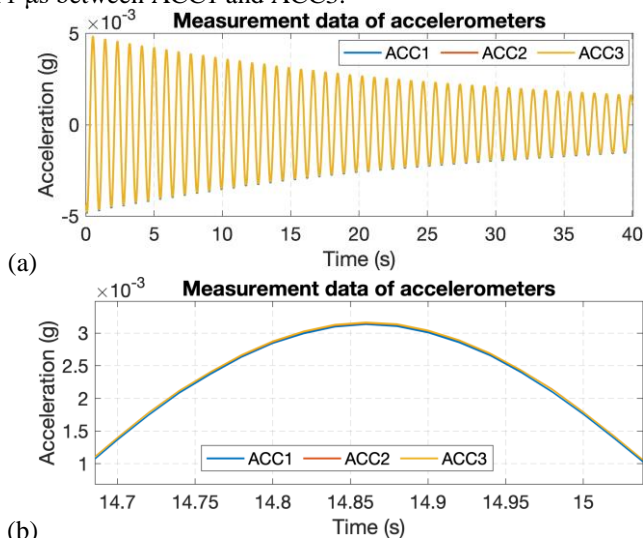

Figure 2 Measurement data of accelerometers.

##### (2) Synchronisation error between camera nodes

Figure 3(a) shows the measurement data from CV1 and CV2, and Figure 3(b) provides a zoomed view. The synchronisation error between the two camera nodes was 32  $\mu$ s.

Figure 3 Measurement data of camera nodes.

##### (3) Synchronisation error between the accelerometer and camera

Acceleration and displacement are two different measurement units, but their waveforms are opposite when the signals are simple harmonic. The ACC1 data was multiplied by -1500 and then compared with the CV1 data. The synchronisation error between the two types of sensors was 309  $\mu$ s.

Figure 4 Measurement data of the accelerometer and camera.

### 4 CONCLUSION

The developed wireless sensors—including anemometers, accelerometers, and vision-based systems—help fill the gap in long-term input-output monitoring of high guyed masts at low cost. These heterogeneous sensors form a wireless sensor network, which also has potential for other structural health monitoring applications, such as using vision-based systems to capture vehicle input and accelerometers to measure structural response on bridges.

## Wireless Multi Sensor Monitoring of Engineering Structures

Markus Rennen<sup>1</sup>, ORCID 0009-0002-5772-4205

<sup>1</sup>Senceive Ltd, Milton-Keynes, UK

**ABSTRACT:** Engineering structures are generally understood to be predominantly functional objects, such as bridges, tunnels, cranes, silos etc. Failure of these structures not only causes physical damage but can also lead to interruption of production, disturbance of infrastructure or traffic and thus disruption of operations with commercial impact for both the asset owner as well as concerned commuters or customers.

Therefore, in-situ monitoring is of major importance. The challenge lies in the need to observe specific parameters in difficult to access locations, under demanding environments, or with high data rate requirements. These conditions often exceed the capabilities of geodetic observation techniques. Wireless Condition Monitoring (WCM) nowadays can breach the gap by implementing a variety of sensors and maintenance-free hardware without the requirements of line-of-sight or cables. Compact Nodes with internal and external sensors and low power consumption are versatile and provide long battery life. Remote access allows adjustment or temporary changes of configuration settings (e.g. recording intervals). Automated data transfer to cloud-based visualization platforms enables continuous data access with configurable alerts, allowing for proactive evaluation of structural health.

The article presents a number of practical field examples that address the challenges mentioned above, while highlighting the specific requirements for interpreting the collected data – supported by examples of result validation using independent techniques.

**KEY WORDS:** Monitoring, Structural Health, Wireless Condition Monitoring, Multi Sensor System

Figure 1 : Installation of tilt sensors for monitoring a retaining wall in a track area with restricted access

Figure 2: Wireless Sensor Nodes: 3-Axes-Tilt-Sensor (Triaxial Tilt Sensor) (Foreground) and Laser Distance Sensor (Background)

## 1 MONITORING OF ENGINEERING STRUCTURES

### 1.1 Motivation

Per definition, the primary focus of engineering structures lies in fulfilling functional tasks. According to DIN 1076, engineering structures include relevant buildings, transportation systems, bridges, tunnels, trough and retaining structures, but also silos, masts, chimneys, cooling towers, industrial facilities, etc. If a structure can no longer fulfill its function, the damage is not limited to the structure itself but also includes the loss of its economic utility. In industrial plants, entire production lines can be affected if a single component fails. Naturally, structural safety is of fundamental importance and ensuring usability while avoiding failure-oriented maintenance is essential.

As an additional challenge, monitoring usually has to be conducted during full operation, which causes limited accessibility and demands an extraordinary robustness of the hardware.

### 1.2 Automation of Monitoring

Monitoring of engineering structures typically focuses on relatively small-scale structures. The motivation to automate monitoring usually stems from one or more of the following:

- The required sampling rate makes manual monitoring impractical or inefficient.
- Access to the monitored object is generally difficult, uneconomical, or dangerous (see Figure 1).
- The observation period is very long. Automation ensures that operations (e.g., traffic flow) remain undisturbed.

Moreover, smart automation of the monitoring process allows operational workflows (e.g. traffic flow) to remain undisturbed.

Monitoring, as a broad term can involve various parameters, including economic or statistical indicators characterizing industrial usage. It may also be necessary to record internal and external timeframes to synchronize operational influences with structural integrity parameters.

Figure 3: Solar powered cellular gateway, intermediately stores the sensor data and transmits it to the server

Figure 4: Sensor locations at the Südzucker Lime Kiln in Wabern/Germany

Automated systems collect data in regular or event-triggered intervals and transmit it to a platform, locally or via cloud-based interfaces accessible through a web browser.

## 2 WIRELESS MONITORING SYSTEMS

Various observation methods can be considered wireless (e.g., prisms, remote sensing). Generally, the term refers to what has become known as Wireless Condition Monitoring (WCM): active sensors with autonomous data acquisition units, or 'nodes', that integrate sensing, power supply, and data transmission. These nodes can incorporate external sensors with various signal types (analog or digital) and are highly compact. Miniaturized low-power MEMS (Micro-Electro-Mechanical Sensors) have opened the door to practical usage. For instance, tilt sensors consist of a chip-based nano-sized probe resting between capacity electrodes recognizing gravity related rotations. Available High-G versions offer considerable resistance to physical shock. Additionally, built-in mechanical as well as statistical filters help eliminate outliers. Some manufacturers include additional accelerometers that allow sensor values to be triggered by outside impacts which occasionally is utilized in slope and embankment monitoring as well as rockfall detection.

In Figure 2 examples for commercial 3-axis tilt sensors, and laser distance sensors, are shown, offering more than 10 years of battery life at half-hourly data sampling rate.

### 2.1 Communication and Operation

Data is typically encrypted and transmitted from nodes to a local gateway (Figure 3), and from there via cellular networks to an online platform. Internally, systems use 2.4 GHz Wi-Fi frequency for high bandwidth or LoRa for long range (868

Figure 5: Correlation of Lime Kiln Deformation with diurnal Sun Exposure (Tilt Units in  $\text{mm/m}$ )

Figure 6: Installation of tilt sensors on the supports and longitudinal beams of the crane rails

MHz licensed in Europe). Due to short sampling intervals and small monitoring areas in structural applications, 2.4GHz is often preferred. LoRa only allows longer reporting intervals and has limited two-way communication, making remote configuration more difficult. 2.4GHz-based systems mitigate shorter range via node meshing, where neighboring nodes act as repeaters. Gateways can be solar powered, enabling flexible placement. Unlike geodetic methods, WCM does not require line-of-sight, allowing sensor placement on hard-to-reach structures. Sensors are maintenance-free and configurable remotely.

## 2.2 Applications and Interpretation

Interpreting WCM results can be challenging. While geodetic methods like Total Station observations provide 3D coordinates, tilt sensors only provide angular data, which must be interpreted cautiously. For instance, when converting angular units via trigonometric calculations, i.e. projection onto real respectively virtual beam lengths, into more intuitive metric values, (e.g. mm/m) structural stiffness and deformation behavior must be considered.

Sometimes, the mere indication of movement is enough to trigger further action. In inaccessible areas like rail zones, ease of installation and maintenance are crucial (see Figure 1). If models of deformation characteristics exist, tilt angles can be

Figure 7: Crack sensor for detecting the internal deformation of the crane bridge

extrapolated to derive horizontal or vertical displacements of masts, walls, foundations, etc.

## 3 CASE STUDIES

### 3.1 Südzucker Lime Kiln, Wabern

#### 3.1.1 Situation

The lime kiln at the Südzucker site in Wabern/Germany was monitored to assess its behavior during operation, including firing and loading phases. The structure is a 48.5m tall cylindrical tower with a diameter of 2.66m. Tilt sensors were mounted in all four cardinal directions near the top of the tower. As mentioned above, extrapolating tilt measurements along the length of a structure requires the assumption that the structure is rigid. If the assumption holds, the recorded tilt values can be projected over the kiln's height to measure the horizontal displacement at the top of the structure. Model assumptions like this naturally must be validated.

As it was rather unlikely that the tower would tilt as a rigid body over the entire almost 50m, three additional sensors were installed in a vertical alignment on the north side from the foundation to the top (Figure 4).

Typically, MEMS tilt sensors provide resolution of approximately  $0.0001^\circ$  or less than  $0.002^{\text{mm}}/\text{m}$  with repeata-

Figure 8: Mobile crane bridge with centrally positioned gateway

bility of roughly  $\pm 0.0005^\circ$  (less than  $\pm 0.01 \text{ mm/m}$ ). Critical though is temperature correlated sensor behavior which can reach a magnitude of  $0.0017^\circ/\text{K}$  ( $0.03 \text{ mm/m je } ^\circ\text{K}$ ) [1]. Therefore, to achieve higher accuracy, temperature compensation is required, or the installation must be configured to separate deformation effects from temperature influences.

### 3.1.2 Interpretation

The installation took place in early September, at a time when temperatures fluctuated between approximately  $15^\circ\text{C}$  at night and, in some cases with strong sunlight, well over  $40^\circ\text{C}$  during the day. Since all nodes are equipped with an internal thermistor, the local temperatures were recorded directly at the sensor.

Figure 5 depicts the nodes' behavior for all four top nodes and the bottom one on the north side. The top graph shows the nodes' temperature recordings for roughly the first week of observations. Temperature peaks shifting from east to west throughout the duration of one day reflect the sun's path. Naturally, no temperature peaks occurred on the north side; however, the bottom and top sensor in the North i.e. the light and dark blue graphs still followed the general daily temperature pattern.

When examining the movements in the horizontal X and Y directions (Figure 5 lower two graphs in  $\text{mm/m}$ ), a temperature-correlated, oscillating motion pattern can be observed in all sensors located in the upper tower area. In contrast, the tilt sensor at the base of the tower showed virtually no movement). These observations essentially allow two conclusions to be drawn:

- The movement in the upper part of the tower is real and not caused by temperature effects on the sensor, as otherwise the sensor at the base would also show temperature-correlated movements.
- The tower deforms increasingly with height and does not tilt as a rigid body.

Therefore, the above demanded separation of temperature impact from the real signal could be achieved by appropriate sensor constellation. The derivation of realistic horizontal displacements at the various levels of the kiln would require more sophisticated differential models not conducted during this task (for comparison see 3.4).

3.2 Crane Track at Thyssen Krupp, Duisburg

Figure 9: Permanent Observation of Abutment Tilt and indicative vertical Displacement of the Bridge Deck

### 3.2.1 Task and Realization

According to the client, German Thyssen Steel Company in Duisburg/Germany, the crane track girders had previously exhibited wear damage with unknown causes in the past. It is suspected that crane movements while transporting heavy steel slabs induce short-term deformations, which remain detectable by geodetic methods among others due to their dynamic nature.

### 3.2.2 Data Considerations

Tilt sensors and crack sensors were installed on supports and beams (Figure 6 and Figure 7), with their positions measured geodetically.

Additional gateways were placed on each crane bridge to allow for independent, stable, yet mobile wireless mesh networks (Figure 8). Data was sampled every 2 seconds and transmitted via cellular network. Through an API-based database interface, approximately 400 MB of CSV data per day was transferred over several months to a local computer.

Moreover, the timestamp of the data allows synchronization between sensor behavior and crane position. This should enable the user to associate specific load cases and crane configurations with the corresponding sensor.

Figure 10: Bridge during load test with 48t mobile crane

Figure 12: Visualization of the deformation during the load test via live access to the cloud portal

At the time of writing, the geometric evaluation of the combined data from sensor readings and crane positioning is still ongoing and will be the subject of a student master's thesis. Even ahead of that outcome, the project has already demonstrated that such high sampling rates can be handled wirelessly over extended periods of time.

### 3.3 Indicative Monitoring Bridge BAB43 Bochum

At a highway bridge in Bochum/Germany the asset owner expressed concerns that the cylindrical roller bearing might exceed its margins due to the abutment tilting outwards. In order to avoid dangerous vertical displacement ("drop") of the bridge deck, wooden supports were inserted that would only allow <10mm sag.

Since the question of whether the vertical displacement occurred was essentially binary - either it happened or did not - a low cost, indicative alarm solution was requested to run alongside the abutment tilt observations. A spring-loaded telescopic crack sensor was installed (Figure 9) that allowed for diurnal and seasonal horizontal movement of the deck while reliably indicating vertical displacement.

### 3.4 Bridge on Wittekindstraße, Dortmund

#### 3.4.1 Situation and Task

Compared to the above, this Dortmund bridge demanded more detailed i.e. quantitative observation. The case presented involves a slab structure built in 1957, consisting of two identical superstructures separated by a joint, each approximately 31 meters in length, with four individual bridge spans of about 15 meters each (Figure 10). At this location, two major traffic arteries of Dortmund intersect in an urban setting: the six-lane B1 and the four-lane Wittekindstraße.

An expert report prepared in 2023 confirmed the load-bearing capacity of the bridge. To ensure continued safe operation, permanent monitoring was recommended as a supplementary measure to the regular structural inspections. As a result, the Civil Engineering Department of the City of Dortmund, in collaboration with the Surveying and Cadastral Office, developed a monitoring concept that included the continuous observation of the structure using WCM sensors.

Following the layout of the prestressing tendons, tilt and strain sensors were installed across the four bridge spans

(Figure 11). The arrangement was designed to approximate the expected deformation trough using four tilt sensors per bridge deck, i.e. two tilt sensors at each shoulder and a strain sensor in the middle, where the greatest tensile stress was expected. In addition, transverse cracks were equipped with potentiometric crack sensors, and temperature probes were embedded in the concrete. The system was installed using a lifting platform within a single day and has been transmitting data to a browser-accessible cloud server at 30-minute intervals since October 2023.

#### 3.4.2 Load Test

The initial expert report had already recommended a dedicated load test, which was carried out in April 2024 using a 48-ton crane provided by the Dortmund fire department (Figure 10).

Figure 11: Arrangement of the WCM sensors (tilt, strain, and crack sensors) and operation of the laser scanner during the load test

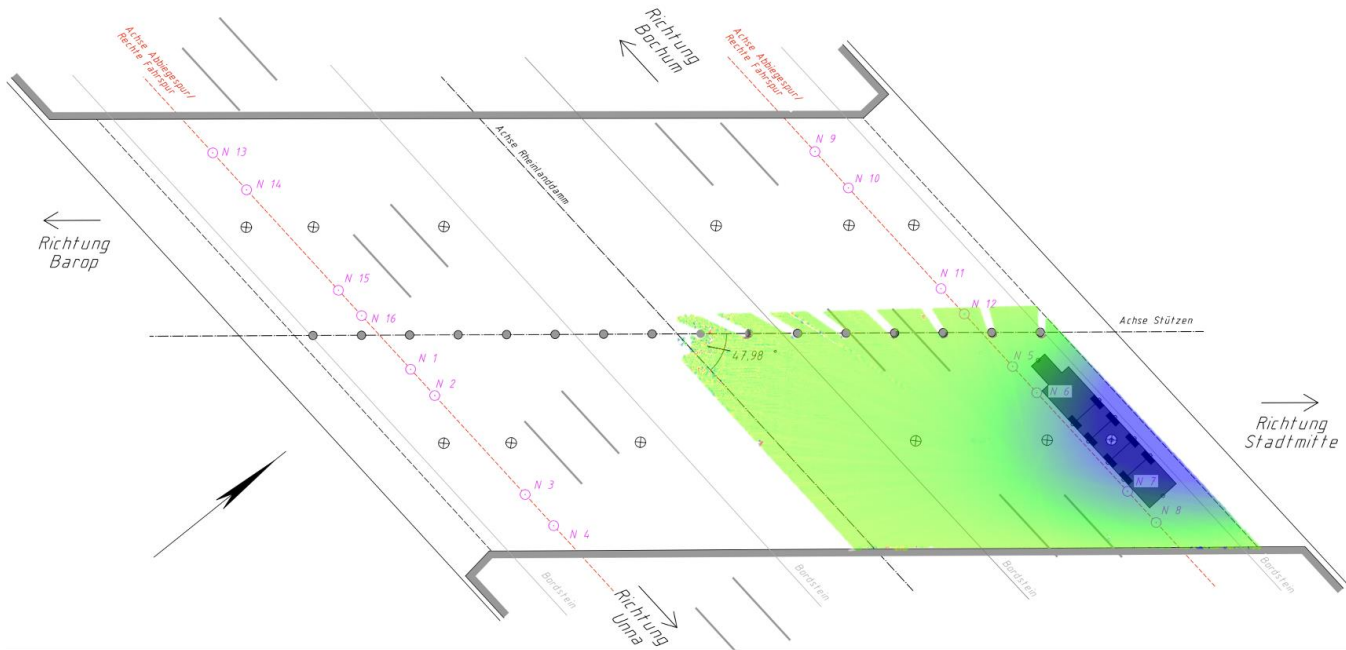

Figure 13: Example visualization of the load-induced deformation pattern of a bridge span from the surface scan  
(Graphic: [2] M.Róžański)

Specific loading points were defined by the Civil Engineering Department and marked by the Surveying and Cadastral Department<sup>1</sup>. For the test, the sensor system was remotely switched into a 30sec interval live mode. This was intended to ensure that the vehicle remained in position until the increase in deformation had subsided and stabilized at a constant level. It turned out that the full deformation occurred almost instantaneously (Figure 12). Accordingly, the crane was held in position for approximately 15 minutes before moving to the next position. This duration allowed precise evaluation of the sag dynamics while providing redundant observations to generate reliable, representative averages in order to avoid data noise bias.

The experts from the Civil Engineering Department of Dortmund predicted a load-induced deformation in the order of

magnitude of 2-4mm that can certainly be detected using geodetic methods. Accordingly, surface scans were carried out before, during, and after the loading using a high-precision geodetic Zoller & Fröhlich phase scanner (Figure 11), and the results were evaluated as part of a bachelor's thesis at the Department of Geodesy at Bochum University of Applied Sciences. Figure 11 shows the significant deformation of the bridge span around the load position by color coding.

To compare the two methods, a cross-sectional profile-spline was calculated through the scan-generated surface, following the layout of the prestressing tendons.

In order to get a comparable graph from the tilt nodes the resulting deformation trough was approximated by a higher order polynomial with the tilt values representing tangents at dedicated "chainage". The tangent gradient is obtained from the

Figure 14: Comparison of the results from surface scanning and tilt sensor data along the course of the prestressing tendons  
(Graphic: [2] M.Róžański)

<sup>1</sup> Vermessungs- und Katasteramt

first derivative of the polynomial. Accordingly, the inclination values can be used to solve the system of differential equations and determine the coefficients of the polynomial. In this way, a deformation profile can be calculated from the inclination values. Thanks to the high data density - through the large number of surface-representing points in the Laserscan and the repeated measurements from the tilt sensors - both systems achieved sub-millimeter relative accuracy at the collocation points.

The resulting graphs are shown in Figure 13. Since a laser scanner profile includes significantly more sample points, local deformations that fall between the gaps of the WCM are only picked up by the scans. Nevertheless, both methods yield similar results, coinciding closely in shape and differing by approximately 0.2mm.

The observed result came reassuring to the local authority. Not only did the results confirm that the installed system provides correct and representative data. The observed deformation of around 2 mm, confirmed the prediction and as such do not indicate any cause for concern regarding the structural integrity of the bridge.

The results of both measurement methods aligned within the submillimeter range. This demonstrates that the automated system is well suited for capturing the deformation behavior in a representative manner. Continuous monitoring can therefore be entrusted to an automated system, which can then trigger more detailed laser scanning if warning thresholds are exceeded.

#### 4 CONCLUSION

Using several practical examples, the capabilities of Wireless Condition Monitoring (WCM) for monitoring complex engineering structures has been demonstrated. While the operation of the system is low-maintenance and the installation is quick and straightforward, interpreting the results requires a certain level of understanding regarding the behavior of the structure.

The versatility of WCM is evident not only in the wide range of sensors available or possible to integrate, but also in the installation possibilities on or within the structure without the need for line-of-sight connections. The sensors operate autonomously, making them suitable for hard-to-reach or inaccessible areas, and their long battery life enables them to be used for long-term monitoring tasks. High sampling rates could be achieved, as well as temporary adjustments via remote access.

It is important to emphasize that WCM should not be seen as a competitor to traditional geodetic methods. Rather, it fills the gap where conventional approaches are impractical or inefficient. For example, WCM enables high-frequency, continuous monitoring and, through automated alerts, trigger manual geodetic verification when needed.

Utilizing WCM sensor technology allows safe extension of the observed structures' life span while reliably identifying approaching deterioration, without compromising on safety or

risking disruptions to increasingly interconnected infrastructure systems.

**ABSTRACT:** When sensor systems are used on outdoor structures (bridges, tunnels, etc.), they are exposed to a wide range of environmental influences. In particular, temperature can significantly affect the quality and accuracy of measurements. While most commonly available sensors are calibrated at temperatures of around 20°C before use, but the influence of variable temperatures is rarely considered. Furthermore, the measuring systems used for these sensors, particularly wireless sensor systems, are often only calibrated for room temperature. For this reason, this paper presents calibration procedures for monitoring systems including the sensors used (here displacement sensors are used as an example). The aim is to provide a practical routine for structural monitoring applications. This involves simulating typical temperature changes in a climate chamber (-20°C to +50°C) while measuring the temperature-induced strain of steel, and analyzing the reproducibility and temperature response of the entire measurement system. Other external influences affecting measurement quality are also discussed, and these are considered when determining the overall measurement uncertainty. This helps to define the requirements and limitations of measurement systems for structural health monitoring, particularly for bridges. The resulting findings should support the standardization process for assessing the suitability of monitoring systems for future SHM applications.

**KEY WORDS:** Calibration; Wireless Sensors; Environmental Influences.

## 1 INTRODUCTION

Structural Health Monitoring (SHM) plays a vital role in maintaining the long-term stability and safety of civil infrastructure. Among the various SHM technologies, wireless sensor networks (WSNs) have emerged as an efficient solution for the real-time monitoring of structural integrity. However, WSNs present specific challenges, particularly when deployed outdoors, where they are exposed to a variety of environmental factors. Bridges, for instance, are subject to extreme temperatures, rapid temperature fluctuations, wind, rain, and vibration, all of which can significantly affect sensor performance and measurement accuracy. Despite these challenges, most calibration efforts focus solely on the sensor itself and are typically performed under laboratory conditions at around 20°C. The effect of variable influences on the entire measurement system is often not sufficiently considered. These include not only external influences, but also aspects such as the stability of the measurement system in relation to its power supply (e.g., wireless sensors are often battery-powered). Such limitations can lead to measurement inaccuracies and impair the reliability of SHM systems in outdoor applications.

This paper presents the calibration process for a wireless monitoring system that measures displacement and strain. This system will later be used on a building to determine changes in strain or crack width with high precision. It should be noted that precision must be defined before selecting the appropriate sensors and sensor system. For example, in the context of service limit states, crack width change may require an accuracy of 0.05 mm. The proposed approach involves placing the complete sensor system in a climate chamber to simulate real-life temperature conditions and fluctuations ranging from

-20 °C to +50 °C. Monitoring the temperature-induced strain of a steel plate under these controlled conditions enables the development of a more comprehensive and practical calibration routine for SHM applications.

It is expected that the findings of this research will enhance the accuracy and reliability of WSN-based SHM systems, particularly for bridges exposed to harsh environmental conditions, and to contribute to the standardization of calibration procedures in this field.

## 2 BACKGROUND AND BASICS

### 2.1 Wireless Sensor Systems in SHM Applications

WSNs for SHM offer a promising alternative to traditional wired sensor systems. The reliance on physical connections for power supply and data transmission in wired systems significantly increases the complexity, manufacturing costs and maintenance requirements of such systems. In contrast, wireless sensor systems integrate power supply or harvesting and wireless communication capabilities directly into the sensor units, enabling efficient data acquisition and real-time signal processing without the need for extensive cabling infrastructure. This self-sufficiency not only simplifies the deployment of SHM systems but also reduces the overall costs and logistical challenges associated with their maintenance [1].

WSNs can be applied to a variety of different use cases. The network usually consists of a series of motes (sometimes also referred to as nodes), each equipped with one or more sensors depending on the measurement task. For example, these sensors can measure temperature, humidity, strain, displacement, pressure, force, tilt, and other variables. The measured values are transmitted wirelessly to a central

processing unit, which primarily stores and pre-processes the data. From there, the data is transmitted to the user for post-processing. It should be noted, however, that WSN applications are only of limited use for high-frequency measurements (vibrations, high-frequency load changes, etc.) due to the limited data transmission via radio and the limited energy supply in battery-powered WSNs (sampling rate correlates with energy consumption).

Figure 1 shows a standard schematic of a sensor mote, which can be described as having four major components: a sensor unit, a processing unit, a communication unit and a power supply unit [2]. When connecting analogue sensors, a suitable signal conditioning device and an analogue-to-digital (A/D) converter are also required.

Figure 1. Block diagram of the hardware for a standard sensor mote [3].

While all these units vary depending on the application, they are subject to the same environmental influences when used outdoors. In this paper, the schematic in Figure 1 will be allocated with the components used in the calibration procedure and considered as a whole. Influences on the communication unit will not be discussed in order to focus on the sensors and the sensor mote themselves. Similarly, environmental influences on the power unit will not be considered, although fluctuations in the energy supply might affect the measurements.

## 2.2 External Influences on WSNs

A variety of external influences can affect both a wireless measurement system and the value being measured. As well as influences from the structure itself and how it is used (e.g. vibrations and deformations), environmental factors such as temperature and humidity also have a significant impact. The extent and nature of these influences depend largely on the structure's geographical location and the motes' specific positioning within it. It is essential to quantify these influences and take them into account when determining measurement results, as this is part of a highly recommended validation process.

For example, significant differences in environmental exposure can arise in the case of a bridge depending on whether sensors are mounted on the deck, beneath the structure, or within enclosed components such as hollow box girders. The Figure

primary influences affecting accuracy in wireless sensor systems can basically be categorized into two key factors, according to [3]:

- The transfer function between the physical quantity to be measured (stimulus) and the sensor system (specifically the sensor's response function). This defines how accurately and consistently the sensor converts the physical stimulus into a measurable signal.
- The cross-sensitivity of external disturbances on the measured quantity, which largely depends on the type of sensor and its underlying measurement principle. Such disturbances can introduce significant errors if not properly accounted for, particularly in environments with variable thermal, electromagnetic, or mechanical conditions.

Figure 2 shows an Ishikawa diagram of the many possible influences on a WSN node, which can impact the quality of the measurement. This categorization especially provides an overview of the basic influences, which are temperature [°K], relative humidity [%], shock [g] and vibration [mm/s]. Depending on the location of the WSN, disturbances due to electromagnetic fields might also be a significant factor (for example, near high-voltage lines). More detailed documentation on the classification of electrotechnical components according to environmental influences can be found in EN 60721/IEC 721 multi-part standard series of the International Electrotechnical Commission (IEC).

This article only considers temperature as a decisive factor influencing the measured value determined by a wireless sensor and the calibration of the sensor system, as the influence of temperature is often not adequately determined during calibration by the manufacturer.

Since the temperature on external structures fluctuates greatly, some assumptions must be made. For example, the climate in a tunnel is more constant than on a bridge, where wind, solar radiation and humidity also play a role in addition to the air temperature. In order to determine upper and lower limits for the air temperature, statistical results for the area in question should be analyzed beforehand.

As an example, for Austria, according to the annual climate report in [4], the minimum air temperature in 2024 was measured at -25.5 °C in mountainous regions and -21.1 °C in urban areas, with a maximum temperature of +36.9 °C.

Another approach could be to use the temperatures used to calculate the integrity of the structure in question, which are mostly regulated in national standards. In case of the European standard in the national appendix, set in [5], a two-day average of the maxima and minima, appearing all 50 years, is used as the dimensioning value. There the lowest temperature expected is set for -32 °C in Austria, while the highest is set for smaller than +39 °C, depending on the sea level.

These values, as can also be seen in Table 1, provide a rough estimate of the required range.

<sup>1</sup> With [g] being a common unit for acceleration with 1 g being the gravitational acceleration of Earth:  $1 \text{ g} \approx 9,81 \text{ m/s}^2$

Figure 2. Ishikawa diagram showing the influences on the uncertainties of WSN nodes.

Table 1. Minima and maxima of air temperature in Austria.

Reference	$T_{\min}$ [°C]	$T_{\max}$ [°C]	$\Delta T$ [°K]
Austrian Measurement 2024	-25.5	36.9	62.4
Austrian Standard	-32	39	71
$T_{\min}$ ...	minimal temperature		
$T_{\max}$ ...	maximal temperature		
$\Delta T$ ...	difference of min and max		

The examples in Table 1 do not apply to every case. Firstly, the effect of direct sunlight is not considered. Depending on the medium, surface temperatures near motes can be much higher, depending on the intensity of the sunlight. Secondly, the values shown are extreme pinpoints of the whole country. They can vary considerably depending on the location. Nevertheless, they demonstrate that the estimated temperature range that a WSN has to endure for long-term SHM, can exceed 60 K, ranging from below -10°C to above 30 °C, depending on various factors.

### 3 PROPOSED CALIBRATION METHODOLOGY

#### 3.1 Experimental Setup

For experimental evaluation, an integrated sensor mote is placed in a climate chamber as a complete unit, including the sensors, but without the sensor mote housing. Approximately once per minute, measurement data is transmitted via a LoRa (Long Range) radio module to a receiver, which forwards the data to a remote database for storage and analysis.

The sensor mote provided by SmartMote [6] consists of two printed circuit boards (PCBs) and is referred to as Smartmote<sup>WS</sup>. The primary PCB contains a microcontroller that is responsible for signal processing and data management. It also contains a communication interface (LoRa – 868 MHz), a

power supply unit comprising two 3.6 V lithium thionyl chloride batteries, and several integrated measurement electronic components and digital sensors for measurement (see Figure 3). The second circuit board serves as a separate sensor interface card, which provides three ports for connecting analogue sensors. The card has a reference voltage and a voltage meter as well as 24-bit high precision analogue-to-digital conversion with adjustable gain for use with different sensor types (see Figure 4).

Table 2. Configuration of the Sensor Mote.

Sensor Mote Name:	SMUSE 143
Onboard measurements:	Acceleration x, y and z Temperature Relative humidity Battery voltage Illuminance
Port 1	Fixed resistors
Port 2	KG 2A – EFA231506
Port 3	KG 2A – EFA231507

Table 3. Specifications of the crack displacement transducers.

Transducer name	KG 2A – EFA231506
Capacity	2 mm
Rated Output	1480 $\mu\text{V/V}$ (2960 $\times 10^{-6}$ strain)
Non-linearity	0,2 %RO
Input resistance	351.6 $\Omega$
Transducer name	KG 2A – EFA231507
Capacity	2 mm
Rated Output	1430 $\mu\text{V/V}$ (2860 $\times 10^{-6}$ strain)
Non-linearity	0,2 %RO
Input resistance	351.2 $\Omega$

For this experiment, the sensor interface board is equipped with two crack displacement transducers (model KG-2A, Tokyo Measuring Instruments Laboratory [7]), which are connected in a mirrored configuration to a steel plate (see Figure 6 and Table 4) to measure the thermally induced strain. Additionally, the third input channel is connected to a fixed resistor network, which acts as a stationary reference input to periodically validate the stability and performance of the measurement system under varying environmental conditions (see Table 2,

Table 3 and Figure 5 for technical details).

Figure 3. Primary PCB with power supply.

Figure 4. Secondary PCB with sensor ports.

Figure 5. Crack displacement transducers on a steel plate.

Figure 6. Steel plate S235 140x30x2 [mm].

A programmable climate chamber (model: VÖTSCH VT 4060) is used to determine the influence of environmental

temperature variations. It allows precise temperature control within the range of  $-40^{\circ}\text{C}$  to  $+180^{\circ}\text{C}$  and includes adjustable ramp rates and programmable dwell times at set points. This enables reproducible temperature profiles to be implemented that are tailored to sensor calibration procedures.

Table 4. Characteristics of the steel plate.

Steel plate grade	S235 JR
Length	140 mm
Width	30 mm
Thickness	2 mm
Temperature coefficient $\alpha_T$	$\sim 12 \cdot 10^{-6} \text{ } 1/^{\circ}\text{K}$
Base length of measurement $L_0$	103 mm

For the present calibration experiment, a temperature range of  $-20^{\circ}\text{C}$  to  $+50^{\circ}\text{C}$  is defined. This range is based on the boundary conditions discussed in section 2.2, with slight modifications to accommodate the technical limitations of the chamber. Although temperatures below  $-20^{\circ}\text{C}$  have historically occurred in the alpine regions of Austria, such extremes have become rare in recent years due to climate change. Conversely,  $+50^{\circ}\text{C}$  approximates the extreme surface temperatures that can be experienced by bridge components exposed to direct sunlight in summer.

The temperature setpoints selected for this calibration are  $-20^{\circ}\text{C}$ ,  $0^{\circ}\text{C}$ ,  $+20^{\circ}\text{C}$ ,  $+35^{\circ}\text{C}$ , and  $+50^{\circ}\text{C}$ , as recommended in [3] for the thermal characterization of wireless sensor motes and their attached sensors. Each setpoint is maintained for 30 minutes to allow sufficient time for data collection and to determine the response time of the sensor system, as well as for statistical evaluation of repeatability. Thus, a minimum of five readings is taken at each plateau.

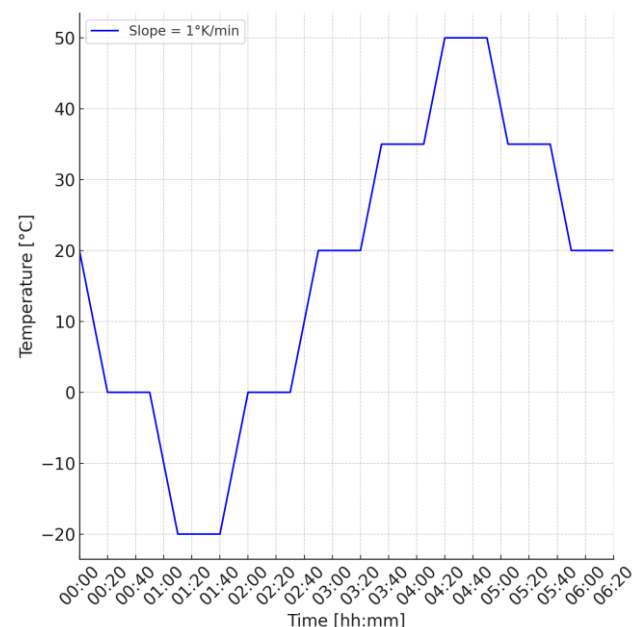

Figure 7. Temperature graph for one calibration cycle.

The full temperature profile is implemented as follows (see Figure 7 for the programmed profile): Starting from a reference temperature of  $+20^{\circ}\text{C}$ , the chamber performs a series of temperature ramps at a constant rate of  $1 \text{ K/min}$ . The temperature then drops to  $0^{\circ}\text{C}$ , falls further to  $-20^{\circ}\text{C}$ , returns

to 0 °C, rises to +20 °C, continues to +35 °C, and finally to +50 °C. It then returns to +20 °C via +35 °C. Each of these temperatures represents a holding period of 30 minutes.

This sequence defines one full temperature cycle, which is repeated ten times to increase the statistical significance of the results and to enable the observation of potential thermal hysteresis and time drift effects in the sensor system.

### 3.2 Calibration Procedure

To evaluate, calibrate and compare the performance of the two displacement sensors mounted on the steel plate (Figure 5), for which thermal expansion was calculated by using the chamber temperature and the characteristics of Table 4. It was decided to use ordinary structural steel for the application, rather than nickel-iron alloys (Invar steel) because the influence of steel strain on the uncertainty determination was expected to be minimal. Due to the homogeneous and predictable thermal expansion behavior of steel, its deformation under temperature change can be considered sufficiently uniform and it is therefore used as the “real” deformation value for comparison purposes.

The expected strain was calculated using the linear thermal expansion equation commonly applied in civil and structural engineering for practical application. The strain induced by temperature is defined as:

$$\Delta l = \alpha_T * \Delta T * l_0 \quad (1)$$

with:

- $\Delta l$  : absolute elongation or contraction [mm]
- $\alpha_T$  : coefficient of linear thermal expansion [1/°K]
- $\Delta T$  : temperature difference relative to a reference [°K]
- $l_0$  : original base length of measurement [mm]

For this experimental setup, the reference temperature is 20 °C and the base length of the steel segment between the two sensors is  $l_0 = 103$  mm. The coefficient of linear thermal expansion for structural steel is assumed to be  $\alpha_T = 12 \cdot 10^{-6}$  1/°K (Table 4) with an assumed standard deviation of  $\sim 0,3 \cdot 10^{-6}$  1/K. The expected median deformation values for the two temperature extremes in the calibration protocol are calculated using equation (1):

- Maximum elongation at +50 °C ( $\Delta T = +30$  K):  
 $\Delta l = 12 (\pm 0.3) \times 10^{-6} \times 30 \times 103 = \underline{0.037 (\pm 0,001) \text{ mm}}$
- Maximum shortening at -20 °C ( $\Delta T = -40$  K):  
 $\Delta l = 12 (\pm 0.3) \times 10^{-6} \times (-40) \times 103 = \underline{-0.049 (\pm 0,001) \text{ mm}}$

The calculated values serve as a reference line for the evaluation of the measurement results of both sensors. When functioning correctly, the cumulative deformation values recorded by the sensors should closely follow this curve, assuming a uniform temperature distribution and negligible mechanical disturbances.

The calibration procedure involves repeating the temperature cycle described in section 3.1 six times. During each cycle, measurements are recorded at a sampling rate of approximately one measurement per minute. It should be noted that this interval is shorter than is typical for long term monitoring applications, and therefore occasional inconsistencies in the data are to be expected as the system is optimized for lower frequency measurements.

Following the temperature programming, the sensors are subjected to controlled thermal load in the climate chamber.

The measurement output consists of a differential voltage signal relative to a reference voltage, which is continuously recorded and transmitted via the wireless mote system. A calibrated transfer function is then used to convert this voltage output into a displacement in millimeters [mm].

This conversion is based on the known sensitivity characteristics of the strain gauges (

Table 3), and the applied formula as shown in Equation (2):

$$X = \frac{main_{mvpv}}{(1000 - ref_{mvpv}) \cdot \frac{R_{sensor}}{R_5}} \cdot \frac{Cap_{sensor}}{RO_{sensor}} \cdot 1000 \quad (2)$$

with:

- $X$  : calculated displacement [mm]
- $main_{mvpv}$  : measured voltage at the sensor output [mV/V]
- $ref_{mvpv}$  : reference voltage equal to all supply voltages of the components [mV/V]
- $R_5$  : reference resistance of the measurement system being 100 in the apparent setup [ $\Omega$ ]
- $R_{sensor}$  : input resistance of the Wheatstone Bridge of the used sensor [ $\Omega$ ]
- $RO_{sensor}$  : characteristic value of the Wheatstone bridge for the measuring range [mV/V]
- $Cap_{sensor}$  : measuring span of the used sensor [mm]

Based on this formula, a data structure (see Table 5) is generated. To align the time domains of the two systems, the temperature measurements from the climate chamber are linearly interpolated to match the timestamps of the wireless sensor node. Figure 8 shows the results of the measurements at the set temperatures. The calculated cumulative displacement is set to zero for the first measurement at 20 °C.

Table 5. Data structure of experiment.

Column name	Description
__time	Datetime of the measurement [YYYY-MM-DD hh:mm:ss]
Ref_mV_per_V	reference voltage equal to all supply voltages of the components [mV/V] (see equation (2))
mV_per_V	measured voltage at the sensor output [mV/V] (see equation (2))
Displacement	Calculated displacement of each timestep in [mm] (see equation (2))
Delta displacement	Calculated displacement subtracted from each timestep before in [mm]
Cumulative displacement	Cumulative displacement started with the first timestep as zero in [mm]
Temperature	Measured temperature of the climate chamber interpolated for each measured timestep in [°C]
Reference temperature	Temperature which is programmed for the cycle (not measured) in [°C]
Cycle direction	Differentiated into cooling, heating and constant
Steel	Expected displacement of the steel plate with ideal strain in [mm] (see equation (1))
Error	Difference of cumulative measurement and steel in [mm]

Figure 8. Raw data of cumulative displacement for both displacement transducers.

Figure 8 shows the results of the cumulative displacement of the two KG-2A sensors (Port 2 and Port 3) plotted against the temperature profile of the climate chamber and the theoretical elongation of the steel reference. Neither of the two sensor curves matches the expected thermal elongation of steel (blue line), which indicates a systematic error in the raw measurement data.

During heating and cooling phases, both sensors follow different curves. However, at the holding points where the temperature was kept constant, the cumulative displacement of both sensors converge to a common value. This behavior suggests that the response time of the sensors may need to be considered when higher accuracy requirements are specified.

### 3.3 System Temperature Compensation

It has not yet been clarified whether the measurement error (Figure 8) is due to the sensors themselves or to the measurement system. In order to isolate and correct the systematic temperature sensitivity of the wireless mote itself, a special reference arrangement was implemented using a full Wheatstone bridge composed of high precision 350  $\Omega$  (0.1%) resistors, which were connected to Port 3 of the sensor mote. This configuration allows sensor specific strain effects to be excluded and ensures that only thermal influences on the measurement electronics are detected.

The entire system was placed into the climate chamber and subjected to the same thermal cycling protocol. Since the strain gauges in the KG-2A sensors also operate with a Wheatstone bridge of approx. 350  $\Omega$ , this setup simulates the electrical behavior of such a sensor. Consequently, all recorded voltage variations can be attributed solely to temperature-related shifts in the signal conditioning circuit.

A correction function can therefore be derived from the resulting data set, which can be used to compensate the systematic temperature error of the wireless measurement system. This step is essential for improving measurement accuracy in an outdoor environment.

Figure 9. Results for the 350  $\Omega$  reference arrangement and linear regression for temperature compensation.

Figure 9 shows the results for the 350  $\Omega$  reference arrangement connected to Port 3. As can be seen, there is a systematic error in the measurement system over the investigated temperature range. To quantify the systematic thermal influence of the mote, a linear regression model was developed based on the stabilized measurement data at the holding points. Specifically, the final ten data points at each temperature plateau were extracted, equivalent to the final ten minutes of each holding phase. This time window was chosen to ensure that the system had reached thermal equilibrium, thereby minimizing transient effects caused by sensor response delays. The resulting data was used to fit a linear correction function with temperature as the independent variable, as shown in the following equation (3) below:

$$main_{corr} = main_{mvpv} - 0,0005 * T - 0,0107 \quad (3)$$

with:

$main_{corr}$  corrected measurement [mV/V]  
 $main_{mvpv}$  measured voltage at the sensor output [mV/V]  
 $T$  measured temperature [°C]

The corrected measurement is then inserted back into equation (2) to calculate the corrected displacement. The results of the corrected measurements can be seen in Figure 10 exemplary for KG-2A on Port 3.

As shown in Figure 10, correcting the error caused by the measuring system reduces the absolute error, but it is still relatively large. The deviation from the ideal strain curve of the steel is most likely due to the design of the sensor. The sensor itself consists largely of a steel construction, with the Wheatstone bridge presumably implemented inside the sensor via a type of spring mechanism. The steel construction therefore deforms almost identically to the steel rail in response to temperature, so that the Wheatstone bridge does not experience any significant strain.

Figure 10. Corrected values on KG-2A@Port 3.

### 3.4 Sensor Temperature Compensation

The procedure for temperature compensation of the sensors is carried out in the same way as for determining the correction function for the temperature error caused by the measuring system. A linear regression over the last ten measurements at each hold point forms the basis for the correction formula for each individual sensor. The linear change in length of the steel plate is then also calculated using a linear function. From these two, a correction function (4) is created with temperature as the independent variable in order to calibrate the sensor with regard to its temperature behavior.

$$X_{cal} = X_{raw} + (k_{steel} - k_{lin.reg.}) * T - (d_{steel} - d_{lin.reg.}) \quad (4)$$

with:

$X_{cal}$	calibrated displacement [mm]
$X_{raw}$	corrected displacement acc. to equation (2) [mm]
$k_{steel}$	slope of the steel function [0.00123]
$k_{lin.reg.}$	slope of the linear regression of the raw measurements [0.0003]
$T$	measured temperature [°C]
$d_{steel}$	intercept of the steel function [-0.0244]
$d_{lin.reg.}$	intercept of the linear regression of the raw measurements [-0.0048]

Following calibration, the corrected measurement data clearly shows a trend towards the expected thermal elongation of the steel reference, as demonstrated in Figure 11 for the KG-2A sensor connected to Port 3.

Figure 11. Calibrated displacements on KG-2A@Port 3.

### 3.5 Uncertainty Analysis

The uncertainty analysis involves evaluating each input parameter according to the classification defined in [8], distinguishing between Type A and Type B uncertainties. This procedure is also described for a comparable experiment in [9]. Type A evaluation is based on the statistical analysis of repeated measurements and is applied to the cumulative measurement value in this setup. Type B evaluation, on the other hand, relies on scientific judgement or prior information. Accordingly, the uncertainty associated with the elongation of the steel for example is classified as Type B. For practical purposes, the temperature is considered ideal. Consequently, rather than the actual temperature measured by the sensor mote, the temperature of the climate chamber (see Table 5) is used as a reference for this analysis.

Furthermore, the displacement calibration performed on a similar KG-2A sensor from [10] will be taken into account as an example.

#### Measurement error:

The measurement error is included in the data structure in Table 5 and is calculated using the following equation (5):

$$\varepsilon(t, T) = \Delta l_{measured}(t) - \Delta l_{steel}(T) \quad (5)$$

with:

$\varepsilon(t)$	error for each timestep [mm]
$\Delta l_{measured}(t)$	calibrated cumulative measurement for each timestep [mm]
$\Delta l_{steel}(T)$	expected steel elongation for each temperature [mm]

#### Type A uncertainty:

For the evaluation of Type A uncertainty, the methodology outlined in ([8], p. 22) is applied to each sensor port individually. This analysis assumes that the measurement deviations approximately follow a Gaussian (normal) probability distribution, which is a reasonable approximation for random fluctuations in sensor readings under stable

conditions. The arithmetic mean and the experimental standard deviation of the measurement error are calculated from the last ten measurements at each holding point to account for sensor response time. This allows for a detailed quantification of the repeatability and consistency of the sensor system under varying thermal conditions. Mathematically, the Type A uncertainty is expressed as follows:

$$u_i = s = \sqrt{\frac{1}{n-1} \sum_{i=1}^n (x_i - \bar{x})^2} \quad (6)$$

With:

$x_i$	individual error values in [mm]
$\bar{x}$	mean error
$s$	sample standard deviation, representing the Type A uncertainty

Following the Type A uncertainty evaluation for each port as shown in Table 6, Figure 12 illustrates the calibrated error including the standard deviation for each temperature holding point. Also shown in Table 6 is the final unweighted mean error and corresponding deviation across the entire temperature span. Figure 12 shows the error bands for raw, corrected, and calibrated data, highlighting the effect of each correction stage on measurement uncertainty.

Table 6. Type A uncertainty for each temperature holding point, after temperature compensation.

Temperature [°C]	KG-2A@Port2		KG-2A@Port3	
	$\bar{x}$ [mm]	$s$ [mm]	$\bar{x}$ [mm]	$s$ [mm]
$u_{t-20}$	0.0033	0.0002	0.0039	0.0004
$u_{t0}$	-0.0004	0.0002	-0.0011	0.0005
$u_{t20}$	-0.0020	0.0003	-0.0020	0.0006
$u_{t35}$	-0.0008	0.0004	-0.0001	0.0007
$u_{t50}$	0.0037	0.0002	0.0029	0.0004
$u_{temp\_full}$	0.00076	0.0001	0.00072	0.0002

Figure 12. Error diagram for raw and compensated values.

The mean error at each holding point should be interpreted as a systematic bias (or also known as truthfulness) relative to the assumed real value. Since the total mean value of the errors across all temperatures after temperature compensation is relatively low, it is not considered in further uncertainty calculations. The decisive factor for the uncertainty assessment is therefore solely the combined consideration of the uncertainties at each hold point.

### Type B uncertainty:

In accordance with the methodology described in [[8], p. 23], Type B uncertainty is evaluated based on input quantities whose variability is derived from scientific judgement, manufacturer specifications or published data, rather than from repeated observations. As the aim of this paper is to establish a practical and field-adaptable calibration approach, not all parameter uncertainties are derived from formal traceable standards. Nevertheless, the main sources of Type B uncertainty in this setup are clearly identified and justified. Three factors are shown: the variance of the temperature coefficient of steel  $\alpha_T$ , assumed to be  $\pm 0.3 \cdot 10^{-6} \text{ 1/}^\circ\text{K}$ , the nonlinearity of each sensor (shown in

Table 3) and the displacement calibration given from an earlier analysis for a KG-2A sensor [10]. Given the variance of  $\alpha_T$  for a base length of 103 mm and a base temperature of  $20^\circ\text{C}$  the uncertainty of the elongation for every holding point is shown in Table 7 (calculated using Equation (1)).

Table 7. Uncertainty of elongation at holding points by variance of steel temperature coefficient.

Uncertainty by Temperature	$s$ [mm]
$u_{steel-20}$	0,0012
$u_{steel0}$	0,0006
$u_{steel20}$	0
$u_{steel35}$	0,00046
$u_{steel50}$	0,00092

According to the manufacturers' datasheet for the displacement sensors [7], the nonlinearity is specified as 0.2 % of the rated output (RO). Given the full-scale measurement range of  $\pm 2 \text{ mm}$  (i.e., a total span of 4 mm), the resulting nonlinearity can be interpreted as contribution to the uncertainty of  $u_{RO} = 0.002 \times 4 \text{ mm} = 0.008 \text{ mm}$ . However, the datasheet does not provide further details regarding the determination of this nonlinearity or whether the 0.2 % RO represents a standard uncertainty or a combined uncertainty with a coverage factor (e.g.  $k=2$ ). Therefore, in the absence of this information, the nonlinearity is conservatively treated as a Type B uncertainty contribution in accordance with the GUM framework.

Additionally, prior calibration using a similar KG-2A displacement sensor yielded a calibration uncertainty of  $u_{dis-cal} = 0.003 \text{ mm}$  based on measurements within a range of  $\pm 1.5 \text{ mm}$ . As no significant nonlinear behavior is expected beyond this range and there is no evidence to suggest otherwise, the same calibration uncertainty is assumed to be valid over the full range of  $\pm 2 \text{ mm}$ . This assumption is also incorporated into the Type B uncertainty budget.

The complete Type B uncertainty is calculated using equation (7) for general purposes and equation (8) for this demonstration, with the results shown in Table 8:

$$u_B = \sqrt{\sum_{i=1}^n u_i^2} \quad (7)$$

$$u_B(T) = \sqrt{u_{\alpha T}^2(T) + u_{RO}^2 + u_{dis-cal}^2} \quad (8)$$

with:

- $u_B$  combined uncertainty for Type B
- $u_i$  individual uncertainty of each factor falling in Type B,  $u_{\alpha T}(T)$  is the variation of the steel elongation depending on the temperature coefficient
- $u_{RO}$  nonlinearity given by the datasheet
- $u_{dis-cal}$  evaluated uncertainty due to displacement calibration

Table 8. Type B uncertainty by temperature.

Type B by Temperature	s [mm]
$u_{B-20}$	0.0086
$u_{B0}$	0.0086
$u_{B20}$	0.0085
$u_{B35}$	0.0086
$u_{B50}$	0.0086
$u_{Btemp-full}$	0.0086

Table 8 shows that the influence of uncertainty on the temperature coefficient is irrelevant in this experiment and will therefore not be discussed any further.

#### Combined uncertainty:

The combined standard uncertainty  $u_c$  is derived by aggregating the individual contributions of Type A and Type B uncertainties. Type A uncertainty reflects the statistical dispersion in repeated measurements, while Type B uncertainty accounts for systematic influences, such as variations in material properties and sensor nonlinearity. Assuming that these contributions are uncorrelated, the combined uncertainty is calculated using the root-sum-of-squares method, as recommended by the GUM framework [8]:

$$u_c = \sqrt{u_A^2 + u_B^2} \quad (9)$$

Substituting the Type A and Type B values for this experiment into Equation (9) the combined uncertainty for this setup is given in Table 9. It shows that for the temperature compensated values the uncertainty is determined by the factors of Type B.

Table 9. Combined uncertainty of the sensors on both ports.

[°C]	KG-2A@P2			KG-2A@P3		
	$u_A$ [mm]	$u_B$ [mm]	$u_C$ [mm]	$u_A$ [mm]	$u_B$ [mm]	$u_C$ [mm]
-20	0.0002		0.0086	0.0004		0.0086
0	0.0002		0.0086	0.0005		0.0086
20	0.0003	0.0086	0.0086	0.0006	0.0086	0.0086
35	0.0004		0.0086	0.0007		0.0086
50	0.0002		0.0086	0.0004		0.0086
Full Span	0.0001	0.0086	0.0086	0.0002	0.0002	0.0086

If the values for Type A and Type B for this experiment are inserted into equation (9), the combined uncertainty is obtained as shown in Table 9. It can be seen that the combined uncertainty for the temperature-compensated values is essentially determined by the Type B uncertainties.

#### Expanded uncertainty:

To express the measurement uncertainty with a defined level of confidence, the expanded uncertainty  $U$  is calculated by multiplying the combined standard uncertainty  $u_c$  by a coverage factor  $k$  as shown in Equation (10):

$$U = k * u_c \quad (10)$$

with:

- $U$  expanded uncertainty
- $k$  coverage factor chosen with
- $u_c$  combined uncertainty

In this study, a coverage factor of  $k=2$  is applied, which corresponds to an approximate 95% confidence level under the assumption of a normal distribution, as recommended in [8]. The resulting expanded uncertainty, as shown in Table 10, defines an interval around the measurement result within which the true value is expected to lie with a high degree of probability. This value is crucial for ensuring the reliability of decision thresholds and condition assessments in the presence of measurement variability, and serves as a practical limit for interpreting sensor data in structural health monitoring applications.

Table 10. Expanded uncertainty of the sensors on both ports

	$u_c$ [mm]	$U$ [mm]
KG-A2@Port 2	0.0086	0.0172
KG-A2@Port 3	0.0086	0.0172

## 4 DISCUSSION AND RESULTS

Previous studies have shown that sensor systems exposed to temperature fluctuations can exhibit irregular and inconsistent behavior with regard to the measured value to be recorded. In the present study, laboratory tests with wireless displacement sensors under the influence of temperature are carried out as examples. The displacement sensors are fixed to a steel plate in order to simulate guided deformation similar to an application on steel or reinforced concrete components with similar thermal expansion behavior.

Measurements (Figure 8) with wireless sensor nodes and displacement sensors have shown that the raw data on deformation deviates significantly from the expected thermal deformation of the steel. In addition, a temperature-dependent sensor response was observed during heating and cooling, which raises the question of how temperature influences and gradual changes can be handled and compensated for in on-site applications. Since convergence and reproducibility are achieved at different temperature holding points, it is possible to perform temperature compensation. In the present case, linear temperature compensation proved to be suitable for compensating for the influences from both the measuring system itself and the connected sensors. However, such temperature compensation is only possible if the sensors stabilize at a consistent value after reaching thermal

equilibrium. A special feature here is that the sensors under investigation themselves exhibit temperature expansion, which overlaps with the deformation to be measured on the component. It is therefore relatively difficult to carry out highly accurate measurements if the sensor temperature and the component temperature are unknown or even different, which can certainly occur in practice. This is particularly important when displacement transducers and discrete measuring paths of several centimeters are used to measure crack width changes in the hundredth of a millimeter range, as sensor and component expansion accompany the change in crack width. The same applies when displacement transducers are used to determine expansion with accuracies of approximately 10  $\mu$ strain. This article has explained that the influences on measurement uncertainty can be very diverse. These range from measurement uncertainties of the measuring system itself, including uncertainties from the power supply, to uncertainties of the connected sensors, to measurement uncertainty regarding the sensor mounting on the object and a wide range of other external influences.

In order to quantify and correct the influence of the measuring system, a special reference arrangement with a Wheatstone bridge consisting of identical high-precision resistors was implemented. This setup, which excludes mechanical components and deformations, shows the inherent temperature sensitivity of the mote and serves as the basis for a sensor node-specific correction function that ultimately also includes the individually connected sensors. For this purpose, temperature compensation functions were derived based on measurements at different temperature plateaus and measurement uncertainties were determined.

A comprehensive uncertainty analysis based on the GUM framework shows that, after calibration, the dominant contribution to the total uncertainty is of type B, provided that the uncertainty contribution of type A could be significantly reduced by applying temperature compensation functions (determined by calibration in temperature change tests). The final expanded measurement uncertainty for the measurement system shown with two displacement sensors is therefore less than 0.02 mm (20  $\mu$ m), whereby without temperature compensation, a measurement uncertainty of at best approximately 50 to 100  $\mu$ m can be assumed, depending on the temperature range.

## CONCLUSIONS

An important finding was that the thermal response of the sensor housing and mounting components largely matched that of the monitored steel structure. This resulted in a partial cancellation of thermally induced displacement, which highlights the need for proper system calibration and temperature compensation. A correction function derived from a temperature-controlled reference experiment and validated using stable measurement intervals effectively reduced systematic errors and extended uncertainty to less than 20  $\mu$ m. Furthermore, the comparison of the two identically installed sensors revealed distinct response behaviors in the raw measurements. This indicates that in this case individual calibration is recommended for each sensor, rather than relying on batch calibration procedures.

This study emphasizes the importance of considering the sensor and its mechanical integration as a unified measurement system. By demonstrating a reproducible calibration routine that considers electronic, mechanical and environmental influences, this study contributes to the practical standardization of wireless SHM devices. It therefore represents a step forward in providing information on the accuracy of sensors and sensor systems under real-world conditions. In the past, this was often not sufficiently taken into account, leading to misinterpretations of the measured values.

# eNodes: GNSS Time-Synchronised Wireless Accelerometer Measurement Nodes capable of operating indoors

Ki-Young Koo, Miaomin Wang, Zuo Zhu, James Brownjohn  
<sup>1</sup>University of Exeter, UK

**ABSTRACT:** This paper presents time-synchronized wireless acceleration measurement nodes, named eNodes, capable of operating indoors by preserving timing information with a temperature-controlled crystal oscillator (TCXO). While GNSS-based time synchronization is commonly effective for outdoor measurements with available GNSS signals, it does not work indoors, such as inside high-rise buildings or box-girder bridges. To extend GNSS-based time synchronization to indoor applications, timing information is acquired outdoors both before and after the indoor deployment. The TCXO maintains this timing information accurately ensuring a stable and accurate frequency. Each eNode is equipped with an Epson M352 MEMS accelerometer, which offers extremely low noise of  $0.2 \mu\text{g}/\sqrt{\text{Hz}}$ , and an ESP32 microprocessor unit. Real-time data transmission is enabled by a Wi-Fi mesh network. A series of experiments were conducted to evaluate the time-synchronization accuracy of the eNodes.

**KEY WORDS:** Structural Health Monitoring, Wireless Sensor, Accelerometer.

## 1 INTRODUCTION

It is a challenging task to measure acceleration responses of large infrastructures such as long-span bridges, or high-rise buildings, due to long easy-to-tangle many wires between sensors and a DAQ system, up to several km's. As an alternative to the conventional wired DAQ system, the idea of wireless sensors emerged a few decades ago, but it has brought a side-effect, the time-synchronisation problem between the nodes for a proper identification of mode-shapes.

There have been a few wireless sensors developed and available commercially or academically. To the best knowledge of the authors, they were either not providing the accuracy of time-synchronisation, or not readily available to buy. Recently a few manufacturers emerged to provide time-synch'ed wireless nodes (from Sensquake, or Guralp), however their main application was not perfectly aligned with the task of campaign-type ambient vibration measurement of infrastructures.

This paper presents a realisation of wireless accelerometer nodes focusing on campaign type field measurement applications on civil infrastructures or high-rise buildings. The GNSS based time-synchronisation [1] method was used and extended to indoor measurements by combining the GNSS method with a stable clock source.

## 2 WIRELESS ACCELEROMETER NODES

### 2.1 Accelerometer

The accelerometer node, as shown in Figure 1, consists of a M5Stack Core2 based on esp32, a GNSS module (M5Stack GPS V2), an accelerometer module for an Epson M-A352 sensor, a battery module (M5Stack Battery 13.2), and battery charging module (M5Stack M5Go). The company M5Stack provides a convenient modular structure for their MPU and modules, so that a user can easily add a feature by added another layer of module stacked below the M5Stack Core2. The Core2 MPU provides a 320x240 pixels LCD and a touchpad, enabling a convenient control and operation of the sensor node.

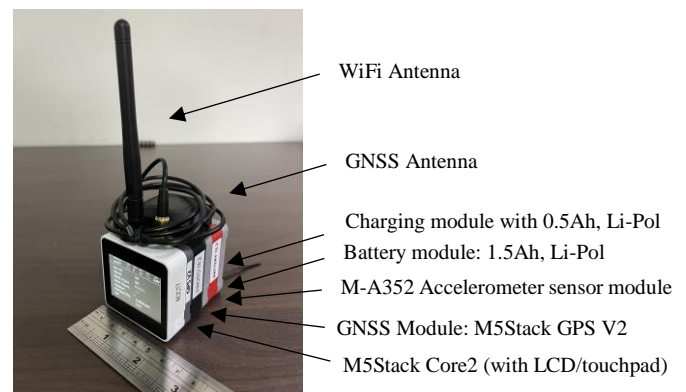

Figure 1. Accelerometer node eNode

Figure 2 shows Epson M-A352 sensor module, which is interconnected to Core2 MPU with 30 GPIO pins as well as the modules stacked together. Epson M-A352 provides the noise floor of  $0.2 \mu\text{g}/\sqrt{\text{Hz}}$ , which is extremely low, hence out-performing for low-vibration measurement of civil infrastructures. M-A352 is a digital sensor with a built-in ADC and output data rates range from 50 Hz to 1000 Hz.

Figure 2. Epson M-A352 Accelerometer module: (left) Top View, and (right) Bottom View

Figure 3. M5Stack GPS V2 module: (left) Top View, and (right) Bottom View

Figure 3 shows the M5Stack GPS V2 module, which plays the critical role for time-synchronisation. This outputs NMEA sentences and PPS (Pulse-Per-Second) signals to the Core2 MPU, which combines these outputs to get a highly accurate timestamping on each measured acceleration. Details method is shown in [1].

Espressif IoT Development Framework (ESP-IDF) was used, rather than the Arduino platform, mainly for the full control on the lower-level timing operations of esp32. In addition, Mesh-Lite was used to utilise a WiFi mesh network, extending maximum allowable distance between nodes, by multi-hops.

### 3 SYNCHRONISATION ACCURACY

Four different experiments were carried out from the ideal condition (Case #1), to the most realistic condition (Case #4) of the indoor capable eNodes with a temperature variation as shown in Table 1.

Table 1. Experimental Cases of timestamping error measurement

Case #	GNSS signal	Clock-Source	Temp. dev.
1	always	GPTimer (10MHz)	No
2	always	TCXO (32.768kHz) for RTC	No
3	limited	TCXO (32.768kHz) for RTC	No
4	limited	TCXO (32.768kHz) for RTC	Yes

#### 3.1 Case #1: Continuous GNSS signals with a GPTimer

Accuracy of time synchronisation for the hardware of the Core2 and the GNSS module was measured using the setup shown in Figure 4. This setup assumed that GNSS signals were always available with a high-frequency General Purpose Timer (GPTimer) of 10 MHz as the basis of the ideal time-sync performance for a comparison with the following Cases #2-4.

A common 10 Hz trigger signal was generated by a function generator, fed to the two identical nodes of Core2 and M5Stack GPS module. Each node was programmed to timestamp each trigger signal. GNSS signal was available all times during the experiment. In theory both nodes should produce the exactly same timestamps, but in reality they differ slightly. Their difference was measured and shown in Figures 5 and 6.

Figure 4. Experimental setup for measuring time-sync accuracy for eNode

Figure 5. Case #1: Difference in timestamps by two identical nodes

Figure 6. Case #1: Histogram of difference in the timestamps

#### 3.2 Case #2: Continuous GNSS signals with a TCXO

Frequency of General Purpose Timer used in Case #1 is influenced by temperature variation, which drastically reduces timestamping accuracy during the period without GNSS signals. There are different ways to improve this using OCXO (Oven Controller Crystal Oscillator) or TCXO. In this study, a TCXO with 32.768 kHz was used as the clock-source for the Real-Time Clock of ESP32 to replace GPTimer of Case #1.

Figure 7 shows the timestamping difference over 2 hours period, showing the step-wise errors between  $\pm 61$  usec. This can be explained two clock-oscillations error in the RTC clock-counter, which only increases by 2. One clock oscillation of a 32.768 kHz clock corresponds to 30.5 usec, and two clock oscillations correspond to 61 usec.

Figure 7. Case #2: Difference in timestamps by two identical nodes with TCXOs

### 3.3 Case #3: Limited GNSS signals with a TCXO

When eNodes are deployed indoors, GNSS signals becomes unavailable. In this Case #3, it was assumed that GNSS signals were missed for 1 hour in the beginning and becomes available again afterwards. Due to the deviation of TCXO, the two timestamps by the identical nodes differ slightly more than Case #1. Figure 8 shows the measured time-stamping difference in the beginning, followed by the normal pattern observed in Figure 7 in the last half hour.

Figure 8. Case #3: Difference in timestamps by two identical nodes with TCXOs

### 3.4 Case #4: Limited GNSS signals with a TCXO under temperature variation

Temperature variation is a crucial factor to reduce timestamping accuracy in the nodes. TCXOs are designed to compensate the variation, but inevitably capable to do up to a certain degree. In this case, the timestamping difference under temperature variation was investigated.

In this Case #4, a temperature variation was imposed on one node by putting it into a refrigerator whilst the other node was kept in room temperature, resulting in 14°C temperature difference. The measured timestamp difference is shown in Figure 9. It was clearly seen that additional error was introduced by temperature variation to the maximum timestamp difference of about 250 usec.

Figure 9. Case #4: Difference in timestamps by two identical nodes with TCXOs

## CONCLUSION

In this study, the time-sync accuracy of indoor capable acceleration nodes were measured. With the used hardware of 32.768 kHz TCXO and ESP32, it was found that the maximum of 250 usec timestamping difference was observed for an hour measurement under 14°C ambient temperature difference.

Further study will carry out to validation tests including a laboratory OMA on a shear building frame and a field OMA for a high-rise building.

**ABSTRACT:** Despite advancements in electromagnetic wave-based communication, challenges such as high attenuation, medium variability, and large antenna requirements persist. Magnetic induction (MI) communication has emerged as a promising alternative, offering stable transmission characteristics and reduced near-field path loss. While previous studies have explored MI waveguide models and relay coil applications, experimental validation of through-the-ground MI transmission, particularly in homogeneous media, remains limited. This study investigates magnetic signal propagation in uniform underground environments through numerical simulations and experimental validation. A finite element model was developed using COMSOL to simulate magnetic signal transmission, focusing on coil geometry and medium properties. Experimental validation was conducted using a custom-built outdoor platform, where mutual inductance coils were employed to measure signal transmission in both air and soil. Key parameters, including coil spacing and medium permeability, were analyzed to evaluate path loss. Results demonstrate excellent agreement between simulations and experiments, confirming that soil's air-like permeability results in minimal path loss over short distances. The study highlights permeability as the dominant factor in signal attenuation, with soil moisture and composition showing negligible effects. These findings validate the theoretical framework for MI transmission in homogeneous media and provide practical insights for optimizing MI-based communication systems in applications such as agricultural monitoring and underground utility networks. Future work should focus on long-distance transmission and the impact of enhanced power levels to further refine system performance in real-world scenarios.

**KEY WORDS:** Magnetic Induction; Signal Propagation; Underground Communication; Path Loss; Steel fabric.

## 1 INTRODUCTION

Despite advancements in electromagnetic wave-based communication, challenges such as high attenuation, medium variability, and large antenna requirements persist [1]. Magnetic induction (MI)-based communication has emerged as a promising alternative, demonstrating stable transmission characteristics and reduced near-field path loss [2][3]. Early studies proposed MI waveguide transmission models with relay coils to extend communication range, successfully applied in underground pipeline monitoring [4].

Subsequent research expanded MI communication models, exploring interactions with underground conductive structures [5] and developing adaptive environmental sensing networks. Studies have improved MI transmission devices by analyzing coil behavior and optimizing system parameters [6]. More recent advancements include rotating permanent magnet pair (RPMP) antenna arrays for extremely low-frequency transmission [7] and tightly wound helix-toroidal coils for underground structural monitoring [8][9].

While significant progress has been made, gaps remain in experimental validation of through-the-ground MI transmission, particularly regarding the impact of soil eddy currents and complex underground conductive structures like rebar networks. To address these gaps, this study develops a detailed finite element model of rebar mesh, analyzing key parameters such as spacing, influence range, and diameter on MI signal path loss. Comparative experiments through soil and

air further validate that soil's impact on MI transmission is minimal over short distances. This work highlights the need for expanded long-distance testing with enhanced transmission power to better understand soil's effect in practical scenarios.

## 2 METHODS

To investigate the propagation law of magnetic signals in underground structures, this study conducted a comparative analysis between numerical simulations and experimental investigations.

The research consists of two phases: (1) numerical simulation of signal transmission in homogeneous media, and (2) experimental validation of signal transmission in homogeneous media of signal transmission in homogeneous media.

### 2.1 numerical simulation

Firstly, this study performs parametric modeling of the magnetic signal transmission process based on COMSOL finite element software, establishes a magnetic induction signal simulation platform, and conducts multi-parameter analysis of the propagation characteristics of the magnetic signal.

First, a numerical simulation of magnetic signal propagation through a uniform medium is performed:

The coil domain consists of two concentric ring geometries: the primary coil and the secondary coil. These are controlled by the parameters: the Inner radius  $r_2$ , the Outer radius  $r_1$ , the

number of turns  $N$ , and the coil center-to-center distance  $d$ . The medium domain is a spherical region through which the signal is transmitted, and it is controlled by the parameter: region radius  $R$ .

The coil domain material is copper, while the material of the medium domain is the propagation medium (soil/air). The material parameters include relative permeability, relative permittivity, and electrical conductivity.

An excitation voltage  $V_0 = \sin(\omega t)$  is applied to the primary coil, where  $\omega = 2\pi f$ ,  $f = 50\text{Hz}$ . The geometric center of the coil set is placed at the center of the simulation domain, as shown in Figure 1 Numerical Model of Magnetic Signal for Mutual Inductance Coils.

Based on the equipment in the reference experimental platform, the model parameters are set as Table 1 Simulation parameter value table:

Table 1 Simulation parameter value table

Parameter	Value	Description
$r_1$	12cm	Outer radius
$r_2$	1cm	Inner radius
$N$	500	Number of coil turns
$d$	40cm	distance between coils
$R$	5m	Radius of the medium domain
$\mu$	1	Relative permeability of the medium

Figure 1 Numerical Model of Magnetic Signal for Mutual Inductance Coils

## 2.2 experimental validation

To investigate the propagation characteristics of magnetic signals in underground environments, validate the conclusions from theoretical and numerical simulations, and prepare for subsequent performance verification of magnetic signal equipment, an outdoor experimental platform for magnetic induction signal transmission was constructed, as shown in Figure 2.

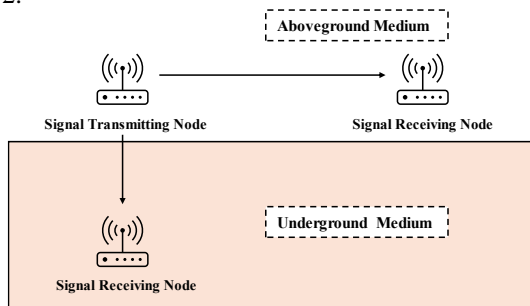

Figure 2 Schematic Diagram of Outdoor Transmission Experiment for Magnetic Induction Signal Using Mutual Inductance Coils

The equipment used in this platform includes

- (1) Coil 1: Diameter 24 cm, 500 turns
- (2) Coil 2: Diameter 24 cm, 500 turns
- (3) Signal Generator (RIGOL-DG2052)
- (4) Regulated Power Supply (ZHAOXIN-PS-23005D)
- (5) Oscilloscope (Tektronix-TBS 2000 SERIE)

Figure 3 Outdoor Transmission Experiment Platform for Magnetic Induction Signal Using Mutual Inductance Coils

First, we connect the signal generator to the primary coil as the signal transmission node and the oscilloscope to the secondary coil as the signal receiving node, placing them in an interference-free open field (as shown in Figure 3 Outdoor Transmission Experiment Platform for Magnetic Induction Signal Using Mutual Inductance Coils). The two coils are fixed on a flat surface using mounting devices, ensuring that the coil axes are aligned and the coil planes are parallel. The distance between the coils is measured before each experiment.

The signal generator is used to apply a 10V excitation to the transmitting coil (left side of Figure 3), which induces a current in the receiving coil that is captured by the oscilloscope.

By varying the coil spacing and recording the peak-to-peak voltage on the oscilloscope, the results can be calculated and visualized as shown in the figure.

To verify that the magnetic signal does not experience additional path loss when passing through soil, we conducted an underground experiment similar to the above-ground magnetic induction signal transmission experiment.

In the underground experiment, the excitation of the coil and the reception of the magnetic signal were the same as in the above-ground experiment. Here, we mainly describe the control of the transmission distance and coil attitude during the experiment.

First, a 31 cm deep pit was dug in the open field, and the bottom surface was leveled. The receiving coil was placed at the center of the pit, and a 1 cm thick layer of soil was added to ensure the receiving coil was just covered by the soil (with the receiving coil's small diameter of 1 cm). Then, a 10 cm thick layer of soil was added, and the surface was leveled again. The transmitting coil was placed at the center of the pit, excitation was applied to the transmitting coil, and the peak-to-peak value from the oscilloscope was recorded. This procedure was repeated for depths of 10 cm, 20 cm, and 30 cm to measure the magnetic signal path loss, as shown in Table 2 Path Loss Above and Below Ground with 10V Transmission Signal.

Figure 4 Schematic of the mutual inductance coil magnetic induction signal through-ground transmission experiment

An alternating signal generates a sinusoidal alternating magnetic field through the primary coil. The change in the magnetic field induces an electromotive force in the secondary coil, which in turn generates the corresponding induced signal. The voltage signal at the receiving end is recorded at different distances, and by combining the coil resistance, the induced power of the signal can be calculated, which allows for the calculation of magnetic signal transmission loss. The above-ground experiment is shown in Figure 4 Schematic of the mutual inductance coil magnetic induction signal through-ground transmission experiment.

### 3 RESULTS AND ANALYSIS

#### 3.1 Propagation in Homogeneous Media

First, a trial calculation is performed under the conditions of a coil spacing  $d=50\text{cm}$  and a uniform medium. The path loss is  $44.16\text{dB}$ , which is in good agreement with the theoretical value. The model performs well, producing the simulation cloud maps shown in Figure 5, Figure 6 Magnetic induction strength contour plot between coils

Next, the coil spacing  $d$  is scanned in the range of  $20\text{cm}$ - $200\text{cm}$  with a step size of  $10\text{cm}$ , keeping all other parameters constant. The path loss is calculated for the model and compared with experimental values (see Figure 8).

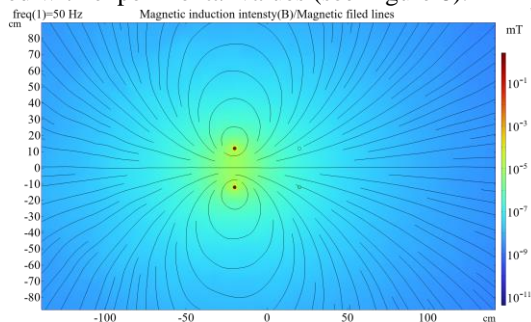

Figure 5 Magnetic induction strength contour plot of the coils cross-section

Figure 6 Magnetic induction strength contour plot between coils

Figure 7 Magnetic Induction Intensity Cloud Map Between Coils

The simulation data of magnetic induction signal variation with coil spacing is shown in Figure 8 Path loss variation with coil distance.

The experimental values generally align well with the simulation results; however, some discrepancies are present due to the following reasons:

- (1) **Background noise interference:** At longer distances, unshielded noise added to the reception power calculation.
- (2) **Coil attitude:** During adjustments for distance, changes in coil angle affected the results.

As a result, the power path loss in the above-ground experiment follows a distance-based decay of approximately the fifth power, while the theoretical equation suggests a sixth power, resulting in some discrepancy. It is believed that with improvements to the filtering equipment, a better match can be achieved.

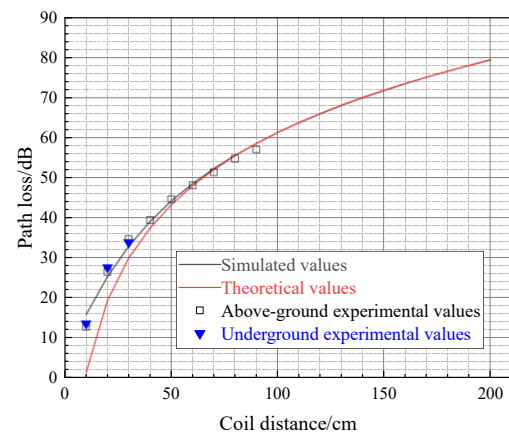

Figure 8 Path loss variation with coil distance

By comparing the path loss in the above-ground and underground experiments in Table 2 Path Loss Above and Below Ground with 10V Transmission Signal, and excluding experimental errors, it can be observed that the soil has no effect on the path loss of the magnetic signal, which is consistent with the theory.

Table 2 Path Loss Above and Below Ground with 10V Transmission Signal

Depth/d	Above Ground Experimental Value	Below Ground Experimental Value
10cm	12.70	13.50
20cm	26.40	27.51
30cm	34.65	33.79

#### 4 CONCLUSION

This study validates magnetic signal propagation theory in uniform underground media through numerical simulations and experimental measurements. The results demonstrate low path loss in soil environments due to their air-like permeability characteristics. Experimental data show excellent agreement with theoretical models, confirming permeability as the dominant factor in signal attenuation, while soil moisture and composition exhibit negligible effects. The consistent correlation between simulation and experimental results establishes a reliable framework for predicting magnetic signal behavior in homogeneous underground environments. These findings provide fundamental insights for developing magnetic induction-based communication systems in applications such as agricultural monitoring and underground utility networks.

**ABSTRACT:** Pavement subsurface deterioration can lead to catastrophic road failures, often caused by long-term settlements and moisture accumulation. These effects develop gradually and are difficult to identify through manual inspection. Although structural health monitoring (SHM) systems have been developed to address these challenges, most are insufficient to collect 3D spatial information due to their limitations. Current systems primarily focus on surface and base courses, neglecting subsurface courses which sustain loads and provide stability. Therefore, it is essential to develop a long-term and scalable monitoring system for subsurface courses. Radio frequency sensing system has great potential to fill the gap.

This study aims to further quantify the uncertainty of using distributed embedded passive radio frequency (RF) sensors in pavement subsurface courses. Laboratory experiments were conducted to investigate the uncertainty sources of the relationships between channel information and structural changes. Key challenges include correlating collected data with subsurface changes and finding the sources of uncertainties.

The results demonstrate the effect of system topology on the relationships between channel information and structural changes. These prove the system's applicability in subsurface spatial monitoring. By addressing implementation challenges and decoupling monitored parameters, the system could be further advanced for real-world deployment

**KEY WORDS:** Structural health monitoring; Transportation monitoring; Pavement monitoring; RF sensing; Sensor network

## 1 INTRODUCTION

Pavement road structures are essential and critical infrastructure to the urban transportation system. However, aging, massive urbanization, and overuse contribute to distress and even catastrophic failure events. For example, part of California State Route 1, which was 150 feet long, was washed out in a landslide, which led to the total cost of repairing and clearing being \$11.5 million [1]. Meanwhile, the ASCE report card states that the grading evaluation on pavement roads is D+ [2]. Structural health monitoring systems can identify the pavement road's deterioration or damage at an early stage, which reduces economic loss and increases life safety.

Structural health monitoring (SHM) systems face a challenge in extracting large-scale spatial information in pavement subsurface courses at a reasonable cost. Current techniques are mainly limited to extracting one-dimensional or two-dimensional information from the structure [3]. However, extracting three-dimensional information gathered throughout the volumes of structural material, such as detection, location, and quantification of distress behaviors (e.g., damage, deterioration, or loss of performance) at an early stage is impossible using current SHM techniques. Meanwhile, most SHM systems primarily focus on the surface and base courses instead of the subsurface course, which sustains loads and provides stability. Therefore, it is essential to develop a 3D spatial monitoring system for long-term and scalable subsurface course monitoring. The recent developments in radio frequency (RF) sensing can be the potential solution to the challenges.

Recent research on radiofrequency (RF) sensing has resulted in hardware systems potentially suitable for the use in subsurface SHM [4]. RF sensors leverage channel information to monitor the 3D distribution of key parameters. A recent experiment demonstrates the feasibility of monitoring deformation and water content [5]. However, the uncertainty of monitoring deformation and water content has never been investigated. This study aims to investigate the uncertainty of monitoring deformation and water content using an RF sensing system.

## 2 UNCERTAINTY IN DECODING

Previous studies have shown that the displacement of sensors (measurand) is linearly related to the phase shift (encoding parameter) of the reflected signals. However, in the implementation scenarios, the exciter, which sends power to sensors, is mobile, and the sensors may have different initial mutual distances. The linear relationship, necessary to decode displacement from RF phase shift, can be affected by these different exciter locations and the initial distances between sensors. Therefore, the uncertainty in encoding function due to variable exciter locations and the initial distances between the sensors has to be investigated.

### 2.1 Method

A set of experiments was performed to determine the change of displacement between sensors in various 1D settings, where the backscatter RF signal propagated through the air. The goal of the experiment setup was to verify the effects of exciter locations and the initial distance of sensors. The 1D experiments consisted of two sensors and one exciter. The

exciter was used to power the two sensors wirelessly. One sensor was placed on the mobile tripod which was installed on a camera slider such that the mobile tripod was displaced by a linear actuator along the slider. Another sensor was placed on a stationary platform. The two sensors were set up with three different initial distances  $D$ : 30 cm, 60 cm, and 126 cm. At each setup of  $D$ , the mobile sensor was displaced by the linear actuator with a change in distance  $\Delta d = 1$  cm at a time while the static sensor remained stationary. After each 1 cm displacement, data were collected for 10 minutes with a sample rate of 30 seconds. The total displacement was 16 cm. After the experiments were conducted with three different  $D$ , the exciter was moved to a different location with repeated experiments of the different initial distances. By varying the initial distance, the effect of different initial distances between sensors on the linear (decoding) relationship could be investigated. By changing the exciter location, the effect of variable exciter location on the linear relationship could be investigated. These experiments can also show which effects have a larger impact on the linear relationship between displacement and phase shift. The experimental setup was shown in Figure 1. The antenna icon represents the location of the sensors, and the left sensor was the mobile sensor. The star represents the locations of exciters for each experiment. A total of 12 experiments were conducted (three initial distance setups with four different exciter locations).

Figure 1. Location of the sensor and various exciters for the experimental setup in the indoor laboratory

## 2.2 Discussion

For each experiment, a linear relationship was obtained by fitting the median value of the recorded phase shift at each displacement, as shown in Figure 2. The slope of the linear fitting line represented the sensitivity of the system (the ratio between phase shift and displacement)  $\Delta\theta/\Delta d$ .

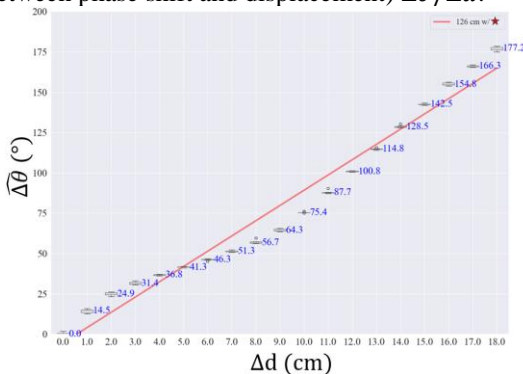

Figure 2. Experimental result of  $D = 126$  cm and the exciter location (red star); the red line indicated the linear fitting line

Table 1.  $\Delta\theta/\Delta d$  (°/cm) Comparison

$D$	Red Star	Blue Star	Green Star	Black Star	Max Min Diff. (%)
30 cm	10.17	10.45	10.11	10.34	3.4
60 cm	9.96	10.02	10.19	10.06	2.3
126 cm	9.54	9.86	11.48	10.87	<b>20.3</b>
Max Min Diff. (%)	6.6	5.98	<b>13.6</b>	8.05	

The results of 12 experiments are shown in Table 1. Maximum and minimum differences were also calculated across different exciter locations and sensor distances  $D$ . The maximum and minimum difference of each  $D$  showed that as  $D$  increased, the difference in  $\Delta\theta/\Delta d$  also increased. This demonstrated that the variation of  $\Delta\theta/\Delta d$  increased as the initial distance between sensors increased. The maximum and minimum difference of each location showed that the largest variation occurred when the exciter was located at the green star, perpendicular to the communication line between sensors. However, this phenomenon was observed only with the case of  $D = 126$  cm. If the case of  $D = 126$  cm was removed, the variation of  $\Delta\theta/\Delta d$  was similar across different exciter locations. The initial distance between sensors was more impactful to the variation of  $\Delta\theta/\Delta d$  comparing to the exciter location.

The linear fitting errors were also investigated in these experiments. As shown in Figure 2, the fitting error was presented in the linear fitting line. The variation of fitting errors across different  $D$  and exciter locations were shown in Table 2. The results showed that as the initial distance between sensors increased, the fitting error also increased. Meanwhile, the location of exciter had smaller effects on the fitting errors compared to the initial distances between sensors.

Table 2 Fitting error ( $\Delta\theta/\Delta d$  error) comparison

$D$	Red Star	Blue Star	Green Star	Black Star
30 cm	<b>5.34</b>	<b>4.16</b>	<b>5.93</b>	<b>4.22</b>
60 cm	8.99	6.29	14.74	6.19
126 cm	15.42	17.84	18.54	16.98

The fitting error and the discrepancy of  $\Delta\theta/\Delta d$  with various sensor spacing issues were potentially caused by the signal multipath effects. Since the experiments were conducted in an indoor laboratory, the surroundings reflected the backscattered signal from the transmitter sensor to the receiver sensor. The superposition of the backscattered signal and reflected signal can potentially affect the accuracy of the data collection. Additional experiments must be conducted to verify the causes.

In real applications, material inhomogeneity (e.g. moisture and density of fine aggregate) inside the structure can potentially affect the system's accuracy. Previous studies have demonstrated the capability of detecting the change of water content using an RF system [5]. Therefore, the material inhomogeneity due to moisture content can be further decoupled. Meanwhile, the effects from other sources of material inhomogeneity have to be further studied. Uncertainty quantification can be used to preliminarily quantify the effects of those sources.

### 3 CONCLUSION

This study investigates the uncertainties in the relationship between the channel phase (encoding parameter) and displacement (measurand) registered by RF sensors. Although distributed embedded passive radio RF sensors have great potential for 3D spatial pavement subsurface monitoring, the relationship between measurand and encoding parameter can be affected by the initial distances between sensors. As the initial distance between sensors increases, the uncertainty in the relationship also increases. Meanwhile, the location of the exciter has a smaller effect on the relationship. The reason behind this finding will be the subject of future work.

**ABSTRACT:** With the aging of civil infrastructures, strain monitoring is essential for predictive maintenance. However, current sensing technologies mainly rely on active battery powered sensors, leading to substantial expenses and low placement granularity. This paper proposes a wireless, passive RFID patch antenna strain sensor, characterized by a favorable linear relationship between its resonant frequency and the applied strain. In this paper, simulation is carried out by using the COMSOL multi-physics coupling software. The solid mechanics field is coupled with the electromagnetic field, and the frequency-domain scanning is conducted after the model generates strain. The simulation results are compared with the experimental results in the literature to determine their correctness. According to the simulation results of the scattering parameter  $S_{11}$ , a patch antenna sensor is designed and fabricated, and corresponding experiments are conducted to detect the variations of the spectral curve before and after the sensor is embedded in concrete, thereby verifying its validity. Finally, the sensor is optimized based on the experimental results.

**KEY WORDS:** Wireless; Passive; Strain Sensor; RFID; Patch Antenna.

## 1 INTRODUCTION

In the field of structural health monitoring (SHM), acquiring accurate, long-term, and stable monitoring data remains a core concern. Structural strain, a critical indicator reflecting the health status of structures, effectively characterizes local deformation and precisely reveals internal stress distributions and health conditions [1]. Traditional strain sensors typically employ wired connections using conductors or optical fibers as media. In large-scale structures, extensive cabling works are cumbersome, costly, and further exacerbated by the complexity of wiring and the need for relay devices, increasing economic burdens. Moreover, excessive cabling significantly amplifies resistance and introduces noise interference, severely degrading strain measurement accuracy and failing to meet high-precision monitoring requirements.

Digital image-based methods [2] leverage precision optical instruments and advanced image processing algorithms to obtain high-accuracy strain data. However, these methods have notable limitations: they impose stringent requirements on light source conditions, limiting adaptability in low-light environments such as tunnels; they also demand extreme equipment stability, making sustained and accurate measurements challenging in complex outdoor settings. The complexity of algorithms and harsh measurement conditions restrict their long-term monitoring applications.

Radio Frequency Identification (RFID) technology, a mature wireless information transmission method [3], has garnered substantial attention from scholars due to its compact size and low cost. Peng Guofeng et al. [4] proposed a wireless passive RFID humidity sensor based on U-shaped resonant units, achieving environmental humidity detection and encoding capabilities through grouped U-shaped resonators. Wang Xian et al. [5] designed a miniaturized wireless passive strain sensor array using split-ring resonators to detect strain magnitude and direction on metal surfaces. Wang Bo et al. [6]

developed a wireless passive metal crack sensor using RFID technology, detecting surface cracks by measuring radar cross-section (RCS) values.

Integrating RFID technology with sensors introduces a novel approach for structural strain measurement. This paper presents a rectangular patch antenna-based wireless passive strain sensor using RFID technology, simulated in COMSOL Multiphysics finite element analysis software. This sensor offers low cost, non-contact measurement, and passive operation, effectively addressing challenges such as cumbersome cabling, noise interference, and real-time power supply limitations in wired systems. Compared to other strain sensors, it features a simple structure and high sensitivity (4.45 kHz/ $\mu\epsilon$ ), demonstrating significant advantages and promising applications in SHM [7].

## 2 THE PRINCIPLE OF ANTENNA STRAIN SENSOR

### 2.1 Relationship Between Strain and Resonant Frequency

The patch antenna strain sensor achieves precise strain measurement by detecting shifts in the antenna's resonant frequency. The resonant frequency, as the optimal operating frequency of the antenna, exhibits distinct electrical characteristics: when the antenna operates at its resonant frequency, the backscattered energy reaches its minimum while the received energy attains its maximum. The resonant frequency shift of the patch antenna is closely linked to changes in antenna dimensions. Specifically, alterations in antenna geometry inherently modify the electrical length. An increase in electrical length leads to a decrease in resonant frequency, whereas a reduction in electrical length results in an increase in resonant frequency.

The RFID-based rectangular patch antenna wireless passive strain sensing structure is illustrated in Figure 1. The sensor consists of an upper radiating patch, a feed line, a dielectric

substrate, and a lower radiating patch. The upper radiating patch detects strain and facilitates signal transmission/reception, while the lower radiating patch grounds the sensor. The feed line serves dual purposes: providing electrical feed and impedance matching. Both radiating patches and the feed line are fabricated from copper. The dielectric substrate, positioned between the upper and lower radiating patches, is constructed from RO4003C material with a dielectric constant of 3.55.

Figure 1. Sensor schematic diagram.

According to classical theory, the initial resonant frequency of a rectangular patch antenna can be expressed as:

$$f_{RO} = \frac{c}{4\sqrt{\epsilon_e} L_1 + 2\Delta L_1} \quad (1)$$

Where  $f_{RO}$  is the resonant frequency of the antenna under the initial condition;  $c$  is the speed of light in a vacuum;  $\epsilon_e$  is the equivalent dielectric constant of the dielectric plate;  $L_1$  is the length of the upper radiation patch;  $\Delta L_1$  is the additional length of the antenna, which is related to the antenna width, thickness and material.

When the antenna experiences strain  $\epsilon$  in the length direction, the resonant frequency  $f_R$  changes accordingly. For:  $\Delta L_1 \leq L_1$ ,  $f_R$  exhibits an approximately linear relationship with strain, expressed as:

$$f_R \approx \frac{c}{4\sqrt{\epsilon_e} L_1 (1+\epsilon)} = \frac{f_{RO}}{(1+\epsilon)} \approx f_{RO} (1 - \epsilon) \quad (2)$$

From equation (2), it can be seen that  $f_R$  is mainly affected by strain in the direction of antenna length, and  $f_R$  has a linear relationship with  $\epsilon$ , the slope is about equal to  $f_{RO}$ , that is, every  $1\mu\epsilon$  strain occurs, the resonant frequency of the antenna will decrease  $f_{RO} \times 10^{-6}$ .

Since the substrate thickness is much smaller than the length-width size, the dielectric constant of the antenna substrate is approximately the same as the relative dielectric constant:

$$\beta_r = \frac{\beta_{r0} + 1}{2} + \frac{\beta_{r0} - 1}{2} \left[ 1 + 12 \frac{h}{w} \right]^{-1/2} \cong \beta_{r0} \quad (3)$$

Where:  $\beta_r$  is the effective dielectric constant of the antenna substrate;  $h$  is the thickness of the substrate;  $w$  is the width of the substrate;  $\beta_{r0}$  indicates the relative dielectric constant of the substrate at room temperature.

## 2.2 Resonant Frequency and Echo Reflection Coefficient

With full The antenna's echo reflection coefficient ( $S_{11}$ ) is a metric that quantifies the ratio of reflected signal power to incident signal power at the antenna port, reflecting the degree of signal matching. A signal transceiver emits an

electromagnetic wave with frequency  $f$  and power  $P_{in}$ . The wave is reflected by the antenna and received by the transceiver with power  $P_{ref}$ . The echo reflection coefficient  $S_{11}$  at this frequency is calculated using Equation (4):

$$S_{11} = 10 \lg \left[ \frac{P_{in}}{P_{ref}} \right] \quad (4)$$

By transmitting an electromagnetic wave spectrum to the antenna and using a signal transceiver to record the echo reflection coefficient  $S_{11}$  at each frequency, the echo reflection curve (i.e., the  $S_{11}$  curve) across the frequency band is obtained. The minimum point of the  $S_{11}$  curve corresponds to the antenna's resonant frequency under the given conditions. As theoretically derived in the previous section, the minimum point of the  $S_{11}$  curve shifts when strain is applied, indicating a change in the resonant frequency, as illustrated in Figure X. Here,  $f_{RO}$  denotes the initial resonant frequency, and  $f_R$  represents the resonant frequency after strain application.

Figure 2. The shift of resonant frequency.

## 3 SIMULATION AND PARAMETER OPTIMIZATION

### 3.1 Finite element modeling of the antenna

The finite element analysis software used in this simulation is COMSOL. COMSOL's multiphysics coupling can accurately describe the interactions between different physical phenomena and achieve multi - field collaborative simulation by establishing and solving the coupled partial differential equations of each physical field.

Following optimization, the Geometric Dimensions of the Sensor in [Table 1] below:

Table 1. Geometric dimensions of the sensor.

Thickness of substrate/ $t_1$	0.8mm
Thickness of metal/ $t_2$	35 $\mu$ m
Width of patch/ $W_1$	20mm
Length of patch / $L_1$	16mm
Width of substrate/ $W_2$	40mm
Substrate length/ $L_2$	36mm
Width of feed line/ $W_3$	1.8mm
Length of feed line/ $L_3$	18mm

In addition, the dielectric constant of the dielectric substrate is 3.55.

Figure 3. Dimensional schematic diagram of the sensor.

The simulation of the patch antenna strain sensor in this paper adopts the dual-physics-field coupling of the electromagnetic field and the solid mechanics field, enabling the calculation of the change in the resonant frequency of the antenna after strain occurs within a single model. The 3D model of this antenna is shown in the following figure. The outer shell-shaped structure is a perfectly matched layer (partially hidden), which serves to absorb the electromagnetic waves propagating outward, thereby simulating the open boundary conditions without reflection.

Figure 4. Sensor's finite element model.

First, an adaptive frequency sweep is performed on the antenna under strain-free conditions, and the curve is plotted to obtain its initial resonant frequency, as shown in the following figure.

Figure 5. Initial resonant frequency.

Apply a specified displacement to the antenna in the length direction of the antenna through the solid mechanics field to simulate the generation of strain in the length direction

of the patch antenna. The total strain is set to  $4000 \mu\epsilon$ , and the step size of strain increase each time is  $400 \mu\epsilon$ . Obtain the curves under different strain values, and according to the obtained results, plot the linear regression curve of the relationship between the strain and the resonant frequency.

Figure 6. Schematic diagram of Strain.

### 3.2 Modeling Results

Figure 7. The relationship between resonant frequency and microstrain.

As shown in the figure, the regression coefficient is 0.979, indicating that there is a good linear relationship between the resonant frequency of the antenna and the strain in the length direction. The sensitivity of the antenna as a strain sensor is  $4.6136 \text{ kHz}/\mu\epsilon$ . The relative error between the simulation result and the theoretical calculation value of  $4.45 \text{ kHz}/\mu\epsilon$  is 3.68%.

## 4 CONCLUSION

In response to the imperative for wireless strain detection of building structures within the domain of structural health monitoring, leveraging the pronounced radiation efficiency, minimal power dissipation, and elevated quality factor characteristic of rectangular patch antennas, a wireless passive rectangular patch antenna strain sensor was meticulously devised. This design is firmly grounded in Radio - Frequency Identification (RFID) technology. Concurrently, a comprehensive finite - element analysis (FEA) simulation of the sensor was successfully executed.

The simulation outcomes unambiguously demonstrate that the sensor exhibits a sensitivity of  $4.6136 \text{ kHz}/\mu\epsilon$  along the lengthwise dimension of the patch, with a linearity regression

coefficient of 0.959. These strain - related simulation results incontrovertibly validate the viability of deploying an RFID - enabled rectangular patch antenna as a wireless passive strain sensor.

Looking ahead, the fabrication of the sensor will be expeditiously completed, and a series of well - designed tensile experiments will be carried out. These experiments are intended to rigorously verify the sensor's detection performance under diverse real - world working conditions. Post - experimentation, a secondary optimization of the sensor's structure will be implemented, with the explicit aim of further enhancing its sensitivity and thereby attaining a more superior strain - detection outcome.

\* Corresponding author

**ABSTRACT:** The Tsing Ma Suspension Bridge in Hong Kong has been the world's first batch of bridges equipped with a long-term health monitoring system since 1997. For the first time, this study reports the first-hand field monitoring data of the bridge from 1997 to 2022. The 25-year data provide an invaluable and rare opportunity to examine the long-term characteristics of loads, bridge responses, and their relationships, thereby enabling the assessment of the bridge's load evolution and structural condition over time. The current status and recent update of the health monitoring system are also reported. This study is the first to report the one-quarter-century status of a structural health monitoring system and the behavior of a long-span suspension bridge. This research provides a benchmark for many other bridge monitoring systems worldwide.

**KEY WORDS:** Structural health monitoring, Long-span bridges, Long-term behavior, Load evolution.

## 1 INTRODUCTION

Large-span bridges are vital economic lifelines, and their failure can have catastrophic human and socio-economic impacts. Proactive maintenance is essential to ensure the serviceability and safety of long-span bridges that are subjected to complex loads (e.g., typhoons, earthquakes) and harsh environments (e.g., corrosion) during operation. Structural Health Monitoring (SHM) is essential for monitoring the health of bridges, assessing their safety, guiding their maintenance and providing early warnings. Although SHM systems are now being adopted in major bridges (e.g., Akashi Kaikyo Bridge, Runyang Bridge, etc.) and newly designed bridges around the world, there is a lack of long-term operational history data for SHM systems. This creates a research gap in analyzing long-term data, actual structural degradation, and service life assessment [1-11].

The Tsing Ma Bridge (TMB), operational since 1997 with a pioneering SHM system, offers a unique 26-year dataset (1997-2022). This study analyzes the long-term data, SHM system status of TMB and the health monitoring system, and investigating long-term trends in environmental loads and structural performance.

## 2 THE TSING MA BRIDGE

The Tsing Ma Bridge is a highway and railroad dual-purpose large-span suspension bridge with a main span of 1,377 m, a total bridge length of 2,160 m and a tower height of 206 m, which was opened to traffic in 1997. An elevation of the bridge is given in Figure 1.

## 3 MONITORING DATA

### 3.1 Temperature

The annual maximum bridge temperatures are given in Figure 2. A linear regression analysis shows that the maximum deck effective and ambient temperatures increase at rates of 0.51 °C/decade and 0.72 °C/decade, respectively. The bridge temperature in 2022 is 44.9 °C, close to bridge design limit of 46 °C.

### 3.2 Deflections

The bridge displacement is subject to the temperature and the traffic effects. The mid-span deflection without traffic load is shown in Figure 3, using data between 2:00 to 4:00 am to exclude the traffic effect.

Figure 1 The elevation of the Tsing Ma Bridge

Figure 2 Annual maximum deck effective temperature of the Tsing Ma Bridge in 1997–2022

Figure 3 Monthly mean mid-span deflection of Tsing Ma Bridge in 1997–2022

## CONCLUSIONS

The operational condition of the Tsing Ma Bridge and its Structural Strength Monitoring (SHM) system has attracted much attention. In this paper, field monitoring data from the past 26 years are analyzed to study the long-term loading and response of the bridge. In addition, this paper discusses the current status and latest updates of the SHM system. The following conclusions are drawn from this study.

(1) Observed trends in bridge deck effective temperatures show significant increases over recent decades. Specifically, the maximum effective temperature has risen at a rate of 0.51 °C per decade, while the mean effective temperature increased at 0.16 °C per decade. Critically, the recorded maximum values are now approaching the original design thresholds for the deck.

(2) The monthly bridge midspan deflection show an increasing trend, the trend can be caused by the cracking and creep of materials.

## ACKNOWLEDGMENTS

**Funding:** This research was partially supported by the Collaborative Research Fund (Project No. PolyU C5004-23G). The authors also would like to thank the Hong Kong Observatory and the highways department for providing valuable data.

**ABSTRACT:** Advancements in road infrastructure health monitoring through sensor networks offer a transformative solution to the limitations of traditional inspection methods by enabling more accurate, real-time assessments of structural conditions. However, once appropriate sensors are selected and deployed, a key challenge remains: converting raw sensor data into meaningful health indicators (HIs) that effectively capture structural changes indicative of potential damage. A health indicator (HI) is a crucial metric derived from structural health monitoring (SHM) data, designed to reflect the current condition and damage state of a monitored structure. This study presents a machine learning-based approach leveraging principal component analysis (PCA) to develop a sensitive and damage-specific HI by extracting and ranking the most relevant current features. The proposed method is first validated through experimental fatigue testing using a four-point bending machine under random thermal conditions. To further evaluate its effectiveness and reliability in real-world applications, the approach is applied to field data collected from a network of fiber Bragg grating (FBG) sensors embedded in asphalt pavement. By analyzing strain measurements, the study demonstrates that the PCA-based HI successfully detects structural changes, providing a robust and data-driven solution for real-time infrastructure monitoring.

**KEYWORDS:** Health indicator, Structural health monitoring, FBG sensor networks, Principal component analysis, Fatigue damage detection.

## 1 INTRODUCTION

A significant amount of money is spent on maintaining infrastructure such as roads, bridges, and other critical structures. To reduce maintenance costs, various non-destructive testing (NDT) methods have been employed to enable predictive maintenance strategies. However, these methods have certain limitations. For instance, most NDT techniques operate offline, making continuous structural evaluation impossible [1].

To address this challenges, extensive research has been conducted to integrate advanced sensor technologies for continuous and real-time Structural Health Monitoring (SHM). Sensors such as accelerometers [2-4], piezoelectric sensors [5-7], and acoustic emission sensors [8-10] have been explored for their ability to collect SHM data continuously, providing valuable insights for early damage detection and improved maintenance planning.

Recently, optical sensors have emerged as a promising technology for infrastructure monitoring due to their unique advantages, such as immunity to electromagnetic interference, lightweight design, and, most importantly, the capability for distributed or quasi-distributed measurements. These features make optical sensors highly suitable for real-time structural health monitoring, enabling continuous and precise data collection over long distances. Additionally, their durability and resistance to harsh environmental conditions enhance their reliability for long-term deployment in critical infrastructure such as bridges, tunnels, and pipelines [11-17].

Although optical sensors offer these advantages, their application in large-span structures generates an enormous

amount of data, requiring specialized strategies for processing, compression, and reduction. Efficient data management techniques are essential to handle this influx of information while preserving critical insights for future interpretation and analysis. Developing advanced algorithms and intelligent data filtering methods can help optimize storage and computational efficiency without compromising the accuracy and reliability of structural health monitoring [18].

Various techniques can be integrated to accomplish this objective, including data reduction methods [19-20] and multi-sensor data fusion [21-22] at different processing levels. A structured approach involves organizing these steps to derive a health indicator (HI) that enables straightforward monitoring of a system's health status. HI is regarded as the most informative feature in SHM data [23] that can be obtained using different frameworks including statistical, signal processing, and machine learning. In the literature, different criteria have been proposed to define an optimal HI. First viewpoint (1VP) suggests that an ideal HI should exhibit monotonicity, which represents a consistent increasing or decreasing trend over time, prognosability, which reflects the distribution of a variable's final values, and trendability, which measures the similarity between different variable trajectories [24].

Alternatively, second viewpoint (2VP) emphasizes that an optimal HI should possess detectability, referring to its sensitivity in identifying the presence of faults, particularly the smallest detectable fault signatures at a given false-positive rate. It should also ensure separability, which is its ability to effectively distinguish between faulty and healthy states. Additionally, trendability is crucial, as the degradation trend of

the HI should maintain a positive correlation with operational time following an initial fault. However, identifying an optimal HI that satisfies all three properties is not a straightforward task. In practice, once an HI demonstrates both detectability and separability, it can already be considered optimal [25]. In this study, the second point of view is adopted as the criteria for defining an optimal HI. The first perspective requires extensive run-to-failure data, which is often challenging to obtain in real-world scenarios due to limited data availability. Ultimately, the developed HI can serve as an input for a prognosis model to estimate the remaining useful life (RUL), which will be explored in future studies.

## 2 OBJECTIVE AND OVERALL METHODOLOGY

The primary objective of this study is to propose a framework that integrates both data reduction and fusion techniques to construct health indicators that effectively represent the damage levels of infrastructures, such as roads, monitored using high-density FBG sensor networks. This method can be applied to individual FBG sensors or groups of sensors within a fiber, where data fusion can be performed at the data level.

In this approach (see Figure 1), following data acquisition via an embedded FBG sensor network and the management of large-scale collected data, a series of signal processing steps is applied to the raw data to prepare them for further analysis [26]. Subsequently, time-domain FBG signal features—including peak width, peak duration, and energy—are extracted from each segment of the pre-processed data.

After conducting long-term monitoring over a predefined period, these features are ranked based on their monotonicity metric to retain only the most significant ones. When new data arrive, the extracted features are normalized relative to the training dataset. Following normalization, a feature fusion technique based on principal component analysis (PCA) is implemented to project these features into a reduced-dimensional space. Since the first principal component captures the direction with the highest gradient in the feature space, it serves as a suitable indicator for representing the health status of the structure.

Figure 1. The overall framework of the study.

As no data is available on damage conditions from the embedded FBG sensor network, two approaches are used to evaluate the proposed framework. The first involves conducting an experimental fatigue test, while the second utilizes available FBG data to generate synthetic damage scenarios to validate its applicability. The following sections discuss these two approaches in detail.

## 3 METHODS

### 3.1 Data Acquisition

#### 3.1.1 Experimental Fatigue Test

An experimental test was conducted to validate the proposed framework for large-scale, real-world damage detection applications. To achieve this, a stress-control fatigue experiment was performed using a four-point bending machine (see Figure 2) on a standard asphalt beam with dimensions of 60×60×400 mm, made from the APO-A mixture. The loading frequency was 10 Hz, and the temperature was varied randomly to simulate real-world conditions.

For the experiment, strain gauge (SG) sensors (3×10 and 3×20 mm) were installed to monitor strain at the bottom of the beam throughout the fatigue test, in order to further investigate the effect of strain gauge length on strain readings in asphalt materials. However, a detailed analysis of this effect is considered outside the scope of the present study. These SGs glued using CC-33A×5 adhesive, provided by KYOWA, between two internal supports. Strain data were collected using a compact recording system (EDX-10) at a sampling frequency of 500 Hz and subsequently processed using DCS-100A software.

Figure 2. Four-point bending setup for fatigue test.

After the test ended, the sample was damaged at the SG2 location, as shown in Figure 3a. The temperature recorded during the test is also presented in Figure 3b. Temperature data were collected using a thermocouple placed near the beam during testing.

Figure 3. Fatigue test: (a) Damaged sample, (b) Temperature variations.

The strain data collected during the test using four strain gauges is presented in Figures 4a–4d.

Figure 4. SG responses during fatigue test: (a) SG1, (b) SG2, (c) SG3, (d) SG4.

As shown in Figure 4, all SG responses exhibit load-induced strain signals after filtering out low-frequency components caused by temperature-induced strain. However, fluctuations in temperature can still influence the amplitude of the load-induced strain response due to temperature-dependent changes in material properties. As damage propagates, the responses of the strain gauges are affected depending on their location. If damage occurs at the sensor's location, an increasing trend will be observed due to strain concentration in that area. Conversely, if damage propagates near a sensor, its response will show a decreasing trend. However, this effect depends on the distance from the damaged region.

### 3.1.2 Field Test using FBG Sensor Network

In addition to the experimental fatigue test, strain and temperature data were collected using a FBG sensor network embedded in the asphalt layer at different locations on a constructed test track in the Port of Antwerp & Bruges. The sensor network configuration is shown in Figure 5, as can be seen this configuration includes 32 FBG in both lateral and longitudinal directions [27].

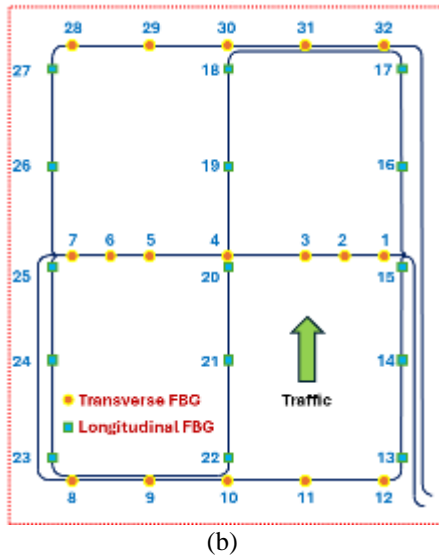

Figure 5. Monitoring system using FBG sensor network: (a) Test track, (b) FBG sensor configuration

After the construction of the test track, a continuous monitoring campaign was initiated from April 28, 2024, to October 17, 2024 (28/04/2024 to 17/10/2024), powered by a solar system and wind turbine. During this campaign, strain and temperature data were collected at a 100 Hz sampling frequency using an eight-channel, 2000 Hz FBG-Scan 708D interrogator. The collected data were then processed using ILLumiSense v2.3.5.5 software. Figure 6 shows the temperature variation in the asphalt during the monitoring campaign.

Figure 6 Temperature during the monitoring campaign collected by FBG sensor

### 3.2 Data Management and Pre-processing

During the monitoring campaign, 20 GB of data were generated daily, requiring efficient management to handle this large volume for future analysis. To address this, an automated system was developed to classify, merge, and prepare the data for subsequent steps, as outlined in Ref. [26].

Then, the data needs to be pre-processed using signal processing techniques to prepare it for the next steps. These steps include filtering, thresholding, concatenation, and windowing. Each technique is applied for a specific purpose: filtering removes strain caused by temperature variations, thresholding eliminates noise while preserving events, concatenation combines short-term monitored data into long-term datasets, and windowing ensures the data contains the same number of events for better comparison, as discussed in

Ref. [26]. Figure 7 shows an example of the daily collected data alongside the long-term pre-processed FBG data.

Figure 7 Collected FBG data during monitoring campaign: (a) daily data (17/05/2024), (b) long-term preprocessed data

### 3.3 Feature Extraction

Feature extraction plays a critical role in transforming raw data into meaningful, compact representations that can be efficiently used for analysis, classification, or prediction. As raw time-series or signal data is often too complex to interpret directly, extracting relevant features helps reduce dimensionality and focus on the most informative aspects of the data. This process not only improves model performance by providing more relevant input but also enhances the results, making it easier to identify underlying patterns or anomalies. In this study, several signal features in the time domain are calculated for each window of data [23], as listed in Table 1, along with peak width, peak duration, and energy. These features are essential for capturing the temporal characteristics of the signal and provide valuable insights into its behavior over time. Peak width and peak duration help describe the shape and spread of the signal's key events, while energy quantifies the overall magnitude of the signal, contributing to a more comprehensive understanding of its dynamics.

Table 1. Common statistical features in time-domain [23]

No	Equation	No	Equation
1	$X_m = \frac{\sum_{n=1}^N x(n)}{N}$	9	$X_{crest} = \frac{X_{peak}}{X_{rms}}$
2	$X_{sd} = \sqrt{\frac{\sum_{n=1}^N (x(n) - X_m)^2}{N - 1}}$	10	$X_{clearance} = \frac{X_{peak}}{X_{root}}$
3	$X_{root} = \left( \frac{\sum_{n=1}^N \sqrt{ x(n) }}{N} \right)^2$	11	$X_{shape} = \frac{X_{rms}}{\frac{1}{N} \sum_{n=1}^N  x(n) }$
4	$X_{rms} = \left( \frac{\sum_{n=1}^N (x(n))^2}{N} \right)^{1/2}$	12	$X_{impulse} = \frac{X_{peak}}{\frac{1}{N} \sum_{n=1}^N  x(n) }$

$$\begin{array}{ll}
5 & X_{rss} = \left( \sqrt{\sum_{n=1}^N |x(n)|^2} \right) \\
6 & X_{peak} = \max|x(n)| \\
7 & X_{skewness} = \frac{\sum_{n=1}^N (x(n) - X_m)^3}{(N-1)X_{sd}^3} \\
8 & X_{kurtosis} = \frac{\sum_{n=1}^N (x(n) - X_m)^4}{(N-1)X_{sd}^4} \\
13 & X_{p2p} = \max(x(n)) - \min(x(n)) \\
14-17 & X_{k\_cm} = \frac{\sum_{n=1}^N (x(n) - X_m)^k}{N} \\
18 & X_{FM4} = \frac{X_{4\_cm}}{X_{st}^4} \\
19 & X_{med} = \frac{\sum_{n=1}^N t(n)}{N}
\end{array}$$

$x(n)$  indicates the signal sequence for  $n = 1, 2, \dots, N$ .

$N$  indicates the number of data points.

$t(n)$  indicates the moments of occurrence of  $x(n)$

### 3.3.1 Feature Ranking

To determine the most relevant feature and develop an appropriate indicator, researchers have employed a specific metric in various studies [28]. This metric, known as monotonicity, captures the dominant increasing or decreasing trend of a feature concerning the target variable. It assesses how consistently a feature progresses in a specific direction. The monotonicity of the  $i$ th feature  $x_i$  is computed using the following equation:

$$\text{Monotonicity}(x_i) = \frac{\frac{1}{m} \sum_{j=1}^m \left| \frac{\text{number of positive diff}(x_i^j) - \text{number of negative diff}(x_i^j)}{n-1} \right|}{1} \quad (1)$$

Where  $n$  represents the number of windows, and  $m$  denotes the number of monitored systems or structures, which, in our case, is 1. In this study, the metric is computed using the training datasets to identify the most important features for subsequent steps.

### 3.4 Feature Fusion

In this step, the most important selected features need to be fused to create a more informative and compact representation in lower dimensions while preserving as much relevant information as possible. Feature fusion helps reduce redundancy and enhances the efficiency of subsequent analyses. In this study, PCA is employed as a dimensionality reduction technique to fuse the selected features. PCA transforms the original feature set into a new set of uncorrelated principal components, ranked by their ability to capture variance in the data.

Before applying PCA, it is crucial to standardize the data to ensure that all features contribute equally to the analysis. Standardization prevents features with larger magnitudes from dominating the principal components. As a best practice, features should be normalized to the same scale before performing PCA. The mean and standard deviation used for normalization using z-score function, along with the PCA coefficients, are derived from the training data and consistently applied to the entire dataset.

## 4 IMPELLIMENTATION ON EXPERIMENTAL DATA

Four strain data sets are available from the SGs for the experimental test, based on the proposed methodology. As the data has already been managed and pre-processed using the DCS-100A software, the next step is feature extraction. In this step, the features mentioned in Section 3.3 are calculated for

the SG signals by segmenting the signals into windows of 2,000 data points. Figure 8 presents examples of the features calculated for the SG signals.

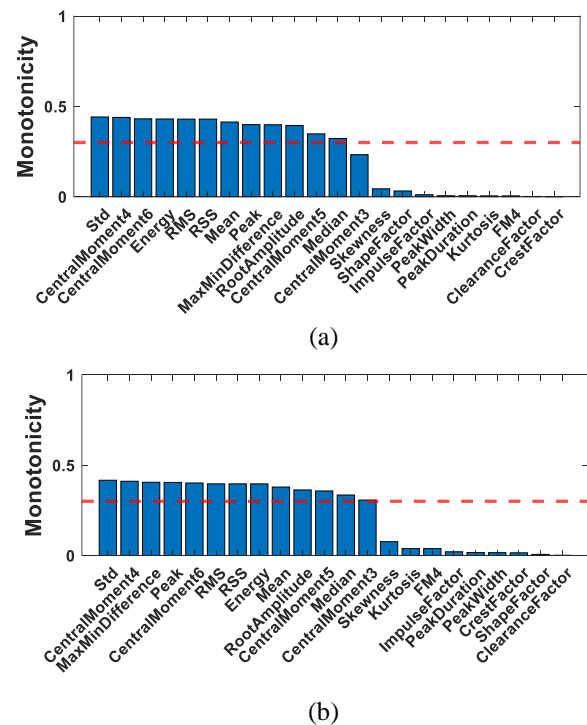

Figure 8 Examples of calculated features for SG sensors

After calculating these features, feature ranking is performed using Equation (1). However, the features are smoothed to enhance the performance of the monotonicity function. In this study, a threshold value of 0.3 is applied to select features for fusion. Figure 9 illustrates the feature importance for each SG. This feature ranking step is conducted using the training dataset, which represents 40% of the total lifetime.

(c)

(d)

Figure 9 Feature importance: (a) SG1, (b) SG2, (c) SG3, (d) SG4

Based on Figure 9, it can be concluded which features exhibit greater importance and maintain a more monotonic trend during the fatigue test. For instance, the standard deviation demonstrates the highest importance across all SG sensors. Therefore, all selected features that meet the predefined threshold will be utilized for fusion.

For each SG sensor, the selected features are transformed to a lower-dimensional space using PCA, with normalization applied relative to the training dataset. The first principal component (PC) is chosen as it captures the maximum gradient in the feature space. Figure 10 illustrates the first principal component for each SG sensor based on the selected features.

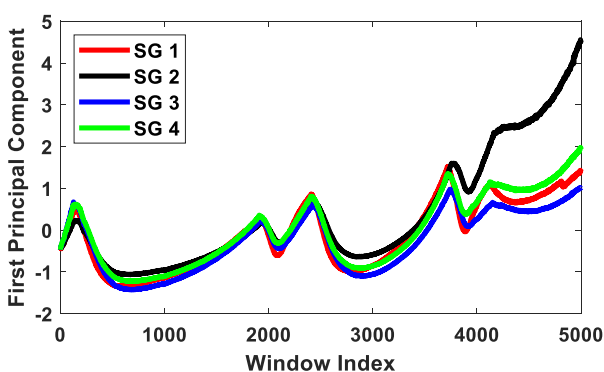

Figure 10 First principal component for each SG sensor

As shown in Figure 10, the first PC appears to be a promising HI derived from the fused features, offering greater robustness compared to any single feature. For better visualization of the first PC as a health indicator, an exponential function is fitted

to each curve, with all curves shifted to zero at the starting point, as shown in Figure 11.

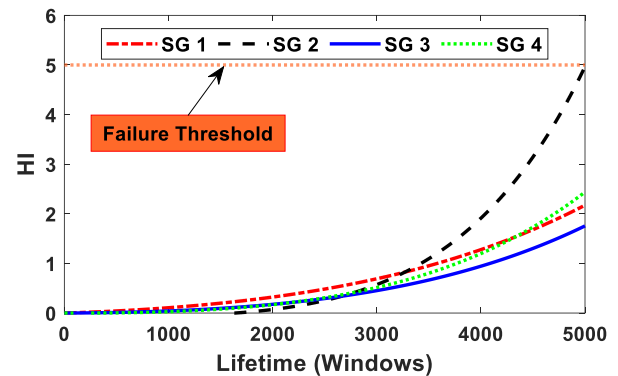

Figure 11 Constructed HI using SG sensor data

As shown in Figure 11, the HI for SG sensor 2 reaches level 5, which is recognized as the failure threshold. Therefore, this threshold can be used as a criterion for any new sample. However, due to the heterogeneous nature of asphalt, more experiments are required to establish a reliable threshold. Once validated, this HI can serve as an input to a prognosis model, such as an exponential degradation model, for estimating the remaining useful life. However, applying this approach in real field conditions remains challenging, as the exact failure point is still unknown.

## 5 IMPLEMENTATION ON IN-SITU DATA

Before implementing a method on in-situ data collected through an FBG sensor network embedded in the road, it is important to consider that, since the pavement is newly constructed, no damage is typically present, and the collected data can be labeled as "healthy." This dataset can then be used to generate synthetic data representing damaged conditions. Unlike experimental tests, where loading conditions are controlled, in this case, the loading is random, and no specific information about it is available. Based on experimental observations, damage affects sensor responses depending on its distance from the sensor. Therefore, two types of data can be generated: one where the damage occurs at the sensor location (G1) and another where the damage is not at the sensor location but within a detectable distance (G2). This can be achieved using an exponential function to generate synthetic data, as illustrated in Figure 12.

(a)

Figure 12 Generated synthetic data using available healthy data: (a) G1, (b) G2

Now, these data can be used to implement the proposed method, beginning with feature extraction. For example, Figure 13 shows the calculated features for both signals after segmentation into windows of 2,000 data points.

Figure 13 Examples of calculated features for G1 and G2

A threshold value of 0.3 is applied again to select features for fusion. Figure 14 illustrates the feature importance for G1 and G2. This feature ranking step is performed using the training dataset, which accounts for 40% of the total lifetime.

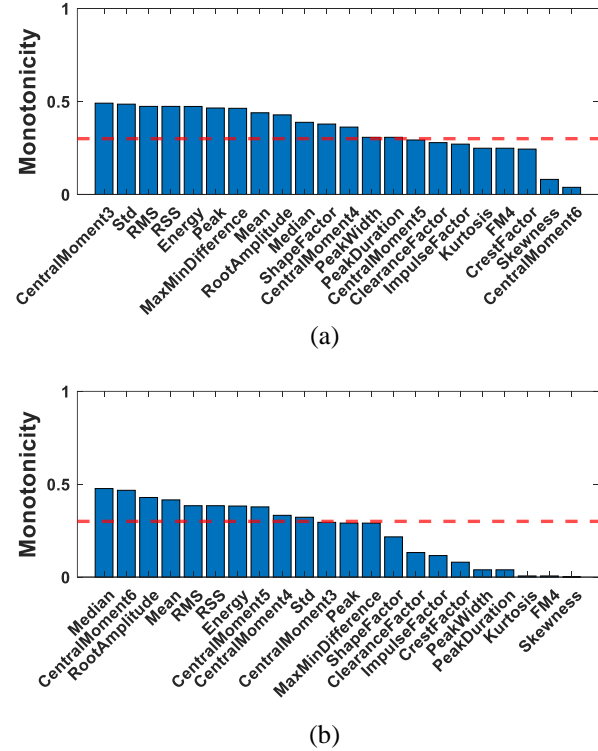

Figure 14 Feature importance: (a) G1, (b) G2

As shown in Figure 14, the important features vary in each case. For example, in the first case, central moment 3 is the top feature, whereas in the second case, it is not even among the selected features. This highlights the importance of feature ranking before fusion. Figure 15 illustrates the first principal component for each generated data based on the selected features.

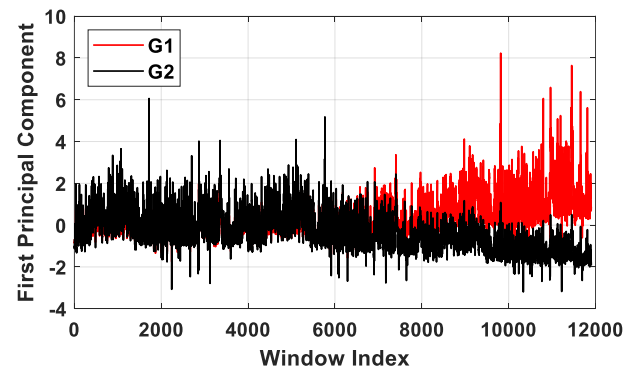

Figure 15 Feature importance: (a) G1, (b) G2

For clearer visualization of the PC as a health indicator, an exponential function is fitted to each curve, with all curves adjusted to start at zero, as shown in Figure 16.

Figure 16 Constructed HI using generated data

As shown in Figure 16, the Health Indicator (HI) for G1 exhibits an increasing trend, while for G2, it shows a decreasing trend. This suggests that the HI can be used for health monitoring, even with real data. Although a specific threshold cannot be defined, an adaptive threshold could be a potential solution, requiring further investigation.

## 6 CONCLUSIONS

This study presents a framework to compress, reduce, and fuse raw data collected from a sensor network into a HI for monitoring road infrastructure using FBG sensor network that produces a sheer volume of data. The integration of sensor data processing, feature extraction, and machine learning methods enables the detection of damage in infrastructure, ensuring timely maintenance interventions. Key findings of this study are as follows:

- Based on experimental tests, it has been confirmed that the sensor response is dependent on its distance from the damage.
- The monotonicity metric is effective in identifying features sensitive to damage propagation and refining features before fusion.
- The use of the first principal component as a health indicator demonstrates its effectiveness in tracking damage progression. In experimental tests, the health indicator's trend helped identify damage once it exceeded a threshold, though further validation is needed to establish a universal failure threshold for real-world applications.
- The proposed HI meets the key criteria for an optimal HI, including detectability and separability, making it acceptable based 2VP. Additionally, trendability can be achieved by taking the absolute value of the HI if needed.
- The constructed HI can be used for RUL estimation using a prognosis model, provided the threshold is known. However, determining a reliable threshold remains a challenge for real-world applications.
- The proposed framework is sensor-independent, except for some specific pre-processing steps that vary for each sensor. This framework can be implemented for infrastructure monitoring using large-scale sensor networks for efficient SHM.

In conclusion, the methodology introduced in this study holds great promise for the future of infrastructure health

monitoring. With further refinement and validation, it has the potential to make road maintenance more efficient and cost-effective.

**ABSTRACT:** As global climate change drives rising sea levels, coastal regions face growing threats from seawater intrusion. This process increases groundwater salinity, accelerating steel corrosion and compromising the structural integrity of concrete infrastructure. However, addressing these challenges is limited by existing salinity monitoring technologies, which often suffer from slow response times and low sensitivity in in-situ conditions. This study proposes a salinity sensor based on Fiber Bragg Grating (FBG), enhanced by chemically etching the fiber cladding to create an etched FBG (EFBG). This modification improves sensitivity to external refractive indices for accurate salinity detection. A three-layer waveguide dispersion model simulated wavelength shifts during sensor etching and testing using MATLAB, revealing how etching diameters impact sensitivity and confirming a linear relationship between wavelength and seawater salinity. To improve EFBG durability and reduce hydrofluoric acid damage, the etching process was divided into rapid, stable, and fine stages. Results demonstrated that higher etching levels increased sensitivity, achieving a sensitivity coefficient of up to 29.432 pm/% in specific conditions. The EFBG salinity sensor offers high sensitivity, fast response, compact size, corrosion resistance, and interference immunity, making it ideal for in-situ groundwater salinity monitoring in aquifers and mitigating risks to coastal structural health.

**KEY WORDS:** Salinity; Fiber Bragg grating (FBG); Chemical etching; Seawater Intrusion.

## 1 INTRODUCTION

Excessive groundwater extraction in coastal areas disrupts the natural balance between freshwater and seawater, driving inland migration of the saltwater-freshwater interface — a phenomenon known as seawater intrusion [1,2]. This process significantly increases groundwater salinity, which accelerates corrosion of steel reinforcements and compromises the structural integrity of concrete infrastructure in coastal regions, posing severe risks to long-term structural health and safety [3].

Monitoring groundwater salinity is crucial for assessing seawater intrusion severity and protecting infrastructure [4,5]. Existing monitoring techniques include electrical conductivity sensors, microwave remote sensing, and fiber optic sensors. Electrical conductivity sensors offer high accuracy, but inductive types are vulnerable to electromagnetic interference, while electrode types suffer from fouling, limiting long-term performance [6,7]. Microwave remote sensing enables large-scale surface salinity observation, but it cannot penetrate below the surface or provide in-situ groundwater monitoring [8,9].

Fiber optic sensors have attracted increasing attention due to their compact size, immunity to electromagnetic interference, and high sensitivity [10]. Among them, Fiber Bragg Grating (FBG)-based salinity sensors can be divided into polymer-coated FBGs and etched FBGs (EFBGs). Polymer-coated sensors, such as those developed by Jun Cong et al. (2002) [11] and Ping Lu et al. (2008) [12], achieve moderate sensitivity, but suffer from slow response and poor repeatability due to polymer swelling and hysteresis.

To improve sensitivity, Kerstin Schroeder et al. (2001) [13] introduced a side-polished FBG, exposing the evanescent field for salinity detection, but the sensor exhibited non-linear response in varying temperature and salinity environments.

Pereira et al. (2004) [14] used hydrofluoric acid to etch FBGs, achieving a salinity sensitivity of 1.28 pm/%, but this approach lacked robust in-situ adaptation for groundwater monitoring.

Most existing EFBG sensors focus on biochemical sensing, with limited research targeting long-term groundwater salinity monitoring for seawater intrusion detection. This study develops a high-sensitivity, fast-response EFBG salinity sensor capable of salinity measurement, providing a compact and reliable solution for real-time in-situ groundwater salinity monitoring, contributing to the protection of coastal groundwater resources and infrastructure health.

## 2 FUNDAMENTAL PRINCIPLE OF EFBG FOR SEAWATER SALINITY SENSING

A Fiber Bragg Grating (FBG) is a reflective grating structure inscribed in the core of an optical fiber. When broadband light propagates along the fiber axis, the FBG reflects a specific wavelength, known as the Bragg wavelength, which is determined by the effective refractive index of the fiber core and the grating period, as shown in Figure 1 [15].

Figure 1. The schematic diagram of FBG sensing principle.

The Bragg wavelength  $\lambda_B$  satisfies the following relationship [16]:

$$\lambda_B = 2n_{eff}\Lambda \quad (1)$$

where  $n_{eff}$  denotes the effective refractive index of the fiber core, and  $\Lambda$  represents the grating period.

In conventional optical fibers, the presence of a complete cladding layer confines light within the fiber core, making the Bragg wavelength largely insensitive to changes in the external refractive index. However, by physically or chemically reducing the cladding thickness, a portion of the light propagating in the core extends into the surrounding medium as an evanescent field. This modification allows the effective refractive index  $n_{eff}$  to be influenced by the external refractive index, thereby shifting the Bragg wavelength  $\lambda_B$ .

As the cladding thickness decreases, the optical fiber gradually forms a three-layer waveguide structure, consisting of the external medium, the remaining cladding, and the core. The modal characteristics of light propagation change accordingly, and the propagation constant  $\beta$  is also affected. To quantify the influence of cladding etching on the propagation constant, the corrected propagation constant for different etched diameters can be expressed as [17]:

$$\beta = \beta_0 + \kappa \eta_P (n_{SRI} - n_{cl}) \quad (2)$$

where  $\beta_0$  represents the propagation constant under normal conditions,  $k$  denotes the wave vector, and  $\alpha$  is the power loss coefficient, representing the proportion of power loss in the etched region relative to the total guided power.  $n_{ext}$  and  $n_{clad}$  denote the refractive indices of the external medium and the cladding, respectively.

From the definition of the propagation constant, the effective refractive index  $n_{eff}$  can be derived as:

$$\partial n_{eff} = \partial n \partial \eta \quad (3)$$

At the end of the etching process, the effective refractive index reaches a stable value, denoted as  $n_{eff, final}$ . Combining this with Equations (1), (2), and (3), the relationship between Bragg wavelength shift and external refractive index can be obtained:

$$\partial \lambda_B = 2\Lambda \eta_0 (n_{SRI} - n_{cl}) \quad (4)$$

This indicates that after etching to a certain diameter, the Bragg wavelength becomes highly sensitive to changes in the external refractive index.

In practice, the primary salt component in seawater is sodium chloride (NaCl). Therefore, the salinity of seawater can be approximated using NaCl solution concentration. At constant temperature, the refractive index of NaCl solution exhibits a linear relationship with salinity [18]:

$$c(\%) = k_s n_{SRI} - k_0 \quad (5)$$

where  $k_s$  is the salinity coefficient, which remains constant under fixed external conditions when only salinity changes. In this study,  $k_s$  is set to 540.5405, and  $k_0$  is 720.5946.

### 3 NUMERICAL MODEL FOR EFBG SEAWATER SALINITY SENSING

To further establish the quantitative relationship between EFBG wavelength shifts and seawater salinity, a numerical analysis was conducted using MATLAB. The calculation of the effective refractive index requires a fiber waveguide model, which can be divided into two-layer and three-layer structures, as shown in Figure 2.

Figure 2. Two types of fiber waveguide models: (a) Three-layer structure; (b) Two-layer structure.

When the fiber cladding is fully etched away or the etching extends into the fiber core, the core and external medium form a simple two-layer circular waveguide model (Figure 2(a)). This type, known as the core-etched FBG, offers high salinity sensitivity. However, due to severe cladding removal, the mechanical strength is significantly reduced, resulting in poor robustness, which limits its suitability for long-term monitoring in harsh environments. To balance mechanical integrity and sensitivity, this study employs a partially etched FBG structure, modeled as a three-layer circular waveguide (Figure 2(b)). The dispersion equation for the three-layer fiber waveguide can be expressed as follows [19]:

$$\begin{cases} [\hat{J}_m(u) - \hat{Y}_m(u'c)][\hat{K}_m(v) - \hat{J}_m(u')] = \frac{J_{m+1}(u'c)Y_{m+1}(u')}{J_{m+1}(u')Y_{m+1}(u'c)} & (\beta < k_0 n_{cl}) \\ [\hat{J}_m(u) - \hat{J}_m(u'c)][\hat{K}_m(v) - \hat{Y}_m(u')] = \frac{J_{m+1}(u'c)Y_{m+1}(u')}{J_{m+1}(u')Y_{m+1}(u'c)} & (\beta < k_0 n_{cl}) \\ [\hat{J}_m(u) - \hat{K}_m(v'c)][\hat{K}_m(v) + \hat{I}_m(v')] = \frac{I_{m+1}(v'c)K_{m+1}(v')}{I_{m+1}(v')K_{m+1}(v'c)} & ((\beta > k_0 n_{cl})) \\ [\hat{J}_m(u) + \hat{I}_m(v'c)][\hat{K}_m(v) - \hat{K}_m(v')] = \frac{I_{m+1}(v'c)K_{m+1}(v')}{I_{m+1}(v')K_{m+1}(v'c)} & ((\beta > k_0 n_{cl})) \end{cases} \quad (6)$$

The mathematical symbols and parameters used in the equation are defined as:

$$\hat{Z}_m(x) = \frac{Z_m(x)}{xZ_{m+1}(x)} \quad (7)$$

$$u = a_1(k_0^2 n_1^2 - \beta^2)^{1/2} \quad (8)$$

$$u' = a_2(k_0^2 n_{cl}^2 - \beta^2)^{1/2} \quad (9)$$

$$v' = a_2(\beta^2 - k_0^2 n_{cl}^2)^{1/2} \quad (10)$$

$$v = a_2(\beta^2 - k_0^2 n_{SRI}^2)^{1/2} \quad (11)$$

$$c = \frac{a_1}{a_2} \quad (12)$$

where  $k_0$  denotes the vacuum wave number. The fiber parameters used in this model match the experimental optical fiber specifications discussed later.  $J_m$  and  $Y_m$  represent the first and second kind Bessel functions, respectively, while  $I_m$  and  $K_m$  denote the modified first and second kind Bessel functions.

Based on the above equations, MATLAB was used to calculate the relationship between FBG wavelength and fiber diameter during the etching process. Figure 3 illustrates the variation in Bragg wavelength as a function of fiber diameter when the external refractive index is set to 1.333.

Figure 3 Diagram of wavelength variation as a function of diameter during etching.

As shown in Figure 3, at the initial stage of etching, the thick cladding confines the optical field within the core, making the wavelength almost insensitive to the external refractive index. As etching progresses and the cladding becomes thinner, the evanescent field begins to interact with the external environment. Due to the lower refractive index of the surrounding medium compared to the cladding, the Bragg wavelength decreases sharply as the diameter decreases. This trend provides a basis for real-time monitoring of fiber diameter during the etching process.

The surface salinity of seawater typically ranges from 3.4‰ to 3.7‰. To evaluate the feasibility of EFBG sensors for seawater salinity monitoring, MATLAB simulations were carried out to investigate the relationship between salinity and wavelength shift under low-salinity conditions. As shown in Figure 4, the smaller the fiber diameter, the higher the salinity sensitivity. Within the salinity range of 0–6‰, EFBG sensors with different diameters all exhibit a clear linear relationship between salinity and wavelength shift. Higher etching levels consistently lead to increased salinity sensitivity, providing important design and fabrication guidelines for EFBG-based salinity sensors.

Figure 4 Relationship between wavelength variation and salinity at low salinity.

## 4 EXPERIMENTAL DESIGN AND SALINITY SENSING TESTS

### 4.1 Etching Process

The fiber optic sensing element used in this study is a single-point fiber Bragg grating sensor with a central wavelength of 1564 nm, a wavelength tolerance of  $\pm 0.2$  nm, and a grating length of 10 mm. The fiber is coated with an acrylate layer, with

a reflectivity of 88.3%, a 3 dB bandwidth of 0.23 nm, and a side mode suppression ratio of 22 dB. The core diameter is 9  $\mu\text{m}$ , cladding diameter is 125  $\mu\text{m}$ , and the coating diameter is 240  $\mu\text{m}$ , consistent with the parameters used in the numerical simulations.

Hydrofluoric acid (HF), known for its strong corrosive properties on glass and silicon-based materials, was used to etch the fiber cladding. The initial HF concentration was 40%, which was diluted with distilled water to prepare solutions of lower concentrations for staged etching. During the etching process, the non-grating sections of the fiber were covered with paraffin wax to protect them from unnecessary etching. The fiber was also connected to an NZS-FBG-A01 interrogator (Suzhou Nanzhi Sensing Technology Co., Ltd.) via patch cords to monitor real-time Bragg wavelength shifts, allowing precise control over the final cladding diameter. The interrogator operates in the wavelength range of 1528–1568 nm with a resolution of 1 pm. To ensure the reliability of etching rate measurements, three bare fibers were fixed in parallel on a T-shaped plastic holder and immersed in HF solutions for parallel etching experiments. Each etching session lasted 60 minutes, after which the fibers were thoroughly rinsed with deionized water to remove residual acid and air-dried in a ventilated area. The diameters of the fibers were measured under an optical microscope, and the average diameter of the three fibers was recorded for each condition. This process was repeated to determine etching rates at different HF concentrations.

Figure 5. Microscope images of bare fibers etched by hydrofluoric acid at different concentrations: (a) 40% concentration; (b) 20% concentration; (c) 5.7% concentration.

The results show that higher HF concentrations lead to faster etching rates but also create rougher fiber surfaces, as shown in Figure 5. To reduce surface irregularities, minimize residual stress, and improve the wavelength stability of the sensor, a staged etching process was employed. In this process, high-concentration HF was first used for rapid bulk etching, followed by lower-concentration HF for gradual surface refinement. This method ensures a smoother grating surface and reduces unwanted stress-induced wavelength shifts.

### 4.2 Salinity Testing

To simulate coastal groundwater conditions, artificial seawater with salinities ranging from 0‰ to 6‰ (in 1‰ increments) was prepared by dissolving NaCl in distilled water. The EFBG sensor was sequentially immersed in these solutions, and the Bragg wavelength was recorded in real time to evaluate its response to salinity changes.

Figure 6. Bragg wavelength variation at different salinities.

The initial wavelength offset of the EFBG was 7.5 nm. Based on the diameter-wavelength relationship established through numerical analysis, the cladding diameter of the EFBG was calculated to be 14.82  $\mu\text{m}$ . The measured Bragg wavelength shifts at different salinity levels are shown in Figure 6. As illustrated, the Bragg wavelength shift increases significantly with rising salinity and demonstrates a clear linear relationship with salinity. The EFBG sensor achieved a salinity sensitivity of 29.432 pm/‰, confirming its potential for high-sensitivity salinity monitoring.

## 5 CONCLUSION

This study developed an etched fiber Bragg grating (EFBG) sensor for in-situ monitoring of groundwater salinity in coastal aquifers affected by seawater intrusion. A combination of numerical modeling, staged chemical etching, and salinity calibration experiments was used to evaluate sensor performance. The key conclusions are as follows:

(1) A three-layer fiber waveguide model was established to simulate the effect of cladding etching on Bragg wavelength shifts. Numerical results confirmed that reducing the cladding diameter enhances evanescent field sensitivity, significantly improving salinity response. A clear linear relationship between Bragg wavelength shift and salinity was observed within the 0–6‰ salinity range.

(2) A staged etching process using high and low concentrations of hydrofluoric acid was employed to optimize both the etching efficiency and surface smoothness. This approach minimized surface defects, reduced stress-induced wavelength drift, and ensured stable sensor performance.

(3) Experimental results demonstrated that the EFBG sensor with a cladding diameter of 14.82  $\mu\text{m}$  achieved a salinity sensitivity of 29.432 pm/‰, with excellent linearity between Bragg wavelength shift and salinity. This high sensitivity, combined with the sensor's compact size, corrosion resistance, and real-time monitoring capability, makes it well-suited for long-term in-situ groundwater salinity monitoring in coastal areas.

Overall, the proposed EFBG sensor offers a practical and effective solution for groundwater salinity monitoring, contributing to improved seawater intrusion early warning and the protection of coastal infrastructure and water resources.

**ABSTRACT:** As the geological body on which humans depend, rock and soil are constantly moving under the action of natural forces and human activities. Their instability often triggers geo-hazards, posing severe threats to the environment, infrastructure safety, and sustainable development. High-quality data acquisition and effective monitoring are essential for geo-hazard prevention and mitigation. The stability of rock and soil is governed by mechanical discontinuous interfaces, which are classified into material, state, and movement interfaces. This paper focuses on distributed fiber-optic sensing (DFOS) technology as an advanced tool for geo-hazard monitoring and early warning. The paper summarizes the authors' achievements over the past two decades in DFOS-based geo-hazard monitoring theory, sensing techniques, and application systems. Key advancements include strain-sensing coupling theory, moisture and seepage monitoring methods, disaster identification and prediction models, and integrated fiber-optic sensing technology platforms. Three representative cases are presented, demonstrating the application of DFOS to monitor the material interface of slope overlying rock, the state interface of land subsidence, and the movement interface of a reservoir slope. Finally, future research directions for fiber-optic sensing in rock-and-soil disaster monitoring are outlined.

**KEY WORDS:** Rock-and-soil, Interface, Geo-hazard, Monitoring, Distributed fiber-optic sensing (DFOS), Application

## 1 INTRODUCTION

Earth habitability has become a critical scientific focus in the 21st century, with rock and soil providing the fundamental foundation for human survival and infrastructure development. These geological bodies are constantly subjected to natural forces, such as earthquakes, rainfall, and landslides, as well as anthropogenic disturbances, including excavation, construction, and resource exploitation. Such internal and external forces continuously reshape the physical and mechanical properties of rock and soil, leading to instability that can trigger a variety of geo-hazards. These disasters pose severe threats to the ecological environment, engineering safety, and the sustainable development of society.

The stability and evolution of rock and soil masses are primarily governed by mechanical discontinuity interfaces, which can be categorized into material interfaces, state interfaces, and movement interfaces, as shown in Figure 1. These interfaces play a decisive role in controlling the deformation, failure mechanisms, and overall stability of rock and soil systems under complex external loads. However, their concealed, heterogeneous, and dynamic nature makes real-time monitoring and early identification of potential disaster signals particularly challenging.

Traditional monitoring methods, such as discrete point sensors, geotechnical instrumentation, and geophysical surveys, often suffer from limitations in spatial coverage, resolution, and long-term reliability. These limitations hinder the accurate depiction of internal mechanical evolution and early identification of critical hazard precursors, especially in large-scale and complex geological settings.

To overcome these challenges, distributed fiber-optic sensing (DFOS) technology has emerged as a highly promising tool for in-situ, real-time, and continuous monitoring of geo-hazards [1].

DFOS enables the long-distance, high-resolution, and distributed acquisition of strain, moisture, temperature, and other critical parameters along the entire length of a sensing cable, offering unparalleled advantages in capturing the spatial evolution of mechanical discontinuities and hazard precursors in rock and soil masses.

Figure 1 Schematic diagram of rock and soil disasters and the three types of interfaces.

This paper summarizes the key advancements achieved in DFOS-based geo-hazard monitoring by the authors' research group over the past two decades, covering areas such as strain-sensing coupling theory, moisture and seepage monitoring techniques, disaster identification and prediction models, and integrated fiber-optic sensing technology platforms. Furthermore, three representative case studies are presented to demonstrate the practical application of DFOS in monitoring material interfaces, state interfaces, and movement interfaces in

complex geotechnical environments, highlighting its unique advantages and future potential in geo-hazard monitoring and early warning.

## 2 DISTRIBUTED FIBER-OPTIC SENSING TECHNOLOGY

DFOS enables continuous spatial and temporal monitoring by utilizing optical fibers as both transmission media and sensing elements. This technology encodes the measured parameter as a function of fiber length, allowing real-time data collection over large areas. By deploying sensing fibers in various configurations, DFOS effectively forms an integrated sensing network within geotechnical structures, providing critical insights into subsurface processes.

DFOS primarily encompasses three key techniques: Distributed Temperature Sensing (DTS) for thermal monitoring, Distributed Strain Sensing (DSS) for strain measurements, and Distributed Acoustic Sensing (DAS) for vibration detection [2], as shown in Figure 2. Additionally, Fiber Bragg Grating (FBG) sensing, including the advanced Ultra-Weak Fiber Bragg Grating (UWFBG) technology, offers high-resolution quasi-distributed measurements.

When embedded within soil and rock formations, DFOS enables real-time monitoring of stress, deformation, temperature, and fluid movement. This capability enhances the early detection of geo-hazards, supports infrastructure health monitoring, and improves disaster prevention strategies. Its ability to provide high-resolution, continuous data makes DFOS an essential tool for geotechnical applications.

## 3 FIBER-OPTIC SENSING THEORY AND TECHNOLOGY FOR ROCK-AND-SOIL DISASTERS

The application of fiber-optic sensing technology in rock-and-soil disaster monitoring requires addressing several key theoretical and technical challenges. The primary difficulties lie in understanding and improving the strain coupling mechanism between optical fibers and geotechnical materials, effectively detecting and quantifying moisture infiltration and seepage processes, developing reliable methods for identifying and predicting disaster-related signal events, and constructing an integrated fiber-optic sensing system tailored for geo-hazard monitoring. These challenges must be overcome to enhance the accuracy and reliability of fiber-optic sensing technology in geotechnical applications. The following sections summarize the advancements achieved by the authors' research team in these areas.

### 3.1 Strain-Sensing Coupling Theory

The strain coupling mechanism between embedded fiber-optic sensors and surrounding geotechnical materials plays a crucial role in ensuring accurate deformation monitoring. Through extensive theoretical and experimental research, the authors have established a progressive failure model for fiber-soil interfaces, revealing the mechanisms governing interfacial bonding strength. On this basis, a criterion for evaluating fiber-soil interfacial adhesion was proposed, alongside a calculation method for determining critical confining pressure and the optimal embedment depth of borehole-installed fibers [3,4]. These findings provide essential guidance for improving fiber installation strategies in geotechnical applications.

To address the challenge of strain transfer in weak soil layers, a novel anchoring approach—fixed-point optical fiber technology—was developed. This technique enhances strain coupling by introducing controlled bonding points along the fiber, preventing signal attenuation due to excessive strain dissipation. By refining strain transfer mechanisms, these advancements have significantly improved the performance of DFOS in complex geological environments, ensuring the accuracy and stability of long-term geotechnical monitoring.

### 3.2 Moisture and Seepage Sensing Methods

Moisture and seepage are fundamental factors affecting the stability of rock and soil masses. Moisture primarily pertains to unsaturated soils, while seepage involves fluid movement

within porous media, often serving as a key trigger for geotechnical failures such as slope instability and land subsidence. Conventional monitoring methods, such as the active heating distributed temperature sensing (DTS) technique proposed by Selker et al., have limitations in accuracy and are only applicable in environments above 0 °C[5]. To overcome these constraints, we introduced the thermal pulse fiber-optic method, which leverages the thermal conductivity variations of geological materials under different moisture and seepage conditions. By integrating optical fibers as active heat sources, this technique enables high-precision, all-weather detection of subsurface moisture and seepage dynamics[6].

To further enhance measurement accuracy, ultra-weak fiber Bragg grating (UWFBG) technology was employed, embedding thousands of ultra-low reflectivity gratings along a single fiber-optic cable. Encapsulated with conductive heating materials, this advancement significantly improved sensing resolution, increasing accuracy from 5% F.S. to 1% and enhancing thermal response sensitivity compared to conventional methods[7]. Once embedded in geological formations, this fiber-optic sensing system enables continuous, high-resolution monitoring of dynamic changes in moisture content, capillary rise, groundwater levels, and seepage velocities. This innovation provides a powerful tool for tracking hydrological processes in unsaturated zones, improving geotechnical disaster prevention strategies, and supporting sustainable groundwater management.

### 3.3 Geo-hazard Identification and Prediction

Accurately identifying and predicting geo-hazards based on fiber-optic sensing data is essential for early warning and disaster prevention. The Random Forest algorithm, known for its efficiency and strong classification performance, has been applied to develop an intelligent multi-hazard classification system for underground engineering. Field tests in tunnels demonstrated its ability to distinguish construction activities (e.g., excavation, drilling) and sudden disasters (e.g., rockfalls, seepage) with 92.3% accuracy providing a reliable approach to geo-hazard detection [8].

For geo-hazard prediction, the Kalman Filter (KF) is widely used due to its precision and robustness. By integrating multi-physics data from fiber-optic sensors, it enhances anomaly detection accuracy. Since traditional KF models are limited to linear systems, an extended Kalman Filter (EKF) incorporating Taylor series expansion was developed to handle nonlinear geotechnical processes. Genetic algorithm optimization further improved prediction accuracy, enhancing the capability of fiber-optic sensing in forecasting disaster events and supporting proactive risk mitigation [9].

### 3.4 Fiber-Optic Sensing Technology Systems

Building on advancements in geo-hazard sensing theory and technology, the research team has developed an extensive fiber-optic sensing framework tailored for rock-and-soil disaster monitoring. Over 50 specialized fiber-optic sensing networks have been designed, alongside nearly 10 proprietary signal acquisition devices. Additionally, more than 10 intelligent geo-hazard recognition systems have been established, forming a comprehensive and systematic approach to fiber-optic sensing for geotechnical disaster detection and early warning (Figure 3). This integrated technology system enhances the accuracy,

efficiency, and applicability of distributed fiber-optic sensing in diverse geological environments, providing a robust foundation for large-scale geo-hazard monitoring and risk assessment [10,11].

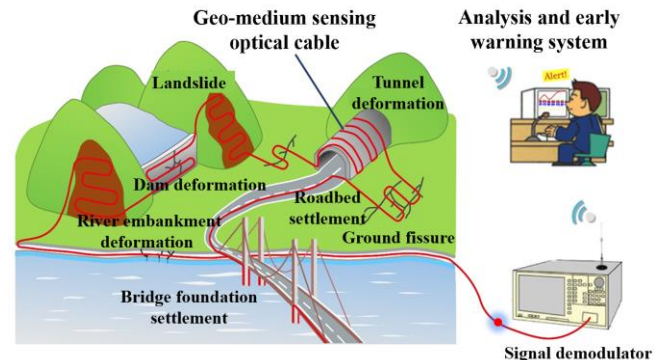

Figure 3 Fiber optic sensing system for rock-and-soil disasters.

## 4 APPLICATIONS OF DFOS IN ROCK-AND-SOIL DISASTER MONITORING

DFOS has emerged as a transformative technology for monitoring rock-and-soil disaster mechanisms by providing continuous, real-time, and high-resolution data over large spatial extents. Unlike traditional geotechnical monitoring systems that rely on discrete measurement points, DFOS allows for full-scale sensing of deformation, stress redistribution, and hydrological changes that contribute to geotechnical instabilities. This section highlights key applications of DFOS in monitoring material, state, and movement interfaces, with a focus on underground mining operations, land subsidence monitoring, and reservoir slope stability assessment.

### 4.1 Monitoring Material Interfaces in Slope Overlying Rock

In underground mining operations, the excavation process induces stress redistribution and fracture propagation within the surrounding rock mass. This often leads to instability in stope overburden, posing a significant risk of roof collapse, rock bursts, and ground subsidence. Material interfaces, such as the contact zones between ore bodies and surrounding rock or between different lithological formations, govern the mechanical response of the overlying strata and influence the failure mechanisms within the mine.

DFOS technology has been successfully deployed in longwall mining, sublevel caving, and room-and-pillar mining operations to monitor stress changes and detect potential failure zones [12,13]. Optical fibers installed along critical interfaces allow for real-time strain measurement, enabling the identification of stress concentrations and early warning of geotechnical hazards. By tracking localized deformation trends, strain redistribution, and fracture initiation, DFOS provides mine operators with actionable insights for optimizing roof support systems, adjusting mining sequences, and implementing safety measures to prevent catastrophic failures.

### 4.2 Assessing State Interfaces in Land Subsidence

Land subsidence is a widespread geo-hazard resulting from excessive groundwater extraction, soil consolidation, and hydro-mechanical interactions. The gradual settlement of soil layers due to subsurface compaction can cause structural

damage to buildings, differential ground deformation, and increased flooding risks, particularly in urban areas. State interfaces within subsiding soil formations represent the transition zones between stable and compacting soil layers, where changes in pore pressure, void ratio, and effective stress dictate the rate and extent of subsidence.

DFOS has been increasingly utilized for long-term land subsidence monitoring by embedding fiber-optic sensors in boreholes and along subsiding zones to capture real-time compaction trends. By measuring strain variations, DFOS allows for the early detection of compaction-related deformations, enabling timely intervention to mitigate damage [14]. For example, in cities experiencing significant subsidence due to groundwater depletion, DFOS networks provide high-resolution subsidence maps, allowing urban planners and engineers to develop effective groundwater management policies and infrastructure reinforcement strategies. Additionally, DFOS can be integrated with satellite-based InSAR (Interferometric Synthetic Aperture Radar) data to enhance the accuracy of subsidence monitoring by correlating surface deformation trends with subsurface strain variations.

#### 4.3 Detecting Movement Interfaces in Reservoir Slopes

Reservoir slopes are highly susceptible to landslides and slope failures triggered by hydrodynamic loading, seasonal water level fluctuations, and infiltration-induced weakening of slope materials. Movement interfaces within reservoir slopes define the boundaries between stable and actively deforming soil or rock masses, making them critical zones for monitoring slope stability and identifying potential failure mechanisms.

DFOS-based monitoring has been successfully applied in reservoir embankments, natural slopes, and engineered slopes near hydropower stations to track shear strain accumulation, deep-seated creep deformation, and progressive failure development [15–17]. Fiber-optic sensors embedded along potential slip surfaces and slope reinforcement structures provide continuous measurements of strain evolution, allowing engineers to identify precursory signs of instability before catastrophic failure occurs.

In large-scale reservoir projects such as the Three Gorges Reservoir in China, DFOS has been instrumental in monitoring slope deformation and evaluating landslide risks under varying hydrological conditions [18]. By integrating DFOS data with numerical slope stability models and geotechnical instrumentation, engineers can develop more reliable landslide prediction models, improve early warning systems, and implement targeted mitigation measures, such as slope drainage optimization and reinforcement design [19,20].

## 5 CONCLUSION

The integration of DFOS technology into geo-hazard monitoring has significantly enhanced the ability to detect, analyze, and mitigate geological and geotechnical disasters. By providing continuous, real-time, and spatially distributed data, DFOS effectively overcomes the limitations of traditional point-based monitoring techniques, enabling more comprehensive and proactive disaster prevention, early warning, and risk assessment. The case studies presented in this paper demonstrate the broad application potential of DFOS technology in underground mining stability evaluation, land

subsidence monitoring, and reservoir slope hazard management, highlighting its adaptability to complex geological environments and diverse hazard types.

Future research should focus on further enhancing sensor durability and environmental adaptability, developing more refined data interpretation and inversion models, and integrating DFOS with artificial intelligence (AI), remote sensing, and multi-source data fusion to build intelligent, automated, and predictive hazard monitoring systems. The continuous advancement and interdisciplinary integration of DFOS technology will play a key role in safeguarding geotechnical stability, infrastructure resilience, and sustainable land use under increasingly complex environmental and engineering challenges.

# Structural Behaviors of Prestressed Double-T Slab under Loadings with Seasonal Effects

Yitian Liang<sup>1</sup>, ORCID (0009-0005-6376-0685), Branko Glišić<sup>2</sup>, ORCID (0000-0002-1852-5310)

**ABSTRACT:** Understanding the effects of temperature on structural behavior is critical in structural health monitoring (SHM), especially for prestressed concrete components with complex geometries due to their complicated internal strain distributions. Temperature-strain relationships in structural components can offer valuable insights into various structural properties, such as the coefficient of thermal expansion (CTE), and boundary and continuity conditions of structures. However, these relationships can be influenced by variability of ambient environmental conditions, especially ambient temperature variations, which can create thermal gradients and complicate the interpretation of relationships and identification of structural properties.

This study presents a preliminary study on the structural behaviors of a prestressed slab with a double-T cross-section through a series of static and dynamic loading tests conducted across four seasons, with ambient temperatures ranging from 8°C to 24°C. The proposed approach utilizes long-gauge strain sensors embedded within the slab to continuously capture strain and temperature data. By analyzing the temperature-strain relationships derived from on-site loading test measurements, the study aims to evaluate how the structural behaviors of the prestressed double-T slab, which can reflect the structural properties, such as boundary and continuity conditions, change under different environmental temperatures.

The preliminary results show clear variations in strain changes for the same loading condition under different temperatures. These variations suggest that environmental temperatures and thermal gradients could affect load response and boundary restraints. Furthermore, the findings demonstrate that the embedded long-gauge strain sensors effectively capture the temperature changes and strain distribution under the loadings, enabling the assessment of structural behaviors of the slab with seasonal effects. This research highlights the importance of accounting for environmental factors in structural health monitoring and provides new perspectives for understanding and predicting the behavior of structures with complex geometrical properties (e.g., double-T slab) under varying conditions.

**KEY WORDS:** Prestressed concrete slab; Thermal behavior of structures; Temperature-strain relationship; Long-gauge fiber-optic strain sensors; Complex geometrical and boundary conditions; Structural health monitoring.

## 1 INTRODUCTION

Prestressed precast concrete components with complex cross sections, such as double-T slabs, are widely used in modern construction due to their high load-carrying efficiency [1]. However, their structural behavior is influenced not only by applied mechanical loading but also by environmental factors, most notably temperature [2,3]. Seasonal fluctuations in ambient temperature can cause significant strain variations within these components, even in the absence of mechanical loading, and complicate the interpretation of measurement data used in condition assessment and damage detection. In addition, temperature-strain relationships can provide valuable insights into material properties (e.g., help evaluate thermal expansion coefficient), restraint and boundary conditions, and the overall stiffness behavior of structural systems [4,5]. Understanding how these relationships evolve under different environmental conditions and loading scenarios is essential for assessing in-situ structural behavior and for developing reliable long-term monitoring strategies.

This project is developed based on the real-life case study. More specifically, it is based on observation of the structural behavior of a prestressed double-T slab located in the Stadium Drive Garage, Princeton University, with a particular focus on the influence of seasonal temperature variations. The slab is instrumented with long-gauge Fiber Bragg Grating (FBG) sensors embedded within the concrete during construction.

These sensors allow for simultaneous, continuous measurement of strain and internal temperature over extended periods.

To explore how environmental conditions influence the load response, four series of load tests were conducted over a period of nine months at different environmental temperatures. Each test series included static loading with various load cases, and dynamic testing. While the mechanical load applied during each test series remained similar, the environmental temperature varied significantly between tests, ranging from 8°C to 24°C. This variation provides a unique opportunity to assess the interaction between thermal conditions and mechanical response in a controlled yet realistic setting.

The aim of this study is to observe how strain responses in a prestressed double-T slab vary under similar loading scenarios across different ambient temperatures, and to explore the potential for identifying temperature-related effects on structural behavior. Preliminary observations confirm that the environmental temperature affects the measured strain distribution under mechanical load.

The originality of this study lies in the following aspects. It combines seasonal on-site testing under varying ambient conditions with embedded long-gauge FBG, which captures internal strain and temperature responses that surface-mounted sensors could miss. In addition, the study focuses on a prestressed double-T slab with complex boundary conditions, a

structural form that presents significant challenges for SHM yet has been underrepresented in previous literature.

While full analysis is ongoing, this extended abstract summarizes the current progress by describing the instrumentation and load configurations and presenting preliminary observations of temperature-influenced structural behavior.

## 2 METHODOLOGY

### 2.1 Sensor layout

The double-T slab of Stadium Drive Garage contains 14 embedded long-gauge FBG sensors, installed at locations denoted with A, B, C, E, F, D, G, and H, as illustrated in Figure 1. The sensors are mostly, but not only, installed in parallel and crossed topologies. For pairs of parallel sensors, such as sensors at locations A, B, C, E, F, the top sensor is denoted as “1” (e.g. “A1”), and the bottom one as “2” (e.g. “A2”). The gauge length of sensors at locations A, B and C was 60 cm (1'11.6”), and all the other sensors in the double-T slab had a gauge length of 25 cm (9.8”). The gauge length of sensors was determined using principles developed in Glisic 2011 [6].

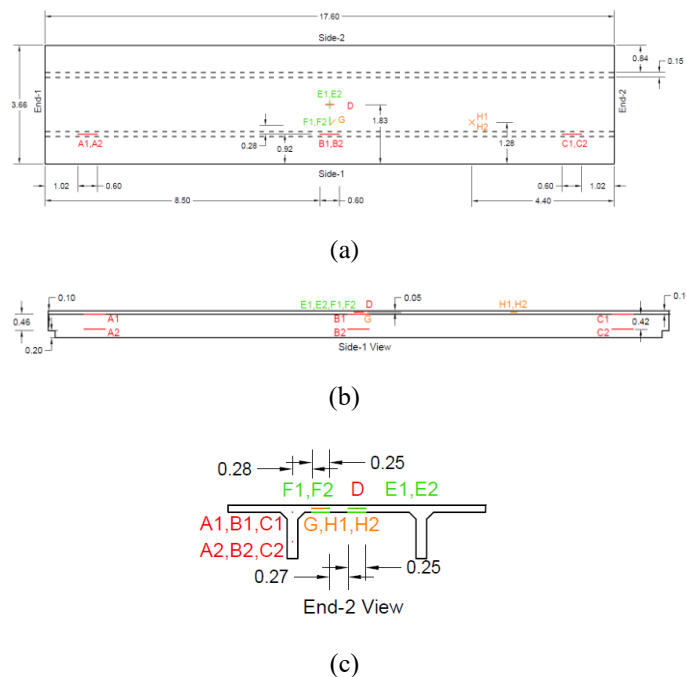

Figure 1. Locations of embedded long-gauge FBG strain and temperature sensors in the prestressed double-T slab: (a) plane view, (b) elevation view, and (c) cross-sectional view; all dimensions are in meters [7].

### 2.2 Experimental setup

The measurement data analyzed in this paper was collected from FBG sensors in the double-T slab during four series of load tests conducted between fall 2024 and spring 2025 at different environmental temperatures. These tests were performed using a truck provided by the Princeton University Facilities (Civil Engineering group), loaded with sandbags in the cargo bed to achieve a target weight of 10,000 lbs (4536 kg). This weight was selected to incur statistically significant

strain, according to the results of previous research on the slab [8]. Each test series included two types of load tests: static and dynamic. This paper focuses on results of static tests only, while dynamic tests are described only for the purposes of the completeness of presentation. In the static tests, the procedure began with the beam unloaded for approximately one minute. The truck was then driven onto a designated position on the beam and held stationary for another minute before being removed, after which the beam remained unloaded for an additional minute. During these static tests, sensors recorded strain at a rate of 1 hertz (Hz), or one measurement per second. An example of the truck with its cargo bed loaded with sandbags positioned on the beam during a static test is shown in Figure 2.

Figure 2. The truck on the slab in a static load test.

In the dynamic tests, the truck was driven across the width of the slab at variable speeds twice during each test series. After each impulse, the slab was allowed to vibrate freely for approximately one minute afterward. During these tests, the sensors measured at a rate of 100 Hz.

Table 1. Summary of load cases in four test series.

Load Case	Test 1 (15°C)	Test 2 (8°C)	Test 3 (10°C)	Test 4 (24°C)
V – center	✓	✓	✓	✓
V – web (w/ sensors)	✓	✓	✓	✓
V – web (w/o sensors)	×	✓	✓	✓
V – seam (closer)	✓	✓	✓	✓
V – seam (further)	×	✓	✓	✓
H – center	✓	×	✓	✓
H – neighbor slab center (closer)	✓	×	✓	✓
H – neighbor slab center (further)	×	×	✓	✓
Column test	✓	×	✓	✓
Dynamic test (mph)	15, 20	22, 25	25, 29	28, 30

Table 1 shows the environmental temperatures during four test series, all load cases each test series contains, and the speed of the truck during dynamic tests. For the load cases with the dash sign, the “V” and “H” before dash stand for “vertical” and “horizontal” respectively, which mean whether the centerline of the truck is along the length or the width of the slab; after the dash is the position of the rear wheels of the truck; “closer” means the side closer to the sensors, and “further” means the

side further away from the sensors. The tick mark “√” means the test series contains marked load case, and the cross “×” means the test series does not contain the load case.

### 3 PRELIMINARY OBSERVATIONS

Figure 3 presents the strain response recorded by FBG sensors embedded in the slab during Test2 with the load case “V – center”. The total strain changes  $\Delta\epsilon$  are plotted over time, with different colored lines representing individual sensors. Notably, sensors B2 shows significantly larger responses compared to others, due to its proximity to the applied load and its position at the midspan of the slab. This observation supports the effectiveness of the sensor network in capturing localized events while providing spatial context for interpretation.

Figure 3. Total strain changes from slab-embedded FBG sensors during a static test.

Figure 4. Total strain changes of sensor B2 under the same load case but at different ambient temperatures.

Figure 4 compares the strain measurement from one specific sensor (sensor B2) under the same type of load case but conducted under different ambient temperature conditions. Four curves represent four separate tests carried out when the slab was exposed to 8 °C, 10 °C, 15 °C, and 24 °C. Although all tests exhibit a similar response pattern (a rapid increase in strain during loading and a drop afterward), the magnitude of the peak strain differs across temperature conditions. This variation suggests that ambient temperature influences the sensor response—potentially due to changes in material stiffness, temperature gradient along cross section, or boundary restraint conditions. For example, the decrease in response with increase of temperature, for temperature higher than 10°C may reflect thermal expansion effects that result in higher stiffness of restrained slabs; inverse behavior for temperature lower than

10°C may indicate change in boundary conditions or interaction at connections. Yet combined effects can be in play in both cases.

These preliminary findings highlight two key observations: (1) the sensor network effectively captures localized strain patterns, and (2) environmental temperature influences the strain response, even under consistent loading scenarios. These effects will be further examined through more comprehensive analysis in future.

### 4 CONCLUSION AND FUTURE WORK

This study assesses the strain changes of a prestressed precast concrete slab with embedded FBG sensors under repeated localized loading and varying ambient temperatures. Through a series of static and dynamic load tests conducted across different seasons, it was observed that the same loading configuration caused different strain changes under varying ambient temperatures. The tests confirmed the effectiveness of the monitoring system and loading configuration. Furthermore, these preliminary observations highlight the significance of temperature as a factor affecting structural response and underline the importance of accounting for thermal effects in condition assessment and long-term monitoring.

Future work will focus on further examining the principles underlying the observed temperature-dependent strain variations, including the potential influences of thermal-induced stiffness changes and boundary conditions. Additional analysis will aim to quantify these relationships to better interpret long-term monitoring data. Moreover, the study will be extended to evaluate the dynamic behavior of the structure under different environmental temperatures to gain deeper insights into the stiffness evolution and structural performance with seasonal effects.

### ACKNOWLEDGMENTS

We would like to thank Gina Talt and Office of Sustainability of Princeton University for coordinating the project, Catherine Altadonna and Office of Capital Projects of Princeton University for providing funding and metadata related to project, George Hand, Ali Akber, and Jersey Precast, Hamilton, New Jersey, for their great assistance during the installation of sensors, Dan Polifroni and Whiting-Turner for their precious on-site help and coordination, Mauricio Pereira and Antti Valkonen, for installing the sensors, Elvis Le, for organizing, conducting, and recording the load tests, and for their contributions at various stages of the project.

**ABSTRACT:** The paper outlines an ongoing research project, incorporating Fiber Bragg Grating (FBG) systems to measure and detect the vibration in a ship's hull. The causes of such vibration are due to the various engines and motors on board, as well as the force induced by the movement of the sea, and the vibration induced into the hull by the propeller. Five ships in all have been monitored using the FBG system, using both 3 sensor rosettes, and chains of 10 sensors. All the sensors used were glued to the ships' hulls and various sea trials carried out. The tests included gathering data with the engines switched off, the engines running at various speeds, both whilst stationary in the harbour as well as whilst sailing.

Change detection is the main application of such monitoring, and such change is evident and detected due to a broken flange on one ship, and a new engine on one ship. Data were gathered before and after such effects were changed. The induced vibration due to the propeller is also evident.

**KEY WORDS:** Fibre Bragg Grating, Deflection monitoring, frequency analysis, SHM.

### 1 INTRODUCTION

Previous work conducted by the authors has focused on using RTK GNSS [1, 2] to monitor the long-term deformations of large bridges [3] as well as measuring the short-term deflections of such structures [4, 5, 6, 7, 8, 9] and extracting the frequencies of the movements [4, 7, 10]. Such deflection measurements and resulting frequency analysis can be used to detect movement characteristics of the structure due to damage or long-term deterioration. In parallel, the use of Fiber Bragg Grating (FBG) approaches was used to measure long term deformations of infrastructure such as roads and tunnels [11, 12, 13].

Both approaches were brought together by the authors [14] to use the high data rate and very precise data of the FBG system to measure dynamic characteristics of ship structures. Ships are structures that deform and deflect. Such deflections are caused by various external forces, such as the force induced on the hull by the sea as well as vibrations in the structure of the ship caused by various engines and motors on board. Ships, like all structures, can experience damage and long-term deterioration. These can result in deflections and vibrations in the ship's structure changing in characteristics over time or even instantly. The hypothesis of our research is that sudden changes in the characteristics of the ship's structure, caused by damage, can be detected by measuring changes in the frequencies observed in the vibration and deflection of the structure. The research objective of this current work is to be able to measure changes in the frequency response of the ship in relation to any damage or changes made to the ship. This was done by carrying out measurements using a FBG system on several ships, three of which exhibited damage or changes in engines, which resulted in the frequency responses changing. We gathered data on such vessels before and after any damage was fixed or engine changes were made.

FBG sensors were installed on a passenger ship in the Faroe Islands, and data were gathered at a rate of 1kHz during normal scheduled activity in 2017 and 2018 [14] and at a rate of 5kHz during the more recent tests. The frequency responses of the data were extracted to identify the frequency characteristics of the structure i.e. ship. The movements are caused by the ships' engines, motors and external factors such as weather and sea effects. In addition, vibrations are caused by the rotation of the propeller inducing force on the ship hull and causing vibrations. Further, change detection in these characteristics is possible, therefore detecting early damage to such infrastructure.

Following the initial sea trials, a three-year research project was undertaken to further this work.

### 2 FBG SENSORS

Fiber Bragg Gratings (FBGs) are patterns of refractive index changes inscribed in the core of a glass fiber with a typical length of about 1cm. When a broadband light source emits light into the fiber, the FBG behaves as a wavelength dependent mirror, meaning that only that portion of light with a wavelength corresponding to the spacing of the grating is reflected whereas other wavelengths can pass the grating unaltered, Figure 1. Hence, several gratings with different wavelengths can be placed along a single fiber enabling tens of sensor locations. The FBG sensors sample strain measurements at a rate of kHz with a precision of better than 1με (= 1 ppm = 1μm/m) and can be used for long term static monitoring as well as dynamic monitoring [11].

If local strain changes occur, the spacing of the patterns change and thus also the wavelength of the reflected signal peak changes. With appropriate calibration of FBG sensors [12] the recorded wavelength change can be reliably converted into a strain change. However, local temperature changes have an impact on the refractive index of the fiber and thus lead to a

wavelength change of the backscattered signal. A common method to numerically compensate the temperature impact is to place one or more FBGs along the sensing fiber, or to use a separate FBG, which are not coupled to the measurement object and thus only sensitive to temperature changes. The recorded wavelength changes of these gratings are in the processing subtracted from the measured wavelength changes from the rigidly connected FBGs. The remaining wavelength changes are then the real strains of the object.

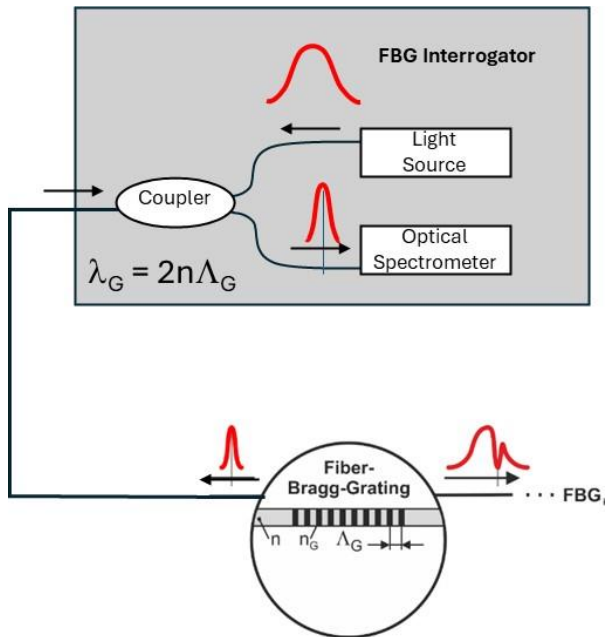

Figure 1. Principle of FBG measurements [14].

To monitor strains of the hull of the ship two different types of FBG sensor chains were used during the field tests. Firstly, a strain rosette, incorporating three FBG sensing elements, Figure 2. The rosette is an equilateral triangle, and the orientation of the three sensors of the strain rosette differs by 60°. Hence with this layout it is possible to determine the magnitude and direction of the principal strain. However, with one strain rosette these values can only be determined on one location.

In order to determine the strain distribution a secondary buffered FBG chain incorporating 13 FBG elements on the original Smyril tests conducted in 2017 and 2018, and 10 on all the more recent tests, Figure 3, were used. One of the sensors is loosely embedded in the chain and acts as temperature sensor, used for compensation measurements whilst the other 12 or 9 are rigidly embedded and capture the strain of the hull. The FBG chains were laid out in a meander shape glued on the inside of the ship's hull with sensors laid in the horizontal and vertical directions. Both the strain rosette and the secondary buffered FBG chain were installed on the inside of the hull of the ships in the engine room.

Figure 2. A strain rosette incorporating three FBG sensing elements [15].

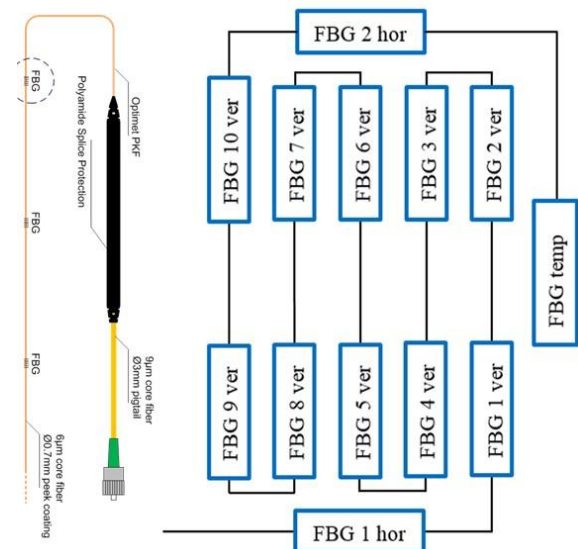

Figure 3. A secondary buffered FBG chain incorporating 1 temperature FBG sensor and 12 strain FBG element [15] positioned in both horizontal and vertical orientation.

### 3 FIELD TESTS

Five vessels were experimented upon, these being

- Smyril passenger ferry, operated by SSL (A 135m long passenger and vehicle ship, data were gathered before and after repairs were made to a flange)
- Jákup Sverri research vessel, operated by Havstovan (55m long research ship)
- Krosstindur, a fish farm vessel operated by Luna (15m long service vessel, we gathered FBG data before and after a new engine was installed)
- Samson, tugboat operated by MEST
- Gadus, a large fishing trawler owned by JFK (88.1 long ship with vibrations detected at high speeds)

The tests were conducted, where possible, under different conditions i.e. main engine on/off, propellor running/stationary, low speed passage and high-speed passage. The various parameters helped to identify the sources of the various vibrations detected using the FBG system. The data from Gadus, Smyril and Jákup Sverri were gathered whilst the ships were operational at sea, whilst the other vessels were gathered in and around the harbour areas but being able to vary the speeds and when the engines were switched on and off.

The sensors come in a number of different formats. They are glued onto a very clean surface on the body of the ship, such as the inside of the hull. The surface of the hull is thoroughly cleaned of grease using alcohol-based products, and the surface is also rubbed with sandpaper in order to create a good surface for the glue to work on. We used a rosette sensor, that incorporates three sensors in an equilateral triangle shaped housing, as well as a chain of 10 sensors. Figure 4 illustrates a rosette (left) and chain (right). Both cost around 1000 euros. However, the rosette is far easier and quicker to install, and the three measurements are at 60° to each other, whereas the chain takes 10 measurements, and each individual sensor along the chain are 1m apart, so it can cover a larger area. The chain also takes longer to install as each of the 10 sensors need to be attached individually using an epoxy resin glue.

Figure 4. Rosette sensor on the Gadus (left) and chain sensor on the Jákup Sverri (right).

Figure 5 illustrates the interrogator unit (left) and the software used to gather the data, showing the real time data from 13 FBG sensors on a chain located on the Smyril (right). The interrogator costs around 30,000 Euros, and this version

gathers data at a rate of 5 kHz. Up to four sensors can be attached to the interrogator unit at any one time. The approach that we have is to install a number of FBG sensors on a number of vessels, and rotate the interrogator unit between them.

Figure 5. The interrogator unit (left) and a screenshot of the software used to gather the data (right).

A test rig was used in order to assess the precision of the system as well as the various sensor types. This is a rotating motor, with weights attached to the drive wheel in order to cause vibrations. Figure 6 illustrates the test rig used on a bench test with a rosette FBG sensor and an FBG chain attached to the table.

The chain was co-located with the FBG in order to compare results, and a couple of the chain sensors located on the chair away from the vibrating table as a baseline.

Figure 6. The vibrating test rig during a bench test, with a FBG chain and FGB rosette located on the table.

Possible applications are as follows. Once an initial installation of the sensors is carried out, subsequent data

collection can be compared to the initial data and change detection in the frequency response of the structure can be determined. Such changes in frequency response can be down to several factors, such as damage to the ship, damage to the propellers, or gradual deterioration of the vessel.

## 4 RESULTS AND DISCUSSION

### 4.1 Smyril

The Smyril data was compared to historical data that we gathered in 2017 and 2018 using a similar system belonging to TU Graz. During the initial tests, a flange was damaged at the stern of the ship, and vibration could be felt throughout the ship. We can see this in the data from 2017 and 2018, Figures 7 and 8, and it being absent in the new data we gathered during this current project, Figure 9.

Figure 7. Waterfall and FFT plots from the tests conducted on Smyril in 2017.

The data from 2017 and 2018, Figures 7 and 8 respectively, illustrate the results showing more and noisier frequency characteristics than the more recent tests in 2023, Figure 9. This is especially true in the data in 2017 below 13Hz, Figure 7. The original setup consisted of a FBG rosette and a chain of 13 sensors glued to the inside of the ship's hull in the engine room. However, the connectors to the rosette had been cut off, for some reason sometime between the 2018 and 2023 tests, so this sensor couldn't be used in 2023. However, the FBG chain worked perfectly well. It is thought that the less frequency responses, and cleaner frequency characteristics are due to there being a broken flange at the rear of the vessel during the 2017 and 2018 tests.

Figure 8. Waterfall and FFT plots from the tests conducted on Smyril in 2018.

Figure 9. Waterfall and FFT plots from the tests conducted on Smyril in 2023.

#### 4.2 Krosstindur

Figure 10. The Krosstindur vessel.

The Krosstindur vessel, Figure 10, was suffering from vibration, and a new engine was installed with a lower vibration characteristic. Again, we gathered data before and after the engine was replaced, and we could see significant differences in the characteristics. More vibrations can be seen in Figure 11 (top) when the old engine was used, compared to the new engine, Figure 11 (bottom).

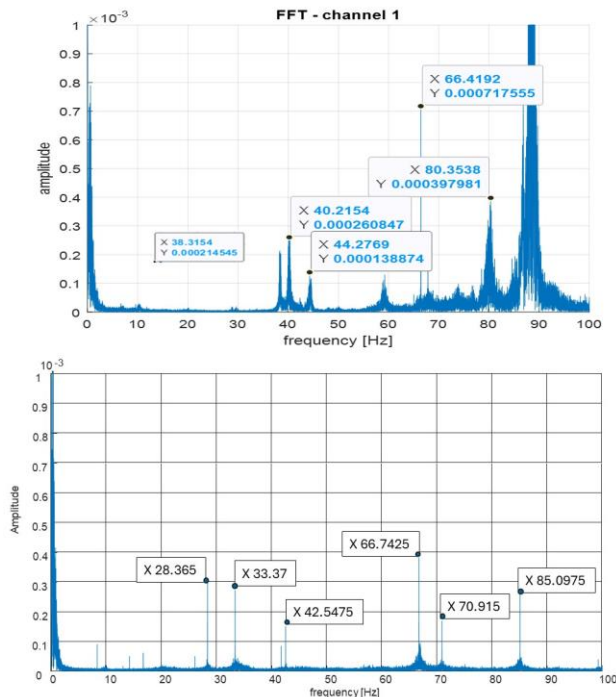

Figure 11. FFT results from the tests conducted on Krosstindur before (top) and after (bottom) the engine was replaced.

#### 4.3 Gadus

Gadus is a relatively new fishing trawler/factory. It is owned and operated by JFK. Rosette sensors were installed next to the rudder housing, Figure 12 (bottom), as well as in the bridge, Figure 12 (top right), and FBG chains were placed in the chief engineer's cabin, Figure 12 (top left), and in the engine room, Figure 12 (middle). The data were gathered during one of the ship tours in the Baren Sea. The interrogator spent periods of time attached to the various sensors during sailing and trawling, and notes were recorded of the ship speed, engine speed etc.

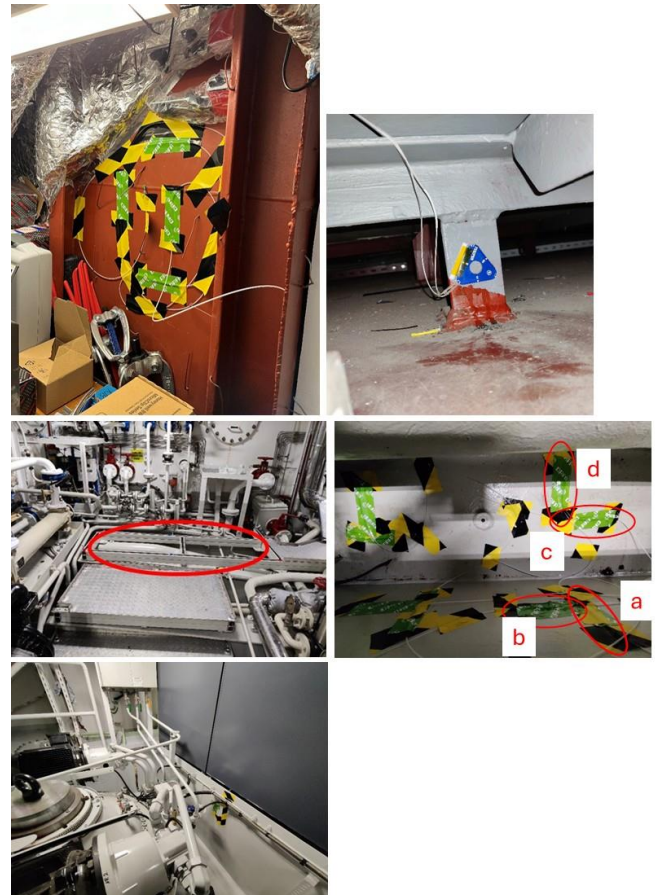

Figure 12. Sensor locations on the Gadus. FBG chain attached to a structural girder in the Chief Engineer's cabin (top left), Rosette attached to the structure in the bridge (top right), Engine room location of FBG chain (middle left) and the chain (middle right), Rosette located adjacent to the rudder (bottom).

Figure 13 illustrates a selection of FFT plots resulting from the FBG chain sensor in the engine room. All the results correspond to the same time series. The graphs show the FFT for the four locations, marked a-d in Figure 12 (middle right). It can be seen that there are different frequency response characteristics for the four locations, even though they are relatively close to each other. It is seen that the two horizontal results on the horizontal girder, a and b, show that there is a stronger vibration response in the bow to stern direction, and that the vertical girder results show that the vertical direction response has least vibration. All such responses have been shown to the chief engineer to help understand the vibration characteristics of the ship. These results illustrate that it is important to understand that the orientation of the sensor is important in order to measure specific frequencies.

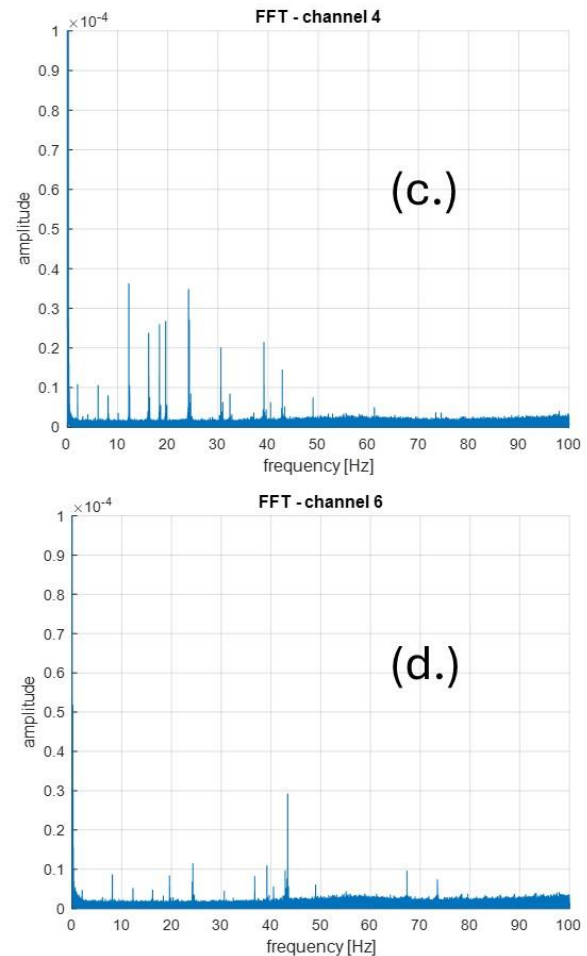

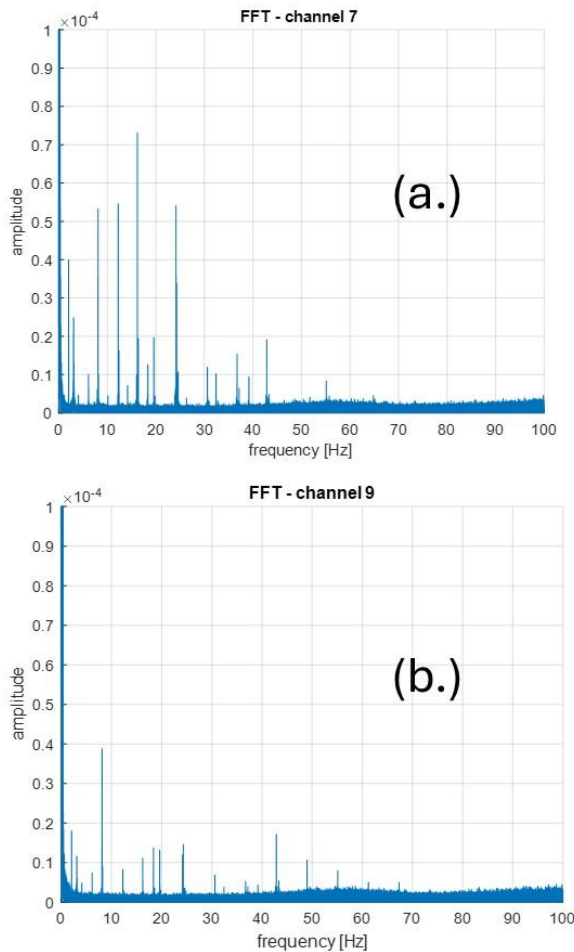

Figure 13. FFT results from the tests conducted on Gadus in the engine room. The graphs show the FFT response in the horizontal direction (stern to bow direction) on the horizontal girder (a.), the horizontal direction (port to starboard direction) on the horizontal girder (b.), the horizontal direction (port to starboard direction) on the vertical girder (c.), and the vertical direction on the vertical girder (left). Figure 12 (d.) a, b, c, d respectively.

Figure 13 (b.) illustrates the details of the FFT response at location b, Figure 12. The engine at this instance was operating at 735 RPM, and the propellor rotating at a speed of 122 RPM. The corresponding frequencies to these values are 12.25 Hz and 2.03 Hz respectively. These correspond well to the values of 12.24 Hz and 2.03 Hz in Figure 13 (b.). Further to this, the propellor has four blades, and  $4 \times 2.03$  Hz is equal to 8.1 Hz, again corresponding to the value of 8.1 Hz in Figure 13.

## 5 CONCLUSIONS

The paper outlines the field tests conducted using the FBG sensors to measure the frequency characteristics of ships. Two types of sensors are used, these being a FBG rosette and a FBG chain of 10 sensors. We can clearly detect changes in characteristics, as well as detecting the vibrations induced into the ship by various elements of the ship such as the engine and propellor.

The FBG sensors are relatively inexpensive, and can be installed on many vessels, then using a single interrogator to

gather data periodically, or when changes are thought to have occurred, in order to investigate any changes.

Gathering such data on a vessel can then be used as a blueprint to compare future data.

The measurements can be carried out at sea, so the vessel doesn't need to return to harbour, resulting in minimal down time in the vessel's activities.

Sudden changes due to damage or gradual changes due to deterioration can be detected.

## ACKNOWLEDGMENTS

The project was funded by the Research Council of the Faroe Islands, through the project (04589) HARMONISE - HeAlth and EnviRonmental MONItoring of Ships and Propellers.

The authors are also very grateful to the help of the staff at MEST, JFK, Luna, SSL and Havstovan for their help and assistance in obtaining access to the vessels and invaluable input to the project.

**ABSTRACT:** To reduce uncertainties associated with its structural re-assessment, the Zeeland Bridge in the Netherlands is currently the subject of a field lab, which will run for 2 years. In this contribution, the structural identification approach, the model updating concept and the first measurement campaign are presented, followed by some preliminary measurement results. The present stage focusses on load testing of the bridge to obtain insight into the possibly varying response in different spans of the bridge. Previously, parametric studies to expose input-output parameter dependencies were performed on a representative sub-system of the bridge, and the results are used to assist in the design of a measurement campaign and the development of a robust model updating strategy for the bridge. The results of the first measurements allow for evaluation of the actual performance of the bridge when subjected to heavy truck loads. This information will be used as a basis for further development of the updating approach.

**KEY WORDS:** Bridge monitoring; Structural identification; Concrete bridges.

## 1 INTRODUCTION

Bridges are vital infrastructure objects, with their availability critical for the operation of infrastructure networks. Many Western European bridges were built in the decades post WW-II, and therefore approach the end of their design lifetime. Depending on the function of a bridge and its location, loads may have substantially increased over the operational period due to increased traffic. Moreover, various time-dependent degradation processes may start to affect the state of a structure and therewith its safety. Examples of prestress loss related effects for prestressed concrete bridges are given in [1] and [2]. This necessitates structural reassessments of existing bridges in order to evaluate their structural reliability and remaining lifetime.

The models used for structural reassessments are developed based on design information, inspection results, and in some cases monitoring data. A key challenge in developing models for structural reassessments is uncertainty quantification. Bayesian techniques can be used to this end, combining data and expert knowledge to best estimate the actual state of a structure [7]-[10]. Where models are typically developed to predict the 'normal' structural response in the governing load scenarios, their results may not represent reality in cases where local deviations of structural response occur. Examples include bridges where the level of damage in for instance orthotropic steel decks varies significantly across spans, cable-stayed bridges suffering from damage concentrations in the deck structures at the location of specific cables, or concrete bridges showing regions with increased prestress losses. Response effects take place in such bridges, that seemingly result in load concentrations with locally increased damage potentials as a result. In such cases, tailored measurement campaigns might be needed to better understand the actual structural behavior.

In this contribution, the measurement strategy for the Zeeland bridge and a selection from the first measurement results are presented, followed by an outlook towards upcoming future measurements.

## 2 ZEELAND BRIDGE

The Zeeland bridge is a 5 km multi-span cantilever balanced prestressed concrete bridge, forming an important connection between the islands of Noord-Beveland and Schouwen-Duiveland in the Province of Zeeland in the Netherlands.

Figure 1. The Zeeland bridge in the local road network

The construction of the bridge was completed in 1964. The bridge spans are 95 m each, with a dowel connection at midspan connecting the two cantilever parts. Fig. 1 shows a picture of the bridge, with red ellipses indicating the locations of the dowel joints, the cantilevers, and

the foundations. These locations are related to the main sources of uncertainty in the bridge's load-response behavior, namely the forces transferred at the midspan joints (Fig. 2), shear stress levels in the cantilever, and foundation support stiffnesses.

Figure 2. The Zeeland bridge, showing the locations of main uncertainties.

Figure 3. Longitudinal cross section of the Zeeland bridge sliding (left) and fixed (right) mid span joints.

In essence, the outcome of a structural reassessment is determined by both structural resistance and internal forces. For specifically balanced cantilever prestress concrete bridges, prestress loss and concrete time-dependent effects (e.g. creep) may occur, resulting in ongoing deformations with a potential effect on resistance as well as on internal force distributions. The potential development of extreme load concentrations in cantilevers depend on the relative stiffness of the cantilevers and midspan joints, and foundation support stiffnesses. Prestress loss in these type of bridges materializes as deformations increasing over time and reductions in shear capacity. According to Borges [1], the level of ongoing deformations can vary substantially per bridge, and is a function of concrete properties, the construction process, and environmental effects. For the Zeeland bridge specifically, potential long-term differential behavior between cantilevers in combination with additional deformations in the foundation or subsoil may contribute to internal loads in the cantilevers as well. Visual inspection of the mid-span joints of the bridge revealed signs of ongoing deformation and permanent load transfer between cantilevers. On the resistance side, the reduction of shear capacity due to time-dependent effects has been estimated in the range 1-5% [1]. Internal force variations due to variable loads, however, can reach levels up to 20%. Adding to these variations the additional internal loads due to possible long-term differential behavior between cantilevers and additional deformation in the foundation or subsoil, it can be concluded that for the Zeeland bridge the uncertainty associated with extreme internal loads is larger than the uncertainty associated with the loss of resistance. As such, we first focus on the identification of the actual load-deformation behavior of the bridge. Estimation of the actual degree of prestress loss per span will not be possible based on measured deformations under operational loads [2]. For specific spans of concern, localized destructive or non-destructive

measurements may at a later stage be considered to further investigate the actual degree of prestress loss.

### 3 MODEL UPDATING FRAMEWORK

In our project we intend to develop a Bayesian Network (BN) based model updating strategy. The BN forms the statistical model covering the dependency structures between model parameters of interest and measurable response quantities. The BN will be developed based on both finite element simulation results and measurement data. Finite element simulation results are used as a basis for parameter dependency evaluation of structural properties (parameters) and load-response characteristics (measurands), for which one is referred to [3]. Measurement data is used to check and optimize the BN structure.

Challenges and limitations that are associated with increasing numbers of model updating parameters in Bayesian inference are known as the curse of dimensionality [4]. In order to deal with this we follow the concept presented in [6], by defining a sub-system as a basis for our structural identification problem. This approach allows us to limit the number of parameters in the identification problem and focus on local measurements for the updating of local sub-system models. The sub-system includes one full span, existing of two connected cantilevers and their two supports, and the balancing cantilevers of this span. The sub-system, including parameters of interest and possible measurement variables, is shown in Fig. 3. The sub-system parameters are the concrete effective stiffness in bending ( $E_{c,i}$ ), the mid-span joint vertical stiffness ( $k_{d,2,3}$ ), and the support rotational stiffnesses ( $k_{s,ij}$ ). The sub-system boundaries are set at the mid-span joints of the two outer cantilevers, and the load transfer at these locations is accounted for using a vertical model boundary spring ( $k_{bc,ij}$ ). The total sub-system length is 190 m. In Fig. 3, the system parameters are shown in (a), and the possible measurement quantities in (b).

Figure 4. Sub-system schematization

The data used for model updating of the sub-systems is load-response measurement data from load tests on the bridge. Displacement response of the bridge is measured in various ways, from which displacement influence lines are constructed. The combined information of the known load, known load

position and measured response quantities serves as input for the updating problem, and overcomes typical issues associated with operational variability.

#### 4 MEASUREMENT CAMPAIGN

As a first test to identify the structural behavior of the bridge, a load test with two 50 tonnes 6-axle trucks and a mobile measurement setup is performed. The objective of this test is to obtain insight in the possibly varying response in different spans of the bridge. The measurement setup during the load test consists of measurements of the displacements at midspan relative to the supports, and the relative displacements of both cantilever ends at mid-span.

Absolute displacements are measured during the load test using Koherent's radio-based displacement measurement technology [12] and laser displacement measurements using GeoLaser L72 systems [13], verified by tachymeter measurements at some of the test locations. The results of the Koherent measurements are not yet included in this paper, because of time limitations and challenges associated with cleaning this data from radio wave reflections caused by the test vehicles.

Midspan joint relative displacements are measured by custom built joint displacement measurement devices (Figure 6). These systems provide high precision relative displacement monitoring of the joints, aiming to identify the load position where the direction of force transfer in the joints reverses. This is an indicator of permanent load transfer across a joint.

Figure 5. Laser receiver at midspan joint location

Figure 6. Midspan joint custom displacement sensor

The monitoring systems are applied in a mobile setup during the first phase load-test campaign, repositioning the systems repetitively across multiple spans of the bridge during a bridge closure by night (Figure 7).

Figure 7. Multiple measurement locations in mobile load test setup

The load test is conducted by driving 1 and 2 trucks over a distance of 4 span lengths over the bridge at a speed of approximately 5 km/h. The setup with a load by both 1 and 2 trucks allows to evaluate the load level effect on the response. The 2 middle spans are equipped with the monitoring systems. By this means we generate influence lines of displacement response parameters for 2 spans.. This concept is illustrated by Figure 8. During 1 night a dataset consisting of load-response data for loads applied to 14 spans was obtained.

Figure 8. Mobile load test setup

## 5 PRELIMINARY MEASUREMENT RESULTS

### 5.1 Generation of response influence lines from measurement systems and GPS logging

The test trucks are equipped with the Witteveen+Bos GeoSaFence RTK-GPS tracking system. The GPS antennas are mounted on the outside top of the truck cabin, approximately above the first axle. Raw GPS measurement data comprises date and time and the location of the truck antenna in geographic coordinates (latitude and longitude in degrees). The positioning data are converted to geographic coordinates, and a coordinate transformation is applied to align the X-coordinate with the bridge's axis. Missing samples are filled by interpolation and the Rauch-Tung-Striebal Kalman Filter is applied to smoothen the positions and remove spurious jumps in the positions which occur during some of the runs. The result maps the bridge responses measured as function of time to the associated truck position on the bridge.

### 5.2 Laser based displacement influence lines

Laser measurements are performed to track the total displacements of the midspan joint relative to the adjacent pier at which the laser transmitter was positioned (see Figure 6). Figure 9 illustrates the laser measurement results for a single test run. The total displacement at midspan corresponded well with the model predictions. Displacements at the sliding joints are 10 to 30 % larger than the displacements at the fixed joints (Figure 3). Two trucks in convoy caused 10 to 20 % larger displacements than a single truck passage. It is interesting to note that displacements did not diminish to zero for trucks moving outside the test area: behavior was observed where the bridge deformations at some point do not seem to change with the truck position anymore, but rather some form of residual deformation remains. Possibly the trucks are not completely out of the zone where they influence the measurements, or time-dependent effects may be associated with the dampers present

in some midspan joints or effects in the soil-structure interaction response of the piers. All such effects may contribute to the observed behavior where displacements at the end of a test run did not return to zero.

Laser receiver E, positioned 1 full span away from the transmitter, was meant as a reference receiver, allowing for correction of measured displacements for support rotations. Rotation of the pier where the laser transmitter is positioned is observed from this receiver. In Figure 9 the blue curve represents the reference receiver positioned at pier 17. A vertical displacement of  $\pm 1$  mm are recorded by this receiver, for the truck moving backwards from pier 18 to pier 14. The data shows how the total midspan displacement consists of a bending component of the cantilever beam and a vertical displacement component associated with pier 'support' rotation, the latter being one order of magnitude smaller. The fact that the vertical displacement influence line for this reference receiver extends over a distance of 4 spans implies that the recorded vertical displacement in fact represents a rotation of the support where the laser transmitter is placed for this stage, and not an actual vertical deformation of the support where this receiver is positioned.

Figure 9. Total vertical displacements of midspan joints 15-16 and 16-17, and reference pier 17, measured by GeoLaser with transmitter positioned at pier 16

Evaluating the performance of the GeoLaser system, we conclude that the technology did perform quite well. The lasers' distance range was specified to be 100 m maximum. The 50 m measurements at the nearest midspan joints did generally perform well. The laser transmitter and receivers' glass screens however suffered from foggy circumstances during some measurement stages and runs, causing the reference receiver measurement to not be successful. For the adverse foggy conditions encountered during the test night the 100 m is concluded to be very much at the limit.

### 5.3 Joint deformation influence lines

The sliding and fixed joints depicted in Figure 2 are used in the Zeeland bridge in different configurations.. Going from North to South for pier 8 to 23 there are alternating sliding and fixed joints. This implies that this part of the bridge consists of sets of 2 coupled piers with balanced cantilevers forming a frame, having in the center a fixed dowel connection, and connected to the next part at the midspans of the outer cantilevers by sliding dowel connections. From pier 23 to 33 the pattern is different and all midspan joints are sliding joints. Figure 10 and Figure 11 show the joint relative displacements for joints 11-12 and 12-13 and for joints 15-16 and 16-17. Joints 11-12 and 15-16 are both sliding joints and 12-13 and 16-17 are fixed joints. In these figures the joint relative displacements at measurement location B and D (Figure 8), on both the East and West side of the bridge are presented.

Figure 10. Joint displacements of joint 11-12 and joint 12-13

The different joint configuration affects both the total vertical displacements measured by the laser receivers and the joint relative displacements. Clearly, very different vertical relative displacement response is observed. Where in the first figure a more gradual increase of vertical joint displacements is recorded, the second figure shows more abrupt displacements when the truck is approaching and when the axles are passing the sliding joint. Also it is clear that the joint relative displacement sensors at joint 15-16 (B\_West and B\_East) do already record substantial negative vertical displacement when the test truck is still at joint 16-17, i.e. one span away from the sliding joint. This behavior deviates from the typical behavior observed at all the other measured spans (e.g. Figure 10). Apparently some displacement allowance is present in this joint which is mobilized by the test truck when it is on the center of the next span. Further research is ongoing to explain the locally deviating behavior around piers 14 to 16.

Figure 11. Joint displacements of joint 15-16 and joint 16-17

It is interesting to note that, as observed for the total displacements measured by the laser, residual displacements are present in the joints at the end of test runs. A certain degree of ‘memory’ seems to be present in the bridge system when it is subjected to heavy truck loads. It could not be established from the data which physical mechanisms causes this typical behavior. This will be further investigated in the upcoming phase.

From the figures it can also be observed that the fixed joint, where the two cantilevers are tied together with prestressed 32 mm steel bars, still show some vertical horizontal displacement allowance of approximately 0.5 mm. Vertical displacements for this joint configuration are limited to tens of millimeters. This is interesting because the same cast iron dowels are present at all joints, also the sliding joints where larger displacements are measured. This implies that the fixation point seems to take over the load transfer from the dowel at the fixed joints, which is an important insight from the perspective of load introduction in the concrete structure.

The part of the bridge with a joint configuration consisting of only sliding joints shows different behavior (Figure 12). The total vertical joint relative displacements are somewhat larger compared to the bridge part with alternating fixed-sliding joints. Horizontal joint relative displacements are much larger as well, up to 10 mm relative displacement amplitude, and shows, for both measured joints, a more or less symmetric response for the truck positioned at either side of the joint. The distance over which the joint relative displacement influence lines show substantial displacement is longer for the part of the bridge with only sliding joints. Especially the vertical joint displacement influence lines show comparable levels of relative joint displacement when the truck axles are passing the measured joint and when the truck is at midspan of adjacent spans.

The system of balanced cantilevers coupled by only sliding joints behaves much more like a continuous chain of rigid rotating elements. Relatively large horizontal compared to vertical displacements indicate the relevance of global rotation of the bridge superstructure and the need for modelling of the degrees of freedom at the supports. These need to be properly accounted for in models. The freestanding height of the foundation piles is around 15 m, which means that the characteristic of the substructure supporting the superstructure is determined by bending of foundation piles and soil-structure interaction of the bridge substructure and foundations. Both need to be integrated into lumped support springs in the model. The data of combined horizontal and vertical measured displacement allows to calibrate the model support characteristics.

Figure 12. Joint displacements of joint 27-28 and joint 28-29

## 6 OUTLOOK TO UPCOMING MEASUREMENTS

The measurement results from the first tests have revealed interesting variations in the deformation response of certain cantilevers and spans, relative to others. These can be indicators for load concentrations in specific spans. In the next measurement campaign we will measure concrete stresses in the bridge indirectly by means of smart aggregates technology developed by TU Delft. These are installed in the box girder floor near 2 supports (locations indicated by  $\sigma_{xx,I}$  in Figure 4), which is in the compression zone of the cantilever gross cross section. Moreover, the mobile displacement measurements with laser and the custom joint sensors will be repeated at more spans to obtain a larger dataset and obtain insight in the response of more spans.

## 7 DISCUSSION

Load-deformation response is investigated for the Zeeland bridge to form a basis for full structural identification of the bridge. This paper builds on the previous paper [3] that introduced the model updating strategy for bridge structural identification. In the previous paper parameter dependencies between structural properties (parameters) and load-response characteristics (measurands) were investigated. The first phase measurement results that are now available form a basis for model updating of the sub-system models. However, given the quite different behaviour observed for the different spans one could question whether the model updating parameters set beforehand suffice to cover this spread in the observed behaviour. The measurement data indicates different ‘states’ of the sub-systems in terms of their neutral state, affecting their load-response behaviour when loaded by heavy test vehicles. It needs to be evaluated further how dependencies between input and output variables can contribute to the identification of the root cause or underlying mechanism that causes different behaviour of the spans. This will be one of the main topics considered in the upcoming phase of the project. Additional parameters that represent such different states might need to be added to the problem. In the upcoming phase it will be investigated how and through which parameters we can best represent the actual state in the updating problem formulation.

## 8 CONCLUSIONS

The present paper introduced the Zeeland bridge field lab and research project as well as an initial measurement campaign and the obtained load testing results. Structural re-assessment of the bridge requires a reduction of the uncertainty associated with internal forces in the bridge structure. The research project involves the development of a modular model updating approach for structural identification, based on load-response evaluation of sub-systems. Load-response influence lines constructed from measurement data are collected during the load tests with a mobile measurement setup. The developed mobile measurement setup performed well for the purpose of structural identification of the load-response behaviour. The total vertical displacements measured with lasers and the joint relative displacements measured with custom joint deformation monitoring systems were successful. It is concluded from the first phase measurement results that different spans exhibit different load-response behaviour. Differences in observed behavior can partially be assigned to different joint configurations across the bridge, but could possibly also be associated with a different ‘neutral’ state of the spans of this 5 km long multi-span bridge. In the upcoming phase of the project, this will be further investigated from both a theoretical (finite element model based) and experimental perspective (additional, more expensive measurements).

## ACKNOWLEDGEMENTS

The authors acknowledge the Dutch Ministry of Water and Infrastructure and the Dutch Provinces for their support to the ongoing research project on improvement of model updating strategies for structural reassessment. Especially we would like to acknowledge the Province of Zeeland for their contribution to this research for the Zeeland bridge and the commitment of their team when performing the first phase measurement campaigns.

**ABSTRACT:** Scotiabank Saddledome, an indoor arena in Calgary, Alberta, constructed in 1983 with a hyperbolic paraboloid (saddle shaped) roof, has concave cables running in the east west direction to support gravity loads and convex cables in the north-south direction to support lateral loads. The stranded cables, encased in concrete and anchored into a ring beam, are not visible to detect the signs of corrosion. Events held in the arena require suspension of entertainment loads from the roof structure which, when coupled with snow loads, pose a major safety concern.

The installation of an acoustic monitoring system in 1999 to detect breaks in cable strands did not perform as intended. In 2014 the roof membrane was damaged by a significant hailstorm exposing concrete to moisture infiltration. In 2022, a Building Condition Assessment of the roof recommended further investigation of the bonded cable system.

Learning from strand failures at the Arizona Veterans Memorial Coliseum resulting in costly remediation work, a Structural Health Monitoring (SHM) system with strategically mounted sensors and a laser-based deflection measuring device, was implemented in July 2023. The objective of this SHM program is to collect data on monitoring parameters for roof movements continually over a period of 3 years in order to identify trends and implement an active alarm system based on data collected in the first year.

This paper presents the field application of SHM for risk management of a complex roof structure.

**KEY WORDS:** Hyperbolic paraboloid roof; Monitoring program; Parameters; Loads; Cables; Risk management; Analysis

### 1 INTRODUCTION

The Scotiabank Saddledome is a multi-use indoor arena located in Calgary, Alberta, Canada. Partnered with the City of Calgary, Calgary Sports and Entertainment Corporation (CSEC) maintains and operates the facility. The Saddledome was constructed in 1983 with a complex hyperbolic paraboloid (saddle) shaped roof. The arena hosts numerous events throughout the year requiring the suspension of entertainment loads from the roof structure. Event loads in combination with heavy snow loads during winter months lead to deformation of the roof structure. The roof structure's safety performance is correlated with the condition of its constituting components. As the facility ages and deteriorates reliable methods are needed to assess the overall condition of the structure.

Figure 1. Scotiabank Saddledome<sup>1</sup>

A Structural Health Monitoring (SHM) system was installed on the underside of the roof structure in July 2023 to monitor deflection and movement at key locations. The system sends an email alert when deflection at any of the key locations exceeds its preset threshold. In addition, the system detects changes in vibration characteristics which could indicate strand failure. This allows the condition of the roof structure to be monitored continually to manage risk while minimizing exploratory destructive testing and interruptions to the daily operation of the facility.

### 2 SADDLEDOME ROOF STRUCTURE

The roof of the Saddledome is a complex structure consisting of sagging (concave) cables running in the east-west direction to support gravity loads on the roof and hogging (convex) cables running in the north-south direction to support lateral loads on the roof. The cables are anchored into a ring beam around the perimeter of the roof, which is supported on thirty-two bearings, four of which are fixed A-frames at the low ends of the saddle. The sagging cables are spaced at 6 m on center and consist of two cables with twelve stainless steel strands each. The sagging cables in the center of the roof supporting the scoreboard consist of fifteen strands. The hogging cables consist of nineteen strands and are also spaced at 6 m on center. Precast panels are supported by intersecting cables to form the roof surface, as shown in Figure 2. Lightweight concrete was poured between the precast panels to encase the strands in concrete and form the ribs of the roof as shown in Figure 3. In addition to the bonded sagging and hogging cables, six unbonded post-tensioned strands are located within the ribs. These cables were most critical during construction and

contribute minimally to the roof's capacity. A catwalk system, scoreboard, and other rigging for event loading are suspended from the main cable system. Entertainment and concert events can impose up to 22,700 kg (50,000 lbs) of load on the roof.

Figure 2. Sagging and Hogging Cables<sup>2</sup>

Figure 3. View of Embedded Cables in a Typical Rib<sup>3</sup>

The main risk to this type of roof structure is deterioration of the anchor connections at the ring beam or the loss of tension in the cables. Moisture infiltration at the anchor connection can result in corrosion of the anchor plate or cable strands. Loss of tension in the cables can occur if one or more strands were to break. The load would be redistributed to the remaining strands increasing and possibly exceeding their tensile stress. There are 4 main causes of strand failure:

- **Overloading of the structure**  
If the load imposed on the structure exceeds the design load the strands can become overstressed and fail.
- **Physical damage**  
During the life of a building new equipment may be installed requiring drilling or coring into the concrete. This can potentially cut or damage the strands.
- **Friction and wear**  
At the points where the cables cross, if a bearing pad is not present, the cables can rub against each other as the structure deflects under load or expands and contracts with changes in temperature. This cyclical rubbing can wear the strands down causing them to break.
- **Corrosion**  
The most common cause of strand failure is due to corrosion of the strand from moisture infiltration into the concrete or moisture build-up in void spaces.

### 3 CONDITION ASSESSMENT OF THE ROOF STRUCTURE

#### 3.1 Experience from Similar Structure

The Arizona Veteran's Memorial Coliseum, located in Phoenix Arizona, has a similar hyperbolic paraboloid shaped roof structure consisting of a grid of post-tensioned cables tied into a compression ring supporting precast roof panels. In 2006 a dip in the roof was discovered and further investigation revealed eleven cables had failed, one due to corrosion from past roof leaks and the others due to overloading. Costly emergency repairs were undertaken to replace the failed end anchorages. From the engineering team involved with the repairs it was understood that various non-destructive testing options to assess the condition of the cables were inconclusive. However, the change in shape of the roof surface was a sign that a loss of tension in the cables may have occurred.

#### 3.2 Saddledome Structural Assessment History

The Saddledome roof has experienced deterioration over the years. In 1999 an acoustic monitoring system was installed in the facility to record potential strand breaks. Since the system was installed, nine potential strand breaks were detected, four of which were in the sagging cables. In 2018 an unbonded post-tensioned strand failed and erupted through the concrete panel at the bottom of the rib where a void in the concrete had formed during construction. This event was not detected by the acoustic monitoring system. It was found that the wi-fi system in the building was interfering with the monitoring system and the event was not recorded.

In 2014 a significant hailstorm damaged the roof membrane exposing the system to moisture infiltration. Due to the strands being encased in concrete the condition of the strands could not be determined through visual assessment.

In 2020 a consultant was engaged to complete a condition assessment of the cable anchors and cable system. The cable anchors were assessed from the roof and found in good condition<sup>4</sup>. Ground Penetrating Radar (GPR) scanning was completed from the roof surface to assess the cables and locate other void spaces in the ribs that may be present however, due to the depth of the concrete and concentration of material in the ribs the results were inconclusive. Completing scanning from below was also challenging due to the access issues. Five locations were then selected to remove the concrete from the underside and expose the cables for visual assessment and penetration testing (two at the midspan of the sagging cables near the center of the building where moisture was likely to collect and three near the perimeter). The cables were found to be in good condition with no corrosion or tension deficiencies<sup>5</sup>.

A Building Condition Assessment (BCA) of the Saddledome completed in 2022 recommended further investigation of the bonded cable system to better understand the condition of the roof structure<sup>6</sup>. Given the inconclusive results of non-destructive testing completed in the past and the challenges of accessing the underside of the roof structure, options for monitoring the roof structure were explored. A monitoring plan was established to measure the shape and movement of the roof on a continuous basis over the next 3 years. This allows the City of Calgary and CSEC to manage the safety risks associated

with the roof structure and better understand how the roof structure behaves under varying loading conditions.

#### 4 MONITORING PROGRAM AND FIELD IMPLEMENTATION

SHM Canada Consulting Limited (SHM Canada) was engaged by CSEC to design, install, and operate a comprehensive structural health monitoring system at Scotiabank Saddledome to provide data on the performance of the saddle-shaped roof on an ongoing basis. The automated structural health monitoring system was installed and commissioned in late July 2023. It is currently active and provides valuable information to help maintain structural integrity of the roof.

##### 4.1 Instrumentation and Plan

The Scotiabank Saddledome roof monitoring system consists of a combination of wired and wireless sensors. The arena roof is divided into three main monitoring zones: Zone-1, Zone-2, and Zone-3. These monitoring zones are equipped with a total of twelve vibrating-wire strain gauges, twelve reflective target prisms, twelve triaxial tiltmeters, and nine triaxial accelerometers:

- *Vibrating-wire strain gauges*

Installed on the roof soffit, these gauges measure strain-related changes in the post-tensioned concrete beam network. These strain gauges are equipped with integrated temperature sensors that detect changes in the internal temperature of the arena. They are connected via signal cables to a datalogging system with highspeed acquisition modules capable of capturing burst strain data based on the required trigger points. The strain gauges were calibrated and set at the mid-range to ensure a sufficient offset for measuring both compression and tensile strain. Six strain gauges are installed in the direction of the two central sagging concrete ribs, while the remaining strain gauges are installed in the direction of the two central hogging concrete ribs.

- *Surveying system with reflective prisms*

The wireless system consists of a total station with a precision of 1 mm + 1 ppm and two types of reflective prisms. The target reflective prisms are installed in the roof soffit and the reference reflective prisms are installed along the peripheral wall. The total station measures the current baseline elevation and the roof elevation to provide precise roof deflection in the targeted regions. Six target reflective prisms track changes in roof elevation at the high-to-high direction along the two central sagging cables. The remaining six prisms record elevation changes at the low-to-low ends along the two central hogging cables. The approximate locations of the target reflective prisms are shown in Figure 4.

- *Triaxial tiltmeters*

Installed on the roof soffit, the wireless triaxial tiltmeters measure angular changes in two directions: in-plane and out-of-plane. Similar to the target reflective prisms, the tiltmeters are placed along both the central sagging and hogging directions. They are positioned near the prisms to measure in-plane and out-of-plane angular movements caused by event-specific loading arrangements.

- *Triaxial accelerometers*

Mounted on the roof soffit, the wireless triaxial accelerometers measure the acceleration in three orthogonal directions. The accelerations are recorded based on the ambient and induced acceleration of the arena roof under regular and event-specific vibrations, impacts, and other dynamic forces. The accelerometers are capable of measuring trigger data depending on their preset threshold limits. Out of the nine accelerometers, five are placed near other monitoring sensors, and the remaining four accelerometers are positioned near the non-axis boundary. Figure 5 demonstrates the axis orientation of triaxial monitoring sensors.

Figure 4. Approximate Positioning of the Survey Prisms

Figure 5. Orientation of the Triaxial Sensors

The monitoring sensors - strain gauges, reflective prisms, and triaxial sensors (including tiltmeters and accelerometers) - are installed in clusters positioned at the midpoint of cross ribs to maintain symmetry along the axes of the arena roof. The specific configuration of each cluster varies, allowing for tailored monitoring that addresses different structural requirements across the roof. This setup systemically provides comparative monitoring data based on the roof profile, helping identify any unbalanced loading effects and anomalies developing in the roof's structural system.

##### 4.2 Implementation

Implementing an effective monitoring program can be a complex task, especially when faced with challenges inherent in the arena and its environment. Several factors can influence the design, implementation, and ongoing management of the monitoring program. A few notable challenges faced by SHM

Canada team during the implementation and management of this monitoring system include access for installing the monitoring sensors due to unique roof geometry, the height of the roof, existing electrical and electronic fixtures, and tight project timelines.

One of the pressing challenges during the installation of monitoring equipment was the complex roof configuration and other hard to access areas. The limited access points, the concave and convex nature of the roof geometry, combined with existing fixtures on the arena roof, created significant complications in positioning, installing, calibrating, and maintaining proper line-of-sight (for reflective prisms) of the sensors. In addition to the roof geometry, sensor installation on the roof soffit of a significant height presented a time-consuming process and required a team of specialized rope access professionals.

Figure 6. Typical Sensor Cluster

The Scotiabank Saddledome is considered the third busiest indoor arena in North America, hosting multiple professional

sports teams as well as a variety of concerts and events throughout the year. As a result, the timeline for implementing the monitoring system posed a significant challenge due to the need to avoid disruptions to the packed event calendar. The limited timeline and opportunities to install the monitoring systems, perform pre-commissioning tests, and commissioning a fully functioning monitoring system without interfering with the arena's operations were essential requirements.

Successfully addressing each of these obstacles required careful navigation and an understanding of each challenge to plan and prepare tailored solutions, ensuring the monitoring system provides accurate, reliable data without interfering with arena operations.

## 5 DATA ACQUISITION AND ANALYSIS

The Scotiabank Saddledome monitoring system collects four different types of SHM data: strain, deflection, tilt, and acceleration at varying acquisition rates. Therefore, data acquisition, communication, and management procedures depend on the capabilities and requirements of the different monitoring sensors. The unprocessed data from various sensors collected by data-logging systems is then transferred and stored in SHM Canada's server for reliability checks and further analysis.

Figure 7 illustrates a typical flow diagram for the Saddledome monitoring program protocol related to data collection, storage, and analysis. This diagram visually illustrates the steps, sequences, and decisions within the monitoring process. Data collected from strain gauges, target reflective prisms, and tiltmeters are processed both individually and collectively to identify data trends, establish relationships, and perform statistical analysis.

Figure 7. Data Acquisition and Analysis Process

The acceleration data is processed separately for peak-to-peak acceleration changes and spectral density analysis to understand the frequency response of the arena roof under ambient and excited conditions. The acceleration analysis helps to determine the overall performance and detect any significant changes in the dynamic behaviour of the arena roof.

Furthermore, the city of Calgary is known for its highly variable weather, often experiencing dramatic shifts in a single day. Located on the eastern slopes of the Canadian Rocky Mountains in Alberta, the city's proximity to the mountain system causes weather patterns to change quickly. During winter months, temperature can drop suddenly, while in the summer, warm spells can occur unexpectedly. Calgary "chinook" winds from the mountains, can raise temperatures by 20°C or more in a matter of hours, leading to a wide range of conditions throughout the year. Calgary's snowfall can be unpredictable, with snowstorms occurring any time during the winter months even as late as April. The city often experiences light and dry snow that accumulates rapidly but doesn't always accumulate for long. However, heavy snowfall can also occur, particularly in the winter and early spring.

Saddledome data analysis, therefore, integrates daily external weather data details (e.g., external temperature, snow on ground, rain, and wind) from the Environment Canada weather station near the Scotiabank Saddledome, along with different loading scenarios for major concerts and events hosted in the arena. This analysis protocol helps explore and incorporate all available internal and external factors that could influence the structural behavior of the arena roof.

The threshold limits are set based on the structure's age and history, combined with engineering judgment, allowing for a 10% increase or decrease over Year-1 recorded data. A notification system was implemented based on the established threshold limits to generate email alerts in the case of exceedance.

## 6 KEY MONITORING RESULTS AND DISCUSSION

This paper provides an overview of key monitoring results generated during the monitoring period from August 1, 2023, to January 31, 2025.

During this period, the Scotiabank Saddledome hosted a total of 51 major concerts and other events. This does not include minor events and other sporting events (such as hockey, lacrosse, skating etc.) The major events and concerts are indicated as vertical lines in Figure 8, 9, 10, 11, and 12. It is a well-established fact according to the National Building Code of Canada (NBCC) that the snow on ground data does not precisely represent actual snow accumulation on the arena roof. Actual snow accumulation on the arena roof and the nature of the accumulated snow plays a significant role in the roof's structural behavior. Due to limited information, the snow on ground data collected from the nearest weather station is integrated to provide context related to potential effects of heavy snow accumulation and snow drift. Any snowfall event is represented and incorporated by light-blue layers added in Figure 8, 9, 10, and 11.

The monitoring results presented as part of this study are referenced from their individual baseline readings and do not

account for preexisting conditions (strain, deflection, tilt) present on the arena roof. The sensor-specific data is primarily analyzed to understand the localized effects of changes related to the internal conditions inside the arena. In contrast, a comparative study of different types of sensors provides insights into the arena roof's structural performance based on both internal and external variations.

### 6.1 Strain

The strain gauges installed on the sagging concrete ribs primarily experience tensile forces, while those on the hogging concrete ribs experience compressive forces. Figure 8 presents differential strains in the most active strain gauges in both the sagging and hogging directions.

Figure 8. Strain Data from Different Zones

Analysis of the strain data revealed that the arena roof experiences event-specific changes in the strain levels both right before and after the events. These localized peak strain variations are primarily caused by the addition of event-specific mechanical and electrical fixture loads and their subsequent unloading from the arena roof. The strain levels are further increased due to snow accumulation and reduction in external temperatures. During these events, the internal temperature in the arena varied between 10°C and 22°C. The results also indicate that, during each scheduled event, the strain variations exhibited a similar pattern as the variation in the internal temperature inside the arena. The maximum tensile and compressive strain recorded by the strain gauge network is 148 µε and 140.5 µε, respectively against the threshold values of 110 µε and 150 µε. During this period, the absolute change in strain registered by a strain gauge was 230 µε.

### 6.2 Deflection

The deflection levels recorded by target reflective prisms are compared with prisms symmetrically positioned about the orthogonal axis of the dome to detect any unbalanced deflection conditions. The comparative differential deflection results showed some localized behavioral patterns. A steep increase in downward deflection is observed during the day of each scheduled event in the arena. When accompanied by snowfall events higher levels of deflection are recorded. Figure 9 provides an overview of comparative differential deflection results from three different zones.

Figure 9. Deflection Data from Different Zones

The prisms located within the central region of the roof experienced higher deflection levels compared to the rest of the prisms. This phenomenon can be directly attributed to the consistent and balanced loading from the Jumbotron digital display system. The peripheral prisms in the hogging direction encountered a sudden increase in deflection levels during each major event. These specific changes in deflection levels are the result of the additional suspended loading. The maximum upward and downward differential deflections recorded by the survey prism network were 39 mm and 216 mm, respectively against the threshold values of 50 mm and 195 mm. The central prism recorded a maximum change of 254 mm in overall roof deflection during this period. The upward movement of the arena roof occurred during the removal of the old Jumbotron and the installation of the new Jumbotron of similar weight. A few hours after lowering the Jumbotron to the arena floor, the central region of the arena roof lifted upwards by 39 mm. With the installation of the new jumbotron, the deflection levels at the central zone returned to their previous deflection levels.

### 6.3 Tilt

The tilt levels are compared with respect to the in-plane and out-of-plane axes of the sensors at their symmetrical positions to infer any unbalanced rotation and its magnitude. The peripheral tiltmeters in both sagging and hogging directions recorded the maximum in-plane rotations. Steep changes in both the in-plane and out-of-plane tilt directions were observed mainly during the scheduled events. The maximum in-plane rotation for both high-to-high (sagging) and low-to-low (hogging) directional tiltmeters were 0.36 and 0.19 degrees, respectively. The absolute rotational range recorded by both high-to-high and low-to-low directional tiltmeters are 0.40 and 0.28 degrees, respectively. Similar to strain and deflection, the tilt is also influenced by event and environmental loading. Apart from the in-plane rotation, the Zone-2 tiltmeters experienced noticeable out-of-plane rotation during scheduled events, with the maximum rotation recorded at about 0.1 degrees. These out-of-plane rotations have primarily occurred due to the additional suspended loading and unloading during scheduled events. Figure 10 demonstrates the in-plane rotation in both the sagging and hogging directional tiltmeters. All the central tiltmeters showed a similar level of rotation on both planes when compared to the peripheral tiltmeters due to the consistent presence of Jumbotron loading. Similar to the deflection behavior, during the replacement of the Jumbotron,

the tiltmeters recorded a reverse angular shift but regained their normal levels after installation of the new Jumbotron.

Figure 10. Tilt Data from Different Zones

### 6.4 Acceleration

The acceleration responses collected by triaxial accelerometers depending on two different acquisition modes: ambient and triggered, provided an understanding of the natural and induced frequency responses of the arena roof under different vibration levels and dynamic forces. The acceleration responses from different zonal accelerometers were analyzed using the Fast Fourier Transformation (FFT) and spectral density analysis. The peak frequencies were extracted and divided into four separate frequency bins based on their acquisition modes. Figure 11 presents the extracted ambient and induced frequency response from a Zone-2 accelerometer in the z-direction. Overall acceleration analysis showed that the natural frequency range of the arena roof is between 0 to 20 Hz. During an excited scenario, the frequency range of the arena roof lies primarily between 30 to 40 Hz.

Figure 11. Typical Frequency Response of Arena Roof

## 6.5 Data Envelope and Discussion

The data acquired from various monitoring parameters, as well as other internal and external factors, are integrated into the analysis program to provide a comprehensive and global understanding of the Scotiabank Saddledome's roof behaviour under both environmental and operational conditions.

The first year of the roof monitoring program at Scotiabank Saddledome helped SHM Canada understand the response of the arena roof, create a monitoring data envelope, and establish threshold limits for individual sensor groups based on their locations. These threshold limits are set to study the performance of this unique roof structure in the coming years. Figure 12 presents an overall monitoring data envelope based on the most active sensors in the system, with respect to external weather conditions.

The global analysis shows that the arena roof experiences significant thermal-induced stresses and deformations, irrespective of their source being of internal or external origin. The changes in the concrete ribs' strain, the overall deflection profile, and the tilt variation at different locations in the arena are primarily driven by the external weather conditions (such as external temperature and snowfall) as seen in figure 9 and figure 10. However, the steep changes in the monitoring data are attributed to the internal conditions (such as event-related loadings and internal temperature of the arena).

In the later months of the year, primarily during the colder months, the monitoring sensors recorded significant variations in their monitoring ranges. The relationship between monitoring data (e.g., strain, deflection, and tilt), and outside

temperature greatly influences changes in the roof components due to its unique shape and internal load positioning.

The sagging concrete ribs in the arena roof are primary load-carrying members, and the tensile strain data recorded by those sensors installed on the sagging ribs showed elevated levels of strain. This period coincided with the increase in deflection and tilt levels observed by the central prisms and peripheral tiltmeters, respectively. In contrast strain gauges and tilt meters installed on the hogging ribs showed lower levels of strain and tilt respectively.

This behaviour can be attributed to movement in the arena roof caused by the temporary stretching of the sagging concrete ribs, the downward displacement of the central roof area, and the compressing of the hogging concrete ribs. In late 2024, accumulated heavy snowfall and additional event loading caused several deflection sensors to exceed their assigned thresholds, including a downward movement of up to 216 mm observed between November 25 and December 5. Upon clearing the accumulated snow, the roof rebounded to within acceptable threshold limits, indicating its elastic response to the loading conditions. The monitoring data indicate that changes related to external weather conditions are time-dependent rather than sudden. Additionally, the data analysis revealed a noticeable time lag between external weather changes and the corresponding monitoring data, likely due to the low thermal conductivity of the insulated concrete structure.

Figure 12. Monitoring Data Envelope for Strain, Deflection, Tilt, Temperature, Snow on the Ground

Figure 13 presents a Pearson correlation table between external temperature and deflection data from various reflective target prisms. Correlation analyses of other monitoring parameters not presented in this paper (strain and tilt) also show a high degree of correlation with external temperature.

The weather starts getting colder in October and remains cold until April of the following year. During the same period, starting in December, the City of Calgary experiences snowfall, which continues until the end of April. During Year 1 of the monitoring period, from August 2023 to July 2024, Calgary's lowest recorded temperature was  $-37^{\circ}\text{C}$ , and the highest was  $34^{\circ}\text{C}$ . So far, during the current period of 2024-25, the temperature has ranged between  $-28^{\circ}\text{C}$  and  $31^{\circ}\text{C}$ . However, the snow on the ground data for the current period shows that the city recorded higher levels of snow on the ground for consecutive days compared to the previous year. Due to the height of the arena roof, combined with heavy winds and adverse weather conditions, the snow removal process from the arena roof can be challenging. This becomes an important factor to consider, particularly when it coincides with an ongoing scheduled event or a concert.

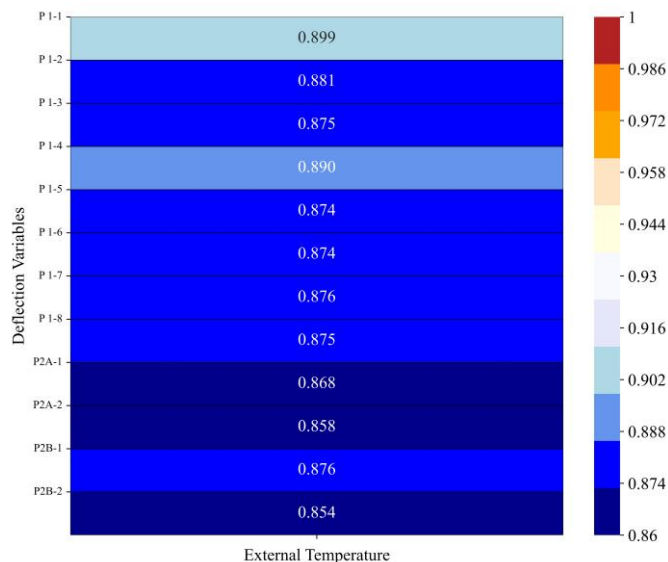

Figure 13. Relationship between Deflection and External Temperature

## 7 CONCLUSION

As asset owner, the City of Calgary is responsible for managing risk and ensuring safety of their assets. As the Scotiabank Saddledome ages the City of Calgary has taken proactive steps to assess the condition of the structure and mitigate potential risks. The monitoring program has provided CSEC and the City of Calgary valuable insight into the behavior of the roof structure under different loading conditions. It has ensured that necessary steps are taken to mitigate the risk of overloading the roof structure when environmental and entertainment loads are imposed on the roof. It has minimized the need to complete destructive exploratory assessments of the roof structure that are cost-prohibitive, disruptive to facility operations, and do not provide a thorough review of the system. In addition, the monitoring system has provided a method for identifying potential strand failures and thus reducing the risk of safety incidents. Structural Health Monitoring programs such as this

uphold the City of Calgary's commitment to engineering excellence, ensuring the highest standard of care in maintaining and operating its infrastructure.

Accounting for the effects of climate change, which is causing aggressive shifts in weather patterns, as well as the age of the arena and other contributing factors, the current monitoring program of Scotiabank Saddledome provides valuable insight into ensuring safety, functionality, and structural integrity, while also aiding in prolonging the lifespan of this iconic arena through proactive measures. Not only is it an important venue, but it also represents the pride, spirit, and cultural heritage of the City of Calgary.

## ACKNOWLEDGMENTS

Dennis Wipf with Gervasio and Associates provided valuable insights into the challenges and risks faced by the Arizona Veteran's Memorial Coliseum and methods for assessing and repairing a similar roof structure.

# Long-term monitoring and data processing of a continuous prestressed concrete bridge

Marc Savard, PhD, Eng., Jean-François Laflamme, MSc, Eng.

Direction de la gestion des structures, Ministère des Transports et de la Mobilité durable, Québec, Canada

email: marc.savard@transports.gouv.qc.ca, jean-francois.laflamme@transports.gouv.qc.ca

**ABSTRACT:** The Grand-Mère Bridge in the province of Québec, Canada, built in 1977, is a cast-in-place, segmental box-girder bridge measuring 285 m (935 ft) in length. Several problems arose during the construction of this bridge and an increasing deflection combined with localized cracking were noted after only a few months of operation. These defects were mainly due to insufficient prestressing, causing high tensile stresses in the deck and possible corrosion of the prestressing steel. A few years after strengthening of the bridge in 1992, a long-term monitoring program was implemented, including vibrating wire sensors (strain and crack sensors), inclinometers and temperature sensors. So far, more than 20 years of data have been collected and processed, leading to the recommendation of the rehabilitation of the structure using stay cables to ensure that the structure performs well until its scheduled replacement. This paper presents the instrumentation strategies, the various trends observed in the data and the relevant interpretations derived from them. In the context of damage detection, finite-element models have been developed and calibrated on measurements. Data indicate that the addition of stay cables eliminated the progression of permanent deflection and provided the structural system with added strength and redundancy. Lessons learned from this investigation are presented, along with a discussion of the conditions required for successful electronic monitoring.

**KEY WORDS:** Bridge monitoring; Bridge modeling; Data processing; Damage detection; Bridge rehabilitation.

## 1 INTRODUCTION

To manage all the structures under its responsibility, the Quebec Ministère des Transports et de la Mobilité durable (MTMD) has set up a periodic visual inspection program. The purpose of these inspections is to quickly detect defects that could reduce the strength of a structure or its durability. Defects that could jeopardize the safety of a structure are considered when assessing its theoretical load-bearing capacity.

Assessing the capacity of a concrete bridge is a complex task. It is very difficult to accurately assess the impact on capacity of a specific deterioration. The loss of capacity associated with a defect depends on its nature, location and extent. Moreover, the deterioration process evolves over time, often to the detriment of structural capacity.

The manager of a structure whose theoretical load-bearing capacity is inadequate can consider various approaches. Firstly, the structure can be reinforced or rebuilt in the very short term. Since financial resources are limited, this solution is only considered for structures with the most acute defects, or when the structure's reliability in the very short term is questionable. Secondly, restrictions on bridge exploitation may be imposed, for instance, reducing the number of lanes open to traffic or limiting maximum allowable loads. In the case of many highway bridges, restrictive measures are often unacceptable. The complete closure of a bridge is also unacceptable when no detour route can be considered or when the length of the detour is important.

When the reliability of a structure is questionable, it is possible, in some cases, to extend its useful life by placing it under electronic monitoring. One of the aims of such monitoring is to gather data that can be used to determine the rate of progression of the damage process. Monitoring may focus on structural properties such as equivalent stiffness, vibration frequencies or modal damping. It is also possible to

monitor the evolution of local parameters such as concrete crack width. Electronic monitoring can therefore be used to ascertain that the bridge is performing adequately under site-specific operating conditions.

Note that only slowly progressive failure modes can be properly monitored, and redundancy within the structural system is highly desirable, if not mandatory. In all cases where remote monitoring is being considered, the reliability of the structure must be ensured in the immediate future and cannot be adversely compromised by any subsequent worsening of the defects.

The Grand-Mère Bridge, in Québec, Canada, built in 1977 and measuring 285 m in length, consists of a three-span continuous prestressed concrete box girder of variable inertia. The central span is 181.4 m in length, while the two end spans are 39.6 m in length. Figure 1 shows an elevation view of the structure. At both ends of the three continuous spans and over one pier (at points B, D and E), roller supports have been chosen to allow the horizontal movement of the box girder. Pin supports are considered at the top of one pier (point C). Figure 2 illustrates cross-section geometry. Designed to limit deadweight stresses, this section depth variation does not meet current design recommendations regarding depth-to-length ratios. Another special feature of this bridge is that instead of prestressing cables, up to 216 longitudinal prestressing bars were distributed over tensioned portions of the box-girder cross section (mainly over the piers and at bottom of center span).

Figure 1. Elevation view of the bridge.

Figure 2. Cross-section geometry of the bridge.

Unfortunately, this bridge has experienced various problems resulting, among other factors, from many defects introduced during construction, such as poor quality of concrete between points B and C and the use of sleeves (joining end-to-end bars) that do not have the expected mechanical properties (many of them snapped). Also, the sheaths chosen were too tight around the prestressing bar, making grouting difficult. As a result, the prestressing bars are partially bonded to the surrounding concrete over undetermined portions of their length. Poor grouting can also lead to corrosion problems. The result of these defects is an asymmetric permanent stress distribution in the structure having a ballast at only one end of the bridge (instead of both ends, as initially designed) and additional compensating prestressing bars placed over pier C. In addition, as soon as the bridge was commissioned, a deflection at mid-span began to increase and shear cracking developed near the supports.

It has been recognized that many of the bridge's serviceability problems were due mainly to insufficient prestressing and limited knowledge at the time of design, especially regarding the estimation of creep and thermal stresses. While numerous studies showed that the short-term safety of the bridge was adequate, long-term integrity could be affected if short-term corrective measures were not taken [1]. Consequently, in 1992, the MTMD decided to strengthen the bridge by adding longitudinal prestressing cables in the box girder over piers C and D. Additional cables connected the bottom of the mid-span section of the bridge to the top of its ends. Since the deformation of the main span continued thereafter, a long-term monitoring program was initiated in 2001. The present paper briefly discusses a few of this program's findings, which led to the rehabilitation of the bridge using stay cables.

## 2 GENERAL CONSIDERATIONS FOR THE DESIGN OF THE BRIDGE'S STRUCTURAL HEALTH MONITORING SYSTEM

### 2.1 Overview

The design of an appropriate structural health monitoring (SHM) system must be tailored to the structure's behaviour under serviceability conditions. In the case of the Grand-Mère Bridge, in addition to its own weight, the dominant loads to which this structure is subjected are traffic loads and temperature variations. Traffic loads are transient loads acting over a short period of time, and fatigue problems associated with repeated loading cycles are not usually a concern for prestressed concrete bridges. Consequently, the bridge response under traffic loads is generally eliminated from long-term monitoring data. Thermal loads vary on daily and seasonal

basis and have a significant impact on the structure's behaviour. Therefore, assessment of the bridge's thermal response is mandatory prior to design and implementation of a suitable SHM program.

### 2.2 Bridge response to thermal loads

The internal temperature variation over the depth of a given cross-section can be broken down into three components: a mean value (TM), a linear vertical temperature gradient (GT) and a self-balancing non-linear component [2]. Given its nature, the latter component does not induce internal forces and global deformation of the structure. Therefore, the bridge response to thermal loads mainly results from variations of TM and GT. To perform data analysis such as linear regression, temperature sensors ought to be recorded simultaneously with measurements characterizing the bridge's response.

The following deformations occur in a structure subjected to temperature variations:

- The natural expansion and contraction of materials following a variation in the TM; these deformations are proportional and in phase with TM variations.
- The flexure strains induced by a thermal gradient GT.

Note that the presence of concrete cracks may lead to non-uniform thermal strain distribution along the structure.

As seen on Figure 2, the thickness of cross-section components is relatively uniform, varying from 279 mm to 381 mm, except for the bottom flange, which gradually increases from 229 mm at the centre to 1,370 mm at the piers. This infers a much greater thermal inertia near supports and a delay in the thermal response of thicker components.

In addition, the Grand-Mère Bridge is a complex hyperstatic structure having roller supports partially restrained that impede the free deformation of the structure. The partial restraint at the movable supports and the continuity of the spans above the piers at point C and D of Figure 1 give rise to additional thermal strains that may not be in phase with TM and GT variations.

Given the complexity of the bridge's thermal response, a finite element (FE) model has been developed (described at section 4) to predict its behaviour under specific loads. For instance, Figure 3 shows, schematically, the bridge deformation as predicted by the model of the Grand-Mère Bridge after a drop in the mean internal box girder temperature (TM). The restraint at roller supports generate axial tensile forces and associated positive strains. Consequently, sensor readings (such as extensometers or strain gauges) are expected to increase and are therefore out of phase with TM variations. In addition, as seen on Figure 3, a decrease in the TM also implies bending of the box girder and piers. Roller support restraint is responsible for these effects on the box girder. Pier bending causes a pair of horizontal forces (red arrows) acting in opposite directions at the bottom of the box girder and contributing to the lowering of the bridge profile. This pair of forces also induces axial tensile forces and bending moments in the girder. Depending on sensor location in the structure, the corresponding axial strains may or may not be in phase with TM variations.

Figure 3. Deformation (amplified) of the structure subjected to a drop in the mean temperature (TM) in the box girder.

Figure 4 presents the bridge profile predicted by the FE model of the Grand-Mère Bridge subjected to a thermal gradient (GT) developing in winter (corresponding to a cooling of top section fibres). The continuity of the spans above the piers causes non-uniform bending moments along the bridge and raising of the bridge centre. Depending on sensor location, the corresponding bending strains may or may not be in phase with GT variations. Also seen on Figure 4, a winter GT implies the bending of the piers and another pair of horizontal forces in opposite directions acting at the bottom of the box girder, which attenuates the raise of the centre of the central span. Note that these horizontal forces act in the same direction as those associated with a TM drop (as seen on Figure 3).

Figure 4. Deformation (amplified) of the structure subjected to a winter GT.

A third factor affecting bridge response to thermal variation is the lengthening or shortening of the piers. Figure 5 illustrates, schematically, the deformation of the box girder as the TM of the piers decreases, as observed in winter. As expected, the continuity of the spans gives rise to internal forces accompanying a drop in the centre of the main span and shortening of the top fibres along the entire length of the bridge. Note that temperature distribution across the width of a pier may not be uniform and might account for twisting movement of the box girder occurring over the piers.

Figure 5. Deformation (amplified) of the structure associated with a drop in mean temperature in both piers.

The Grand-Mère Bridge response to a specific profile of temperature variation is therefore the result of a combination of contributions that differ in importance from one another. The information provided by a numerical model enables a better understanding of bridge behaviour and the detection of possible damage processes.

### 2.3 Long-term effects

Among long-term effects that may affect this bridge, creep, shrinkage, prestress losses and concrete cracking are the main factors.

Creep, and to a lesser extent shrinkage, is a complex process that plays a major role in the gradual increase in deflection of such bridges [3]. Several models have been proposed in the literature [4] to predict the effects of creep over long periods of time. A suitable model ought to be adopted for long-term deflection and prestress losses predictions.

In prestress concrete members, prestress losses [2] can lead to cracking of fibres in tension, which may promote more prestress losses, water intrusion in the concrete mass and relaunch of creep. Passive steel rebars help control the development of cracks. Predicting crack location is difficult, and the possible addition of sensors must be anticipated when designing the monitoring system.

## 3 INSTRUMENTATION FOR THE STRUCTURAL HEALTH MONITORING OF THE BRIDGE

### 3.1 Objectives

The objectives of this SHM program were mainly to track the progression of mid-span vertical deflection and to collect information relevant to ongoing damage processes (mainly cracking, concrete delamination and spalling, corrosion, and breakage of steel tendons). As mentioned earlier, consideration of the evolution of these measurements helped in the management of the structure, to ensure user safety and bridge sustainability. During the more than 20 years of the monitoring campaign, sensors have been added, dictated by the necessity to validate and cross-check collected data, better understand bridge behaviour and detect initially unexpected progressive failure modes.

Considering the expected modes of failure of the Grand-Mère bridge and the selected structural health indicators, the SHM program features the following parameters.

### 3.2 Temperature measurement

Since the bridge profile and internal forces are strongly influenced by the vertical thermal gradient and the mean temperature, these parameters had to be recorded. In 2001, 24 resistance temperature detectors (RTDs) were installed at a cross-section located near the centre of the main span to measure internal temperature variations. Temperature sensors distributed over a section of the bridge allow for the calculation of the mean internal temperature as well as the thermal gradient (variation of internal temperature over the height of the section). Figure 6 presents TM and GT measured near the centre of the main span since 2001. Note the excellent performance of the monitoring system, which has experienced very few breakdowns over the past 24 years. As can be seen, GT is maximized in winter and TM and GT are almost perfectly out-of-phase.

Figure 6. Internal average temperature and thermal gradient.

### 3.3 Estimation of mid-span deflection and box-girder torsion using tiltmeters

To estimate vertical deflection of the main span, a total of 17 biaxial tiltmeters (sensors measuring rotation in both vertical planes) were used. Figure 7 shows the tiltmeter layout. These sensors were spaced approximately 15 m apart along the first two continuous spans. They were installed in the centre of the lower flange of the box girder. A numerical integration procedure ([7] and [8]) enables the estimation of the vertical deflection at each rotation measurement point. Measurements in the other vertical plan give indications on torsional behaviour of the box girder.

Figure 7. Tiltmeter layout and main cross-section identification.

### 3.4 Strain measurement

Thirty-two vibrating wire strain sensors located at the top and bottom of both webs allow the measurement of longitudinal strains at eight sections located in the central span at longitudinal coordinates 47, 70, 120, 125, 135, 140, 190 and 213 m. Figure 7 shows five of these sections. Figure 8 illustrates the layout of the vibrating wire sensors (VW\_i). Note that these sensors are set to zero when installed, so that only strain variations are measured.

Combining a realistic value of the concrete modulus of elasticity with four longitudinal strain measurements, the variation of the four internal forces present at a measuring section (axial force, two bending moments and distortion) can be estimated [5]. Note that these calculations are made using as-built section properties and measured elastic modulus is assumed constant over time. Also, given the small size of these sensors (125 mm in length), measurements are sensitive to cracks developing nearby. Therefore, care must be taken when interpreting the data. Localization of the neutral axis (NA) is useful in this respect.

Figure 8. Typical vibrating wire sensor layout.

### 3.5 Rotation and displacement at abutments and at the top of piers

Potentiometers were installed to measure the relative horizontal movement between the box girder and supports at points B, C,

D and E. Tiltmeters were also added at the top of piers at points C and D to capture pier bending. A clockwise rotation at top of piers is considered positive. These sensors aimed to assess support mobility, as discussed at section 2.2. These restraints have an impact on main span vertical deflection.

### 3.6 Telescopic extensometers

A total of eight telescopic extensometers were installed at different locations where cracks are expected in concrete. In the case of this bridge, the sensors were between 5 m and up to 6.5 m in length. These sensors measure total longitudinal displacement and axial strains occurring between their anchor points. Should a new crack (oriented generally perpendicular to sensors' axis) appear between sensor anchor points, the associated movement will be added up with the breathing of other existing cracks and the total movement will be captured by the sensors. The concrete thermal expansion response is also measured by these sensors, and only sensor thermal response is eliminated from the recordings.

Four extensometers were installed in the main span on top of the box girder close to each pier (Extensio\_44 Upstream and Extensio\_44 Downstream, Extensio\_216 Upstream and Extensio\_216 Downstream) as tension may develop in those areas prone to concrete cracks. Two other sensors were also installed outside at the bottom of the box girder near the centre of the central span (Extensio\_130 Upstream and Extensio\_130 Downstream), since cracks may also appear in that area. Figure 9 shows four extensometers, two that are 6.5 m long (Extensio\_216) and two that are 5 m in length (Extensio\_232 and Extensio\_239), the latter installed under the top slab of the side-span girder.

Figure 9. Telescopic extensometer layout.

## 4 FINITE ELEMENT MODEL

Concurrently with the SHM of the bridge, a numerical finite-element model of the crack-free structure has been developed to provide accurate estimates of expected behaviour under given load cases. Prestressing tendons were not explicitly included in the model, which means that total strain estimates are not available. However, concrete prestressing allows for the assumption of the linear and elastic behaviour of concrete, in both traction and compression areas. This assumption implies that under serviceability conditions, the largest compression stress in concrete shall never exceed 45% of concrete strength.

Moreover, prestressing forces are indirectly considered in the calibration process of the overall model. Calibration is done by adjusting the modulus of elasticity of different strategic structural components and the rigidity of the bearing devices. The objective of the calibration process is to have predicted vibration frequencies as close as possible to frequencies measured experimentally, in both bending and torsion. For instance, specific concrete properties have been established for certain portions of the webs, flanges and piers. Linear spring elements have been introduced to simulate actual support restraints. No rigidity is allocated for ballast weights.

The FE model has 48,830 nodes, 27,166 parabolic 20 noded brick elements for a total of 146,465 degrees of freedom. The piers have also been modelled (embedded at their base), since their flexibility significantly influences the overall behaviour of the structure, acting like elastic supports. Figure 10 presents a general view of the model, including the stay cables and the pylons that have been designed for the rehabilitation of the structure. Tensioning of all cables was completed in September 2022.

Figure 10. Isometric view of the rehabilitated bridge model.

## 5 DATA PROCESSING

This section presents some measurements gathered over the last 22 years with the various sensors presented above. A brief interpretation of the data is also provided.

### 5.1 Modal analysis and load tests

Modal analysis provides valuable information about the dynamic structural characteristics of a bridge. Recorded signals from accelerometers are analyzed and vibration frequencies and corresponding mode shapes are identified. A mode shape is a structural property that depends mainly on mass distribution and stiffness along the structure. Assuming mass remains constant over time, a change in the mode shapes or frequencies would indicate a change in rigidity resulting from cracks, concrete damage or changes to the support conditions.

A total of 12 modal analyses have been carried out at the Grand-Mère Bridge, the first one in fall 2003 and the last one in fall 2022. Since temperature affects support conditions and mode shapes, it is important to compare results under similar thermal conditions to detect damage or structural deficiencies. As reported by Cremona [6], measured frequencies may vary up to 5% for a 15°C (27°F) variation of the ambient temperature. Fall has been chosen for *in situ* modal analysis because thermal gradients are minimal during this season, thus limiting the effects of temperature on the behaviour of the structure. Vibrations have been measured under ambient traffic conditions.

Uniaxial and triaxial accelerometers individually connected to a data acquisition system have been distributed according to different schemes, for a total of 52 measuring points. The sampling frequency has been set at 200 Hz. In 2011, a wireless system was introduced, simplifying the data acquisition procedure. The location of the measuring points (schemes) has remained the same over the years. Representative results (flexural and torsional modes) of these modal analyses are gathered in Table 1.

Comparing the results for 2003 with those for 2021 at approximately the same internal temperature, a very slight decrease of the first seven frequencies of vibration is noted under normal traffic conditions. Those small variations may be caused by the thermal response of the structure, which affects

support conditions and internal forces, and are not necessarily the result of a damage process. In fact, the state of stress associated with thermal variations also depends on the weather conditions on the days preceding the *in-situ* modal analysis.

To assess seasonal temperature changes on the bridge behaviour, Figure 11 presents variations of the fundamental frequency of vibration (Flex.1 in Table 1) of the bridge along with TM as a function of time. The frequency is minimal in summer (approximately 1.02 Hz) and maximal in winter (around 1.07 Hz). Bridge response to thermal variations indicates that roller supports are partially restrained and incidental bridge internal forces have an influence on modal frequencies.

Structural rigidity has also been assessed through load testing. A total of eight load tests were performed in November of each of the following years: 2008, 2012, 2013, 2018 and each year thereafter until 2022. Load tests are intended to acquire data when the bridge is solely loaded by truck loads of known intensity. Generally, the loads consisted of semi-trailer trucks of about 40 tons each, for a total load never exceeding bridge service load. Measured data are used to validate the proper functioning of all sensors and provide valuable insight for FE model calibration.

The number of trucks and their relative position on the deck varied according to predefined load cases. Associated longitudinal and lateral force distribution in the structure can be established and bridge symmetry under symmetric loading conditions may be ascertained. The linearity of the bridge response under increasing loads is also verified and upon unloading, recordings indicate if the bridge returns to its initial profile. Detailed analysis of the test measurements showed that no significant changes in structural rigidity were detected from one year to the next, even with the seasonal support restraints above-mentioned.

Table 1. Measured frequencies [Hz] of some bridge's modes.

Modes	FE model estimates	Nov. 2003	June 2013	Nov. 2021
Mean temp.		1.5°C	20.4°C	1.0°C
Flex. 1	1,038	1,034	1,024	1,025
Flex. 2	2,177	2,134	2,117	2,124
Flex. 3	3,644	3,712	3,668	3,687
Tor. 1	4,625	4,665	4,605	4,639
Flex. 4	5,498	5,664	5,551	5,615
Tor. 2	6,794	7,102	6,966	7,056
Flex. 5	7,441	7,480	7,444	7,397

Figure 11. Variation of the fundamental frequency of vibration.

## 5.2 Tracking of roller support longitudinal movements and top of pier rotations

This section presents longitudinal movements recorded at each support. Figure 12 illustrates longitudinal support movement as a function of time. The dotted line added in many figures indicates when the stay cables have been tensioned. Very small relative movements are recorded at point C where a pin support is present. Maximum annual values are occurring in winter, as expected. Figure 13 shows top of piers rotations. Rotation recordings made at point C are the counterpart of those made at point D. Also, minimum rotation measurements at top of pier D occur in winter, as predicted by Figures 3 and 4.

Figure 12. Box-girder longitudinal displacement relative to top of piers.

Under similar thermal loads year after year, the annual longitudinal displacement range decreases gradually from 2018 to 2022 (Figure 12), while top of pier rotation range is also decreasing (Figure 13). Measurements are linked together, and this result is in line with the gradual increase of mid-span deflection.

Figure 13. Top of piers rotation.

## 5.3 Tracking of mid-span deflection

Figure 14 shows mid-span daily average deflection as a function of time from November 2008, until February 2025. On the same figure, the blue dots represent bridge centre levelling and good agreement is observed.

Considering that temperature gradients have a greater influence on vertical deflection than average temperature, maximum mid-span deflection occurs early in winter. Regardless of creep, the annual deflection range is about 30 mm, close to the deflection caused by traffic serviceability loads (as confirmed by load tests). This result explains the significant variations that are observed in Figure 14, even with daily averages. This bridge is part of a freeway with an estimated average daily truck traffic of 1,600. The running average fit shown on the figure highlights the deflection trend over time.

Under similar thermal loads year after year, the mid-span deflection has been increasing since the sensors started recording. Furthermore, the process is accelerating.

Several factors have contributed to the increase in deflection at the centre of the bridge, including:

- concrete cracking under recurrent thermal loads and traffic loads.
- concrete shrinkage and creep.
- prestressing losses from steel relaxation, concrete long-term deformation, sleeve failure, bar corrosion, etc.

In addition to these phenomena, the bridge's response is influenced mainly by:

- the different thermal expansion coefficients of the various materials.
- the friction intrinsic to roller supports, which varies with temperature.
- the various thermal inertia of the structure's components (being a function of thickness and geometry).

Figure 14. Mid-span deflection over the last 16 years.

In addition, 32 external prestressing tendons added to reinforce the structure in 1992 are exposed to ambient temperature inside the box girder, unlike the internal prestressing tendons, which are embedded in concrete.

Ambient temperature in the box girder varies more rapidly than internal concrete temperature, and this fact justifies the multiple oscillations observed even on the running average display, and to the deflection which is not perfectly in phase with TM or GT.

As seen on Figure 14, the tensioning of the cable stays caused the observed rise at the centre of the central span. The centre continues to rise months after tensioning, indicating a probable subsequent creep recovery.

#### 5.4 Tracking the breathing of groups of cracks using telescopic extensometers

As mentioned above, a total of eight telescopic extensometers were installed at longitudinal coordinates (length of the extensometer is indicated in parenthesis): two at coordinate 44 (6.5 m), two at coordinate 130 (6.5 m), two at coordinate 216 (6.5 m), one at coordinate 232 (5 m) and 239 (5 m) metres from B axis (Figure 1).

Figure 15 presents maximum seasonal response predictions at different locations where telescopic extensometers have been installed. These predictions have been made using the calibrated crack-free FE model. Two support conditions have been considered, whether the roller at point D is free to move horizontally or is partially restrained. Having the reference temperature set at 15°C, the annual mean temperature varies from 15°C (from Figure 6, the maximum temperature is about 30°C) to -35°C (the minimum temperature is approximately -20°C). As seen on Figure 6, the annual GT varies from 9°C/m in winter to -12°C/m during the summer.

Predictions indicate that a restraint at roller of point D (dark colours) reduces the annual total range of expected measurements. Also, a negative value is expected in summer for all sensors on the central span, meaning that these minimums are out of phase with mean temperature. For sensors of the side span (sections 232 and 239), expected maximum and minimum are in phase with mean temperature when roller at point D is restrained. With a free roller at D, maximum and minimum are out of phase with mean temperature. Depending on the stiffness of the restraint at the roller, a change in the sign of the bending moment can be observed from the central span to the approach span.

Figures 16 and 17 show twelve years of data recorded from extensometers 44 and 216. A positive recording corresponds to an extension of the sensor and crack opening. Note that in this figure, all sensors record their maximum value in winter, when the deck shortens. The contrary is noted in summer. Similar observations can be made at section 130.

Figure 15. Maximum and minimum expected responses at five extensometer sections and different roller conditions.

Figure 16. Recordings by extensometers 216.

At sections 44 and 216, measurements are therefore out of phase with concrete mean internal temperature, as predicted in Figure 15. However, the annual range of 2.5 mm is larger than expected with a crack-free model of the structure. This result seems to indicate the presence of active cracks. Recall that when a crack occurs, strain energy is released locally and thermal deformations along the prestressing bar are no longer uniformly distributed. Therefore, cracks may be considered as strain concentrators and if a sensor overlapped some of them, measurements can be amplified, especially when prestressing bars are not fully grouted.

Furthermore, sensors 44 and 216 experienced a permanent drop of approximately 0.75 mm following tensioning of the stay cables in September 2022. This result combines compressive strains and crack closures, since compression is induced in that area by the stay cable tensioning.

Figure 17. Recordings by extensometers 44.

Contrary to what can be seen in Figures 16 and 17, Figure 18 shows recordings from sensors 232 and 239 that are in phase

with internal temperature variations. In that area, side-span predictions (Figure 15) made with the roller partially restrained are confirmed. However, the recorded annual measurement range shown in Figure 18 are much larger than the range expected with the crack-free model of the structure. Once again, active cracks may be present, and the compression resulting from cable stays tensioning induced permanent closing of these cracks, as shown on Figure 18.

As seen in Figure 18, Extenso\_232 captured a permanent crack opening of 0.5 mm from the beginning of summer 2020 to fall 2021. This expansion is apparently not sufficient to eliminate the prestressing effect (decompressing crack lips). Also, as the stay cables were tensioned, Extenso\_239 experienced a 0.75 mm shortening, which is in line with the negative bending moment expected in this portion of the rehabilitated bridge.

Once cracks are closed, additional compression in concrete induces a minute variation in extensometer response. In winter, the deck shortens (see Figure 3), and compression in concrete decreases up to a point where the cracks re-open. The opening (breathing) of these cracks is captured by the extensometers and the measurements are amplified accordingly, as shown in Figures 16, 17 and 18. It should be emphasized that total or partial horizontal restraint at point D is mandatory for such crack breathing. Mean temperature and thermal gradient are then contributing.

Also, it should be kept in mind that when cracks widen and concrete decompresses locally, the mechanical properties of the box girder at crack surroundings are locally modified and the axial and bending rigidities are significantly reduced. This may invalidate the estimate of local stress from strain measurements in the vicinity of cracks, as discussed later in this paper.

Figure 18. Recordings by extensometers 232 and 239.

### 5.5 Tracking of internal forces

In the case of the Grand-Mère Bridge, prestressing bars may be partially, if not fully, bonded to the surrounding concrete over most of their length. Consequently, the failure of a bar has generally a negligible effect upon vertical deflection and cannot be detected with strain sensors unless they are anchored close

to the failure. However, cracking and delamination of large portions of concrete may significantly affect the intensity and distribution of the forces within the structure. Therefore, to grasp the effects of concrete deterioration, internal forces can be good estimators. It should be emphasized that measured strains (and resulting calculated stresses) do not represent the total strain (including the permanent state), but rather the strain increase that occurred after the sensors were installed. Also, it should be kept in mind that the average elastic modulus of prestressed reinforced concrete may depend on local conditions such as cracks, delamination, corrosion, and other disorders.

Figure 19 shows the variation of bending moments computed at measuring sections 47 (near pier B), 70, 135 (near the centre), 190 and 213 (near pier D). As shown in that figure, although there were no significant permanent load variations, the bending moment gradually decreased at sections 47 and 70 between fall 2008 and summer 2022. At the opposite side of the main span, measurements at section 190 (the counterpart section) also decreased, while a surprisingly slight increase has been observed at section 213. At the centre of the main span, bending moments increased, as we expected them to. Meanwhile, less significant decreases have been observed at sections 120 and 140 (not shown on the figure). Note the large variations observed after the tensioning of the cable stays in September 2022. These measurements have been useful in confirming the adequacy of the cable stay arrangement.

Figure 19. Bending-moment variations over time.

In a defect-free structure, bending moments vary according to the vertical deflection at the centre. To validate this statement and give insight to possible damage detection, a regression analysis has been performed between average daily bending moment  $M_z$  at a given cross-section and mean daily deflection at the centre as the explanatory variable. Figure 20 presents mean daily  $M_z$  at cross-section 47 as a function of mean daily deflection at the centre. The coefficient of regression for this distribution is equal to 0.85. Predictions from the defect-free numerical model are also presented. The comparison with the predicted behaviour indicates that for a given vertical deflection, the associated bending moment at section 47 is larger than expected.

Figure 20. Bending-moment variations and predictions as a function of mid-span deflection.

The same regression analysis has been made with section 135 (near the centre) and section 213 (close to pier D). Figures 21 and 22 gather the results. At section 135, computed bending moments compare very well with predicted values, indicating that the bridge is behaving as expected under normal serviceability conditions. However, this is not the case at section 213 (Figure 22) where bending moments are not correlated with mid-span deflection (coefficient of regression for this distribution is less than 0.001). The comparison with the predictions (red line) makes this assessment apparent.

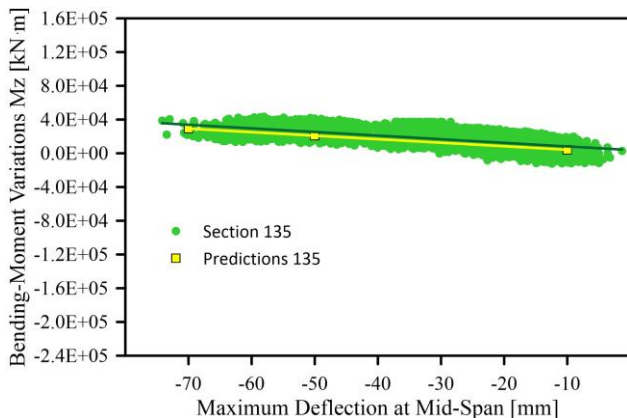

Figure 21. Bending moment variations and predictions as a function of mid-span deflection.

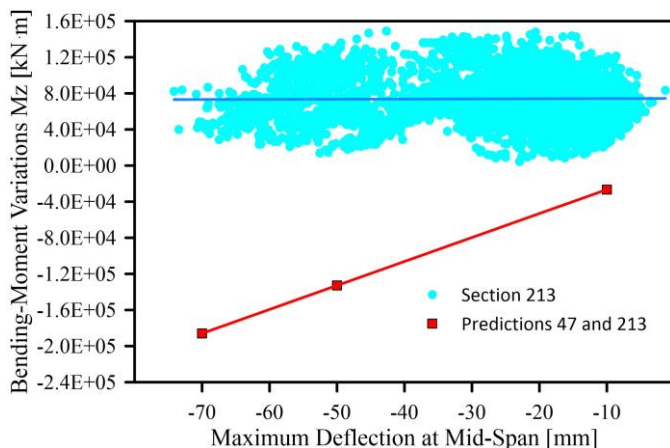

Figure 22. Bending moment variations and predictions as a function of mid-span deflection.

### 5.6 Tracking of mid-span box-girder torsional rotation

Figure 23 shows the recordings of the tiltmeter installed at the bridge centre, which measures box girder torsional rotation. A positive rotation is measured when the downstream web shifts downwards with respect to the upstream web, which may rise accordingly. In other words, a clockwise rotation around the bridge's longitudinal axis pointing east is assumed to be positive.

The data trend shown in Figure 23 indicates that girder torsional rotations are greatly correlated with internal temperature variations (the coefficient of regression being greater than 0.9). Also, an “event” may be noted around the end of April 2012, characterized by a rapid decrease of about  $0.012^\circ$  (from  $0.0055^\circ$  to  $-0.0065^\circ$ ) of the girder torsional rotation. Meanwhile, the internal temperature varies in the same way as in previous years. With permanent loads unchanged, this result suggests that structural damage took place, and the so-called event that occurred at the end of April 2012 may be the starting point of this apparent damage process. In fact, it can be shown that damage to a portion of a symmetrical cross-section (becoming unsymmetrical) induces such a torsional deformation. In Figure 19, the bending moment at section 213 became desynchronized from the bending moment at section 47 at approximately the same time.

Figure 23. Box-girder torsional rotation at mid-span.

## 6 CONCLUSIONS

The structure under investigation was monitored for many years before it was strengthened. *In-situ* modal analysis and controlled load tests were conducted and recorded data were used to calibrate a representative numerical model of the bridge. Insights from a numerical model greatly helped bridge behaviour understanding and eventual damage detection. The model, in conjunction with long-term monitoring data, allowed for the identification of the following findings:

- Under ambient traffic conditions, 12 modal analyses have been carried out between 2003 and 2022. No significant changes were detected for the frequency of the first seven modes of vibration. Frequencies varied according to

internal concrete temperature and the sudden slips that may occur at the roller as the bridge expands or contracts. The numerical model showed that the rollers at points B, D and E needs to be partially restrained to fits the measured frequencies.

- Free relative longitudinal movement was expected at the roller between the box girder and the top of D axis pier. Sensors showed that such movement was partially restrained, and that the piers bend according to internal temperature changes. The C axis pier is topped with pin bearings. Consequently, an horizontal force developed in the box girder between points C and D—compression in summer when the deck lengthens and traction in winter when the deck shortens. Incidentally, a permanent and progressive tilting was detected in these piers, a result that is in line with the observed permanent mid-span deflection.
- In addition to a slow and progressive permanent mid-span deflection, there was no unexpected or spontaneous sag increase over time. Creep and prestress losses were the dominant parameters contributing to the permanent sag of the main span.
- A permanent box-girder torsional rotation was detected at mid-span. Along with longitudinal stresses estimated at different sections along the deck, these observations revealed structural damage over the support at point D. Structural damage may take different forms, such as concrete cracking (accompanied by tension stress relaxation) or prestress loss (breaking of a tendon, loss of anchorage, corrosion), the latter being accompanied by compression stress relaxation.
- Telescopic extensometers were used to track the breathing of groups of cracks. Recorded data indicate that concrete in the vicinity of some cracks is decompressed when the temperature is low. In winter, the deck shortens and compression in concrete reduces up to a point where cracks widen. Crack openings are picked up by extensometers and the detected amplitude is larger than expected. The frozen bearings mentioned earlier are mandatory for this behaviour to occur, and residual prestressing forces are not sufficient to prevent crack breathing. Consequently, prestress loss causes a reduction of the structure's load-carrying capacity. Moreover, breathing cracks and concrete decompression cause larger stress cycles in prestressed tendons. This phenomenon promotes the premature failure of tendons, especially those located in the top flange, which is a corrosion-friendly environment (de-icing salts are spread on the roadway). Note that this diagnosis is achieved with no information on total applied stress, only with the help of long-term electronic monitoring data.
- The addition of cable stays was the solution chosen to strengthen the bridge. Since the cables have been tensioned, no progress has been observed in the damage processes of this structure.

Given the low relative stiffness offered by the stay-cable structure compared to that of the prestressed concrete box girder, this reinforcement:

- has little impact on the bridge's overall live load and thermal load responses (deflections, stress distribution and intensity, etc.).
- contributes to the bridge's structural redundancy, by enabling alternative load paths in the event of failure or excessive deformation of the box girder.
- introduces permanent stresses in the box girder that reduced the intensity of stresses caused by gravity loads, thus enabling some cracks to close and subsequent creep recovery.
- does not contribute to segment joint decompression, though new cracks were visually detected near the centre of the bridge.

Given the deficient design and erection problems affecting the strength and durability of this bridge, its reliability was questionable. Since the initial reinforcement of the structure, the electronic monitoring program presented has played a crucial role in managing this structure and keeping it in service for almost 50 years. The program has also enabled us to validate the structural effects induced by the reinforcement of the structure using stay cables.

## ACKNOWLEDGMENTS

The authors would like to express their sincere thanks to all of those involved in this project, namely, Mr. Mathieu Lacoste, Eng., Ms. Geneviève David, Eng., and Mr. Éric L'Heureux, Tech., colleagues at the mobile laboratory team of the Direction de la gestion des structures of the MTMD, as well as the many dedicated engineers and technicians at Maurice-Centre-du-Québec regional office who have been involved in the project since 2001.

# Smart Structural Health Monitoring with Acoustic Emission

Dr. Michael Häuserer<sup>1</sup>, Horst Trattnig<sup>1</sup>

<sup>1</sup>Vallen Systeme GmbH, Bürgermeister-Seidl-Strasse 8, 82515 Wolfratshausen, Germany  
email: info@vallen.de

## ABSTRACT:

It is common sense that civil infrastructure like tunnels or bridges are coming in age and needs to be renewed in the next years. These issues are, amongst others, related to massive increased traffic load nowadays compared to the time of construction and material issues which turned out after many years of operation. In concrete structures with tendons, the stress corrosion cracking of the used steel is one of the main issues and leads to tendon failure with significant impact on the stability of the structure. SHM with Acoustic Emission is used successfully for many years to detect tendon failures. The products on the market have been adapted since many years to the needs of the customers and the full measurement chain from a self-checking smart sensor network, high performance and scalable data acquisition systems to automate data analysis, processing and alarming is available. A cloud-based dashboard rounds up the package and makes processed data available for customers. Since May 2024 a guideline from DGZfP “Richtlinie SE 05 Detektion von Spanndrahtbrüchen mit Schallemissionsanalyse” is available and give a general frame about the approach, definitions and help to specify tenders in a correct way.

**KEY WORDS:** Acoustic Emission, Structural Health Monitoring, Smart AE sensors, Wire break detection, SE 05

## 1 INTRODUCTION

Acoustic emission (AE) testing is a well-established nondestructive testing method for pressure vessel, pipeline and tank inspection in industry [1]. Integrity, leakage and corrosion tests are in the focus. Apart from these applications, the demand increases for continuous monitoring of civil structures like bridges and tunnels. The civil infrastructure e.g. in Germany is coming in age and was mainly constructed 50 or more years ago. The structures face nowadays a much higher traffic load than at the time of planning and it turned out that some of the materials used, especially the steel for tendons, had not the predicted quality in the long term perspective. The tendons are facing the risk of stress corrosion cracking which can lead to a catastrophic collapse of the structure in the worst case. To ensure the availability of the structure, operators often choose various inspection and maintenance strategies. Therefore, acoustic emission (AE) can be an outstanding tool to support the operators. Davies [2], Nakasa [3], Allevato [1] and others have shown that acoustic emission is a suitable method for permanent monitoring applications. In the last years, the number of projects increased especially in Germany and more than 25 structures were equipped with Acoustic Emission to detect wire breaks. The time period of the projects varies between a few months to several years. To fulfill the requirements the Acoustic Emission hardware and software had been improved significantly to enable a continuous, reliable and available permanent monitoring of the structure.

Civil infrastructure like bridges and tunnels are mainly in public hand and the size of monitoring projects requires tender processes. The community in Germany developed over the last years a guideline as general frame about the approach, definitions and help to specify tenders in a correct way. The guideline “Richtlinie SE 05 Detektion von Spanndrahtbrüchen

mit Schallemissionsanalyse” from DGZfP is available since May 2024 [4].

## 2 ACOUSTIC EMISSION AND TENDON FAILURE DETECTION

Acoustic Emission (AE) is a well-established NDT Methode and has been applied for many years in various applications in the industry like pressure vessel testing or testing of above ground storage tanks. The “passive” character of AE makes the method suitable for permanent monitoring of the structures and to “listen” for tendon failures. The available AE equipment was mainly driven by the requirements of the above-mentioned industrial applications, and it was the starting point for further investigations to adapt the AE equipment to the needs of permanent monitoring of civil infrastructures like concrete bridges. Several publications are available on the detection and location of wire breaks by Acoustic Emission [7-8]. Investigations were carried out to identify suitable AE sensors to detect wire breaks in concrete. In one internal feasibility study several sensors with different peak frequency sensitivities and preamplifications were mounted on a concrete beam (Figure 1) with tendons at different positions on the beam. Artificial AE was triggered with HSU-Nielsen source and several tendons were cut to see the behavior of the acoustic waves and the response of each individual sensor. It turned out that low frequency sensors around 30kHz peak frequency are suitable.

Figure 1: Evaluation of several AE sensors on a concrete beam to investigate the capability to detect wire breaks

During the investigation it turned out that the typical artificial AE source, a HSU-Nielsen source (Figure 2 (top)), is suitable to verify the sensor mounting quality close to the sensor but the artificial source is not strong enough to be detected by an AE sensor in several meters distance to the sensor due to the high attenuating properties of concrete for the propagation of acoustic waves. After several tests, it turned out that a rebound hammer, which is normally used by civil engineers to evaluate the quality of concrete, is a suitable tool to trigger artificial sources. The rebound hammer (Figure 2 (bottom)) is spring loaded and a reproducible source. Detection of a rebound hammer hit in 20 to 30m distance to the AE sensor is possible.

Figure 2: HSU-Nielsen source (0.5mm) to verify the sensor mounting quality (top).

Rebound hammer to trigger reproducible artificial AE sources on concrete structures (bottom)

Another difference between industrial applications and wire break detection is the preamplification of the sensor output. Observing the data after an artificial wire break, it turned out that measurement channels with a typical amplification for

industrial applications like 34dB or 40dB were saturated related to the high energy released by the wire break. Based on the results, preamplification with 0dB is beneficial and the preamplifier purpose is to convert the sensor output to be transported over long cable distances (approx. 600m) without significant losses.

## 2.1 Permanent monitoring of a concrete bridge in southwest Germany

The following example of the SHM is part of a bigger project and published in [5]. In autumn 2018, a concrete bridge in the southwest of Germany was equipped with a monitoring system consisting out of several NDT methods. A renewal of the bridge is required, and the existing structure should be permanently monitored during planning and approval phase. Apart from acoustic emission, various other parameters like temperature, displacement and strain (strain gauge) are part of the monitoring system. Acoustic Emission and temperature are recorded by an integrated system, whereas strain gauge and displacement parameters are fused and analyzed in post processing.

Bridge construction was finalized in 1950 and traverses the river Danube (Figure 3). It has a length of 96 m and a max. span of 81m. The width is 18m and the bridge has 4 lanes and 2 sidewalks. Damages caused by corrosion were found at the tendons of the bridge. Because the damage is unrepairable, a replacement of the bridge is planned. The bridge operator, an engineering office, a service provider and Vallen Systeme as measurement equipment provider are working together in this project [5].

Figure 3: Gänstorbrücke

The Acoustic Emission measurement system and data analysis must run automatically, recognize changes in the condition and trigger alarms if predefined criteria are fulfilled. Low frequency AE sensors with IP68 rating were used for the installation and the first version of a spring-loaded mounting mechanism which can be screwed to the concrete was used in this approach. The mounting mechanism has protection covers to protect the AE sensors against vandalism and animals (e.g. birds). AE sensors were installed in a linear setup on the beams with sensors distances between 12 to 14m and the line of sensors follows the course of the tendons in the concrete as good as possible. The acoustic emission measurement system AMSY-6 with 36 channels is stored in a cabinet which is installed in the bridge abutment at a height of 5m to guarantee flood protection. Besides acoustic emission measurement system, measurement

computer, communication equipment for a mobile network and additional measurement equipment for recording data of 71 temperature sensors are included in the cabinet. AE and temperature measurements are recorded with a synchronized time stamp and so data analysis is comfortable for the service provider. The other NDT methods were recorded with separate equipment, but all data is transferred to a cloud-based dashboard and the service provider can do further analysis across all data [5].

The project is still running, and the monitoring concept provides the security to operate the bridge in a safe way till renewal is properly planned.

Figure 4: First approach for a sensor mounting device including protection cover [5]

## 2.2 Tendon failure detection with AE and other NDT methods: “Altstädter Bahnhof”

The following example is part of a bigger project published in [6]. The bridge at the “Altstädter Bahnhof in Brandenburg an der Havel” was opened in the year 1969 and tensioned concrete structure was used. The used steel, “Hennigsdorfer” steel, was state of the art at this time. Today it is known that this type of steel has a high risk for stress corrosion cracking. Inspections and investigation on the bridge revealed significant and irreversible damages and a new construction was decided. In the meantime, a monitoring system including Acoustic Emission was installed as early warning system in case of detected tension breaks. Before final removal of the “old bridge” several measurement techniques were applied on the bridge to investigate their potentials on such objects during

artificial damaging of the structure. The approach was to cut parts of the bridge including the tendons with a “wire saw” (Figure 6). Two parts of the bridge were cut, one with known, existing damages and the other with no existing damages. The focus in this text is on Acoustic Emission results provided by Bilfinger Noell. The acoustic emission signals triggered by the wire breaks at the sensors are displayed by the acoustic emission system with a delay of a few milliseconds. The analysis of the acoustic emission data is carried out immediately on-site in monitoring and test mode. A classification of the data into the classes wire break, construction noise, background noise could be done immediately. The determination of the source location of the acoustic emissions was automatically done by the measuring system. The investigation showed that acoustic emission analysis is very well suited to detect wire breaks reliable and in real time.

### 2.2.1 Construction of the bridge

For the bridge at the Altstädter Bahnhof, the “clamping block method” was used on the main supporting structure in a longitudinal direction. Tension wires with a cross-sectional area of 35 mm<sup>2</sup> were used. Additionally, a larger tensioning box was necessary to accommodate the total of 392 individual wires and to be able to introduce a tension force of 12 MN per main girder. The 392 individual wires were installed in layers and secured in their position by spacers, as can be seen in Figure 5.

Abbildung 2.2a: Blick in den Hüllkasten an einer Umlenkstelle [Bautechnik 1969]

Figure 5: Photography of the open concentrated tendon before grouting [6]

The typical brand for such tendons at this time was “Hennigsdorfer” steel. The hardened and tempered tension wires were used as pretensioned steel.

### 2.2.2 Monitoring concept and results

Due to the described material properties of the tension wires, it was necessary to implement a monitoring strategy. This was the only way to ensure the safety of the traffic passing the bridge. The monitoring concept included a regular inspection combined with a permanent structural health monitoring. For the permanent monitoring, next to others, acoustic emission was selected as method to detect tendon breaks.

The acoustic emission system with 75 sensors was installed and put into operation in June 2020 by the company Bilfinger Noell. Until the demolition of the bridge in May 2021, 111 spontaneous tension wire breaks were detected. There were no technically related downtimes during the runtime of the system.

### 2.2.3 Comparison of NDT methods

Due to the condition of the bridge, it was decided that the bridge has to be removed and replaced by a new construction. The bridge was selected by the Federal Ministry of Transport and Digital Infrastructure to do an extensive case study to compare different NDT methods. The following NDT techniques were used: Strain gauging, geodesic measurement, vibration analysis, fiber optic measurements, photogrammetry and acoustic emission. The approach was to cut parts of the bridge, including the tendons, with a “wire saw” [6]. Two parts of the bridge were cut, one with known existing damage and the other with no existing damage.

Early-stage failure of this bridge, with concentrated tendons, is not indicated by flexural cracks at a span’s center. It was shown that for this bridge about one third of all wires in one concentrated tendon must fail before the cracks reach the concrete surface. One outcome of this evaluation study is that Acoustic Emission is the only technique that detects wire breaks in real-time and without the need to be close to the origin of the wire break. In addition, AE can locate the wire breaks origin. Vibration and geodesic measurements can detect changes in the rigidity of the structure if sensing elements are close to where failure occurs. Strain measurements, photogrammetry and fiber optic sensors are suitable for detecting cracks in the concrete structure [6]

Figure 6: Wire saw to cut the concrete and tendons

## 3 IMPROVED ACOUSTIC EMISSION EQUIPMENT FOR SHM

It is necessary to provide a solution covering the entire measurement process, including data analysis, alerting and information dissemination workflows. Third-party acquisition modules need to be supported. Expandable and versatile monitoring systems can be configured using modular components and customized products where necessary.

Figure 7: Example of a schematic Workflow of a monitoring system

### 3.1 AE sensors

Sensors need to work reliably 24/7 throughout the monitoring period, withstand varying and extreme conditions, moisture, and rain as well as excessive heat and frost. Special, low frequency sensors are available meeting the harsh demands of permanent monitoring. The sensors are optimized for the specific requirements of the application. Each AE sensor is connected to the AE data acquisition system with a single cable. The commonly used acoustic emission sensor for monitoring is e.g. VS30-SIC-V2-0dB sensor or the specifically developed SHM-MP1 measurement point for structural health monitoring. The SHM-MP1 (Figure 8) measurement point offers several advantages over conventional monitoring sensors: Vallen Smart Line™ sensor technology with automatic registration of the device at the monitoring hardware and reliable self-checking of its function and sensitivity that can be automatically triggered in regular intervals or on demand are some benefits. The reliable self-checking functionality enables the operator to verify the sensor mounting quality on a regular basis to proof the sensitivity of the sensor network without accessing the sensors personally which is beneficial in cases where the sensors are hard to access. The easy-to-install mechanical device, including strain relief and rugged protection lid is an additional improvement in sensor technology compared to the first approaches like in Figure 4. Both sensor types have integrated preamplifiers with 0dB amplification and the power for the preamplifiers is provided by the data acquisition system via phantom power along the sensor cable. The temperature range from -40°C to +85°C of both variants is designed for operation in all seasons of the year and covers cold and hot temperatures during winter and summer.

Figure 8: SHM-MP1 Vallen Smart Line™ sensor

### 3.2 AE hardware and software

The AE data acquisition hardware needs to be scalable and flexible in the number of channels to provide a suitable system size related to the structure. The AE system needs to be integrated into an enclosure specified for the environmental

conditions at the bridge. 19" racks are beneficial including data acquisition PC and mobile data communication.

A reliable and state-of-the-art software complements the measurement hardware. Flexible analysis is required to be adjusted to specific requirements of a job. Even user-specific evaluation routines need to be implemented and executed during the measurement. Fast online location, even at high data rates from many channels, is a key aspect of data analysis. Criteria for alarms and warnings can be set and notifications received via email or digital outputs.

On top of data analysis runs the Vallen Automation Manager software. It enables an autonomous operation of the data acquisition system and is an instance designed to inform the operator or other selected audience about alarms and the general status of the system. Amongst simple tasks is, for example, an automatic start-up of the monitoring system after a power outage, switching between data storage files in regular intervals and carrying out sensitivity checks of the installed sensors. Beneficial is the maintenance mode, which can be activated for a user defined time span. In this recording mode, all data is recorded but the alarm chain is blocked. It is used when, e.g. construction work is done on the bridge which will generate lots of activity and fails alarms.

Additional to the software running on site at the local PC, processed data can be uploaded to a cloud-based dashboard. The Vallen Dashboard is an important part of the software solution if the monitoring results need to be distributed to a broad audience. It provides an encapsulated and safe environment for viewing and analyzing data. Access and rights/privileges for this service can be restricted based on user roles. Data available in the dashboard has been transferred to it from the acquisition PC avoiding the necessity to log-in and possible manipulation of the running monitoring system.

It can be hosted on any Linux Ubuntu server. This may be rented services from local providers or a company-controlled internet server. Rented services can provide guarantees for accessibility, data safety (back up, but also storage locations in your own country) and security (access). An encrypted connection is established between the dashboard and the acquisition PC via internet.

Data upload from the acquisition PC is automated. If the connection is interrupted, upload data is cached and transferred once the connection is working again. The Dashboard engine informs selected users when the internet connection to the measurement system is lost.

Under the hood, the Vallen Export processor and Uploader program running on the data acquisition PC are responsible for supplying the dashboard with data. Both pieces of software can be configured according to the requirements of the scope/job/user. One has full control of what is uploaded and how frequently it is uploaded. The Vallen Dashboard displays the information in a user-defined layout.

The dashboard and layouts can be easily adapted and customized by the user. The administrator of the dashboard sets out the rules which information may be viewed, and which actions are available to certain users. Information can be displayed in bar charts, scatter plots, heat maps, line charts, tables, static images, and texts. Data can be downloaded for archiving purposes or offline analysis. The responsive design

of the front-end enables equally well access experience from PCs and mobile devices.

The open API of the Vallen Dashboard provides the possibility to integrate third-party time series measurement data to be uploaded, stored, and fused with acoustic emission data. This data does not even have to come from the acoustic emission data acquisition system or PC. The Vallen Dashboard is a true multi-source, multi-channel data management, visualization, and analysis tool from a single source.

#### 4 GUIDELINE TO "DETECT WIRE BREAKS WITH AE"

The increasing demand of monitoring post-tensioned concrete structures in Germany and the complexity of how to setup such projects and how to involve all required parties motivated the development of a guideline to solve the issue. The German Society of Non-Destructive Testing (DGZfP) published in May 2024 the guideline "Richtlinie SE 05 Detektion von Spanndrahtbrüchen mit Schallemissionsanalyse" [5]. The guideline is written by civil engineers, bridge responsible from the public authority, Acoustic Emission specialists and AE measurement equipment suppliers.

It is a detailed guideline with more than 30 pages on the planning, tendering, installation and operation of monitoring systems to detect wire breaks. One focus of this guideline is, of course, the description of the use of Acoustic Emission in order for successful monitoring

The guideline covers all required topics right from the beginning, like explanation of the terms e.g. how is a wire break defined or what artificial reference AE sources are available. It covers the topic Acoustic Emission and the capability for wire break detection, requirements for measurement equipment and data analysis as well as sensors, sensor distances and limitations. A summary of the requirements for the measurement technology is in Table 1 Next to the technical part another focus is on the project implementation and project participants, proposed sensor networks related to the different construction types like box girders, T-beams etc. It finally results in a guideline on how to set up the tender specifications.

NDT technique	Acoustic Emission (AE)
Codes	EN 1330-9, EN 13477, EN13554, EN 14584
Temperature Range for AE sensors	-40 °C to 60 °C
Type of AE sensors	Piezoelectric
Pre-amplification	0 dB or higher
Frequency range acquisition	5 kHz to 200 kHz
Resonant frequency AE sensor	20 kHz to 80 kHz
Sampling frequency AD converter	2 MHz or higher
Resolution AD converter	16 bit or higher
Dynamic range AD converter	65 dB or higher
Measured Features from Hits	RMS or equivalent Amplitude and/ or Energy Arrival Time (resolution µs) Frequency information Waveform recording
Analysis in time	Occurrence of wire breaks
Analysis with location	Position of wire breaks by linear or planar location
No. of sensors for wire break location	Linear: 3 or more Planar: 4 or more
Accuracy of location	+/- 2 m or better
Sensor cables	Coaxial cable (50 Ohm)
Reference sources	Hsu-Nielsen Source (0,5 mm 2H) Rebound Hammer Type N with an impact energy of 2.207 Nm

Table 1: Overview of the recommended measurement equipment [5]

It is common sense that each bridge is different, and it is not possible to copy one project 100% to another. It is recommended to do a feasibility study before tendering to evaluate amongst other parameters the noise level, the attenuation and the speed of sound. Artificial triggered AE can be used to evaluate the parameters and additionally it is recommended to open the concrete and remove a piece of the tendon for further analysis in the laboratory. In this case cutting of tendons are required and so a “real” wire break can be detected and the propagation of the waves in the structure evaluated. The target is to find a suitable sensor network with ideal sensor distances. It brings the public administration the position to make a clear and transparent tender specification about the size and dimension of the required monitoring system.

Figure 9 shows the peak amplitude in dB(AE) from one wire break of a post-tensioned concrete bridge. It is part of the guideline and gives an orientation on the relation between wire breaks and the artificial source from a rebound hammer. Sensors were positioned at three different distances from the location of the artificial wire break. The acoustic emission signals from the wire break and from the use of the reference source were recorded. The reference source was triggered in the closest possible proximity to the wire break location. Each position has its own value of K. It is recommended to use the smallest value of K to calculate the maximum possible sensor distance. For example, the signal from the wire break at a distance of about +200 cm in Figure 9 is saturated with a maximum amplitude of 134 dBAE, which means that the true peak amplitude cannot be determined. Therefore, the smallest value of K from Figure 9 with 101 dBAE - 121 dBAE results in -20 dB.

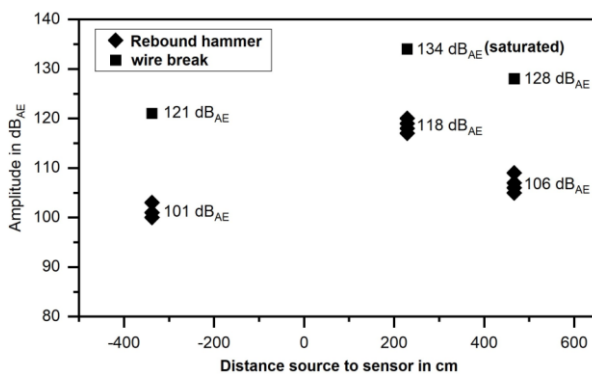

Figure 9: Representation of the peak amplitude(s) of a wire break and triggering of the reference source (rebound hammer type N) at three different distances in order to determine the value of K [4]

The method described here represents one possibility for determining the maximum possible sensor distance. However, other procedures or procedures based on this are also conceivable. The maximum possible sensor distance is the maximum distance between sensors to allow reliable detection and localization of sources (here: wire break). The wire breaks differ from the reference source by the value of K in dB. This

method is based on EN14584 [10], which describes the use of planar location for the testing of pressure vessels. The use of a fixed detection threshold is assumed. In contrast to EN14584, the reference source defined here is the rebound hammer type N and not the breakage of a pencil lead (Hsu-Nielsen source).

## 5 CONCLUSION

Wire break detection with Acoustic Emission is nowadays state of the art and a well-documented application. The NDT method AE has proved to be able to detect and locate wire breaks in concrete structures in many investigations and practical approaches and projects.

AE hardware and software have been optimized over the last years to the needs of the engineering companies and service providers to be a reliable tool. Easy to install, comfortable to use and stable in the long run. The automated alarming makes it possible to handle several projects in parallel and next to routine checks detailed analysis is required in case of alarms.

The alignment of more data sources in one platform like the dashboard gives more confidence and reduces the risk of false alarms.

Finally, guideline SE 05 was established to line up all approaches and to create a common sense of the application, the benefits and limits of AE and give public administrations a tool to formulate tenders in a way to get what they require.

**ABSTRACT:** The events of September 11, 2024, will remain etched in the collective memory of Germany's bridge engineering community. The sudden and unannounced partial collapse of a prestressed concrete bridge rightfully reverberated across society at large. The structure in question was the Carola Bridge in Dresden. This architecturally refined and exceptionally slender bridge is, with good reason, regarded by professionals as an icon of its time's structural engineering. Even by today's standards, its design and construction would pose a considerable challenge. This paper presents the main findings from investigations undertaken to determine the cause of the collapse and attempts to reconstruct the failure process. Additionally, the acoustic monitoring system implemented to safeguard the remaining superstructures is also presented.

**KEY WORDS:** Carola Bridge; Bridge Collapse; Prestressed Concrete; Stress Corrosion Cracking; Bridge Monitoring; Acoustic Emission Analysis; Forensic Engineering.

## 1 INTRODUCTION

The partial collapse of the Carola Bridge on September 11, 2024, sent shockwaves not only through the city of Dresden but also across the engineering community. The abrupt failure of an urban structure of such infrastructural importance raised fundamental questions: How could such an incident occur? What mechanisms led to the structural failure? At which location did the critical deficit manifest? And why did early indications of the developing failure remain undetected for so long despite routine structural monitoring?

These questions extend far beyond the technical assessment of a singular event. They also pertain to the derivation of potential implications for other structures that may be subject

to previously undetected load-bearing deficiencies. Moreover, they address the issue of accountability for this structural failure, although a definitive attribution of responsibility may prove elusive.

To investigate the incident, a comprehensive examination of both the collapsed section and the remaining superstructures was initiated. This paper presents the main findings of those investigations and elaborates on the subsequent failure analysis, with particular attention to the ad-hoc measures taken to assess the condition in the region of the fracture cross-section at axis D. In addition to material testing, an in-depth review and interpretation of the original construction documentation supplemented the analysis. This integrative approach enabled a reconstruction of the sequence of events leading to the collapse. Furthermore, the report outlines the monitoring that was enacted to ensure the continued operational safety of the remaining superstructures during their residual service life.

## 2 THE STRUCTURE

### 2.1 Overview

Based on the winning competition design, the new bridge over the river Elbe was designed by the state-owned VEB Design and Engineering Office for Road Construction (EIBS, Dresden division), under the leadership of Eckhardt Thürmer.

The Dr.-Rudolfs-Friedrich Bridge, inaugurated for traffic on 3 July 1971, was the longest-span prestressed concrete bridge in the German Democratic Republic (GDR) at the time [1], and has since become a defining feature of Dresden's cityscape (Figure 1). In 1992, it was renamed the Carola Bridge.

The approximately 400 m long structure, with five individual spans ranging from 44 to 120 m, has an overall width of 32 m and comprises three separate superstructures, each designed as a single-cell prestressed box girder (Figure 3). The fixed point is located at the pier in axis D, where the superstructure reaches its maximum structural height of 5.2 m. Towards the

Figure 1. The Carola Bridge in the heart of Dresden's historic city centre, photographed on December 12, 2024, from a south-westerly perspective, with the Frauenkirche prominently in the foreground and the Albert Bridge visible in the background (Photo: Alex Burzik).

abutments, the cross-section tapers to 1.6 m and 1.8 m, respectively.

Due to pronounced moment variations under continuous beam conditions, the superstructure was subdivided by three hinges. This resulted in a two-span girder between axes A and C with a 12 m long cantilever towards the Elbe (hinge I). A single-span girder with two cantilever arms—44 m towards the Elbe (hinge II) and 10 m towards the Neustadt side (hinge III)—rests on piers D and E. A 64 m long suspended main-span beam bridges the gap between the cantilever arms. An additional suspended beam was placed in the edge span on the Neustadt side.

Superstructures a and b carried two-lane roadways in opposing directions (bridge class 60), while superstructure c accommodated a double-track tramway. The outer edges of superstructures a and c featured 3.2 m wide sidewalks for pedestrians and cyclists [3]. Utility lines for district heating, gas, electricity, and water were integrated into the interior of the box girders.

One of the design-specific challenges was developing an appropriate tendon layout. In the construction stage—before the installation of the suspended beams—positive bending moments prevailed in approximately 70% of the span between supports D and E. In contrast, the final state was characterised predominantly by negative bending moments. In addition, significant creep and shrinkage deformations were anticipated during the construction period. The chosen solution involved the use of three different types of tendons: permanent tendons to carry the dead load, construction-stage tendons for temporary stabilisation during erection, and post-tensioned tendons that were activated in the final state. From today's perspective, this tendon strategy represents a key construction-related contributing factor to the collapse, as some of the tendons were exposed to extended idle periods in ungrouted sheaths.

Another noteworthy structural feature was the transverse connection at the location of hinge II, where the three individual superstructures were interconnected via a cross-beam (Figure 2). During construction, vertical stressing jacks were used at this location to compensate for height differences between the successively erected superstructures. In the final state, the transverse connection equalised differential

deflections between the three very slender and separate box girders, which resulted from shrinkage, creep, thermal effects, and traffic loading. Furthermore, it enabled the redistribution of transverse loads, effectively enforcing load-sharing between adjacent superstructures.

### 3 MAINTENANCE AND REHABILITATION

#### 3.1 Monitoring of Structural Deformations

A prerequisite for the structural integrity of the bridge was sufficient prestressing of the coupling bolts between the steel hinges and the web tendons. Of the total 504 bolts installed across all joints, 121 were designed as measuring bolts. The existing bolt forces were inferred from the difference in elongation between the zero reading and the measurement under load, recorded using high-precision mechanical dial gauges. Data on bolt forces is available from the time of construction and subsequently from the years 1974, 1979, 1982, and the early 1990s.

Significant deflection at hinge II had been known since the 1980s. A measurement campaign conducted in the early 1990s aimed to determine the causes and assess the impact on the usability of the structure. Within the box girder of superstructure c, inclinations, displacements, vibrations, and temperatures were recorded using various measuring instruments at different locations, partly over a period exceeding one year. The absolute values of the coupling bolt

Figure 2. Building immediately after the collapse.

Figure 3. Longitudinal section and ground plan of the Carola Bridge, from [2].

forces exhibited large scatter and decreased continuously since the initial prestressing, though at a progressively slower rate. These force reductions were attributed to creep and shrinkage deformations and were thus considered explainable. At the time, damage to the prestressing tendons was not considered a possible cause. Nor was the structural safety called into question.

The passage of a tram caused vertical displacements at hinge II in superstructure c of approximately +12 mm (downward) and -3 mm (upward). Deformations due to temperature variations were significantly larger, reaching up to 65 mm within 1.5 days. Relative to the zero position, deflections ranged from -20 mm to +80 mm. Based on measured data and theoretical evaluations, it was estimated that by early 1993, hinge II had experienced an average downward deflection of approximately 30 cm, equivalent to roughly 80% of the total deformation expected over the entire 80-year design life.

In addition to long-term monitoring, short-term measurements were performed in 2004 as part of static and dynamic load testing on superstructure a, to assess the actual structural behaviour and the effective interaction with adjacent superstructures b and c. The tests did not reveal any plastic deformations. Movements of transverse cracks in the underside of the roadway slab remained minimal. Load redistribution through the transverse connection at hinge II was quantified at a maximum of 39–34–27% (superstructures a–b–c, respectively) under traffic loading applied to a. Neither the long-term nor short-term investigations indicated any critical implications for the global structural integrity.

### 3.2 Issue of Prestressing Steel

The issue of stress corrosion cracking (SCC) in prestressing steel was already known in connection with the Carola Bridge. Structural inspections were conducted regularly, following DIN 1076 [4], and initially revealed no abnormalities. A first recalculation was carried out in 1996, following [5], which successfully demonstrated the structure's failure annunciation behaviour.

Transverse cracks have been definitively documented since the year 2000. Two leading causes were considered: excessive creep deformations or failure of the prestressing reinforcement, e.g. as a result of SCC. Since high creep deformation was known, it was plausibly assumed to be the primary cause of the cracking. Potential tendon failures were not taken into account. The cracks showed only minor widths, within the permissible limits for prestressed concrete structures. As the failure annunciation behaviour had been analytically verified, larger crack widths would have been expected in the event of an actual pre-failure condition.

The limited rotational capacity of the cross-sections, caused by the high reinforcement ratio and high utilisation levels, was not sufficiently considered. Additionally, the transverse load distribution via the cross beam at hinge II was underestimated. The mutual support between superstructures resulted in minimal changes in crack width, even in the presence of critical damage in one of the superstructures.

From 2004 onwards, deformation monitoring was performed by measuring crack widths and joint openings at hinge II. From today's perspective, these measurements were not suitable for identifying early indicators of failure.

### 3.3 Chloride Exposure

Sections of the three superstructures—especially between axes D and E—were affected by chloride-induced corrosion. The failure of a drainage line was the cause of this. The resulting damage was repaired. Following a non-destructive electrochemical chloride extraction, the interior surfaces of the box girders were sealed with a crack-bridging protective coating.

During the structural investigation in autumn 2024, corroded prestressing steel and passive reinforcement were identified. However, these were not determined to be the cause of the collapse.

### 3.4 Other Aspects

Throughout the bridge's service life, numerous investigations were carried out. All irregularities were followed up, and the condition of the structure was continuously assessed. No serious deficiencies have been identified in the repair works.

As a result, a rehabilitation programme was initiated, beginning with the superstructure a in 2020/21. Due to chloride contamination, this superstructure was considered particularly critical. Rehabilitation of superstructure c was scheduled to start in early 2025. Measures to enhance the durability of this structure were also planned.

## 4 COLLAPSE

In the early hours of September 11, 2024, at approximately 02:58 a.m., the collapse of superstructure c of the Carola Bridge abruptly altered the Dresden cityscape. A camera operated by Sächsische Dampfschiffahrt, mounted on the bow of a ship,

Figure 4. Recordings from a surveillance camera: initial state and moment of collapse.

captured the incident as it unfolded (Figure 4). Facing upstream, the camera recorded precisely the critical area—the river span between axes C and D.

A frame-by-frame analysis of the footage reveals the sequence of events: initially, the region around hinge II began to subside, while a crack opened at the support cross-section in axis D. Moments later, the overhead tram catenary came into contact with the river. A flash of light illuminated the night sky, accompanied by a column of spray erupting from the water's surface.

Just eight minutes before the failure, a tram had crossed this very span, likely initiating the kinematic chain leading to collapse. Fortunately, no pedestrians or cyclists were present on the structure at the time of failure. Only a delivery van travelling on superstructure a was crossing the river span as superstructure c gave way.

## 5 MATERIAL INVESTIGATIONS

### 5.1 Ad-hoc Measures for Assessing the Damage Condition of Superstructure c

In the very first hours following the collapse, an extensive photographic documentation of the general structural condition—and particularly of the fracture cross-section—was carried out. The aim was to ensure that the assessment of the exposed tendons and reinforcement would not be compromised by environmental influences or incipient corrosion. With the support of numerous contributors, nearly all components were documented on the day of the collapse itself.

The condition of the prestressing tendons was evaluated visually and classified into damage categories. It became evident that the post-tensioned tendons in the roadway slab area, in particular, showed advanced pre-existing damage and had failed long before the collapse. These post-tensioned tendons had only been stressed after a time delay, following the installation of the suspended main-span beam; see also [2]. This conclusion was drawn from the almost black fracture surfaces of many tendons (top right in Figure 6), indicating an oxygen-deficient environment within the still-intact sheathing. As such, these wire fractures occurred either during construction or shortly thereafter, but in any case, a considerable amount of time ago.

Later microscopic investigations of fractured wires, conducted by the Federal Institute for Materials Research and Testing (BAM), Berlin, revealed mortar residues on some fracture surfaces—clear evidence that these fractures had occurred before or during the grouting process. Fresh fracture surfaces appeared metallic and glossy, without signs of corrosion, and also showed no ductile necking in the failure zone (bottom right in Figure 6). Even the prestressing steels without pronounced crack initiation lenses showed signs of embrittlement.

A characteristic feature of the fracture cross-section—beyond the failed prestressing tendons—was the presence of reinforcement bars that had been pulled out from the concrete section in the upper reinforcement layers (Figure 5). In several cases, the reinforcing bars exhibited no signs of fracture, necking, or cross-sectional loss. Only isolated and minimal indications of chloride-induced corrosion were visible externally (e.g. slight pitting corrosion at the ribs).

Subsequent analyses of concrete samples taken from the fracture zone confirmed that chloride-induced pitting corrosion did not play a relevant role in this area. The tightly spaced arrangement of tendons and reinforcement bars likely impaired the bond performance, which may have contributed to the complete pull-out of some reinforcing bars from the roadway slab.

Figure 5. Failed cross-section in axis D with pulled-out steel reinforcement.

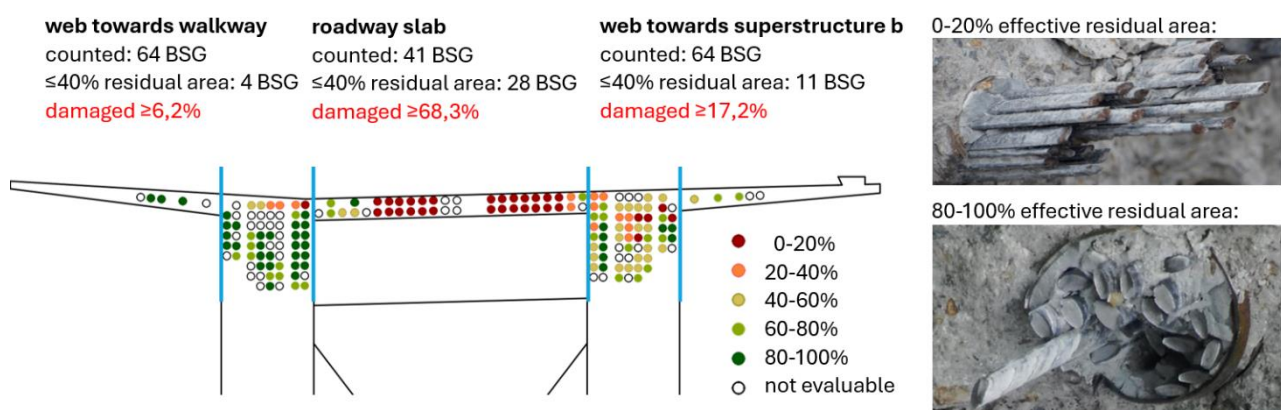

Figure 6. Results of photographic documentation of the condition of the broken prestressing wires at axis D of superstructure c, view direction Dresden-Neustadt (mid of December 2024).

## 6 ACOUSTIC MONITORING FOR THE SUPERSTRUCTURES A AND B

As the Elbe River and the southern (Altstadt-side) riverbank were gradually cleared of the remnants of superstructure c in December 2024, increasing attention was directed toward reopening the waterway and ensuring the safe underpassage beneath the remaining superstructures a and b. However, a general opening of the adjacent banks and associated roads, footpaths, and cycleways was not pursued, as these areas would soon have to be closed again for the dismantling of the remaining bridge sections. In contrast, due to its role as an international waterway critical to freight transport for the Czech Republic, the navigability of the Elbe was given priority.

An evaluation of the structural safety could not be guaranteed solely through static analysis under the prevailing conditions. Therefore, a prerequisite for reopening the Elbe to ship traffic was the implementation of acoustic emission monitoring to detect new wire break events [6], [7]. Shortly after the partial collapse, a small number of sensors were installed in the roadway slab above pier D in superstructures a and b to ensure safety during on-site diagnostic investigations. In January 2025, this system was expanded to cover the entire main river span and the support regions at axis C (Figure 7 and Figure 8).

As of February 3, 2025, controlled ship passages were permitted based on real-time monitoring data, solely for operationally critical transit (Figure 9). Initially, a ship-specific clearance protocol was applied. From 18 February onward, clearance was planned to be issued daily, allowing navigation within predefined time windows. However, on the morning of 18 February at 04:50 a.m., the first wire break events were recorded. Several additional events followed within hours, concentrated on the axes and adjacent roadway slabs. At axis D, up to six spatially correlated events were detected within 24 hours. This sudden development was most likely triggered by pronounced temperature differentials compared to previous days.

In preparation for the monitoring program, quantitative threshold values were determined through static analysis for the monitoring region. Engineering assumptions were made to estimate the loading condition that, with high confidence, had still been acting on the superstructure shortly before the partial collapse. Based on this load model, the equivalent number of prestressing wires available as structural reserve was determined. For axis D, a calculated reserve of 14 locally correlated wire breaks was established. Approximately 40% of this reserve was consumed within a very short period.

Figure 7. Overview of the monitoring area and the sensor layout for the acoustic emission monitoring system.

Figure 8. Acoustic emission sensor in superstructure b.

Figure 9. First ship passage after the collapse of the bridge and the installation of the monitoring system.

It was assumed that further significant temperature fluctuations would occur in the following weeks, which could again lead to an abrupt reduction in the remaining structural reserve. As an immediate response, a wire-break-free monitoring period of 72 hours was mandated before any further ship passages could even be considered. Subsequently, a day-by-day clearance protocol was reintroduced. Ship passages were permitted only under direct real-time monitoring using the installed measurement systems.

Ultimately, these events highlighted the vulnerable and undefined structural condition of the remaining bridge components, forming the basis for the decision to proceed with prompt deconstruction.

## 7 CONCLUSION

With knowledge of the brittle failure risk associated with the prestressing reinforcement, re-commissioning of superstructures A and B was deemed unacceptable. This decision was thoroughly examined and carefully weighed, as the Carola Bridge had represented an essential component of Dresden's road infrastructure. Among the options considered was a controlled load test. However, such a test would have only provided a snapshot of the current load-bearing capacity. Its predictive value for future performance would have remained uncertain, as the damage mechanism—stress corrosion cracking—may temporarily cease under the alkaline conditions of the grouting mortar. Still, the progression of fatigue-related damage could not have been reliably assessed at the observed level of deterioration, even if a load test had returned positive results, a residual risk would have persisted, one that could not be ethically or technically justified.

It must be acknowledged that the bridge had been inspected and monitored in accordance with established engineering standards. This highlights the need for a critical review and update of these standards. Current regulations prescribe recalculations, diagnostic investigations, and visual assessments from the exterior. However, it remains challenging to make definitive statements about the internal condition of structural components. Insights gained from the Carola Bridge investigations are now being systematically compiled and evaluated within the research initiative "Investigation and Verification of the Causes of the Carola Bridge Failure concerning the Review and Potential Revision of Concrete Bridge Design Codes" (Project No. FE-15.0729/2024/HRB). The objective is to assess the broader implications for similar structures and to initiate corresponding changes to design and inspection standards.

Measurement-based monitoring techniques—such as acoustic emission monitoring for detecting wire breaks in prestressed tendons—are playing an increasingly important role in this context and must be formally incorporated into regulatory frameworks. Ultimately, this method remains the only available approach capable of directly detecting and localising wire breaks at the moment of occurrence, thereby enabling meaningful insights into the progression of damage. Within the broader context of the tragedy resulting from the partial collapse, the successful application of this technique stands out: it was only through this method that navigation on the river Elbe could be safely resumed at minimal residual risk.

**ABSTRACT:** Dynamic Messaging Signs (DMS) are much larger and heavier roadside signs than typically placed on their respective support systems. The excess weight and size of these signs, in conjunction with their breakaway support systems, introduces wind-induced vibration problems not seen in the past. The AASHTO LRFD Specification for Structural Supports for Highway Signs, Luminaires, and Traffic Signals (SLTS), including interim revisions through 2022, does not yet address vibration design for these nontraditional roadside signs. The DMS support system, specifically the friction fuse connection, is susceptible to the formation of stress concentrations and potential fatigue issues. A DMS was instrumented with strain gages, accelerometers, anemometers, and temperature sensors to characterize both the wind loading and response of the structure. A dynamic numerical model was validated with experimental field data and used to evaluate the fatigue life of the DMS instrumented in the field. The results of the dynamic analysis performed with the validated FEM model differed significantly from the analysis with the equivalent static pressure equation for natural wind gusts prescribed in the AASHTO Specification, which highlights the importance of considering the dynamic behavior of these heavier sign panels. Extension of the dynamic method to models of other large DMS in service showed a greater fatigue stress and corresponding shorter estimate of the fatigue life.

**KEY WORDS:** Field Monitoring; Wind Loading; Sign Structures.

## 1 INTRODUCTION

Wind-induced vibrations are often a key consideration for the design of the structural supports of signs and signals. These vibrations introduce oscillations that can lead to fatigue concerns and potentially premature failure of the structure. The current AASHTO LRFD Specification for Structural Supports of Highway Signs, Luminaires, and Traffic Signals (SLTS) addresses fatigue design for overhead sign and signal structures and high mast light towers [1]. Fatigue design for roadside signs is not addressed because these are traditionally smaller and have not observed fatigue problems in the past. However, as roadside signs get heavier and larger, there is concern that these structures may be susceptible to fatigue under wind loading.

Dynamic messaging signs (DMS) include luminous elements that display words, numbers, or symbols to communicate real-time roadway and traffic information to drivers [2]. The roadside versions are often located in the clear zone alongside the roadway and as a result, must feature breakaway or yielding supports to limit injury to drivers and damage to vehicles that may swerve off the roadway [1], [3]. The DMS are much larger and heavier than signs typically placed on breakaway posts. The signs range from 1.8m x 4.3 m to 2.4m x 5.5m, weigh over 680 kg, and have post heights that range from 4.7m to 6.7m [4].

The 2025 interim revision of the AASHTO 2013 (ASD) Specification for SLTS acknowledges the potential impact of the mass of dynamic messaging signs and requires their cantilevered support structures to be designed for fatigue [5]. However, the revision states that design of these structures will require considerations beyond the specification. This ambiguity leaves the designer to determine if equivalent static

analysis or dynamic analysis is more appropriate to evaluate the fatigue life of the support structure.

In this work, the behavior of roadside dynamic messaging signs under wind loading was investigated to determine which analysis method should be considered in design. A DMS was instrumented in the field and the experimental field data were used to characterize the wind loading and response of the structure. The field data was further used to update a dynamic numerical model for comparison with an equivalent static pressure analysis. Ultimately these were used to evaluate the fatigue life of these DMS support structures.

## 2 DMS FIELD MONITORING

A post-mounted DMS (DMS 169-142.45NB) located in Brooklyn Park, MN with a Type A support detail was instrumented in the field to investigate its structural performance under wind loading. The Type A support featured a slip base and a friction fuse connection just below the sign panel (Figure 1). The friction fuse consisted of two plates used to splice two lengths of the support post: (1) a fuse plate with a weakened portion designed to fracture under impact, and (2) a hinge plate designed to yield.

The instrumentation consisted of two accelerometers, two cup and vane anemometers, one temperature probe, and 76 strain gages. Figure 2 provides an overview of the instrumentation. The single-axis accelerometers were used to identify the natural frequencies of the structure. The cup and vane anemometers measured the mean wind speed and direction. The strain gages were used to measure the dynamic response of the support and friction fuse connection under wind loading. The supports were expected to undergo strong-axis bending, weak-axis bending, and potentially torsion. The post

strain gages included two strain rosettes on each face of the web as well as strain gages at the tip of the flanges. These strain gage sets were located at four different locations along the two support posts. The field data was collected over five months from August 2017 through January 2018.

Figure 1. Type A breakaway connection: (a) slip base, (b) friction fuse.

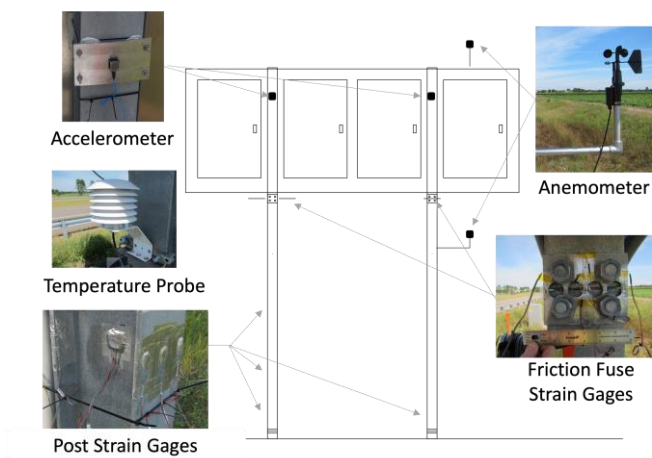

Figure 2. Overview of DMS field instrumentation.

### 3 ANALYTICAL MODELS

Three different models were used for analysis of the DMS structure: two simplified models and one finite element model. The simplified models consisted of a static beam model and a dynamic beam model. In the static beam model, the wind pressure applied to the sign was assumed to distribute evenly to the four panel support points. The resulting point loads on the cantilever posts were used to determine the stresses and the corresponding strains along the height. In the dynamic beam model, the inertial effects of the sign mass were considered by applying the mass of the sign to a rectangular prism that was supported by a cantilever beam with stiffness equivalent to the two columns. A single-mode dynamic model was used to capture the behavior of this system subjected to a dynamic drag forcing function due to the wind pressure on the sign face.

The third model featured a linear elastic finite element (FE) model created to evaluate the fatigue stresses generated in the friction fuse connection during wind loading. The friction fuse connection was modeled as a separate detailed three-dimensional component to capture stress concentrations, particularly in the fuse plate. The support posts were modeled with standard beam elements and the panel was modeled using standard four-node shell elements. The FE model was validated with the field data assuming the structure would have similar natural frequencies to those measured in the field.

All three analytical models assumed ASTM A36 steel with an elastic modulus of 200 GPa and yield strength of 248.2 MPa. The posts were W8x24 cross-sections with a moment of inertia of 3442.3 cm<sup>4</sup>. Additionally, the dynamic models assumed a damping ratio of 0.02.

### 4 RESULTS

The two simplified models were compared using the measured wind demand and corresponding strain response. A change in the measured wind speed normal to the sign face corresponded to a change in pressure that was applied as a drag force to the sign supports. For the simplified static model, the expected change in strain at the base of the post was determined and compared with the measured change in strain in the cross section. For the dynamic model, a transient drag force due to the measured wind speeds and corresponding pressure was applied to the single degree-of-freedom system. The change in strain at the base of the post between two times of interest was determined from the transient response for comparison. The strain distributions predicted by the dynamic response aligned better with the measured strains than those strains predicted by the static model (Figure 3). The comparison of the two simplified models demonstrated that considering the effects of the inertia of the sign panel is important to capture the behavior.

Figure 3. Comparison of the strains predicted by the simplified models and measured strains in the east post for a specific wind event. Error bars on predicted strains reflect the noise on the measured strains.

Based on the comparison, a dynamic FEM was used and required dynamic wind loading functions as inputs to the model for fatigue analysis. To generate the limit-state wind loading, a representative wind spectrum was used to generate zero-mean wind speed time histories. A Davenport spectrum with a terrain coefficient of 0.005 for open, unobstructed terrain best characterized the power spectrum of the measured wind data during the deployment [6]. The spectrum was scaled to the mean hourly wind speed of the region and a corresponding filter was applied to white noise inputs with unit covariance to generate wind speed time histories [7]. The pressure loading functions were generated from these simulated wind speed histories using a variation of the method presented in reference

[8]. Typically, the stress range only due to the fluctuating wind load would be considered in the fatigue analysis. However, because the gravity load of the sign was thought to play an important role in the resulting stresses within the connection, the wind pressure function included both the mean and fluctuating pressure. The combined mean and fluctuating pressure were thought to provide a more realistic representation of the magnitude of the fluctuating tension stresses and whether these would overcome the compressive stresses due to gravity. Five independent pressure functions were applied to the dynamic FEM to determine an average wind-induced stress range. The fatigue limit-state stress range was taken as the resulting amplitude of the tension stress within the friction fuse connection.

The fatigue demand in the connection was computed using two methods: (1) using the equivalent static pressure equations outlined in Article 11.7 of the AASHTO 2015 LRFD Specification for SLTS [1], (2) the dynamic FEM model with wind loading functions mentioned above. When using the equivalent static approach, the peak fatigue stress range was 49.6 MPa. The dynamic FEM model resulted in a peak fatigue stress range of 63.9 MPa. Both results exceed the constant amplitude fatigue threshold (CAFT) of 48.3 MPa for an infinite fatigue life. Further, the equivalent static approach underestimates the stress range predicted by the dynamic model.

## 5 CONCLUSION

The additional weight of dynamic messaging sign (DMS) panels requires fatigue under wind loading to be considered in design. However, the AASHTO 2015 LRFD specification does not address fatigue design for these nontraditional roadside sign structures. Field monitoring of a DMS structure was used to validate simplified and detailed numerical models and determine the fatigue life of the instrumented DMS structure. Additionally, the effectiveness of the different modeling approaches to capture the behavior of the sign structure to wind loading was evaluated.

A comparison of the modeling approaches to the field data highlighted the importance of considering the inertial effects of the sign panel mass on the response of the structure. Limit state pressure loading functions were generated as inputs to the validated dynamic FE model. The resulting fatigue stress demand in the breakaway connection was compared with the traditional equivalent static pressure analysis method. The peak stress demand from the dynamic FE model was 28% larger than the static approach further emphasizing the importance of using a dynamic model when evaluating these structures.

The resulting stress demands were used to calculate the fatigue life of the instrumented DMS. The dynamic modeling technique can be extended to other in-service DMS support structures to estimate their fatigue life.

## ACKNOWLEDGMENTS

Funding support was provided by the Minnesota Department of Transportation (MnDOT). Numerical computations were performed using resources provided by the University of Minnesota Supercomputing Institute (MSI). The work does not necessarily represent the views or policies of MnDOT or MSI.

**ABSTRACT:** The rapid expansion of the wind energy sector has necessitated remote monitoring of wind turbines to ensure safe, reliable, and cost-effective operations. While traditional inspection methods remain in use, there is an increasing shift toward passively monitored, real-time solutions to detect and localize potential damage. The present study makes a novel attempt to explore the potential of 6-component seismic data for use in structural damage detection frameworks for wind turbine monitoring. Measuring both translational and rotational ground motions is a relatively recent advancement in Structural Health Monitoring, offering valuable insights into the dynamic behavior of towers.

In the present study, two 6-component (6-C) seismometers were placed at the foundations of two different wind turbine types in the wind park of Kirchheilingen, Germany. The monitoring campaign lasted 7 weeks and focused on capturing vibrational data during operation. By analyzing these signals, in conjunction with Supervisory Control and Data Acquisition (SCADA) Data from the turbine operator, the research aims to identify patterns indicative of structural damage, such as changes in modal frequencies, damping ratios, or signal coherences. It will contribute to the development of scalable, cost-efficient SHM systems tailored for the wind energy industry. Furthermore, the insights gained could inform future design improvements and predictive maintenance strategies, ultimately supporting the sustainable growth of renewable energy infrastructure.

**KEY WORDS:** Structural health monitoring; wind turbines; 6C-seismic data; damage detection; renewable energy; operational modal analysis; wind turbine tower

### 1 INTRODUCTION

Wind energy has become one of the key pillars in the global transition toward sustainable and low-emission power generation. As one of the most environment-friendly alternatives to fossil fuels, wind turbines contribute significantly to meeting international climate targets and reducing carbon footprints. However, as the number and size of installed wind turbines continue to grow, so do the demands on their structural integrity, operational efficiency, and service life. In this context, monitoring the condition and performance of wind turbines has emerged as a critical aspect for both industry and research. Modern sensor technology and data-driven analysis methods allow for the continuous observation of dynamic loads, vibration behavior, and early detection of potential damage. A particular focus lies on the measurement and analysis of vibration signals and the identification of structural eigenfrequencies, as changes in these parameters can indicate material fatigue, loosened connections, or structural weakening. The development of reliable and efficient monitoring techniques is therefore essential — not only for extending the lifetime of wind turbines but also for ensuring economically optimized and safe operation. Previous work on wind turbine monitoring has primarily focused on using SCADA data, strain gauges, accelerometers, and optical fiber sensors [1], [2]. Seismic observations have also been utilized to

assess the influence of wind turbines on ground motion and operational states [3]. However, to our knowledge, this study is the first to employ six-component (6C) seismic data — recording translational and rotational ground motion — specifically for the structural health monitoring of a wind turbine.

### 2 METHODS

#### 2.1 Location and instruments

The experiment was conducted in a wind park near Kirchheilingen, containing multiple wind turbines. Two turbines, differing in tower construction — a steel tower (LDST) and a concrete hybrid tower (CHT) — were selected for detailed analysis. The two turbines, each with a height of 166 meters, were commissioned in September 2022 and are therefore among the latest generation of models.

Their locations, highlighted in blue on the map in Figure 1, are situated only a few hundred meters apart.

Inside each of these turbines at the ground (on the top of foundation), a BlueSeis 3A and a Trillium Compact 120s Seismometer have been placed for a timespan of about seven weeks. The BlueSeis 3A station measures rotations about the three axes and the Trillium compact 120s measures translations providing 6 degree-of-freedom (DOF) data. Figure 2 shows the setup inside of the towers. The rotational seismometer on the

right as well as the translational seismometer directly next to it forming a 6-component (6C) station.

Additionally, two reference stations - marked in red in figure 1 - were used to characterize the local noise field. Each reference station was equipped with two Trillium Compact 120s seismometers. One station was placed directly next to the foundation of one of the turbines, while the other was located outside the wind park, behind a lake but near a road. During the days of setup of the two 6-component stations inside the tower these reference stations were setup to gain reference data.

Figure 1. Location of the two wind-turbines in Kirchheilingen monitored using BlueSeis3A and Trillium Compact for 7 weeks.

Figure 2. Example setup of instruments

## 2.2 Data acquisition

The experiment was carried out over a period of seven weeks, beginning on November 18, 2024, and concluding on January 9, 2025. This specific timeframe was chosen to coincide with a period of typically high wind activity, increasing the likelihood of capturing a wide range of operational states of the turbine. Additionally, we aimed to collect data during non-operational hours, hoping to observe the tower's behavior under different load conditions. The data of the 6-C stations was saved to local disks which were carried after the experiment. SCADA data (Supervisory Control and Data Acquisition) is collected by sensors at the turbine to provide engineers with valuable data for monitoring and maintaining the turbine. The data is collected in databases to which we have access. Data such as the rotor speed, windspeed and temperature are just a few of the environmental data. Combining these datasets, seismic and SCADA data might be good to get clearer insights into the dynamics of the tower and therefore for a setup on the structural health monitoring of the tower.

## 3 DATA ANALYSIS & RESULTS

The reference stations marked in Figure 1 already show expected results. The noise level at the outer station is significantly lower than at the directly next to the turbine. This meets the expectation. However, stable frequency bands are still observed between 1-10 Hertz and amplitudes are quite high for frequencies below 1 Hertz for the station which is far away. Figure 3 shows a spectrogram for the reference station which is near one turbine. The black line indicates the speed of the Rotor which lines up with the frequencies above 10 Hertz. There can be seen other frequencies such as this steady one between 25 to 30 Hertz which is likely to be caused by turbine operation. The short peaks over a wide frequency band between 22:30 and 23:00 local time could be related to the nacelle turning into the wind.

Figure 3. Frequencies rotor speed

To gain better insights into the frequencies recorded at the tower, Power Spectral Densities (PSDs) were calculated. The seismic signal from the Trillium Compact sensor was divided into two-minute time sections to ensure relatively constant conditions. For each of these sections, the corresponding rotor

speed was averaged and assigned to specific rotor speed ranges. The PSD for each time section was then calculated and colored according to its assigned rotor speed range. This approach allows differentiation of the PSDs based on the rotor speeds that drive turbine motion and induce seismic signals. Figure 4 shows the PSD peaks for all time sections. Differences in both amplitudes and frequencies can be observed. For instance, the frequency peak above 10 Hz appears to increase in amplitude with higher rotor speeds. Higher amplitudes, particularly at low frequencies, seem to be associated with elevated rotor speeds. The dominant peak at 1 Hz is clearly visible. Furthermore, a shift from lower to higher frequencies around 14 Hz with increasing rotor speed can be clearly identified and connected to the generator speed. Spectrograms also revealed sudden changes in frequency over time, likely related to variations in generator behavior.

Following the methodology of Neuffer et al. [1], we calculated hodograms for the translational seismic data at the bottom of the foundation. Hodograms provide a graphical representation of seismic motion in two dimensions over time. These hodograms illustrate the seismic movement of the turbine at the foundation, with time represented by color. By filtering for specific frequency bands, in this case between 0.9 and 1.1 Hz, which covers the dominant frequency, we observe smooth movement in particular directions.

Figure 4. Power Spectral Density with respect to Frequency plot

The calculation was performed for all three planes: East-North, East-Vertical (Z), and North-Vertical (Z) directions. Figure 5 illustrates the corresponding hodogram. Focusing on the East-North (E-N) plane, which represents the bending of the tower, it becomes evident that the bending is predominantly polarized in one direction, but changes over time, in this case, within approximately 6 seconds. There is a main direction of bending, which raises the question of whether the tower predominantly bends in alignment with the wind direction. To further explore this, we calculate the covariance matrices along with their eigenvectors and eigenvalues, which allows us to determine a linearity factor with a directional component. The linearity index  $L$  is defined as 1 minus the ratio of these eigenvalues. A value close to 1 indicates high linearity, while a value close to 0 suggests circular motion for the respective time sections.

Figure 5. Hodograms for frequencies between 0.9-1 Hertz in the (a) East-North direction (b) Vertical-East direction and (c) Vertical-North direction.

We calculated linearity indices and vectors over short time windows during which translational motion was dominant. By filtering for high linearity values, we minimize the effects of whirling motions and identify the principal direction angles for each time section. Figure 6 displays the principal direction angles for the wind turbine tower alongside the measured wind direction. The wind direction is taken from the SCADA data, with the angle of the wind being subtracted by 180 degrees. This means that if the tower were to bend in the direction of the wind, we would observe that in the data. However, we instead see an offset of about 30–50 degrees for both towers. Furthermore, we notice that the principal direction angles align with the wind direction, but the tower seems to exhibit some inertia when the wind direction changes, as the principal direction angles do not increase as much as the wind itself. We also observe different principal direction angles across various frequency bands, though the reason for this remains unclear.

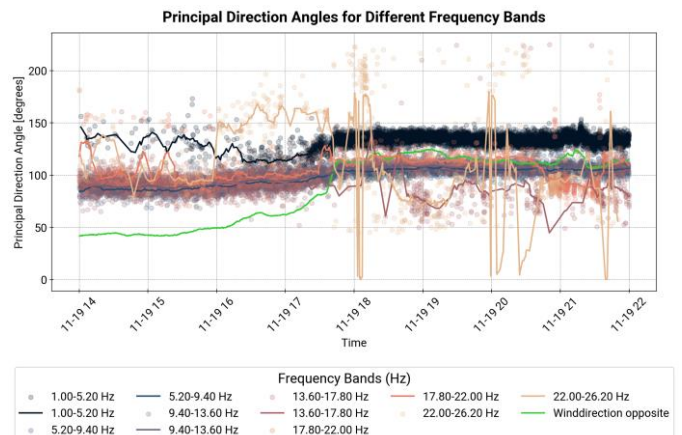

Figure 6. Principal direction angles for different frequency bands.

#### 4 FURTHER INVESTIGATION

As the present study is one of the first to leverage the three-component rotational ground-motions combined with translations for structural health monitoring of wind-turbines, we aim to determine how the 6-component measurements can be used to reliably replicate some of the SCADA data. One of the most important parameter measured as a part of SCADA data is the acceleration at the top of the tower. We aim to use this acceleration data from the top of the tower, located inside the nacelle, and compare it with the acceleration data at the bottom. By doing so, we may be able to predict the movement of the tower at the top. Additionally, we hope to extrapolate the

displacement at the bottom, assuming the stiff end is located inside or at the bottom of the foundation. This would allow us to measure the tower's eigenmodes. Given the extended time span of the data, we aim to detect any differences in the eigenfrequencies and modes over time. If successful, this approach could help identify structural damage using directional information. Previous studies [4], [5] have demonstrated such damage identification based on translational acceleration data through operational modal analysis.

To further investigate the dynamics of the wind turbine tower, we plan to use Campbell diagrams, wavelet transformations, and stabilization diagrams. We want to investigate more signal coherences, damping ratios and the advantage of rotation motion measurements for the structural health monitoring.

## 5 CONCLUSION

In this study, we identified significant eigenfrequencies in the seismic data and successfully correlated them with environmental changes. The Power Spectral Densities (PSDs) revealed distinct peaks corresponding to these eigenfrequencies. Hodograms further demonstrated the linear movement of the tower, with a slight offset relative to the wind speed and noticeable differences across various frequency bands. These observations suggest that the tower's behavior is influenced by both the wind and its structural dynamics. Ongoing investigations include the use of Campbell diagrams, wavelet transformations, and additional analyses to gain deeper insights into the tower's dynamic response.

**ABSTRACT:** The demand for renewable energy sources is increasing, making it essential to develop effective maintenance plans for existing infrastructure. This study represents the initial step in a process designed to estimate the settlement of onshore wind turbine foundations, as well as its associated uncertainties. The method relies on high-resolution dual-orbit satellite data, which help to reduce cost and time required for instrument installation and on-site inspections. The turbine is modeled as a 1D rigid body and is assumed to be firmly constrained to the foundation slab. The proposed formulations allow for the estimation of the turbine motion components – translations in the W-E and vertical directions and rotation along the S-N axis –, which can be generally linked to foundation settlement. The components are determined by solving a linear system which accounts for the mean annual velocities of the Permanent Scatterers on the wind turbine surface, turbine height and incidence angles of satellite orbits. At the present stage, analytical formulations for the a posteriori estimation of the motion component uncertainties are proposed, with a particular focus on the positioning error in elevation of Permanent Scatterers. To assess the accuracy of these expressions, Monte Carlo numerical simulations are conducted. The strong agreement between numerical and analytical results demonstrates that the turbine motion components can be estimated with high accuracy.

**KEY WORDS:** Structural Health Monitoring; Foundation settlement; Wind turbines; Monte Carlo simulations; Uncertainty evaluation.

## 1 INTRODUCTION

As stated by the Global World Energy Council [1], the necessity to install new renewable energy sources grows stronger every year. In fact, to pursue the Paris Agreement goal – reducing greenhouse gas emissions by 43% by 2030 to limit global warming to 1.5°C – it was estimated that by 2030, 2 TW of wind energy will be installed. As for now, 78 GW of wind power capacity, of which 68.8 GW provided by onshore installations, were added globally in 2022.

In order to sustain the existing wind power structures, a solid maintenance plan is needed. Structural Health Monitoring (SHM) systems can contribute significantly to enhance wind turbines reliability and ensure their optimal performance, through different management approaches [2]. Various parts of the wind turbine, in fact, can be affected by structural issues, such as corrosion and cracks on the tower, or surface damage to the rotor blades [3]. Furthermore, particularly in the case of onshore installations, foundation settlement may occur: differential settlement, which manifests as tower rotation, can lead to a reduction in turbine efficiency, potentially resulting in economic losses. This phenomenon can take several months, or even years, to develop.

In [4], large vertical movements were observed in some onshore wind turbines, particularly in the case of concrete foundations in which embedded rings were used as connection systems, potentially leading to the sudden and catastrophic collapse of the turbine. Beyond the risk of structure failure, foundation settlement needs to be closely monitored for preserving the verticality of the tower and ensure an overall good health of the entire system. In particular, remote sensing

techniques enable the investigation of foundation settlement while ensuring an off-site and non-invasive monitoring of the turbines.

Satellite data based monitoring was largely applied to investigate landslides and ground deformation in non-urban areas [5, 6], but, in the past few years, it also gained popularity in the structural field [7, 8]. In fact, multi-temporal Differential Interferometric Synthetic Aperture Radar (DInSAR) techniques allow obtaining the displacement information of several points, called Permanent Scatterers (PSs) [9], both on the ground and on reflective elements with millimetric precision [10] – also thanks to the developments of X band SAR systems [11].

Combining displacement information from both satellite orbits – ascending (ASC) and descending (DES) – of PSs belonging to structure surfaces, it is possible to obtain displacement information about the structure itself [12, 13]. For instance, through the use of high-resolution dual-orbit satellite data, it is possible to estimate the 3D rigid motion components of buildings, which can be generally linked to their foundation settlement [14]. Specifically, rigid translations can be an indicator of total settlement, while rigid rotations may indicate a differential settlement.

Besides the potential to investigate displacements over large areas with high accuracy, advantages of satellite data use in SHM include the possibility of portraying off-site and non-invasive monitoring, thus reducing both time and costs of instrument installation. Moreover, traditional monitoring equipment does not allow for obtaining results in a reasonable time if the foundation settlement phenomenon is slow; on the

contrary, satellite techniques enable the analysis of past data - even 10 years before the time of analysis - proving to be effective when there is a need to obtain information from the past.

As part of a broader effort to detect potential foundation settlements in wind turbines, this paper introduces the initial stage of a procedure to estimate the 3D motion components of wind turbines using high-resolution dual-orbit satellite data. Formulations provided by Bassoli et al. [14] were adapted to the wind turbine case, which is modeled as a 1D rigid body. Also, analytical formulations for evaluating uncertainties regarding each motion component are presented. The main sources of error are related to measurement and positioning. Specifically, the measurement error includes the unavoidable uncertainties associated with measuring the displacements of PSs along the lines of sight. The positioning error refers to the uncertainties involved in placing the scatterers along the height of the turbine. At the present stage, a posteriori estimates of the uncertainties are presented and validated based on simulated data. Monte Carlo simulations were conducted to generate synthetic satellite data and obtain results under various conditions - detailed in section 3 - accounting for both primary sources of error. This allowed for a thorough assessment of the reliability of the proposed analytical expressions and supports their applicability to real-world scenarios. In future research, the procedure will be further developed by proposing a priori estimates based on simplified hypotheses and by applying them to real wind farms.

The paper is organized as follows. In section 777, analytical expressions relating 3D motion components of the turbine with displacement read along the line of sight are shown, as well as the procedure used to derive the uncertainties, with a specific emphasis on the positioning uncertainties. In section 3, the numerical simulations performed to verify the analytical expressions are outlined, while numerical and analytical results are presented and compared in section 4. Finally, conclusions are drawn.

## 2 IDENTIFICATION OF RIGID MOTION COMPONENTS FROM SATELLITE DATA

### 2.1 Geometry and satellite data definition

The wind turbine is modeled as a 1D rigid body firmly constrained to the foundation slab. Supposing that the slab-turbine connection happens at the exact center of gravity of the foundation, a reference system can be built as described: origin in the center of gravity (G), and  $x$ ,  $y$  and  $z$  axes along the W-E, S-N and vertical directions respectively. In Figure 1, satellite geometry as well as an example of the PSs placement along the turbine height are reported. Note that all PSs are assumed to be aligned along the turbine  $z$ -axis; therefore, the planar positioning error is not considered.

In this study, all satellite geometry parameters — such as heading angles, measurement accuracy, and ground resolution — were assumed to match those of the COSMO-SkyMed constellation operating in StripMap mode over Italian regions. Specifically, the heading angles  $\beta_A$  and  $\beta_D$ , representing the satellite orbit inclination with respect to the S-N direction, were set to  $\beta_A = 350^\circ$  and  $\beta_D = 190^\circ$ . The measurement accuracy was assumed to range from 1 to 2 mm/yr, and the ground resolution was taken as  $3\text{m} \times 3\text{m}$ .

Figure 1. Satellite geometry: incidence angles and PSs positioning (a) and heading angles (b).

The same parameters were also used in the methodology to estimate rigid motion components and their associated uncertainties in [14]. The high resolution provided by this constellation makes COSMO-SkyMed data particularly well-suited for structural monitoring applications.

### 2.2 3D motion component estimation

In this study, the 3D rigid motion of wind turbines is estimated using the approach proposed by some of the authors in [14]. This method was originally developed to assess the motion of buildings modeled as 3D rigid bodies. Based on the structural geometry and satellite parameters, it allows for the evaluation of translations along the W-E and vertical directions, as well as rotations around the W-E, S-N, and vertical directions. The expressions proposed in [14] are adapted here to the case of wind turbines. Specifically, since the wind turbine is modeled as a 1D body, the rotation component along the  $z$ -axis was neglected. As with buildings, the translation along the S-N axis cannot be accurately assessed due to the limited sensitivity of SAR measurements in detecting displacements in the S-N direction [10, 15, 16].

It is important to emphasize that, to evaluate the full 3D rigid motion of the turbine, displacements of PSs measured in both orbits are required [15].

To avoid temporal misalignment of PSs displacements, the formulations are applied to the mean annual velocities of PSs (mm/yr), rather than to specific time instants. Additionally, due to the rigid motion assumption, spatial resampling to align PSs measured in ascending and descending orbits is unnecessary [17]: all permanent scatterers associated with the turbine contribute to the motion estimation.

Considering clockwise rotations as positive, the displacement of the generic point P with respect to G can be written as:

$$\begin{cases} v_{x,P} = v_{x,G} + \Phi_{y,G} D_{z,P} \\ v_{y,P} = v_{y,G} - \Phi_{x,G} D_{z,P} \\ v_{z,P} = v_{z,G} \end{cases} \quad (1)$$

where  $v_{x,G}$ ,  $v_{y,G}$ ,  $v_{z,G}$ , represent the translations along the three directions while  $\Phi_{x,G}$  and  $\Phi_{y,G}$  are the rotations around the  $x$ - and  $y$ - axes. Finally,  $D_{z,P}$  indicates the elevation of point P relative to G.

The displacement of point P is then projected along the ascending and descending lines of sight (LOSs) of the satellite constellation. Incidence angles  $\alpha_A$  and  $\alpha_D$  indicate the inclination of the satellite LOSs with respect to the vertical

direction, while  $\beta_A$  and  $\beta_D$  are the heading angles. Adopting the values reported in section 2.1,  $\sin \beta_A$  and  $\sin \beta_D$  can be approximated as 0 while  $\cos \beta_A$  and  $\cos \beta_D$  can be approximated as +1 and -1, respectively. Based on these considerations, and since that the translation component along the y-axis cannot be estimated due the limited sensitivity of SAR data in S-N direction, the displacement of point P projected onto the ascending and descending LOSs can be expressed as:

$$\begin{cases} d_{A,P} = v_{z,G} \cos \alpha_A - v_{x,G} \sin \alpha_A - \Phi_{y,G} D_{z,P} \sin \alpha_A \\ d_{D,P} = v_{z,G} \cos \alpha_D + v_{x,G} \sin \alpha_D + \Phi_{y,G} D_{z,P} \sin \alpha_D \end{cases} \quad (2)$$

A system of two equations in three unknowns – that are the translations in W-E and vertical directions and the rotation along the S-N direction – is obtained. To determine  $v_{x,G}$ ,  $v_{z,G}$  and  $\Phi_{y,G}$ , at least three PSs from the two orbits are required. Assuming  $n$  PSs are available for the ascending orbit and  $m$  for the descending one, the system can be expressed as:

$$\begin{bmatrix} d_{A,1} \\ \vdots \\ d_{A,n} \\ d_{D,1} \\ \vdots \\ d_{D,m} \end{bmatrix} = \begin{bmatrix} -\sin \alpha_A & \cos \alpha_A & (-D_{z,1} \sin \alpha_A) \\ \vdots & \vdots & \vdots \\ -\sin \alpha_A & \cos \alpha_A & (-D_{z,n} \sin \alpha_A) \\ \sin \alpha_D & \cos \alpha_D & (D_{z,1} \sin \alpha_D) \\ \vdots & \vdots & \vdots \\ \sin \alpha_D & \cos \alpha_D & (D_{z,m} \sin \alpha_D) \end{bmatrix} \begin{bmatrix} v_{x,G} \\ v_{z,G} \\ \Phi_{y,G} \end{bmatrix} \quad (3)$$

and can be synthesized as:

$$\mathbf{M} = \mathbf{S} \boldsymbol{\vartheta} \quad (4)$$

where  $\mathbf{M}$  is a  $Ns \times 1$  vector, being  $Ns=n+m$ , containing PSs displacements along the LOSs,  $\boldsymbol{\vartheta}$  is a  $3 \times 1$  vector containing rigid motion components of the turbine, and  $\mathbf{S}$  is a  $Ns \times 3$  matrix containing satellite geometries and the height of PSs.

Note that, due to measurement uncertainties thoroughly described in section 2.3, the theoretical displacement measurements in  $\mathbf{M}$  are never exactly equal to the ones directly obtained from the satellite  $\mathbf{M}^*$ . Thus, to obtain the best  $\boldsymbol{\vartheta}$  estimate, the least square operation must be applied:

$$\hat{\boldsymbol{\vartheta}} = (\mathbf{S}^T \mathbf{S})^{-1} \mathbf{S}^T \mathbf{M}^* \quad (5)$$

To assess the turbine motion relative to the ground, the terrain motion components must also be estimated and subtracted from the turbine motion. However, for the sake of simplicity, this study assumes the ground motion components to be zero.

### 2.3 Uncertainties estimation of rigid motion components

This section outlines the evaluation of the uncertainties associated to the above estimated motion components according to the procedure proposed in [14]. As previously stated, there are two main sources of error working with PS displacement data: measurement and positioning errors. Measurement error concerns the inevitable uncertainty committed when detecting the PS displacements along the LOSs, while positioning error regards the placement of the PS inside the resolution cell [14]. In this case, since PSs are supposed perfectly aligned to G, positioning uncertainties only regard the PS placement along the vertical direction. Using the product rule for derivatives, the variation of the  $\boldsymbol{\vartheta}$  vector can be expressed as:

$$\Delta \boldsymbol{\vartheta} = \Delta \mathbf{B} \mathbf{M} + \mathbf{B} \Delta \mathbf{M} = \sum_k \left( \frac{\partial \mathbf{B}}{\partial D_{z,k}} \right) \mathbf{M} \Delta D_{z,k} + \mathbf{B} \Delta \mathbf{M} \quad (6)$$

where  $\mathbf{B} = (\mathbf{S}^T \mathbf{S})^{-1} \mathbf{S}^T$  represents the pseudo-inverse of matrix  $\mathbf{S}$ ,  $\mathbf{M}$  contains the PSs displacements along the LOSs, and  $D_{z,k}$  is the elevation of the  $k$ -th PS. Lastly,  $k=1, \dots, n$  or  $k=1, \dots, m$  for the ascending or the descending PSs, respectively.

Assuming that measurement and positioning errors are not correlated [14], the total covariance matrix  $\Sigma(\boldsymbol{\vartheta})$  can be expressed as the sum of the measurement covariance matrix and the positioning covariance matrix as follows:

$$\Sigma(\boldsymbol{\vartheta}) = \Sigma_M(\boldsymbol{\vartheta}) + \Sigma_P(\boldsymbol{\vartheta}) \quad (7)$$

where the terms  $\Sigma_M(\boldsymbol{\vartheta})$  and  $\Sigma_P(\boldsymbol{\vartheta})$  indicate, respectively, contributions of measurement and positioning errors to the covariance matrix. Particularly, on the main diagonals, variances associated with each motion component can be found.

The covariance matrix associated to the measurement error  $\Sigma_M(\boldsymbol{\vartheta})$  can be obtained as:

$$\Sigma_M(\boldsymbol{\vartheta}) = \mathbf{B} \Sigma(\mathbf{M}) \mathbf{B}^T \quad (8)$$

Under the non-correlation hypothesis among the measures of PSs,  $\Sigma(\mathbf{M})$  can be assumed as a  $Ns \times Ns$  diagonal matrix with terms equal to  $\bar{\sigma}_M^2$  on the main diagonal, representing the measurement accuracy. Thus, eq. (8) can be written as follows:

$$\begin{aligned} \Sigma_M(\boldsymbol{\vartheta}) &= \bar{\sigma}_M^2 \mathbf{B} \mathbf{B}^T = \bar{\sigma}_M^2 (\mathbf{S}^T \mathbf{S})^{-1} \mathbf{S}^T ((\mathbf{S}^T \mathbf{S})^{-1} \mathbf{S}^T)^T = \\ &= \bar{\sigma}_M^2 (\mathbf{S}^T \mathbf{S})^{-1} \end{aligned} \quad (9)$$

According to section 2.1, typical values for  $\bar{\sigma}_M$  for COSMO-SkyMed data range from 1 to 2 mm/yr. However, to assess the applicability of the procedure, numerical simulations presented in the next section were conducted using values of 1, 2 and 5 mm/yr.

The positioning covariance matrix can be expressed as follows:

$$\Sigma_P(\boldsymbol{\vartheta}) = \left( \frac{\partial \mathbf{B}}{\partial \mathbf{D}} \mathbf{M} \right) \Sigma(\mathbf{D}) \left( \frac{\partial \mathbf{B}}{\partial \mathbf{D}} \mathbf{M} \right)^T = \mathbf{J} \Sigma(\mathbf{D}) \mathbf{J}^T \quad (10)$$

where  $\mathbf{J}$  is the  $3 \times Ns$  Jacobian matrix whose components can be expressed as:

$$\mathbf{J}_k = \frac{\partial \boldsymbol{\vartheta}}{\partial D_{z,k}} = \begin{bmatrix} \frac{\partial v_{x,G}}{\partial D_{z,k}} \\ \frac{\partial v_{z,G}}{\partial D_{z,k}} \\ \frac{\partial \Phi_{y,G}}{\partial D_{z,k}} \end{bmatrix} \quad (11)$$

$\mathbf{J}_k$  can also be written as:

$$\begin{aligned} \mathbf{J}_k &= \frac{\partial \boldsymbol{\vartheta}}{\partial D_{z,k}} = \frac{\partial [(\mathbf{S}^T \mathbf{S})^{-1} \mathbf{S}^T]}{\partial D_{z,k}} \mathbf{M} = \\ &= \frac{1}{|(\mathbf{S}^T \mathbf{S})|} \left[ -\frac{\partial |(\mathbf{S}^T \mathbf{S})|}{\partial D_{z,k}} \mathbf{I} + \frac{\partial [\text{adj}(\mathbf{S}^T \mathbf{S})]}{\partial D_{z,k}} \mathbf{S}^T \mathbf{S} + \right. \\ &\quad \left. + \text{adj}(\mathbf{S}^T \mathbf{S}) \frac{\partial \mathbf{S}^T}{\partial D_{z,k}} \mathbf{S} \right] \boldsymbol{\vartheta} \end{aligned} \quad (12)$$

with  $\text{adj}(\mathbf{S}^T \mathbf{S})$  and  $|\mathbf{S}^T \mathbf{S}|$  indicating the adjoint matrix and the determinant of  $(\mathbf{S}^T \mathbf{S})$ , respectively. Finally,  $\mathbf{\Sigma}(\mathbf{D})$  is a diagonal matrix with elements  $\bar{\sigma}_{Pz}^2$ , representing the positioning accuracy along the vertical direction.

Monte Carlo simulations were carried out for estimating  $\bar{\sigma}_{Pz}$ , considering the resolution cell size of the COSMO-SkyMed constellation, equal to  $3\text{m} \times 3\text{m}$ . The turbine tower can be divided into resolution segments  $RS$ s, which represent the projection of the ground resolution cell along the vertical direction. Random PS positions inside the ascending and descending resolution segments were simulated. The value of  $\bar{\sigma}_{Pz}$  was defined as the standard deviation of the distance of the PS from the segment centre. For this specific case, the formulations were applied to incidence angles of  $\alpha_A = 32.64^\circ$  and  $\alpha_D = 37.10^\circ$ . The obtained results are displayed in Table 1, while the trends of resolution segment lengths and standard deviations with the incidence angle are displayed in Figure 2. It is interesting to note that, since the resolution segment dimension depends on the incidence angles  $\alpha_A$  and  $\alpha_D$ , scatterers measured in the ascending orbit will display a different resolution than those measured in the descending orbit. In summary, the analytical formulation of the total uncertainty affecting each motion component can be derived by directly applying the error propagation law to both measurement and positioning errors:

$$\sigma_T(\vartheta_r) = \sqrt{\sigma_P^2(\vartheta_r) + \sigma_M^2(\vartheta_r)} \quad (13)$$

where  $\sigma_M(\vartheta_r)$  and  $\sigma_P(\vartheta_r)$  indicate, respectively, the measuring and positioning errors associated with the generic  $r$ -th motion component.

### 3 PROCEDURE FOR DATA SIMULATION

This section presents the numerical analyses designed to assess the performance of the procedure described in section 2. The analysis is based on: (i) applying rigid motion to an hypothetical turbine, (ii) simulating satellite measurements with incorporated measurement and positioning uncertainties, (iii) evaluating the rigid motion as outlined in section 2.2, (iv) comparing the imposed and estimated displacements, and (v) assessing the variability of the results.

The first step involved defining the geometric parameters of the wind turbine. A typical height of modern wind turbines is about 100 meters. For this reason, a maximum height  $D$  of 100 m was assumed. Next, the satellite characteristics of the COSMO-SkyMed constellation are chosen according to section 2.1. Incidence angles of the ascending and descending orbit are set equal to  $\alpha_A = 32.64^\circ$  and  $\alpha_D = 37.10^\circ$ , respectively.

To simulate PS mean annual velocities and positions, motion component values needed to be imposed to the turbine, thus defining vector  $\mathbf{\vartheta}$ . Matrix  $\mathbf{S}$  was reconstructed by incorporating

Figure 2. Trend of the standard deviation  $\bar{\sigma}_{Pz}$  and of the resolution segment  $RS$  with the satellite incidence angle.

the previously defined satellite geometries and a specific number of PSs, which was constrained by an upper limit based on the tower height and the resolution cells dimensions.

To simulate the measurement errors, quantities extracted from a Gaussian distribution with zero mean and a standard deviation of  $\bar{\sigma}_M$  were added to the velocities in vector  $\mathbf{M}$ . Measurement uncertainties were assessed in the cases of  $\bar{\sigma}_M=1$  mm/yr,  $\bar{\sigma}_M=2$  mm/yr and  $\bar{\sigma}_M=5$  mm/yr.

To clearly evaluate the impact of measurement and positioning errors, three scenarios are analyzed: the contribution of measurement errors alone, the contribution of positioning errors alone, and the effect of both. To account for the contribution of only measurement errors, the PSs were positioned at the exact center of each resolution segment. The PSs velocities along the lines of sight were then computed applying eq. (4). Instead, to account for only positioning errors, the PS velocities were kept without any uncertainties, while random errors were introduced into the PS heights within matrix  $\mathbf{S}$ . These errors shifted the PSs positions randomly within their resolution segments, displacing them from the center but ensuring they remained within the segment boundaries. Finally, the case where both measurement and positioning uncertainties are considered was evaluated. Total uncertainty for each motion component was numerically estimated by combining the two approaches: both the PS velocities in vector  $\mathbf{M}$  and the PS elevations in matrix  $\mathbf{S}$  were perturbed from their exact values by adding random quantities extracted as described above. For quantifying the analytical uncertainty, the measurement and positioning errors formulas were combined through the error propagation law (eq. (13)).

For each of these three scenarios, the analytical error formulations were compared to the numerical ones across three different cases:

- 1) The PS number was kept constant, while the motion components were varied in discrete steps, ranging from zero to their maximum values according to Table 2.
- 2) The motion components were kept at a constant value – equal to the maximum one – while the PS number was varied from a minimum of two per orbit up to the maximum one;

Table 1. Positioning accuracy.

Orbit	Incidence angle $\alpha$ [°]	Incidence angle $\alpha$ [rad]	Resolution segment $RS$ [m]	Standard dev. $\bar{\sigma}_{Pz}$ [m]
ASC	32.64	0.57	4.684	1.351
DES	37.10	0.65	3.967	1.144

Table 2. Ranges of variation of the imposed motion parameters.

Motion component	Min value	Max value	Step
$v_{x,G}$ [mm/yr]	0	10	0.2
$v_{z,G}$ [mm/yr]	0	100	2
$\Phi_{y,G}$ [mrad/yr]	0	2	0.04

- 3) The PS number was kept constant, while one motion component at a time was varied in discrete steps, as in case 1), with the others held at a constant zero value.

For each step of the three cases, Monte Carlo simulations were performed to characterize the rigid motion component uncertainties, which are then compared with the analytical ones obtained from in eqs. (9), (10) and (13).

## 4 RESULTS

In this section, the results obtained for each of the cases outlined above will be discussed and presented in the form of graphs and tables. Note that, for simplicity, only the results related to the vertical translation and rotation of the turbine are shown, as they are considered the most representative of foundation settlement. However, the procedure can also be applied to W-E translation.

### 4.1 Measurement uncertainties

The first scenario, which includes only measurement errors and excludes positioning errors, is presented in this subsection. The results are presented in terms of the uncertainty values of the rigid motion components as the value of the component itself and the number of PSs on the structure vary.

#### 4.1.1 Case 1: variation of the uncertainties with the motion amplitude

The results are presented in graph form (Figures 3 and 4) for the cases of  $\bar{\sigma}_M=1, 2$  and 5 mm/yr. Both the error and the coefficient of variation (CoV) associated with each motion component are shown as the corresponding motion component varies. For clarity, results for the maximum step are also provided in Table 3 for the case of  $\bar{\sigma}_M=2$  mm/yr, which is considered the most representative measurement precision for this specific case.

As expected, both numerical and analytical uncertainties decrease as measurement accuracy increases – namely, the value of  $\bar{\sigma}_M$  decreases. Additionally, it is important to note that the measurement uncertainty is independent on the motion component amplitude. This result is expected because eq. (8) states that the value of  $\sigma_M(\mathbf{\theta})$  is independent on  $\mathbf{\theta}$ . On the other hand, the coefficient of variation of the uncertainty decreases if the motion component increases. As observed from both the tables and graphs, the numerical uncertainty appears to be well approximated by the analytical formulations at each motion step, indicating that the motion entity does not affect the accuracy of the analytical models.

#### 4.1.2 Case 2: variation of the uncertainties with the number of PSs

The results are presented in Figures 5 and 6. The first graph depicts the values of  $\sigma_M(v_{z,G})$  and the CoV of  $v_{z,G}$  as a function

of the number of PS in the ascending and descending orbits for the cases of  $\bar{\sigma}_M=1, 2$  and 5 mm/yr, while the second one shows the values of  $\sigma_M(\Phi_{y,G})$  and the CoV of  $\Phi_{y,G}$  under the same conditions. For simplicity, the results are presented for the case where both orbits have the same number of PSs; in fact, the final step involves the use of 21 scatterers per orbit. Note that, as stated in section 2.2,  $n$  and  $m$  indicate, respectively, the number of PSs available for ascending and descending orbit.

Table 3. Measurement uncertainties on the rigid motion components -  $\bar{\sigma}_M=2$  mm/yr, last step.

Component		$v_{x,G}$ [mm/yr]	$v_{z,G}$ [mm/yr]	$\Phi_{y,G}$ [mrad/yr]
Imposed		10.000	100.000	2.000
Simulated		9.992	100.002	2.000
$\sigma_M(\mathbf{\theta}_r)$	Numerical	1.048	0.375	0.018
	Analytical	1.028	0.363	0.018
CoV( $\mathbf{\theta}_r$ )	Numerical	10.48%	0.375%	0.917%
	Analytical	10.29%	0.363%	0.900%

Figure 3. Influence of  $v_{z,G}$  on the measurement uncertainties: (a)  $\sigma_M(v_{z,G})$  and (b) CoV of  $v_{z,G}$ .

Figure 4. Influence of  $\Phi_{y,G}$  on the measurement uncertainties: (a)  $\sigma_M(\Phi_{y,G})$  and (b) CoV of  $\Phi_{y,G}$ .

Figure 5. Influence of the PS number on the measurement uncertainties: (a)  $\sigma_M(v_{z,G})$  and (b) CoV of  $v_{z,G}$ .

Figure 6. Influence of the PS number on the measurement uncertainties: (a)  $\sigma_M(\Phi_{y,G})$  and (b) CoV of  $\Phi_{y,G}$ .

To obtain uncertainties, at least two permanent scatterers are required per orbit. The results corresponding to the maximum number of permanent scatterers align with those shown in Table 3 for the  $\bar{\sigma}_M = 2$  mm/yr case. As expected, the uncertainties in the rigid motion parameters decrease as the number of PSs increases. For instance, in the case of S-N rotation  $\Phi_{y,G}$ , the coefficient of variation approaches nearly 20% if only 4 PSs are given and it decreases to a value less than 4% in the case of a number of PS greater than 18. Additionally, the numerical uncertainties appear to be well approximated by the analytical formulations, regardless of the PSs number. However, when only 2 scatterers per orbit are considered, the analytical formulations tend to underestimate the uncertainty, especially at lower measurement accuracy values. It can be observed that, to obtain significant results, at least five scatterers are needed in each orbit.

#### 4.2 Positioning uncertainties

In this subsection, the results including only the positioning error are presented as a function of the amplitude of the motion component as well as of the number of observed PSs.

##### 4.2.1 Case 1: variation of the uncertainties with the motion amplitude

Results are displayed in Figures 7, 8, and Table 4. The variation of  $\sigma_P(v_{z,G})$  and CoV of  $v_{z,G}$  with the value of  $v_{z,G}$  are shown in Figure 7, while the variation of  $\sigma_P(\Phi_{y,G})$  and CoV of  $\Phi_{y,G}$  with the value of  $\Phi_{y,G}$  are shown in Figure 8.

Numerical simulations were performed by introducing random perturbations to each PS position, as described in section 3. In contrast, analytical errors were computed using the method and parameters described in section 2.3.

The good agreement between the numerical and analytical uncertainties, as well as the CoVs for each motion component, demonstrates that the proposed analytical models provide a reliable approximation of the numerical errors, even in the case of positioning errors. It is also observed that, as predicted by eq. (12), positioning errors increase with the magnitude of the considered motion component, indicating that the positioning uncertainties do depend on the motion entity.

Figure 7. Influence of  $t v_{z,G}$  on the positioning uncertainties: (a)  $\sigma_P(v_{z,G})$  and (b) CoV of  $v_{z,G}$ .

Figure 8. Influence of  $\Phi_{y,G}$  on the positioning uncertainties: (a)  $\sigma_P(\Phi_{y,G})$  and (b) CoV of  $\Phi_{y,G}$ .

Table 4. Positioning uncertainties on the rigid motion components, last step.

Component		$v_{x,G}$ [mm/yr]	$v_{z,G}$ [mm/yr]	$\Phi_{y,G}$ [mrad/yr]
Imposed		10.000	100.000	2.000
Simulated		10.166	99.999	1.997
$\sigma_P(\vartheta_r)$	Numerical	0.718	0.259	0.013
	Analytical	0.723	0.258	0.013
CoV( $\vartheta_r$ )	Numerical	7.06%	0.259%	0.634%
	Analytical	7.11%	0.258%	0.631%

Figure 9. Influence of the PS number on the positioning uncertainties: (a)  $\sigma_P(v_{z,G})$  and (b) CoV of  $v_{z,G}$ .

Figure 10. Influence of the PS number on the positioning uncertainties: (a)  $\sigma_P(\Phi_{y,G})$  and (b) CoV of  $\Phi_{y,G}$ .

#### 4.2.2 Case 2: variation of the uncertainties with the number of PSs

Figures 9 and 10 show the results as a function of the PS number. Specifically, Figure 9 illustrates the variation in positioning uncertainty  $\sigma_P(v_{z,G})$  and in the CoV of  $v_{z,G}$ , while

Figure 10 presents the variation in positioning uncertainty  $\sigma_P(\Phi_{y,G})$  and in the coefficient of variation of  $\Phi_{y,G}$ .

Note that, in line with the measurement error case, the values of  $\sigma_P(v_{z,G})$  and  $\sigma_P(\Phi_{y,G})$  tend to increase as the number of PSs decreases. Specifically, although the numerical uncertainty is generally well approximated by the analytical formulations, when only 2 PSs per orbit are considered, the analytical formulations underestimate both the uncertainties and the coefficients of variation.

#### 4.2.3 Case 1: variation of the uncertainties with the motion amplitude

As observed in the previous case, positioning error is indeed influenced by the motion entity. Therefore, it is crucial to identify which motion components have the greatest impact on the error. Figure 11, Figure 12 and Figure 13 show the variation in positioning uncertainty with the magnitude of the motion components. As shown, positioning errors seem to be uncorrelated with variations in  $v_{x,G}$  and  $v_{z,G}$ . Specifically, their values are in the order of  $10^{-10}$  mm/yr and rad/yr.

On the other hand, positioning errors appear to be strongly correlated with rotation; therefore, only the turbine's rotation can induce errors in the positioning of the PS.

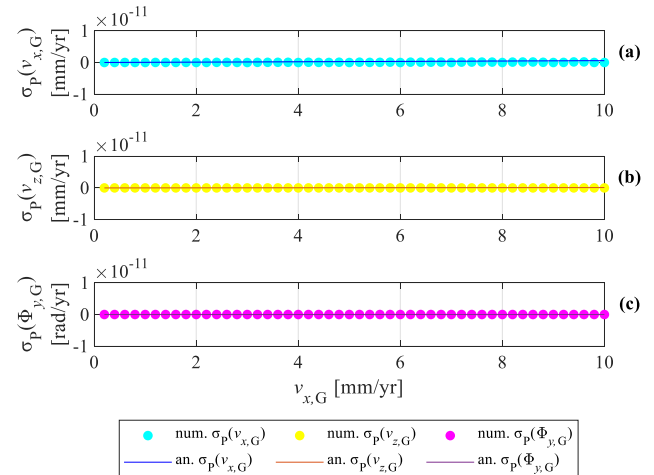

Regardless of the variations in motion components, analytical formulations appear to provide a good approximation of numerical errors.

#### 4.3 Total uncertainties

##### 4.3.1 Case 1: variation of the uncertainties with the value of the motion component

Figures 14 and 15 display the results in the form of graphs: as previously stated, the considered positioning precision is detailed in

, while for immediacy measurement precision is fixed at  $\bar{\sigma}_M = 2$  mm/yr. Particularly, Figure 14 details how the variation in  $v_{z,G}$  influences the total error  $\sigma_T(v_{z,G})$  and CoV of  $v_{z,G}$ , while Figure 15 illustrates the total error  $\sigma_T(\Phi_{y,G})$  and CoV of  $\Phi_{y,G}$  as a function of  $\Phi_{y,G}$ . For the sake of clarity, results regarding the maximum  $v_{z,G}$  and  $\Phi_{y,G}$  values are also displayed in table form in Table 5.

Figure 11. Influence of  $v_{x,G}$  on the positioning uncertainties:  $\sigma_P$  of  $v_{x,G}$  (a),  $v_{z,G}$  (b) and  $\Phi_{y,G}$  (c).

Figure 12. Influence of  $v_{z,G}$  on the positioning uncertainties:  $\sigma_p$  of  $v_{x,G}$  (a),  $v_{z,G}$  (b) and  $\Phi_{y,G}$  (c).

Figure 13. Influence of  $\Phi_{y,G}$  on the positioning uncertainties:  $\sigma_p$  of  $v_{x,G}$  (a),  $v_{z,G}$  (b) and  $\Phi_{y,G}$  (c).

Numerical simulations of uncertainties were performed as outlined in section 3. In contrast, analytical errors were computed using the method and parameters described in Section 2.3; in particular, adopting the formula described in equation (13). The good agreement between the numerical and analytical uncertainties, as well as the CoVs for each motion component, demonstrates that the proposed analytical models provide a reliable approximation of the numerical errors, even in the case of total errors. Note that measurement errors seem to be the largest contributor to the total uncertainty, while positioning error becomes a more significant factor as the motion component increases.

#### 4.3.2 Case 2: variation of the uncertainties with the number of PSs

In Figure 16, the variations of the total error  $\sigma_T(v_{z,G})$  and of the total CoV of  $v_{z,G}$  as a function of PSs number are displayed. Moreover, Figure 17 depicts the variation of the total error  $\sigma_T(v_{z,G})$  and of the total CoV of  $v_{z,G}$  as a function of PSs number. Note that, as anticipated, errors increase as the number of PSs decreases.

Figure 14. Influence of  $v_{z,G}$  on the total uncertainties: (a)  $\sigma(v_{z,G})$  and (b) CoV of  $v_{z,G}$ .

Figure 15. Influence of  $\Phi_{y,G}$  on the total uncertainties: (a)  $\sigma(\Phi_{y,G})$  and (b) CoV of  $\Phi_{y,G}$ .

Table 5. Total uncertainties on the rigid motion components -  $\bar{\sigma}_M=2$  mm/yr, last step.

Component		$v_{x,G}$ [mm/yr]	$v_{z,G}$ [mm/yr]	$\Phi_{y,G}$ [mrad/yr]
Imposed		10.000	100.000	2.000
Simulated		10.143	99.996	1.997
$\sigma_T(\vartheta_r)$	Numerical	1.273	0.447	0.022
	Analytical	1.248	0.444	0.022
CoV( $\vartheta_r$ )	Numerical	12.55%	0.447%	1.119%
	Analytical	12.31%	0.444%	1.092%

Similarly to the cases of measurement and positioning uncertainties, the numerical uncertainty is generally well approximated by the analytical formulations. The only exception occurs when 2 scatterers per orbit are considered, where the analytical formulations underestimate the numerical errors.

Figure 16. Influence of the PS number on the total uncertainties: (a)  $\sigma(v_{z,G})$  and (b) CoV of  $v_{z,G}$ .

Figure 17. Influence of the PS number on the total uncertainties: (a)  $\sigma(\Phi_{y,G})$  and (b) CoV of  $\Phi_{y,G}$ .

#### 4.3.3 Case 1: variation of the uncertainties with the motion amplitude

Results are presented in Figures 18, 19 and 20. In particular, the three graphs depict how the variations in  $v_{x,G}$ ,  $v_{z,G}$  and  $\Phi_{y,G}$ , respectively, influence the total errors  $\sigma_T(v_{x,G})$ ,  $\sigma_T(v_{z,G})$  and  $\sigma_T(\Phi_{y,G})$ .

As already observed in the positioning uncertainties case, the rotation appears to be the only motion component affecting the uncertainty, while the translations have no effect on the error. Specifically, an increase in  $\Phi_{y,G}$  directly translates in an increase of the component total errors. In any case, the analytical formulations provide an effective approximation of the numerical errors: their quality is validated by their accurate approximation of numerical errors in each of the presented cases.

## CONCLUSIONS

This paper proposes a method for estimating the 3D rigid motion components of wind turbines and the corresponding uncertainties using DInSAR satellite data.

Figure 18. Influence of  $v_{x,G}$  on the total uncertainties:  $\sigma_T$  of  $v_{x,G}$  (a),  $v_{z,G}$  (b) and  $\Phi_{y,G}$  (c).

Figure 19. Influence of  $v_{z,G}$  on the total uncertainties:  $\sigma_T$  of  $v_{x,G}$  (a),  $v_{z,G}$  (b) and  $\Phi_{y,G}$  (c).

Figure 20. Influence of  $\Phi_{y,G}$  on the total uncertainties:  $\sigma_T$  of  $v_{x,G}$  (a),  $v_{z,G}$  (b) and  $\Phi_{y,G}$  (c).

Rigid motion of wind turbines can be generally associated with foundation settlement, a gradual phenomenon that can potentially cause damage to both structural and non-structural elements. Traditional Structural Health Monitoring techniques typically require extended acquisition times, making them economically impractical, particularly in foundation settlement cases. In contrast, satellite-based monitoring allows for the direct analysis of historical displacement time series without the need for on-site instrumentation, while enabling the monitoring of displacements over large areas with high accuracy. The proposed approach utilizes the mean annual displacement of permanent scatterers along the lines of sight, thereby eliminating the need for temporal and spatial resampling of satellite data.

The accuracy of the proposed approach was evaluated using Monte Carlo numerical simulations, in which satellite data were generated while accounting for uncertainties in both the displacement of the considered scatterers (measurement errors) and their vertical positioning along the wind turbine (positioning errors). The numerical results were then compared with those derived from the analytical expressions initially presented in [14] and adapted for application to wind turbines. The satellite data parameters were based on those of the COSMO-SkyMed constellation, which is particularly well-suited for structural monitoring applications. Numerical errors and analytical uncertainties were evaluated across various scenarios, including variations in the 3D motion components and the number of available PSs on the turbine. As expected, an increased number of available PSs leads to reduced uncertainties, while larger turbine rotations result in greater errors. In contrast, the uncertainties remain uncorrelated with both vertical and horizontal translations.

The method presents certain limitations, including the approximation of the turbine as a purely rigid body, which necessitates fitting the data to a rigid model without accounting for possible structural deformations. Additionally, the approach relies on Permanent Scatterers (PS), which – depending on the processing technique – can be affected by noise due to both decorrelation and atmospheric effects, potentially impacting the accuracy of the results. Nevertheless, the strong agreement observed between numerical simulations and analytical predictions confirms the robustness of the proposed procedure in estimating the rigid-body motion of wind turbines and the associated uncertainties. The method demonstrates high precision, with uncertainties on the order of tenths of millimeters and/or milliradians per year.

The next steps of the research involve attempting to obtain a priori estimates of the uncertainty based solely on the knowledge of the potential number of PS present, to assess whether satellite data can already provide the required accuracy during the phase of selecting the monitoring methodology. For this purpose, simplifications regarding the distribution of PS will be made. Additionally, data from a wind farm will be analyzed to evaluate the possibility of applying the methodology to real cases.

**ABSTRACT:** The decommissioning of wind turbine blades (WTBs) presents significant environmental challenges due to their non-biodegradable composition. To promote sustainable reuse and repurposing, it is essential to establish effective structural health monitoring (SHM) techniques that can accurately assess the residual performance of decommissioned WTBs. This study investigates the feasibility and applicability of distributed fibre optic sensing (DFOS) as an advanced monitoring tool for evaluating the structural integrity of decommissioned WTBs intended for reuse in civil engineering applications. A four-point bending test was conducted on a WTB segment, with DFOS deployed alongside other monitoring techniques, including strain gauges, and digital image correlation (DIC). The DFOS measurements demonstrated strong agreement with those obtained from strain gauges and DIC, with negligibly small variations in strain magnitude, validating its accuracy and reliability for continuous strain monitoring. The results further confirmed sufficient load-bearing capacity of the WTB segment, indicating its potential for second-life structural applications. This study highlights the capability of DFOS in providing high-resolution, distributed strain measurements, offering a promising approach for assessing the suitability of decommissioned WTBs for reuse. Future research aims to incorporate material characterisation studies and long-term monitoring to establish standardised frameworks for the sustainable repurposing of WTBs, contributing to a circular economy in the wind energy sector.

**KEY WORDS:** Decommissioned wind turbine blades; Repurposing; Four-point bending test; Distributed fibre optic sensing.

## 1 INTRODUCTION

Wind energy has become a cornerstone of sustainable energy solutions worldwide, significantly contributing to the reduction of carbon emissions. In Ireland, the expansion of onshore and offshore wind farms is expected to play a critically significant role in achieving the country's 2030 renewable energy targets, potentially reducing its carbon emissions by 51% [1]. However, as wind energy industry grows and matures, a growing challenge is the decommissioning of the wind turbine blades (WTBs). By 2025, approximately 11,000 tons of WTBs are expected to be decommissioned in Ireland alone [2]. These blades are predominantly made from glass fibre reinforced polymer (GFRP) composites, which are non-biodegradable and pose significant disposal challenges, often ending up in landfills and leading to environmental degradation [3].

Despite the environmental challenges, WTBs possess unique structural properties, including high strength-to-weight ratios and resistance to harsh environmental conditions, making them promising candidates for reuse and repurposing in civil engineering applications [4]. Previous studies have explored various repurposing strategies. For example, Martini and Xydis (2022) reviewed the common practice of WTB reuse and recycling in the United States, which included whole and partial blade reuse, and grinding material reuse [5]. In another study, Hasheminezhad et al. (2024) further reviewed its reuse for construction and infrastructure applications [4], such as powerline poles [6], slow-traffic bridges [7], picnic tables [8], playground [9], etc.

However, despite the growing interest in repurposing WTBs, a critical challenge lies in understanding the residual structural performance after years of service. Long-term exposure to

environmental influences, such as UV radiation, moisture, and cyclic loading, can degrade the mechanical properties of the GFRP composites used in WTBs, which may influence their structural integrity and impact their long-term performance and suitability for reuse in civil engineering applications.

To enable the safe and sustainable reuse and repurposing of decommissioned WTBs, effective condition monitoring and structural health assessment is essential. While traditional monitoring methods, such as strain gauges, provide valuable insights, they are often limited to their discrete measurements. In contrast, distributed fibre optic sensing (DFOS) offers a high-resolution, continuous, and long-term monitoring solution capable of capturing detailed strain distributions over large structural elements. DFOS has been successfully implemented in various infrastructure applications such as tunnels [10], but its feasibility and applicability for monitoring the residual structural performance of decommissioned WTBs remains largely unexplored.

This study aims to evaluate the feasibility of DFOS as a monitoring technique for assessing the residual performance of a decommissioned WTB segment subjected to four-point bending tests. The segment was instrumented with DFOS, alongside other monitoring techniques such as strain gauges, linear variable differential transformers (LVDTs), and digital image correlation cameras to enable a comparative assessment of measurement accuracy and reliability. By examining the strain distribution and mechanical behaviour of the WTB segment, this study aims to determine the suitability of DFOS for structural health monitoring in second-life applications of decommissioned WTBs. The findings will contribute to the development of robust monitoring frameworks for WTB reuse

in civil engineering, supporting a circular economy in the wind energy sector and enhancing the sustainability of wind turbine decommissioning.

## 2 METHODOLOGY

### 2.1 Wind turbine blade preparation

The decommissioned wind turbine blade used in this study was sourced from a V42/600 wind turbine manufactured by Vestas in Denmark. Each turbine has a power rating of 600 kW and consists of three blades. The turbines have a rotor diameter of 42m, and each blade has a total length of 21 meters from root to tip. A 4-meter long segment was cut from the tip side for laboratory testing. In the initial preparation stage, the geometry of this blade segment was measured using vernier callipers, as illustrated in Figure 1(a). Surface stains were cleaned to facilitate a visual inspection for any potential damage. Subsequently, the blade segment was divided into 500 mm-long sections using a measuring tape and a chalk line. To accurately identify the location of the spar on the tip side, the final 500 mm portion at the blade tip was removed. The centre of the blade segment was then marked, with 600 mm measured on each side of the centreline to designate the positions for the spreader beams. A line was drawn connecting the top spar on the root side to the top spar on the tip side of the blade segment. To accommodate the installation of spreader steel beams, which are designed to transfer loads onto the spar cap, 110 mm square sections were cut from both the high-pressure and low-pressure sides of the blade aerofoil at the points where each 600 mm mark intersected with the spar cap line. This process is depicted in Figure 1(b).

(a) Geometry of the WTB segment [11]

(b) WTB segment preparation for testing  
Figure 1. Geometry of the WTB segment

### 2.2 Loading arrangement

The blade was positioned in the edgewise direction with the trailing edge facing upward and was supported by two timber saddles, each placed 170 mm from the ends to avoid areas of local skin damage. Loading was applied using two hydraulic jacks acting on both spreader beams, simulating a four-point bending test. Load cells beneath each jack recorded the applied force. Two four-point bending tests were conducted on the blade segment. In test 1, a total load of 30kN was applied, while in test 2, the total load reached 50kN. The objective was to maintain loading within the blade's elastic range, enabling multiple repetitions if necessary. In both tests, loading was applied stepwise: for the 30kN test, a designed step loading of 2-5kN was used, whereas for the 50kN test, increments of 10kN were used. Figure 2 illustrates the loading system. The four-point loading was carried out by manual handling of two hydraulic jacks due to the dysfunction of the automatic system. The loading details of both tests were shown in Figure 3.

Figure 2. Illustration of the four-point bending test

Loading record of test 1

Loading record of test 2

Figure 3. Loading details of both tests

### 2.3 Monitoring system setup

To monitor the strain and displacement development of the WTB segment under four-point loading tests, a comprehensive monitoring system was implemented to capture multiple sets of displacement measurements, enabling a thorough assessment of its mechanical performance. This system incorporated diverse techniques, including strain gauges, LVDT, DIC) and DFOS. The setup of each monitoring system is detailed below. A general view of the installed monitoring systems on the WTB segment is shown in Figure 4.

**Strain gauge and LVDT:** Two strain gauges were deployed on the back of the WTB segment, as shown in Figure 4. The strain gauge fixed at the upper part of the blade segment is 80 mm from the top and the other gauge fixed at the lower level is 80mm from the bottom of the segment. Both strain gauges were deployed in the middle span of the blade segment. Three LVDTs were installed at three distinctive locations on the back of blade segment, as demonstrated in Figure 4. The LVDT mounted on the left was placed at a distance of 63mm below the bottom of the left spreader beam, while the one mounted on the right was at a distance of 70mm from the bottom of the right spreader beam. The middle one was fixed at 430mm from the top of the blade in the vertical direction.

Figure 4. Monitoring system setup on the WTB segment

DIC and DFOS: One DIC camera was positioned to capture and monitor the deformation and displacement of the front side of the WTB segment. Line gauges and reference points were marked at key locations to facilitate deformation tracking. These markers were symmetrically aligned on the front face with the two strain gauges and three LVDTs positioned on the back of the segment, as shown in Figure 5. To get continuous strain measurements of the WTB segment, a Brillouin-based DFOS system was deployed. DFOS cables were installed on both the front and back surfaces of the segment, with two fixed loops: one horizontal and one vertical, as shown in Figures 4 and 5. The data logger used in this experiment was the VISION dual interrogator, manufactured by Omnisens, which integrates Brillouin Optical Time Domain Reflectometry (BOTDR) and Brillouin Optical Time Domain Analysis (BOTDA), enabling short- to long-distance strain measurements over a single fibre.

Figure 5. Line gauges and points to mark locations for DIC

#### 2.4 DFOS instrumentation details

Theoretically, the four-point bending of the WTB segment is expected to induce the highest strain in its top and bottom regions, while the central portion is supposed to experience the lowest strain magnitude. Consequently, the monitoring systems are strategically positioned around the top and bottom areas to capture the most significant strain responses. To ensure consistency and comparability in the monitoring program, DFOS was deployed at locations corresponding to the strain gauges and LVDTs, as illustrated in Figure 6. The front and back surfaces of the WTB segment were instrumented with a single loop of longitudinal DFOS cable, which was virtually divided into three segments on the front and three on the back

(Figure 6(a)). In addition, an out-of-plane loop comprising five loops was installed at the mid-span of the segment and virtually segmented into ten sections on both the front and back surfaces (Figure 6(b)). Figure 6 provides a schematic representation of the DFOS instrumentation design for the WTB segment.

(a) Deployment of DFOS longitudinal loop

(b) Deployment of DFOS out-of-plane loop

Figure 6. DFOS deployment on the WTB segment

The DFOS cables used for monitoring strain development in the WTB segment are single-mode fiber optic cables. These cables were affixed to the front and back surfaces of the WTB segment using Loctite EA 3421 adhesive. For the longitudinal loop of DFOS cables, the top section was installed horizontally along DIC marker Line 1, as indicated in Figure 4-6, rather than being aligned parallel to the top edge of the WTB segment. The middle and bottom sections were also affixed horizontally. The vertical spacing between the top and middle section is 295 mm, while the distance between the middle and bottom sections is 210 mm, with the bottom section positioned 80 mm from the lower edge of the segment. The deployment sequence of the longitudinal loop followed the following order: Section 1-Section 2-Section 4-Section 3-Section 5-Section 6.

For the out-of-plane loop of DFOS cables, five sub-loops were installed on both the front and back surfaces of the WTB segment. The deployment sequence followed the order: Section 2-Section 1-Section 3-Section 4-Section 6-Section 5-Section 7-Section 8-Section 10-Section 9. The spacing between adjacent sub-loops was approximately 190 mm. Loop 1 was positioned 170 mm from the right load-spreader beam, while Loop 5 was located 188 mm from the left load-spreader beam.

Once the DFOS cables were installed, they were left undisturbed for approximately 48 hours to allow the adhesive to cure fully and ensure a secure bond between the cables and the segment surface, preventing slippage. Following the curing period, laser beams were used to verify the integrity of the DFOS deployment. Once the installation was confirmed to be intact, the formal testing phase commenced.

### 3 MONITORING RESULTS

#### 3.1 DFOS measurements

Figure 7 presents the monitoring results obtained using DFOS under test 1 and test 2 for the longitudinal loops, alongside the strain gauge (SG) and DIC measurements for comparison. As previously discussed, the middle section of the WTB segment (Section 3 and Section 4) is theoretically expected to exhibit the lowest strain magnitude, which is corroborated by the results in Figure 7. Given the minimal strain observed in these sections, their performance will not be further analysed in this paper.

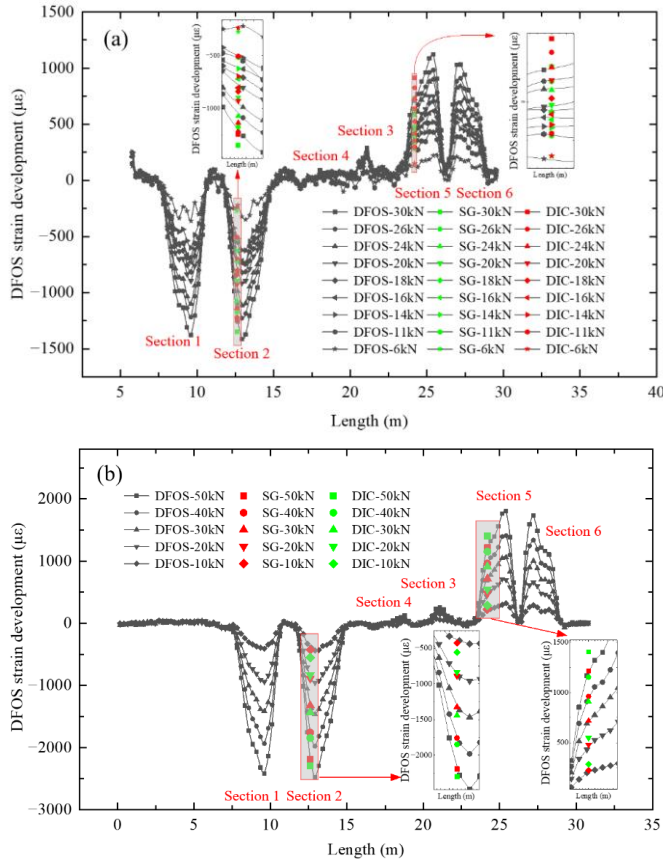

Figure 7. DFOS monitoring results of longitudinal sections under (a) test 1 and (b) test 2

Figure 8 presents enlarged graphs of the measurements obtained in Section 2 and Section 5, corresponding to locations where the DFOS sensors were positioned adjacent to two strain gauges. These graphs provide further insights into the bending behaviour of the WTB segment and facilitate a comparative analysis of different monitoring techniques. As illustrated in Figure 6, Section 1 and Section 2 were affixed to the back and front surfaces of the turbine blade, respectively, at the same height. Theoretically, the bending patterns observed in these areas should be similar under both test 1 and test 2, a hypothesis that is confirmed by the results presented in Figures 8(a) and 8(c). A comparable trend was observed in Sections 5 and 6, further validating this expectation. The consistency in bending patterns across these sections underscores the repeatability and reliability of the DFOS system employed in this study.

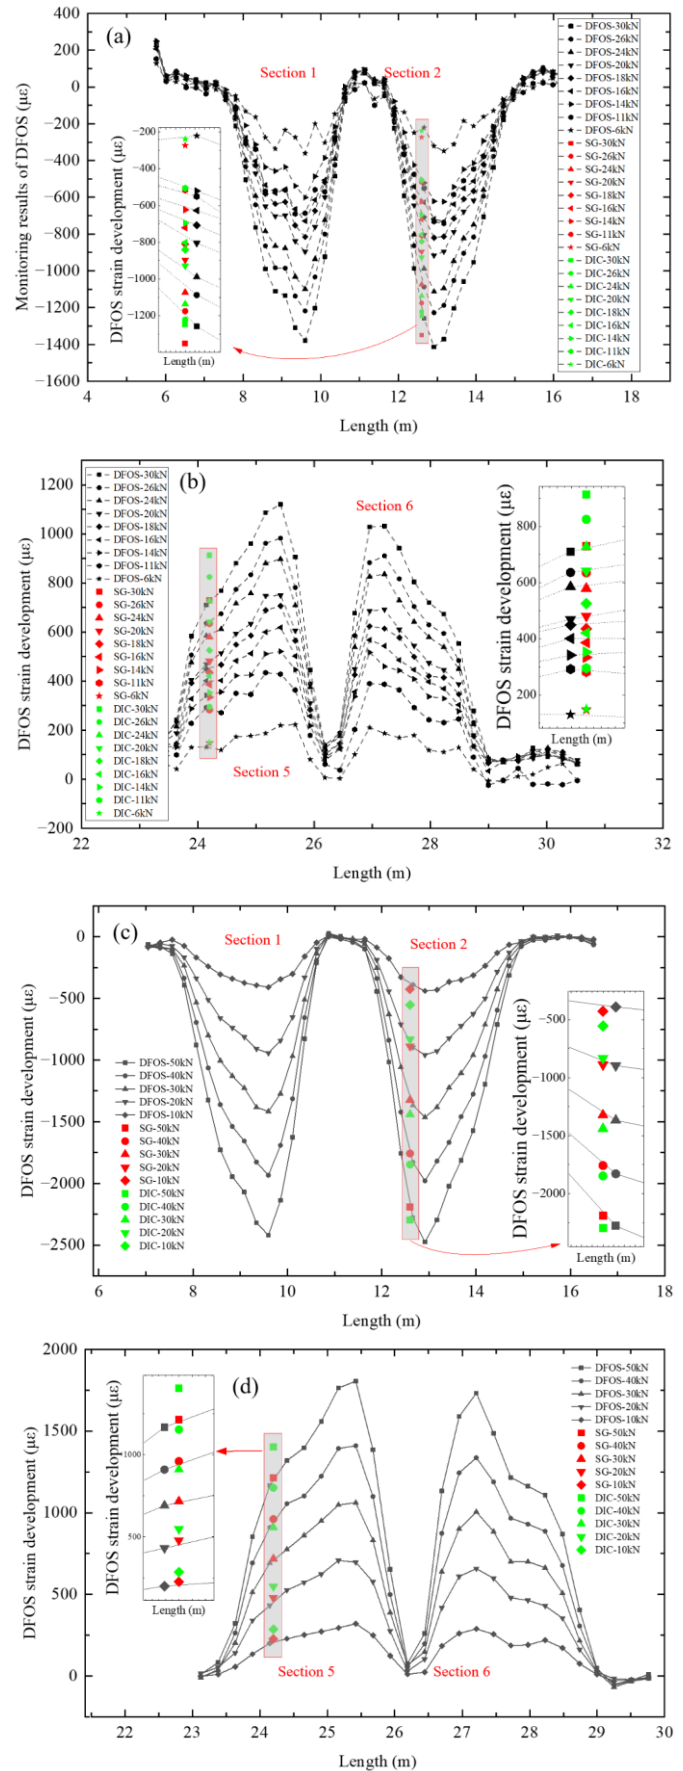

Figure 8. Enlarged graphs of section 2 and section 5 under test 1 (a and b) and test 2 (c and d)

### 3.2 Test results comparison

Figure 9 presents a comparative analysis of the monitoring results obtained using different techniques. The detailed values recorded by the strain gauge, DIC, and DFOS at the top and bottom area of the WTB under test 1 and test 2 are summarised in tables 1 and 2, corresponding to the conditions where total loadings of 30kN and 50kN were reached, respectively.

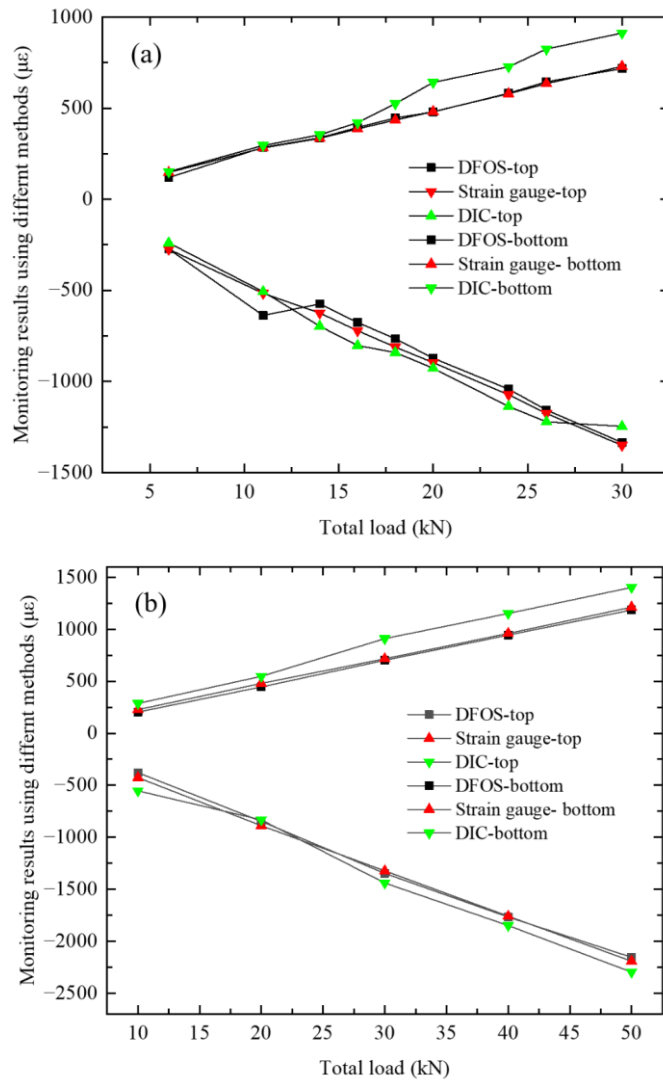

Figure 9. Comparison of monitoring results under (a) test 1 and (b) test 2

Table 1. Monitoring results under test 1

Strain/ $\mu\epsilon$	6kN	11kN	14kN	16kN	18kN	20kN	24kN	26kN	30kN
DFOS-top	-272.6	-637	-574.2	-675.8	-765.1	-871.5	-1041.4	-1155.9	-1334.4
SG-top	-274	-516	-624	-721	-811	-896	-1073	-1175	-1350
DIC-top	-239.6	-506.7	-696.2	-802.2	-840.5	-927.3	-1136.4	-1221.2	-1246.1
DFOS-bottom	119.6	284.7	337.4	393.8	446.4	479.5	581.8	644.7	717.2
SG- bottom	147	282	334	386	435	481	579	634	729
DIC-bottom	150.9	295.5	353.2	420.6	524.8	641.4	727.2	824.3	912.3

Figure 9 illustrates that measurements obtained using different monitoring techniques exhibit consistent deformation patterns in the turbine blade under both test 1 and test 2. The results indicate that the upper region of the blade experienced tensile stress, while the bottom region was subjected to compressive stress. Furthermore, as the external loading increased, the measured strain values exhibited an approximately linear increase, confirming the expected mechanical response of the WTB structure.

Overall, the DFOS measurements in both tests exhibited strong agreement with the results obtained from strain gauges and DIC, confirming its reliability. However, fluctuations were observed in the first two measurements of DFOS-bottom under test 1, which may be attributed to inaccuracies in the manual control of the loading increment. Despite these initial variations, the results affirm the effectiveness and reliability of DFOS as an innovative structural health monitoring technique for analysing the performance of decommissioned WTBs for repurposing.

Table 2. Monitoring results under test 2

Strain/ $\mu\epsilon$	10kN	20kN	30kN	40kN	50kN
DFOS-top	-379.0	-846.8	-1346.8	-1766.2	-2153.2
SG-top	-426	-888	-1323	-1758	-2191
DIC-top	-553.3	-832.1	-1439.7	-1847.9	-2296.4
DFOS-bottom	204.6	445.2	702.5	943.8	1185.1
SG-bottom	228	479	717	960	1213
DIC-bottom	286.6	548.1	909.7	1152.3	1403.1

## 4 CONCLUSION

This study evaluated the suitability and applicability of distributed fibre optic sensing for monitoring the second-life performance of decommissioned wind turbine blades in reuse and repurposing scenarios. Four-point bending tests were conducted on a decommissioned WTB segment, with DFOS deployed alongside strain gauges, digital image correlation, and linear variable differential transformers to assess its residual structural performance. The results revealed consistent strain measurements obtained from DFOS, strain gauges, and DIC, with only negligible differences in magnitude, confirming the accuracy and reliability of DFOS in capturing strain distributions in the WTB.

Through comparative analysis, this study confirms that DFOS is a viable and effective monitoring technique for assessing the structural behaviour of decommissioned WTBs, supporting their reuse in civil engineering applications. The tested blade exhibited adequate static load resistance and beam-like behaviour under bending loads, indicating its suitability for structural applications such as bridges and other load-bearing elements. Considering the growing demand for sustainable construction materials, the reuse of decommissioned WTBs, coupled with advanced sensing techniques like DFOS, can contribute to a circular economy in the wind energy sector, reducing waste generation and environmental impact.

However, to ensure the long-term reliability and safety of decommissioned WTBs in civil infrastructure, further research is recommended. Future studies should incorporate material characterisation tests to better understand the degradation effects of aging, UV exposure, and cyclic loading on GFRP composites. Additionally, long-term monitoring under real-world environmental conditions is necessary to validate the feasibility of DFOS for field applications. These steps will help establish standardised design and assessment frameworks, facilitating the widespread adoption of repurposed WTBs in civil engineering applications.

**ABSTRACT:** Tropical cyclones (TCs) stand as one of the most destructive extreme weather events, posing significant threats to human safety and urban infrastructure. One critical phenomenon associated with TCs is the occurrence of strong winds; thus, accurate prediction of urban wind speed during TCs can provide essential information for decision-making, which is vital for enhancing urban resilience. This study proposes a deep learning-based model that accounts for the spatial and temporal dependencies of wind speed data collected from sensors of meteorological stations while addressing the impacts of climate change. The model integrates temporal and spatial encodings with measured time series data, enabling the capturing of long-term temporal dependencies that reflect periodic weather patterns and climate change through the attention mechanism of a Transformer architecture. The outputs derived from this computation are further utilized to identify dynamic patterns of wind speed during TCs. Additionally, a graph neural network (GNN) is integrated to capture spatial dependencies, considering the non-Euclidean distribution of meteorological stations. To evaluate the performance of the proposed model, wind speed measurements from Hong Kong between 2000 and 2023 are used for training and testing. Comparative analyses with sequence-to-sequence models and GNN-recurrent neural network or GNN-Transformer hybrid models demonstrate that the proposed model enhances prediction performance.

**KEY WORDS:** Tropical cyclones; Wind speed; Transformer; Graph neural network.

## 1 INTRODUCTION

Urban wind speed is a critical factor influencing human comfort, safety, and urban resilience [1] [2]. Its dynamics directly affect energy management systems [3], infrastructure durability, and ecological balance [4], while extreme wind events, such as tropical cyclones (TCs), pose significant threats to life and property. Rapid urbanization and climate change exacerbates these challenges by intensifying urban heat island effects and creating complex wind environments [5][7], further complicating prediction efforts. Accurate forecasting of urban wind speed, particularly during TCs, is thus essential for effective disaster mitigation, early-warning systems, and urban planning [8].

There are three primary methods for analyzing and predicting urban wind speed: physical models, statistical models, and hybrid models [9]. Physical models rely on geographic information and meteorological fields to solve complex physical equations. For instance, the Weather Research and Forecasting (WRF) model is often combined with complex urban canopy models to predict urban wind speed profiles during TCs [10] [11]. Additionally, WRF can be integrated with computational fluid dynamics (CFD) to investigate time-series wind speed data [12]-[14]. However, these models are typically time-consuming and computationally intensive, which may introduce time lags, and they are sensitive to parameter settings, particularly during extreme TCs.

In contrast, statistical models utilize historical data to develop statistical regressions for predicting future wind speeds. For example, autoregressive moving average (ARMA) models and generalized autoregressive conditional heteroskedasticity (GARCH) models have been employed to forecast seasonal [15]

or hourly [16] wind speed. Moreover, model decomposition methods are often integrated with ARMA to enhance wind speed predictions [17]. While statistical models offer rapid inference, they may sacrifice accuracy, especially when wind speed exhibits strong nonstationary behavior [18]. Hybrid models, which combine physical and statistical approaches, aim to leverage the strengths of both methodologies, though they also inherit the limitations of each model type.

Recent advancements in deep learning have attracted considerable attention across diverse fields, such as medicine, transportation, civil engineering, and aerospace, and the application of deep learning for predicting wind speed has also been explored. One approach treats wind speed prediction as a sequence-to-sequence task, employing recurrent neural networks (RNN)-based or convolutional neural networks (CNN)-based models. For instance, long short-term memory (LSTM), gated recurrent unit (GRU), CNN, and CNN-LSTM architectures have been assessed for their performance in long-term wind speed predictions, with forecast horizons ranging from 6 months to 5 years [19]. In addition to long-term predictions, LSTM models have been utilized to forecast 10-minute wind speeds using data from only two measurement sites [9]. Furthermore, ConvLSTM has been employed to predict 10-minute wind speeds based on weather-related images, considering six measurement sites [3]. Beyond RNN- and CNN-based models, Transformer has emerged as a popular alternative for sequence-to-sequence predictions. Various Transformer-based models have been compared for predicting 10-minute wind speeds at three meteorological stations [20].

Another approach incorporates spatiotemporal correlations, rather than treating the problem purely as a sequence-to-

sequence task. A notable example of this is the development of a temporal graph convolutional network (TGCN), which combines graph neural networks (GNN) and GRU to predict hourly wind speeds based on data from six measurement stations [21]. However, it is evident that the studies mentioned primarily focus on a limited number of measurement sites, with temporal resolutions typically set at 10 minutes or longer. The prediction of urban wind speed during TCs remains an area requiring further exploration, particularly regarding the application of Transformer-based models that account for spatiotemporal dependencies.

The contributions of this study are three-fold: Firstly, a dense meteorological station network that covers most urban areas is selected, enabling 1-minute resolution wind speed predictions during TCs—an improvement over existing sparse, low-frequency datasets. Secondly, the study develops a novel Transformer-GNN hybrid model that explicitly captures spatial topology through GNN while leveraging Transformer for temporal dependencies, thus advancing beyond conventional sequence-to-sequence approaches. Lastly, a comparison is conducted against current mainstream models, including pure sequence-to-sequence models, GNN-RNN, and GNN-transformer hybrids, demonstrating superior accuracy in extreme wind scenarios and providing valuable insights into spatiotemporal feature engineering for urban meteorology.

The remainder of this paper is structured as follows: Section 2 details the problem formulation, data source and processing, and model architecture. Section 3 presents experimental results with comparative analysis and ablation study, while Section 4 concludes the main findings of this study.

## 2 METHODOLOGY

### 2.1 Problem statement

The prediction of urban wind speed during TCs can be framed as a task where, given a series of wind speed measurements from the past  $P$  time steps  $X_P \in \mathbb{R}^{P \times C}$ , the wind speed for the future  $F$  time steps  $X_F \in \mathbb{R}^{F \times C}$  can be predicted by,

$$X_F = f(X_P) \quad (1)$$

where  $C$  represents the number of meteorological stations, and  $f(\cdot)$  denotes the deep learning-based models trained. Additionally, the meteorological station network can be described as a graph structure  $G = (V, E, A)$ , where  $V$  represents the nodes (the stations),  $E$  indicates the edges, and  $A$  denotes the adjacency matrix. The adjacency matrix is established based on the geographic distances between the stations.

### 2.2 Data source and processing

Hong Kong is located in the southeast of the Pearl River Estuary in southern China, facing the vast South China Sea to the south. It features a long coastline, with most of its low-lying areas concentrated along the coast. Additionally, Hong Kong has a high urbanization rate and is characterized by high-rise buildings, such as the International Finance Centre [22]. These urban and geographical characteristics make Hong Kong vulnerable to TCs [23]. In this study, urban wind speed data collected by 28 meteorological stations from the Hong Kong Observatory (HKO) is used to train and test model performance. It is important to note that the map and locations of the stations

shown in Figure 1 are for illustration purposes only; for official information, please refer to the HKO website. The 28 stations cover the main areas of Hong Kong and have maintained continuous data collection over a long period.

Figure 1. Schematic of distribution of meteorological stations.

The data is recorded at a 1-minute interval. A TC is considered to have an effect on Hong Kong if a TC signal has been issued by the HKO. Consequently, data from the entire lifecycle of each TC is extracted. The extracted data for the years 2000–2019 is used as the training set, for 2020–2021 as the validation set, and for 2022–2023 as the test set, as summarized in Table 1. Linear interpolation is employed to address missing data, while the mean and standard deviation are used for normalization and de-normalization.

Table 1. Summary of three data sets.

Data sets	No. of TCs	No. of samples	Rate
Training set	98	920,258	82%
Validation set	11	88,391	8%
Test set	10	115,210	10%

### 2.3 Model architecture

The model architecture is shown in Figure 2, and it is similar to the logic referenced in [21] [24]–[26]. However, urban wind speed is significantly influenced by TC intensity, which varies with climate change [27], as well as the distance between the TC location and the city. Therefore, this study incorporates long-term dependency, short-term dependency, and spatial dependency to effectively predict future 3-h urban wind speed during TCs using historical 3-h measurements from the meteorological station network. Specifically, both the input length and output horizon are set to 180.

**Patch embedding and positional encoding:** To improve computational efficiency, this study employs patch embedding to partition the input. Given the input  $X_P \in \mathbb{R}^{P \times N}$ , patch length  $L$  is used for patch embedding to obtain the patched sequence  $X^P \in \mathbb{R}^{L \times N \times C}$ , where  $N$  is the number of patched blocks. Positional encoding  $PE(\cdot)$  is added to the patched blocks using the commonly employed sinusoidal method in Transformer architectures [28], resulting in,

$$X_{enc} = X^P + PE(X^P) \quad (2)$$

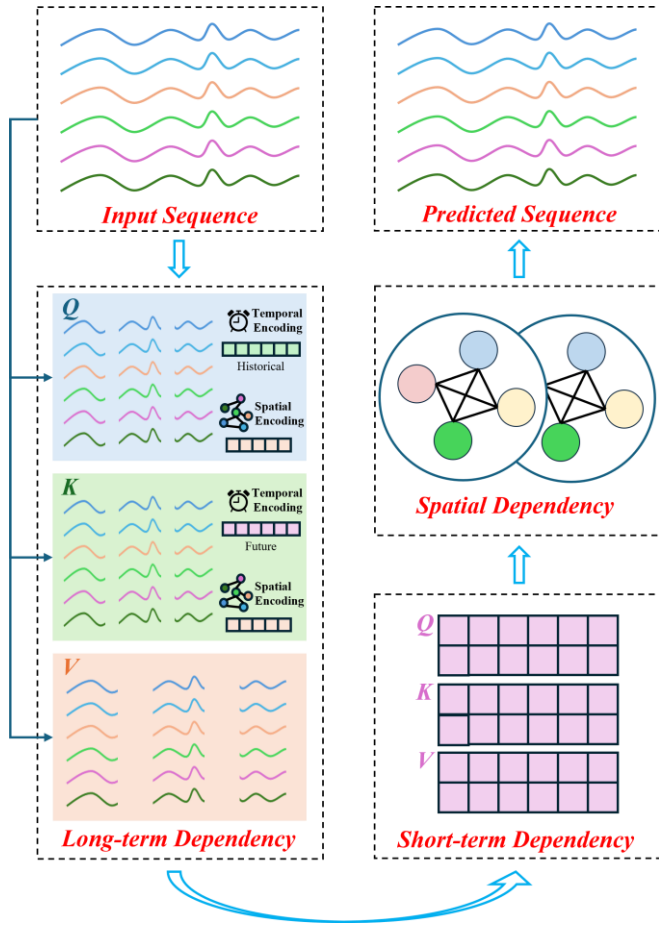

Figure 2. Overview of model architecture.

**Temporal encoding and spatial encoding:** Climate change [27] and the distance between the TC location and the city significantly influence TC intensity, which in turn affects urban wind speed. However, these factors are not explicitly incorporated into the training process. Regardless of climate change or distance, both are directly related to temporal evolution, which spans from days (for distance) to years (for climate change). Therefore, temporal encoding is necessary to account for both temporal scales.

In this study, temporal encoding is derived by considering various time components: the minute of the hour  $E^s$ , the hour of the day  $E^h$ , the day of the month  $E^d$ , the month of the year  $E^m$ , and the year  $E^y$ . This encoding embeds more time-related information using linear layers. The components of the temporal encoding are concatenated as follows,

$$E^T = \text{concat}[E^s, E^h, E^d, E^m, E^y] \quad (3)$$

where each  $E^s$ ,  $E^h$ ,  $E^d$ ,  $E^m$ , and  $E^y$  has a shape of  $L \times d/5$  (with  $d$  being the embedding dimension), resulting in a final temporal embedding  $E^T$  with shape  $L \times d$ .

Given that meteorological stations are located in various regions with different latitudes, longitudes, and altitudes, it is important to consider the spatial characteristics that may influence urban wind speed. In this study, spatial encoding is employed. Specifically, the normalized Laplacian matrix is calculated as,

$$\Delta = I - D^{-1/2}AD^{-1/2} \quad (4)$$

where  $I$  and  $D$  are the identity and degree matrices, respectively, and the adjacency matrix is calculated using the latitude, longitude, and altitude of each station. Following this, eigenvalue decomposition is performed as,

$$\Delta = U^T \Lambda U \quad (5)$$

where  $U$  and  $\Lambda$  are the eigenvector and eigenvalue matrices. The  $k$  smallest non-trivial eigenvectors are then used to generate the spatial encoding  $E^S \in \mathbb{R}^{C \times d}$  through linear transformation.

**Long-term dependency:** Based on the temporal and spatial encodings, temporal dependencies can be more effectively captured by the attention mechanisms of the Transformer architecture. It is important to note that the terms "long-term" and "short-term" differ from those used in the weather prediction field; they are merely used to distinguish between the different horizons considered in this study.

In addition to the long-term effects of climate change on urban wind speed, wind speed exhibits different characteristics across seasons, demonstrating periodic behavior [29]. Thus, long-term dependencies can be implicitly considered, as temporal information is encoded from minutely to yearly. Specifically, long-term dependency is addressed according to the temporal encoding as follows,

$$Q_l^h = w_{ql}^h(E_{his}^T + E^S) \quad (6)$$

$$K_l^h = w_{kl}^h(E_{fut}^T + E^S) \quad (7)$$

$$V_l^h = w_{vl}^h X_{enc} \quad (8)$$

where  $E_{his}^T$  is the temporal encoding derived from known historical temporal information, while  $E_{fut}^T$  is the temporal encoding derived from future temporal information. The attention mechanism, along with aggregation using the computed attention matrix, can be used to capture the long-term dependency as follows,

$$X_l^h = \text{softmax}\left(\frac{Q_l^h K_l^{hT}}{\sqrt{d_h}}\right) V_l^h \quad (9)$$

where  $w_{ql}^h$ ,  $w_{kl}^h$ , and  $w_{vl}^h$  are learnable parameters for heads  $h$ , and  $d_h$  is the scaling factor.

**Short-term dependency:** In addition to long-term dependency, urban wind speed during TCs may vary significantly within a short period as the TCs approach and make landfall in the city. Therefore, short-term dependency is also considered to capture these dynamics. The short-term dependency is addressed by the Transformer architecture based on the known sequence, enabling  $X_l^h$  to be used to derive the query, key, and value through commonly used linear layers as follows,

$$Q_s^h = w_{qs}^h X_l^h \quad (10)$$

$$K_s^h = w_{ks}^h X_l^h \quad (11)$$

$$V_s^h = w_{vs}^h X_l^h \quad (12)$$

where  $w_{qs}^h$ ,  $w_{ks}^h$ , and  $w_{vs}^h$  are learnable parameters. The short-term dependency can be computed as follows,

$$X_s^h = \text{softmax}\left(\frac{Q_s^h K_s^{hT}}{\sqrt{d_h}}\right) V_s^h \quad (13)$$

**Spatial dependency:** Spatial dependency is addressed using a graph convolutional neural network (GCN) as follows,

$$G = \delta[\alpha X_s + (1 - \alpha)(w_g \bar{A} X_s)] \quad (14)$$

where  $w_g$  are the learnable parameters and  $\bar{A}$  is the normalized adjacency matrix. After aggregating spatial information,  $\alpha$  balances the previous information with the aggregated information, and  $\delta$  is a function used to reduce overfitting.

Residual connections are then utilized as follows,

$$O^{(l)} = \text{SwiGLU}[\text{RMSN}(G^{(l)} + O^{(l-1)})] + G^{(l)} \quad (15)$$

where  $O^{(l)}$  and  $O^{(l-1)}$  represent the outputs of layer  $l$  and layer  $l-1$  of the aforementioned spatiotemporal dependency computation layer, respectively. Here, SwiGLU denotes the activation function, and RMSN represents the RMSNorm [30].

## 2.4 Experimental setup

In this study, three types of models are selected to compare their performance with the proposed model, representing three typical categories: statistical model, pure sequence-to-sequence models, and hybrid models combining GNN-RNN or GNN-Transformer architectures. The ARMA model is chosen as the baseline for statistical models, while LSTM, GRU, and vanilla Transformer models are selected as pure sequence-to-sequence models. For hybrid models, TGCN [26] is chosen for the GNN-RNN approach, and PDFormer [25] is selected for the GNN-Transformer approach.

The model setup for ARMA is derived from [16], where sensitivity analysis is performed. The configurations for TGCN and PDFormer follow the original papers [25] [26]. For GRU and LSTM, the number of RNN layers and embedding dimensions match those of TGCN [26], while the number of blocks and embedding dimensions for the Transformer align with the proposed model in this study. The specific configurations include an embedded dimension of 250, a Laplacian dimension for generating spatial encoding of 8, five heads for computing temporal dependency, a depth of 3 for spatiotemporal dependency computation, a drop rate of 0.1 for attention computation, and a linear drop rate within the range of [0, 0.1] for each depth.

## 2.5 Evaluation metrics

To evaluate the model's performance, three metrics are used: mean absolute error (MAE), root mean square error (RMSE), and the  $R^2$  score.

$$\text{MAE} = \frac{1}{n} \sum |y - \hat{y}| \quad (16)$$

$$\text{RMSE} = \sqrt{\frac{1}{n} \sum (y - \hat{y})^2} \quad (17)$$

$$R^2 = 1 - \frac{\sum (y - \hat{y})^2}{\sum (y - \bar{y})^2} \quad (18)$$

where  $y$ ,  $\hat{y}$ , and  $\bar{y}$  represent the target values, predicted values, and mean value of urban wind speed, respectively, while  $n$  denotes the total number of urban wind speed values. A lower MAE and RMSE signify superior model performance.

Additionally, a higher  $R^2$  score reflects improved model performance.

## 2.6 Optimization details

For each model, training is conducted three times, with the best result selected for performance evaluation. Each training session is set for a large number of epochs, and an early stopping mechanism is implemented to avoid overfitting. The batch size is set to 256, the learning rate is 0.0003, and *Adam* is employed as the optimizer. Mean squared error is chosen as the loss function. The programming is carried out using Python and PyTorch, with models trained on an RTX-6000 Ada GPU card featuring 48GB VRAM and 512GiB of system memory.

# 3 RESULTS AND DISCUSSIONS

## 3.1 Evaluation of model's performance

The model's performance is summarized in Table 2. It is evident that the conventional statistical model struggles to deliver reliable predictions in scenarios involving extreme wind speeds across the entire network of stations. The MAE of the ARMA model is approximately three times greater than that of the other deep learning models listed in Table 2, while the RMSE for ARMA is five times larger than that of the other models. Additionally, the  $R^2$  score indicates that the predicted results exhibit greater fluctuations compared to those generated by the deep learning models.

Table 2. Summary of model's performance.

Models	MAE	RMSE	$R^2$
ARMA	3.230	7.600	0.6539
LSTM	1.103	1.593	0.8638
GRU	0.990	1.464	0.8849
Transformer	0.909	1.376	0.8985
TGCN	0.919	1.372	0.8989
PDFormer	0.914	1.360	0.9007
Proposed	0.902	1.348	0.9026

Regarding the sequence-to-sequence models, the results indicate that the Transformer outperforms the other two models (GRU and LSTM) across all metrics, including MAE, RMSE, and  $R^2$  score. This demonstrates the Transformer's superior ability to capture temporal dependencies. However, compared to the GNN-RNN and GNN-Transformer hybrid models, the pure sequence-to-sequence models tend to yield less reliable predictions. This suggests that spatial dependencies are not adequately addressed in these models, leading to decreased performance. Notably, both LSTM and GRU exhibit larger errors compared to TGCN and PDFormer. While the Transformer has a smaller MAE, it also shows a larger RMSE and a lower  $R^2$  score compared to the two hybrid models. This indicates that, despite the Transformer's average performance being slightly better than that of TGCN and PDFormer, it may be less effective in predicting extreme values.

Regarding the hybrid models, the proposed model demonstrates superior performance in predicting urban wind speed across all metrics. It exhibits smaller errors compared to the other two hybrid models that also incorporate spatial dependency computation, as well as the pure sequence-to-sequence models. Notably, while TGCN and PDFormer have larger MAE values than the Transformer, the proposed model achieves smaller error rates than all other models listed in Table

2. This highlights the effectiveness of the proposed model in addressing both temporal and spatial dependencies in urban wind speed prediction.

### 3.2 Ablation study

To illustrate the role of the modules in the proposed model, an ablation study is conducted. The first experiment (Delete-LTD) involved removing the long-term dependency module, the second experiment (Delete-STD) removed the short-term dependency module, and the third experiment (Delete-SD) eliminated the spatial dependency module. In these three additional experiments, all other components (except for the deleted modules) are maintained exactly as in the proposed model (Full). The MAE, RMSE, and  $R^2$  scores from these experiments are presented in Figure 3.

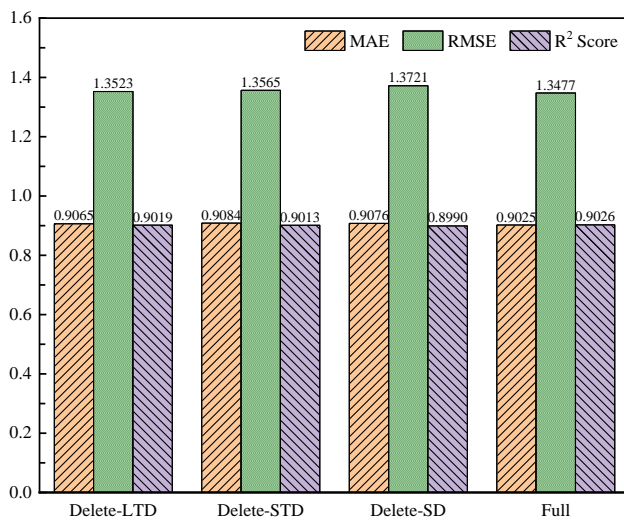

Figure 3. Performance comparison of ablation study experiments.

The results indicate that removing any component from the proposed model leads to a decrease in performance based on the evaluation metrics. This finding clarifies the contributions of each module to the overall effectiveness of the model, underscoring the significance of long-term, short-term, and spatial dependencies in achieving accurate predictions. Each module plays a crucial role in enhancing the model's ability to capture the complexities of urban wind speed dynamics.

When the GNN module is removed, the model resembles the vanilla Transformer, resulting in the outcome of experiment Delete-SD being closer to that of the vanilla Transformer listed in Table 2. However, the result of experiment Delete-SD is slightly better than the vanilla Transformer. This can be explained by the fact that the vanilla Transformer primarily focuses on correlations within the known sequence (the short-term dependencies in this study). When both short-term and long-term dependencies are incorporated, the performance improves slightly. On the other hand, the experiment Delete-SD does not perform as well as the proposed model due to the absence of the GNN module. This highlights the importance of the GNN in enhancing the performance of urban wind speed prediction. The presence of the GNN significantly contributes to capturing the spatial dependencies, resulting in more accurate predictions.

In the experiments Delete-LTD and Delete-STD, the results are similar, but neither provides better predictions than the proposed model. This indicates that both long-term and short-term dependencies are crucial for achieving accurate predictions. Furthermore, the results of these two experiments are better than those of the Delete-SD experiment, which further underscores the importance of spatial dependency in enhancing model performance. This highlights the necessity of integrating all three types of dependencies for optimal prediction accuracy in urban wind speed prediction.

### 3.3 Case study

Figure 4. Wind speed prediction of four stations during Typhoon Saola.

To illustrate predicted urban wind speeds, two case studies are conducted: Typhoon Saola and Typhoon Koinu. Saola, the third TC in Hong Kong in 2023, prompted signal No. 10, the first since Super Typhoon Mangkhut in 2018. Koinu triggered signal No. 9 and brought heavy rain, with 369.7 millimeters recorded—over three times the normal monthly total and the highest daily rainfall for October.

Figure 5. Wind speed prediction of four stations during Typhoon Koinu.

For Typhoon Saola, four stations—Hong Kong International Airport (HKA), HKO, Sai Kung, and Shek Kong—are selected to illustrate the predicted wind speed, as shown in Figure 4. The selection of these stations is based on two key principles: first, HKA and HKO were chosen for their strategic locations;

second, the remaining stations were selected due to their relatively higher measured wind speed during the cyclone, with an emphasis on decentralization. Similarly, for Typhoon Koinu, HKA, HKO, Lau Fau Shan, and Tseung Kwan O were selected to represent the predicted wind speed, as depicted in Figure 5.

The proposed model demonstrates strong predictive capabilities for the two selected cases. The trends in the predictions align closely with the target measurements, even as wind speeds increase when the TCs approach Hong Kong. However, it is evident that the model tends to underestimate the peak values, which may be attributed to the inherent tendency of neural networks to produce smoother outputs—a phenomenon commonly observed in many deep learning models. Additionally, the results for Typhoon Saola are more consistent with the measurements than those for Typhoon Koinu. This discrepancy may be partially due to the fewer local peaks observed during Typhoon Saola, as well as the model's limitations in effectively capturing peak wind speeds.

#### 4 CONCLUSIONS

In this study, a novel deep learning-based spatiotemporal model is proposed for predicting urban wind speed during TCs. The following key conclusions can be drawn:

- The proposed model achieves better prediction accuracy compared to the statistical model and pure sequence-to-sequence models, with a MAE of 0.902. This represents a 0.78% improvement over the vanilla Transformer, a 9.76% improvement over GRU, and a 22.28% improvement over LSTM. Additionally, it outperforms GNN-RNN and GNN-Transformer hybrid models by more than 1%.
- The vanilla Transformer demonstrates potential in predicting urban wind speed during TCs. The proposed model's integration of long-term, short-term, and spatial dependencies significantly enhances its performance compared to the vanilla Transformer. This improvement underscores the importance of considering various types of dependencies in achieving more accurate predictions in complex environments like urban areas during TCs.
- The proposed model effectively captures the trends in urban wind speed during TCs. Specific case studies reveal strong performance in predicting peak values for Typhoon Saola; however, some smoother predictions were observed for Typhoon Koinu.

#### ACKNOWLEDGMENTS

This work was supported by the Research Grants Council of the Hong Kong Special Administrative Region, China (Grant No. T22-501/23-R), and the Innovation and Technology Commission of the Hong Kong Special Administrative Region, China (Grant No. K-BBY1). The authors would like to express their gratitude for the computing platform provided by the University Research Facility in Big Data Analytics (UBDA) at The Hong Kong Polytechnic University, as well as for the data supplied by the Hong Kong Observatory, which was used solely for research purposes.

**ABSTRACT:** As the most vulnerable part of the infrastructure transportation network, bridges will inevitably encounter problems such as aging and degradation throughout their entire service life [1]. The maintenance costs for all bridges within the region are increasing year by year [2]. When the financial conditions are insufficient to fully cover the costs, many domestic provinces and cities adopt the maintenance and repair plans based on single bridges relying on experience and the "fire-fighting" post-event repair mode [3]. There are few scientific management models that focus on the overall service performance of the regional bridge clusters. This leads to either excessive or insufficient detection and maintenance. Therefore, there is an urgent need for a systematic intelligent assessment framework for existing bridge clusters. However, current research on service performance evaluation and prediction for large-scale bridge networks suffers from multiple limitations, such as limited research objects, simplified modeling forms, difficulty in quantitative assessment, generalized prediction outcomes, and insufficient consideration of maintenance decision-makings [4].

Therefore, this study focuses on graph network representation and intelligent evaluation for service performance of bridge clusters. Firstly, a systematic comparative analysis of two distinct graph network representation methodologies (undirected and directed network) is conducted based on actual bridge cluster cases of different scales. Secondly, tailored intelligent assessment frameworks of vulnerability are developed for each representation. Finally, benchmarking against evaluation outcomes reveals critical performance differentials across methodologies. This work thus establishes a theoretical foundation for intelligent operation and maintenance strategies in bridge network management.

## (1) For the undirected graph network representation methodology

As shown in Figure 1, the National highway (NH) network in the northeast of China connects 11 cities and 37 counties, and has 1772 bridges. It can be seen that the bridge assessment states are unevenly distributed. Funds for maintaining expressway bridges are abundant, and thus such bridges are in relatively good condition. Meanwhile, ordinary highway bridges, especially in poverty-stricken counties near the border, are underfunded.

Figure 1. NH network with evaluated bridges.

Figure 2. modelling result of the NH bridge network.

As a bridge network contains a significant amount of information, modelling a large-scale bridge network is complex. In this study, a undirected bridge network can be treated as an overlay of a topological graph and the corresponding information network. The nodes and edges in the topological graph of a bridge network represent intersections (or cities) and highways between nodes, respectively. Regarding the information group, a bridge network should contain the properties of nodes and edges, including the city (or node) name, the actual length of each edge (or NH) between nodes, and the assessment state of bridges on each edge. The NH bridge network is established as shown in Figure 2.

The intelligent assessment framework for the undirected bridge network adopts vulnerability as an indicator, utilizing backward thinking to evaluate network resilience. It methodology intentionally disrupts a portion of the network and quantifies

component importance by comparing pre- and post-damage performance indices. In detail, the proposed vulnerability index accounts for both bridge failures and their impact on bridge network performance from a probabilistic perspective. Additionally, the probability of bridge network connectivity, denoted as  $P(C)$ , is used to evaluate the performance of bridge networks with unreliable components. Therefore, the vulnerability index of the  $i$ th bridge  $V_{bridge}(i)$  and the bridge network  $V_{network}(G)$  are defined as:

$$V_{bridge}(i) = [P(C) - P(C | \bar{B}_i)] P(\bar{B}_i) \quad (1)$$

$$V_{network}(G) = \sum_{B_i \in G} [P(C) - P(C | \bar{B}_i)] P(\bar{B}_i) \quad (2)$$

Herein,  $G$  represents the undirected bridge network, and  $C$  and  $\bar{C}$  indicate the events of the bridge network being connected and disconnected, respectively.  $B_i$  and  $\bar{B}_i$  indicate the event of the  $i$ th bridge safety and failure, respectively.  $P(\bar{B}_i)$  and  $P(C | \bar{B}_i)$  are the  $i$ th bridge failure probability and the network connectivity probability given the  $i$ th bridge failure, respectively. Evidently,  $P(C | \bar{B}_i)$  demonstrates the effect of a bridge failure on network connectivity performance from a probabilistic view. The results indicate that vulnerability index of the NH bridge network is  $4.80 \times 10^{-3}$ , and the vulnerability of each equivalent bridge in the NH bridge network is shown in Figure 3. This approach effectively identifies critical bridges that elude detection by conventional indicators, a finding that should be emphasized in the future maintenance strategies formulated by the provincial management department.

Figure 3. Vulnerability index of each equivalent bridge in the undirected NH bridge network.

## (2) For the directed graph network representation methodology

As shown in Figure 4, it considered a city located in the southern part of the Yangtze River Delta, China. As an important economic centre, a well-functioning transportation network is the foundation of regional economic development. Therefore, based on the inspection information of 299 actual bridges in the city, the directed bridge network was established by fully considering the direction of the streets (one- or two- way street) and bridge types (single- or double- deck bridge) between all nodes in the urban city. As shown in Figure 5, the topological model contained 63 nodes and 216 directed edges, including 107 two-way edge pairs and two one-way edges are constructed.

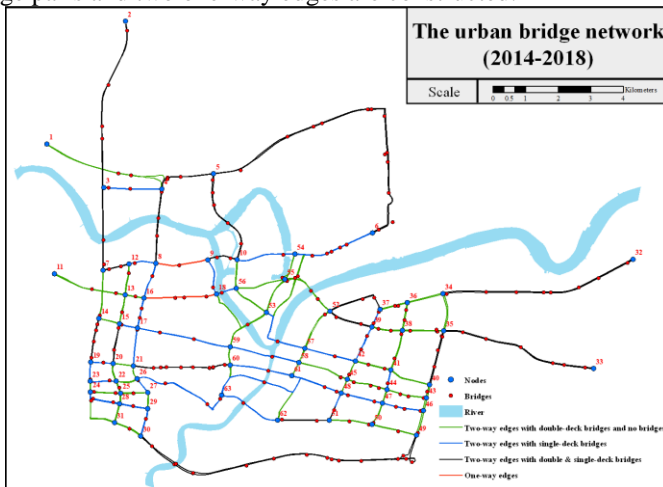

Figure 4. Physical location of the bridge network.

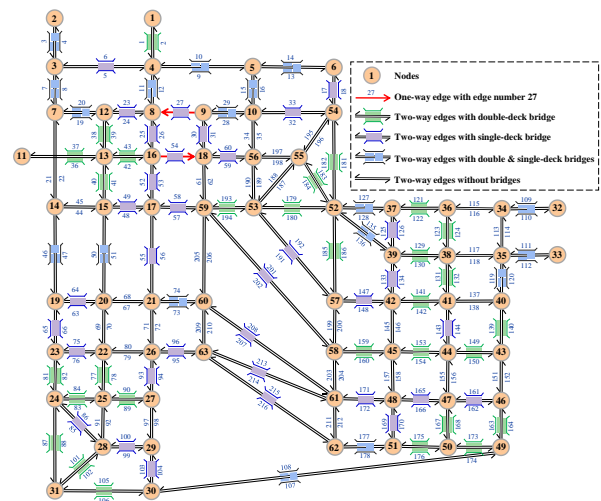

Figure 5. modelling result of the directed bridge network.

To describe the different edge dependencies in the directed bridge network, an extended network model and importance index  $\gamma(i, j)$  is proposed, and simulation methods are applied to calculate the results.

$$G_{\text{extended}} = (V, E_1, E_2, \dots, E_m) \quad (3)$$

$$\begin{aligned} \gamma(e_{i \rightarrow j}) &= P(G, \bar{e}_{i \rightarrow j}) = P(G | \bar{e}_{i \rightarrow j}) P(\bar{e}_{i \rightarrow j}) = \frac{\text{Num}(G | \bar{e}_{i \rightarrow j})}{N} P(\bar{e}_{i \rightarrow j}), m=1, 2, 3 \\ \gamma(e_{i \rightarrow j}) &= P(G, \bar{e}_{i \rightarrow j}, e_{j \rightarrow i}) + P(G, \bar{e}_{i \rightarrow j}, \bar{e}_{j \rightarrow i}) \\ &= P(G | \bar{e}_{i \rightarrow j}, e_{j \rightarrow i}) P(\bar{e}_{i \rightarrow j}, e_{j \rightarrow i}) + P(G | \bar{e}_{i \rightarrow j}, \bar{e}_{j \rightarrow i}) P(\bar{e}_{i \rightarrow j}, \bar{e}_{j \rightarrow i}) \\ &= \frac{\text{Num}(G | \bar{e}_{i \rightarrow j}, e_{j \rightarrow i})}{N} P(\bar{e}_{i \rightarrow j}, e_{j \rightarrow i}) + \frac{\text{Num}(G | \bar{e}_{i \rightarrow j}, \bar{e}_{j \rightarrow i})}{N} P(\bar{e}_{i \rightarrow j}, \bar{e}_{j \rightarrow i}), m=4, 5, 6 \end{aligned} \quad (4)$$

where  $\text{Num}(G | \cdot)$  represents the number of connected states to the bridge network, given the state of edge  $e_{i \rightarrow j}$  or edge pair  $(e_{i \rightarrow j}, e_{j \rightarrow i})$  in  $N$  samples.

Figure 8 shows the importance ranking of all edges (equivalent bridges) with non-zero failure probability in the directed bridge network during 2018. It can be observed that the importance of the upstream and downstream edges of an edge pair is not equal. It is related to the position and direction of the edge and the failure probabilities of single- and double-deck bridges. It is proved that the proposed index can effectively distinguish the relative importance of all edges in a network, thereby providing important guidelines for the designing novel network-level maintenance strategies.

Figure 6. Important index of the directed urban bridge network.

email: guoyapeng@hit.edu.cn, lishunlong@hit.edu.cn

**ABSTRACT:** Vision fundamental models demonstrate considerable competitiveness in structural surface crack segmentation due to their strong generalization ability. Vision fundamental models improve the fitting capacity for various objects by increasing image encoder complexity. However, for crack segmentation, the excessive number of these parameters leads to slow running speeds and large space occupation. This paper presents a lightweight Segment Anything Model (SAM)-based crack segmentation method using model distillation technology, aiming for consistent crack image embedding. Firstly, end-to-end automatic crack segmentation is achieved by modifying the SAM model through the addition of a crack segmentation head. Secondly, model distillation is employed to transfer features from the heavy-parametric encoder in SAM with minimal loss. Comparative analysis of cutting-edge crack segmentation techniques across eight frequently utilized datasets demonstrates their effectiveness and precision. The findings reveal the potential of mobile deployment of civil structure damage identification based on vision fundamental models.

**KEY WORDS:** Crack segmentation, vision fundamental model, model distillation, lightweight, deep learning, bridge damage

## 1 INTRODUCTION

Crack is a kind of critical apparent damages in civil structures, and crack identification serves as a fundamental basis for evaluating structural condition and determining maintenance strategies [1,2]. Currently, structural surface crack identification heavily relies on visual inspection by engineers, which suffers from limitations such as low efficiency and subjectivity. To address this issue, researchers have started to replace human eye inspection with visible light cameras, enabling the automatic identification of cracks through the acquisition of structural visual images and the design of corresponding algorithms. Common methods of image acquisition include portable digital cameras, fixed monitoring systems, smartphones, unmanned aerial vehicles, climbing or underwater robots, etc., which significantly reduce the cost and risk associated with obtaining apparent structural information [3,4].

After obtaining structural visual images, researchers employ digital image processing algorithms for structural surface crack identification. Considering the impressive advancements of deep learning (DL) in various fields, there is a gradual shift within the field of crack identification towards automatic feature extraction utilizing deep learning models [5,6]. Researchers have employed DL-based object classification algorithms to classify multiple patches cut from crack images to judge the presence or absence of cracks, achieving patch-wise crack identification [7-9]. Another important direction in this type of research is using DL-based object detection algorithms to find crack locations in crack images automatically, enabling box-wise crack identification [10-13]. However, the accuracy of patch-wise and box-wise crack identification may not meet the requirements for assessing the apparent condition of structures. As a result, DL-based pixel-

wise crack identification (i.e., crack segmentation), has emerged to address this limitation.

DL-based crack segmentation methods can be categorized into two main groups: convolutional neural network (CNN)-based and transformer-based. CNN-based crack segmentation mainly employs "encoder-decoder" architecture, including fully convolutional network (FCN) and its variants, as well as generative adversarial network (GAN). For FCN, Li et al. [14] proposed using FCN for pixel-to-pixel segmentation of various damages in civil structures. Chen and Jahanshahi [15] developed a rotation-invariant FCN to explicitly consider the rotational invariance of crack images. Hoskerc et al. [16,17] introduced a FCN-based multi-class semantic segmentation approach using multi-task learning, which achieved better results than training multiple tasks independently for multi-type structural materials and defects. To address the high noise and background interference in pavement crack images, Huyen et al. [18] established the CrackU-net framework with a modification on U-net, which also addressed the false-positive crack detection issue. Jiang et al. [19] applied attention mechanisms to U-net for detecting corrosion defects in steel box girders. Liu et al. [20] introduced a framework for concrete crack segmentation and quantitative calculation that considers the weight of crack boundaries. Xiang et al. [21] proposed a crack image augmentation method using active learning to enhance the accuracy of crack segmentation methods. Nguyen et al. [22] discussed the influence of different training loss functions using U-net on different crack datasets. Xu et al. [23] proposed a limited-supervised deep learning framework for damage segmentation (including cracks) using meta learning based on U-net.

For GAN, Zhang et al. [24] aimed to address the severe imbalance between cracks and backgrounds with a crack-patch-only GAN framework. Kim et al. [25] tackled the issue of data

scarcity in detecting cracks in steel structures using laser thermography for data augmentation by employing GAN. Similarly, to overcome the issue of limited training data, Ma et al. [26], Jin et al. [27], Li and Zhao [28], as well as Zhang et al. [29], utilized various variants of GAN to generate various crack images.

Transformer models have demonstrated significant progress in vision-based crack segmentation. Shamsabadi et al. [30] introduced Vision Transformer (ViT) into this area and attained higher detection accuracy in asphalt and concrete surface crack segmentation than CNNs. Wang and Su [31] developed a multi-level structure Transformer as an encoder to output multi-level features and fuse different levels of features. Ding et al. [32] analyzed the characteristics of crack recognition and proposed a boundary refinement Transformer for automatic segmentation of crack images obtained by drones. Guo et al. [33] used Swin Transformer to encode road crack images and employed UperNet to generate segmentation results. Tong et al. [34] combined Dempster-Shafer theory and Transformer network to construct a crack segmentation framework considering uncertainty and proposed a corresponding training strategy. Zhang et al. [35] proposed a segmentation Transformer framework called ShuttleNet v2, which can detect not only cracks but also multiple other diseases simultaneously. Furthermore, the amalgamation of CNNs' local modeling capability and Transformers' global modeling capability to build more powerful crack segmentation models is also an important research direction. Zhou et al. [36] fused Swin Transformer blocks and inverse residual blocks based on Deeplab v3 plus framework and combined channel attention mechanism to improve crack segmentation accuracy.

With the emergence of vision fundamental models, the inherent paradigm of object segmentation has been disrupted. These vision fundamental models, characterized by a massive number of network parameters and extensive training data, exhibit unprecedented robust generalization capabilities, allowing for precise segmentation of most common objects in zero-shot and few-shot forms [37]. However, when applied to crack segmentation tasks, vision fundamental models face two primary issues: (1) the need for specific prompts during application or a lack of semantic information for automatic segmentation; (2) the excessive number of network parameters in vision fundamental models leads to slow segmentation speeds and deployment difficulties in hardware-constrained environments.

This paper's primary goal is to significantly lighten the vision fundamental model while preserving its strong generalization ability, to achieve precise and efficient segmentation of cracks. To achieve this objective, this paper proposes the following two innovative approaches: (1) modifying SAM structure by adding a crack segmentation head to incorporate semantic information for automatic segmentation, and (2) utilizing model distillation techniques to substantially reduce the parameters of SAM and significantly improve its running speed, with only acceptable loss in segmentation accuracy.

This paper's primary contributions are twofold: (1) it represents an early attempt to apply vision fundamental models to automatic crack segmentation, providing a feasible approach for the application of such models in civil engineering, thereby offering valuable reference results for future research; (2) it

verifies the feasibility of lightweighting crack segmentation networks based on vision fundamental models, enabling effective transfer of the powerful generalization ability of these models under hardware-constrained conditions.

The remaining content of this paper are structured as follows. Section 2 provides an overview of the advancements in DL-based crack segmentation. Section 3 delves into the intricate framework of the proposed lightweight vision fundamental model-based crack segmentation approach. Section 4 outlines the implementation specifics. Section 5 offers the testing results under both full supervision and limited supervision, as well as the results evaluated on hardware-constrained platforms. Lastly, Section 6 concludes the paper.

## 2 METHODOLOGY

The proposed lightweight vision fundamental model-based crack segmentation method comprises a lightweight crack encoder and a crack segmentation head (shown in Figure 1). The former extracts the robust features of the crack image to generate crack image embeddings, while the latter uses high-quality embedding to complete pixel-level crack segmentation. The lightweight crack encoder's initialization weight originates from the SAM original heavy-parametric vision fundamental model through the utilization of model distillation technology (using common object segmentation dataset), the distillation objective is set to minimize the embedding difference of the image after the encoder. Finally, the crack segmentation model proposed here undergoes fine-tuning using the crack dataset.

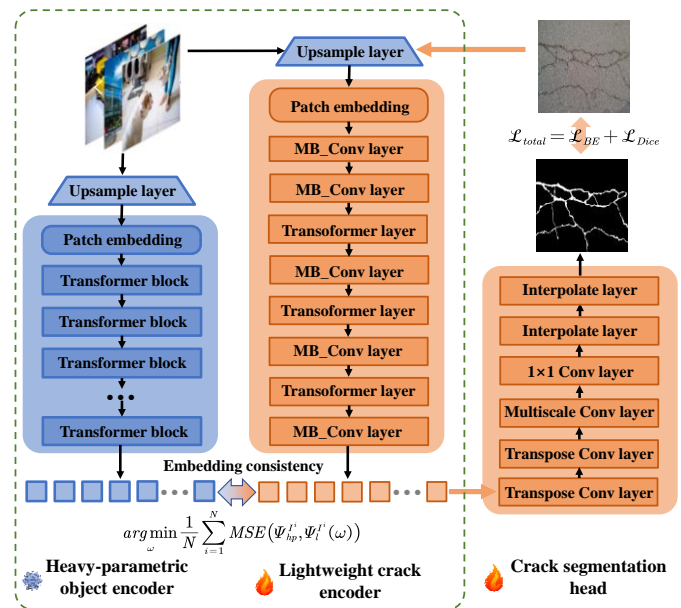

Figure 1. Overall architecture of the lightweight vision fundamental model-based crack segmentation method.

### 2.1 Lightweight crack encoder using model distillation

The heavy parameter encoder in SAM adopts the ViT model. To ensure the uniformity of the architecture, this study uses the lightweight TinyViT [38] as the crack encoder. TinyViT adopts a hierarchical vision transformer, serving as the foundational architecture, which can better integrate multiscale features for downstream tasks. TinyViT comprises four stages, leading to a gradual reduction in the resolution of the feature map. Each

stage includes a feature extraction (FE) layer and a down-sampling (DS) layer. The FE layer of stage 1 adopts MB\_Conv, and stages 2-4 adopt transformer. The DS layer of all stages adopts the MB\_Conv. TinyViT has been efficiently designed from three aspects: the sliding window mechanism corresponding to the FE layer (limiting the transformer attention mechanism to the window to reduce the computational complexity), the hierarchical design mechanism corresponding to the DS layer (taking advantage of the CNN to save the amount of calculation while extending the window attention to the global) and the model size control mechanism (customizing models of different sizes by adjusting the model control parameters).

To make full use of the effective information in the vision fundamental model SAM, this paper proposes to transfer the features in the heavy-parametric encoder of SAM to the proposed lightweight crack encoder by means of model distillation. That is, SAM is used as the teacher model, and the student model is employed as the proposed model. By setting the optimization goal, the knowledge in the teacher model is transmitted to the student model as lossless as possible.

It is assumed that the output image of the  $i^{\text{th}}$  image  $I^i$  after entering the SAM's heavy-parametric encoder is embedded as  $\Psi_{hp}^{I^i}$ , and the output image of the proposed lightweight encoder is embedded as  $\Psi_l^{I^i}$ . The crack segmentation head of the proposed framework directly uses image embedding as input, so it is not necessary to minimize the segmentation error after adding the crack segmentation head to SAM, but only to minimize the difference between the two embeddings [39] (illustrated in Equation (1)), where  $N$  represents the total count of training crack images required for model distillation, MSE is the least square error function, and  $\omega$  is the trainable weight parameters of the proposed lightweight encoder.

$$\arg \min_{\omega} \frac{1}{N} \sum_{i=1}^N \text{MSE}(\Psi_{hp}^{I^i}, \Psi_l^{I^i}(\omega)) \quad (1)$$

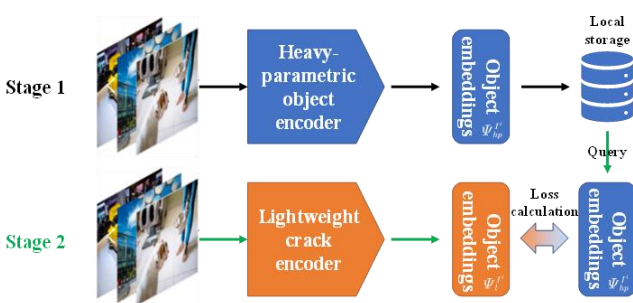

Figure 2. Processing procedure of model distillation.

Specifically, as shown in Figure 2, there are two stages during model distillation, the encoder parameters in the original SAM are frozen (untrainable), while the proposed lightweight encoder parameters are trainable. In stage 1 (embedding preparation), the image to be trained is input into the original SAM in advance to obtain the corresponding image embedding  $\Psi_{hp}^{I^i}$  and then stored locally. In stage 2 (lightweight encoder training), the image is fed into the proposed lightweight encoder to obtain the image embedding  $\Psi_l^{I^i}$ ,  $\Psi_{hp}^{I^i}$  can be

queried from the local storage. The optimization goal of training can be directly calculated. Taking such a training strategy will greatly reduce the time and cost of training while ensuring the distillation effect.

## 2.2 Crack segmentation head

To assist object segmentation, SAM employs prompts through the integration of incorporating prompt encoder and mask decoder into image embedding process. This encompasses the handling of image and prompt embedding, and output tokens subsequent to the image encoder. However, since the crack segmentation task in this study is automatic and does not require prompt input, the latter part of SAM needs to be modified. To address this, this paper introduces a crack segmentation head to fulfill the necessary functions.

The crack segmentation head is composed of several key components, including two transposed convolution layers, a multiscale convolution layer, a convolution layer with the size of  $1 \times 1$ , and two interpolation layers (shown in Figure 1). The transposed convolution layer is designed to increase the resolution of the encoded crack image embedding by a factor of 2, thereby restoring spatial information. The multiscale convolution layer is utilized to leverage feature fusion at different scales, enabling the model to learn information in various ranges around crucial pixels through backpropagation gradient. Figure 3 illustrates the detailed architecture of the multiscale convolution. According to the channel dimension, features from  $n$  channels of the transpose convolutional layer are partitioned into  $k$  groups. To retain features at the current scale, a  $1 \times 1$  convolution is applied to the first group. For the remaining  $k-1$  groups,  $3 \times 3$  convolutions with varying dilation rates are utilized to capture features at different scales, where the dilation rate is determined by the number of groups minus 1 [40]. The  $1 \times 1$  convolutional layer is responsible for integrating information from different channels and adjusting the output dimension accordingly. Finally, the interpolation layer further upsamples the output to fine-tune the output dimension.

Figure 3. Architecture of the multiscale convolution.

A combined loss ( $\mathcal{L}_{total}$ ) comprising binary entropy ( $\mathcal{L}_{BE}$ ) and Dice ( $\mathcal{L}_{dice}$ ) is set as the objective of fine-tuning the proposed method, as illustrated in Equations (2)-(4). Here,  $N$  denotes the image's pixel number, while  $y_i$  and  $p_i$  respectively

denote the annotated label and predicted value for the  $i^{\text{th}}$  pixel. Additionally,  $Y$  and  $\hat{Y}$  represent the crack mask annotations and predictions, respectively.

$$\mathcal{L}_{total} = \mathcal{L}_{BE} + \mathcal{L}_{dice} \quad (2)$$

$$\mathcal{L}_{BE} = -\frac{1}{N} \sum_{i=1}^N y_i \log(p_i) \quad (3)$$

$$\mathcal{L}_{dice} = 1 - \frac{2|\hat{Y} \cap Y| + 1}{|\hat{Y}| + |Y| + 1} \quad (4)$$

### 3 IMPLEMENTATION DETAILS

#### 3.1 Dataset

**Distillation on common object dataset** SAM's powerful segmentation generalization ability comes from the large-scale segmentation dataset SA-1B. The dataset is generated by SAM's data engine and is divided into three stages: preliminary manual, semi-automated, and fully automated. During the initial stage, SAM aids the annotator to annotate the mask, akin to the traditional interactive object segmentation scenario. During the second stage, SAM is capable of autonomously producing the mask for certain objects by proposing their potential locations, and the annotator annotates the remaining objects, which helps to increase the diversity of the mask. In the last stage, the regular grid prompt SAM of the foreground point is employed to produce approximately one hundred high-quality masks for each image. Ultimately, SA-1B generates over 1 billion object masks across 11 million images. Since the proposed crack segmentation framework uses a lightweight encoder, the parameters are much smaller than the original SAM encoder. Therefore, 0.1% of the SA-1B dataset (11,000) is randomly sampled according to the literature results as the training dataset of the model distillation [39].

**Fine-tuning on crack dataset** Lately, crack recognition field have achieved significant progressions, and several crack segmentation datasets have been released to the research community. While many studies have trained and evaluated models on specific datasets, there is a lack of comprehensive testing across multiple datasets, which hinders our understanding of the generalization capabilities of crack segmentation models [41]. To address this limitation, this paper selected eight influential datasets for evaluating the proposed method. These datasets include CFD, Crack500, Cracktree200, DeepCrack, EugenMiller, GAPS, Rissbilder, and Volker (referred to as Datasets 1-8) [41]. These datasets exhibit significant variations in terms of structural materials, structural parts, image quality, and quantity, thereby enabling an effective evaluation of the generalization abilities of crack segmentation models. Figure 4 offers a summary of the quantity of training and testing images contained within each of the eight datasets. The entire set of training images, amounting to 7754, is partitioned into training subset (90%) and validation subset (10%). The testing images, collectively referred to as the testing subset, are employed to evaluate the segmentation methods proposed in this paper.

Figure 4. Numbers of training and testing images of eight datasets.

#### 3.2 Distillation and fine-tuning strategy

During the model distillation, the image embedding vector of the training image through the SAM heavy-parametric encoder has been calculated in advance and saved to the local storage. The training image only needs to go through the lightweight encoder to obtain the new image embedding vector, and then read the previously saved SAM embedding vector and calculate mean squared error (MSE). During the training, a single GPU was used, the batch size was 2, and a total of 50,000 iterations were performed. The MSE value obtained by the final convergence was 0.977, indicating the effectiveness and accuracy of the model distillation.

Throughout the proposed crack segmentation model fine-tuning, the initial learning rate was established as  $1e-5$ . The total training iteration count was determined as 24,000. A multi-step learning rate change approach was employed, where it was reduced to 0.1 times the previous value at the 16,000th and 20,000th iterations, respectively. The fine-tuning process implemented an early stopping strategy. The parameters at this iteration were taken as the final model weights. In addition, the batch size was 2.

The configuration utilized for fine-tuning and evaluating the proposed method comprised an Intel Xeon(R) E5-2620 v4 central processing unit (CPU), complemented by a robust Nvidia RTX 3090 graphics processing unit (GPU) offering 24GB memory. Additionally, the system was equipped with an ample 128GB of memory.

### 4 RESULTS AND DISCUSSIONS

The quantitative and qualitative results of the proposed lightweight crack segmentation method under full supervision and limited supervision conditions are illustrated in this section, and the state-of-the-art CNN-based method Deeplab v3 plus (with MobileNet v3) [42] and transformer-based Segformer [43] are employed to be comparison. Additionally, the weight file space occupation, the running speed on different hardware

platforms and the possibility of mobile deployment of the proposed method are discussed.

#### 4.1 Testing results under full supervision

Full supervision refers to training on the entire training subset (6,978 pairs of crack images and masks) and testing on the entire test subset (955 crack images). This condition facilitates the transfer of feature parameters from vision fundamental models to the domain of crack segmentation, enabling exploration of the segmentation accuracy limits across different models.

Table 1 elucidates the testing Dice scores ( $\times 100\%$ ) for eight datasets under full supervision, as well as the total parameter numbers of different algorithms and their GPU memory occupancy during training (with an input size of  $1024 \times 1024 \times 3$  and a batch size of 2). In Table 1, SAM represents the crack segmentation method based on vision fundamental models that employs the heavy-parametric encoder from the original SAM. Compared to Deeplab v3 plus, the proposed method significantly improves the Dice score by 13.6, and although the parameter count increases to twice that amount, the required GPU memory during training decreases to 36%, which is the most direct assessment of algorithm training expenses. Compared to Segformer, the proposed method is on par in terms of accuracy, but with a 45% reduction in parameter count and a 37% reduction in required GPU memory. Compared to the original SAM-based method, the proposed approach experiences a 5.4 decrease in Dice score, but with a parameter count reduced to 7% and at least an 85% reduction in required GPU memory. In summary, the proposed method not only maintains segmentation accuracy in comparison to other cutting-edge methods but also significantly reduces training costs.

Table 1. Testing Dice scores ( $\times 100\%$ ) on eight datasets, total parameter numbers and GPU memory occupation under full supervision

Method	DL v3p	Segformer	SAM	Proposed	
Dataset	1	52.6	51.8	68.5	56.1
	2	54.9	68.4	71.1	65.6
	3	24.3	24.4	37.6	24.4
	4	69.6	72.8	79.9	68.8
	5	36.2	56.1	57.7	53
	6	25.8	28.9	45.4	44.77
	7	30.9	50.1	54.9	50.8
	8	60	67.5	75.5	68.7
Average	44.4	58	63.4	58	
Params	3.2M	13.6M	89.8M	6.2M	
Mem	10.3G	10.1G	>24G	3.8G	

Figure 5 displays representative results of crack segmentation using different methods, where each row corresponds to a representative crack image from each dataset, and each column represents the original image, ground truth, and the test results using Deeplab v3 plus, Segformer, the original SAM-based method, and the proposed method, respectively. Whether they are concrete or asphalt surface cracks, whether they are dot-like, strip-like, or mesh-like, the

crack segmentation results of methods based on vision fundamental models are superior in terms of integrity and connectivity compared to CNN-based and transformer-based. While the proposed method's segmentation effect is slightly lacking in local detail handling compared to the original SAM-based crack segmentation method, it exhibits evident advancement over other methods, demonstrating the proposed method's efficacy in enhancing accuracy.

Figure 5. Representative testing results: (a) raw image, (b) annotation, (c) DL v3p, (d) Segformer, (e) SAM, (f) the proposed method.

#### 4.2 Testing results under limited supervision

In contrast to prior CNN-based and transformer-based object segmentation approaches, the primary advantage of object segmentation methods grounded on vision fundamental models is their robust generalization capability. This means that they can achieve high segmentation accuracy with minimal domain-specific supervision information. Hence, this part showcases the proposed method's strong generalization ability by comparing the test accuracy of different methods under two limited supervision cases (1%-shot and one-shot). The 1%-shot case refers to training with 1% of the training subset of full supervision (77 crack image-mask pairs), while the one-shot case refers to training with only one crack image-mask pair per dataset (a total of 8). These two cases provide an extreme test of the generalization capabilities of different methods.

The testing Dice scores of different algorithms under limited supervision are illustrated in Table 2. Consistent with

theoretical analysis, the crack segmentation method based on vision fundamental models significantly outperforms those based on CNNs and transformers in terms of segmentation accuracy in both the 1%-shot and one-shot cases.

Table 2. Testing Dice scores ( $\times 100\%$ ) on eight datasets under limited supervision

Data size		1%-shot			
Method	DL v3p	Segformer	SAM	Proposed	
Dataset	1	39.6	47.2	54.2	46.8
	2	53.7	60	65.8	57.4
	3	23	17.3	21.1	24
	4	66.4	65.6	70.5	63.2
	5	23.4	44.8	48.1	38.2
	6	9.7	23	32.9	19
	7	26.7	47	48.3	50.3
	8	54.5	64.2	66.8	66.1
Average		40.4	52.5	56.3	52.8
Data size		one-shot			
Method	DL v3p	Segformer	SAM	Proposed	
Dataset	1	35	47	44.8	49.2
	2	21.4	22.4	34.1	25
	3	20.1	22.2	16.5	20.3
	4	48	51.4	59.3	67.1
	5	46.1	48.7	54.2	53.9
	6	29.3	34.8	34.7	24.2
	7	24	36.1	39.3	42.8
	8	48.3	58.9	58	56.8
Average		27.4	34.3	39.9	38

Notably, in the one-shot case, the proposed method improved the Dice score by 3.7 compared to Segformer and only decreased by 1.9 compared to the original SAM-based method. Considering that the proposed method has fewer parameters and lower training costs, it is substantiated that the approach can reach high precision with maintaining operational efficiency. Former transformer models necessitated a substantial volume of supervised training data to attain elevated segmentation precision, although vision fundamental models are also based on transformer architectures. Preliminary judgments can also be made based on experimental results, the vision fundamental model-based crack segmentation method demonstrates good generalization capability even under extremely limited supervision conditions.

### 4.3 Deployment of the proposed method

Although the vision fundamental model has strong segmentation generalization ability, its deployment difficulty and cost are high, which aligns with the primary research concentration of this paper. Therefore, this subsection deploys the original SAM-based and the proposed lightweight vision fundamental model-based crack segmentation models on different hardware platforms to illustrate the advantages of the latter.

The weight file space occupancy serves as a metric for gauging the complexity of the model, encompassing all parameters and configurations stored on the disk. Table 3 demonstrates that the space occupancy of SAM-based models based on backbones of different sizes is 404MB, 1230MB, and 2665MB, respectively, while the proposed model is only 70MB (17% of the minimum SAM-based).

Table 3. Weight file space occupancy and running speed of the proposed method

Method	Space occupancy	Running speed	
		GPU	0.107s
SAM	ViT-B 404MB	x86	5.498s
		arm	/
	ViT-L 1230MB	/	/
	ViT-H 2665MB	/	/
Proposed	70MB	GPU	0.016s
		x86	0.637s
		arm	2.245s

The running speed is the most direct indicator to measure the complexity of a model. Although it is affected by factors such as code implementation, the relative speed of different models can still be compared after controlling variables. This paper tests on three common hardware platforms (GPU, x86 CPU and arm CPU), and the results are shown in Table 3. With  $1024 \times 1024$  images as input, the SAM-based model takes 0.107 s and 5.498 s on GPU and x86 CPU respectively. Because the model is too complex to be deployed on the arm CPU used in this experiment. Meanwhile, the proposed model consumes 0.016 s and 0.637 s on GPU and x86 CPU (15% and 12% of SAM-based, respectively), and 2.245s on arm CPU (twice as fast as SAM-based on x86 CPU).

It is worth noting that the arm CPU used in this experiment is Kirin 970, a consumer and low-cost chip released six years ago. Compared with the current mobile phone CPUs, the performance difference is huge. Employing the most cutting-edge chip would significantly enhance the performance of the proposed method. Figure 6 illustrates the exemplary testing outcomes of the deployed proposed method on a mobile phone.

Figure 6. Representative testing results on mobile phones

## 5 CONCLUSIONS

A novel crack segmentation method using lightweight vision fundamental model is developed in this paper. The approach incorporates model distillation techniques to substantially decrease the model parameters and enhance operational speed while maintaining the robust generalization capabilities of the vision fundamental model to the greatest extent possible. In light of the findings, the following conclusions can be inferred: (1) By substituting the ViT encoder in the original SAM with the lightweight encoder TinyViT and using model distillation techniques with image embedding consistency as the optimization goal, effective transfer of the vision fundamental model's generalization ability is achieved. (2) Under full supervision, the proposed method surpasses current cutting-edge methods based on non-vision fundamental models, achieving a segmentation Dice score of 58.0. Moreover, relative to the original SAM, the model's parameter count is reduced to 7%, and the required GPU memory is decreased to 15%, with only a 5.4 decrease in Dice score. (3) Under limited supervision, the proposed method comprehensively surpasses methods based on non-vision fundamental models in terms of segmentation accuracy and algorithmic efficiency, with Dice scores reaching 52.8 (1%-shot) and 38.0 (one-shot). Furthermore, as the degree of available supervision information decreases, the proposed method demonstrates a heightened advantage, resulting in a diminished disparity with respect to the original SAM. (4) The proposed method achieves a sixfold and eightfold acceleration on GPU and x86 CPU, respectively, compared to the original SAM, and has been successfully deployed on cost-effective ARM CPUs.

The crack segmentation method developed from lightweight vision fundamental model serves as a reference for the efficient application of vision fundamental models in the field of automatic identification of civil engineering damages. Nevertheless, there remains potential for enhancing the detailed recovery of crack identification outcomes in this study. Future work will concentrate on incorporating crack boundary constraints into the loss function and bolstering the post-processing methodologies within the crack segmentation framework to enhance the precision of crack detail identification. To facilitate practical applications, follow-up research should further develop a quantitative measurement and evaluation module for crack dimensions.

**ABSTRACT:** Recent research for correlation prediction from spatial-temporal monitoring data of bridge groups has explored graph neural networks and state space models, offering new angles and advanced algorithms. However, current research still faces significant challenges: (1) constructing suitable graph structures to accurately reflect complex spatial-temporal correlations, (2) designing an effective spatial-temporal neural network to capture spatial-temporal dependencies during the service state evolution of bridge groups, and (3) fully making use of spatial-temporal monitoring data to boost prediction accuracy and efficiency. To tackle these challenges, this study introduces a graph selective state space model for spatial-temporal prediction of environmental temperature and traffic flow for bridge groups. Firstly, a spatial-temporal graph structure is set up to account for data characteristics in both spatial and temporal aspects and forecast the dynamic evolution of bridge group system. Then, a state space model is built to produce a structured state space sequence and introduce a selective mechanism to dynamically adjust model behaviors and optimize computational resources. Lastly, through decomposing and reintegrating spatial-temporal features of monitoring data for bridge groups under different complexities, validation experiments are performed to show the efficacy, universality, and efficiency using multi-type, multi-scale, and multi-granularity spatial-temporal monitoring data of environmental temperature and traffic flow.

**KEY WORDS:** Spatial-Temporal Correlation; Time Series Prediction; Graph Model; Environmental Temperature; Traffic Flow.

## 1 INTRODUCTION

The rapid progression of urbanization in China has made the consistent serviceability of bridge groups a pivotal factor in determining the efficiency and safety of urban traffic. As urban transport system essentials, bridge groups consist of multiple interconnected bridges with interdependent serviceability. These bridges inside a city region are exposed to various related factors including environmental conditions and traffic flow, which can notably affect their structural integrity and operational efficiency. Accurately predicting the serviceability of bridge groups is crucial for traffic safety and maintenance strategy optimization. Traditional methods employed for predicting the service state of bridge groups often focus on individual bridges, neglecting the spatial-temporal correlations amongst different bridges in the group. This can cause inaccurate predictions and thus insufficient maintenance strategies, potentially causing significant safety risks and leading to considerable economic losses.

Recent deep learning advances have created new ways to predict the service state of bridge groups. Graph neural networks (GNNs) have shown great ability in dealing with data that has complex relational structures, like the interactions between different bridges in a group. Additionally, state space models (SSMs<sup>[1-4]</sup>) have drawn increasing interests due to their capability to model dynamic systems and capture the temporal evolution of structural service states. But even with these advances, current research faces big challenges. A main challenge is building a suitable graph structure that can truly reflect the complex spatial-temporal correlations embedded in the monitoring data of bridge groups. Another challenge is designing an effective neural network architecture that can

capture both spatial and temporal dependencies during the dynamic evolution of service states for regional bridges. Furthermore, it is crucial to leverage the abundant spatial-temporal data available for bridge groups to enhance prediction accuracy and efficiency.

To tackle these challenges, this study proposes a graph selective state space model for spatial-temporal prediction of environmental temperature and traffic flow for bridge groups. The model uses the core capacities of GNNs and SSMs to achieve comprehensive and accurate predictions of spatial-temporal variables. The main contributions of this study are as follows:

- An adaptive multi-granularity data fusion is designed to integrate multi-granularity data of recent, cyclic, and trend information from bridge groups. This fusion method not only captures various temporal patterns but also assesses their impacts on operational states of bridges. This approach strengthens the model's ability to handle complex spatial-temporal dependencies, thereby improving prediction accuracy.
- A novel spatial-temporal graph convolution module (STGCM) is introduced to consider the spatial-temporal correlation of environmental temperature and traffic flow.
- A graph selective state space module (GSSSM) is developed to model how spatial-temporal dependencies in regional monitoring data evolve for bridge group, which dynamically adjusts the model's learning behavior and optimizes computational resources. The GSSSM prioritizes the most relevant parts of regional monitoring data for environmental temperature and traffic flow,

thereby enhancing the model capacity to capture spatial-temporal correlations.

## 2 RELATED WORKS

### 2.1 Spatial-Temporal Graph Neural Networks

Most spatial-temporal graph neural networks (STGNNs) are categorized into three types: those based on recurrent neural networks (RNNs), those based on convolutional neural networks (CNNs), and those based on attention mechanisms.

Seo et al. (2018)<sup>[5]</sup> presented a graph convolutional recurrent network, capturing spatial-temporal dependencies by filtering inputs and hidden states in a recurrent unit via graph convolution. Later works adopted different strategies, for example, Li et al. (2017)<sup>[6]</sup> developed a diffusion convolutional recurrent neural network, integrating diffusion convolution with gated recurrent units (GRUs) to grasp spatial and temporal dependencies at the same time, and Zhang et al. (2018)<sup>[7]</sup> proposed gated attention networks, which combine GNNs with a convolutional subnetwork to assess the importance of each attention head. Another parallel work was that Jain et al. (2016)<sup>[8]</sup> used node-level and edge-level RNNs in their work to handle different aspects of temporal information. The main drawbacks of RNN-based approaches are that they become inefficient for long sequences and the gradients are more likely to explode when combined with graph convolution networks (GCNs). CNN-based approaches combine graph convolutions with standard 1D convolutions, for example, Yu et al. (2018)<sup>[9]</sup> proposed a spatial-temporal graph convolution network (STGCN), combining GCNs with temporal convolutional networks (TCN<sup>[10]</sup>) to capture spatial and temporal dependencies. A recent work about attention-based approaches is that Li et al. (2023)<sup>[11]</sup> proposed GCN-Informer, which combines GCNs with Informer to capture long-term dependencies in time series data. Although these three types of approaches are computationally efficient, they generally need to stack multiple layers or use global pooling to expand the neural network model's receptive field, which is a limitation that the proposed Spatial-Temporal Graph Selective State Space Model (STGSSSM) addresses by employing stacked dilated casual convolutions to capture temporal dependencies more effectively with fewer layers.

### 2.2 State Space Models

State Space Models (SSMs) are powerful tools for modeling dynamic systems, offering flexible frameworks to capture temporal evolution through state transitions influenced by external inputs. The recent fusion of SSMs with GNNs has achieved promising results in managing complex spatial-temporal graph-structured data.

For instance, Zhao et al. (2024)<sup>[12]</sup> proposed the graph state space network, the first model to incorporate SSMs into the spectral filter design of GNNs, thus overcoming the limitations of conventional methods in dealing with complex graph spectra. Behrouz et al. (2024)<sup>[13]</sup> introduced graph mamba (selective state space model) networks, an SSM-based framework for graph learning, which uses neighborhood tokenization, token ordering, bidirectional SSM encoder, and local encoding to efficiently handle long-range dependencies and heterophilic graphs. Wang et al. (2024)<sup>[14]</sup> presented graph-mamba, a novel graph model that uses a mamba module for efficient context

selection, achieving linear complexity and superior performance in long-range graph tasks. Yuan et al. (2024)<sup>[15]</sup> proposed dynamic graph-mamba, a dynamic graph structure learning framework that combines mamba and a kernelized dynamic message-passing operator to efficiently learn dynamic graph structures and capture long-range dependencies.

Although these approaches can dynamically adjust the learning behavior of the model and has high computational efficiency, they are relatively singular in feature extraction and lack in-depth extraction of spatial-temporal features, which is a limitation that the proposed STGSSSM addresses by utilizing STGCM to extract diverse spatial-temporal features.

### 2.3 Spatial-Temporal Traffic Forecasting

Traffic forecasting is crucial for optimizing urban transportation systems. Recent progress in spatial-temporal graph neural networks have greatly boosted the prediction accuracy by capturing complex spatial-temporal dependencies. Spatial-temporal traffic forecasting has been also investigated by RNN-based, CNN-based, and attention-based approaches.

For example, Zhao et al. (2019)<sup>[16]</sup> combined GCN with GRU to model temporal dynamics, effectively capturing long-term dependencies and achieving validation on the Los-loop dataset. Wu et al. (2019)<sup>[17]</sup> developed Graph WaveNet, using dilated causal convolutions to grasp long-term dependencies. Wu et al. (2020)<sup>[18]</sup> proposed the multivariate time series graph neural network (MTGNN), which integrated GCN and TCN for adaptive graph learning, delivering high performance on the large-scale METR-LA and PEMS-BAY datasets. In the attention-based approach, Zheng et al. (2020)<sup>[19]</sup> proposed graph multi-attention network, which utilized multi-attention mechanisms to weigh the significance of different nodes and time steps, achieving high accuracy on Xiamen and PeMS datasets. Guo et al. (2021)<sup>[20]</sup> developed an attention-based spatial-temporal graph neural network, combining dynamic GCN with transformers to adapt to dynamic traffic patterns, and showing robustness on the PEMS dataset.

### 2.4 Spatial-Temporal Temperature Forecasting

Environmental temperature greatly affects the service state of bridge groups, and spatial-temporal graph models can conduct highly efficient and accurate temperature predictions, which are summarized from RNN-based, CNN-based, and attention-based aspects.

Zhao et al. (2024)<sup>[21]</sup> presented an adaptive spatial-temporal graph recurrent network model. It used dynamic graph structures with a spatial-temporal recurrent network for sea surface temperature forecasting. Yang et al. (2023)<sup>[22]</sup> introduced a hierarchical graph recurrent network which utilized adaptive node embedding and hierarchical graph convolution to predict global sea surface temperatures accurately. Yu et al. (2021)<sup>[23]</sup> proposed a spatial-temporal graph neural network model that integrated graph attention networks and GRU for air temperature forecasting. Guo et al. (2025)<sup>[24]</sup> introduced spatial-temporal fusion graph neural networks with mixed adjacency, a model that leveraged spatial-temporal fusion GNNs with mixed adjacency and integrated GNNs with self-attention mechanisms to capture both long-term temporal periodicity and short-term spatial-temporal dependencies for temperature forecasting. Xu et al. (2024)<sup>[25]</sup> proposed the dynamic graph former model, a physics-guided

dynamic graph neural network for weather forecasting which combined GNNs and the Reformer architecture for temperature forecasting.

Despite the progress in traffic and temperature forecasting based on novel deep learning models, some challenges remain in multi-granularity data fusion, in-depth extraction of spatial-temporal features, dynamic adjustment of learning behavior and computational efficiency. This study addresses these limitations by integrating the multi-granularity data fusion, STGCM and GSSSM to enhance the prediction accuracy and efficiency.

### 3 METHODOLOGY

In this section, the mathematical definition is first formulated for the investigated issue of environmental temperature and traffic flow prediction of bridge groups in this study. Then, the overall schematic of the proposed STGSSSM is presented, along with detailed descriptions of its two core modules, i.e., spatial-temporal graph convolution module (STGCM) and graph selective state space module (GSSSM), which are combined together to capture the spatial-temporal dependencies.

#### 3.1 Problem Definition

A graph of bridge groups can be represented as  $\mathbf{G}_t = (\mathbf{V}, \mathbf{E}_t, \mathbf{A})$ , where  $\mathbf{V}$  denotes the set of nodes, representing bridges in a bridge group;  $\mathbf{E}_t$  denotes the set of edges (connections), describing the relationships between different bridges at time step  $t$ ; and  $\mathbf{A}$  denotes the adjacency matrix with elements  $A_{ij}$  representing the connection weight between nodes  $v_i$  and  $v_j$ . The input feature matrix of the bridge group at time step  $t$  is denoted as  $\mathbf{X}_t \in \mathbb{R}^{N \times D}$ , where  $N$  is the number of bridges in a bridge group, and  $D$  represents the number of feature dimensions, i.e.,  $D = 1$  represents the investigated variable of environmental temperature or traffic flow.

The graph-based spatial-temporal prediction task is to use the graph of bridge groups  $\mathbf{G}_t$  and feature matrix  $\mathbf{X}_t$  to learn a mapping function  $f$  (the proposed STGSSSM) which can accurately predict the prospective environmental temperature and traffic flow of bridge groups.

Assuming a future time step  $T$ , the prediction process can be expressed as:

$$[\mathbf{X}_{t+1}, \dots, \mathbf{X}_{t+T}] = f([\mathbf{X}_{t-T+1}, \dots, \mathbf{X}_t]; [\mathbf{G}_{t-T+1}, \dots, \mathbf{G}_t]) \quad (1)$$
 where  $[\mathbf{X}_{t+1}, \dots, \mathbf{X}_{t+T}] \in \mathbb{R}^{N \times D \times T}$  is the predicted environmental temperature or traffic flow in the future  $T$  time steps,  $(\mathbf{X}_{t-T+1}, \dots, \mathbf{X}_t) \in \mathbb{R}^{N \times D \times T}$  is the observed environmental temperature or traffic flow in the current  $T$  time steps.

#### 3.2 Overall Schematic of STGSSSM

The proposed STGSSSM comprises two primary modules of STGCM and GSSSM for environmental temperature and traffic flow prediction of bridge groups, as depicted in Figure 1.

Three temporal granularities of input data, recent data  $\mathbf{X}^r$ , cyclic data  $\mathbf{X}^c$  and trend data  $\mathbf{X}^q$  are individually fed into STGCM, which consists of  $N$  ST-Blocks and an output layer that consists of the *ReLU* activation function and a linear layer, each ST-Block employs a series of layers including  $1 \times 1$  convolution, gated temporal convolution (Gated TC), self-attention diffusion graph convolution (SADGC), residual

connection (Add), and batch normalization (BN); and adaptively fused after being passed through  $N$  layers of spatial-temporal graph convolution blocks (ST-Block) with skip connections and the output layer; In each ST-Block, the result of Gated TC is processed via a  $1 \times 1$  convolution, and the resulting output is skip-connected to the result of the last ST-Block.

Furthermore,  $\mathbf{X}^r$  is fed into GSSSM, which consists of  $M$  GSSS-Blocks. Each GSSS-Block incorporates a series of layers including layer normalization (Layer Norm),  $m$  parallel dynamic filter graph convolution (Dynamic Filter GC), concatenation and linear layer (Concat & Linear), graph state space selection mechanism (GSSS-Mechanism) which consists of two main algorithms of Parameter Calculation and Graph Selective Scan, linear layer and residual connection (Linear & Add).  $N$ ,  $M$  and  $m$  are hyperparameters.

The outputs of three STGCMs are first fused using an adaptive fusion module and then adaptively fused with the output of GSSSM. The final fusion result of STGCM and GSSSM is then passed through a fully connected layer to obtain the final output  $\mathbf{X}_{pred}$ .

The regularized mean squared error (MSE) is used for training the proposed STGSSSM and defined as

$$L = \frac{1}{B} \left( \sum_{b=1}^B \left( \frac{1}{TND} \sum_{i=t+1}^{t+T} \sum_{j=1}^N \sum_{k=1}^D (\hat{X}_{i,j,k}^b - X_{i,j,k}^b)^2 \right) + \lambda R(\Theta) \right) \quad (2)$$

where  $X_{i,j,k}^b, \hat{X}_{i,j,k}^b$  represents the model-predicted and ground-truth data for the  $b$ -th segment;  $i, j, k$  denote the indexes of time step, bridge node, and feature dimension;  $B$  and  $D$  denote the number of batch size and considered feature dimension (i.e.,  $D = 1$  represents environmental temperature or traffic flow);  $\lambda$  is the regularization coefficient, and  $R(\Theta)$  is the regularization term.

Figure 1. Overall schematic of the proposed STGSSSM.

### 4 EXPERIMENT STUDIES

#### 4.1 Datasets

Two real-world datasets are utilized here to assess the proposed approach for spatial-temporal prediction of environmental temperature and traffic flow for bridge groups. Training samples for time series are typically obtained by sliding a window of length  $P + T$  across the original time series. Here, the first  $P$  time steps are used as historical data, and the subsequent  $T$  time steps are used as future data; and the datasets are detailed as follows:

- **KnowAir<sup>[26]</sup>**: This temperature dataset contains spatial-temporal temperature data from weather stations across 184 main cities in China from September 1, 2016, to

January 31, 2017. It contains 184 nodes (weather stations) and 11688 time steps of temperature data with a 1-hour time interval; and the adjacency matrix of the graph is constructed based on the geographical locations of the weather stations. In the released KnowAir dataset,  $P = 7 \times 24$ , and  $T = 12$ .

- **PEMS04**<sup>[9]</sup>: This traffic dataset consists of spatial-temporal traffic flow data on California road network from January 1, 2018, to February 28, 2018. It contains 307 nodes (traffic monitoring stations) and 16992 time steps of data with a 5-minute time interval; and the adjacency matrix of the graph is constructed based on the geographical locations of the traffic monitoring stations. In the released PEMS04 dataset,  $P = 7 \times 24 \times 12$ , and  $T = 24$  or 36.

#### 4.2 Experimental Setup

All the datasets are split with a ratio of 7:1:2 for training/validation/testing sets, respectively. Before starting the model training process, all the data samples are normalized into range [0,1] with min-max normalization. The batch size is set as 48, and AdamW is employed as the optimizer. Model training epochs is set as 200. The number of ST-Blocks is set as  $N = 8$  with a sequence of dilation ratios  $R = 1$  or 2, and the number of GSSS-Blocks is set as  $M = 4$ . The diffusion step  $K = 2$  in Eq. (5), and the number of parallel Dynamic Filter GC,  $m = 3$  in Eq. (7). Hyperparameters in Eq. (3) of MSE loss function are set as the regularization coefficient  $\lambda$  of  $1e^{-2}$  and the learning rate of  $1e^{-4}$ .

All experiments are conducted under the software environment of PyTorch 1.12.1 and Python 3.8.10 with a NVIDIA GeForce RTX 3090 24GB GPU to accelerate neural computing. The training process requires nearly 4h for obtaining a well-trained model with acceptable accuracy.

#### 4.3 Comparative Studies with Baseline Models

Two recent Graph-based spatial-temporal predictive model of STGCN<sup>[9]</sup> and MTGNN<sup>[18]</sup> are utilized as baselines for comparative studies. STGCN integrates graph convolutional layers to model spatial dependencies and gated temporal convolutional layers to capture temporal dynamics in traffic data. MTGNN considers the features in the time-series to be multivariate and captures spatial dependencies through a learned graph structure, which uses a mix-hop propagation layer to handle spatial dependencies and a dilated inception layer for temporal dependencies.

In comparative studies with STGCN and MTGNN models, to ensure fairness, several trials are conducted to select an acceptable model with good accuracy though not necessarily optimal. For STGCN, the graph and temporal convolution kernel sizes are set to 3. Chebyshev polynomial approximation and first-order approximation are used in STGCN. For MTGNN, the propagation depth and dilation factor are set to 2 and 1, respectively. During training, the Adam optimizer is employed with a  $1e^{-3}$  learning rate, a regularization coefficient of  $1e^{-4}$ , and a dropout rate of 0.3. These adjustments made sure that the baseline models performed well on our datasets, which enable a fair comparison of model performances and a better evaluation of the proposed STGSSSM's strengths.

Evaluation metrics of mean absolute error (MAE), root mean squared Error (RMSE), and mean absolute percentage error

(MAPE) are utilized to measure and assess the accuracy of various methods.

The MAE is defined as

$$MAE_{test} = \frac{1}{TND} \sum_{i=t+1}^{t+T} \sum_{j=1}^N \sum_{k=1}^D |\hat{X}_{i,j,k} - X_{i,j,k}| \quad (3)$$

The RMSE is defined as

$$RMSE_{test} = \sqrt{\frac{1}{TND} \sum_{i=t+1}^{t+T} \sum_{j=1}^N \sum_{k=1}^D (\hat{X}_{i,j,k} - X_{i,j,k})^2} \quad (4)$$

The MAPE is defined as

$$MAPE_{test} = \frac{100\%}{TND} \sum_{i=t+1}^{t+T} \sum_{j=1}^N \sum_{k=1}^D \left| \frac{\hat{X}_{i,j,k} - X_{i,j,k}}{\hat{X}_{i,j,k}} \right| \quad (5)$$

Table 1 shows the performance comparison of the proposed STGSSSM with baseline models of STGCN and MTGNN. In the experimental results, 12 hours with a time interval of 1 hour corresponds to 12 time steps for temperature prediction; 6 hours with a time interval of 5 minutes corresponds to 72 time steps for traffic flow prediction; 9 hours corresponds to 108 time steps for traffic flow prediction.

Table 1. Performance comparison of the proposed STGSSSM with baseline models of STGCN and MTGNN.

KnowAir	12h		
	MAE	RMSE	MAPE
STGCN	0.35	0.51	3.77%
MTGNN	0.33	0.48	3.34%
STGSSSM	<b>0.28</b>	<b>0.44</b>	<b>3.02%</b>
PEMS04	6h		
	MAE	RMSE	MAPE
STGCN	14.21	20.85	12.95%
MTGNN	<b>13.28</b>	19.67	12.34%
STGSSSM	13.39	<b>19.47</b>	<b>12.12%</b>
PEMS04	9h		
	MAE	RMSE	MAPE
STGCN	17.60	26.39	14.96%
MTGNN	16.76	25.13	14.39%
STGSSSM	<b>16.37</b>	<b>24.01</b>	<b>14.23%</b>

#### 4.4 Ablation Study

To assess the effectiveness of each model component within STGSSSM, three kinds of model variants are first designed, and their forecasting performance is evaluated on the KnowAir and PEMS04 datasets: (1) the full model of STGSSSM, (2) GSSSM without STGCM, (3) STGCM without GSSSM.

To further evaluate the effects of three temporal granularities of recent, cyclic, and trend data, another three kinds of model variants are designed: (4) STGSSSM without cyclic and trend data, (5) STGSSSM without cyclic data, (6) STGSSSM without trend data.

Table 2. Model performances of ablation study for different modules of STGSSSM.

KnowAir	12h		
	MAE	RMSE	MAPE
STGSSSM	<b>0.28</b>	<b>0.44</b>	<b>3.02%</b>
GSSSM w/o STGCM	0.39	0.54	4.15%
STGCM w/o GSSSM	0.31	0.47	3.27%
STGSSSM w/o cyclic and trend	0.40	0.55	4.27%
STGSSSM w/o cyclic	0.30	0.45	3.16%
STGSSSM w/o trend	0.29	0.44	3.13%
PEMS04	6h		
	MAE	RMSE	MAPE

STGSSSM	<b>13.39</b>	<b>19.47</b>	12.12%
GSSSM w/o STGCM	18.86	28.94	15.72%
STGCM w/o GSSSM	14.48	21.46	12.29%
STGSSSM w/o cyclic and trend	13.94	20.25	12.22%
STGSSSM w/o cyclic	13.51	19.57	12.01%
STGSSSM w/o trend	13.45	19.63	<b>11.93%</b>
<b>PEMS04</b>			
	9h		
	MAE	RMSE	MAPE
STGSSSM	<b>16.37</b>	<b>24.01</b>	14.23%
GSSSM w/o STGCM	18.99	29.21	15.66%
STGCM w/o GSSSM	18.38	27.86	15.11%
STGSSSM w/o cyclic and trend	16.83	24.92	14.81%
STGSSSM w/o cyclic	16.39	24.36	13.95%
STGSSSM w/o trend	16.38	24.27	<b>13.93%</b>

The results in Table 2 show the contributions of each module to the overall performance.

(1) Influence of STGCM: The STGCM, which processes recent, cyclic, and trend data through a series of spatial-temporal graph convolution operations, is essential for capturing complex spatial-temporal dependencies. The results show that removing the STGCM leads to a substantial decline in performance across both datasets. For instance, on the KnowAir dataset, the MAE, RMSE, and MAPE increase from 0.28, 0.44, and 3.02% (full model) to 0.39, 0.54, and 4.15% (GSSSM w/o STGCM), respectively. Similarly, on the PEMS04 dataset, the MAE, RMSE, and MAPE rise from 13.39, 19.47, and 12.12% (6h prediction) to 18.86, 28.94, and 15.72% (GSSSM w/o STGCM). This shows that the STGCM greatly boosts the model's ability to handle multi-granularity data and extract meaningful spatial-temporal features.

(2) Influence of GSSSM: The GSSSM, which models the evolution of spatial-temporal dependencies and optimizes computational resources, also makes a significant contribution to the model's performance. Removing the GSSSM results in a significant decline in performance. On the KnowAir dataset, the MAE, RMSE, and MAPE increase to 0.31, 0.47, and 3.27%, respectively. On the PEMS04 dataset, the MAE, RMSE, and MAPE rise to 14.48, 21.46, and 12.29% (6h prediction). This demonstrates the importance of the GSSSM in dynamically adjusting the model's behavior and focusing on the most relevant parts of the data.

(3) Influence of Multi-Granularity Data Fusion: The fusion of recent, cyclic, and trend data is another critical aspect of the model. The results illustrate that removing both cyclic and trend data (STGSSSM w/o cyclic and trend) results in a significant decline in performance. On the KnowAir dataset, the MAE, RMSE, and MAPE increase to 0.40, 0.55, and 4.27%, respectively. On the PEMS04 dataset, the MAE, RMSE, and MAPE rise to 13.94, 20.25, and 12.22% (6h prediction). This shows that the fusion of multi-granularity data is crucial for seizing diverse temporal patterns and enhancing prediction accuracy.

(4) Influence of Individual Data Components: The results also illustrate the contributions of individual data components (cyclic and trend data). Removing only the cyclic data (STGSSSM w/o cyclic) or only the trend data (STGSSSM w/o trend) leads to moderate performance declines. On the

Temperature dataset, removing cyclic data results in MAE, RMSE, and MAPE of 0.30, 0.45, and 3.16%, while removing trend data results in 0.29, 0.44, and 3.13%. On the PEMS04 dataset, removing cyclic data leads to MAE, RMSE, and MAPE of 13.51, 19.57, and 12.01% (6h prediction), while removing trend data results in 13.45, 19.63, and 11.93%. These results indicate that both cyclic and trend data boost the model's performance, with cyclic data having a slightly more significant impact.

The proposed STGSSSM model gains from the integration of the multi-granularity data fusion, STGCM and GSSSM, which jointly deliver accurate and efficient spatial-temporal predictions for bridge groups.

## 5 CONCLUSION

This study introduced a Graph Selective State Space Model (STGSSSM) for predicting environmental temperature and traffic flow in bridge groups, integrating Graph Neural Networks (GNNs) and State Space Models (SSMs). The main contributions of the model include adaptive fusion of multi-granularity data, a Spatial-Temporal Graph Con-volution Module (STGCM), and a Graph Selective State Space Module (GSSSM). Experiments on real-world datasets (KnowAir and PEMS04) show STGSSSM outperforms state-of-the-art models like STGCN and MTGNN in prediction accuracy and efficiency. Ablation experiments validate that each component is effective, necessary, and enhances accuracy in capturing complex spatial-temporal dependencies. The proposed STGSSSM achieves overall prediction accuracy improvements of environmental temperature at the ranges of [13.70%, 20.00%] and [8.30%, 15.15%] and traffic flow at the ranges of [4.90%, 9.00%] and [1.02%, 4.46%] compared with STGCN and MTGNN, respectively. Specifically, the reported STGCM, GSSSM and multi-granularity data fusion decreases the relative prediction error at the ranges of [7.93%, 28.99%], [1.32%, 13.80%], and [0.49%, 29.50%], respectively.

Future work may extend the model to more complex data and other infrastructure systems.

## ABSTRACT:

### Introduction:

Concrete girders are a type of widely used structures in small and medium span bridges. The ultimate flexural strength of concrete main girders serves as a critical foundation for assessing the structural performance of small and medium span simply supported girder bridges, and is essential for ensuring their safe operation. After the installation of prefabricated concrete girders, cement and asphalt concrete are sequentially poured on the top surface of the girders as bridge decks. The bridge deck pavement and concrete girder jointly bear the overall external loads. However, during the design and operation stages, the bridge deck pavement is typically regarded as secondary dead load when estimating bearing capacity, without considering its inherent reinforcement effect on the main girder. Thus, understanding the damage mechanism and destructive behaviour of concrete girders whilst considering the deck pavement effect is crucial for bridge safety assessment. The currently prevalent laboratory-based research method using scaled models can effectively elucidate the failure mechanisms of concrete girder members by controlling the experimental environment, the findings cannot be directly extrapolated to evaluate the service performance of actual bridge structures.

### Description of the serving concrete main girders:

This study focused on retired concrete main girders from real-world service environments, conducting ultimate flexural strength tests. The full-scale retired prestressed concrete girder used in this study was taken from a highway bridge in Northeast China. The bridge span, deck width, and structural form are typical representatives of medium and small-sized highway concrete girder bridges in this region. The superstructure is a post-tensioned prestressed concrete hollow slab girder with a calculated span of 17.60 m. The total width of the deck is 13 m, and the width of the motor vehicle lane is 12 m. The deck pavement is made of 10 cm thick cement concrete and 8 cm thick asphalt concrete. When the bridge was demolished, the top layer of asphalt concrete was milled off first, and then a cutting machine was used for longitudinal cutting to remove the cement concrete deck pavement along with the main girder as a whole. The research object of this paper is one of the middle girders, with a girder height of 90 cm and a width of 124 cm. Both the main girder and the deck pavement are made of C40 concrete. The stirrups of the top slab use HPB300 steel bars with a diameter of 12 mm, while the remaining stirrups and longitudinal bars use HPB300 steel bars with a diameter of 8 mm. The specification of the prestressed steel strands is  $1 \times 7 \phi^s 15.2$ , with a standard strength of 1860 MPa and a low-relaxation high-strength steel strand, and the initial tensile stress is 1178 MPa.

To study the crack development and failure mode of full-scale prestressed hollow slab girders in combination with the bridge deck pavement layer, the material properties of the test girders were tested. The compressive strength test of concrete was carried out in accordance with the "Technical specification for inspecting of concrete compressive strength by rebound method" (JGJ/T 23 - 2011). Before the failure test, rebound tests were conducted on the web and bottom slab of the girder. A total of 18 test areas were selected on the web and bottom slab of the test girder at intervals of 1 m, with 16 test points in each area. The average carbonation depth was tested using alcohol phenolphthalein solution, which was 2.5 mm. The rebound values of the concrete in each test area of the web and bottom slab of the test girder were basically the same, with an average value of  $R_{mc} = 52.2$ . The concrete strength was converted using a unified strength curve, which was 56.1 MPa.

During the test, to restore the boundary conditions as accurately as possible, fixed and sliding supports were respectively set up at both ends of the test girder, with a center distance of 17.30 m. The loading points were arranged at 7 m and 11 m away from the girder ends, and four-point bending loading was carried out using reaction frames and jacks. The 4 m range at the mid-span of the test girder was the pure bending section. A pressure sensor with a range of 2000 kN was installed between the jack and the reaction frame to monitor the pressure value in real time. To prevent the stress concentration effect from crushing the bridge deck pavement concrete, a  $0.5 \text{ m} \times 0.5 \text{ m}$  pad was placed between the jack and the test girder. Strain gauges and displacement transducers (Linear Variable Differential Transducers, LVDTs) were used to monitor the response of the test girder under static loading. Measuring points were arranged vertically at intervals of 20 cm on both side webs, and were densified at the variable cross-section positions. LVDTs were installed below the webs at 1/4 span, mid-span and 3/4 span of the test girder to monitor the deflection. Considering that the supports would deform downward during loading, LVDTs were arranged below the sliding and fixed supports to calibrate the actual deformation of the test girder. LVDTs were arranged along the longitudinal direction of the girder at the end of the sliding support, and a high-speed camera was placed in front of the web in the pure bending section to record the crack propagation process. Loading and sensor arrangement for flexural test can be seen in Fig.1.

### Establishing of FEMs:

To further investigate the mechanical behavior of the failure process of retired prestressed concrete girders and the influence of bridge deck pavement, two three-dimensional FEMs were established based on ABAQUS, namely the model with bridge deck pavement (Model 1) and the model without bridge deck pavement (Model 2). Then, the global response (deflection) and local response (strain and cracking) at each load level were calculated. The dimensions of each component in Model 1 were the same as those in the test field. Reference points were established and connected to the action surfaces of the supports and loading points through "coupling", and the boundary conditions and loads were controlled through the reference points. The main girder, bridge deck pavement, loading block and supports were simulated using continuous linear three-dimensional stress elements (C3D8R) with a mesh size of 5 cm. The prestressed steel strands were simulated using linear three-dimensional truss elements (T3D2), and the "embedded" constraint method was used to bond the prestressed steel strands with the surrounding concrete elements. The prestress was applied to the steel strands through the thermal stress method. Python scripts were used to batch establish line elements between the top plate of the main girder and the bridge deck pavement and specify them as sliding plane elements. The FEMs can be seen in Fig. 2.

Fig.2. Establishing the FEMs

During the test, when a certain load was applied, a slip occurred between the bridge deck pavement layer and the main girder. This indicates that in the FEM, the connection between the bridge deck pavement and the main girder cannot be simulated by the

"binding" consolidation method. In this paper, the detachment of the bridge deck pavement is simulated by the failure of the connecting element. This study refers to the shear strength proposed by Mohama, considers the adhesive effect of concrete and the shear friction effect between components, and modifies the expression. Based on the results of experimental tests and FEM calculations, the coefficient corresponding to the peak bond force was derived according to the load at which the bridge deck pavement and the main girder cracked. The coefficient of concrete friction force was derived based on the load when the bridge pavement completely slipped. The derived formula is as follows:

$$\tau = \left(0.2378e^{0.237R_{pm}}\right)f_t + \left(0.5479R_{pm}^{0.3978}\right)\sigma_n$$

Through the observation of the test phenomena, the failure process of the test girder can be divided into three stages. The first stage is the elastic stage, during which the test girder is in an intact state as a whole, and the mid-span deflection increases linearly with the load. The second stage is the working stage with cracks. After reaching the cracking load, the cracks extend from the bottom plate to the web. As the load increases, the length and width of the cracks gradually increase, and they no longer extend when they approach the top plate. Cracks first appear between the bridge deck pavement and the main girder, and then they completely separate. The test girder enters the third stage of the failure process. At this time, the main girder mainly bears the load, and the strengthening effect of the bridge deck pavement on the main girder basically disappears. With the further increase of the load, the test girder completely breaks.

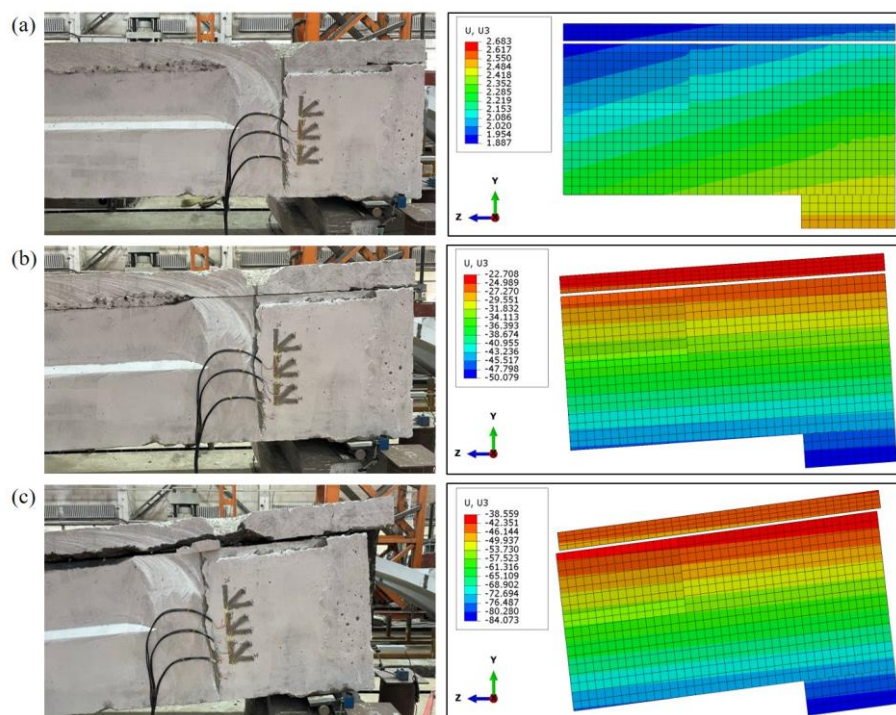

Fig.3. The three stages of main girder failure

## Results and analysis:

The load-deflection curve at mid-span is the most direct indicator for evaluating the bearing capacity of the test girder, which can be seen in Fig.4. The state of the test girder can be divided into three stages: the first stage is the elastic state, where the load is within the range of 0 to 200 kN, and the load-displacement curve is basically linear. When the load reaches 200 kN, the deflection-span ratio of the test girder is 1/1193; the second stage is the working state with cracks, when the load is greater than 200 kN, as the cracks extend towards the top slab, the stiffness of the test girder significantly decreases, and the mid-span displacement begins to increase at a larger rate. When the load reaches 541.5 kN, the bridge deck pavement layer completely detaches from the main girder, at which point the deflection-span ratio is 1/95. The structural system undergoes a sudden change, and the load suddenly decreases; in the third stage, the test girder enters the plastic state, loses its bearing capacity, and the mid-span displacement increases significantly before complete fracture. Without considering the effect of the bridge deck pavement, the bearing capacity of model 2 is significantly lower than that of model 1. Due to the reduction in section height, the displacements corresponding to the cracking point and the inflection point of the curve are slightly larger than those in model 1. Similar to model 1, the inflection point of the curve lags behind the cracking point. The slope of the load-deflection curve can be used to characterize the stiffness of the test girder. In the elastic stage, due to the strengthening effect of the bridge deck pavement layer, the overall stiffness of the test girder increases by 27.7%, the cracking load increases by 16.4%, and the load at the state inflection point increases by 16.7%. After the bridge deck pavement layer is completely separated from the main girder, the strengthening effect of the pavement layer disappears, and the load is mainly borne by the main girder. The load at the complete fracture of the test

girder is 496.7 kN, and the ultimate load before the bridge deck pavement detaches is 541.5 kN. Under the strengthening effect of the bridge deck pavement layer, the ultimate load of the test girder increases by 9.0%.

Fig.4. Load –displacement in mid span curves: (a) entire process; (b) local zoom in red box of (a)

The widths of key cracks under each loading step were recorded using a crack tester during the experimental process. Fig. 5 shows the maximum width of cracks under critical loads. According to the Specifications for design of highway reinforced concrete and prestressed concrete bridges and culverts (JTG 3362 – 2018), the maximum allowable crack width for PC components using steel strands in freeze–thaw areas under normal use is 0.10 mm. According to the test results, when the load was 170 kN (corresponding mid-span moment of 1190 ), the crack width reached the limit allowed by the specifications. The “condition rating” recommended by the International Atomic Energy Agency guidelines defines three types of damage levels based on the maximum crack width: grade I (minor damage: < 0.2 mm), grade II (moderate damage: 0.2–1.0 mm), and grade III (critical damage: > 1.0 mm). Based on the maximum crack width, the structure had minor damage when the load was 210 kN, when the load was approximately 210–320 kN, the structure was moderately damaged, and when the load exceeded 320 kN, the structure was critically damaged.

Fig.4. Maximum crack width in critical loads

In fact, for prestressed concrete girder bridges, whether in the design or inspection process, the strengthening effect of the bridge deck pavement on the main girder is not considered when calculating the bearing capacity of the main girder. Instead, it is applied to the main girder as a second-stage dead load. If its strengthening effect is taken into account, the design and inspection results are often overly conservative. The research on the strengthening effect of the bridge deck pavement on the main girder in this paper is not aimed at guiding the design optimization of prestressed concrete girder bridges. During the dynamic and static load inspection of prestressed concrete simply supported girder bridges in cold regions, the bridge deck pavement is also regarded as a second-stage dead load without considering its strengthening effect on the main girder. This will lead to an inability to grasp the true state of the main girder when inferring the bridge's bearing capacity from the inspection results, and thus an inaccurate assessment of its safety performance. If the structural state of the main girder does not meet the standards for normal use, the

inspection results may still meet the requirements under the strengthening effect of the bridge deck pavement, which will pose potential risks during the operation of the bridge. If the strengthening effect of the bridge deck pavement is considered in the simulation calculation, the threshold for the safety assessment of prestressed concrete girder bridges can be corrected, thereby more accurately evaluating the safety margin of the bridge structure. At this time, it is very necessary to consider the reinforcing effect of the bridge deck pavement.

# Structural Health Monitoring of Transport Infrastructures using Drive-by Monitoring

# Data-Driven Monitoring Solutions for Concrete Structures: Long-Term Insights with CorroDec2G Sensors

Christian Steffes<sup>1</sup>

<sup>1</sup>Infrasolute GmbH, An den Kreuzen 3, D-56154 Boppard  
email: Christian.steffes@infrasolute.com

**ABSTRACT:** Passive sensor technologies offer a robust solution for monitoring concrete structures. These technologies utilize advanced methods to measure critical parameters such as moisture, corrosion, and temperature within the concrete. By employing RFID technology, the sensors operate wirelessly and require no maintenance. With a lifespan exceeding 80 years, passive sensors enable comprehensive and efficient long-term structural monitoring.

This article provides insights into the installation methods, the benefits of the cloud-based data platform, and how this technology contributes to improved safety, durability, and the preservation of infrastructure.

**KEY WORDS:** SHMII-13; Full paper; Corrosion monitoring; Moisture monitoring; Passive RFID sensors; Bridge rehabilitation

## 1 INTRODUCTION

### 1.1 *The importance of preventive monitoring of concrete structures*

In modern structural monitoring, the early detection of damage plays a central role.

Concrete structures such as bridges are exposed to extreme loads and environmental influences on a daily basis. The increasing demands on the safety and durability of such structures make continuous monitoring indispensable [1]. Preventive monitoring helps to identify potential damage at an early stage and to initiate appropriate measures before costly repairs or even critical failures occur [2].

In this context, the passive sensor technology CorroDec2G by Infrasolute offers innovative solutions. This technology enables long-term monitoring of structural integrity by capturing key parameters such as moisture, corrosion progression, and temperature within the concrete. Since 2018, these sensors have been used in various reinforced concrete structures and have established themselves as a reliable early warning system. The robust design of the sensors and their easy integration into existing structural elements facilitate their use in both new constructions and retrofit applications.

The advantages of this technology lie particularly in its passive nature—meaning it does not require an external power supply, which reduces maintenance costs. In addition, the sensors deliver precise long-term data that can be processed using modern data analysis systems to identify trends and potential damage patterns at an early stage.

This article uses two practical examples (Figure 1) to explain how Infrasolute's sensor technology works, how installation is carried out, and what kind of data is collected. These case studies demonstrate how the use of CorroDec2G technology

can extend the service life of structures and improve operational safety.

### 1.2 *Moisture as a risk factor*

In the case of durability-relevant bridge damage, moisture penetration is the most common cause, which can lead to corrosion-related damage to prestressing steel in older bridges [3]. Therefore, both the determination of the amount of moisture and the moisture condition are of great importance—on the one hand to monitor the long-term functionality of structures, and on the other to quantify the direction of moisture flow. This enables timely and effective decisions regarding necessary maintenance measures.

Moisture can be measured either directly or indirectly. Direct moisture measurement methods are usually based on extracting the amount of water from the material and determining it directly [4]. This approach allows for very accurate results; however, it is considered a destructive method and is therefore only suitable to a limited extent for use on bridges [5].

Alternatively, the moisture content can be determined indirectly by measuring certain material properties of the water that are functionally related to the moisture level. For example, by measuring the conductivity of the water, the actual moisture content can be inferred using specific calibration curves [5]. Indirect methods are well-suited for continuous measurements; however, the results can be influenced by various parameters such as temperature, density, material composition, and conductivity [4].

Figure 1. A selected practical example: Elevated Road Oberwerth, B327, in Koblenz (Copyright: Christian Steffes, Infrasolute).

## 2 FUNCIONALITY AND MEASUREMENT PRINCIPLE

The CorroDec2G sensors from Infrasolute are based on the indirect measurement method. They are characterized by their passive mode of operation. In contrast to active sensors, they do not require any cables or batteries to collect measurement data. Developed in cooperation with the Fraunhofer Institute for Microelectronic Circuits and Systems (IMS) in Duisburg, the sensors are designed to remain fully enclosed and maintenance-free within the concrete for the entire service life of a structure—at least 80 years—while transmitting data (moisture, temperature, corrosion) from within the structure [6].

The energy required for passive operation is supplied externally via RFID (radio-frequency identification) technology. RFID is a technology also used in everyday applications such as contactless credit card payments and enables wireless, contactless data transmission. With a reading range of up to 30 cm through concrete, the sensors can be reliably interrogated [10]. A specially designed antenna setup can extend this range up to 100 meters. In such cases, the measuring unit is embedded in the concrete, for example in the center of the roadway, while the reading unit is positioned in a strategically advantageous location outside the flow of traffic, allowing data retrieval without disrupting traffic.

The system's special design ensures that no component extends beyond the concrete surface, thereby eliminating potential weak points in the structure. This concept not only protects the structural integrity but also significantly extends the service life of the sensors by shielding them from environmental influences such as moisture, temperature fluctuations, and mechanical stress [5]. Such innovative RFID-based systems represent an important step toward sustainable structural monitoring, as they are cost-efficient in

the long term and do not interfere with the structure's operation.

## 3 INSTALLATION METHODS

### 3.1 New construction and rehabilitation

The installation of the sensors can be carried out both in new construction and during rehabilitation works. In new construction projects, as illustrated in Figure 2, the sensors are directly attached to the reinforcement using binding wires to ensure stable anchoring and to maintain their position during concreting—preventing, for example, floating within the fresh concrete. During rehabilitation works, such as after hydrodemolition (high-pressure water jet removal), the sensors can likewise be installed by affixing them to the exposed reinforcement. This allows for effective integration of the monitoring system even in existing structures without major modifications.

Figure 2. Attachment of moisture sensors in a new construction project using binding wires directly on the reinforcement (Copyright: Christian Steffes, Infrasolute).

Such precise installation procedures are particularly important to ensure accurate measurement data, which are crucial for condition assessment and maintenance planning [5].

### 3.2 Retrofitting installation

The sensors can be retrofitted into existing structures using core drilling. As shown in Figure 3, a core hole with a diameter of 100 mm allows the sensors to be embedded into the concrete without significantly affecting the structural integrity of the building. The sensor is placed in a thin layer of a special mineral-based, open-pored coupling mortar. This layer ensures optimal bonding with the existing concrete.

After installation, the coupling process begins. During this phase, moisture measurements can be used to monitor the drying of the surrounding coupling mortar. Once equilibrium moisture content is reached, the sensor can deliver precise data about the surrounding environment. The design of the coupling mortar ensures effective moisture migration from the existing concrete to the sensor.

To avoid creating a structural weak point, a sealing mortar is applied above the sensor after installation. This ensures a durable and secure integration into the structure while maintaining the mechanical and protective properties of the original concrete.

Figure 3. Core drilling with a diameter of 100 mm and installation of the sensor using coupling mortar (Copyright: Eugen Kronhardt, Infrasolute).

## 4 SENSORS AND DATA TRANSMISSION

### 4.1 Sensor variants

The **corrosion sensor** developed by Infrasolute can be identified by its characteristic red housing and the four surrounding wire layers (Figure 4).

The measurement method is based on the principle of proxy corrosion, in which the properties of the wires are specifically designed to closely replicate the corrosion behavior of reinforcement steel. Over time, the wires corrode in response to the surrounding environmental conditions [7].

The wire layers arranged around the sensor provide information about the presence and progression of corrosion, acting as indicators for the location of the passivation front. By analyzing the depth-wise arrangement of the wires, it is

possible to determine at what depth the passivation has broken down and how quickly the passivation front is advancing toward the reinforcement.

This data is critical for assessing the condition of the structure, planning further structural investigations, and initiating timely countermeasures to prevent the progression of corrosion [7].

Figure 4. Corrosion sensor with two measurement wire layers (Copyright: Christian Steffes, Infrasolute).

The sensor operates using a redundant system, in which two circumferential wires form a single measurement layer. This design enhances the reliability of the measurement results and reduces potential sources of error. In addition, the corrosion sensor also measures temperature within the concrete, as temperature fluctuations can significantly influence corrosion dynamics [8]. The combination of corrosion monitoring and temperature measurement makes the corrosion sensor a vital tool for long-term monitoring and for implementing preventive maintenance strategies in reinforced concrete structures.

The **moisture sensor** (Figure 5) measures both moisture and temperature within the concrete. The moisture condition is a critical parameter in the formation of corrosion, as it affects the electrophysical environment required to initiate corrosion processes. By combining moisture and temperature data, it is possible to gain detailed insights into moisture development within the concrete. Early detection of moisture fluctuations allows for minimization of potential damage and contributes significantly to extending the service life of the structure.

Figure 5. Moisture sensor (Copyright: Christian Steffes, Infrasolute).

By combining a corrosion sensor and a moisture sensor placed approximately 15 cm apart, early information on corrosive processes and anomalies can be obtained. This spatial proximity enables detailed observation of the correlation between changes in moisture levels and the dynamics of corrosion processes, providing a deeper understanding of the environmental conditions that influence structural degradation.

#### 4.2 Data acquisition and transmission

There are two methods for retrieving data from the sensors embedded in the concrete. One option is to enable continuous data transmission, allowing the data to be accessed remotely at any time. For this purpose, a gateway, as shown in Figure 6, is installed near the sensor. This gateway both powers the sensor and transmits the collected data directly to the Infrasolute cloud platform.

Data transmission is carried out via NB-IoT (Narrowband Internet of Things), a communication standard specifically designed for reliable, energy-efficient data transfer in monitoring applications [7].

Figure 6. Solar-powered gateway (Copyright: Christian Steffes, Infrasolute).

As a low-bandwidth radio technology, NB-IoT (Narrowband Internet of Things) enables highly energy-efficient data transmission, allowing sensors and gateways to operate with minimal power consumption [10]. The technology also provides excellent building penetration, ensuring reliable signal transmission even through thick concrete structures (e.g., the new IT center in Koblenz, ground floor, wall thickness approx. 80 cm).

Thanks to support from existing mobile networks, NB-IoT is widely available, making it ideal for use in remote or hard-to-reach structures. Additionally, the low data transmission rate results in reduced operating costs, making NB-IoT a cost-effective solution for long-term monitoring applications.

The gateway is flexible in terms of power supply and can be operated via mains power, a long-life battery, or solar energy, depending on the construction site and local infrastructure. This flexibility enables deployment even in locations with limited access to conventional power sources. The combination of NB-IoT and energy-autonomous gateways represents a significant advancement in structural monitoring,

as it not only improves data quality but also reduces maintenance efforts.

Alternatively, there is the option of using a handheld reading device to manually retrieve sensor data on-site. The device shown in Figure 7 has been specially developed for this application. The process of collecting a sensor's measurement takes only a few seconds and is often carried out during routine bridge inspections by simply bringing the handheld device close to the sensor, enabling contactless and wireless data acquisition [7].

Figure 7. IoT handheld reader for manual sensor data acquisition (Copyright: Christian Steffes, Infrasolute).

The data collected by the handheld reader is transmitted directly to the cloud-based data platform via NB-IoT technology. This enables immediate verification and visualization of the measurement values on-site at the structure [8]. Both the gateway and the handheld reader transmit their data wirelessly via NB-IoT after sensor readout.

The sensor data is stored, referenced, visualized, and analyzed in the cloud platform by comparing it with previous measurements to enable precise trend analyses. Users can define threshold values, which—when exceeded—trigger automatic alerts, allowing potential issues to be identified at an early stage.

The platform also allows the integration of collected data into existing monitoring systems and can proactively send reports via email to all relevant project stakeholders. The data generated on the platform is presented in a user-friendly and easily understandable format, enabling all involved parties—regardless of their technical background—to effectively interpret the information.

## 5 SENSORS AND DATA TRANSMISSION

### 5.1 Südtangente in Koblenz – sensor variants

The Südtangente in Koblenz (Figure 8), constructed between 1972 and 1975, is a major traffic artery located just before the South Bridge crossing the Rhine River. It plays a key role in reducing urban traffic congestion. With a daily traffic volume of approximately 45,500 vehicles, including around 3% heavy goods traffic, it is considered part of the region's critical infrastructure [9]. The bridge connects important

transportation routes and is essential for both regional and long-distance traffic.

Figure 8. Südtangente in Koblenz (Copyright: Martin Lichtl, Infrasolute).

To meet the demands of increasing traffic volumes and to ensure the long-term durability of the bridge, the Südtangente in Koblenz has been undergoing comprehensive rehabilitation since 2020. As part of these measures, the roadway surface, structural waterproofing, guardrails, edge beams, and drainage systems have been renewed. In addition, all concrete surfaces have been repaired to enhance the load-bearing capacity and improve protection against environmental influences.

### 5.2 Sensor installation

As part of the rehabilitation, a comprehensive monitoring system was installed. The foundation for this was the execution of a potential field measurement, which enabled the precise localization of corrosion hotspots within the concrete. The results served as the basis for the targeted placement of sensors.

During the first two construction phases of the rehabilitation of the South Bridge in Koblenz, a total of 22 corrosion sensors and 62 moisture sensors were installed. The sensors were placed at critical and representative locations such as low points, expansion joints, waterproofing areas, structurally sensitive points, reference zones, and the corrosion hotspots identified by the potential field measurement. The final sensor placement was defined in coordination with the planning team. The installation layout is shown in Figure 9.

Figure 9. Potential field measurement and sensor positioning (Copyright: Christian Steffes, Infrasolute).

The sensors were installed into the existing concrete using core drilling (Figure 10). To optimize data retrieval, they were equipped with remote antennas. This allowed the readout units to be placed within the box girder of the bridge, providing protection from mechanical stress and weather conditions.

The gateways, which are connected to the existing power supply within the box girder, handle the data transmission. Each gateway collects the measurement data from four sensors and transmits the data wirelessly via NB-IoT to the Infrasolute cloud platform.

Figure 10. Installed sensors with remote antennas (Copyright: Benedikt Seuss, Infrasolute).

### 5.3 Measurement data and analyses

The continuous monitoring of the Südtangente in Koblenz, which has been carried out since the installation of the first sensors in the initial construction phase at the end of 2020, has so far shown no signs of corrosive activity.

An exception was one measurement point that reported corrosion on the first wire level three months after installation (Figure 11). The cause was identified as a construction-related weakness in the waterproofing, which was subsequently corrected during post-processing. Following this measure, the sensors detected no further corrosion progression.

Figure 11. Data analysis in the software – display of a corrosion sensor showing corrosive activity at the first measurement wire level (Copyright: Christian Steffes, Infrasolute).

When corrosion is detected at the first wire level, the indicator K1 is no longer displayed within a green circle with a “0”, but instead within a red circle with a “1”. This provides a clear and unambiguous indication that corrosion has occurred at the first measurement wire level. The K2 value represents the status of the underlying wire level, allowing the progression of corrosion into deeper areas to be monitored and enabling a multi-layered condition analysis [7]. The values S1 and S2 serve the system’s internal self-referencing. These reference mechanisms ensure the accuracy and validity of the measurement data by automatically detecting any internal deviations or errors. This significantly enhances the reliability of the monitoring system and minimizes the risk of false diagnostics [8]. In addition, the sensor temperature within the concrete is shown under the indicator “Temp. Sensor”, providing essential information on the thermal conditions that may influence corrosion dynamics. The temperature of the gateway, located at the surface of the concrete inside the bridge’s box girder, is displayed separately as “Temp. Gateway”. In all other areas of the bridge, the moisture sensors showed a normalization to equilibrium moisture levels within the first six months after installation, without any notable irregularities or significant fluctuations. These results confirm both the effectiveness of the rehabilitation measures and the stability of the moisture conditions within the structure.

#### 5.4 Conclusion

By implementing sensor technology, the operator of the South Bridge gains the ability to monitor the success of rehabilitation measures in the short term. At the same time, the 24/7 online monitoring allows for the long-term observation of the internal condition of the structure, enabling the early detection of damage and the proactive initiation of maintenance actions. This minimizes the risk of unexpected damage and supports a preventive maintenance strategy that significantly enhances operational safety [7].

#### 5.5 Structure overview: Dieblich Bridge

The bridge along federal road B 411 near Dieblich serves as an important connection to the motorway network and

functions as a regional access route. Compared to the heavily trafficked South Bridge in Koblenz, the traffic volume on this structure is significantly lower. The two-lane bridge spans a length of 92 meters and is used by both passenger vehicles and agricultural traffic.

In 2023, a comprehensive concrete rehabilitation was carried out after elevated chloride levels were detected in the concrete. As part of the refurbishment, it was also necessary to partially replace the reinforcement to ensure the continued structural integrity and durability of the bridge.

#### 5.6 Sensor positions and installation

With a budget of under €10,000, an efficient moisture monitoring system was implemented to continuously provide data on the structural moisture content. This monitoring serves to track moisture levels following the rehabilitation measures and to draw conclusions about the success of the repair works and the containment of corrosive processes.

In the first step, the most critical areas of the structure were identified. This was achieved through a combination of a previously conducted potential field measurement and a detailed analysis of the structural topology. This comprehensive assessment allowed for the precise localization of potentially vulnerable zones.

Based on this analysis, it was jointly decided to install the moisture sensors at the lowest points of the structure, as these areas are particularly susceptible to moisture accumulation due to their proximity to the drainage system, as illustrated in Figure 12. The sensors were equipped with remote antenna configurations, allowing the actual measurement point to be positioned directly in the drainage area, while the readout unit was installed at a central, traffic-independent location behind the safety barrier near the expansion joint. This strategic positioning ensures easy maintenance and data retrieval without interfering with traffic.

For secure placement, the sensors were directly attached to the exposed reinforcement, as depicted in Figure 13.

Figure 12. Potential field measurement and positioning of sensors and the readout point (Copyright: Christian Steffes, Infrasolute).

Figure 13. Installation of a moisture sensor on the reinforcement (Copyright: Eugen Kronhardt, Infrasolute).

### 5.7 Data acquisition and transmission

Data acquisition is performed using an IoT handheld reader. The readout process takes less than 5 seconds and can be carried out at any time on-site from a centralized location. In this project, the readout point was placed at the beginning of the bridge, behind the guardrail, at the height of the bridge cap.

By surveying and documenting the sensor installation positions on the structural plan, and marking them on-site with reference markers, the sensors and their readout points can be easily relocated during follow-up inspections.

Furthermore, the selected location allows for the optional retrofitting of a gateway to enable automated and remote data acquisition in the future. This ensures that the system remains flexible and scalable for long-term monitoring needs.

### 5.8 Measurement data and analyses

Since their installation, the moisture sensors have shown a continuous drying trend without any irregularities. The moisture levels are visualized on the data platform and can be correlated with precipitation data from the nearest weather station.

This type of analysis enables a deeper understanding of moisture changes within the structure and helps determine whether these changes are caused by temperature variations or external influences, such as heavy rainfall events.

## 6 SUMMARY

The CorroDec2G monitoring system developed by Infrasolute offers a durable and forward-thinking solution for the structural health monitoring of concrete. With a lifespan exceeding 80 years, the system operates entirely without batteries, cables, or external power sources, making it uniquely suited for both new construction and retrofit applications. It enables the measurement of moisture, actual temperature, and corrosion activity—without compromising the structural integrity of the concrete. The wireless and battery-free technology, based on RFID, enables long-term and maintenance-free monitoring of structural conditions. Particularly noteworthy are the system's high reliability and

energy efficiency, which are specifically tailored to meet the demanding requirements of structural diagnostics.

Thanks to its simple data retrieval process, the system is especially user-friendly. Measurement data can be collected within seconds, without the need for specialized expertise, and analyzed immediately. This significantly lowers the entry barrier for application and facilitates the integration into existing maintenance and monitoring workflows. Moreover, the data is presented in a clear and understandable format, enabling well-founded decisions regarding maintenance and repair actions to be made efficiently. This transparency benefits not only structure operators but also engineers and planners in ensuring the long-term safety and durability of concrete structures.

The primary advantages of CorroDec2G include its extremely long service life, energy independence, user-friendliness, and cost-efficiency. It supports condition-based maintenance strategies, contributes to the extension of structural service life, and helps optimize life-cycle costs by enabling the early detection of degradation mechanisms. Its rugged design and wireless operation allow for reliable performance in harsh environments such as underground garages or bridge structures. Moreover, its modular setup allows for flexible configurations and scalable integration into both small-scale and complex monitoring scenarios. Another key advantage of the CorroDec2G system is its cost-effectiveness. Continuous monitoring allows for the early detection of damage, minimizing expensive repairs and unforeseen failures. This not only contributes to the extension of the structure's service life but also supports sustainable resource use and optimizes maintenance costs.

Sensor data is accessible anytime and from anywhere, enabling efficient monitoring of multiple structures simultaneously. This is especially beneficial for critical infrastructure, where it supports effective prioritization of maintenance tasks and optimal use of resources [8].

Despite its strengths, CorroDec2G has inherent limitations. As a point-based early warning system, it provides localized data and does not offer full-surface or high-resolution spatial coverage. Strategic sensor placement - especially in critical zones identified by structural engineers - is therefore essential to obtain meaningful results. Furthermore, the system is not designed for high-frequency dynamic measurements but rather for long-term trends and early anomaly detection. Its value lies in its simplicity, reliability, and practical applicability in real-world construction environments

In an increasingly data-driven world, precise and reliable data collection plays a pivotal role. Advanced technologies such as Artificial Intelligence (AI), which are becoming more significant in the field of structural health monitoring, are also built upon such high-quality data. As a result, CorroDec2G serves as a bridge between traditional engineering and modern data science.

In summary, the CorroDec2G system provides an effective, forward-looking solution that actively promotes the safety,

functionality, and preservation of concrete structures over the long term.

**ABSTRACT:** Publicly accessible vehicle measurements for testing and validating drive-by bridge monitoring techniques are currently insufficient. Although relevant monitoring campaigns have been conducted, their results are limited and generally inaccessible to the research community. Consequently, this paper introduces a numerical dataset designed to advance drive-by monitoring methods. The dataset is freely available and can be downloaded from an online repository. It comprises numerically simulated vehicle responses generated using an open-source vehicle-bridge interaction model. The repository includes over half a million individual vehicle crossing events, covering various monitoring scenarios, bridge spans, damage locations, damage magnitudes, road profile conditions, and vehicle properties. This dataset is intended to serve as a reference solution and benchmark for future developments in drive-by bridge monitoring.

**KEY WORDS:** Indirect Monitoring; Damage Detection; Vehicle-Bridge Interaction; Drive-By Inspection.

## 1 INTRODUCTION

To facilitate the advancement of data-driven drive-by bridge damage assessment techniques, this paper presents an openly accessible dataset [1]. The dataset consists of numerically simulated vehicle responses from crossings over diverse bridge spans with varying damage conditions. Additionally, it includes results that consider variations in road profiles, vehicle models, mechanical properties, and speeds. The objective is to offer the research community a valuable resource that serves as a reference for testing and benchmarking new developments in the field.

## 2 THE DATASET

This section offers an in-depth overview of the NuBe-DBBM dataset (Numerical Benchmark for Drive-By Bridge Monitoring methods), which is available to the public in [1]. The dataset encompasses vehicle response data from over half a million numerically simulated vehicle-bridge crossings, spanning a broad spectrum of road, bridge, and vehicle conditions. Furthermore, the repository provides additional materials to support users of the dataset.

The dataset was generated using VBI-2D [2], an open-source MATLAB tool designed to simulate vehicle-bridge interaction (VBI) for road traffic crossing bridges. This tool allows for the specification of various vehicle models, road irregularities, bridge characteristics, and structural conditions. In VBI-2D, bridges are modelled as beams within a finite element framework, while vehicles are represented as mechanical systems with multiple degrees of freedom. The coupled vehicle-bridge response is determined through direct integration of the corresponding equations of motion. For more detailed information on the numerical model, solution method, and user manual, readers are referred to [2]. Figure 1 provides a schematic overview of VBI-2D's simulation capabilities. Specifically for the dataset, simulations involved simply supported bridge configurations of single vehicles crossings at

constant speeds under varying road, vehicle, and bridge conditions.

Figure 1. Illustration of VBI-2D model.

The dataset consists of individual MATLAB files, each containing information and vehicle responses for a single event. An event is defined as a single vehicle traveling at a constant speed over a specified road profile while crossing a bridge without any initial vibrations. The dataset includes five primary problem variables: Bridge length (B), Damage location (DL), Damage magnitude (DM), Vehicle type (V), and Profile (P). It is further divided into two subsets, named DSA and DSB, corresponding to two distinct monitoring scenarios. For each possible combination of problem variables and monitoring scenarios, 800 events are included, with vehicle properties randomly sampled.

The dataset comprises numerical results for six distinct simply supported bridges with span lengths varying from 9 m to 39 m, increasing in 6 m increments. These bridges are modelled as finite element representations using beam elements, each 0.25 m in length. The numerical properties of the beam models were chosen to represent typical bridges of these span lengths, with detailed values of the properties for the beam models provided in [3].

Bridge damage is modelled as a decrease in stiffness affecting either 2 or 4 elements, which equates to bridge lengths of 0.5 m or 1 m. The severity of the damage is expressed as a percentage reduction in stiffness, with the dataset providing results for three levels: 0% (undamaged bridge), 20%, and 40%. Furthermore, two damage locations are examined,

specified in relation to the bridge span  $L$ , namely at quarter-span ( $L/4$ ) and at mid-span ( $L/2$ ).

The dataset encompasses results for three distinct vehicle models, which are numerically represented through combinations of concentrated masses, rigid elements, springs, and dashpots. These models, generated using the open-source tool VEqMon2D [4], are schematically depicted in Figure 2, illustrating the names of all mechanical properties, relevant dimensions, and degrees-of-freedom (DOF) notation. The vehicles are classified based on their total number of axles: a 1-axle model (V1), a 2-axle model (V2), and a 5-axle model (V5). The V1 model, often referred to as a quarter-car model, has been extensively utilised in previous studies to evaluate the performance of drive-by methods. The V2 model represents a car or a 2-axle heavy vehicle, such as a van or truck. The V5 model characterises an articulated heavy vehicle, comprising a tractor and trailer connected by an articulation.

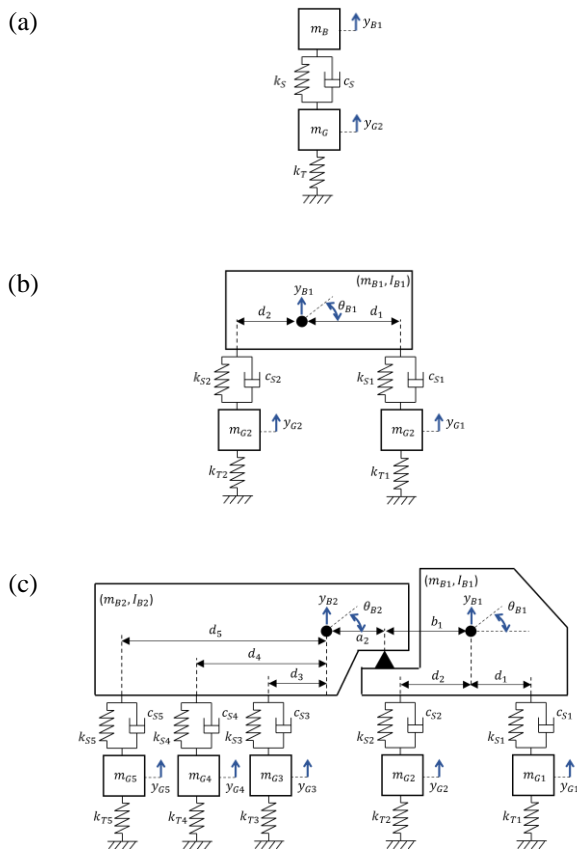

Figure 2. Vehicle models; (a) V1: 1-axle vehicle model; (b) V2: 2-axle vehicle model; (c) V5: 5-axle articulated vehicle model.

Each event in the dataset models the response of one of the vehicle types. For each simulation, the actual speed, along with the mechanical and geometrical properties, are randomly sampled based on probabilistic descriptions provided in the repository [1]. The variability in vehicle model parameters is intended to represent fleets of similar vehicles, although no two are identical. While the geometry of all vehicles within a specific model type remains consistent, their mechanical properties differ between simulations. This mirrors real-world conditions, where vehicles vary due to differences in payloads, suspension characteristics, and tyre pressures.

The dataset also incorporates the impact of road conditions. Some simulations assume a perfectly smooth road surface, labelled as P00. Additionally, the dataset features simulations with two randomly sampled Class A road profiles, generated according to the standardized procedure specified in ISO 8608. To simulate the actual wheel footprint, a moving average filter with a window size of 0.25 m is applied to the generated profiles. These profiles are 600 m in length, with their reference system centred at the midpoint. The profiles are consistently used across all bridge spans, with the left beam support positioned at the origin of the profile's reference system. For all simulations, vehicles include a 100 m long approach distance before crossing the bridge.

The dataset encompasses two distinct monitoring scenarios. Scenario A (DSA) depicts a situation where the target bridge has substantial damage, necessitating more controlled and detailed drive-by inspections while maintaining regular operational conditions. In this scenario, the bridge damage spans 4 elements (1 m), and the vehicle fleet gathers signals at high sampling rates while travelling at controlled, nearly uniform speeds. Scenario B (DSB), in contrast, represents normal operational conditions aimed at detecting early signs of bridge deterioration. Here, the damage spans only 0.5 m (2 elements), with vehicles travelling at varying permitted speeds (resulting in high variability) and signals collected at a lower sampling rate. Table 1 outlines the specifications for both scenarios, reflecting different levels of difficulty for drive-by methods. Scenario A, with more extensive bridge damage and less variability in vehicle speeds, is anticipated to enhance the performance of data-driven damage detection methods. Conversely, Scenario B presents a more challenging environment due to smaller damage and greater variability in operational conditions.

Table 1. Monitoring scenarios specifications.

Dataset code name	DSA	DSB
Number of damaged elements	4	2
Sampling rate of signals (Hz)	1024 (210)	256 (28)
Speed variation (km/h)	70 to 80	30 to 80

Table 2 gives an overview of all dataset dimensions together with their possible values.

Table 2. Summary of dataset's dimensions.

Property	Notation	Possible values
Monitoring scenario	DS + letter	DSA – DSB
Bridge	B + span in m	B09 – B15 – B21 – B27 – B33 – B39
Damage location	DL + location in % of span	DL25 – DL50
Damage magnitude	DM + % of stiffness reduction	DM00 – DM20 – DM40
Vehicle	V + number of axles	V1 – V2 – V5
Road profile	P + Class + Number	P00 – PA1 – PA2
Event number	E + number	E0001 – E0002 – ... – E0800

As mentioned earlier, the dataset consists of individual files containing numerical results and other relevant details for each vehicle crossing event. Each file is uniquely named to indicate the specific characteristics of the simulated event based on the dataset dimensions (see Table 2). The naming convention for each file is:

**DSa** + **\_** + **Bbb** + **DLcc** + **DMdd** + **Ve** + **Pfg** + **Ehhhh** + .mat

for:

**DSa** = Dataset name, where *a* indicates either A or B monitoring scenario

**Bbb** = Bridge type, where *bb* indicates span length

**DLcc** = Damage location, *cc* indicates the location as % of span length

**DMdd** = Damage magnitude, *dd* indicates % of stiffness reduction

**Ve** = Vehicle type, *e* indicates the number of axles of the vehicle model

**Pfg** = Profile, *f* indicates the class of profile (A), and *g* is the profile number

**Ehhhh** = Event number, *hhhh* indicates the event number

For example, the event file *DSA\_B15DL50DM20V5PA2E0327.mat* corresponds to event number 327. This event features a 5-axle truck traversing the 2nd Class A profile and a 15 m simply supported bridge, which has a 20% stiffness reduction at mid-span, under monitoring scenario A.

The dataset includes 518,400 events, totalling 52GB of files that are freely available for download [1]. These files are organised into compressed subfolders based on bridge span and monitoring scenario. Each event file contains the simulated acceleration responses from all degrees of freedom (DOFs) of the vehicle model, including both off-bridge and on-bridge responses, i.e., the vehicle's responses while approaching and crossing the bridge. The file also records the exact time the vehicle enters the bridge. Additionally, it includes the specific realisation of the vehicle's mechanical properties for the simulated event, along with the corresponding natural frequencies of the vehicle model.

Moreover, the repository includes supplementary files that detail the vehicle models and their DOF notation (*Vehicles\_DOF.zip*), the road profiles used in generating the dataset (*Profiles.zip*), and the bridge model parameters (*Bridges.zip*). It is important to note that the vehicle responses in the dataset are clean signals. To simulate real measurements, these signals should be corrupted with noise. To assist with this, the file *Noise.zip* offers two equivalent implementations (for MATLAB and Python) to add noise to the signals.

Readers are referred to the documents *ReadMe.pdf* available in the repository [1] for further information about the stored content and practical guidelines to read the event files. Also refer to the original publication [3] for additional details about the problem variables, vehicle property variability, and the stored information within the dataset.

### 3 CONCLUSION

This paper has introduced a publicly accessible dataset designed as a benchmark for drive-by monitoring techniques. The dataset comprises numerically simulated vehicle responses during bridge crossings. A wide array of configurations and conditions have been modelled and systematically stored in files, which are readily available at [1]. The dataset's variability includes different bridge spans, damage locations, damage magnitudes, road profile irregularities, monitoring scenarios, and vehicle properties. It contains over half a million files with vehicle responses and additional information for individual crossing events. This paper encourages the research community to employ this dataset to test and enhance drive-by monitoring methods.

**ABSTRACT:** Structural health monitoring (SHM) has gained significant attention in recent decades due to several structural failures and the increasing maintenance demands from stakeholders. This urgency has been further amplified by the impact of predictive climate changes worldwide. Footbridges, as critical components of modern transportation systems, play a vital role in daily life and therefore require meticulous attention to their health conditions. Traditionally, monitoring footbridge conditions involves installing many sensors directly on the structure, which is often cost-prohibitive in engineering applications. Recent advancements have highlighted the indirect method of bridge health monitoring, where sensors are mounted on passing vehicles rather than the bridge itself. This approach is not only more economical but also easier to implement in practical engineering scenarios. This paper further extends the indirect monitoring method to classify footbridge damage using the responses of shared scooters. Advanced deep learning techniques are utilized to predict the severity of damage to the footbridge based on the vibrations recorded from shared vehicles. The proposed method was validated through field tests involving scooters and a footbridge. Furthermore, to interpret the outputs of the deep learning model, SHapley Additive exPlanations (SHAP) values were calculated, offering insights into the decision-making process of the model.

**KEY WORDS:** structural health monitoring; footbridge; damage classification; convolutional neural networks; SHAP.

## 1 INTRODUCTION

The assessment of bridge health has gained significant attention over the past decades due to widespread aging and deterioration. This concern stems from the fact that many of these structures were built in the previous century, with a large proportion having been in service for over 50 years. For instance, in Finland, the Finnish Transport Infrastructure Agency reported that, as of 2023, 882 out of 17,351 highway bridges (5.1%) were in poor condition, with aging structures from the 1960s and 1970s accumulating a growing maintenance backlog [1]. The European Commission has noted that bridges constructed after 1945 were typically designed for a lifespan of 50 to 100 years. In 2001, it was reported that bridges in France, Germany, and the UK showed deficiency rates of 39%, 30%, and 37%, respectively [2]. These figures highlight the urgent need for effective health monitoring of in-service bridges, which can provide critical information on their condition and support informed decision-making by stakeholders.

Traditional bridge inspections rely heavily on human vision, requiring engineers to conduct on-site visits and determine whether maintenance is needed [3]. However, as modern bridge construction becomes more extensive and complex, this approach faces several limitations, including being labor-intensive, inefficient, and time-consuming. At the beginning of this century, structural health monitoring (SHM) systems gained popularity [4]. These systems involve installing various sensors on bridges to continuously collect different types of data. In practice, however, this approach has proven to be expensive. It typically involves a one-to-one setup, where the monitoring system is customized for a specific bridge and cannot be easily transferred to others. Moreover, the cost of installing numerous sensors can be high. As the number of

aging and newly built bridges continues to rise, there is an increasing need for cost-effective and scalable monitoring technologies.

In 2004, Yang et al. [5] proposed the indirect method, where sensors are installed on passing vehicles instead of the bridge itself. This approach is based on the vehicle-bridge interaction (VBI) process. During this interaction, the dynamic characteristics of the bridge are transferred to the vehicles equipped with sensors, allowing the vehicles to act as moving sensors that collect information about the bridge. In this pioneering study, the bridge was simplified as a simply supported beam, and the vehicle was modeled using a spring-mass system. Under these assumptions, the authors demonstrated that the fundamental frequency of the bridge could be extracted from the vehicle's response, laying the groundwork for future research in this area.

In recent studies, researchers have further investigated the extraction of bridge modal shapes and damping ratios from vehicle response [6,7]. For example, Yang et al. [8] proposed using the Hilbert Transform to extract mode shapes from filtered vehicle responses, while González et al. [9] introduced a method for retrieving damping ratios by minimizing the errors in identified road roughness between the front and rear axles. In 2018, Yang et al. [10] introduced the concept of contact-point (CP) response, which represents the response at the interface between the vehicle and the bridge. This response was found to be independent of vehicle characteristics, making it useful for identifying bridge properties from vehicle data [11]. In addition to vehicle influence, road roughness is another major source of interference when identifying bridge dynamic parameters from vehicle accelerations. This issue can be mitigated by using residual CP responses between vehicle axles,

which eliminates the effects of road roughness [12–14]. However, in practical applications, modal parameters often show limited sensitivity to structural damage and may be significantly affected by operational conditions. Moreover, most existing studies on the indirect method have focused on road bridges. Although footbridges play an essential role in modern transportation and logistics, they are rarely equipped with SHM systems and have received little attention in indirect monitoring research.

Over the past decade, advancements in computer science algorithms and hardware have significantly enhanced deep learning techniques, particularly through the widespread use of neural networks. Technologies such as large language models (LLMs) have transformed many aspects of daily life and have also made a notable impact on SHM for bridges. Researchers have increasingly applied machine learning and deep learning methods to assess bridge health using structural responses [15]. In the context of the indirect method, vehicle responses typically consist of three components: vehicle dynamics, road roughness, and bridge vibrations [16,17]. This complexity makes it challenging to isolate bridge-specific information for use as damage indicators. However, deep learning models are sensitive to subtle signal variations, making them well-suited for detecting damage-related changes in vehicle responses. For example, Li et al. [18] applied support vector machines and Mel-frequency cepstral coefficients (MFCCs) to predict the severity of bridge damage based on vehicle responses. Unlike earlier studies that focused only on low-frequency signals [19], this research also explored high-frequency responses. In addition, Corbally and Malekjafarian [20] used convolutional neural networks (CNNs) to classify the type, location, and severity of bridge damage using drive-by data. In their study, particle swarm optimization was employed to fine-tune the vehicle model, and the resulting simulated data were used to train the CNN. Laboratory experiments validated the framework, demonstrating its ability to accurately detect and classify damage in most cases. These studies highlight the promising role of deep learning in bridge health monitoring. However, most research to date has focused on road bridges, with footbridges largely overlooked [21]. Additionally, deep learning models are often applied without adequate explanation of how features are selected or interpreted, limiting the transparency and broader adoption of these approaches.

In this paper, an explainable deep learning-based method is proposed to detect and classify damage in footbridges. Shared scooters equipped with smartphones are used to assess the health condition of footbridges when they pass the footbridge structures and collect dynamic data. 2D CNN is employed to extract key features from the time-frequency representations (TFRs) of the scooter's response as it moves over the footbridge. A field test is conducted to validate the effectiveness of the proposed method. The structure of the paper is as follows: Section 2 introduces the fundamental scheme of the proposed method and architecture of the used 2D CNNs. Section 3 describes the field test setup and discusses the results. Finally, Section 4 presents the conclusions of the study.

## 2 PROPOSED METHODOLOGY

### 2.1 Data collection

In this study, smartphones were mounted on a scooter to record vibration data. The scooter first crossed the bridge multiple times when it was in a healthy state to establish a baseline. After the bridge had been in use for several months or years and potential damage had developed, the scooter was used again to collect vibration data. These recordings, from both healthy and possibly damaged states, were used to train neural networks for predicting the bridge's health condition.

### 2.2 Data processing

Before feeding scooter data into the 2D CNNs, signals are preprocessed in 3 steps: (1) synchronization: two smartphones on different scooter parts are synchronized using Unix time to align data collection; (2) channel formation: only vertical and pitch accelerations, the most relevant signals, are retained. Signals from misaligned sensors are combined to extract these components; (3) segmentation: only data collected while the scooter is on the footbridge is kept, removing unrelated signals before and after crossing. This ensures clean, relevant input for 2D CNN training.

### 2.3 2D CNN

CNNs are widely used for extracting damage-sensitive features from signals. In this study, the 2D CNNs based on a simplified Visual Geometry Group (VGG)-16 [22] architecture (with two instead of four fully connected layers) were developed to analyze scooter vibrations for footbridge monitoring. When sensors are mounted on a scooter, fewer measurement points are available, but key inputs: vertical body acceleration ( $\ddot{z}_s$ ), angular acceleration ( $\ddot{\theta}_s$ ), and front wheel acceleration ( $\ddot{z}_t$ ), can be collected using two smartphones. The 2D CNN uses TFRs of scooter vibrations as input. To standardize input size, signals are first truncated to a uniform time length (5 s in this study), then transformed into 2D representations using methods like short-time Fourier Transform [23]. Each CNN channel uses 2D kernels (kernel\_size=3) with zero padding to keep the input size. The max-pooling (kernel\_size = 2, stride = 2) is utilized to extract key features. Activation function was selected as rectified linear unit (ReLU), and the Cross-Entropy (CE) loss was employed [24]. The architecture of the 2D CNNs are shown in Table 1.

Table 1. Architecture of the 2D CNNs.

Layers	Output shape	Kernel size	Activation
Input	$3 \times 402 \times 257$	-	-
Conv 2D	$64 \times 402 \times 257$	3	ReLU
Conv 2D+MaxPooling	$64 \times 201 \times 128$	3	ReLU

### 3 FIELD TESTS AND DISCUSSIONS

#### 3.1 Field test setups

Field tests were carried out using scooters equipped with two smartphones to validate the proposed footbridge damage detection method (see Figures 1 and 2). Smartphone 1 (iPhone 12) was mounted on the scooter body, and Smartphone 2 (iPhone 8) on the front wheel. The scooter passed the footbridge multiple times under similar road roughness. A short acceleration zone was used for the scooter to reach a top speed of 20 km/h, which can be powered by an electric motor without human pedaling force. MATLAB Mobile was used on smartphones to collect data with sampling frequency of 100 Hz. The footbridge investigated in the field tests is shown in Figure 3. To simulate experimental damage cases (EDCs), different masses (people standing at the center) were used, which is a practical approach and has been validated in prior studies [25–27]. The added masses were 55 kg, 125 kg, and 185 kg for damage cases 1, 2, and 3, respectively. EDC 0 refers to the undamaged case with no added mass.

Figure 1. Scooter with two smartphones.

Figure 2. Scooter with a rider.

Figure 3. Experimental damage cases.

All EDCs and corresponding scooter runs are detailed in Table 2. Impulse excitation was applied by having a person

jump on the bridge to assess the effect of added mass. A smartphone placed at the 1/4 span of the footbridge recorded the resulting vibrations. For EDC 0, accurate natural frequencies cannot be obtained with this method, as at least one person is required to apply the excitation. Instead, an alternative approach using the bridge's free vibration after scooter crossing is utilized. Frequency values for all EDCs are listed in Table 2, where  $f_{b1} - f_{b4}$  represent the first four frequencies of the explored footbridge. It can be seen that when more people are standing on the footbridge, the first two frequencies of the footbridge  $f_{b1}$  and  $f_{b2}$  decrease apparently. However, for the third and fourth frequencies  $f_{b3}$  and  $f_{b4}$ , the frequency values sometimes remain unchanged due to the measuring accuracy. Even though the frequency changes can be observed from the first two frequencies, the change ratio can be minor, say 1.22% for the fundamental frequency in EDC 1 compared to that of EDC 0. It can be challenging to determine the damage condition only based on the changes in frequencies. Therefore, the following will investigate the use of data-driven methods for damage detection of the footbridge using scooter vibrations.

Table 2. Footbridge frequencies in all EDCs.

EDCs	People mass	$f_{b1}$	$f_{b2}$	$f_{b3}$	$f_{b4}$	Runs
EDC 0	0 kg	4.028 Hz	4.468 Hz	10.486 Hz	11.316 Hz	124
EDC 1	55 kg	3.979 Hz	4.443 Hz	10.486 Hz	11.304 Hz	65
EDC 2	125 kg	3.955 Hz	4.431 Hz	10.486 Hz	11.304 Hz	63
EDC 3	185 kg	3.918 Hz	4.370 Hz	10.437 Hz	11.304 Hz	60

#### 3.2 Results and discussions

For analysis, 63 runs were randomly selected from EDC 0, yielding a total of 251 runs in the experimental dataset. Of these, 70% were used for training and 30% for testing. The CNN configurations matched those used in simulations. Hyperparameters were set as follows: batch size = 32, optimizer = Adam, learning rate =  $1e^{-6}$ , weight decay =  $1e^{-5}$ , loss function = CE loss, activation = ReLU, and number of epochs = 400. CE loss and damage prediction accuracy are shown in Figure 4.

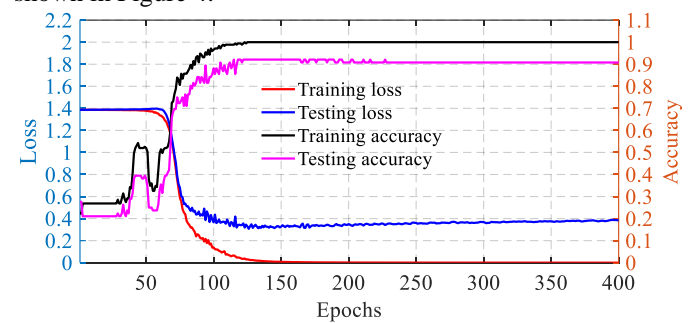

Figure 4. Loss and accuracy using 2D CNNs.

Figure 4 showed that the 2D CNN achieved early and sharp drops in both training and testing losses. The training loss nearly reached zero, and despite a minor rise in testing loss after 150 epochs, testing accuracy remained consistently above 90%.

To further interpret these findings, Shapley Additive Explanations (SHAP) were used to explain the 2D CNN's predictions. SHAP values reveal each feature's contribution to the model's output [28,29]. One sample from each EDC was analyzed to show how the 2D CNN classified bridge conditions. Figure 5 displays the SHAP values and predicted probabilities

for each TFR image. Red pixels (positive SHAP values) support the model's prediction, blue pixels (negative SHAP values) oppose it, and grey pixels have little impact.

The SHAP value images reveal that most significant features, those with strong positive or negative contributions, are concentrated in the 0–30 Hz range. This aligns with the fact that the bridge's natural frequencies, identified through impulse excitation (Table 2), also lie below 30 Hz. In EDC 0, for instance, image 2 shows that key features appear between 0.5–3.5 s as distinct non-horizontal lines and points, corresponding to peaks in the footbridge's frequency response. The 2D CNN confidently classified this sample as EDC 0 with a 99.98% probability. Images 4 and 5 contain blue regions indicating features that helped the model rule out EDCs 2 and 3. However, image 3 shows some overlap with EDC 1, resulting in a small 0.01% probability being assigned to that class. In EDC 1 (image 8), time-varying features near 1.5 s played a critical role, especially in distinguishing it from EDC 2. Because of the resemblance to EDC 0 around the same time, the model assigned a minor 0.08% probability to EDC 0. For EDC 2, distinct features were noted at 2.5 s and 4 s, while in EDC 3 (image 20), key contributions appeared around 4 Hz and 20 Hz. Although EDC 3 shared similar patterns with EDC 0 between 1.5–2.5 s, additional higher-frequency features around 1.5 s enabled the 2D CNN to correctly identify it as EDC 3.

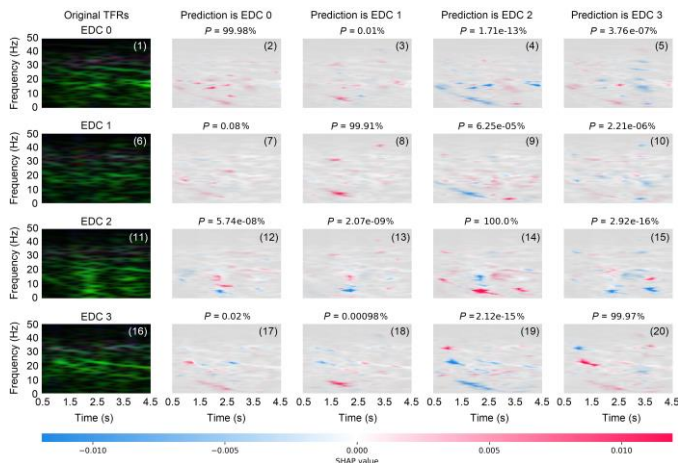

Figure 5. Explanation of 2D CNNs ( $P$ : Probability).

These observations confirm that the 2D CNN identifies damage-sensitive features based on both time and frequency information. Therefore, using TFRs as input to a 2D CNN provides good damage detection performance in the indirect method with vehicle-mounted sensors. This advantage stems from the inherently non-stationary dynamics of VBI systems, where both vehicle and bridge frequencies shift during interaction [30–32]. Therefore, by preserving time-varying characteristics, the 2D CNN in this study can effectively identify key features in scooter vibrations.

#### 4 CONCLUSIONS AND FUTURE WORK

This paper proposes a method for detecting and classifying footbridge damage by analyzing scooter vibrations collected via smartphones and processed through explainable deep learning. Specifically, TFRs of scooter vibrations were used with a 2D CNN to assess damage severity. The method was validated through real-world field tests. It was found that the

2D CNN can accurately predict the damage severity of the footbridge by using the TFRs of scooters. The 2D CNN's superior performance is linked to its ability to capture the non-stationary characteristics of VBI responses. SHAP analysis confirmed that damage-sensitive features vary over time in the scooter's vibrations.

Future work will focus on enhancing the practicality and robustness of the proposed method by exploring alternative smartphone placements (e.g., on the standing slab or handlebar), considering the behaviors of the drivers, incorporating influential factors such as temperature, road roughness variations, and pedestrian presence, and reducing reliance on labeled data through unsupervised learning. Furthermore, the authors understand that using standing people on the footbridge to simulate synthetic damage scenarios can not fully represent the real damage in practical engineering. In our future studies, we would like to test the proposed method on other bridges with real damage to evaluate the generalization.

#### ACKNOWLEDGMENTS

This research is financially sponsored by the Jane and Aatos Erkko Foundation in Finland (Decision number: 210018) and Aalto University (research project funding in ENG 2022). The help from colleagues on the field tests is highly appreciated.

# Drive-by bridge modal identification under multi-source excitations

Jiantao Li, Jie Tan

School of Civil Engineering, Zhejiang University of Technology, Liuhe RD. 288, 310023 Hangzhou, China  
email:jjiantao@zjut.edu.cn

**ABSTRACT:** The drive-by bridge modal identification (BMI) method, which employs a sensory system mounted on a moving vehicle, offers an efficient and cost-effective alternative for monitoring the health of bridge structures, particularly for short- to mid-span bridges. This technique allows for real-time, large-scale bridge assessments without the need for stationary sensors or traffic disruptions. However, extracting accurate modal parameters, such as frequencies and damping ratios, from vehicle responses is challenging due to the influence of multi-source excitations, including road surface roughness, random traffic loads, and dynamic vehicle-bridge interactions. These factors introduce noise and complexity that can compromise the reliability of the BMI method.

To address these challenges, this study integrates an adaptive signal decomposition technique, Successive Variational Mode Decomposition (SVMD), with Operational Modal Analysis to accurately identify the modal frequencies and damping ratios from drive-by measurements. The impact of multi-source excitations on the vehicle-bridge interaction process is systematically investigated, and key factors affecting the accuracy and reliability of BMI under such conditions are analyzed. Based on these findings, recommendations are made to improve the robustness and precision of the drive-by BMI method. This work might contribute to advancing the practical implementation of BMI in real-world bridge health monitoring applications.

**KEY WORDS:** Drive-by Modal Identification; Vehicle-Bridge Interaction; Successive Variational Mode Decomposition; Operational Modal Analysis; Multi-source Excitations.

## 1 INTRODUCTION

Vehicular onboard sensing technology dynamically collects bridge response data through moving vehicles, offering advantages such as wide coverage and low cost (Yang et al. 2020). However, its application in bridge monitoring still faces multi-faceted challenges. On one hand, multi-source random excitations (e.g., road roughness, the simultaneous operation of multiple vehicles, and environmental loads) induce time-varying non-stationarity and strong uncertainty in the dynamic responses of the vehicle-bridge coupled system. On the other hand, the coupled interference from system transfer characteristics, speed fluctuations, and environmental noise results in multi-component mixing and quality heterogeneity in the collected data, significantly compromising the reliability of bridge vibration characteristic identification and condition assessment (Zhu and Law, 2015).

The extraction of bridge related dynamic information from the multi-component vehicle responses for bridge condition assessment is the key task of drive-by bridge monitoring (Tan et al. 2019).

Successive variational mode decomposition (SVMD) (Nazari and Sakhaei 2020) has been used to accurately extract the mono-component from the multi-component dynamic signal without much manual parameter setting or adjustment. Li et al. (2022) investigated its feasibility and effectiveness for the extraction of bridge related dynamic components from vehicle response considering a random Class A road surface roughness. This paper studies the feasibility of SVMD for the drive-by bridge modal identification considering the multi-source excitation.

## 2 VBI MODELING CONSIDERING RANDOM OPERATIONAL EXCITATIONS

Figure 1 The model of drive-by bridge inspection in operational condition

The VBI model for the drive-by bridge modal identification is shown in Figure 1. The vehicle parameters are:  $m_v$  the mass of vehicle,  $k_s$  and  $c_s$  the stiffness and damping of suspension spring and damper, respectively. The equation of motion of vehicle can be expressed as

$$m_v \ddot{y}_v(t) + c_s \dot{y}_v(t) + k_s y_v(t) = F_{cp}(t) \quad (1)$$

where  $y_v$  is the displacement response of vehicle.  $F_{cp}(t) = k_v d_{cp}(t)$ , and  $d_{cp}(t) = w(\hat{x}_1(t), t) + r(\hat{x}_1(t))$  is the displacement input to the sensing vehicle at location  $\hat{x}_1(t)$ .

The multi-source excitations are considered as the road profile and a moving random operational load  $P$  (Sadeghi et al., 2020). The operational load enters the bridge ahead of the sensing vehicle with a moving speed  $v_1$  and the speed of the sensing vehicle is  $v_2$ . The road surface roughness is given as follows:

$$r(x) = \sum_{i=1}^{N_f} \sqrt{4S_d(f_i)\Delta f} \cos(2\pi f_i x + \theta_i) \quad (2)$$

where  $S_d(f)$  is the displacement power spectral density of road surface roughness;  $f_i = i\Delta f$  is the spatial frequency(cycles/m);  $\Delta f = \frac{1}{N_f\Delta}$ , and  $\Delta$  is the distance interval between successive ordinates of the surface profile;  $N_f$  is the number of data points;  $\theta_i$  is a set of independent random phase angle uniformly distributed between 0 and  $2\pi$ . The degree of road roughness is determined by the  $S_d(f_0)$  value, where  $f_0(=0.1$  cycles/m) is the reference spatial frequency. Class A road roughness defined using specified  $S_d(f_0)$  value in ISO specification is considered.

The flowchart of the proposed drive-by bridge modal identification is shown in Figure 2.

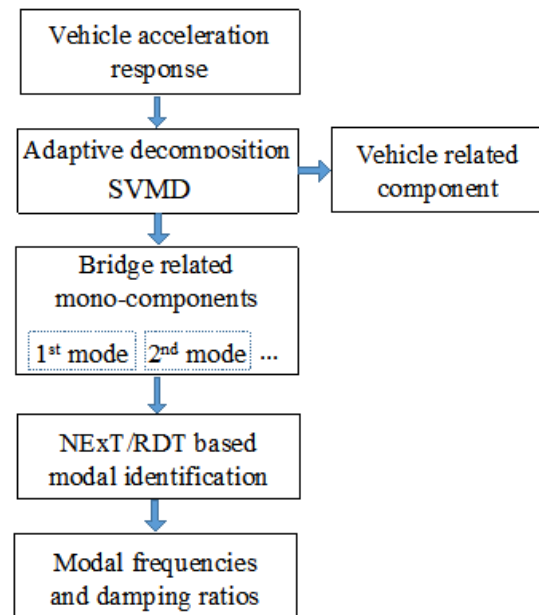

Figure 2 Flow chart of the bridge modal identification using moving test vehicle

### 3 DRIVE-BY BRIDGE MODAL IDENTIFICATION: NUMERICAL STUDY

Numerical study is conducted to analyze the effectiveness of the method for extracting mono-components from vehicle responses and drive-by bridge modal identification. The properties of the bridge are: length  $L = 35$ m, density  $\rho = 5000$  kg/m, and flexural rigidity  $EI = 2.178 \times 10^{10}$  Nm<sup>2</sup>. The damping ratio is set as 0.01 and the theoretical values of the first three bridge modal frequencies are 2.68, 10.71 and 24.09Hz, respectively. The properties of the sensing vehicle are: body mass  $m_v = 466.5$ kg, suspension stiffness  $k_s = 9.00 \times 10^5$  N/m, suspension damping  $c_s = 0.14 \times 10^3$  N s/m and its fundamental frequency  $f_v$  is 6.99Hz. The vehicle speed is set as 2m/s and the operational load to simulate the traffic on the bridge is a randomly generated load.

The dynamic modes decomposed by SVMd are used to estimate the bridge frequencies. To evaluate the accuracy of

the proposed drive-by bridge modal identification method, the Monte Carlo method with 50 simulations is used to generate the vehicle response dataset to simulate multiple passes of the sensing vehicle considering random operational load. Each of these responses is analyzed by SVMd, and the components related to the first two dynamic modes of bridge are used for the identification of frequency and damping ratio. Three different damping ratio values of bridge, i.e., 0.01, 0.02 and 0.03 are considered in simulating vehicle responses. The mean values and the standard deviation (std) of the identified frequencies for 50 passes are presented in Table 1. It can be seen that the mean values are very close to the theoretical values and the errors are all less than 1.5%. The results confirm that the bridge modal frequencies can be identified with high accuracy using the developed method.

Table 1 Identified frequency considering different damping ratios

Identified frequency (Hz)						
Damping ratio	0.01		0.02		0.03	
	mean	std	mean	std	mean	std
First mode	2.674	0.0561	2.667	0.0419	2.658	0.085
Second mode	10.589	0.0842	10.559	0.1012	10.549	0.182

### 4 CONCLUSIONS

This study investigates drive-by bridge modal identification under multi-source excitations based on the adaptive decomposition of vehicle responses using SVMd. The investigation confirms that the SVMd can be incorporated with the NExT/RDT to analyze the bridge related dynamic components to estimate the modal frequencies and damping

ratios. The bridge modal frequencies are identified accurately by computing the mean value of multiple tests to reduce the effects of the multi-source random excitations. A more sophisticated operational traffic model is required to meets more realistic situation in the simulation. Besides, experimental investigations on actual bridges in operational condition are necessary to further verify the effectiveness and robustness of the proposed method.

**ABSTRACT:** To explore the potential application of the tunnel damage identification method based on train acceleration, a three-axis accelerometer was installed on a metro train carriage to collect acceleration signals. The original signals are segmented and aligned according to the stations, with data analyzed in terms of station sections. Next, the probability density distribution, fast Fourier transform spectrum, and one-third octave spectrum of the signal are calculated. A time-frequency domain fast analysis software for acceleration data is then developed. By comparing changes in time-frequency domain features, the anomalous section of the tunnel is identified. The results confirm that the tunnel damage identification method based on train acceleration is applicable for real-world metro tunnels.

**KEY WORDS:** Field test; Probability density distribution; Fast Fourier transform; One-third octave.

## 1 INTRODUCTION

With the rapid pace of urbanization, metro systems are playing an increasingly vital role in alleviating urban traffic congestion [1]. As a critical support infrastructure for metro trains, metro tunnels can experience issues such as settlement, water leakage, and lining cracks during their operational period [2]. These problems can arise from the combined effects of geological conditions, material aging, dynamic loads from trains, and nearby construction activities, all of which can compromise the structural integrity of the tunnels [3]-[4]. Therefore, monitoring the health condition of metro tunnels and performing timely maintenance are crucial for ensuring the safe and efficient operation of the metro system [5].

Li [6] proposed a method that involves installing acceleration sensors on metro trains to identify tunnel damage or anomalies by analyzing changes in train acceleration. The feasibility of this approach was demonstrated theoretically. This method offers advantages such as high efficiency and low cost, providing a novel approach to metro tunnel health monitoring. Following this, damage indicators based on wavelet packet energy change rates [6], spectral kurtosis change rates [6], and relative entropy of wavelet packet energy [7] were introduced for analyzing train acceleration signals to identify tunnel anomalies. Deep learning techniques, including convolutional variational autoencoders (CVAE) [7], convolutional neural networks (CNN) [8], and long short-term memory (LSTM) [8] networks, have been applied to classify tunnel damage types, with their performance validated through model tests. Compared to traditional damage indicators, deep learning methods effectively reduce the interference from noise and data inconsistencies. Although the feasibility of the tunnel damage identification method based on train acceleration has been theoretically and experimentally verified, real-world acceleration data from metro trains have yet to be collected to assess the feasibility of the method in field conditions.

In this study, a three-axis accelerometer was installed on a metro train carriage to collect the train acceleration. The time-

frequency domain features of the acceleration signals are then calculated. By analyzing the changes in these features, the anomalous section of the tunnel is identified. The results confirm that the tunnel damage identification method based on train acceleration is feasible for real-world applications.

## 2 FIELD TEST

In this study, a field test was conducted on a complete metro line in a certain city, which includes two tunnels on the up and down lines, with a total of 19 stations. A wireless three-axis accelerometer, with a measurement range of 2g and a sampling frequency of 4000Hz, was installed under the seat in the middle of the train carriage to collect the train acceleration. The test, as outlined in Table 1, was conducted in three phases from April 16 to September 20, 2021, spanning a total of 24 days. For each test day, a set of acceleration data was recorded from the starting station to the terminal station, with separate data sets collected for both the up and down line tunnels.

Table 1. Test dates.

Phase	Dates
Phase 1	April 16 - April 28
Phase 2	May 12 - May 21
Phase 3	September 20

## 3 TEST DATA ANALYSIS

### 3.1 Original data

The original signal is segmented and aligned based on the 19 stations, dividing the line into 18 station sections for sectional data analysis. Taking a specific section as an example, the acceleration signal is shown in Figure 1. In this figure, the X direction represents the forward direction of the train, while the Z direction is perpendicular to the ground of the carriage. The acceleration in the X direction shows a clear ascending or

descending trend due to changes in train speed, whereas the acceleration in the Y and Z directions exhibits similar patterns of variation.

In this study, the Z direction is selected to analyze the changes in train acceleration. The acceleration in the Z direction for 18 sections is shown in Figure 2. The number above each curve corresponds to the section's serial number. Due to variations in tunnel length, geological conditions, and track irregularities across the sections, the time-domain waveforms of acceleration exhibit distinct differences.

The acceleration in the Z direction for 6 days in the same section is shown in Figure 3. The numbers above the curves in the figure represent the corresponding dates, with April 19 recorded as 4.19, and so on. Since the train's speed and the mass of the carriage vary slightly each day, the acceleration values in the same section show some differences in amplitude.

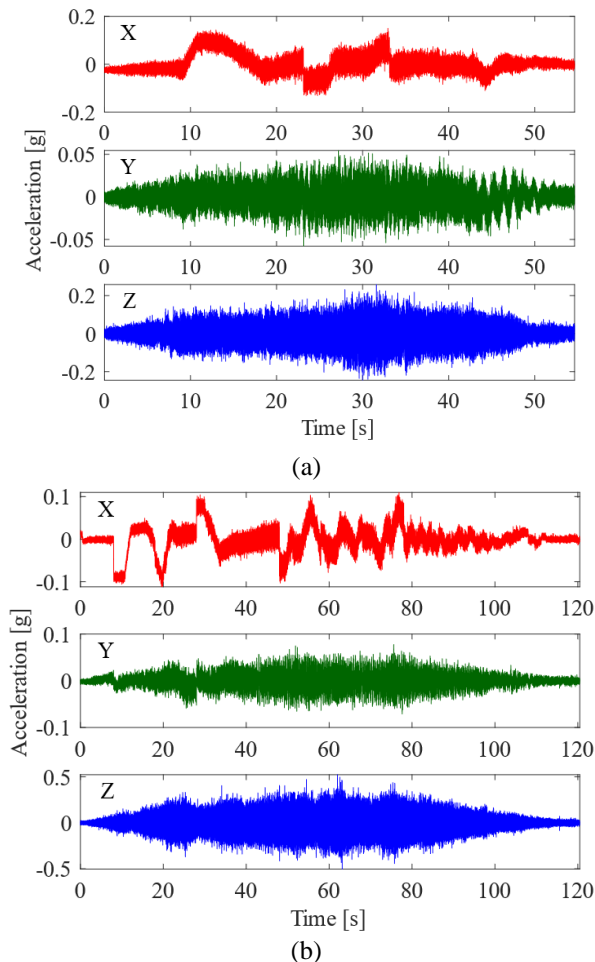

Figure 1. Acceleration signals in the X, Y, and Z directions:  
(a) Up line; (b) Down line.

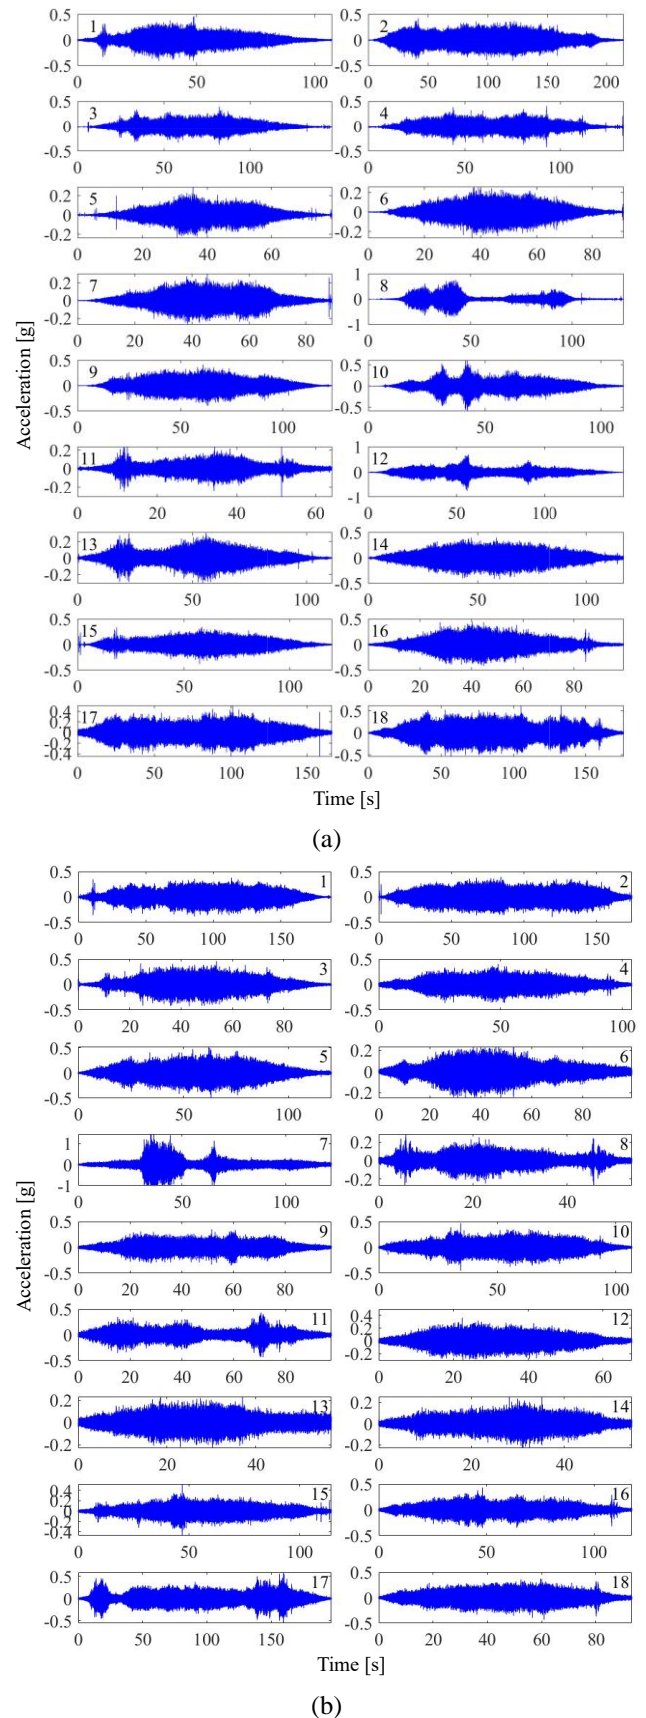

Figure 2. Acceleration signals in different sections: (a) Up line; (b) Down line.

(a)

(b)

Figure 3. Acceleration signals on different dates: (a) The 1st section of the up line; (b) The 18th section of the down line.

### 3.2 Probability density distribution

The probability density distribution curve of the acceleration signals for 6 days within the same section is shown in Figure 4, with the FIT curve representing the normal distribution fit. The mean acceleration values within the same section are similar, while there are differences in variance.

(a)

(b)

Figure 4. Probability density distribution curves of acceleration signals on different dates: (a) The 1st section of the up line; (b) The 18th section of the down line.

### 3.3 Fast Fourier transform

The acceleration signals from 24 days are analyzed using fast Fourier transform (FFT), converting the time-domain signals into the frequency domain. As shown in Figure 5, the blue curve represents the average of the FFT results from all the signals. The signal energy is concentrated between 200 and 800 Hz, with peaks around 450 Hz and 700 Hz.

(a)

(b)

Figure 5. Fast Fourier transform spectrum of acceleration signals: (a) The 1st section of the up line; (b) The 18th section of the down line.

### 3.4 One-third octave

Figure 6 shows the one-third octave spectrum of the acceleration signals over 24 days, illustrating the distribution of signal energy across different frequency bands. The blue curve in the figure represents the average energy of all the signals. Similar to the FFT spectrum, the signal energy exhibits a peak around 700 Hz.

Figure 6. One-third octave spectrum of acceleration signals: (a) The 1st section of the up line; (b) The 18th section of the down line.

### 3.5 Time-frequency domain fast analysis software

As shown in Figure 7, a time-frequency domain fast analysis software for acceleration data is developed using MATLAB App Designer. First, click “Data loading” to read the train acceleration signal from the input “File name”. Next, select or enter the line direction (Left, i.e., Down, or Right, i.e., Up), section number, date, and acceleration direction (X, Y, or Z). Finally, by clicking the “Time domain data”, “Probability density curve”, “Fast Fourier transform”, and “One-third octave” buttons, users can quickly compute and visualize the time-frequency domain features of the signal, facilitating further comparative analysis.

Figure 7. Time-frequency domain fast analysis software for acceleration data: (a) Software interface; (b) Visualization of analysis results.

## 4 DATA ANALYSIS OF ANOMALOUS SECTION

### 4.1 Time domain analysis

As shown in Figure 8 and Figure 9, during the data analysis, it is observed that the acceleration signals in the 2nd section of the up line and the 17th section of the down line show significant changes over time. These two sections correspond to the left and right tunnels of the same station segment. Comparing this with the section's operation and maintenance records reveals that, during the field test, the tunnel linings of this station segment experienced excessive uplift, which altered the tunnel's stiffness and boundary conditions. This change is reflected in noticeable differences in the train's vibration signal waveforms. Additionally, on the test day, September 20, which was a rainy day, the tunnel's boundary conditions were further modified, resulting in a significant increase in the train's acceleration amplitude.

(a)

(b)

Figure 8. Acceleration signals of the anomalous section: (a) The 2nd section of the up line; (b) The 17th section of the down line.

(a)

(b)

Figure 9. Probability density distribution curves of acceleration signals in the anomalous section: (a) The 2nd section of the up line; (b) The 17th section of the down line.

#### 4.2 Frequency domain analysis

Further analysis of the frequency domain features for the acceleration signals in the anomalous section, shown in Figure 10 and Figure 11, reveals an increase in energy around 700 Hz compared to the normal sections.

The discovery of the anomalous section validates the feasibility of tunnel damage identification method based on train acceleration for field applications. By analyzing the changes in the time-frequency domain features of the train's acceleration signals, tunnel anomalies can be indirectly identified.

(a)

Figure 10. Fast Fourier transform spectrum of acceleration signals in the anomalous section: (a) The 2nd section of the up line; (b) The 17th section of the down line.

Figure 11. One-third octave spectrum of acceleration signals in the anomalous section: (a) The 2nd section of the up line; (b) The 17th section of the down line.

## 5 CONCLUSIONS

In this study, a three-axis accelerometer was installed on the train carriage to collect acceleration signals throughout the entire journey. The time-frequency domain features of the

signals are analyzed. The main conclusions of this study are as follows:

1) The acceleration in the direction of the train's motion shows distinct ascending or descending segments due to changes in train speed. The acceleration in the two directions perpendicular to the train's motion exhibits a similar trend.

2) The train acceleration signals in normal sections on different dates show slight differences in amplitude due to variations in train speed and carriage mass. In contrast, the train acceleration signals in anomalous sections on different dates exhibit significant differences in waveform, caused by changes in the tunnel's stiffness and boundary conditions, with more substantial fluctuations in signal amplitude.

3) By calculating the probability density distribution, fast Fourier transform spectrum, and one-third octave spectrum of the acceleration signals, changes in the time-frequency domain features can reveal anomalous sections of the tunnel. This analysis validates the feasibility of tunnel damage identification method based on train acceleration in real-world applications.

Future work will involve selecting additional metro tunnels, installing sensors on trains to collect field data, and building a comprehensive dataset. Machine learning or deep learning techniques will then be applied to further identify tunnel anomalies.

**ABSTRACT:** Population-based Structural Health Monitoring (PBSHM) provides insights based on data derived from comparing multiple structures' responses, providing a shift towards an integrated data domain. This presents significant challenges in data collection and integration of data across diverse structural populations, such as sensor systems, environmental data, and maintenance records and requires substantial engineering effort. This fragmentation of data across different formats and systems creates substantial engineering overhead when integrating new data sources, limiting the practical implementation of population-based approaches. This paper introduces a structured data flow architecture for systematic data collection and aggregation in PBSHM ecosystems by defining distinct functional components within the data collection process and enabling the structured integration of diverse data sources. The results establish a foundation for scalable PBSHM data collection, supporting the broader transition towards integrated structural health monitoring ecosystems.

**KEY WORDS:** Population-based Structural Health Monitoring (PBSHM); Data integration architecture; Data collection; Data aggregation

## 1 INTRODUCTION

Structural health monitoring (SHM) has the potential to reduce operational costs and increase infrastructure safety by augmenting existing primarily qualitative condition management processes using quantitative sensor data to track an asset's condition over time. More recently, population-based structural health monitoring (PBSHM) has been proposed to exploit the similarities between data from multiple structures to gain additional insights into their condition.

To date, the development of SHM sensing systems has largely been application-driven, such as in the Intersection Bridge 5 (IB5) [1] and the Telegraph Road Bridge [2] projects. As data acquisition (DAQ) systems were largely developed in isolation due to commercial interests, differing approaches to data measurement and transport for SHM exist. Consequently, there is no broadly agreed way to integrate these diverse, competing technical solutions into a PBSHM system. One potential approach is to develop a process that adapts all existing SHM sensing systems to support data representations compatible with current PBSHM data domains. However, this is largely impractical due to the complexity, cost, and time required to modify numerous existing systems.

To address this issue, this work proposes a methodology for the design, implementation, and operation of PBSHM data collection systems, allowing data to be merged from various sources to provide a unified view. This process is essential for analysing and making informed decisions based on comprehensive datasets in PBSHM.

A degree of data integration exists in existing SHM systems; for example, when utilising multiple vendors' sensors on a single structure. In this case, the operator may require that all the data be accessible from a single data system, therefore transforming data from multiple sources into a single database.

A common approach to transforming data makes use of an extract, transform, load (ETL) process, where the data is first

extracted from the original data source, transformed into the target format and loaded into the new data store. The methodology proposed here permits the integration of sensing systems for a wide variety of structures (incl. bridges, wind turbines, masts, etc.) into a collection system for PBSHM data, that allows the aggregation and translation of data from a given structure to the shared PBSHM standard, in a defined, consistent manner. Additionally, the methodology is applicable to both existing and future systems.

Our architecture proposes a PBSHM integration pipeline that offers a flexible, modular approach to aggregating data from multiple existing SHM data sources. To demonstrate our work, we present a design study based on the existing IB5 and Telegraph Road Bridge monitoring systems, that illustrates how these may be integrated with a wider PBSHM ecosystem. This design study is presented using UML component diagrams due to its widespread use in system modelling [3].

The main contributions of this work are:

- Introduction of the concept of PBSHM integration pipelines for systematic data collection and aggregation in PBSHM ecosystems;
- An architecture for these integration pipelines, including functional definitions for the mandatory and optional components within these; and
- Demonstration of the application of the design principles of our approach to integrate two existing bridge monitoring systems into a PBSHM system.

The paper is structured as follows: Section 2 describes the current landscape of PBSHM research and identifying key challenges; Section 3 describes data pipelines that enable the integration of individual structure data collection systems; Section 4 describes the functionality in the pipelines; Section 5 details a design study that demonstrates the efficacy of the proposed architecture with conclusions given in section 6.

## 2 BACKGROUND

To design a robust data architecture for supporting PBSHM, it is essential to first identify the benefits and requirements of PBSHM. Additionally, a thorough examination of the current landscape of SHM systems and existing data silos is necessary to pinpoint the needs and challenges for the data architecture.

### 2.1 PBSHM and the associated data ecosystem

As the availability of SHM data for a given structure is incomplete, a population-based SHM approach by collecting data from a group of similar structures to infer the condition of one structure. Bull et al. [4] showed that it is possible to represent the behaviour of these structures using a general form of the population that encapsulates behaviour of all structures within the population of "strongly homogeneous" or nominally identical structures. This is particularly useful for large populations that are manufactured identically and experience similar conditions, such as a farm of wind turbines where each turbine undergoes near-identical manufacturing and construction processes.

This concept, however, can be expanded to include structures that only share significant structural similarities otherwise known as homogenous populations [5], [6] with the challenge to identify those which are similar enough to transfer data between, without compromising model quality. Gosliga et al. [5] proposed an irreducible element (IE) model to represent such structures which solely captures the geometric properties of a structure, whereas a finite element (FE) model contains additional construction information. Brennan et al. [7] introduced an expanded IE model using a set of reduction rules which eliminate author ambiguity, ensuring that each is created using a consistent canonical form while maintaining all structural knowledge. Representing structures with IE models allows the creation of an attributed graph (AG) from the model, which can then be processed using a graph-matching algorithm to determine a "similarity score" between two structures.

Using this similarity score, it is possible to predict the possibility of positive data transfer across heterogeneous populations of structures. Gardner et al. [6] show that features and labels can be mapped from a source structure to a target structure, even among topologically different structures, by using IE and AG representations to extract the similarity between structures within a heterogeneous population.

Given the diverse and extensive data required for the successful realisation of PBSHM, meaningful comparisons between multiple data sources are needed. This requires the data to be standardised to allow large-scale analyses and efficient data processing. Attempts to extend open standards such as Bridge Information Management (BrIM) in Jeong et al. [8], look to address this shared-data problem within their specific regions, but extending to PBSHM is non-trivial.

As such, PBSHM has introduced a standard for its associated shared data. Brennan et al. [7] introduced a PBSHM technical ecosystem made up of the PBSHM Network, Framework, and Database. The Network is the shared data domain in which the similarity between structures is represented; the Database is the shared-data domain in which PBSHM data is stored in a common format and; the Framework is the computational domain in which all algorithms (both similarity and knowledge

transfer) exist. Each domain is valid in its own right, but independent from others.

This comprehensive PBSHM ecosystem integrates data storage and software but can be expanded to accommodate larger databases and additional software modules. It may store various data categories, including sensor data, IE and FE models, reports, features, information and similarity metrics. The authors use a NoSQL database for the PBSHM ecosystem due to its increased flexibility over relational ones allowing the expansion of the database to accommodate any data that may be used in the future to develop PBSHM. Brennan et al. implemented the database using MongoDB, using a detailed "PBSHM Schema" to standardise and store the aforementioned data categories, ensuring compatibility and allowing efficient data retrieval and analysis. The flexibility provided by these choices allow for current knowledge to be embedded within the schema, however, allows for the future needs of PBSHM by enabling the adaptation of the schema to include yet-unknown data at a future date.

### 2.2 SHM data acquisition systems for civil infrastructure

Many SHM systems collect data for civil infrastructure and are made up of either one or multiple data acquisition systems. Various vendors can be used and provide comprehensive DAQs that manage data capture and storage, but these cannot be integrated across vendors, requiring the creation of bespoke SHM systems. Whilst this has the potential of creating a comprehensive system for an SHM structure, it may produce data that is incompatible for the purposes of PBSHM and will not easily be shared.

To highlight this, two bridges, the Intersection Bridge 5 (IB5) and the Telegraph Road Bridge have been selected, due to their extensive sensor networks and well-documented cyber-physical systems.

**IB5** - IB5 is designed to continuously monitor the structural health of the bridge by recording and analysing various signals, using a variety of high-precision sensors that capture data on vibrations, strain, temperature, rotation, and other parameters. Data acquisition units collect the sensor data and convert it into a digital format suitable for real-time wireless transmission to a central server, which processes the data to detect any anomalies. The system includes an application programming interface (API) for authorized users to access the data remotely, facilitating ongoing monitoring and analysis. Additionally, power supply units ensure reliable operation of all components, even in harsh environmental conditions [1].

**Telegraph Road Bridge** - The Telegraph Road Bridge in Michigan employs a network of wireless sensors, including a variety of sensors that measure strain, acceleration, and temperature and are strategically placed to capture detailed data on the bridge's response to truck loading and thermal variations. Data acquisition units collect and digitize the sensor data, which is then transmitted to a central server. This bridge utilises a solar-powered wireless sensor network architecture that can also be used in hard environmental conditions [2].

Following the observations made on both systems [8], [9], [10], differences between the storage and representation between the two systems are described in Table 1.

Although both monitoring systems may appear very similar (each having a physical layer, cyber-physical layer and data storage/processing capability), the systems differ in their underlying data management technologies. Both display a well-thought-out, cyber-physical architecture; however, the systems have been developed largely in isolation, with differing goals leading to a clear difference in data representations. This presents a challenge when trying to compare both structures in a PBSHM context for reasons discussed in section 2.1. Therefore, for PBSHM to be effective, it can be deduced that data integration needs to occur across the two structures.

Table 1. Comparing data representation between IB5 and Telegraph Road Bridge monitoring systems

Structure	IB5	Telegraph Road Bridge

<b>Sensor Information Schema</b>	“ID”, “Type” and “Location” fields in database	User-defined OpenBrIM Object

### 3 ARCHITECTURE

One of the key processes within SHM is gathering and capturing monitoring data to ultimately determine the health state of a structure. This is the same for PBSHM, but the process is compounded when considering the very nature of the population-based approach is to accumulate knowledge across multiple structures and types.

While the aforementioned PBSHM technological domains encompass knowledge when in a central ecosystem, they lack the understanding, definitions, and details of the procedures of migrating data from the SHM capture systems associated with the structures and the central system. This part focuses on proposing the missing link between the existing SHM systems – henceforth referenced as data generators – and the PBSHM technical ecosystem introduced by Brennan et al. [11].

#### 3.1 Data Generators

A data generator is any entity that can produce data potentially valid within the PBSHM schema. As data generators can consist of existing SHM data acquisition systems, data generators can produce many different possible representations of SHM data. Therefore, to preserve this, data representation within the PBSHM data domains needs to be facilitated. This gives two possible options: a) development of a process to adapt existing data formats to representations that are supported in the existing PBSHM data domains or, b) retroactive adaption of existing SHM capture systems to support this as well as every future representation. This is significantly hindered by the need for commercial systems to remain compatible with existing solutions.

Thus, we define data pipelines which allow the transport of data from these existing, and future, data generators to the PBSHM data-domains.

#### 3.2 PBSHM Integration Pipelines

The process of getting data from the aforementioned data generator into the PBSHM Framework is referred here to as a data pipeline. Pipelines describe the overall transmission of data from the location(s) at which the data is first introduced into the PBSHM domain to the desired end location.

#### 3.3 Pipeline organisation

Through this data pipeline, it is important to denote the responsibility of each actor within this pipeline, by dividing it into sections. These divisions will furthermore be referred to as scopes with their own set of responsibilities, purpose and defined goals for any data requirements, transformations, and formats that may occur within its remit.

Whilst we must acknowledge that each data pipeline will be unique to the requirements of the data generator(s), there is still an abstract delimitation between each scope area. As such, this paper proposes the following aspects (see Figure 1):

**Structure:** The structure scope describes all the cyber-physical infrastructure required to capture information regarding a physical attribute of a structure. This scope provides an interface that allows this information to be provided to the next scope in the pipeline. Any solution implemented to this scope is specific to the set of measurements desired for a given structure.

**Aggregation:** The aggregation scope is defined by a generic set of processes that universally apply to every application to allow the communication of data from the structure scope to the PBSHM database and vice versa. It receives data from the previous scope and transmits this to the next.

**PBSHM Network, Framework and Database:** This establishes the shared data domain for which the relationships between structures, the shared domain in which PBSHM-specific algorithms and computations reside and the database where PBSHM data resides.

Figure 1. Pipeline flows through the aggregation scope from data generators to the PBSHM Framework

Due to the segregation of responsibility within the data pipeline, when acting within one scope, it is necessary to view the other scopes within the pipeline as black box systems. When implementing within the aggregation scope, it may not

be possible to modify or understand the implementations and behaviours within the structure and PBSHM server scopes.

## 4 FUNCTIONALITY

To describe the functionality required in the pipeline, a roles-based approach is used. Each role dictates the functionality that is required to produce a valid PBSHM data integration system. Each role provides an interface through which data is communicated. Data flows describe the transfer of data from one role to the next. By utilising the abstract form of a roles-based approach to describe the implementation of data flows, we can define a consistent terminology within the context of the PBSHM ecosystem, allowing the methodology to apply to not just existing technologies, but future technologies. In principle, roles can be described as actors, which perform some operation on data within the pipeline.

Figure 2 outlines mandatory and optional roles. Mandatory roles (which are denoted in grey) must be implemented to create a valid data pipeline from a data generator to the PBSHM server and the optional roles (denoted in pink) describe additional functionality that can be added to the system. Arrows are used to describe the data flows where the arrowhead indicates which direction the data flow is initiated.

### 4.1 Mandatory Roles

Initially, there is some required functionality that must be implemented to allow the movement of data from a given data generator to the PBSHM core. It is important to note that data generators may encompass a wide variety of data i.e. channel data, feature data, reports, etc.

A pipeline may be configured as follows: Initially, data is generated by the data generator contained within the structure scope. These roles provide some interface to the aggregation layer.

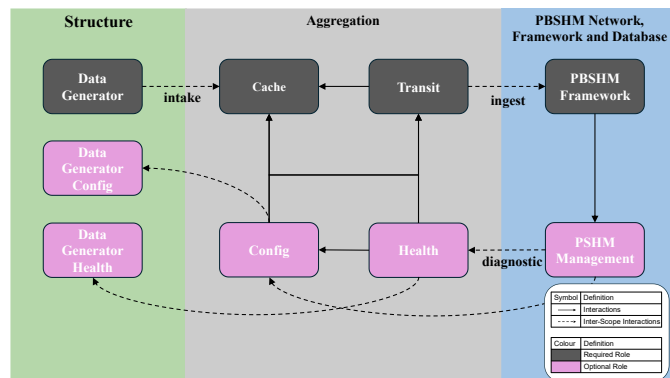

Figure 2. PBSHM data integration roles

Cache roles play a simple yet vital role in the PBSHM data integration pipeline. By utilising a buffer to store incoming data from data generators, we can aggregate multiple data streams at the cache to group the incoming data. In a PBSHM system where it can be expected to have many structures each with many data generators, it becomes infeasible to have each data generator directly interact with the PBSHM Framework.

Finally, the purpose of the transit role is to serve as the gateway between the data cache and the PBSHM Framework. Data provided by the transit role must be in the PBSHM schema

format to allow compatibility with the PBSHM database. This will then perform redundancy checks, parity checks etc.

### 4.2 Optional Roles: Config & Health

Additionally, there is potential within the PBSHM integration pipelines to anticipate the need for reconfigurability and insight into downstream aspects of the data pipeline from the PBSHM Framework to allow effective data infrastructure management and support decision systems. Therefore, it is possible to introduce the health and config roles. The function of the health role is to provide statistics and system state information to the PBSHM framework whereas config provides an interface of the components within the aggregation and structure scope to be modified with supported configuration options.

Both health and config roles pose a significant challenge due to the unending complexity of both existing and future technologies due to both differing configurable attributes of data generators and differing statistics provided by data generators. Furthermore, cache roles can take multiple technical forms, with a further set of differing configurable attributes and properties on which insight could be desired.

For the most part, these roles are beyond the scope of this work and will be covered in more depth in future work.

## 5 DESIGN STUDY

The objective is to validate and demonstrate the effectiveness of the proposed data integration architecture for PBSHM by demonstrating the integrity of live data transfer from various sensor systems to a central PBSHM server. Also demonstrated is interoperability by integrating different sensor types and data formats into a cohesive pipeline. To reflect the existing landscape of SHM deployments, the design study uses the two examples given in Section 2.2. We first establish the existing methods that the systems use to access collected data.

### 5.1 Existing data retrieval mechanisms and assumptions

IB5 supplies a representational state transfer (REST) API (built using Fast-API) that allows researchers or stakeholders to access both stored raw and processed data. This enables end-users to access stored data of the digital twin, including raw sensor data from the physical implementation [9]. Although the cyber-physical system supporting the IB5 bridge is a comprehensive and well-designed example of developing a digital twin for a bridge, the REST API implemented for the IB5 is not publicly documented, highlighting the data integration challenges in the current SHM landscape.

29  </xs:element>
30 </xs:schema>

```

Figure 3. Assumed XSD of the API response from the IB5 monitoring system

As such, some assumptions have been made about the structure of their API queries and the resultant data that can be retrieved. The following fields are presumed necessary for the query: (1) Sensor IDs, and (2) Time window. It is assumed that the data is returned in an XML document is returned in the structure dictated by an XML schema definition (XSD) presented in Figure 3 where the values returned are:

- Sensor ID(s)
- An array of:
  - Timestamp
  - Value from sensor

An example of an object returned by the assumed API can be seen in Figure 4.

```

1 <TimeSeriesCollection>
2   <TimeSeriesData>

26    </data>
27  </TimeSeriesData>
28 </TimeSeriesCollection>

```

Figure 4. Example XML file based on the XSD of Figure 3

The monitoring system of the Telegraph Road also provides its own API to retrieve data. Its bridge information repository framework contains an Apache Cassandra database which provides the Cassandra Driver API for retrieving data. This used in conjunction with its “data mapper” (which maps the

time series data stored in the database with the BrIM sensor information) provides the data necessary by the PBSHM schema via the “Sensor data retrieval” service which provides a REST API. This allows the system to be integrated into the PBSHM ecosystem. Literature on the Telegraph Road Bridge both details the structure of the API queries and provides examples of data returned [10].

## 5.2 The proposed data integration system

Using the information supplied about the two systems’ APIs, and details inferred in section 5.1, it is possible to propose an integration system based on the architecture and roles detailed in sections 3 and 4. These roles are set out in Table 2.

This proposed integration system is defined in terms of a UML component diagram (shown in Figure 5). In this case, each component is a distinct software service. Relationships between the components which show how they interact, are drawn between each component. These components are grouped to detail in which deployment environment these would be implemented. Most have been implemented in the “PBSHM Integration Cloud Server”; however, an additional component has been added to the “PBSHM Integration Cloud Server” to show an additional module that could be added to the PBSHM Framework that would allow the insertion of records to the PBSHM Database over HTTP(S).

An important observation from Table 2 is the designation of the IB5 and TRB fetchers as data generators. Although these are part of the structure scope, in this case, they have been implemented in the “PBSHM Integration Cloud Server”. As data generators must be the actors of any data transaction to the cache (Figure 2), it is necessary to add a component that fetches from the existing APIs provided by both bridges and subsequently pushes the results to their respective RabbitMQ caches. To avoid changing the existing back-ends of both structures, these are implemented in the “PBSHM Integration Cloud Server”. However, this is an example of a deployment environment implementing roles across two scopes.

Table 2. Identifying how each role is fulfilled by components in the proposed PBSHM data integration system for IB5 and Telegraph Road Bridge

Role	IB5 Component	TRB Component
Data Generator	IB5 Fetcher	TRB Fetcher
Cache	IB5 Queue (RabbitMQ)	TRB Queue (RabbitMQ)
Transit	PBSHM Framework Loader	PBSHM Framework Loader
PBSHM Core	REST API	REST API

Within the proposed data integration system, most of the components could be implemented by a multitude of technologies. However, where new data transfer components are required, RabbitMQ has been chosen as the technology to represent to reception of these data transfers.

Figure 5. Universal markup language diagram showing the proposed population-based structural health monitoring data integration system for the Intersection Bridge 5 and Telegraph Road Bridge

Whilst these components could most likely be replaced with similar technologies or even a more traditional data transfer and storage method, RabbitMQ has been chosen as it both dictates the protocol in which messages are sent/read and provides a data store in the form of the message queue. Furthermore, it is open-source and well-documented, allowing ease of use without complications surrounding licensing [12], [13].

As stated, no changes have been made to the functionality provided by either the IB5 or Telegraph Road back-ends. Therefore, to bring data into the “PBSHM Integration Cloud Server”, two “Fetcher” components (each for their respective monitoring system) have been added which periodically sends requests to their respective APIs to check whether new data has been added to the databases and then fetches and loads it onto a RabbitMQ, therefore fulfilling the role of the data generator. An example application provided in [10] documents how automated data retrieval could be implemented for the Telegraph Road Bridge.

Once the sensor data from each bridge has been loaded into their respective message queues, sensor data from both bridges is then extracted from their message queues into ETL components. The purpose of these ETL components is to transform the data in the message queues from their respective data formats and schemas into a JSON format that follows the PBSHM schema. Whilst the data from both bridges is undergoing similar processes to be transformed into PBSHM schema, the underlying technologies will take significantly different methods to undertake this due to the difference in the data format and structure (schema) of the data generators. The key differences being:

- In IB5, data is assumed to be returned in XML format whereas Telegraph Road returns data in JSON format.
- It is assumed that IB5 returns data in a similar schema to that shown in Figure 3 whereas Telegraph Road produces data in its schema (examples given in [10]).

Once the data from either structure has been transformed into PBSHM Schema, this can then be loaded onto another RabbitMQ labelled the “Ingest Buffer”.

By transforming the data into the PBSHM schema data integrity and interoperability are ensured as the schema provides a unified way to represent sensor data and contains information about the origin of the data.

From this point, as the data from both bridges is in the same structure and format it can be manipulated by the same components through the rest of the pipeline. The data is then extracted by the ingest buffer and loaded onto “PBSHM Server” via a REST API with an HTTP(S) request at which point the “PBSHM Server” API will load the data onto the database.

## 6 CONCLUDING REMARKS

This paper presents a methodology for the design, implementation and operation of PBSHM data collection systems. By defining mandatory roles for data transfer from structure to PBSHM Network, Framework and Database scope and demonstrating their application to real-world, bridge monitoring systems, it is shown how diverse existing SHM data acquisition systems can be integrated into a PBSHM ecosystem, whilst maintaining data integrity and interoperability as provided by the standard PBSHM schema. Future work will focus on refining the optional components within the aggregation scope, particularly the config and health role which present significant challenges due to the variability in configurable attributes and operational performance. Robust reference implementations of the aggregation scope components will also be developed to provide practical guidance for SHM system operators seeking to integrate their monitoring systems with PBSHM systems, thereby accelerating the adoption of PBSHM. Furthermore, work will include the development of software modules for the PBSHM framework that allow for the use of external software tools by

providing interfaces to the data collected as defined by security policies.

**ABSTRACT:** The practical implementation of Population-based Structural Health Monitoring (PBSHM) often involves distributed which face challenges from limited compute resources, power budgets, and variable communication bandwidths, for example, IoT devices with battery-powered wireless sensor network gateways uploading data over metered connections. Building upon the data flow architecture presented in our first paper in this special session, this paper demonstrates how inherent state within data streams' can be leveraged for optimisation. This paper introduces a novel, plug-and-play aggregation pipeline specifically designed to address these limitations. We present an optimised data representation and transmission strategy that minimises computational and bandwidth requirements at the network edge. By leveraging efficient data serialisation techniques, our pipeline achieves a significant reduction in data payload size with negligible information loss, thereby enhancing the scalability and financial viability of PBSHM systems. This work validates an enabling technology for the real-world deployment of large-scale, low-power monitoring ecosystems. It does so by comparing two data formats, JavaScript Object Notation (JSON) and Concise Binary Object Representation (CBOR), using monitoring data from a long-term bridge campaign. The results show a reduction in the volume of transmitted data by up to 12.2 times.

**KEY WORDS:** Population-based Structural Health Monitoring (PBSHM); Resource-constrained systems; data optimisation; data serialisation.

## 1 INTRODUCTION

Infrastructure monitoring requires methods to track structural condition and optimise maintenance schedules. Structural health monitoring (SHM) has developed considerably in recent years [1]. Population-Based SHM (PBSHM) offers potential advantages over traditional SHM approaches by analysing data across multiple structures rather than analysing each independently. This approach enables knowledge transfer between similar structures, improving damage detection and diagnostic capabilities [2], [3], [4], [5].

While the definition of a computing framework for PBSHM is established [6], the practicalities of data logistics in heterogeneous, resource-scarce environments remain a significant research gap. Implementing PBSHM systems requires the integration of data from many different monitoring systems. Previous work has developed a methodology for the transmission of data from a data generator, to the PBSHM database [7].

Practical deployment faces challenges that haven't been fully addressed to date, for example, many monitoring scenarios such as wireless sensor networks, remote sites, and temporary deployments operate with limited resources. These systems must operate within constraints on bandwidth, computing power, energy supply, and storage capacity. These limitations become more significant as PBSHM networks expand to include more structures and sensors.

The focus of this work lies in the creation of a holistic and optimised data aggregation pipeline tailored for resource constrained systems on the network edge. We directly address the challenge of minimising data footprints prior to their arrival at a central repository, a critical step that has hitherto been underexplored. This paper thus provides a foundational

component for the next generation of truly scalable and deployable PBSHM systems.

This paper presents a stateful, connection-oriented approach to PBSHM data transmission designed for resource-constrained environments. Our transmission process establishes session contexts for data generators, handling metadata exchange during session initialisation rather than with each data sample for the period of the session. This reduces redundant information while maintaining schema compliance and plug-and-play functionality, allowing new data generators to join the system with minimal configuration. Functionality that becomes particularly useful for temporary monitoring campaigns or rapid PBSHM monitoring system rollout.

The main contributions of this work are:

- Development of a stateful, session-oriented pipeline architecture for PBSHM data transmission that reduces redundancy through session payload optimisation while retaining plug-and-play data generator integration.
- Demonstration and validation of a resource-efficient aggregation pipeline, using empirical evaluation with field monitoring campaign data to demonstrate its feasibility for real-world PBSHM applications.

The paper is organised as follows: Section 2 introduces the concept of a session-oriented pipeline; Section 3 details the case study used to validate the data and a proposed pipeline design; Section 4 analyses the results; and Section 5 concludes with a summary and future directions.

## 2 METHODOLOGY

To optimise data flow from a structure to a PBSHM server, a key aspect that must be considered is the data representation

used. The PBSHM schema defines the representation that must be provided to the PBSHM Framework.

The PBSHM data integration pipeline (Figure 1) segments the process from the data generator, which is an entity that produces data either already compliant with or transformable to the PBSHM schema, to the PBSHM Network, Framework, and Database, using defined scopes [7]. Using this definition, anything in and transmitted to the PBSHM Network, Framework and Database scope must be within the PBSHM schema representation. However, this approach allows data within scopes preceding the PBSHM Network, Framework, and Database to take any form, as long as it can be reconciled with the PBSHM schema, even if it does not initially conform to it. By exploiting this, we can attempt to optimise the data representation in the “structure” and “aggregation” scopes.

Figure 1. The PBSHM data integration system in which scopes where data representations are not enforced is highlighted

Although the data representation is not explicitly defined within these scopes, there are significant advantages to developing a reusable implementation, particularly for time series channel data. Optimising data representations is crucial when considering the application of streaming techniques to handle vast amounts of data efficiently. Given the potential for integrating multiple data generators to monitor a single system, such as data from various sensors in an SHM system, SCADA data, and weather data from an application programming interface (API) - a unified aggregation pipeline can provide a sensible solution. This approach would support all these sensors cohesively, ensuring efficient and effective data management. Creating a generic data representation that reduces redundancy within that data and therefore communications bandwidth utilisation would allow systems with resource constraints to share data integration pipelines which increases scalability while maintaining acceptable bandwidth utilisation.

A primary motivation for performing data reduction and standardisation directly on the sensor node is to achieve a truly 'plug-and-play' and interoperable system. While it is possible to offload metadata enrichment to a gateway or middleware server in its entirety, such an approach creates a dependency, binding the sensor node to a specific gateway with the requisite processing capabilities. This method, by contrast, ensures that each sensor node transmits a self-contained, efficient, and standardised data packet. This makes the capable of being integrated into any PBSHM ecosystem with a compatible endpoint, without requiring specialised intermediate hardware. This approach enhances deployment flexibility, as a node can

be replaced or relocated with the guarantee that it will function correctly with the central server, independent of the local network topology or available gateway resources. This is particularly advantageous in large-scale, heterogeneous deployments where multiple vendors and network types may coexist.

For a plug-and-play aggregation pipeline, enough information must be encoded into the data representation to enable compliance with the PBSHM schema when the data is transmitted to the PBSHM server whilst reducing the redundancy of information within said data representation. To achieve this, we must first identify the key aspects of the PBSHM schema that must be retained.

In this paper, we focus on time series channel data. Therefore, the key information that's encoded into a channel data object and must therefore be recoverable is:

- Structure name
- Population name
- Timestamp
- Channel name(s)
- Channel type(s)
- Channel unit(s)
- Channel value(s)

First, we must consider implementing this in such a way that all this information is explicitly stated for each timestamp. To illustrate this, consider two JavaScript object notation (JSON) objects compliant with the PBSHM schema that represent multiple sensor readings at two different time stamps one second apart as shown in Figure 2.

We can identify multiple items of redundant information across the two objects (i.e., structure name, population, channel names, channel types and channel units).

Many communication protocols incorporate mechanisms for tracking the origin of messages, enabling the inference of the communication state. For instance, protocols like TCP/IP and MQTT include metadata that identifies the sender and the context of the message. This capability allows us to avoid sending redundant information, as we can pair existing data with the sender's identity.

Therefore, we can split up the object into duplicated and non-duplicated data (when considering multiple objects from the same data generator) as shown in Table 1. As can be seen; by only transmitting updated data (or non-duplicated fields), we can significantly limit the number of fields that have to be transmitted for every object.

Table 1. Identifying duplicated and non-duplicated fields within the PBSHM Schema when considering multiple time series objects

Duplicated Fields	Non-duplicated Fields
Structure name	Timestamp
Population name	Channel value(s)
Channel name(s)	
Channel type(s)	
Channel unit(s)	

As such, we can define two new objects, the *initialisation* in which all the duplicated fields for a given data generator are

```

1 {
2   "name": "test-structure",
3   "population": "test-population",

Figure 2. Two example JSON documents containing multiple sensor readings one second apart

represented and the *sample* in which we represent the non-duplicated fields.

With these new objects, we can define the process by which communications take place. For the data generator, first, we send the initialisation object, and then we send every sample object available as shown in Figure 3. These sample objects can optionally be added to a buffer to increase the efficiency of communications (i.e. only turning on radios for brief periods or trying to limit the number of packets sent). For the case in which each sample object is sent individually the buffer size would be one.

With these communication processes if there was a need to change the format of the sample objects (i.e. adding a channel, removing a channel or changing properties about a channel) this could also be achieved by closing the communication session and re-opening it with the new channel information in the same way the session is initialised as described previously. Furthermore, if the data generator was disabled for any reason the communications would be closed, and the process would also have to be re-initialised. In such cases, any incomplete sample objects and session state affected by the disconnection would be discarded. Any samples still in the send buffer would then need to be retransmitted where de-duplication would take place between the transit and the PBSHM framework, network and database.

Within the aggregation scope (shown in Figure 4), we then receive the initialisation message from the data generator and then receive the buffer (which fulfils the role of the cache from the PBSHM data integration system). From the buffer, we add the “redundant fields” to the sample to make a JSON object compliant with the PBSHM Schema and then transmit

said object to the PBSHM Framework. We then wait to receive a new buffer or close the communication.

Figure 3. Data generator communications process

These two processes allow the use of a reduced communication schema to reduce the bandwidth utilised in the transmission of PBSHM data from a given data generator.

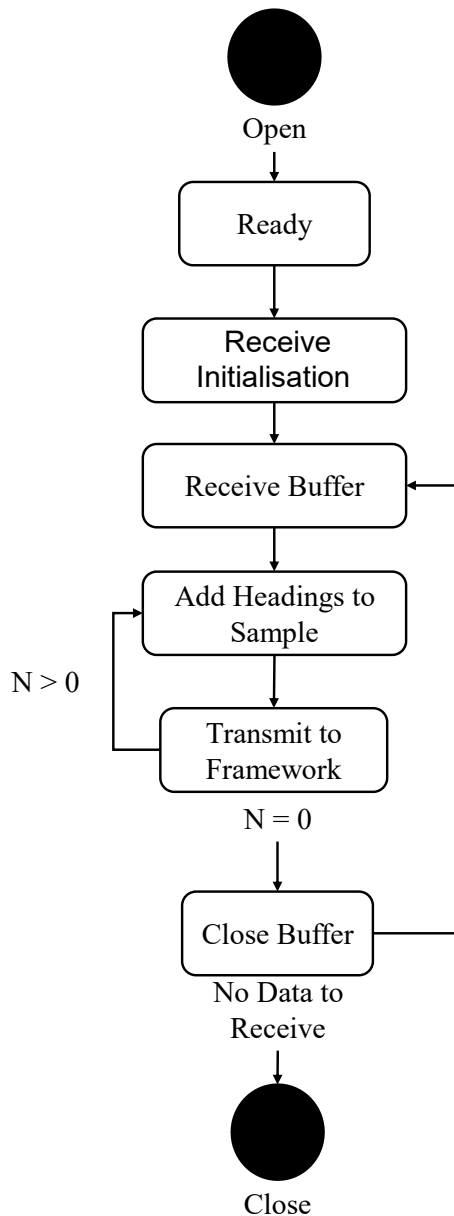

Figure 4. Aggregation pipeline communication process

### 3 CASE STUDY

The structure under test is a bridge that supports a dual carriageway, which consists of two lanes designated for one-way traffic, as well as a footpath for pedestrians. The structure of the bridge is composed of 13 concrete Y beams that provide support for a reinforced concrete deck. Adjacent is an older masonry arch bridge. These two bridges are constructed without any visible gap between them, making it unclear how much the concrete bridge deck is restrained on one side.

Figure 5. The structure under test in the case study

The SHM system implemented for this bridge was designed with versatility and ease of installation in mind. This system allows for the accelerometer to be installed directly on the surface of the bridge deck. The placement of the accelerometer is optimised by accounting for the variations in bridge types. It comprises a single MEMS accelerometer and an environmental sensor. The accelerometer employed is the Multifunction Extended Life (MEL) Data Logger from Gulf Coast Data Concepts. This device measures acceleration in three axes within a range of  $\pm 2$  g and includes a real-time clock to timestamp each acceleration measurement. The acceleration data collected by the sensor is stored locally on an SD card at a sampling rate of 128 Hz, and the sensor is powered by two D-cell batteries, which provide a run-time of up to 60 days of continuous recording. The MEL accelerometer is housed in an enclosure that is securely attached to the deck of each bridge. An example of one of these enclosures is shown in Figure 6.

Figure 6. MEL accelerometer and enclosure

Figure 7. MEL sensor in place

In addition to the accelerometer, the SHM system includes an environmental sensor that measures both air temperature and humidity. To ensure accurate temperature readings, the environmental sensors are not placed within the enclosure to avoid the effects of solar gain. Instead, these sensors are positioned out of direct sunlight, to provide a representative measurement of the local air temperature.

### 3.1 Data description

The data provided by the system is in a comma-separated values (CSV) format, of which an example showing ten values is shown in Table 2. Within the CSV document, the first 9 rows contain contextual information about the samples. The following rows contain time series data.

Table 2. Extract from the CSV data provided by the data logger containing headers and 15 samples

To evaluate the efficacy of the proposed pipeline architecture, a 30-minute window of the data has been selected. This can be seen represented in Figure 10.

### 3.2 Test pipeline models

As such, we can develop a pipeline that would allow transmission of data from the bridge under test to the PBSHM server which is shown at the top of the Universal Markup Language (UML) diagram of Figure 8. This model of the pipeline first extracts the data from the GCDC data store and converts it to the PBSHM schema format. Data in the PBSHM schema format is then loaded into the PBSHM Schema Cache on the Docker Server, where it is then loaded into the PBSHM server via a Representational State Transfer (REST) API.

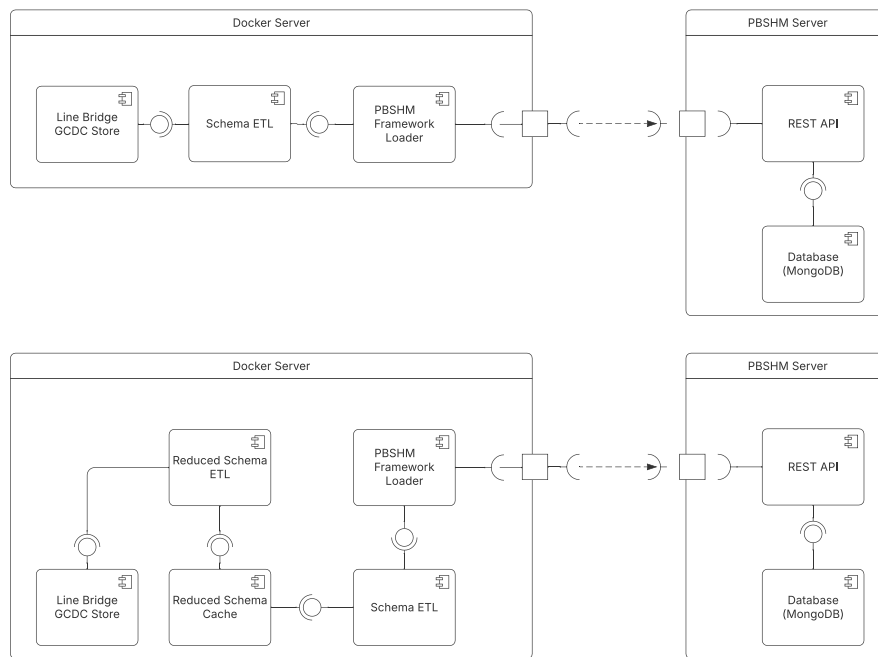

Figure 9. Universal markup language diagram showing the simulation test bench (PBSHM Schema rep. above, reduced data rep. below)

Figure 10. Single-axis raw acceleration over 30 minutes measured using the MEL accelerometer

The diagram at the bottom of Figure 8 shows a similar pipeline, however, this uses a reduced data representation as discussed in Section 2. Within the on-premises computer, data is extracted from the GDC store and transformed into an initialisation object (which contains all the duplicated fields shown in Table 1) and a set of samples objects. The initialisation object, of which an example is given at the top of Figure 11, is first transmitted to the Reduced Representation Cache which resides on the docker server. Samples, an example of which is shown in the bottom of Figure 11, are then transmitted to the Reduced Representation Cache. These samples are then transformed into PBSHM Schema compliant files which are then uploaded to the PBSHM server via the PBSHM server.

From these models, we can simulate the performance of the multiple data representations (namely the PBSHM schema in a JSON format and concise binary object representation (CBOR)

format as well as a reduced representation in both JSON and CBOR formats) using real-world data captured from the line bridge over a simulation test bench.

## 4 RESULTS

To assess the performance of the methodology presented in Section 2 a simulation of the systems shown in Figure 8 was developed using individual docker containers running on a docker server (with the PBSHM schema version of the pipeline shown above in Figure 9 and the reduced representation version shown below).

This simulation test bench emulates all of the components in the systems described in Figure 8, however, integrates all the components that were shown to be implemented with on-premises equipment in the Docker Server to allow for greater control of the data pipeline and easy access to metrics.

In this paper, the size of the total payload for the selected 30-minute window is the metric used to evaluate the efficacy of the pipeline. This was chosen as within this setting, the size of the data transmitted over the period will likely impact bandwidth requirements and power requirements for resource-constrained systems.

This test bench was used to evaluate multiple data representations. The PBSHM Schema in JSON format was used as a benchmark data representation as it provides all the necessary context for the PBSHM server. This was then repeated by the reduced representation in JSON format. Finally, both tests were repeated with CBOR which allows a 1:1 mapping with JSON allowing it to be implemented with little to no modification to the existing PBSHM schema.

Table 3. Size of a 30-minute capture (230,400 samples of tri-axis acceleration data) in CSV, PSBHM Schema, and reduced representation data formats

Format	Size (MiB)	Ratio to CSV
CSV	5.14	1.00
PBSHM Schema (JSON)	131.42	25.58
Reduced (JSON)	34.30	6.68
PBSHM Schema (CBOR)	45.26	8.81
Reduced (CBOR)	10.77	2.10

From the results captured and presented in Table 3, it can be concluded that using the PBSHM schema in a JSON format dramatically increases the storage required for the 30-minute sample window compared to the original CSV data. This can be significantly reduced using a compressed format like CBOR, reducing the data size by 2.9x.

However, by using the reduced data representation, this can be further reduced. In the JSON format, the reduced data representation offered a 3.8x size reduction whilst the CBOR format of the reduced data representation offered a 12.2x size reduction when compared to the PBSHM Schema in JSON format. These results are plotted as shown in Figure 12.

By utilising the reduced data representation in the CBOR format, the ultimate size of data to be transmitted is 2.1x the original CSV data.

Figure 12. Bar chart plotting the different data representations and formats of a 30-minute capture (230,400 samples of tri-axis acceleration data)

## 5 DISCUSSION, LIMITATIONS AND FUTURE WORK

The findings presented in this paper provide a strong proof-of-concept for the proposed pipeline; however, several limitations should be acknowledged, and these point towards avenues for future research.

The results in Table 2 show a reduced file size from CSV format produced by the data acquisition system when compared to the schema under test. This shows that in situations in which an aggregation pipeline can be implemented on a case-by-case basis dependent tailored to the data produced by the data generator there is an inherent advantage to doing so. This will be true in almost all cases where this is possible as no extra information is required to allow the transformation of data produced by the data generator into the PBSHM schema format. However, as stated, this requires that each implementation of the aggregation scope be tailored to the specific data generator.

By utilising this plug and play aggregation pipeline design, it is possible, to reuse components across multiple data generators. This limits the effort required to develop new tailored aggregation components for each data generator as well as allows data from many data generators to be integrated into the PBSHM data ecosystem using few data aggregation components.

However, the validation was conducted using a homogenous set of accelerometer data. The “plug-and-play” architecture is designed to be extensible, yet its performance with a more diverse array of sensor modalities, such as strain gauges, acoustic emission sensors, or environmental sensors has not yet been empirically validated. Future work will focus on developing and testing data models for these sensor types within the pipeline.

Furthermore, while our work focuses on data representation, it does not currently incorporate specific protocols for secure data transmission. For deployment on critical infrastructure, ensuring data integrity and confidentiality through authenticated encryption schemes (e.g., using TLS/DTLS) could be employed.

A key focus of our future work will be on hardware-in-the-loop testing, further developing robust reference implementations of the technology demonstrated within the

aggregation scope to provide practical guidance for both current and future SHM system operators seeking to integrate their monitoring within PBSHM data domains.

## 6 CONCLUDING REMARKS

This paper has presented the potential of session-defined communication for PBSHM data within PBSHM data aggregation pipelines. By defining the processes that would be undertaken to achieve reduced bandwidth utilisation, we have demonstrated how to achieve reduced bandwidth requirements whilst maintaining plug-and-play functionality for PBSHM monitoring systems.

We demonstrate that it is possible to reduce the amount of data required to provide the necessary context for PBSHM when transmitting sample data providing a method to reduce the required data by 12.2x. This results in a transmission size that is 2.1x the original data size, which whilst a marked increase, allows for reasonable requirements for resource-constrained PBSHM monitoring systems.

**ABSTRACT:** Population-Based Structural Health Monitoring (PBSHM) is an emerging field in Structural Health Monitoring that leverages data from multiple structures to enhance the assessment of individual structures. Unlike traditional SHM, which generally relies on data from a single structure, PBSHM utilises collective knowledge from a population to facilitate increasing the knowledge on an individual structure. Transfer learning enables the inference from a source structure to a target structure within the population. One of the limitations of this method is that a lot of transfer-learning methods require data models that are trained using substantial amounts of high-quality data which can be difficult to obtain. To support PBSHM research, the concept of the Population-based SHM Engineered Asset Resource (PEAR) has been introduced. PEAR is conceptualised as a benchmark dataset containing semi-realistic structures and associated data intended to drive the development and validation of PBSHM methodologies. This work advances the PEAR prototype by developing complete populations for two types of bridges, along with their associated data. The pipelines for generating these populations are presented, detailing how they produce structural data and PBSHM-specific models. Additionally, a simple analysis of the generated populations is conducted, demonstrating their utility in PBSHM research and showcasing the potential of PEAR as a resource for current and future PBSHM research.

**KEY WORDS:** SHMII-13; Population-based Structural Health Monitoring, Benchmark Dataset, Irreducible Element Model, Bridges

### 1 INTRODUCTION

In traditional Structural Health Monitoring (SHM), benchmark datasets such as the S101 [1] and Z24 [2] bridges have been pivotal in advancing the field. These datasets have provided researchers with common platforms to test, validate, and compare new SHM methods and algorithms. However, in the emerging field of Population-Based Structural Health Monitoring (PBSHM), data are leveraged from multiple structures to enhance the assessment of individual assets, no equivalent benchmark datasets currently exist. This gap is not only a reflection of the relative recency of PBSHM but also the inherent complexity of gathering multi-structure data necessitated to form a meaningful population.

To address this challenge, the Population-based SHM Engineered Asset Resource (PEAR) was devised as a potential solution. The foundational principles and envisaged structure of PEAR were outlined in a previous conference paper [3], laying the groundwork for a benchmark dataset that integrates curated synthetic populations. The envisioned PEAR dataset aims to serve as a standard for evaluating and advancing PBSHM methodologies by providing researchers with readily-accessible, semi-realistic data representative of various structural populations.

The fundamentals of the PEAR database have been established, this paper extends that work by developing two specific bridge populations for inclusion in the PEAR dataset. This work not only demonstrates the feasibility of generating synthetic populations but also how these populations can serve as a practical resource for PBSHM research.

The remainder of this paper is structured as follows. First, a background section provides an overview of PBSHM, detailing existing databases, schemas, and benchmark datasets, and highlighting the motivation for this work. This section is followed by an overview of the foundations of PEAR and the specific requirements for creating a benchmark dataset that is applicable for a population-based approach. Next, the "Developing Bridge Dataset" section describes the process of generating the two initial bridge populations, focussing on the design of semi-realistic bridge structures and the simulation of their structural response data. Subsequently, the "Bridge Datasets" section presents the developed populations, including a simple analysis to showcase their utility in PBSHM methods. Finally, the paper concludes with a discussion of the current dataset's limitations, potential avenues for future expansion, and the broader implications for advancing PBSHM research.

### 2 BACKGROUND

Population-Based Structural Health Monitoring (PBSHM) represents a shift from traditional SHM by focussing on the analysis of data from multiple structures within a related population. This approach not only provides valuable insights into the collective behaviour of the population but also enhances the understanding of individual structures. In contrast to conventional SHM methods that typically concentrate on a single structure, PBSHM enables the application of advanced techniques such as transfer learning, where knowledge gained from one task or structure is leveraged to improve performance on a related task in another structure. This methodology allows models to be adapted rather than built from scratch, thereby

enhancing efficiency and potentially making inferences about the condition of a structure that would otherwise be missed.

A critical aspect of implementing transfer learning in PBSHM is the careful identification of structural similarities across the population. Without a clear understanding of these similarities, there is an increased risk of negative transfer, where inappropriate model adaptation could degrade performance. To combat this risk, techniques such as Irreducible Element (IE) models combined with graph-based approaches have been developed [4], [5]. These methods are instrumental in identifying and quantifying both the similarities and variations among structures, ensuring that transfer learning is applied only where it is most appropriate. This framework for similarity assessment forms the foundation for effective knowledge transfer across structures.

Despite these methodological advancements, a significant challenge in PBSHM remains: the scarcity of comprehensive data representing populations of structures. Previous studies have attempted to address this gap by collecting data from similar populations, for example, one study collected data from four beam-and-slab bridges and two pedestrian footbridges [6]. Other research efforts have simulated populations using models with 10 degrees of freedom [7] or even toy structures to validate PBSHM transfer-learning methods and graph-matching algorithms [8]. However, these approaches have been limited in scope, so the developed datasets cannot always be used to test novel PBSHM methods.

It is within this context of data scarcity and the development of new PBSHM methods that the need for benchmark datasets in PBSHM becomes evident. A robust benchmark dataset would not only facilitate the testing and validation of new methodologies but also drive forward the development of PBSHM research. This motivation underpins the development of the Population-based SHM Engineered Asset Resource (PEAR) dataset, which aims to provide the PBSHM community with a dedicated set of synthetic populations that represent real-world structures and realistic structural behaviours for algorithm development and benchmarking.

### 3 PEAR OVERVIEW

This section gives an overview of the PEAR database, including its key requirements (Section 3.1), how the database is structured (Section 3.2), and the stages involved with producing populations of structures and data (Section 3.3).

#### 3.1 Requirements

##### Requirement 1:

The primary objective for the dataset is to function as a robust testbed for both established and emerging PBSHM methods. It must support the development and evaluation of methods and techniques across the entire remit of PBSHM. This remit includes the calculation of similarity scores and transfer-learning methods. Moreover, the dataset should facilitate structural comparisons via similarity metrics, including IE models and graph-matching algorithms, which are essential for guiding successful knowledge transfer. The datasets should also be compatible with various machine-learning techniques, ensuring high-quality data are available for training and validation purposes.

##### Requirement 2:

The dataset should be designed for ease of searchability, enabling users to quickly locate and extract relevant data subsets. To ensure this level of accessibility, the dataset must be thoroughly indexed so that key variables, such as the type of structure or, in the case of bridges, the number of spans, are easily queried and filtered.

##### Requirement 3:

The methodologies employed to generate the structures within the dataset must be transparent, clearly documented, and, whenever possible, grounded in real-world structural design practices. This approach guarantees that the simulated structures accurately reflect their real-world counterparts. Additionally, the dataset should capture the natural variability seen in practice, for instance, differences in span lengths, beam dimensions, and deck thicknesses in bridge designs, thus representing the diversity found in actual structural stocks.

##### Requirement 4:

A shared-data domain is fundamental to the success and broad adoption of PBSHM practices. Building on the work of Brennan et al. [5], the dataset will adhere to the PBSHM schema, a standardised format that ensures consistency in data storage and interpretation for PBSHM. All data and future additions to the dataset must comply with this schema. In cases where the current PBSHM schema does not accommodate certain data components, it will be necessary to propose and integrate an extension to the PBSHM schema to incorporate this data.

#### 3.2 Dataset Structure

Designing the dataset's structure is important to ensure effective data retrieval and utilisation. A well-structured dataset will facilitate users to quickly access the specific data they need, making it easier to perform tasks with the datasets and subsets of the data. In the context of PEAR, the structure is crafted not only to organise the data logically for easy retrieval but also to accommodate the addition of new data without disrupting existing records.

Figure 1 illustrates the four-level hierarchical organisation of the PEAR dataset: root category, subtype, dataset, and scenario. To illustrate how these levels interact, consider the analogy of a file system. At the highest level is a main "PEAR" folder. Inside this folder, there is a separate folder for each root category. Each root category folder contains folders for its various subtypes, which differentiate structures based on design or purpose. Within each subtype folder, there are individual dataset folders; each dataset represents a collection of structures forming the population. At this level of the database a descriptive file outlining the general forms of the population and allowable variations of these structures will be stored. The IE models and the meta data about each structure will also be stored at this level. The final level, scenario, is analogous to a load case in a structural model, for example, applying a 40-ton load to the mid-span of a bridge would constitute a single scenario.

Figure 1: The hierarchical structure of the PEAR dataset

In this hierarchical structure, a root category groups structures that are typically classified together, such as aeroplanes and bridges. Within each root category, subtypes further differentiate the structures. For example, within the aeroplane category, subtypes may be single-engine and multi-engine, while the bridge category could be divided into truss bridges and suspension bridges.

During the initial planning phase for PEAR, three primary root categories were identified for inclusion: bridges, masts, and wind turbines. Figure 2 shows the initial dataset organised into root and subtype levels. This work specifically generates data for two bridge populations: a beam-and-slab bridge population and a ladder-deck bridge population, each accompanied by a corresponding scenario.

Figure 2: The initial 'root categories' and 'subtypes' for PEAR

### 3.3 Dataset Stages

PEAR has been designed from the ground up to develop over time by iterations and expansion of the data included within. Defined stages serve as clear milestones, enabling collaborative efforts across the diverse disciplines involved in PBSHM. The initial design of the structure within any population is undertaken in Stage 0, the development of IE models in Stage 1 and the simulation of structural responses in Stage 2+. By breaking the development into stages, different teams can contribute depending on their area of research. For example, one team can focus on constructing the IE models needed to derive similarity metrics (Stage 1) while another develops simulations for scenario data (Stage 2). Importantly, each stage builds exclusively on the data from the preceding stages; for instance, any Stage 2 processes rely only on the outputs from Stages 0 and 1.

For a dataset to be integrated into PEAR, it must, at a minimum, complete Stage 0 and Stage 1. Once a dataset reaches this milestone, it is assigned a unique reference within PEAR, and the structures it contains are fixed to ensure consistency and reproducibility of results. The specific processes of Stage 2 are left flexible, allowing researchers to select the most relevant structural responses for their research as well as the most appropriate simulation method. The overall staging structure is designed to be generic, applying to all datasets regardless of their root category or subtype.

#### Stage 0: Design of the Dataset Population

In this initial stage, realistic structures are generated with pseudo-random properties drawn from a predefined range of parameters. These parameters, along with the methods used for their selection, are detailed and stored in the dataset. For each structure, a Structural Information (SI) model is created alongside a structural report. The report offers a detailed, human-readable description, while the SI model provides a computer-interpretable format that facilitates indexing and querying.

#### Stage 1: IE Models

At this stage, Irreducible Element (IE) models are developed for each structure in the population, i.e. one IE model for each SI model in Stage 0. The typical workflow for producing IE models will be using the parameters defined in the SI for each structure to create detailed IE models. After the completion for Stage 1 the dataset may be included in PEAR.

#### Stage 2+: Scenario Data

Using the data from Stages 0 and 1, simulated scenarios are then produced using the information in the generated IE models. Although PEAR does not prescribe specific simulation methods, the simulation outputs must be saved back into the dataset as valid PBSHM Schema data. Scenarios might include, but are not limited to, static-load displacements, natural frequencies, mode shapes, or frequency response functions. Moreover; a scenario can simulate conditions where the structure is considered 'healthy' or introduce 'damage' prior to simulation, with the results documented accordingly.

## 4 DEVELOPING BRIDGE DATASETS

This section outlines the process by which the two initial bridge populations have been developed for the PEAR dataset. The development process is divided into two major phases. The first phase focusses on designing semi-realistic bridges and creating their associated Irreducible Element (IE) models, corresponding to Stage 0 and 1 of the dataset. The second phase involves simulating the structural responses of these bridges, which represents Stage 2. This section describes these processes to create both a beam-and-slab bridge population and a ladder-deck bridge population.

### 4.1 General Form of Population

For each population included in PEAR, the first step is to define the general form of the structure. This general form specifies the primary structural components and their arrangement, ensuring a consistent yet flexible framework for generating individual structures. Once the general form is established, a set of rules and parameters is defined to guide the creation of each structure within the population. These rules, grounded in engineering principles, ensure that the generated structures are

both realistic and representative of real-world variations. The diversity within each population is achieved by systematically varying these parameters, allowing for a range of structures that share a common form while exhibiting meaningful differences. The following subsections detail the general forms and parameterisation approaches for the beam-and-slab bridge population and the ladder-deck bridge population.

#### 4.1.1 Beam-and-Slab Bridge

The general form of a beam-and-slab bridge consists of precast concrete beams that serve as the primary structural components of the bridge. These beams are typically lifted into place, where they are supported by piers or abutments that have been constructed in advance. Once the beams are positioned, an *in situ* concrete deck is poured over them to form the main deck of the bridge. Below are the main components and a brief description of a typical beam-and-slab bridge:

- **Precast Prestressed Bridge Beams:** These are the primary load-bearing components of the bridge. Precast off-site and prestressed to increase their load-carrying capacity, these beams are designed to resist the main traffic loads of the bridge.
- **Reinforced Concrete Deck:** The reinforced concrete deck is poured *in situ* on top of the precast beams, forming the main surface of the bridge.
- **Diaphragm:** The diaphragm is a transverse structural element placed between the bridge beams. Its primary function is to distribute loads evenly across the bridge and provide lateral stability, and help transfer load to the supporting structure of the bridge.
- **Columns:** Columns are vertical structural supports that transfer the load from the bridge deck and beams down to the foundation.

#### 4.1.2 Ladder-Deck Bridge

The general form of a ladder-deck bridge consists of steel girder beams that serve as the primary structural components of the bridge. These beams are situated at the edge of the bridge with smaller steel girder beams spanning transversely, connecting the main beams. Once the beams are positioned and connected, an *in situ* concrete deck is poured over them to form the main deck of the bridge. Below are the main components and a brief description of a typical beam-and-slab bridge:

- **Longitudinal Girder Beams:** These are primary load-carrying members that run along the length of the bridge (parallel to the roadway). They bear the main loads from the deck and transfer them to the piers or abutments. These are typically made of steel and are placed at the two edges of the bridge.
- **Transverse Girder Beams (Cross Beams):** These are secondary beams that span between the longitudinal girders, providing lateral support and distributing loads from the deck to the longitudinal girders. These are also typically made of steel.
- **Concrete Deck:** The reinforced-concrete deck is poured *in situ* on top of the longitudinal and transverse beams, forming the main surface of the bridge.
- **Columns:** Columns are vertical structural supports that transfer the load from the bridge deck and beams down to the foundation.

## 4.2 Structural Parameters

This section outlines the parameters that can be adjusted within the general forms described in the previous section. These parameters are the tools used to create a varied population of structures while ensuring that each model remains realistic and grounded in sound engineering principles. Methods have been developed to select these parameters, ensuring that any variations still adhere to the constraints of real-world structural behaviour. For clarity, the parameters are divided into two groups:

1. **Generic Bridge Variables:** These parameters are common to all bridges, such as the number of spans and overall bridge length.
2. **Subtype-Specific Parameters:** These parameters are unique to each bridge subtype. For instance, in a beam-and-slab bridge, a key parameter might be the selection of the precast beam geometry.

By systematically varying these parameters, the PEAR dataset is able to generate diverse yet realistic bridge structures.

### Generic Bridge Parameters

The generic bridge parameters define common characteristics shared by both bridge populations, such as the number of spans, span lengths, deck dimensions, column details, and material properties. The selection process for these parameters combines random selection from predefined ranges with engineering constraints to ensure that the resulting structures remain realistic and consistent with real-world practices. For example, the number of spans is determined by randomly choosing a value within a range that typically mirrors actual bridge stocks, usually between one and five spans. Once the number of spans is set, the span lengths are similarly selected from a defined range. However, to avoid unrealistic configurations, such as pairing an exceptionally long span with an extremely short one, an additional constraint is imposed. All selected span lengths must fall within 70% of each other, ensuring a realistic design.

Other parameters, like the width and thickness of the deck, are also chosen from ranges that reflect standard practices in bridge construction. The inclusion of columns is treated as a variable feature; whether columns are present is determined randomly, and if they are included, further details, such as their height and quantity, are specified. These column characteristics are based on established engineering principles; for instance, the minimum column height adheres to government standards for bridge clearance. Material properties, too, are selected from realistic ranges that reflect common construction materials, contributing to the overall authenticity of the generated structures while proving realistic variation in the population.

### Subtype-Specific Parameters

Subtype-specific parameters are the parameters that are only relevant to each bridge subtype. For the beam-and-slab population, some key parameters include the beam centre-to-centre distance, the number of primary beams, the geometry of both primary and edge beams, and the diaphragm geometry. For the ladder-deck bridges, the parameters include the number of transverse beams and the geometry of both the primary and secondary girders. The methods for selecting these parameters tend to be more involved than those used for generic bridge variables to ensure that each choice results in realistic engineering practices.

The process of selecting these parameters is highly dependent on the subtype and the accepted process for designing the structure. For instance, when determining the primary bridge beam geometry for each beam-and-slab bridge, the process begins with a list of common bridge beam types. Beam types that are incompatible with the given span length or bridge width are eliminated using span tables provided by bridge beam manufacturers. From the remaining viable options, a beam type is then randomly selected. This method ensures that the chosen beam geometry is suitable for that span length while allowing for variation in the population.

Similarly, for the ladder-deck subtype, the main structural component is determined using a range of acceptable span-to-depth ratios sourced from the encyclopedia for UK steel construction (SteelConstruction.info). A random ratio is selected from this range and, together with the predetermined span length, used to set the depth of the girder. Additional properties such as flange width and thickness are subsequently determined using comparable ratios from the same source.

The parameterisation strategy for the two bridge datasets employs a total of 17 distinct parameters for beam-and-slab bridges and 23 for ladder-deck bridges. By integrating randomness while adhering to sound engineering principles, the established general form and corresponding parameter sets create a robust framework for generating a diverse yet realistic population of bridge structures. This approach not only mirrors real-world variability but also enables the production of thousands of unique and plausible structures, significantly enhancing the utility of the PEAR dataset for PBSHM research.

### 4.3 Dataset Scenarios

A scenario is defined as a specific set of actions applied to the generated structures within a given population. These scenarios are designed to simulate various conditions or loads to determine the structural responses. The scope of the scenarios is flexible and can vary considerably based on the intended requirements. There is no single prescribed workflow for transforming the generated population into simulated structural responses, provided that the outputs remain compliant with PBSHM standards. In this work, we implement a simple scenario for both bridge types by employing finite-element models (software: LUSAS) to simulate their structural responses. However, alternative approaches, such as computational fluid dynamics, might be more appropriate for other applications, leaving the choice of methodology to the scenario authors.

#### 4.3.1 Description of the Implemented Scenario

In this study, two simple scenarios were implemented to evaluate the structural response of the two generated bridge populations. Scenario 1 was the application of only the dead load on the bridge. Scenario 2 was the application of a point load of 40 kN at the mid-span of every span on each structure. After the mid-span load is applied, the maximum displacement and its corresponding location are extracted and recorded in a PBSHM-compliant format. This scenario is intentionally simple, which facilitates basic validation, such as comparing the self-weight of the structures with reaction forces of the FE models.

The implementation of this scenario can be defined using the following three actions.

1. The Irreducible Element (IE) models are converted into Finite Element (FE) models. This conversion uses the detailed information contained within the IE models to generate FE model files.
2. Loading parameters are defined by extracting necessary information from the Structural Information (SI) models. This step involves producing scripts for each load case, with one script generated per span for each bridge.
3. The generated loading scripts are integrated with the FE models to run simulations. Once the simulations are complete, the mid-span vertical displacements and reaction forces are extracted from the simulation results and stored in the output folder in the correct PBSHM format.

#### 4.3.2 Validation of Structures and Data

Validation of the populations ensures that the generated structures and associated data are reliable, accurate, and true to the design intentions. By confirming that both the individual models and the overall dataset behave as expected, researchers can trust the integrity of the PEAR dataset and confidently use it for their PBSHM research.

During Stage 0 (design of structures), there are two main validation checks. The first is to check if the produced IE models comply with the required PBSHM schema. They are required to comply with the format to ensure consistency and that the developed PBSHM methods can be used on the IE models. The second validation step during Stage 0 is the examination of dataset statistics. These statistics verify that the composition of the populations aligns with the predetermined design process. Analysing parameter distributions and other statistical metrics ensures that the variability within the population matches what is expected based on the defined ranges and engineering principles. A discussion of the two populations developed for this work can be found in Section 5.1.

Further validation is carried out during the scenario stage by comparing simulated structural responses with theoretical predictions. The specifics of this will depend on the workflow to obtain the structural responses of the structure. For illustration purposes, the validation methods that were used in this work will be described. These methods are expected to be applicable when FE models are used as part of the workflow. After converting the IE models to FE models, two key validation methods are employed. First, dead-load reaction forces are extracted from the FE models and compared with the calculated weights of the structures as determined in Stage 0. This comparison confirms that the transition from the IE model to the FE model has maintained the integrity of the original design, ensuring that the overall weight remains consistent. Figure 3 presents the percentage difference between the design self-weight and the reaction forces from the produced FE models. With the average percentage difference being 1.69% and 1.55% for the beam-and-slab population and the ladder-deck population, respectively, there is very good agreement between the design stage and the FE model stage. For the second validation, a point load was applied to the structures, and displacement across the deck was recorded from the FE

simulation. These displacements were checked to ensure there were no discontinuities in the deformed mesh. This comparison serves to verify that the FE models are simulating sensible structural behaviour.

Figure 3: Percentage difference between the design self-weight of the bridges and the reaction forces from the FE models for (a) beam-and-slab population and (b) Ladder-deck population

As a further validation step data from all stages will go through a testing phase here the data will be accessible to the public for review and comments for a period of time. Following this review period it will be uploaded to the published version of the PEAR database.

## 5 BRIDGE DATASETS

In this section, the populations for both beam-and-slab bridges and ladder-deck bridges are presented. Firstly the structural composition of each population is examined, detailing how the individual structures come together to form a representative population of each bridge subtype. Following this, a simple analysis of the outputs from the scenario described in Section 4.3 is presented to demonstrate the practical application of these populations within the PBSHM framework. Finally, a similarity analysis of the populations is presented in section 5.3. This analysis serves to highlight how the PEAR dataset can be used as a valuable benchmark resource for evaluating transfer learning and other advanced PBSHM methods.

### 5.1 Dataset Statistics

Examining the overall composition of the two generated bridge populations provides insights and validation at the population level. By presenting a range of statistics, including the distributions of key parameters and variability, this analysis provides an insight into the composition of the populations. The main purpose of examining the dataset statistics is to ensure that the variations in the dataset reflect realistic engineering principles and expected real-world trends. Additionally, these statistical insights serve as a validation step, confirming that the

methods used to select the parameters yielded the expected set of structures.

For illustration, Figure 4 below displays the distributions of four key parameters for the beam-and-slab bridge dataset: the number of spans, the centre-to-centre spacing of the beams, the number of primary beams, and the width of the deck (subplots (a) to (d), respectively). The distribution of the number of spans is approximately even between one and five, which aligns with expectations, given that this value is selected randomly without influence from other design factors. In contrast, the distributions for the centre-to-centre spacing, the number of primary beams, and the deck width are less uniform because of their interdependent selection processes.

In Figure 4(b), the distribution of the centre-to-centre spacing reflects the specific weighting applied during parameter selection, following a ratio of 4:2:3:1:1, which is clearly visible in the resulting histogram. Figure 4(c), which shows the number of primary beams, indicates a skew towards higher numbers. Although the number of beams is randomly chosen between 4 and 10, this selection is further refined by ensuring that the combination of the number of beams and the centre-to-centre spacing produces a bridge width within the range of 6 to 20 meters. This constraint necessitates reselecting the number of beams when the initial combination falls outside the acceptable range, thereby skewing the distribution toward larger values. Finally, the distribution seen in Figure 4(d) for the deck width is a direct consequence of the deck width being determined by using the centre-to-centre spacing and the number of primary beams.

Figure 4: Beam-and-slab population statistics (a) the number of spans (b) the centre-to-centre spacing of the beams (c) the number of primary beams and (d) the width of the deck

Figure 5 presents the distributions of four key parameters for the ladder-deck bridge dataset: the number of spans, the width of the deck, the height of the main girder, and the height of the cross girders (subplots (a) through (d), respectively). The number of spans is distributed approximately evenly between one and five, similar to the statistics for beam-and-slab bridges. In contrast, the deck width, shown in Figure 5(b), displays a roughly even distribution as well; this is because of its independence from other design parameters in ladder-deck bridges, unlike in the beam-and-slab case.

The height of the main girders, illustrated in Figure 5(c), is determined using defined span-to-girder depth ratios and so is dependent on the length of the spans, with the span limitations setting clear upper and lower bounds for the distribution. Similarly, the height of the cross girders, depicted in Figure 5(d), is selected based on specific span-to-girder depth ratios, but with the additional constraint that they must not exceed the depth of the main girder.

Figure 5: Ladder-deck population statistics (a) the number of spans (b) the width of the deck (c) the height of the main girder and (d) the height of the cross girders

## 5.2 Scenario Analysis

In this section, the results from the two implemented scenarios and conduct a simple analysis are presented. The aim is to provide the reader with a clear example of the types of data that can be generated from the populations, illustrating the applications of the PEAR dataset within PBSHM research.

Figure 6 illustrates the displacement responses of a representative ladder-deck bridge under the various loading

conditions simulated. In Figure 6(a) the vertical displacement of the bridge under dead load is presented. Figure 6(b) to (d) present the displacement responses when a 400 kN load is applied at the mid-span of each of the three spans, respectively. From the displacement results shown in Figure 6, the maximum displacement values for each load case were extracted. These values were then compared against the corresponding maximum displacements from the rest of the population.

Figure 6: Vertical displacement output from FE model for (a) dead load (b) 400 kN applied to span 1 (c) 400 kN applied to span 2 (d) 400 kN applied to span 3

Figure 7 presents the combined maximum displacement values extracted from all of the FE models from the ladder-deck population, plotted against the span length where the point load was applied. In this figure, the colour of each data point represents the height of the main beam, with blue indicating the smallest beam depths and yellow indicating the largest. The displacements vary from 0.0018 m to 0.0653 m. This figure illustrates the relationship between the span length, the main beam depth and the displacement of the bridge. One of the key observations from the figure is the presence of distinctive bands. These bands show that as the span length increases, there is a corresponding increase in the depth of the beams, a trend that is consistent with design principles used for the ladder-deck bridges.

Figure 7: Span length vs the max displacement with the datapoints coloured with respect to main beam depth

### 5.3 Similarity Analysis

In this section, a basic similarity analysis between the populations will be presented. As stated in the prior, similarity assessments are key to PBSHM as they show where it is appropriate to undertake transfer learning between structures. In this work, the Jaccard index, a method used in graph theory [9], is employed to measure the similarity between IE models. The method used here will be slightly amended by embedding a geometry attribute of the elements in the IE model, specific details of this method can be found in [5]. The goal of this section is to highlight the suitability of the data in the PEAR being used for similarity analysis. Figure 8 shows the similarity matrix for a subset of 125 ladder-deck bridges. In the figure each pixel represents the similarity of one ladder-deck structure with another with dark blue representing least similar and yellow representing most similar. In this figure the structures are grouped by how many spans the bridges have; one-span bridges being grouped in the first 25 structures (indicated by the red box) and two-span bridges grouped in the next 25 positions and so on. Grouping in this way means that patterns can be observed about the relationship between the number of spans a bridge has and the similarity of other bridges with the same number of spans. In the case presented in Figure 8 it can be seen that the one-span bridges show a higher level of similarity with each other than with bridges of differing span. This pattern is repeated with the two-span bridges but the pattern seems to be diminished as the numbers of spans increase.

Figure 8: Similarity matrix for a subset of 125 ladder-deck bridges grouped by number of spans

To investigate this pattern further the similarity scores can be averaged across bridges with the same number of spans. This average is presented in Figure 9 and confirms the pattern seen in Figure 8. The bridges with the highest similarity are those with one span and as the number of spans increases the level of similarity decreases.

Figure 9: Similarity matrix for a subset of 125 ladder-deck bridges averaged by number of spans

This process was repeated for the beam-and-slab bridge population and the results are presented in Figure 10. This population largely follows the same pattern however the variability seems to be higher than that compared to the ladder-deck population this is most likely because of the other variations (other than number of spans) in the population affecting the similarity score.

Figure 10: Similarity matrix for a subset of 125 beam-and-slab bridges averaged by number of spans

The similarity analysis in this section is the result of the question of how the number of spans of structures effects the similarity score between other members of the same population? This was chosen as an illustrative example of how a similarity analysis may be undertaken; however, it is only a single example of what may be considered in a similarity analysis. This produced dataset allows for a bespoke similarity assessment based on the needs of the specific research.

## 6 CONCLUSION

A fundamental challenge in Population-Based Structural Health Monitoring (PBSHM) is the need for data spanning multiple structures within a population. Ideally, these data would be sourced from real-world structures; however, acquiring comprehensive datasets across similar populations is challenging because of practical constraints, including data availability, monitoring costs, and access limitations. To address this issue, the database presented in this paper provides a synthetic dataset specifically tailored to the requirements of PBSHM research.

This work serves as a proof of concept for generating realistic populations of structures and associated data within a structured database. Two distinct bridge populations, beam-and-slab bridges and ladder-deck bridges, have been developed using engineering principles to maximise their realism. These structures have been validated via statistical analysis and comparison with theoretical expectations obtained from FE simulations. The FE models enabled structural responses under different loading conditions to be obtained.

The processes outlined in this work have been developed to be generalisable, meaning that aspects of engineering design can be incorporated into the population, such as varying material properties to adjust the material's strength. More complex design aspects, such as the amount of reinforcement or prestressed reinforcement, can be incorporated if the numerical simulation (e.g., an FE model) allows for it.

The results presented in this study demonstrate that it is feasible to create synthetic bridge populations that exhibit realistic structural behaviours, making them suitable for PBSHM development and validation. Although the analysis performed in this paper is relatively simple, it highlights the potential of the database for a range of PBSHM methodologies,

including data-driven condition assessment and transfer-learning applications.

The approach outlined in this paper has been intentionally designed to be flexible, allowing for the generation of both bespoke structural populations and corresponding datasets depending on specific research needs. Future work will build on this foundation by expanding the database with additional structural populations and scenarios, further enhancing its applicability for PBSHM research and facilitating broader adoption within the field.

**ABSTRACT:** A major limitation in data-driven Structural Health Monitoring is the scarcity of labeled data for training machine learning models. Transfer Learning addresses this by enabling knowledge sharing across similar structures, reducing datasets distribution shift. This study proposes a novel Transfer Learning framework for damage identification in operational viaducts with similar spans, using modal frequencies as damage-sensitive features. Domain Adaptation is performed via Normal Condition Alignment, to map source and target features in a shared latent space. A baseline normal condition is established on source features through a linear regression model. Gaussian Mixture Models are trained on source residuals, and used to detect anomalies in the target domain, based on residual distributions. A real viaduct for which long-term monitoring data are available is used as a case study. The structure comprises two homogeneous datasets collected on the deck of similar spans. Source data pertain to a deck with extensive measurements, whereas target data refer to a second deck with a reduced dataset, due to sensor malfunctions. Damage is simulated in the target dataset by reducing the measured frequencies. Validation using data from real damaged scenarios will enable future scaling of the proposed framework to operational conditions, providing a practical tool for data-driven SHM of viaducts, enabling damage detection in under-instrumented areas by leveraging data from other spans.

**KEY WORDS:** Domain adaptation; transfer learning; operational viaduct; SHM; anomaly detection; GMM; linear regression; temperature variations.

## 1 INTRODUCTION

The deterioration of infrastructures poses a considerable challenge to the safety and efficiency of Europe's roadway network, as evidenced by the significant number of bridges that are nearing the conclusion of their service life [1]. The implementation of permanent monitoring systems, designed to observe the evolution of structural behavior over time, is imperative to support effective management of the structure, planning of maintenance activities and timely interventions. However, the financial implications associated with the deployment of such systems across an entire bridge network constitute a major obstacle to the widespread implementation of continuous monitoring campaigns. Consequently, less costly alternatives are often considered, as point-in-time monitoring campaigns or the selective installation of sensors in critical sections or structural components.

To tackle the limitations imposed by cost-saving measures and limited investments, while still guaranteeing an adequate level of safety, a promising solution involves transferring knowledge acquired from heavily instrumented structures or components to others with limited data availability to support the assessment of their structural behavior. This can be achieved through Transfer Learning (TL), a method which has recently gained significant attention among researchers in the field of civil infrastructure monitoring, as a means to overcome the issue of scarcity of labelled data for operating structures [2], [3], [4]. The concept of leveraging data – and, by extension, knowledge – from multiple structures to inform inferences about a target structure was introduced for the first time within the Population-Based SHM framework [5], [6], [7], [8], [9]. Notably, Poole et al. [10] proposed a domain adaptation

approach, referred to as Normal Condition Alignment (NCA), that aligns source and target datasets in a shared latent space, preserving the intrinsic meaning of damage-sensitive features, a capability not offered by other non-statistical approaches, such as DL. This statistical alignment technique has proven effective in several works concerning experimental and numerical datasets [11], [12], [13], in supervised settings with labelled data.

This paper investigates the application of NCA to an operational bridge equipped with a permanent monitoring system. Data from a well-instrumented span are leveraged to allow anomaly detection on a second span, where sensor failures have resulted in intermittent data acquisition.

The novelty of the proposed approach consists in the integration of a simple yet effective temperature compensation procedure following domain adaptation, to mitigate the confounding effect of temperature-induced variability on modal frequencies.

In the considered case study, no damage has been identified through field inspections, thereby the data from the source span are assumed to represent the undamaged state. For the target span, only the first year of monitoring data is considered representative of the undamaged configuration. Damage scenarios are synthetically introduced into the target dataset by increasingly reducing natural frequencies, to perform a sensitivity analysis of the proposed anomaly detection framework.

After domain adaptation is performed, a baseline normal condition for the source domain is established using a linear regression to model the relationship between temperature and natural frequencies. Residuals from this model are

subsequently employed to train a Gaussian Mixture Model (GMM) that is then used for anomaly detection in the target domain. The proposed approach is compared to a baseline method, where the GMM is trained directly on domain-adapted features of the source domain, and tested on domain-adapted features of the target. The results, evaluated in terms of F1-score, indicate that training the GMM on residuals improves performance, particularly when a moderate temperature-frequency correlation is present.

This study demonstrates the effectiveness of a simple domain adaptation technique and regression framework in enhancing novelty detection for bridge monitoring. The proposed framework offers a practical and cost-effective solution for optimizing the use of available monitoring data for critical infrastructure integrity management.

The remainder of the paper is organized as follows: Section 2 illustrates the methodology, Section 3 describes the case study and the datasets, Section 4 discusses the results, and the final section provides conclusion remarks.

## 2 METHODOLOGY

### 2.1 Domain Adaptation via NCA

Traditional machine learning algorithms rely on the assumption that training and testing data originate from the same underlying distribution [14]. When transferring knowledge from a source domain to a target domain, this assumption not necessarily holds, due to possible differences in the statistical distributions of the two domains. These differences may lead to degraded performance and increased generalization error. Domain Adaptation addresses this limitation mitigating the distribution shifts between source and target domains, aligning feature distribution into a shared latent space.

In this work, source and target domains are aligned into a common feature space exploiting NCA. This statistical alignment technique incorporates prior knowledge about the health state of the structure: alignment is achieved by matching both the mean and standard deviation of the normal-condition data distributions to effectively reduce domain discrepancy between the source and the target datasets.

Let  $D_S = \{\mathbf{x}_{s,i}, y_{s,i}\}_{i=1}^{n_s}$  be the source domain, with  $\mathbf{x}_{s,i}$  the source feature vector,  $n_s$  the number of observations and  $y_{s,i}$  the labels associated with each instance of the feature vector. Let also  $D_T = \{\mathbf{x}_{t,l}, y_{t,l}\}_{l=1}^{n_t}$  be the target domain, with  $\mathbf{x}_{t,l}$  the target feature vector,  $n_t$  the number of observations and  $y_{t,l}$  the labels associated with each instance of the feature vector in the target domain. NCA is developed in two steps. First, the source domain is standardized:

$$\mathbf{z}_{s,i} = \frac{\mathbf{x}_{s,i} - \boldsymbol{\mu}_s}{\boldsymbol{\sigma}_s} \quad (1)$$

being  $\boldsymbol{\mu}_s, \boldsymbol{\sigma}_s$  respectively the mean and the standard deviation of the source domain dataset. Then, the subset of the source domain consisting only of healthy instances  $\mathbf{x}_{s,n,i}$  is considered, and its statistics are computed  $\boldsymbol{\mu}_{s,n}, \boldsymbol{\sigma}_{s,n}$ .

Assuming that the target domain includes data associated with the undamaged configuration, reasonably identified as those collected from the start of the monitoring activity up to one year later, the statistics of this subset are computed and the following transformation is applied:

$$\mathbf{z}_{t,l} = \frac{\mathbf{x}_{t,l} - \boldsymbol{\mu}_{t,n}}{\boldsymbol{\sigma}_{t,n}} \boldsymbol{\sigma}_{s,n} + \boldsymbol{\mu}_{s,n} \quad (2)$$

being  $\boldsymbol{\mu}_{t,n}, \boldsymbol{\sigma}_{t,n}$  respectively the mean and the standard deviation of the target undamaged subset.

In this paper we assume that the entire source dataset is referred to the undamaged configuration of the structure, hence resulting in  $\boldsymbol{\sigma}_{s,n} = \mathbf{1}$  and  $\boldsymbol{\mu}_{s,n} = \mathbf{0}$ .

### 2.2 Linear regression

Natural frequencies are sensitive to the influence of environmental and operational fluctuations, being temperature the most significant source of variability. To filter out the effect of temperature on the modal properties of the structure, regression models have been widely proven effective, being able to characterize the relationship between temperature and eigenfrequencies [15], [16].

Considering the frequencies time history depicted in Figure 2, a linear dependency of the modal parameters on temperature can be appreciated. Hence, following the alignment of source and target data in the latent feature space, we train a linear regression model on the source features  $\mathbf{z}_{s,i}$  to learn the expected, temperature-dependent behavior of the structure. By doing so, the regression model establishes a baseline that characterizes the normal behavior of the source span. For each mode, the linear regression model reads as follows:

$$\hat{\mathbf{z}}_{s,i} = \beta_0 + \beta_1 \mathbf{T}_i \quad (3)$$

being  $\hat{\mathbf{z}}_{s,i}$  the predicted source feature in the latent space,  $\mathbf{T}_i$  the temperature corresponding to the  $i$ -th source feature  $\mathbf{z}_{s,i}$  in the latent space, and  $\beta_0, \beta_1$  the regression coefficients.

We then use this model to predict the features for both the source and the target domain, using the temperature values pertaining to each of them. The residuals, defined as the differences between the observed and predicted features values, are subsequently analyzed to detect potential anomalies or deviations from the expected structural behavior.

### 2.3 Gaussian Mixture Models for anomaly detection

Gaussian Mixture Models (GMMs) are probabilistic models employed in unsupervised machine learning for identifying clusters in data. They assume that data are generated from a mixture of multiple Gaussian distributions, each with unknown parameters. This assumption makes them suitable for modelling real-world monitoring data, which often exhibit multimodal distributions characterized by overlapping Gaussian components, due to changes in the data induced by factors such as temperature fluctuations and potential structural damage. Formally, the probability density function of the GMM is defined as:

$$p(\mathbf{x}) = \sum_{k=1}^N \pi_k N(\mathbf{x} | \boldsymbol{\mu}_k, \boldsymbol{\Sigma}_k) \quad (4)$$

where  $\pi_k$  is the mixing coefficient (the weight) for the  $k$ -th Gaussian component, satisfying  $0 \leq \pi_k \leq 1$  and  $\sum_{k=1}^N \pi_k = 1$ , and  $N(\mathbf{x} | \boldsymbol{\mu}_k, \boldsymbol{\Sigma}_k)$  is the  $k$ -th Gaussian distribution of the mixture, having  $\boldsymbol{\mu}_k$  mean vector and  $\boldsymbol{\Sigma}_k$  covariance matrix. The parameters of the GMM are estimated via the Expectation Maximization algorithm, which iteratively optimizes them by maximizing the likelihood of the observed data [14], [17].

GMMs are soft clustering algorithms, as they assign samples to a cluster based on the likelihood that each data point belongs

to that cluster in particular. In this paper we use the GMMs for anomaly detection. Specifically, for each mode, we train a GMM on the source domain residuals. Once the model is fitted, the log-probability density function (log-PDF) of each instance is evaluated and a detection threshold is established based on a low quantile of the log-PDF distribution, to distinguish normal from anomalous data points. The trained GMM is then applied to the target domain residuals and the log-PDF is computed and compared to the previously defined threshold. Instances falling below this threshold are identified as anomalies, indicating a deviation from the normal behavior modeled using source data.

Last, we compare the results of the proposed anomaly detection framework, combining linear regression and GMM, to those obtained using GMM alone. This is to assess the effectiveness of the integrated approach versus a direct application of GMM. More specifically, a separate GMM is trained, for each mode, using a dataset comprising the frequency and temperature vectors associated with the source domain in the latent space. Each GMM employs full covariance matrices to capture the correlations between frequency and temperature, and the optimal number of components for each model is selected based on the Akaike Information Criterion (AIC), to balance model complexity and goodness of fit. Then, for each mode, each GMM is tested against the target dataset in the latent space, including once again the frequency and temperature vectors associated with the selected mode.

#### 2.4 Performance evaluation

To assess the performance of the proposed anomaly detection framework, the number of true positives (TP), true negatives

### 3 CASE STUDY

#### 3.1 The viaduct

The structure under consideration in this study is an operational viaduct located in northern Italy. Constructed in 1968, the viaduct comprises 41 spans, extending for a total length of 1673.5 meters. The deck features continuous pre-stressed Gerber beams, each resting on two cast-in-place piers, and suspended Gerber spans (Figure 1). Of particular note is the monitoring of eleven spans that intersect with a river bed. In this section, the piers are spaced 61.5 meters apart, with a total length of 676.5 meters.

The instrumentation installed on the eleven monitored spans comprises a total of 219 biaxial MEMS inclinometers and 100 triaxial MEMS accelerometers, installed in 2020 to monitor the dynamic characteristics of the bridge and trigger alarms when fixed thresholds are exceeded. The accelerometers are not distributed uniformly across each span; rather, they are positioned on only half of each span.

The present study focuses on accelerometer data collected from May 2022 to December 2024. The structure is found to be in normal condition and is currently in service. Consequently, no damage configuration labels are available, as there is no evidence of damage to the structure. Temperature information is available for each of the set of eigenfrequencies obtained from the acceleration time histories.

#### 3.2 Description of the dataset

The objective of this study is to leverage the large volume of monitoring data available for a single span of the viaduct (the

Figure 1. Part of the longitudinal section of the viaduct. Span 34 is the source one. In magenta the accelerometers installed.

(TN), false positives (FP), false negatives (FN) is computed. These quantities enable the evaluation of precision and recall metrics, which in turn are used to compute the F1 score. Precision measures the proportion of detected anomalies among all instances ( $TP / (TP + FP)$ ), while recall measures the fraction of correctly detected anomalies ( $TP / (TP + FN)$ ) [14]. Then, the harmonic mean of the two metrics is computed, resulting in the F1-score:

$$F1 - score = 2 * \frac{Precision * Recall}{Precision + Recall} \quad (5)$$

The F1-score is a commonly used metric to assess the performance of classification algorithms in presence of unbalanced dataset, a common issue in SHM datasets, where the number of healthy instances often exceeds the number of damaged ones by far.

source) to perform anomaly detection on another similar span (the target), with reduced data availability due to sensors malfunction. Two continuous spans are considered. Both the source and target dataset consist of time series observations that include the first three eigenfrequencies and the corresponding temperatures measured at each time step. Specifically, the source dataset comprises 4346 observations organized in a  $4346 \times 4$  matrix, while the target dataset includes 2143 observations structured in an analogous  $2143 \times 4$  matrix.

As previously stated, according to available inspection records, there is not any evidence of damage affecting the viaduct so far. Hence, both the source and target dataset considered contain observations which are reflective of the normal condition of the relative spans. For the source dataset, this condition is treated as factual throughout the study. Instead, we assume that only the observations acquired during the first year of monitoring of the target span are associated with its undamaged configuration. Additionally, we simulate the

occurrence of damage in the target by reducing the frequency values acquired from August 2024 by 2% and 5%. This enables us to conduct a sensitivity analysis on the performance of the anomaly detection procedure implemented.

The study is conducted in an unsupervised setting. However, to assess the performance of the framework in detecting anomalies in a real scenario, labels are assigned to the target dataset to mark the instances of reduced frequencies simulating damage, making it possible to compute the F1-score.

Figure 2 illustrates the first three natural frequencies for both source and target spans. The fundamental frequency  $f_1$  is approximately equal to 1.5 Hz for both the spans, and exhibits a similar trend for both domains. The second natural frequency  $f_2$  oscillates around 2.6 Hz. In this case, while there is a marked dependency of the source  $f_2$  on temperature, the corresponding target frequency displays a smoother trend. Finally, the third natural frequency of the two spans differs significantly, with  $f_3$  of the source domain having a mean value of 4.4 Hz, whereas  $f_3$  of the target dataset is lower, with a mean value of 3.6 Hz. Furthermore, a strong sensitivity to daily temperature fluctuations can be appreciated in the third eigenfrequency of the source span, with respect to the target one. Figure 3 depicts the temperature measurements recorded by the accelerometers installed on both spans. Figure 4 illustrates the time histories of  $f_1$ ,  $f_2$  and  $f_3$  of the target domain, highlighting the artificially reduced frequencies starting from August 2024 onward to simulate damage.

Figure 2. First three natural frequencies for source (in blue) and target dataset (in red). Frequencies  $f_1$  and  $f_2$  range around 1.5 and 2.6 Hz respectively, while  $f_3$  is around 3.6 Hz for the target domain and higher, around 4.3 Hz, for the source domain.

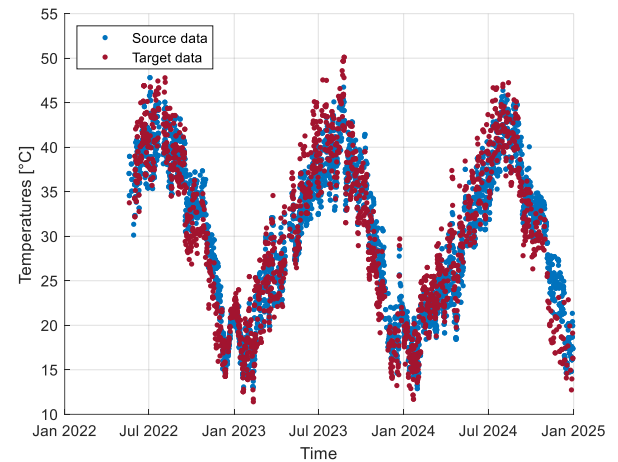

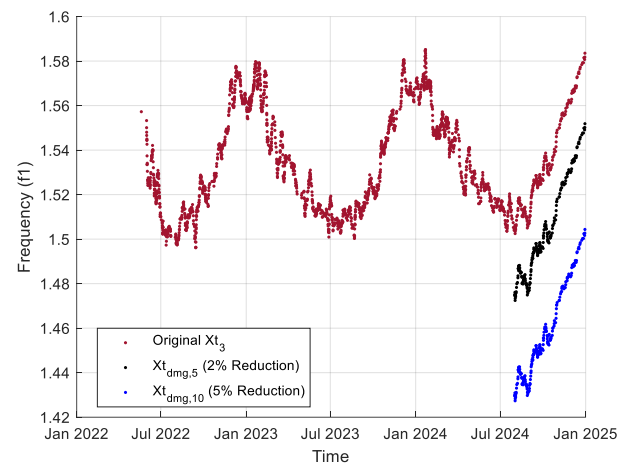

Figure 3. Source and target dataset temperature records.

b)

Figure 4. Original and synthetic data for the target domain. Frequencies of the target domain are reduced by 2% and 5% starting from August 2024 to simulate damage. Subfigures a), b), c) refer respectively to the first, second, and third natural frequencies.

Figure 5. Source and target features ( $z_1$  and  $z_2$ ) after domain adaptation. Figure 5a depicts the scenario in which damage is simulated through a 2% reduction in natural frequencies, whereas Figure 5b corresponds the case of a 5% frequency reduction.

#### 4 RESULTS

Normal Condition Alignment has been applied to the source and target datasets, and the resulting features in the latent space are depicted in Figure 5 and Figure 6. Figure 5a and Figure 6a are relative to the case where damage is simulated as a 2% reduction in natural frequencies, while Figure 5b and Figure 6b refer to a 5% frequencies reduction.

As a result of the application of NCA, when a 5% frequency reduction is introduced to simulate damage (Figure 5b and Figure 6b), we see that the normal instances of the target domain overlap the healthy features of the source. In contrast, the simulated damage instances tend to form distinct and distant clusters in the latent space. On the other hand, when damage is simulated through only a 2% reduction in frequencies, the corresponding damage instances of the target tend to cluster closely with, and even overlap, the healthy source and target features (Figure 5a and Figure 6a).

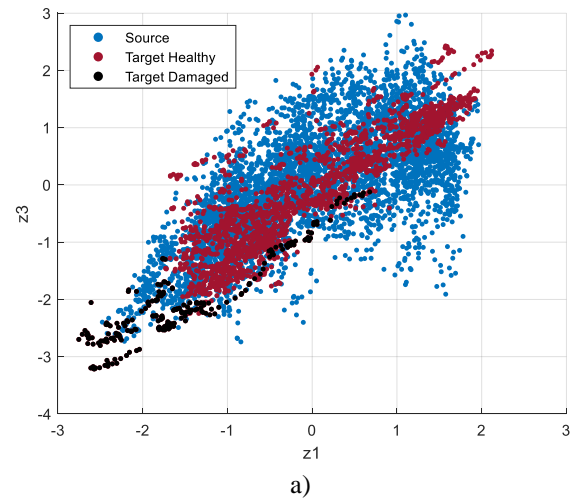

Figure 6. Source and target features ( $z_1$  and  $z_3$ ) after domain adaptation. Figure 6a depicts the scenario in which damage is simulated through a 2% reduction in natural frequencies,

whereas Figure 6b corresponds the case of a 5% frequency reduction.

In the following, the results associated with the 5% reduction in frequencies will be first illustrated, while those associated with the 2% frequency reduction for damage simulation will be discussed in the remainder of this section.

Separate linear regression models have been trained for each of the three source features (Figure 7, Figure 8, Figure 9) to capture their relationship with the corresponding temperature values. Each trained model has then been utilized to make predictions on both source data and target data, and the residuals between the actual feature values and the predicted ones have been computed.

Figure 7. Linear regression of feature  $z_1$  of the source domain vs temperature.

Figure 8. Linear regression of feature  $z_2$  of the source domain vs temperature.

Figure 9. Linear regression of feature  $z_3$  of the source domain vs temperature.

A Gaussian mixture model has been independently trained on the source residuals for each mode. Following the training, the log-PDF of each GMM was evaluated, and a detection threshold was established at the 5th quantile for modes 1 and 3, and at the 1st quantile for mode 2. Subsequently, the trained GMMs have been applied to the target residuals for the corresponding modes, enabling anomaly detection by comparing the log-PDF values for the target against the predefined thresholds. The results are illustrated in Figure 10, Figure 11, and Figure 12, and the performance metrics are listed in Table 1.

Table 1. Anomaly detection results using GMMs trained on source residuals, evaluated on the target dataset with synthetic damage simulated by a 5% reduction in natural frequencies.

	TP	FP	FN	TN	Precision	Recall	F1 score
f1	219	95	0	1829	0.70	1.00	0.82
f2	219	475	0	1449	0.32	1.00	0.48
f3	219	14	0	1919	0.94	1.00	0.97

As we can see from the table, the GMMs tested on target residuals are in all cases able to detect the true damage instances, while detecting few false positives for  $z_1$  and  $z_3$ . In the case of  $z_2$ , the number of false positives is considerable, and this is probably due to the fact that frequency  $f_2$  of the target does not exhibit the same strong temperature dependence that is inherently present in the second natural frequency of the source domain.

Comparing these results with those obtained by training, for each mode, a GMM directly on the source features and temperatures (Table 3) in the latent space, a slight improvement in the F1-score can be appreciated when residual analysis is applied. As a matter of fact, from Table 2 we can see that, even though also in this case all the true anomalies are correctly identified, the baseline GMM produces a slightly higher number of false positives with respect to the residual-based approach. This demonstrates that the proposed framework can enhance the anomaly detection process by reducing the false alarms that would otherwise arise from applying the GMM to latent variables directly.

Table 2. Anomaly detection results using GMMs trained on source features directly, evaluated on the target dataset with synthetic damage simulated by a 5% reduction in natural frequencies.

	TP	FP	FN	TN	Precision	Recall	F1 score
f1	219	126	0	1798	0.63	1	0.78
f2	219	520	0	1404	0.30	1	0.46
f3	219	57	0	1867	0.79	1	0.88

Figure 10. Target anomalies detected by GMM trained with source features residuals  $r_1$ . The threshold is set to the 0.05 quantile of the log-PDF.

Figure 11. Target anomalies detected by GMM trained with source features residuals  $r_2$ . The threshold is set to the 0.01 quantile of the log-PDF.

Figure 12. Target anomalies detected by GMM trained with source features residuals  $r_3$ . The threshold is set to the 0.05 quantile of the log-PDF.

Table 3. F1 scores comparison on the target dataset with synthetic damage data, reduction of 5%.

5% reduction	GMM trained on source features	GMM trained on source residuals	F1-score improvement
f1	0.78	0.82	5.13 %
f2	0.46	0.48	4.35 %
f3	0.88	0.97	10.23 %

Finally, Table 4 illustrates the results for the scenario where damage is simulated via a reduction of the actual target frequency values by 2%. In this case, we can see that the performances of the GMMs trained on source residuals are slightly worse than in the case with the 5% frequency reduction, standing the same detection thresholds. Nevertheless, the F1-scores computed for the residual-based anomaly detection approach still exhibit higher values than those achieved by GMMs trained on source latent features (Table 5), registering an increase in the F1-score value up to 10.5% for the third natural frequency (Table 6). This outcome highlights that the proposed framework is effective even when the damage is subtle, helping to mitigate the number of false positives that can occur in such cases.

Table 4. Anomaly detection results using GMMs trained on source residuals, evaluated on the target dataset with synthetic damage simulated by a 2% reduction in natural frequencies.

	TP	FP	FN	TN	Precision	Recall	F1 score
f1	202	94	17	1830	0.68	0.92	0.78
f2	178	472	41	1452	0.27	0.81	0.41
f3	168	14	51	1910	0.92	0.77	0.84

Table 5. Anomaly detection results using GMMs trained on source features directly, evaluated on the target dataset with synthetic damage simulated by a 2% reduction in natural frequencies.

	TP	FP	FN	TN	Precision	Recall	F1 score
f1	201	126	18	1798	0.61	0.92	0.74
f2	180	543	39	1381	0.25	0.82	0.38
f3	171	62	48	1862	0.73	0.78	0.76

Table 6. F1 scores comparison on target dataset with synthetic damage data, reduction 2%.

2% reduction	GMM trained on source features	GMM trained on source residuals	F1-score improvement
f1	0.74	0.78	5.41 %
f2	0.38	0.41	7.89 %
f3	0.76	0.84	10.53 %

## 5 CONCLUSIONS

In this paper, we have proposed a novel domain adaptation framework aimed at enhancing unsupervised anomaly detection in operational viaduct components. We have utilized the Normal Condition Alignment algorithm to leverage the extensive dataset available for a source span, to support anomaly detection in a target span with limited observations due to sensor malfunction. The novelty of this work lies in the use of a linear regression model to capture the dependency between frequency and temperature in the source domain after domain adaptation. This enables the establishment of a baseline normal condition for the source span in the latent space, which can then be “transferred” to the target span. Residuals from the source linear regression model have been used to train a Gaussian Mixture Model for each mode, enabling the detection of deviations from the expected normal behavior in the target domain when the trained models are tested against the target residuals.

We have compared the results of our residual-based framework against those obtained by training and testing the GMMs directly on domain-adapted features. The outcomes have highlighted that our method reduces the number of false positives, especially for modes where the natural frequencies are strongly influenced by temperature fluctuations, and even in the case in which the presence of damage is subtle, such as when frequencies from the normal condition are reduced by 2%. This is particularly relevant considering that even slight shifts in natural frequencies may correspond to severe structural damage.

Furthermore, from Figure 5a and Figure 6a we have seen that in the case of a 2% frequency reduction, the damaged instances of the target domain tend to overlap the healthy clusters of both source and target domains in the latent space. Relying solely on source features to train the GMM, without accounting for temperature in the establishment of a baseline normal condition, would have led to even poorer performances compared to using both features and temperatures. In fact,

overlapping damaged instances would likely be misclassified as healthy, thus increasing the number of false negatives.

In conclusion, the findings of this study underscore the significance of explicitly incorporating environmental variability into the knowledge transfer process. Future research will focus on examining the applicability of the proposed framework in contexts involving dissimilar source and target spans, as well as datasets with substantial data gaps. Additionally, validating the framework with data from actual damaged scenarios will pave the way for its future application to operational conditions. This will support the development of a practical, data-driven SHM tool for viaducts, capable of detecting damage even in under-instrumented spans by leveraging information from other ones.

## ACKNOWLEDGMENTS

The authors acknowledge SINA S.p.A. for sharing monitoring data and all relevant documentation related to the case study. Further, the authors thank Eray Temur for the development of the automated Operational Modal Analysis procedure used for extracting natural frequencies from the acceleration time histories.

**ABSTRACT:** This study investigates the effectiveness of photomonitoring as a remote sensing technique for cultural heritage conservation, focusing on the Aurelian Walls (Rome) and the Church of Santa Apollonia (Ferrara), Italy. Using mobile devices such as smartphones and tablets, structural changes—including brick detachment and vegetation growth—were detected through Structural Similarity Index (SSI) mapping. The results highlight both the advantages and limitations of mobile-based monitoring, emphasizing its flexibility and rapid deployment. Key challenges include variations in pixel size and lighting conditions, which influence data consistency. Despite these limitations, the study supports the potential of citizen science integration to enhance spatial and temporal data collection. By leveraging crowdsourced imagery, monitoring efforts can become more comprehensive and cost-effective. The findings align with broader citizen science initiatives, demonstrating how non-invasive, mobile-based techniques can contribute to sustainable heritage preservation. Future research should focus on optimizing data acquisition and processing methodologies to improve the robustness of this approach.

**KEY WORDS:** Photomonitoring, Structural Similarity Index, Cultural Heritage Monitoring, Mobile Sensing, Citizen Science, Remote Sensing, Image-Based Analysis

## 1 INTRODUCTION

The preservation of cultural heritage is a crucial endeavor, safeguarding the tangible expressions of human history and identity. The monitoring of immovable cultural assets—including monuments, archaeological sites, and historic buildings—is essential to ensure their longevity and structural integrity. While traditional monitoring methods have long been utilized in heritage conservation, recent advancements in image analysis techniques, coupled with the growing role of citizen science, have significantly enhanced these practices. Cultural heritage sites face numerous threats, including environmental factors such as weathering, pollution, and natural disasters, as well as human-induced damages such as vandalism and urban expansion. Regular monitoring is essential for detecting early signs of deterioration, enabling timely interventions to prevent further damage and preserve the historical value of these sites. Additionally, continuous assessment supports informed decision-making regarding conservation strategies and resource allocation.

Historically, cultural heritage monitoring has relied on several established techniques. Visual inspections remain a fundamental approach, with conservators and archaeologists conducting systematic assessments to identify surface anomalies, structural cracks, or material degradation. However, this method is inherently subjective and may fail to capture subtle changes over time. Standard photography has been widely used to document sites, facilitating comparative

analysis, yet it is often insufficient for detecting underlying structural issues or material compositions. Furthermore, environmental monitoring devices such as dataloggers provide valuable data on temperature, humidity, and vibrations affecting cultural assets. While effective, these sensors often require intrusive installation, which may pose risks to fragile structures.

In recent decades, the integration of advanced image analysis techniques has revolutionized cultural heritage monitoring, offering precise and non-invasive methods for assessing and preserving historical sites. The fusion of image analysis with geomatics and remote sensing technologies has significantly expanded heritage monitoring capabilities. The use of satellite imagery, such as data from Sentinel-2, allows for large-scale monitoring of archaeological sites, providing critical insights into environmental impacts and structural changes over time [1]. The incorporation of artificial intelligence (AI), particularly deep learning algorithms, has enhanced damage assessment accuracy in cultural heritage conservation. Automated detection and classification of deterioration patterns improve the efficiency of preservation efforts [2].

Moreover, linking hyperspectral imaging with other non-destructive analytical methods has further advanced research potential in this field. The integration of hyperspectral imaging with tensor-based learning models has improved the automated inspection of cultural monuments, allowing for detailed material characterization and defect classification, enhancing

the accuracy of preservation strategies [3]. The application of unsupervised clustering techniques to hyperspectral images has been explored for monitoring cultural heritage degradation, enabling the detection of decomposition and corrosion levels, providing valuable data for conservation efforts [4]. Deep learning methods, such as autoencoders and Generative Adversarial Networks (GANs), have been successfully employed for anomaly detection on ancient stone stele surfaces [5], while convolutional neural networks (CNNs) have been utilized to identify structural damage in heritage buildings [6]. By processing high-resolution images, these AI-driven techniques facilitate the timely detection of defects, supporting proactive conservation efforts.

These image-based techniques offer several advantages over traditional methods: they are non-invasive, minimize direct interaction with artifacts, and generate high-resolution data that can be quantitatively analyzed. Furthermore, their digital nature allows for the creation of permanent records that can be revisited for future studies or restoration initiatives.

In 2022, the Italian Ministry of Culture and the CERI Research Center at the University of Rome Sapienza entered into a collaboration agreement to develop new guidelines for the monitoring of deformations that affect cultural heritage sites. Within this framework, our research group is testing various innovative, non-invasive monitoring techniques, from the landscape scale down to individual cultural heritage buildings. Photomonitoring has emerged as a cost-effective, precise, and rapid alternative to traditional analytical methods [7; 8]. By leveraging low-cost tools such as smartphones and entry-level cameras, photomonitoring enables accurate multitemporal analysis to detect vegetation growth, mortar detachment, and structural deterioration. Based on Digital Image Processing principles, this approach extracts both qualitative and quantitative insights into structural changes by analyzing and comparing images of the same area taken at different time intervals [9;10]. This paper explores the potential of photomonitoring through case studies, including the Aurelian Walls in Rome and S. Apollonia Church in Ferrara. The results demonstrate its effectiveness in providing detailed insights into structural changes, offering a sustainable solution for heritage management.

Having established the reliability of photomonitoring, the next objective is to involve communities in data collection through mobile and web applications. Initiatives such as IntelligEarth exemplify the intersection of technology and citizen science. This startup aims to revolutionize heritage monitoring by integrating crowdsourcing systems and citizen participation, enabling real-time reporting and analysis of environmental risks to cultural sites.

Citizen science—the active involvement of non-professional researchers in scientific initiatives—has become an invaluable component of cultural heritage monitoring and conservation. Integrating citizen science not only complements traditional monitoring efforts but also democratizes the preservation process, fostering a sense of collective responsibility. Equipped with smartphones and digital cameras, individuals can capture

and upload images of heritage sites, contributing to large-scale monitoring databases. This approach significantly expands the spatial and temporal scope of data collection beyond what professional teams alone can achieve. Furthermore, engaging the public in heritage monitoring raises awareness about cultural preservation. Educational programs and workshops can empower communities to take an active role in conservation efforts.

Recent case studies highlight the effectiveness of citizen participation in heritage monitoring. The Tirtha project, launched in 2023, exemplifies the integration of technology and public engagement in cultural heritage preservation. This web platform enables crowdsourcing of heritage site images to generate detailed 3D models using advanced photogrammetry techniques. Contributors submit photographs that are processed to create accurate three-dimensional representations of cultural landmarks [11]. Monitoring and documenting remote heritage sites pose significant challenges for large heritage organizations. By encouraging tourists and local residents to share images captured during their visits, organizations can collect valuable data to assess the condition of sites, especially those that are unstaffed or in remote locations. This approach proved particularly valuable during the COVID-19 pandemic, ensuring continued monitoring despite travel restrictions [12].

The role of citizen science in cultural heritage conservation extends beyond data collection, fostering increased public awareness and community engagement. A compelling example of this dynamic is presented in the study of Kumar [13], which analyzed the response to the 1966 Florence flood and demonstrated how crowdsourcing efforts—long before the internet era—enabled effective heritage recovery through monetary donations, volunteer labor, and material support. The study further identified key motivational factors for public participation in such initiatives, including direct calls to action, media influence, and personal connections to affected cultural assets. These findings suggest that properly structured citizen science initiatives have the potential to mobilize extensive public participation in cultural heritage conservation, even in the aftermath of disasters.

The monitoring of immovable cultural heritage is a complex yet evolving field that has been greatly enhanced by technological advancements. While traditional methods have provided the foundation for conservation practices, the integration of sophisticated image analysis techniques has significantly improved the precision and efficiency of monitoring efforts. Simultaneously, the rise of citizen science has introduced a collaborative dimension, enriching data collection and fostering public involvement. Together, these advancements contribute to more effective and inclusive strategies for preserving the invaluable cultural legacies of humanity.

## 2 MATERIALS AND METHODS

### 2.1 Instrumentation and Source Data

In the frame of this work, the acquisitions have been performed with two different sensors, one for each site. In both cases, it has been chosen a multi-temporal approach to monitor the evolution of the phenomenon over time, providing a more comprehensive and accurate perspective.

The first dataset of images was taken using a Tablet Samsung Galaxy Tab S7+, whose features are shown in Table 1.

Table 1 - Samsung Galaxy Tab S7+ characteristics

Sensor	13 MP
Sensor size	1/3.4"
Focal length	3 mm

To acquire the second dataset, a Smartphone Samsung Galaxy A54 was used, whose characteristics are shown in Table 2.

Table 2 - Samsung Galaxy A54 characteristics

Sensor	12 MP
Sensor size	1/1.56"
Focal length	6 mm

As for the acquisitions, the images taken with the tablet were captured manually, while a tripod was used for those acquired with the smartphone. In order to keep the same position and the same camera orientation between one acquisition and another, it has been used the software of feature tracking CARE, that allows to obtain the same exact position of the previous acquisition. This is essential to ensure the best performance during the analysis, giving a more accurate result in the co-registration process.

Data collection lasted for more than a year. The tablet dataset has been collected in two phases, the first one from November to December 2022; the second one from December 2023 to November 2024. The smartphone dataset has been acquired over a period of one year, from February 2024.

Table 3 - Images characteristics

Subject	Date	Dimensi ons	Dista nce	Pixel Size
K11-K12 section	27-12- 2022/19-01- 2024	6.27 MB – 5.84 MB	30 m	19,3 mm
K12-K13 section	19-01- 2024/19-09- 2024	6.67 MB – 6.19 MB	32 m	20,6 mm

Sant' Apolloni a Church	13-06- 2024/26-09- 2024	9.56 MB – 8.39 MB	6 m	2,67 mm

## 2.2 Methodology

The data acquired for this study were processed using Change Detection (CD) algorithms. Change Detection is a Digital Image Processing (DIP) technique that allows to identify variations between images acquired at different time intervals by comparing a reference image (master) with one or more successive images (slave) [14]. Digital images, represented as numerical matrices, enable the identification of features such as points, lines, patterns, color, brightness, and contrast. The comparison of these features between temporally successive images allows for the precise detection of changes within the area of interest [9]. Several Change Detection methods have been developed to date. Pixel-based approaches directly compare intensity values between successive images. Statistical approaches, such as the Mean Squared Error (MSE) and the Peak Signal-to-Noise Ratio (PSNR), quantify variations based on error metrics [14, 15]. Perceptual-based methods, such as the Structural Similarity Index (SSIM), analyze changes while accounting for human visual perception [16]. The accuracy of Change Detection, regardless of the method adopted, depends on the quality of the acquired images and the ability to distinguish actual structural modifications from variations induced by atmospheric conditions or illumination differences. Additionally, the presence of distinctive patterns or appropriate speckle models in the scene is also essential to ensure robust identification of corresponding features in successive images. Therefore, accurate image co-

registration is essential to guarantee proper spatial alignment between consecutive datasets, minimizing geometric distortions that could compromise the analysis [16]. The CD approach implemented within the software utilizes the Structural Similarity Index (SSIM) method [16; 17]. SSIM is an algorithm developed to quantify image similarity by analyzing three fundamental components: luminance, contrast, and structure [17]. Compared to conventional metrics such as MSE and PSNR, SSIM is based on a perceptual model, offering a more accurate assessment of visually perceptible modifications [16]. This method has demonstrated considerable potential for detecting changes due to its robustness and accuracy [18].

The SSIM index is defined by the following equation (Eq. 1):

$$SSIM(x, y) = [l(x, y)]^\alpha \times [c(x, y)]^\beta \times [s(x, y)]^\gamma \quad (1)$$

where  $l(x, y)$  represents luminance, which evaluates the difference in brightness between the two images,  $c(x, y)$  expresses contrast, which differentiates the intensity range between the brightest and darkest regions of the images, and  $s(x, y)$  represents structure, which compares the local luminance pattern between two images to assess similarity and dissimilarity. The exponents  $\alpha$ ,  $\beta$  and  $\gamma$  are positive constants that govern the weight of each component in the final computation. The algorithm is applied to local windows within the images and returns a value ranging from 0 to 1, where 0 indicates a complete change and 1 indicates an area where no changes have been detected. Intermediate values suggest partial variations, indicating potential structural modifications or illumination changes. The Change Detection analysis in the IRIS software begins with the selection and uploading of the master and slave images, followed by an additional image co-registration phase to achieve perfect dataset alignment [7]. The next step involves selecting the Window Size (WS) parameter. This parameter is crucial as the software employs a sliding window approach, computing the SSIM index on patches defined by the Window Size (WS) and assigning the calculated SSIM value to the central pixel of each patch.

Fig. 3: Conceptual scheme illustrating the process of change detection (CD) analysis. Two images are compared to identify changes that occurred during the time interval  $t_0$ – $t_1$

Once the desired Window Size is selected, the next step involves assigning the weight of the individual contributions in the SSIM computation. This step is critical for ensuring the

correct execution of Change Detection. The software allows for adjustment of the  $\alpha$ ,  $\beta$  and  $\gamma$  exponents, exponentially increasing the analysis sensitivity based on specific cases. Operating at a local scale, the software iteratively evaluates image similarity within small pixel subsets defined by the WS, enabling the automatic detection of change regions.

The choice of the Window Size (WS) is fundamentally informed by the expected scale of detectable changes within the monitored structures. A properly defined WS allows the analyst to selectively filter out minor disturbances or non-structural changes that are not relevant to the analysis objectives. This tuning capability is particularly useful when addressing noise induced by lighting variations or acquisition-related inconsistencies, such as slight displacements, shadows, or differences in ambient conditions.

To further refine the detection process, the software supports semi-automatic calibration of the exponential weighting factors  $\alpha$ ,  $\beta$ , and  $\gamma$  within the SSIM algorithm. These parameters respectively control the contribution of luminance, contrast, and structural components, and their adjustment is essential for minimizing false positives caused by non-structural changes (e.g., shadow displacement or illumination shifts). By modulating these parameters in accordance with the selected WS, it is possible to enhance the robustness of the analysis, isolating meaningful structural variations while attenuating the influence of irrelevant fluctuations. This methodological flexibility is key to adapting photomonitoring workflows to diverse environmental and acquisition conditions.

The result of this analysis is a raster map that visualizes SSIM values for each individual pixel through a color gradient. Green indicates an SSIM value of 1, implying no change, while blue represents an SSIM value of 0, indicating a complete change.

### 3 CASE STUDY

One of the selected case studies is the Aurelian Walls in Rome, a monumental archaeological structure that once served as the primary defensive boundary of the city and now forms a significant part of Rome's UNESCO World Heritage designation. As the largest surviving monument in the city, the walls hold immense historical and architectural value. However, they are increasingly threatened by invasive vegetation, including species such as *Hedera helix* L., *Ficus carica* L., and *Capparis orientalis* Veill. (*Capparis spinosa* L.), with *Ailanthus altissima* emerging as the most invasive and difficult species to control [19, 20, 21, 22].

Geologically, the Aurelian Walls are located in an area characterized by Quaternary volcanic formations and Holocene alluvial deposits from the Tiber River. Constructed under Emperor Aurelian between 270 and 275 AD, with subsequent completion under Emperor Probus, the walls originally extended approximately 19 km, though only 12.5 km remain today due to partial demolitions. Structurally, they consist of a combination of tuff and brick masonry, with an inner core composed of loosely bonded tuff blocks. Over the centuries, conflicts and environmental factors have contributed to their deterioration, prompting numerous restoration interventions.

Notably, during the 16th century, Pope Pius IV commissioned extensive reinforcements to enhance their stability [23, 24]. More recently, the Capitoline Superintendence has undertaken conservation projects aimed at safeguarding the remaining sections and preventing structural collapses.

The second case study focuses on the Church of Santa Apollonia in Ferrara, a city recognized as a UNESCO World Heritage Site since 1995. Originally built in the 15th century, the church underwent significant reconstruction in 1612, transforming into an oratory with an expanded classical octagonal layout. Further modifications were made in 1662, including the incorporation of the portal from the Church of the Holy Spirit (*Chiesa dello Spirito Santo*), which had been demolished in 1839. The church remained closed since 1975 and was later deconsecrated. Over time, it has fallen into severe neglect and structural decay. Santa Apollonia has since been placed under state management as part of a broader restoration and redevelopment initiative aimed at repurposing its interiors into an exhibition space for the nearby National Archaeological Museum of Ferrara. The building, like many others in the region, is constructed on permeable fluvial sand deposits, which have contributed to significant water infiltration and accelerated degradation. Located north of the so-called Isola di Sant'Antonio, the structure exhibits pronounced signs of moisture-induced deterioration, with severe cracking observed along the left lateral wall, highlighting the urgent need for intervention.

## 4 RESULTS

Over a time span of more than a year, numerous changes have been identified in the two datasets. The changes observed during this period affect the vertical external curtain of the Aurelian Walls and the wall facing of Santa Apollonia church and consist mainly in detachments of bricks or mortar and vegetation growth. The product of the analysis is shown as a Structural Similarity Index Map where the changes are differentiated on the SSI values. Areas where no changes are present are highlighted in green, while changes are highlighted in red/purple, depending on their magnitude.

### 4.1 Aurelian Walls

**K11-K12 section:** The map in Fig. 4 c) shows some brick detachment on the external curtain. These bricks have a low similarity index value and are highlighted in red. Although the primary objective of the analysis was to detect structural changes, in this specific case the SSIM mapping also revealed variations associated with the growth of invasive vegetation (see upper-left portion of the image). These changes, while not structural in nature, contribute to the overall degradation of the wall surface and are thus relevant for conservation monitoring.

Fig. 4 - Detail of the Change Detection Map showing the bricks detachment from the K11-K12 section.

**K12-K13 section:** The map in Fig. 5 c) shows the vegetation growth. The areas of growth can be seen in red due to their low similarity index value.

Fig. 5 - Detail of the Change Detection Map showing vegetation growth from the K12-K13 section.

#### 4.2 Sant'Apollonia Church

**Sant'Apollonia Church:** The map in Fig. 6 c) shows a brick detachment in conjunction with the pre-existing crack.

Fig. 6 - Detail of the Change Detection Map showing the brick detachment from the facing wall of Santa Apollonia Church.

**Sant'Apollonia Church:** In the Change Detection map in Fig. 7 c) it is shown, in purple, a mortar detachment connected to a pre-existing crack.

Fig. 7 - Detail of the Change Detection Map showing mortar detachment from the facing wall of Santa Apollonia Church.

## 5 DISCUSSIONS

The results of this study highlight both the effectiveness and the limitations of using mobile devices, such as smartphones and tablets, for environmental and cultural heritage monitoring. A key logistical advantage observed during field activities was the increased speed of repositioning and orienting the sensor when used manually compared to tripod-mounted systems. In this context, the tablet proved more efficient than the tripod-mounted smartphone, allowing for immediate sensor realignment and reducing the time required for data acquisition. This aspect is particularly relevant in scenarios where monitoring must be performed rapidly or in spatially constrained environments, confirming previous findings on the advantages of mobile device-based monitoring methodologies [12].

The type of changes detected by the two sensors was comparable, suggesting that smartphone and tablet cameras can provide similar results in image-based monitoring. However, a critical aspect to consider is pixel size, which depends not only on the intrinsic characteristics of the sensor but also on the distance from the observed object. In field conditions, this distance is often dictated by logistical constraints rather than experimental design, making it a variable that is not always controllable. Since pixel size directly affects the level of detail in image analysis, these factors must be carefully considered when designing a monitoring approach based on mobile sensors. Previous studies on cultural heritage monitoring through crowdsourcing emphasize the importance of such considerations, particularly when comparing images acquired with different devices under varying shooting conditions [13, 25].

Another critical factor influencing data quality was the variability in lighting conditions. Sudden changes in natural light posed challenges for image acquisition, affecting both processing and interpretation of results. This issue is well-documented in the literature, particularly regarding the impact of brightness variations on image-based analyses [25]. In some cases, excessive differences in lighting conditions between successive images introduced artifacts or inconsistencies in the final data, highlighting the need for adaptive calibration techniques or post-processing corrections to minimize these effects.

To address these lighting-related challenges, during this study we experimented with the adjustment of the  $\alpha$ ,  $\beta$ , and  $\gamma$  exponential parameters in the SSIM computation. Fine-tuning these parameters proved effective in minimizing the influence of illumination variation between successive image acquisitions. By reducing the contribution of luminance and contrast inconsistencies, the analysis becomes more sensitive to actual structural changes rather than to superficial alterations induced by light fluctuations. As a result, this approach enhances the robustness of the change detection process by suppressing noise and emphasizing the “true” changes that are structurally relevant to the monitored object.

An alternative but more computationally intensive strategy could involve the use of a redundant analytical framework, leveraging a broader image database for each observation. This would allow for comparative filtering and normalization across multiple acquisitions, thereby reducing the risk of localized errors introduced by individual source images. While this method could significantly improve result stability, it requires higher processing power and longer computation times, which may limit its applicability in real-time or field-based contexts.

Additionally, adjusting the Window Size (WS) also contributed to filtering the results based on the expected scale of the changes of interest. Smaller WS values allowed for detection of fine-grained alterations, while larger WSs enabled the system to disregard minor fluctuations and focus on broader structural modifications. This flexibility supports the customization of the methodology to different conservation goals, depending on whether fine detail or macroscopic patterns

are prioritized. Moreover, the application of photomonitoring for field-based heritage monitoring must also consider several site-specific environmental factors that may compromise the accuracy and interpretability of the results. As discussed in [26], there are a number of additional techniques and methodological improvements that can be adopted to enhance the overall accuracy, precision, and sensitivity of the analysis. However, the effective implementation of these advanced strategies requires careful calibration and expert knowledge, underscoring the importance of involving trained professionals in the design and interpretation of photomonitoring protocols.

Future studies should explore solutions such as High Dynamic Range (HDR) imaging or automated color correction algorithms to mitigate the impact of uncontrollable lighting variations and improve the robustness of mobile-based monitoring techniques. Alternatively, integrating the workflow presented in this study with Citizen Science approaches would enable the collection of large datasets with high temporal resolution, allowing for the calibration of AI models and mitigating the issue of varying lighting conditions and/or shadows.

Despite these challenges, the results demonstrate that effective monitoring can be achieved without the installation of fixed cameras or permanent sensors, relying solely on mobile devices. This outcome is particularly significant in the context of non-invasive cultural heritage monitoring, where minimizing physical interference is often a priority. Similar conclusions have been reached in Citizen Science studies, which emphasize how mobile technology can be leveraged for large-scale data collection while maintaining high methodological rigor [27, 28]. The ability to conduct fully contactless monitoring without requiring pre-installed instrumentation broadens the applicability of these methodologies, particularly in remote or sensitive sites where conventional instrument installation is impractical.

Overall, these findings support the potential of mobile device-based monitoring approaches as viable alternatives to traditional fixed-sensor systems, offering a flexible and scalable solution for environmental and cultural heritage analysis. However, further refinement of data processing techniques is needed to account for environmental variability and ensure consistency across different devices and observational conditions.

## 6 CONCLUSIONS

The primary objective of this study was to assess photomonitoring as a remote sensing technique for the monitoring and preservation of cultural heritage. The results demonstrate that photomonitoring represents an effective and non-invasive approach to detecting structural variations, such as mortar detachment in the masonry of the Aurelian Walls and the Church of Santa Apollonia in Ferrara. The use of widely accessible devices, including smartphones, tablets, and entry-level cameras, makes this methodology not only cost-effective but also adaptable to the specific requirements of different monitored sites.

The potential integration of citizen science into this framework presents a promising opportunity for expanding spatial and temporal data collection. Volunteers, acting as "sensor-visitors," could contribute images and observations that complement the work of professional conservation teams. This collaborative approach has the potential to enhance data coverage, bridging the gaps between scheduled professional surveys and ensuring more continuous monitoring of degradation dynamics. As noted by Bonney et al. [27], citizen science has been successfully implemented across various scientific fields, significantly improving data collection and public engagement. The economic implications of photomonitoring are particularly relevant, considering the extraordinary volume of images generated daily. It is estimated that in 2023, approximately 4.7 billion photographs were taken per day, predominantly using smartphones (93%), resulting in an annual total of approximately 1.8 trillion images. This statistic highlights an immense, yet largely untapped, visual resource that could be harnessed for cultural heritage monitoring. Through crowdsourcing and advanced data analysis, the simple act of taking a photograph can be transformed into a valuable tool for conservation. This approach not only reduces costs but also increases the frequency and geographical coverage of observations. As the quality of images and computational capabilities continue to improve, the integration of citizen-generated data into heritage conservation strategies could evolve into a sustainable and scalable solution [12].

The findings of this study align with a broader context of citizen science initiatives, which have demonstrated dual benefits: enhancing scientific productivity and democratizing research. Unlike basic crowdsourcing, citizen science projects are designed to achieve specific scientific objectives, involving non-expert volunteers in both data collection and analysis [26]. Contributions from participants are not limited to quantitative data but often include qualitative observations, reports of unauthorized interventions, and even personal narratives related to historic sites. As highlighted in studies such as that of Constantinidis [28], these elements provide valuable contextual information that can influence both short-term conservation decisions and long-term management strategies.

Looking ahead, the integration of photomonitoring with structured citizen science programs could be further explored through collaborations with other institutions (i.e. Superintendences for Cultural Heritage), and local governments. A promising development in this direction is the potential use of civil service programs for structured photomonitoring campaigns. By engaging volunteers through civil service initiatives, it would be possible to create systematic and large-scale monitoring efforts that ensure sustained data collection and improved methodological rigor. This approach could also provide training opportunities, fostering a new generation of conservation advocates equipped with digital skills relevant to heritage preservation.

As imaging technologies and computational capabilities continue to advance, the integration of citizen-generated data into professional conservation strategies could evolve into a

sustainable and idely adopted practice. Future research should focus on refining methodologies to optimize data acquisition and processing while exploring policy frameworks that support the ethical and effective implementation of citizen science in heritage conservation. By embracing photomonitoring as a collaborative tool, the preservation of cultural heritage can be made more accessible, inclusive, and resilient to emerging threats.
