**ABSTRACT:** While Structural Health Monitoring (SHM) has potential to aid bridge managers, its adoption has been limited, with one of the challenges being determining a bridge's condition without a historical reference point for that structure. Researchers have started investigating Population-Based Structural Health Monitoring (PBSHM) to tackle this, facilitating the sharing of data from comparable structures. The key advantage of PBSHM is that it potentially enables us to use data from one structure to make inferences about the health of another structure in the same population.

Whilst, to date, populations that have been used for PBSHM have been defined using structural similarities alone, you might be missing out on information that could be useful for bridge managers, which raises the question: Could we define populations in a different way? This research investigates if it is potentially useful to define a population of bridges based on whether they experience the same environmental conditions. To answer this, long-term natural frequency data from two bridges close to each other are analysed to determine the level of correlation between them. This work shows that it may be potentially useful to define populations based on factors other than structural similarities, which allows greater opportunities for PBSHM.

**KEY WORDS:** Structural Health Monitoring (SHM); Population-Based Structural Health Monitoring (PBSHM); Bridge Monitoring; Natural Frequencies; Environmental Effects; Correlation Analysis; Temperature Influence; Vibration Data; Graph-Based Structural Similarity; Machine Learning in SHM.

## 1 INTRODUCTION

### 1.1 Challenges in current bridge inspection

Bridges are vital pieces of infrastructure, enabling the movement of goods and people [1]. Currently, bridges are monitored primarily through periodic visual inspections, which provide valuable insights. However, these visual inspections can be subjective, and some defects, such as internal cracks or corrosion, may not be visible during routine inspections.

In the worst-case scenario, undetected structural deficiencies can lead to catastrophic bridge failures, resulting in substantial financial costs and loss of life. For example, in 2018 the Morandi Bridge failed, killing 43 [2]. Additionally, the subjectivity of visual inspections makes it challenging to efficiently allocate limited resources. In 2024, the Carola Bridge in Dresden, Germany, collapsed due to hydrogen-induced stress corrosion cracking in the bridge's steel components [3]. The aftermath of the collapse can be seen in Figure 1. This type of corrosion began during the bridge's construction between 1967 and 1971 and progressed internally over decades, remaining undetectable through standard visual inspections. The eventual collapse of the Carola Bridge is a good example of highlighting a significant limitation of traditional monitoring methods.

Figure 1. Carola Bridge (Dresden, 1971).

### 1.2 Background on Structural Health Monitoring (SHM)

Over the past 30 years, there has been increasing interest in using quantitative data, such as acceleration or displacement, to assess bridge health, a practice known as Structural Health Monitoring (SHM) [4]. Its widespread adoption has been limited, however, with one of the challenges being determining whether a bridge is healthy or damaged without a historical reference point for that structure. This process is challenging because SHM systems often rely on baseline data to detect structural deterioration. If you do not take measurements from the 'healthy' state, it is difficult to determine the difference between normal changes (caused by things like weather or traffic) and real damage, which raises the risk of false alarms or missed defects [4].

### 1.3 Overview of Population-Based Structural Health Monitoring (PBSHM) to date and current limitations

Researchers have begun exploring Population-Based Structural Health Monitoring (PBSHM) as a solution to address the challenges in traditional SHM, enabling the sharing of data across comparable structures. It allows data from one structure to be used to make inferences about the health of another structure within the same ‘population’ [5].

The foundations of PBSHM have been established through a series of published papers *Towards Population-Based Structural Health Monitoring* [6, 5, 7, 8, 9, and 10]. These papers examine methods for representing structures as graphs and developing similarity measures to compare them.

PBSHM extends traditional SHM by focusing on monitoring populations of structures rather than individual assets. Unlike conventional SHM, which relies on baseline data for a single structure, PBSHM enables the transfer of knowledge across a group of similar structures. By leveraging data from one structure, engineers can make inferences about the condition of others within the population, helping to mitigate the challenge of missing baseline data [5].

However, for PBSHM to be effective, the population must consist of sufficiently similar structures. If the differences are too significant, knowledge transfer may become inaccurate, leading to negative transfer; indeed, the application of insights from one structure can act to introduce error rather than improving understanding [7].

In practice, populations of bridges in PBSHM are typically formed by identifying structures that are structurally similar. For instance, Gosliga et al. [11] identified a pair of similar truss footbridges and a group of two beam-and-slab bridges. These bridges were represented as graphs, and using a graph matching algorithm, a high similarity metric was observed. Following field testing, the authors compared their dynamic responses and confirmed that the frequencies and mode shapes of bridges identified as similar through graph matching were indeed consistent [12].

If populations are defined solely based on structural information, potentially valuable factors that could aid in SHM might be overlooked. This raises the question: Could populations be defined differently? For example, a population could include bridges within the same geographical area, meaning they would be subject to the same environmental conditions. While populations in PBSHM have thus far been considered based on structural similarity, exploring alternative conceptualisations of populations may prove to be equally useful.

### 1.4 Contribution of this work

To explore whether bridges located in close proximity and therefore notionally experiencing the same environmental conditions could potentially form a population, long-term natural frequency data from two bridges 540 metres apart were analysed to determine the level of correlation between them. The results suggest that defining populations based on factors other than structural similarities could be potentially valuable, offering greater opportunities for PBSHM.

## 2 BRIDGE SITES USED AND TEMPERATURE CORRELATION BETWEEN SITES

### 2.1 Bridge selection and data collection

For this study, two bridges located 540 metres apart along the same river were selected. Bridge 1 is a 98-metre-long, 27-metre-wide bowstring girder bridge (Figure 2a), while Bridge 2 is a 76-metre-long, three-span composite concrete and steel bridge (Figure 2b). The proximity of these bridges allowed for a controlled investigation of how environmental factors influenced their dynamic behaviour.

Figure 2. (a) Schematic of Bridge 1 (b) Schematic of Bridge 2.

As described by O’Higgins et al. [13], long-term vibration data was collected using a single accelerometer on each bridge. It was observed that positioning the sensor near the quarter-span point on both bridges allowed it to detect most modes and frequencies.

The Structural Health Monitoring (SHM) system used for long-term monitoring consisted of one MEMS accelerometer and one environmental sensor. The accelerometer employed was the Multifunction Extended Life (MEL) Data Logger from Gulf Coast Data Concepts. This accelerometer was housed in an enclosure, which was then attached to the deck of each bridge. One of these enclosures is shown in Figure 3.

The environmental variables were measured using an environmental sensor capable of recording both air temperature and humidity. To ensure accurate temperature readings, the sensors were not placed within the enclosure to avoid the effects of solar gain. Instead, they were positioned out of direct sunlight to provide a representative measure of the local air temperature. On each bridge, the temperature sensors were placed on the abutment shelf or at the base of an abutment, both out of direct sunlight.

Figure 3. Monitoring enclosure and MEL data.

## 2.2 Correlation of temperature data

A key objective of this study was to determine whether the two bridges experienced similar environmental conditions. To assess this, temperature data from both bridges were compared using a hexbin plot (Figure 4). A hexbin plot is a 2D histogram where the bins are hexagonal, and the colour intensity represents the number of data points within each bin.

Figure 4 shows a strong positive correlation between the temperature measurements of both bridges, with a correlation coefficient of 0.98, indicating that higher temperatures on Bridge 2 correspond to higher temperatures on Bridge 1. This suggests that the two bridges experience nearly identical environmental exposure.

However, some variability was observed between January 6 and February 17, during which Bridge 1 exhibited slightly higher temperatures in the 0-5°C and 5-10°C ranges. The cause of these anomalies remains uncertain, but potential explanations include differential shading and differences in material thermal properties.

While these discrepancies are noticeable in the plot, they do not significantly impact the overall trend. There are up to 14,000 data points in the yellow bins and fewer than 2,000 data points in the dark blue bins, reinforcing the stability of the best-fit line. This indicates that most of the data follows a linear relationship, with only a brief period showing anomalous values.

Figure 4. Temperature data from Bridge 1 versus temperature data from Bridge 2.

## 3 NATURAL FREQUENCY ANALYSIS

### 3.1 Extraction of Natural Frequency

As per O'Higgins et al. [13], acceleration data was segmented into 30-minute intervals and processed using the Stochastic Subspace Identification (SSI) method to extract the bridge frequencies. The data was recorded from October 2018 to May 2021, though some gaps occurred due to limited personnel availability for data collection and disruptions caused by the COVID-19 pandemic.

For this work, a simple outlier analysis was undertaken on natural frequency data so that the complexity of data analysis was reduced and data visualisation was clearer. Any data point that was more than three scaled median absolute deviations from the median of the data was removed.

### 3.2 Time-domain work

Figure 5 presents the time-series data for the natural frequencies of both bridges. Bridge 1 exhibits five natural frequencies ranging from approximately 1.2 Hz to 5.2 Hz, while Bridge 2 has five natural frequencies ranging from approximately 2.7 Hz to 9.3 Hz. Overall, Bridge 2 demonstrates higher frequency values compared to Bridge 1.

Figure 5. All frequency data over the whole monitoring period.

Figure 6 consists of two subplots, both illustrating the relationship between bridge frequencies and temperature over time. Frequency and temperature are plotted against the left and right vertical axes, respectively.

In plot (a), the temperature (purple line) exhibits seasonal variations, with distinct peaks and troughs. When analysing annual data, a seasonal trend is observed for frequency 5 of Bridge 1 and frequency 4 of Bridge 2, with evidence of an inverse correlation between the frequencies and temperature. Additionally, Bridge 1 and Bridge 2 appear correlated, with both bridges showing an inverse relationship with temperature on an annual scale.

In plot (b), which focuses on daily temperature cycles, there is some correlation between the two frequencies. As seen in plot (a), higher temperatures correspond to lower frequency values, a trend that is even more noticeable in plot (b). This aligns with expectations, as increasing temperature may cause a reduction in structural stiffness, leading to lower natural frequencies [14].

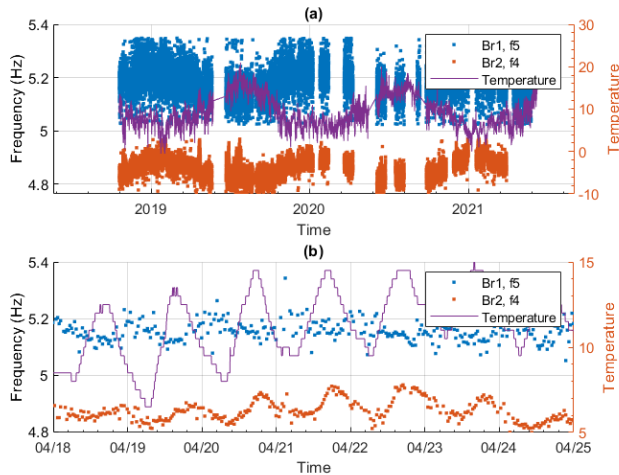

Figure 6. Frequency 5 of Bridge 1 and frequency 4 of Bridge 2 (a) Whole monitoring period (b) A week of monitoring data.

### 3.3 Frequency correlation work

Figure 7 presents hexbin plots for all the frequencies of Bridges 1 and 2, with the correlation coefficient displayed in the top left

Figure 7. All correlation plots for all the frequencies.

corner of each plot. The histograms on the diagonal illustrate the distribution of each frequency.

The figure reveals a strong correlation between frequencies within the same bridge (rows 1-5, columns 1-5). However, the most relevant information is in the top right section of the figure, highlighted by a dashed black box, which shows the correlation between frequencies of Bridge 1 and Bridge 2. The column references (1 to 10) are displayed at the top, while the row references are shown on the right.

For example, the plot in row 1, column 6 represents the correlation between frequency 1 of Bridge 1 and frequency 1 of Bridge 2, with a correlation coefficient of 0.31, indicating a relatively weak correlation. Similarly, the plot in row 1, column 7 shows the correlation between frequency 1 of Bridge 1 and frequency 2 of Bridge 2, with a coefficient of 0.5. A zoomed-in view of the area inside the dashed black box in Figure 7 is shown in Figure 8. Figure 8 illustrates the varying correlations between frequencies, with correlation coefficients ranging from 0.13 to 0.64.

Figure 8. Correlation between pairs of frequencies in Bridge 1 and Bridge 2.

The highest correlation of 0.64 is observed between frequency 3 of Bridge 1 and frequency 2 of Bridge 2 (shown in row 3, column 7 in the dashed red box in Figure 8), and this is shown on a larger scale in Figure 9.

The lowest correlation of 0.13 is observed between frequency 4 of Bridge 1 and frequency 3 of Bridge 2 (shown in row 4, column 8 in the dashed magenta box in Figure 8), and this is shown on a larger scale in Figure 10.

Figure 9. Most correlation between frequencies.

Figure 10. Least correlation between frequencies.

Having identified the pair of frequencies with the highest correlation (Figure 9) and the lowest correlation (Figure 10), we now look at the time series plots associated with these frequencies to try and get further insight into why some are better correlated than others. To this end, Figure 11 presents the pair of frequencies with the highest correlation, specifically frequency 3 of Bridge 1 (plotted against the left-hand vertical axis) and frequency 2 of Bridge 2 (plotted against the right-hand vertical axis). Plot (a) displays data spanning the entire monitoring period from October 2018 to May 2021, while plot (b) focuses on a 7-day period. The strong correlation between these frequencies is evident from the synchronised sinusoidal patterns observed in both bridges.

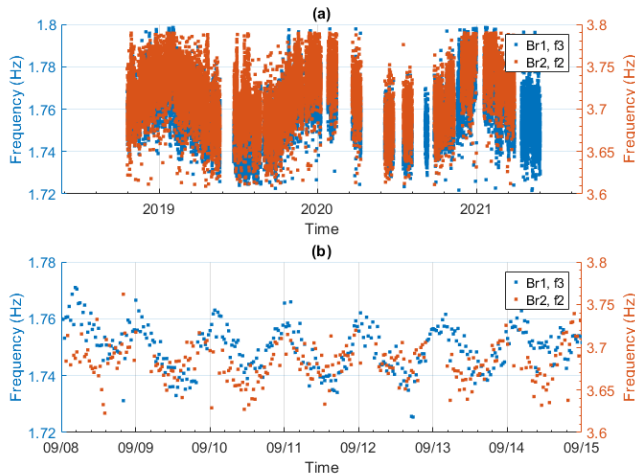

Figure 11. Frequency 3 of Bridge 1 and frequency 2 of Bridge 2 (a) Whole monitoring period (b) A week of monitoring data.

Figure 12 shows the least correlated frequencies between both bridges, specifically frequency 4 of Bridge 1 and frequency 3 of Bridge 2. This figure follows the same format as Figure 11, with the overall monitoring period shown in plot (a) and the same 7-day period shown in plot (b). When plotted as a time series, these natural frequencies exhibit a lower correlation to those shown in Figure 11, which is consistent with the expectations based on the hexbin plot in Figure 10.

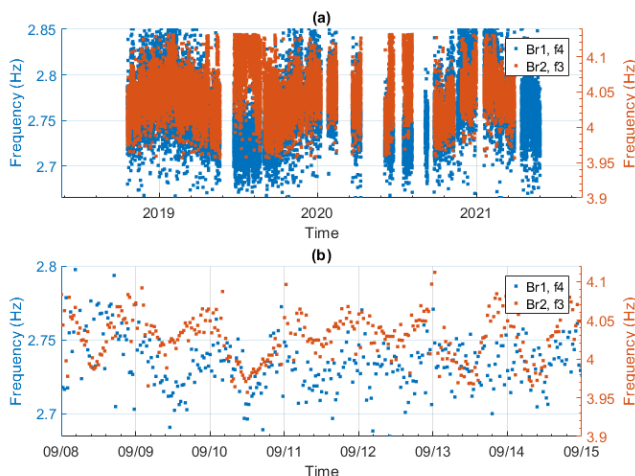

Figure 12. Frequency 4 of Bridge 1 and frequency 3 of Bridge 2 (a) Whole monitoring period (b) A week of monitoring data.

## 4 CONCLUSION

Temperature data from two bridges located near each other shows a strong correlation (with a correlation coefficient of 0.98), suggesting that the bridges experience similar environmental conditions. The natural frequencies of the two bridges also exhibit significant correlation, with coefficient values for some pairs of frequencies reaching up to 0.64. Traditionally, Population-Based Structural Health Monitoring (PBSHM) has defined populations based on structural similarities. This paper suggests the potential for defining populations based on shared environmental conditions. Given the sufficient correlation in temperature and frequency data, it may be possible to infer information about Bridge 1 based on the data collected from Bridge 2. This will be further explored in future work through correlation analysis, such as cointegration on the data.

Future studies will examine a wider range of bridge types to determine whether the same correlations apply. Additional research could also explore the conditions under which these correlations remain valid and when they begin to break down.

**ABSTRACT:** Structural Health Monitoring (SHM) plays a vital role in ensuring the safety, durability, and operational efficiency of critical infrastructure. Traditional SHM methods often fall short in detecting subtle damage patterns, particularly when faced with noisy signals, missing data, or the complex, time-varying behavior of real-world structures. To address these challenges, this study presents a hybrid framework that integrates Discrete Wavelet Transform (DWT) with a deep learning architecture combining Convolutional Neural Networks (CNN) and Long Short-Term Memory (LSTM) networks. The proposed approach begins by segmenting long-duration acceleration signals into fixed-length windows and applying DWT to extract informative time–frequency features. CNN layers are then used to learn spatial representations from the transformed data, while LSTM layers capture temporal dependencies critical for detecting structural changes over time. The model is trained and evaluated using benchmark SHM datasets under both healthy and damaged states. Moreover, supervised learning is utilized for accurate damage severity classification, while unsupervised learning is used to facilitate anomalies detection without relying on labeled samples. Experimental results demonstrate improved performance in classifying damage conditions compared to conventional machine learning approaches. This framework offers a robust and scalable solution for data-driven SHM, supporting more accurate diagnostics and paving the way for predictive maintenance in complex monitoring environments.

**KEY WORDS:** SHM; Deep Learning; Damage Detection; Wavelet; Hybrid AI Models.

## 1 INTRODUCTION

Structural Health Monitoring (SHM) has become an essential field across civil, mechanical, and aerospace engineering, ensuring the functionality, longevity, and safety of critical infrastructure. SHM enables periodic or continuous assessment of structural performance and supports the early detection of system degradation. This allows for timely maintenance interventions and reduces the risk of unexpected failures. As infrastructure systems age and endure increasing stress from environmental and operational loads, effective SHM plays a crucial role not only in ensuring safety but also in optimizing life-cycle costs and extending service life.

Over the past few decades, SHM has evolved significantly, with numerous techniques developed to detect and assess damage and degradation in critical infrastructure. Conventional SHM approaches frequently rely on manual feature extraction, threshold-based anomaly detection, and classical signal processing techniques such as the Fast Fourier Transform (FFT) and Principal Component Analysis to extract frequency-domain features and reduce data dimensionality [1]. While these methods have demonstrated effectiveness in controlled environments or specific applications, they often struggle in real-world conditions where non-stationary signals, sensor noise, and data loss are prevalent. Moreover, they are often inadequate for capturing the complexity of real-world structures, particularly those exhibiting nonlinear and time-varying behavior. The reliance on expert-defined thresholds and manual feature selection further limits their scalability and suitability for automated or large-scale SHM deployment. These limitations underscore the need for more adaptive,

intelligent, and data-driven SHM methodologies capable of handling the dynamic behavior of structural systems.

To address these limitations, classical machine learning (ML) methods such as Decision Trees, k-Nearest Neighbors (k-NN), and Support Vector Machines (SVM) have been progressively applied to SHM tasks such as damage detection and anomaly classification [2]. These models offer greater adaptability than rule-based techniques and have shown effectiveness in certain SHM scenarios. However, they largely depend on handcrafted or engineered features, which may fail to capture the full complexity of structural responses. Also, classical ML algorithms often struggle with noisy, sequential data, or high-dimensional, limiting their scalability and generalizability in complex monitoring environments.

In response to the limitations of classical machine learning approaches, deep learning techniques have gained significant attention in SHM due to their ability to automatically learn hierarchical and abstract representations from raw sensor data. Models such as Convolutional Neural Networks (CNNs), Recurrent Neural Networks (RNNs), and their variants have shown promising results in tasks such as damage localization, classification, and prognostics. Unlike traditional methods, deep learning (DL) models can effectively capture nonlinear, time-dependent patterns in complex vibration signals without the need for manual feature engineering. Their robustness to noise, scalability to large datasets, and suitability for end-to-end learning make them especially well-suited for real-world SHM system operating under dynamic and uncertain conditions.

More recently, DL models, mainly CNNs and Long Short-Term Memory (LSTM) networks have demonstrated notable

success in processing spatial and temporal data for SHM applications. CNNs are well-suited for extracting spatial features from raw sensor data or transformed representations such as spectrograms [3], while LSTMs effectively model long-term dependencies in time-series signals [4]. Several studies have also proposed hybrid CNN–LSTM frameworks that jointly capture spatial and temporal patterns, resulting in improved damage detection accuracy, especially in complex structural systems [5].

Despite these advancements, significant challenges remain in applying AI to SHM, including the presence of noise, missing data, and the continued need for domain-specific feature engineering. Furthermore, many existing AI-based SHM approaches tend to overlook the advantages of time–frequency domain analysis an essential component for capturing complex, transient structural responses [6]. To address this gap, wavelet transforms have garnered significant attention in SHM due to their ability to localize features simultaneously in both the time and frequency domains. Unlike the FFT, which provides only a global view of frequency content, wavelet analysis enables the detection of localized, transient events such as those caused by impact damage or cracking [7]. The Discrete Wavelet Transform (DWT) has been widely used for feature extraction, denoising, and time–frequency characterization in structural vibration signals.

However, wavelet-based methods typically require the manual selection of proper mother wavelet and decomposition level, and often depend on thresholding heuristics. Also, wavelets are often used only as preprocessing tools, rather than being fully integrated into modern AI systems [8]. These limitations constrain their effectiveness in contemporary deep learning–based SHM frameworks. Although progress has been made, a clear gap remains in the integration of wavelet-based signal processing with advanced AI architectures. Existing approaches often either apply wavelets solely for noise reduction without enabling feature learning, or use DL models without exploiting the time–frequency structure inherent in SHM signals [9], [10].

To bridge these gaps, this study proposes a novel deep learning framework that seamlessly integrates the DWT with a hybrid CNN–LSTM architecture. The DWT is employed to extract multiscale time–frequency features from segmented acceleration signals, capturing both transient and stationary structural behaviors. These wavelet-derived features are then processed by a CNN to learn spatial patterns, followed by an LSTM network that models temporal dependencies across time steps. The framework supports both supervised damage classification and unsupervised anomaly detection, making it adaptable to a wide range of SHM scenarios and contributing to the advancement of intelligent, data-driven infrastructure monitoring.

## 2 PROPOSED FRAMEWORK

This section describes proposed SHM, which integrates wavelet-based signal processing with a hybrid deep learning combining CNN and LSTM networks as shown in Figure 1. The framework is designed to extract meaningful spatial and temporal features from structural vibration signals to enable reliable damage detection and anomaly identification under complex monitoring scenarios.

The process begins with long-duration signals, which are preprocessed and segmented into fixed-length time windows to standardize the input size and ensure consistency. Each segment is then processed using the DWT, which decomposes the signal into multiscale time–frequency components. These wavelet coefficients capture both localized and global signal characteristics and serve as rich input features for the deep learning model.

The CNN component s used to extract spatial features from the wavelet coefficients, while the LSTM network captures temporal dependencies across time window. This combination allows the system to recognize both long-term structural trends and transient events, improving its effectiveness in both damage classification and anomaly detection tasks. Both learning strategies are supported within the framework: supervised learning uses labeled damage states, while unsupervised learning applies autoencoders and clustering on latent features.

This integrated architecture leverages the strengths of both wavelet-based signal processing and DL: it enables automated feature learning from rich time–frequency data, enhances robustness to noise and nonstationary, and improves classification and anomaly detection performance across a variety of structural conditions. The following sections detail the data preprocessing, wavelet-based signal decomposition, and the architecture and training process of the DL model.

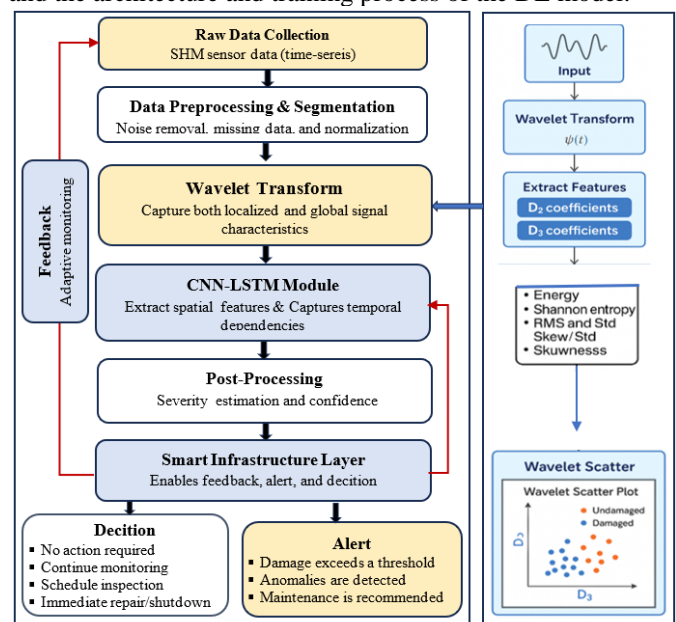

Figure 1. Hybrid methodology combining wavelet-based signal processing with deep learning.

## 3 EXPERIMENTAL VALIDATION USING TIANJIN YONGHE BRIDGE MONITORING DATA

The proposed framework was validated using data from the Tianjin Yonghe Bridge, a cable-stayed structure located in China connecting Tianjin and Hangu. The bridge spans 510 m, consisting of a 260 m main span and two 25.15 + 99.85 m side spans. The bridge wide is 11 m (9 m for vehicles and 2 x 1 m for pedestrians [21]). Originally constructed in 1983 and opened to traffic in 1987, the bridge began exhibiting structural degradation after nearly two decades of service, including the development of 2 cm cracks in the midspan and signs of

corrosion in the stay cables. To address these issues, major repairs were carried out between 2005 and 2007, including full replacement of all stay cables and reinforcement of the midspan girder [16], [17]. Following these repairs, a SHM system was installed by the Harbin Institute of Technology to monitor the bridge's condition under both undamaged (January 17, 2008) and damaged (e.g., July 31, 2008) states. The system included over 150 sensors at critical structural components such as the deck, towers, and cables including 14 single - axis accelerometers installed along the deck and a dual-axis sensor mounted at the top of the south tower.

The vibration data collected by this SHM system were used to evaluate the effectiveness of the proposed wavelet-based CNN-LSTM framework for damage detection and anomaly identification. The signals were segmented and preprocessed to ensure consistency, then processed using discrete wavelet transform before being fed into the hybrid deep learning model. This case study demonstrates the applicability of the proposed method to complex, real-world SHM scenarios and confirms its potential for robust damage classification and condition assessment.

Figure 2. General view of Tianjin Yonghe bridge

Figure 3. Tianjin Yonghe bridge elevation and health monitoring system

### 3.1 Visualization of structural acceleration data

To illustrate the structural vibration data characteristics, Figure 4 shows time-domain acceleration signals recorded from the bridge deck over a duration about 3600 s for healthy and damaged conditions state. These signals reflect the structure dynamic response under operational conditions. As shown, there is transient spikes, variations in amplitude and frequency content indicate changes in structural behavior, making them suited for SHM applications. Also, the acceleration data show nonstationary behavior that motivate the use of advanced time-frequency analysis. In this study, long-duration acceleration signals were segmented into fixed-length windows (15 minutes) to standardize input size and increase the number of training samples. Figure 5 shows segmentation of a 1-hour acceleration signal into four 15-minute windows. Each segment

is color-coded and vertically offset for clarity. This approach facilitates data preparation for time-series learning models and ensures consistency across training samples [4]–[6]. Also, these visualizations help highlight differences in dynamic response and support the need for data-driven SHM approaches.

#### 4 SIGNAL DECOMPOSITION USING DISCRETE WAVELET TRANSFORM

To capture both time and frequency characteristics of structural vibration signals, the DWT was employed for signal decomposition. Unlike the FFT, which provides only global frequency information, DWT enables multiresolution analysis by breaking the signal into approximation and detail coefficients across multiple levels. This allows transient events and localized structural responses often indicative of damage to be effectively identified. In this study, each acceleration signal segment was decomposed using an appropriate mother wavelet and a predefined number of levels, facilitating the extraction of discriminative time–frequency features suitable for both supervised and unsupervised learning models. Based on our previous studies [11], [12], the db3 wavelet was selected as due to its effectiveness in capturing signal characteristics relevant to structural changes and level 4 was chosen as optimal level for further analysis based on optimal energy and classification performance observed in all extracted features Figure 5.

Figure 6. correlation index, root mean square and relative energy versus decomposition level

The signal is decomposed up to level 4, resulting in one approximation signal (A4) and four detail signals (D1–D4). In wavelet analysis, signal decomposition is carried out by projecting the signal onto subspaces of scaling and wavelets basis functions at different scales and their transmission. Figure 7 shows multi-level wavelet decomposition process of the signal. The original signal is recursively decomposed into approximation and detail components. Each approximation captures low-frequency trends (global behavior and long-term structure), while the corresponding detail captures high-frequency information related to transient events or damage. After 4 levels, the final detail and approximation components are used for damage detection and anomaly identification.

Figure 7. multi-level wavelet decomposition process of the signal.

Figure 8 illustrates the four-level wavelet decomposition of the second 15-minute segment of the acceleration signal using the db3 wavelet. The signal is decomposed into detail coefficients (CD1–CD4) capturing high- to low-frequency components, and an approximation (CA4) representing the global, low-frequency trend. This multilevel decomposition enables the extraction of both transient and long-term structural behaviors, supporting more effective damage detection and anomaly identification in SHM applications.

Figure 8. Multi-Level Discrete Wavelet Coefficients of the Acceleration Signal (db3, 4 Levels)

##### 4.1 Features extraction

Feature extraction is a vital step in data-driven structural health monitoring (SHM), converting raw acceleration signals into meaningful representations that support effective damage detection and classification. In this study, wavelet-based time–frequency decomposition is applied to one signal segment, and from each of the four detail sub-bands (D1 to D4), seven statistical features are computed: mean, standard deviation, root mean square, energy, skewness, kurtosis, and Shannon entropy. This results in 28 features for that segment, as summarized in Table 1. While additional segments and features were extracted in the full analysis from detail and approximation coefficients, only this representative example is presented here due to space constraints. These features serve as inputs to deep learning models, enabling them to learn complex structural dynamics and behavioral patterns.

Table 1. Extracted Wavelet-Based Statistical Features

Level	Sub band	Mean	Std. Dev	RMS	Energy	Skewness	Kurtosis	Entropy
Level 1	D1	D1_F1	D1_F2	D1_F3	D1_F4	D1_F5	D1_F6	D1_F7
Level 2	D2	D2_F1	D2_F2	D2_F3	D2_F4	D2_F5	D2_F6	D2_F7
Level 3	D3	D3_F1	D3_F2	D3_F3	D3_F4	D3_F5	D3_F6	D3_F7
Level 4	D4	D4_F1	D4_F2	D4_F3	D4_F4	D4_F5	D4_F6	D4_F7

To improve model interpretability and efficiency, feature importance analysis is carried out to select the most informative variables, allowing the AI model to concentrate on features with the highest predictive value. Figure 9 shows feature importance ranking showing the relative effect of each input variable on the model's prediction. Features with higher importance values contribute more to decision-making, highlighting the most critical parameters for accurate structural condition assessment.

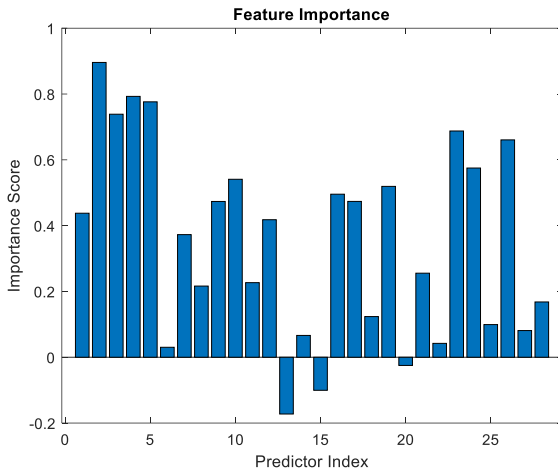

Figure 9. Feature importance ranking illustrating the relative influence of each input variable

## 5 NEURAL NETWORKS MODEL

Neural networks have widely used in SHM due to their ability to model complex data patterns. Deep architectures like CNNs and LSTMs are mainly effective for capturing spatial and temporal features. A CNN usually includes convolutional layers, pooling operations, and one or more fully connected layers. These components collaboratively extract and refine informative features from input data. The fully connected layers serve as the classifier based on the learned features. Through a sequence of operations, the CNN can reduce the dimensionality, which improves computational efficiency and support more effective model training [15]. LSTM is a variant of recurrent neural networks designed to learn long-term dependencies in sequential data. Its internal structure includes memory cells and gating mechanisms, exactly the input, forget, and output gates, which control the info flow through time. This architecture allows the LSTM to retain relevant time-based features and discard irrelevant ones, making it effective in time-dependent tasks [16]. Combining these models offers improved performance in analyzing dynamic, time-varying signals. This hybrid model is well-suited for SHM tasks, as it can capture both spatial features, such as vibration signatures, and temporal patterns, such as degradation over time both of which are critical for accurate classification and anomaly detection. A detailed summary of the proposed hybrid CNN-LSTM configuration is given in Table 2. Further architectural specifications and theoretical background can be found in [12].

Table 2. A detailed summary of the proposed hybrid CNN-LSTM configuration

Layer	Input Shape	Output Shape	Kernel Number	Kernel Size	Activation
Convolution 1-D	(500, 1)	(496, 32)	32	5	ReLU
Max Pooling 1-D	(496, 32)	(248, 32)	—	2	—
Convolution 1-D	(248, 32)	(244, 64)	64	5	ReLU
Max Pooling 1-D	(244, 64)	(122, 64)	—	2	—
LSTM	(122, 64)	(122, 64)	—	—	tanh

## 6 RESULTS AND DISCUSSION

All experiments were executed in MATLAB R2023a using built-in toolboxes for signal processing and deep learning. Signal processing tasks and wavelet analysis, were done using DWT with db3. Features were extracted from detail components obtained through decomposition, up to level 4. For supervised classification tasks, SVM, Random Forest, CNN, LSTM, and CNN-LSTM hybrids models were trained with appropriate layer configurations. A max of 100 epochs was used with early stopping if validation performance stagnated for 10 epochs. The Adam optimizer with a learning rate of 0.001, cross-entropy loss, mini-batch size of 64, and dropout (rate = 0.3) were used to ensure convergence and prevent overfitting. For unsupervised anomaly detection, autoencoders were trained using wavelet-based features extracted from database. MSE between reconstructed and raw signals was used as the reconstruction loss. Thresholds were determined from the 95th percentile of reconstruction error on training data. To assess performance, multiple evaluation metrics were used, accuracy, precision, recall, F1-score, and area under the ROC curve. Visual diagnostics such as ROC curves were generated for comprehensive interpretation. Model strength was validated using 5-fold cross-validation with stratified sampling to preserve balanced class distributions across damage states. The proposed WCNN-LSTM framework outdid existing SHM methods across many assessment metrics. The CNN-LSTM without wavelet achieved 86-accuracy, and wavelet-based models exceeded 89 accuracies, with notably higher F1-scores and. The WCNN-LSTM hybrid further contributed by capturing both spatial and temporal features, leading to better generalization across damage types and environmental conditions. As shown in Table 3, model assessment using metrics such as accuracy, precision, and recall confirms that the proposed framework's robustness.

Table 3. Model assessment using metrics such as accuracy, precision, and recall

Model	Accuracy (%)	Precision (%)	Recall (%)	F1-Score (%)
SVM (RBF kernel)	78.2	75.5	74.8	75.1
Random Forest	80.6	78.1	76.5	77.3
CNN Only	83.7	82	81.3	81.6
LSTM Only	84.1	82.5	82	82.2
CNN-LSTM Hybrid	86.4	85.1	84.2	84.6
Proposed Wavelet-CNN-LSTM	<b>89.2</b>	<b>88</b>	<b>87.4</b>	<b>87.7</b>

For unsupervised anomaly detection, autoencoders were trained using wavelet-based features extracted from database. To evaluate classification performance across five classes, we compared per-class ROC curves for the baseline CNN and the enhanced WCNN model. The comparison of ROC curves in Figure 10 highlights that the Wavelet-Combined CNN (WCNN) model offers more balanced and robust performance across all damage classes compared to the conventional CNN. While the CNN model achieves higher AUC values in some individual classes (e.g., Class 4), it performs poorly in others (e.g., Class 0). In contrast, the WCNN demonstrates more consistent AUC scores across all classes, indicating improved generalization and reliability for multi-class damage detection. This suggests that integrating wavelet-based time-frequency features enhance the model's ability to capture both transient

and global signal characteristics, leading to superior classification performance in structural health monitoring applications.

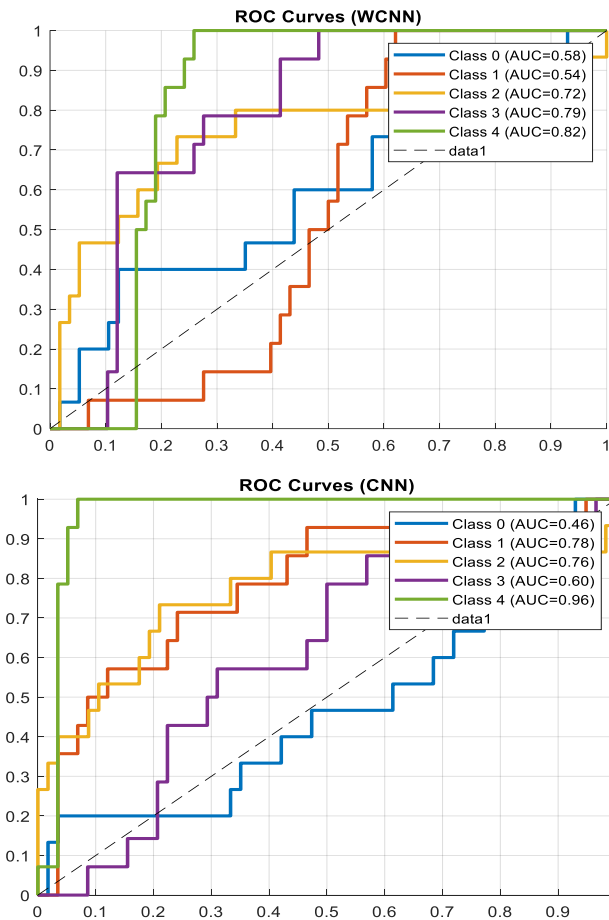

Figure 10. ROC curves for both CNN and WCNN models

Figure 11 shows the progression of training and validation accuracy over 100 epochs. While both curves show consistent improvement and reach above 93%, a slight performance gap remains, particularly toward the final epochs. The training accuracy marginally exceeds the validation accuracy, suggesting that some degree of overfitting may still be present. Also, the flattening of both curves indicates that the model has reached a learning plateau, beyond which additional training yields diminishing gains. This suggests that while the current architecture is effective, there is still room for enhancement, particularly in improving generalization, increasing robustness across classes, or reducing confusion between structurally similar samples. Future improvements could include techniques such as attention mechanisms, hybrid feature fusion, or advanced assembling strategies to push performance beyond the current ceiling.

Figure 11. Receiver Operating Characteristic in Class 1 vs. Rest AUC = 0

Figure 12 shows the reconstruction errors distribution for normal and anomalous data. Normal samples exhibit low reconstruction errors, predominantly below the threshold of 0.03, indicating accurate reconstruction by the model. In contrast, irregular samples show higher reconstruction errors, with important portion exceeding the threshold. This separation reveals the effectiveness of reconstruction error as a discriminative feature for anomaly detection, with the threshold serving as a decision boundary between damaged and healthy states. The results confirms that error of reconstruction effectively separates anomalous and normal states, supporting its use as a reliable indicator for anomaly detection in SHM.

Figure 12. Wavelet-Autoencoder Reconstruction Error Distribution

## 7 CONCLUSION AND FUTURE WORK

This paper presented a wavelet-based deep learning framework for structural health monitoring (SHM) using benchmark data. By combining Discrete Wavelet Transform (DWT) for time-frequency feature extraction with a hybrid CNN-LSTM architecture, the method aimed to address some of the limitations in conventional SHM approaches, particularly under noisy and complex signal conditions. Experimental results showed that the proposed approach offered

improvements over baseline ML and standard DL models in terms of classification performance, including accuracy and AUC. The framework supported both supervised and unsupervised learning modes, making it adaptable to different data labeling scenarios.

Nevertheless, further research is needed to improve the framework's performance and adaptability under more diverse operational conditions, larger datasets, and real-time deployment constraints. Future work may focus on optimizing the model architecture, exploring additional feature representations, and validating performance under real-world deployment scenarios.

**ABSTRACT:** Vibration-based Structural Health Monitoring is of the foremost importance for critical civil infrastructures, especially concerning the safety of the train transport network. In fact, even minor structural changes might cause derailment and potentially fatal accidents. This contribution reports some preliminary analyses carried out on 52 accelerometric recordings collected over two consecutive days from three spans of a railroad bridge. The acquisitions include several train passages and the quiet periods between them, when the structure was excited only by ambient vibrations (i.e. random microtremors), thus allowing Ambient Vibration Testing (AVT). Specifically, a newly developed Automated Operational Modal Analysis (AOMA) algorithm was applied. Its results are here compared to state-of-the-art commercial software (ARTEMIS). Some considerations regarding the effects of train passages are also briefly reported, as well as directions for current and future research work in this field.

**KEYWORDS:** automated operational modal analysis, railway bridge, structural health monitoring, operational modal analysis, vibration-based monitoring

## 1 INTRODUCTION

Railways are an essential component of civil infrastructures, representing one of the most critical parts of national and transnational transportation and communication systems. In particular, railway bridges are a crucial element in this context. Being affected by degradation processes of various natures and durations, they constitute the most vulnerable elements for the safety of the whole railway infrastructure, with potential consequences for the safety of goods and people.

In fact, considering that different parts of every railway infrastructure are connected from the superstructure, i.e. the ballast and the rails, even minor structural changes without complete structural failure might cause derailment and potentially fatal accidents.

For all these reasons, a robust understanding and awareness of the daily operations and safety concerns is required, given that many passengers use railway lines daily. In Europe, 35% of the more than 300,000 railway bridges, which are distributed over a total of 200,000 km of railways, exceed 100 years of operational life [1]. In particular, in Italy, the majority of railway viaducts built between the 1950s and 1970s consist of prestressed concrete bridges (PRC); hence, special attention should be granted to these ageing infrastructures [2].

Railway bridges are exposed to several factors which cause degradation. These include harsh environmental conditions, significant live loads – mainly due to the increase of traffic loads in the last decades, including high-speed trains – material ageing, and other rare or extreme events (i.e. impacts from accidents, earthquakes, etc.). Other than material ageing, PRC bridges are subjected to damages due to: corrosion of normal reinforcement steel bars as well as prestressing tendons; prestressing losses; construction errors (incorrect grouting of

tendons ducts, for example); and many other potential natural or human-made hazards [3]. Inadequate maintenance is also a practice that could result in further damages, often non-recoverable. Finally, hidden grouting defects of prestressing sheaths can lead to corrosion, reducing the area of prestressing steel with consequent bearing capacity decrease.

As a result, all these factors contribute to the potential development and growth of structural damage over time.

Per established tradition, visual inspection still plays an essential role in identifying superficial defects and evaluating the overall condition of the examined structure. However, visual inspections are labour-intensive, time-consuming, and often rely on the operator's experience level, which significantly impacts the accuracy, objectiveness, and reliability of structural condition evaluations.

Hence, the application of automated and objective anomaly detection is fundamental. This is the paradigm of Structural Health Monitoring (SHM) solutions [4]; their application to railway bridges is important to maintain operational safety, expand the structure's lifespan, and reduce maintenance costs. In particular, Vibration-Based SHM, which relies on analysing the vibrational response of structures to identify damage indicators, is one of the most used techniques to identify and monitor changes in the dynamic properties of a structure. In this framework, to identify such pathologies, the first step involves extracting the target structure's damage-sensitive features (DSFs) from the monitoring data – that is, natural frequencies, damping ratios, and associated mode shapes from acceleration time series. Possible changes in modal parameters over time could be a manifestation of both global and local damages.

In particular, natural frequencies are mainly sensitive to global damages and structural modifications. However, the global stiffness of a structure is often influenced by variations in normal environmental factors, such as temperature, and their influence (daily or seasonal gradients) can be significant enough to mask the presence of certain damages. Notably, local damage up to moderate severity has a minor influence on eigenfrequencies. On the other hand, mode shapes are more sensitive to local damages than natural frequencies and less sensitive to temperature variations [5], [6]. The main disadvantage is that a dense sensor grid is required to ensure effective damage localisation, a choice which is generally costly when conventional sensors, such as accelerometers, are employed.

Nevertheless, in both mode shape-based and natural frequency-based SHM, the key point is to extract high-quality modal parameters from the recorded time series; henceforth, accurate identifications are strictly required.

This short contribution presents the results of a novel output-only System Identification (SI) algorithm, applied to an experimental test campaign on a prestressed reinforced concrete railway bridge. In this context, the present study focuses on analysing the recorded accelerometric monitoring data of the viaduct's deck.

The case study presented here has been equipped with highly sensitive accelerometers on three spans, collecting data for two consecutive days. The acquired acceleration data are processed using the proposed Automated Operational Modal Analysis (AOMA) approach based on the SSI-COV algorithm [7] using a code developed in MATLAB environment. Dynamic identifications obtained considering ambient vibrations provide repeatable and directly comparable results between identical spans. Furthermore, as a benchmark, the results are compared to the ones obtained with the commercial software (ARTEMIS).

The remainder of this paper is organised as follows. Section 2 describes the structure, the dynamic monitoring system and the data acquired. In Section 3, the Automated Operational Modal Analysis procedure for dynamic monitoring is briefly described. The results obtained considering the environmental excitation of the structure are then reported in Section 4, followed by the analyses repeated with the commercial software ARTEMIS; such results are then compared. Finally, the conclusions of the study carried out for this structure follow in Section 5.

## 2 EXPERIMENTAL TEST CAMPAIGN

### 2.1 Description of the structure

The railway viaduct under investigation consists of 46 spans, each equal to 20 m, for a total length of 920 m. The individual spans are characterised by a simply supported static scheme and consist of eight prestressed concrete girders with I cross-sections, connected by a 20 cm thick upper slab, and four transversal beams having rectangular cross-sections. The main beams are 1.40 m high and have 1.20 m spacing, such that, considering the two lateral cantilever slabs supporting the parapets, the total width of the deck is approximately 12.40 m, allowing the support of two train tracks (see Figure 1 and Figure 2). The beams' prestressing reinforcement is arranged in the lower flange and, according to the original design drawings, consists of a total of 29 cables arranged in 3 rows, sheathed in

ducts at the supports. As mentioned, PRC beams are widely used in railway bridges, where dynamic loads from passing trains demand high stiffness and serviceability. The prestressing process introduces compressive forces into the concrete; these forces counteract tensile stresses, preventing cracking and the resulting stiffness reduction. This, compared to a beam of equivalent size in conventional (non-prestressed) RC, results in lower deflections under load and allows for larger spans. At the same time, lower amplitude vibrations are generated under working conditions, which is useful for safety and comfort in operating conditions but makes AVT and output-only identifications more challenging, requiring high-quality accelerometers.

Figure 1: View of a typical span of the railway viaduct.

The standard pier has a pseudo-rectangular reinforced concrete geometry (maximum dimensions 11.0 x 1.50 m). The 45 piers range from a minimum height of 2.5 m to a maximum of 5 m along the longitudinal direction. The foundation of the piers consists of a RC plinth lying on deep foundations (i.e. piles).

Figure 2: Intrados view of a typical span of the case study with the PRC beams.

## 2.2 Structural health monitoring (SHM) system

Because of the extension of the viaduct and its static scheme, with simply supported and nominally equal spans, only a part of the entire structure has been investigated. Specifically, three spans have been instrumented. Four uniaxial accelerometers were installed for each span under study in the positions showed in Figure 3 and with the numbering indicated. Measurements of only the vertical acceleration components were acquired for two consecutive days. This placement aimed to associate the obtained frequencies with both vertical and torsional vibrational modes.

Due to the high stiffness of prestressed reinforced concrete railway bridges, accelerometers with high sensitivity and low background noise are required. In the present case, PCB piezoelectric accelerometers model 393B12 were used, with a sensitivity of 10 V/g and a noise of  $0.32 \mu\text{g}/\sqrt{\text{Hz}}$  on the 10 Hz band.

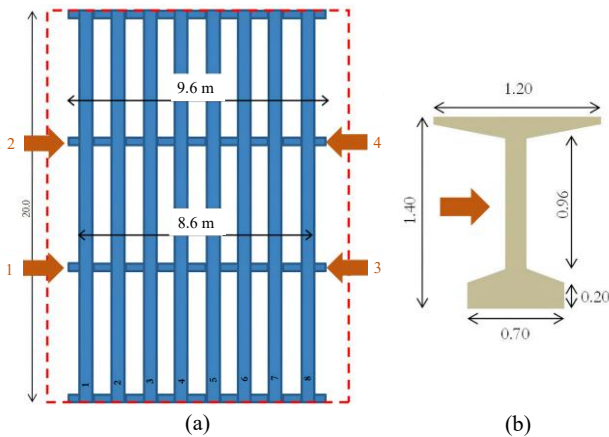

Figure 3: Scheme of the typical span (a) and position of the accelerometers on the main beams near the cross beams (b). The numbers in red (1 to 4) indicate the different output channels.

The instrumentation configuration differs between the spans as follows:

- in one span, the four accelerometers were installed at the end of the cross beams (transverse distance 9.6 m).
- in the other two spans, the four accelerometers were installed on the web of the main beams in proximity of the cross beams (transverse distance 8.6 m, see Figure 3 (b)).

The experimental tests were designed to identify the bridge's modal parameters and verify the structure's response under normal operating conditions. For this reason, some signals would inevitably contain train passages alongside ambient vibrations. 20 recordings were acquired for the first span; 16 other recordings were taken for the other two spans, referred to as numbers 2 and 3. All acquisitions were made with a sampling frequency  $f_s = 100$  Hz and a 24-bit acquisition system. That provides a wide margin with respect to the highest natural frequency of interest (16 Hz, as will be shown in the following Sections, thus well below the Nyquist limit  $f_s/2 = 50$  Hz). The duration of each measurement was about 15 minutes. Examples of recorded time series of the raw acceleration data for one of

the instrumented spans, showing all acquisition channels, are displayed in Figure 4.

The vertical acceleration signals acquired by the four acquisition channels for each instrumented span were analysed after the cleaning and pre-processing phase. In particular, after identifying the signals containing train passages, the corresponding signal portions were isolated and saved separately. The remaining parts, thus corresponding to ambient excitation, were likewise isolated, stored separately, and analysed in the subsequent steps. In this way, 80 signals were obtained, of which only those of appropriate length ( $> 4$  minutes) were used for the successive identification steps. The signal duration was found to be consistent with the range recommended in [8] for accurate damping estimation, i.e. 1000-2000 times the natural period of the first mode (2 to 4 minutes in the present case study), thus reliable results are ensured even when signals are segmented.

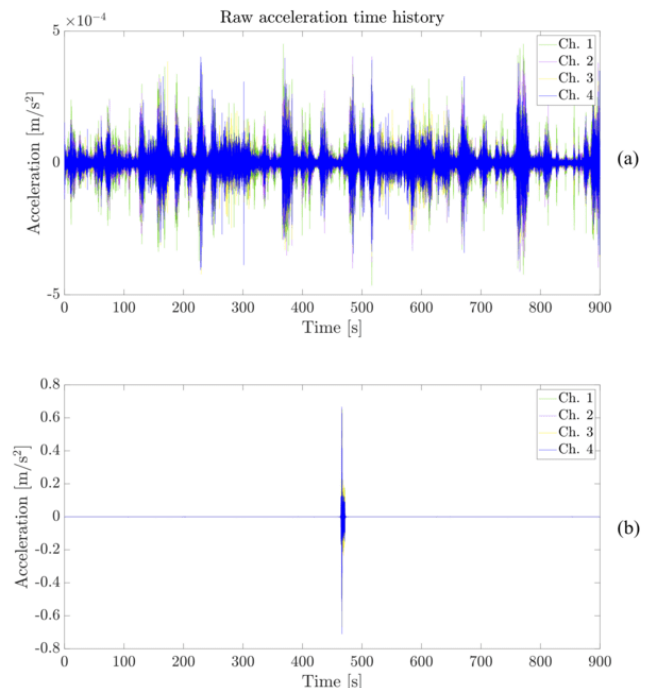

Figure 4: Example of a signal acquired in one of the spans under ambient vibration conditions (a) and with a passing train (b) after the pre-processing.

## 3 AUTOMATED OPERATIONAL MODAL ANALYSIS (AOMA) FOR SHM

The objective of any Automated Operational Modal Analysis (AOMA) procedure is the extraction of modal parameters through the analysis of vibration measurements. The procedure is a multi-stage process that involves several sequential steps. It begins with data pre-processing and the choice of the optimal algorithm parameters, followed by the system identification phase, then the sifting of the identified modal parameters, and finally, the estimation of cluster-wide values and their validation, as well-documented in [9] and [10]. In this context, the core of the procedure, i.e. the system identification phase, is carried out by applying the Stochastic Subspace Identification (SSI) method, which is a popular parametric time

domain algorithm based on state-space identification [7]. Several authors have proposed AOMA procedures to try to address the aspect of automating the interpretation of the stabilisation diagram and the following extraction of the physically meaningful modes of the structure [8], [11], [12].

### 3.1 AOMA algorithm and modal parameters' selection

In the present study, the dynamic identification of the structure decks was performed using the well-known SSI (Stochastic Subspace Identification) Operational Modal Analysis algorithm with clustering analysis (DBSCAN - Density-Based Spatial Clustering of Applications with Noise) to facilitate the identification of actual vibration modes [13], [14].

SSI returns all identified modal parameters, which are generally represented in a stabilisation diagram, which is a visual tool used to facilitate the interpretation of results showing the poles (modes) characterised by the natural frequencies, damping ratios, and eigenvectors identified in relation to the order of the dynamic system chosen a priori. However, these identified poles include the physical modes as well as many spurious modes; the latter ones, which are due to measurement noise misidentified as vibration modes, need to be disregarded to identify only valid results correctly. In the stabilisation diagram, poles aligned in a vertical line are stable as the model order changes and, therefore, are deemed to represent a physical mode. The automatic cleaning and interpretation phase of the stabilisation diagram consists of defining a set of criteria to distinguish physical poles from spurious and mathematical ones. The steps enabling this procedure are briefly outlined below:

- hard validation criteria (HVC), consisting of the elimination of poles with negative or excessively high damping ratios ( $> 20\%$ ) and those with eigenvectors not coming in complex conjugate pairs;
- soft validation criteria (SVC), concerning the introduction of comparison parameters between the modal parameters of the different poles (hence the distance in the stabilisation diagram) and elimination of those that do not fall within the selected thresholds, following the work done by Mugnaini et al. [15];
- application of the DBSCAN algorithm to group the poles with similar modal characteristics and discard any other outlier poles according to parameters that vary for each dataset. Each identified cluster individuates a set of probable physical modes; therefore, the modal parameters representative of an entire cluster are estimated as the average of the cluster values  $f_m$ ,  $\xi_m$  [10].

Determining the corresponding mode shape is essential to discern the modes with actual physical significance.

### 3.2 ARTeMIS software

The commercial dynamic identification software ARTeMIS was used as a benchmark to validate the results obtained from the developed AOMA code. ARTeMIS is a powerful operational and experimental modal analysis software. The results are obtained through a Data-Driven Stochastic Subspace Identification algorithm implementation.

## 4 DISCUSSION OF RESULTS

### 4.1 AOMA results

SSI needs the definition of two fundamental parameters:

- the range of model order, going from  $n_{\min} = 20$  to  $n_{\max} = 130$ ,
- the number of block rows of the Hankel matrix, defined as  $f_s/2$  [7].

For a fair comparison, these parameters were set once and kept untouched for all analyses (all signal tracts of all spans). The comparison parameters for the stabilisation diagram [13] reported above are set equal to:

- $df < 0.005$
- $0 < d\xi < 10\%$
- $(1 - \text{MAC}) < 0.05$

Figure 5 shows a 'cleaned' stabilisation diagram at the end of the clustering phase (in fact it can be seen how each cluster is identified by a different colour), taken by one example of one of the instrumented spans. In this particular case, the frequency range of interest goes from 8 to 20 Hz, where clear peaks can be observed. In the same way, a diagram of the damping ratios versus natural frequencies is represented in Figure 6. The identified clusters are linked to the ones in Figure 5, i.e. displayed with the same colours.

Figure 5: Example of stabilisation diagram with identified clusters.

Figure 6: Example of frequencies vs damping ratios diagram with identified clusters.

Finally, Figure 7 shows the occurrence of the values of identified natural frequencies for the deck of one of the instrumented spans, considering all the ambient vibration signals used.

By comparing all the results obtained from the different signals, the natural frequencies with the highest occurrence and corresponding to mode shapes with physical significance were identified. The following figure (Figure 8) shows the experimental vibration modes of the structure, with distribution diagrams of the natural frequencies and an axonometric view of the mode shapes with an indication of measurement points for each identified mode.

Concerning the 2<sup>nd</sup> mode, it is noteworthy to point out the fact that it has been identified twice. Although the identified mode shape seems to indicate that it is the same mode, there is no certainty as to the exact corresponding frequency. One could conservatively assume that one of the two estimated modes corresponds to some residual effects of a lateral mode. Still, since all output channels are vertical, the algorithm can only extract the mode shape of the closest mode with vertical components, i.e., the first torsional. Here and for the rest of the article, these are referred to as modes ‘2a’ and ‘2b’. Instead, the 1<sup>st</sup> mode can be identified as the first flexural mode of the deck.

Figure 7: Histogram representing the occurrence of natural frequency estimates of probable physical vibration modes.

For the mode identified as ‘mode 3’ in Figure 8, given the positioning and limited number of sensors, the corresponding mode shape is similar to the first flexural one. It could be assumed that the mode in question is instead related to a local mode of the deck, whose shape could only be detected with a denser sensor network. However, it should be noted that for the practical purposes of detecting damage structural phenomena for this type of structure, the first two modes are generally significant, as they are also identifiable with greater accuracy and repeatability. The estimated damping ratios are around 2 % for most identifications, except for mode 3, for which it is about 1 %.

Table 1 shows the values of the identified natural frequencies for each span. The first torsional mode identified twice with different frequencies is reported as ‘mode 2a’ and ‘mode 2b’. Furthermore, the low standard deviation values confirm that the three instrumented spans, nominally identical, are very similar in terms of dynamic response (and thus mechanical properties). This suggests that any damage in one of them would be easily detected not only by comparing the historical and current response of the span in question but also by comparing it with the other spans contemporaneously monitored – i.e. a sort of population-based SHM [16]. Indeed, this approach falls into the concept of population-based SHM.

Table 1: Summary of the natural frequencies identified by the MATLAB code (all values in Hz) for the relevant modes in the three instrumented spans, with average and standard deviation values (St.Dev).

	Mode 1	Mode 2a	Mode 2b	Mode 3
Span 1	8.148	9.205	10.084	15.873
Span 2	8.117	9.181	10.112	16.020
Span 3	8.126	9.142	10.123	15.907
<b>Average</b>	<b>8.130</b>	<b>9.176</b>	<b>10.106</b>	<b>15.933</b>
<b>St.Dev</b>	<b>0.016</b>	<b>0.032</b>	<b>0.020</b>	<b>0.077</b>

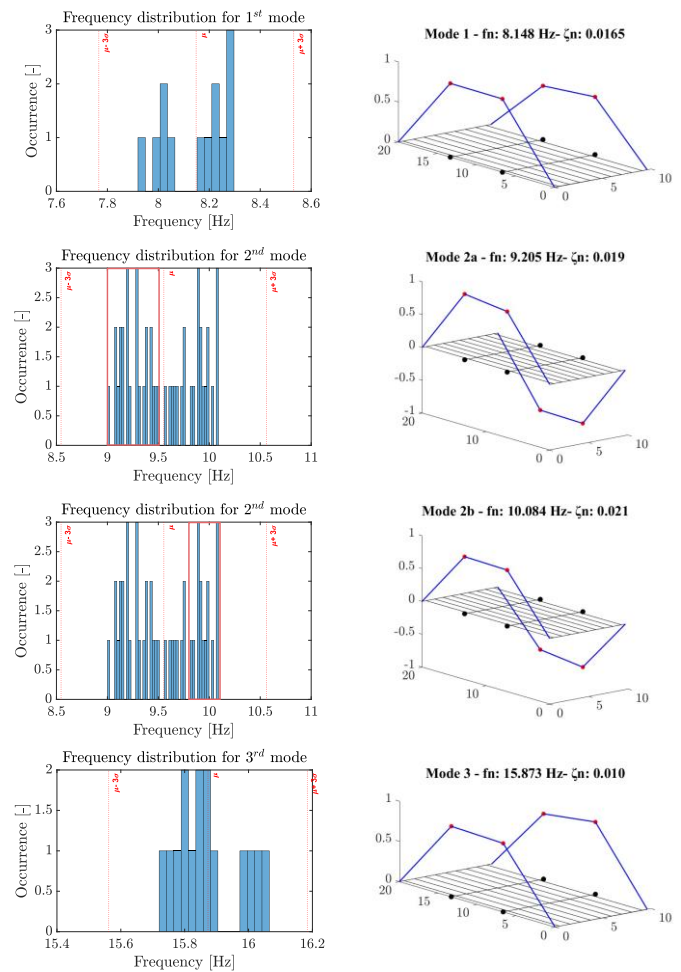

Figure 8: Distribution diagram of the identified natural frequencies and axonometric view of the identified mode shapes with an indication of the measurement points in red for mode 1 (a), modes 2a (b), and 2b (c), and local mode 3 (d).

Notably, the first mode shape was found to be slightly asymmetric, with the vibrations on one side ~20% larger than the other. This behaviour was confirmed in all acquisitions with both the MATLAB code and ARTeMIS (see next Section). Conversely, the other three mode shapes behave very symmetrically, with differences <4% between the two sides.

#### 4.2 ARTeMIS results comparison

The results from the ARTeMIS software were obtained by importing, via a .cfg text file, the geometric model of the

individual deck and the information regarding the actual position of the sensors, which was the same for the three instrumented spans. The acceleration time histories used are those from the pre-processing phase described in Section 2.2 and relative to ambient vibrations. The results showed in this section refer to a single example file belonging to one of the instrumented decks, but the overall outputs, analysed manually, are in line with those of the other acquisitions on the same span and the others. All results refer to the analysis with ambient noise, i.e. eliminating train passages.

At first, Frequency Domain Decomposition (FDD) was used, a frequency domain features extraction technique with manual peak selection to perform a preliminary analysis; the results obtained with this method are shown in Figure 9 on the left side. All natural frequency values estimated for the first three modes are very similar to those verified by MATLAB code on the entire dataset of available signals. As already observed through the AOMA code, there is a substantial similarity between the first and third modes. Moreover, as better detailed below, for each span, just one of the two modes named as ‘mode 2’ can be estimated by applying FDD.

Stochastic Subspace Identification with Unweighted Principal Component (SSI-UPC) [7] was then used. Regarding the definition of the SSI parameters, the same model order range as selected in the MATLAB code, i.e. from  $n_{\min} = 20$  to  $n_{\max} = 130$ , was set for direct comparability. Relative to the same example presented and discussed so far, the obtained results are shown in Figure 9 on the right side.

Although only the representation of the mode referred to above as ‘mode 2a’ is shown here, the results for both modes

2a and 2b are still identified with the same mode shape. Moreover, as can be noticed for the representative case here depicted, but is valid for all three instrumented decks, the estimated damping ratios for the first and second modes are slightly higher than those estimated and reported in the previous section.

At the bottom of the images in Figure 9 (d), (e), and (f) the Modal Assurance Criterion (MAC) can be observed to verify the similarity between the identified modes. As already observed through the MATLAB AOMA code, a substantial similarity is observable between the first and fourth (denoted as Mode 3) modes. Similarly, it is possible to visualise complexity plots, which make it possible to indirectly verify whether a mode is physical or, for example, due to numerical effects or acquisition noise, given its complexity.

Finally, the results in terms of identified frequencies for the different system identification approaches used are reported in Table 2. The analysis carried out on the signals of the three spans using commercial software ARTEMIS, using the FDD and SSI-UPC techniques and considering the first three modes, indicates a good correlation in terms of natural frequencies, while a discrepancy is noted in the estimation of modal damping, which on average is higher in ARTEMIS than in the MATLAB code. However, this parameter is known to be the most uncertain of those to be estimated [17] and, for this very reason, is generally not considered in terms of structural monitoring. Given the low standard deviation values, the same conclusions as in Section 4.1 can be replicated here.

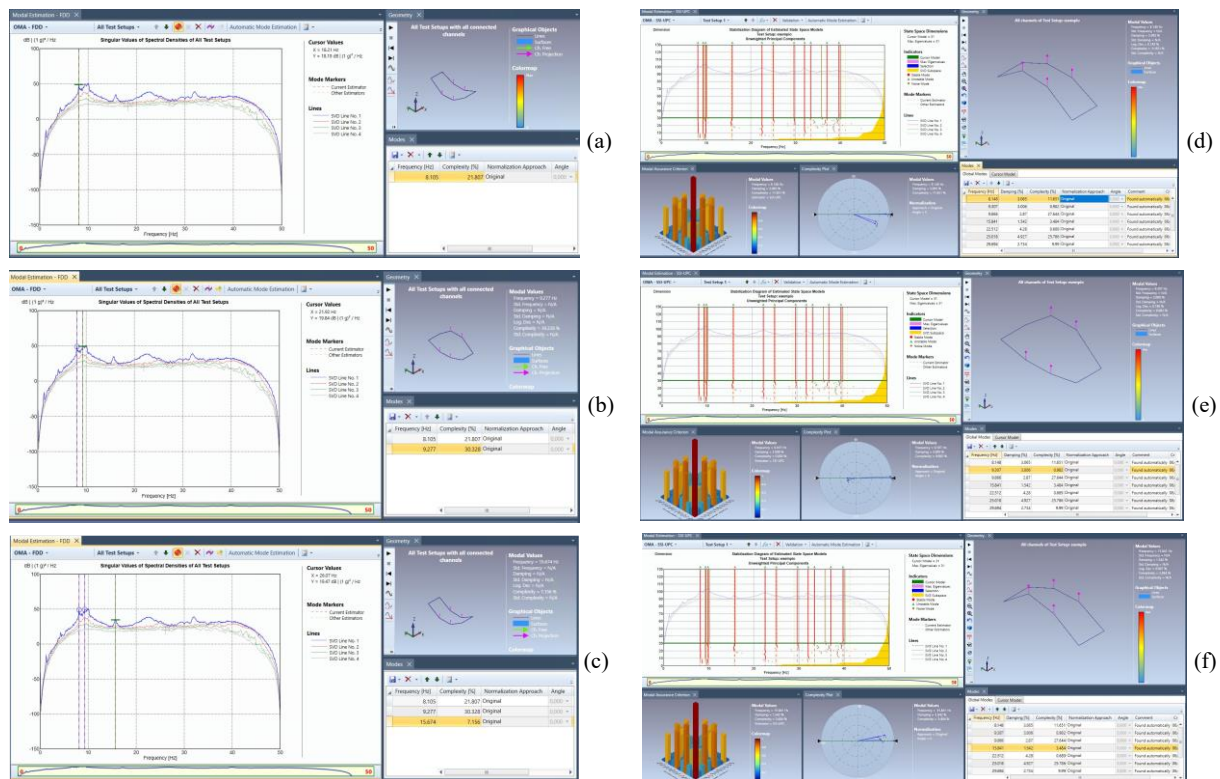

Figure 9: Results obtained in ARTEMIS by applying the FDD method on the left, reporting mode 1 (a), mode 2 (b) and mode 3 (c) manually selected from the signals PSD; and by applying SSI-UPC on the right, showing mode 1 (d), mode 2a (e) and mode 3 (f) estimated automatically.

Table 2: Summary of the natural frequencies identified by ARTeMIS (all values in Hz) for the relevant modes in the three instrumented spans with the FDD and SSI-UPC methods, with computation of the average and standard deviation values (St.Dev). The sign ‘-’ indicates unidentified modes.

		Mode 1	Mode 2a	Mode 2b	Mode 3
FDD	Span 1	8.562	9.684	-	15.789
	Span 2	8.255	9.365	10.101	16.034
	Span 3	8.297	-	10.108	16.219
	<b>Average</b>	<b>8.371</b>	<b>9.524</b>	<b>10.104</b>	<b>16.014</b>
	<b>St.Dev</b>	<b>0.166</b>	<b>0.226</b>	<b>0.005</b>	<b>0.216</b>
SSI-UPC	Span 1	8.461	9.631	10.030	15.777
	Span 2	8.171	9.168	10.197	16.092
	Span 3	8.125	9.231	10.320	16.217
	<b>Average</b>	<b>8.252</b>	<b>9.343</b>	<b>10.182</b>	<b>16.029</b>
	<b>St.Dev</b>	<b>0.182</b>	<b>0.251</b>	<b>0.145</b>	<b>0.227</b>

Finally, the mode shapes identified in Section 4.1 through the AOMA algorithm developed in MATLAB and those obtained with the two methods implemented in ARTeMIS, as in the present Section, are compared based on Modal Assurance Criterion (MAC), defined as [18]:

$$MAC(\phi_j, \phi_k) = \frac{[(\phi_j) * (\phi_k)]^2}{[(\phi_j) * (\phi_j)][(\phi_k) * (\phi_k)]} \quad (1)$$

The MAC correlation matrices for the instrumented span 1 are summarised in Table 3. The top part of the table shows the MAC values computed between the MATLAB-identified mode shapes and those obtained via the ARTeMIS SSI-UPC method, while the bottom section reports the MAC values with the FDD method. For the other couple spans the results are consistent with those presented.

The resulting MAC values for the modes indicated as 1, 2a, and 3 are reported, with the values of interest highlighted. Such values indicate a high correlation between the two sets of mode shapes.

Table 3: MAC correlation matrices of mode shapes identified for span 1 computed between MATLAB code vs ARTeMIS SSI-UPC (top part) and MATLAB vs ARTeMIS FDD (bottom part).

		MATLAB AOMA		
		Mode 1	Mode 2a	Mode 3
ARTEMIS SSI	Mode 1	0.9948	0.0202	0.9846
	Mode 2a	0.0455	0.9980	0.0046
	Mode 3	0.9667	0.0001	0.9958
ARTEMIS FDD	Mode 1	0.9846	4.44e-05	0.9882
	Mode 2a	0.0031	0.9697	0.0044
	Mode 3	0.9974	0.0189	0.9971

The results suggest that the modes obtained from the SSI-UPC automated method present excellent comparability with those obtained in MATLAB, showing a better reliability with respect to the FDD identifications.

It is noteworthy to notice the high MAC values between modes 1 and 3 in both cases, as expected by the nature of the mode shapes (see Figure 8 and Figure 9).

#### 4.3 Effects of train passages

The dynamic data recording included train transit events, presenting signals with much higher acceleration amplitudes but extremely short durations. The analysis of such portions of signals could be of particular interest in the case where less performing accelerometers are used, and as a consequence, are not able to detect vibrations due to environmental excitation, or in the case where load tests need to be performed on the structure, since in such loading conditions the identified modal parameters are in general more sensitive to longitudinal prestressing losses. These signals, if taken in their entirety (i.e. including train passages), become non-stationary and, therefore, difficult to analyse with algorithms intended for stationary analysis, such as SSI. For this reason, if one wants to exploit the excitation given by the passage of trains to extract damage-sensitive modal parameters, it is necessary to resort to other algorithms designed for modal identification and exploiting the excitation contained in the free vibration following a train passage. This aspect will be further explored as part of future developments of this project.

## 5 CONCLUSIONS

The primary aim of this study was to evaluate the applicability of a novel Automated Operational Modal Analysis (AOMA) algorithm for continuous Structural Health Monitoring (SHM) of a railway bridge. Three spans of this case study were instrumented with high-performance accelerometers. The workflow followed here, from the pre-processing phase of the ambient vibration measurements data to the Automated OMA, made it possible to identify natural frequencies, damping ratios, and mode shapes for the first relevant modes in the frequency range from 0 to 20 Hz, discarding spurious identifications.

The comparison between the AOMA algorithm developed in the MATLAB environment and the commercial software ARTeMIS shows that both approaches provide consistent and reliable results. The similarity in outcomes confirms the validity and robustness of the proposed method, ensuring its applicability. Since the bridge spans are nominally identical, the approach followed for this research study enables the estimation of the variability of the results under the same analysis methodology.

Overall, in view of a broader approach to infrastructure monitoring, maintenance, and management, these findings validate the feasibility of using AOMA for continuous SHM of railway bridges and damage detection.

## ACKNOWLEDGMENTS

The study presented here was carried out as part of the program of activities carried out within the MOST – Sustainable Mobility National Research Center and received funding from the European Union Next-GenerationEU

(PIANO NAZIONALE DI RIPRESA E RESILIENZA (PNRR) – MISSIONE 4 COMPONENTE 2, INVESTIMENTO 1.4 – D.D. 1033 17/06/2022).

**ABSTRACT:** In Japan, visual inspections have been conducted as every five years duty since 2014. To improve the quality of inspections, it is necessary to record the evaluation of the structure's condition and its performance until the next inspection. However, methods and technical level depend on the judgement of the road administrator. A city of Kitami, Hokkaido, Japan where our university is located, was merged with one city and three towns in 2006, and has the largest area ranking in Hokkaido area and 4th in Japan. The total number of bridges, viaducts and functional culverts over 2.0 m length became more than doubled to 524 bridges compared to before the merger. Therefore, it is necessary to establish a labor saving and cost-effective method to assess the performance of bridge structures. In recent years, it has become possible to easily measure structural responses by the improvement of sensor performance, and more research has been conducted on maintenance management methods. Among those, vibration characteristics have a significant effect on the stiffness and mass of a bridge member and will be the index that grasps easily various damage effects. In this study, a damage location screening method was investigated for concrete slab bridges where segregation was suspected, based on correlation between mode shapes by using the COMAC. As a result, it is shown that these techniques will identify the damaged location and be used as an effective method to screen damaged locations.

**KEY WORDS:** Damage screening method; Mode shape; Concrete slab bridge; Maintenance.

### 1 INTRODUCTION

In Japan, visual inspections have been conducted as every five years duty since 2014. Under the established inspection specification, to improve the quality of inspections, it is necessary to record the evaluation of the structure's condition and its performance until the next inspection. However, methods and technical level depend on the judgement of the road administrator [1]. A city of Kitami, Hokkaido, Japan where our university is located, was merged with one city and three towns in 2006, and has the largest area ranking in Hokkaido area and 4th in Japan. Farmland is spread out in the suburbs and road network is expanding widely. The total number of bridges, viaducts and functional culverts over 2.0 m length became more than doubled to 524 bridges compared to before the merger [2]. Therefore, it is necessary to establish a labor saving and cost-effective method to assess the performance of bridge structures.

In recent years, it has become possible to easily measure structural responses by the improvement of sensor performance, and more research has been conducted on maintenance management methods [3], [4]. Among those, vibration characteristics have a significant effect on the stiffness and mass of a bridge member and will be the index that grasps easily various damage effects. Our research group has been studying a maintenance method using the COMAC focusing on a pedestrian bridge slab [5]. Consequently, it was shown that damage screening by co-relationship between mode shape is effective.

In this study, a damage location screening method was investigated for concrete slab bridges where segregation was suspected, based on correlation between mode shapes by using the COMAC.

### 2 TARGET BRIDGE

#### 2.1 Bridge specifications

The target bridge of this study is a reinforced concrete slab bridge. Since there is no detailed information such as construction records and drawing, shape measurements on site were taken as shown in Figure 1.

Figure 1. General arrangement drawing (unit: mm).

Figure 2. Inspection photos.

Figure 3. Inspection results.

## 2.2 Inspection results

Visual inspection was conducted to grasp degree of damage of each component by our research group in 2023. As a result of this inspection, widespread flaking has been found at the pavement on both sides, and corrosion and free lime can be seen on the reinforcement steel plates underside of the slab. Especially, icicle-like free lime has been found upstream side on the A2 abutment. Since this bridge does not have a waterproof layer on the concrete slab, it was suspected that segregation of the slab surface occurred more than in other areas. However, the pavement and steel plates make it difficult to see damage directly. A non-destructive survey by using electromagnetic waves was conducted on the pavement, but it did not obtain a clear waveform from the surface of the slab. Inspection status and results are shown in Figure 2 and Figure 3.

## 3 VIBRATION MEASUREMENT

### 3.1 Measurement conditions

Vibration characteristics were identified from acceleration data obtained by passing vehicle. The location of the accelerometer and passing situation of the vehicle are shown in Figure 4. Since this bridge has a short span and a roughly square planar shape, nine accelerometers were installed at equal spacing on the pavement surface to identify the bowl-shaped vibration mode shapes. In addition, accelerometers of number 1~3 and 7~9 were located under the tire lane, so they were moved 300mm outward.

Accelerometer is 3-axis MEMS type manufactured by Japan Aviation Electronics Industry, shown in Figure 5, with a sampling rate of 2000Hz. The vehicle passed over the bridge at 20km/h and measurements were taken 3 times in each direction.

Figure 4. Measurement position and the test vehicle.

Figure 5. Accelerometer (JA-70SA).

Figure 6. Mode shapes.

### 3.2 Conditions for data processing

The data processing was carried out by the following steps. First, the power spectrum of each set of acceleration data was obtained by Fast Fourier Transform (FFT). Next, natural frequencies were identified by the peak picking method. Finally, mode shapes were estimated from the filtered wave amplitude in each sensor node.

### 3.3 Measurement results

As shown in Figure 6, the five vibration modes were identified from the experiment. In addition, the points at both ends where no accelerometers are plotted as zero value to make the mode shape easier to understand.

As a result, the first mode was the lower vertical symmetric bending mode. The second mode was the lower torsional mode. The third mode was the unsymmetric bending mode. The fourth mode was the higher torsional mode. And the fifth mode was the higher vertical symmetric bending mode.

## 4 ESTIMATION OF DAMAGE AREA BY MODE SHAPE CORRELATION

### 4.1 Estimation method

As a result of the inspection shown in Figure 3, icicle-like free lime has occurred upstream side on the A2 abutment, then it is thought the segregation has progressed more than in other areas. At the relationship between sensor position and icicles position shown in Figure 7, it shows that the icicle-like free lime is near the sensor number 3. In this study, the COMAC (Coordinate Modal Assurance Criterion) [6] technique is adopted to try to

identify the damaged location. This technique is the calculation of correlation values at each coordinate over all the correlated mode pairs via the use of equation (1).

$$\text{COMAC}(j) = \frac{\sum_{i=1}^N |\{\phi_o\}_i^j \{\phi_D\}_i^j|^2}{\sum_{i=1}^N [\{\phi_o\}_i^j]^2 \sum_{i=1}^N [\{\phi_D\}_i^j]^2} \quad (1)$$

Where,  $j$  is sensor number,  $N$  is the number of the modes,  $\{\phi_o\}_a$  and  $\{\phi_D\}_i$  are the mode vectors in different situations respectively. In this study, the sensors were set at 9 locations, and the modes are 5 as total identified modes.

Now, there was no initial data for this bridge, it wasn't able to

Figure 7. The icicle-like free lime and the position.

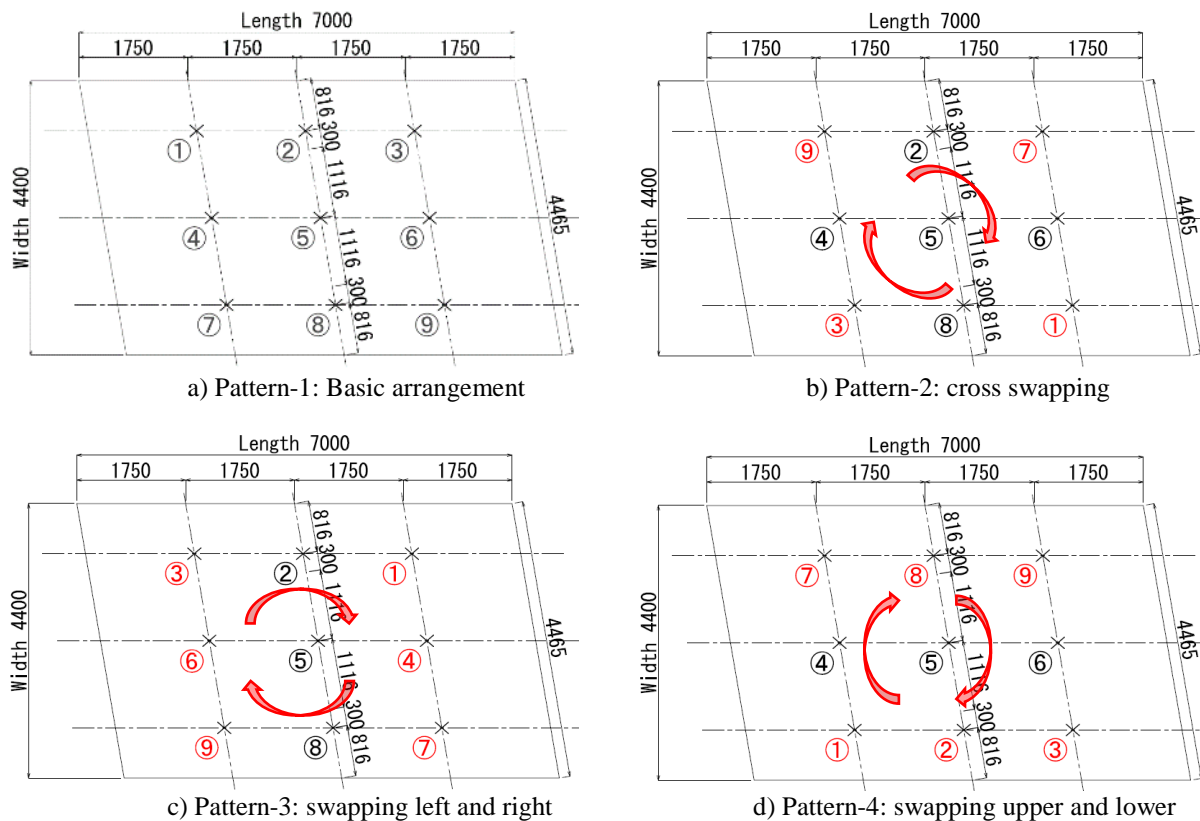

Figure 8. Swapping mode vectors.

calculate the COMAC. Therefore, the following assumption was assumed. Since the planar shape of this bridge is biaxially symmetrical, it was assumed that the mode vectors at the measurement points on the diagonal line can switch each other as shown in Figure 8b). The same assumption was also assumed for the axes at the center of the span and the center of the width as shown in Figure 8c) and Figure 8d). Hence, the COMAC was calculated by the four patterns combination as shown in Figure 8. However, since the sensor number 5 is located in the center, it cannot swap. And even numbered sensors are limited to only two patterns. Here, considering bridge shapes of small span concrete slab bridges that were managed by Kitami City. Since many of these bridges are almost symmetrical shape include skew angles, this swapping approach method is widely applicable. Many of bridge located on suburban routes with little traffic and cracks do not tend to occur on the underside of the slab. In addition, the cross section of the pavement has a 2% drainage gradient, and the ends of the girders are prone to damage due to pooled water. Therefore, simply identifying damaged areas at the four corners of the slab provides extremely useful information for maintenance.

#### 4.2 Result of estimation

The calculated results of the COMAC are shown in Figure 9. The vertical axis of this graph indicates the COMAC value, and the horizontal axis indicates the sensor number of the basic arrangement as shown in Figure 8a). As the COMAC approaches 1.0, it indicates that the correlation between these two different situations is high.

In the COMAC comparison between patterns 1 and 2, it shows the values at sensors 3 and 7 are relatively low. Also, in the COMAC comparison between patterns 1 and 4, it shows the values at the sensor number 3 and 9 are more clearly lower. On the other hand, the COMAC result between patterns 1 and 3 is less clear than the others, it barely lowered sensors 1 and 3. From these results, the COMAC value at sensor number 3 is generally low. Here, a graph of the three results multiplied together is shown in Figure 8d) in order to clarify the difference in the COMAC values for each sensor. The correlation at the sensor number 3 was the single lowest.

As a result of the above, it was considered that the COMAC value of sensor number 3 which was located near the icicle-like free lime was the lowest, the rigidity of the concrete slab may have been reduced by the pooled water at the invisible inside, it affected the mode shape of the sensor number 3. It was also shown that even without initial structural values or historical measurement data, it is possible to screen for the damaged locations by swapping vibration mode vectors, even the locations are limited.

#### 5 CONCLUSIONS

In this study, a damage location screening method was investigated for concrete slab bridges where segregation was suspected, based on correlation between mode shapes by using the COMAC. The results of this study are as follows:

- According to the inspection results for the reinforced concrete slab bridge, it was suspected that segregation of the slab surface at the upstream side on the A2 abutment.

- Vibration characteristics were identified from acceleration measurement by vehicle passing, six vibration modes and natural frequencies were obtained.

a) correlation Pattern-1 and Pattern-2

b) correlation Pattern-1 and Pattern-3

c) correlation Pattern-1 and Pattern-4

d) multiplication between a) - c)

Figure 9. COMAC results.

- From the results of COMAC, the sensor number 3 which was located near the icicle-like free lime was the lowest. The rigidity of the concrete slab may have been reduced by the pooled water at the invisible inside, it affected the mode shape of the sensor number 3.
- Since many of these small span concrete slab bridges that were managed by Kitami City are almost symmetrical shape include skew angles, this swapping approach method is widely applicable.

## ACKNOWLEDGMENTS

I would like to express my appreciation to Professor Emeritus Shuichi Mikami and graduate student Hitomi Onoda for their assistance in inspecting this bridge.

**ABSTRACT:** This paper explores the use of single-pass Synthetic Aperture Radar (SAR) images to remotely measure the vibrational response of reflective ground targets, aiming to support vibration-based Structural Health Monitoring (SHM) of civil infrastructure. A Sub-Pixel Offset Tracking (SPOT) technique is applied to SAR imagery to reconstruct the time history of radial velocity, using the principle of micro-motion (m-m) effects induced by vibrating targets. Validation is by comparing SAR-extracted velocity profiles with synchronous ground measurements of a vibrating Corner Reflector (CR). Three representative test cases—including single-frequency, and amplitude-modulated vibrations—with maximum displacement values of 24.1 mm, 1.1 mm and 0.5 mm are analyzed using SAR images collected by the Umbra X-band SAR constellation. The extracted vibrational features are evaluated through time-domain correlation, spectral accuracy, and error metrics. Results confirm that SPOT can reconstruct velocity time histories and frequency content reliably for medium-to-high velocity scenarios ( $> 10$  mm/s) and single-frequency signals. Even under low-velocity, complex signal conditions, the main frequency peaks are detectable, with negligible frequency errors and correlations of 0.61 (time) and 0.82 (frequency). This study demonstrates the potential of SAR m-m processing for fully remote vibration-based SHM, offering a scalable, installation-free alternative for assessing structural dynamics.

**KEY WORDS:** Structural Health Monitoring, Remote sensing, SAR-Imaging, Micro-Motion, Micro-Doppler, Modal Analysis.

## 1 INTRODUCTION

### 1.1 Background

Structural Health Monitoring (SHM) traditionally relies on contact-based sensors such as accelerometers to detect changes in a structure dynamic response [1]. While its claimed effectiveness in extracting the modal parameters—such as natural frequencies, damping ratios and modeshapes—they often face limitations in terms of costs, installation complexity, and sensor coverage [2], especially for large civil infrastructure. The need for prompt, scalable, and contactless sensing has led to increasing interest in remote sensing technologies [3]. Among these, spaceborne Synthetic Aperture Radar (SAR) stands out. SAR uses radar signals emitted from a sensor mounted on a satellite, to create images of the Earth surface. A SAR image appears as a complex matrix in range and azimuth coordinates, range corresponding to the radial direction (sensor to ground target) and azimuth to the direction of velocity of the platform (e.g., the satellite) motion [4].

Figure 1.1. SAR image (from Umbra Sensor [5]) reflectivity map of the Stonecutters Bridge (Hong Kong harbor) compared to its optical image.

SAR has gained considerable attention thanks to its ability to cover large areas—ranging from 5 km to 200 km in width [6], [7]—and to detect ground movement through Interferometric SAR (InSAR), which reconstructs displacement trends by combining multiple images of the same area acquired over time [8]. Whilst InSAR is a widely recognized technique for measuring millimetric precision displacements [9], it requires a large dataset [10] and cannot extract SHM-related information from a single pass (i.e., single image). In contrast, recent literature shows that it is possible to overcome these limitations of InSAR and use single-pass SAR images to extract vibrational information from reflective ground targets, through different techniques based on the measurement of micro-motions (m-m) using the micro-Doppler (m-D) phenomenon [11].

### 1.2 Micro-motion in SAR images

In a SAR image, each pixel contains magnitude (reflectivity) and phase information. Targets with strong reflectivity, such as metallic objects with sharp geometries, are prominently visible in the reflectivity map. Figure 1.1 shows an example of a reflectivity map alongside its corresponding optical image of the Stonecutters Bridge in Hong Kong.

The spatial resolution of the SAR image—defined as the size of each pixel in meters along the range and azimuth directions—depends on several factors, particularly the acquisition time ( $t_a$ ) in the azimuth direction. Acquisition time refers to the duration over which the satellite observes the same ground target, from the start to the end of the collection. This duration can vary significantly depending on the type of satellite sensor and the acquisition mode employed.

Figure 1.2. SAR acquisition geometry in case of spotlight acquisition mode.

In this work, SAR imagery collected in spotlight mode is studied. In this acquisition mode, the radar beam is continuously steered (or "squinted") to remain focused on the same ground area for an extended duration – typically between 5 and 20 seconds – greatly improving azimuth resolution. An example of the geometry of the SAR collection is shown in Figure 1.2. For spotlight acquisitions, the azimuth resolution  $\Delta x$  is given by Eq. (1):

$$\Delta x = \frac{\lambda R}{2 v_p t_a} \quad (1)$$

where  $\lambda$  is the wavelength of the SAR sensor (typically 25-40 mm for X-band radars),  $R$  is the radial distance to the ground target,  $v_p$  is the platform (satellite) velocity in the azimuth direction, and  $t_a$  is the acquisition duration (or illumination time). When generating a SAR image, the scene is typically assumed to be static – i.e., objects still on the surface. However, when a target is moving, its position in the image will be shifted in the range-azimuth plane due to uncompensated signal phase shift associated with the motion (imparted by the Doppler effect), causing a defocusing and smearing of the object. A point moving at constant speed, will be displaced mainly in the azimuth direction by a distance governed by Eq. (2) [12]:

$$x = \frac{v_r R}{v_p} \quad (2)$$

where  $v_r$  is the radial velocity of the object,  $R$  is the radial distance to the ground target, and  $v_p$  is the platform velocity in the azimuth direction. Since it is the change in radial velocity  $v_r$  relative to the moving satellite that produces this effect, the radial velocity is the key quantity of interest in this study.

Micro-motions of a target, such as vibrations, cause periodic fluctuations in the radar signal frequency due to the Doppler effect, where this is specifically referred to as micro-Doppler (m-D) [13]. In SAR imagery, this effect results in the formation of paired echoes along the azimuth direction around the real target [14], as shown in Figure 1.3. These effects are visible in the reflectivity image and can be exploited to measure the vibrations of reflective ground targets. The faster the velocity of vibration, the more evident these echoes appear. The earliest studies in this field, such as [15], explored how to extract vibrations and rotations from moving targets. Later works investigated the potential of employing this principle for SHM in civil engineering, applying it to a dam and a bridge, respectively [11], [16].

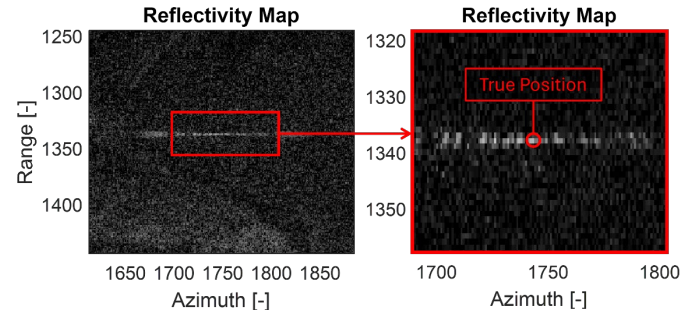

Figure 1.3. Micro-Doppler from an isolated target, vibrating vertically with an amplitude of 45 mm and frequency 0.8 Hz.

### 1.3 Research objective

The objective of this work is to assess the feasibility of using single-pass SAR images to extract vibration characteristics (i.e. micro-motions) from isolated reflective targets. Specifically, the performance and limitations of the extraction technique are assessed under different conditions of target vibrational amplitude, frequency, and movement time history complexity. Three representative test scenarios are used, and synchronous ground truth measurements are used as validation benchmarks.

The paper is structured as follows: Section 2 introduces the algorithm used to implement the m-m SAR method. Section 3 provides an overview of the experimental validation setup and the SAR datasets employed. Section 4 presents the results along with a detailed discussion. Lastly, Section 5 reports conclusions and summarizes the key insights of the study.

## 2 METHODOLOGY

### 2.1 Sub-Pixel Offset Tracking (SPOT)

The m-m SAR technique uses single-pass SAR imagery to estimate the radial velocity time history of a ground target within the observation window of the SAR image. The core algorithm used for this purpose is the Subpixel-Offset-Tracking (SPOT), as the one used in [11] and [16]. After cropping the area around the target (Region of Interest – ROI), SPOT segments the SAR image (full-aperture), into  $N$  sub-images (sub-apertures), each focused from a fraction of the full image observation time. To achieve this, a Fast Fourier Transform (FFT) is performed on the ROI along the azimuth dimension to convert the data from *range versus azimuth* to *range versus azimuth-frequency*. A segmentation in sub-apertures along the azimuth frequency axis is then performed using window lengths defined by the aperture fraction  $\alpha$  (see Figure 2.1):

$$\alpha = \frac{t_{\text{sap}}}{t_a} \quad (3)$$

where  $t_{\text{sap}}$  represents the duration in time of the sub-aperture, and  $t_a$  the acquisition duration (full aperture). Adjacent sub-apertures can share portions of the azimuth frequency domain (and therefore time); as controlled by the overlap ratio  $\Omega$ :

$$\Omega = \frac{t_{\text{ol}}}{t_{\text{sap}}} \quad (4)$$

where  $t_{\text{ol}}$  is the overlap duration between adjacent sub-apertures.

Given  $\alpha$  and  $\Omega$ , the total number of sub-apertures  $N$  can be computed as:

$$N = \frac{\alpha^{-1} - \Omega}{1 - \Omega} \quad (5)$$

The  $N$  azimuth-frequency sub-apertures are individually transformed into to  $N$  range versus azimuth images by means of an Inverse FFT. The target azimuth displacement  $x$  is then tracked across the sequence of sub-apertures using 2D cross-correlation. Each target azimuth shift  $x_k$  – given a specific  $k$ -th sub-aperture – depends on the instantaneous value of the radial velocity  $v_{r,k}$ . Therefore, it is possible to invert Eq. (2) to obtain the value of the radial velocity given the azimuth shift  $x_k$ :

$$v_{r,k} = \frac{x_k v_p}{R} \quad (6)$$

The time vector associated with the reconstructed velocity is a linearly spaced sequence of  $N$  values, starting at  $t_{\text{sap}}/2$  and ending at  $t_a - t_{\text{sap}}/2$ . The temporal resolution is then given by:

$$\Delta t = \frac{t_a - t_{\text{sap}}}{N - 1} \quad (7)$$

To ensure the desired frequency content is captured by the time series, the sampling frequency must satisfy the Nyquist criterion for the maximum frequency,  $f_{\text{max}}$ , to be observed:

$$f_s = \frac{1}{\Delta t} \geq f_{\text{max}} \quad (8)$$

There are two main ways to increase the sampling frequency: reduce the aperture fraction  $\alpha$ , or increase the overlap ratio  $\Omega$ . It should, however, be noted that reducing the aperture fraction shortens the illumination time for each sub-aperture and consequently worsens the azimuth resolution of each sub-aperture image. When the aperture fraction becomes too small, the target may no longer appear as a distinct feature, thereby degrading the tracking performance. This imposes a practical limit on how finely the aperture can be segmented, although this can be mitigated by increasing the overlap.

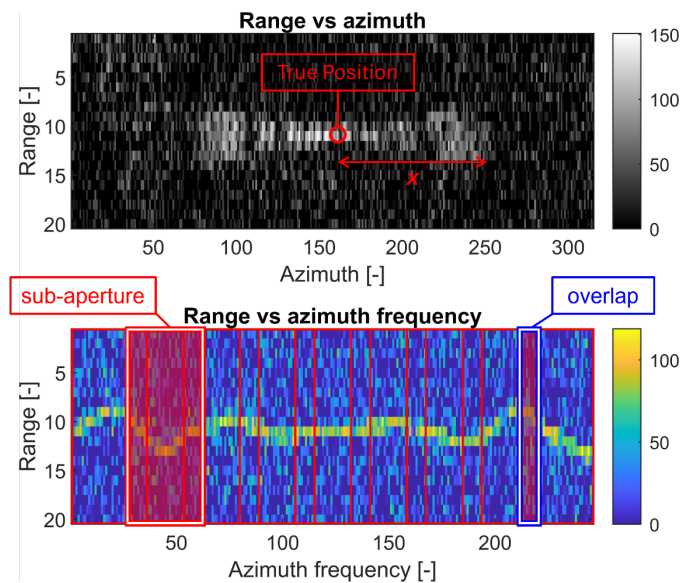

Figure 2.1. Top: range versus azimuth ROI (with highlighted and the azimuth shift  $x$ ); bottom: FFT of ROI along azimuth, yielding range versus azimuth frequency data, with the segmentation of sub-aperture data indicated.

The fundamental steps of the SPOT algorithm are as follows:

1. Crop the SAR image around the ROI;
2. Apply an FFT along azimuth to convert the ROI to the range versus azimuth-frequency domain;
3. Segment the azimuth-frequency spectrum into  $N$  sub-apertures according to selected parameters  $\alpha$  and  $\Omega$ ;
4. Apply IFFT to obtain  $N$  range versus azimuth sub-aperture images;
5. Track the azimuth pixel displacement of the target across sub-apertures;
6. Compute the velocity and the associated time-vector.

### 3 EXPERIMENTAL VALIDATION

#### 3.1 Tests sites and ground instrumentation

To evaluate the effectiveness of the m-m SAR technique, controlled experiments were conducted using artificially vibrating targets with ground truth data measured synchronously with the satellite passage. Tests took place in open fields in Trento, Italy, and Glasgow, UK, to avoid interference from nearby objects (see Figure 3.1).

The instrumentation setup included a Corner Reflector (CR) mounted on a shaker device, with motion captured using a Linear Variable Displacement Transducer (LVDT) (see Figure 3.2). The sensor recorded vertical displacement at a sampling rate of 50 Hz, where this was later projected onto the satellite radial direction and synchronized to match the satellite passage. As the m-m SAR algorithm measures velocity rather than displacement, the ground displacement signals were numerically differentiated to obtain the synchronized radial velocity profiles. This allowed for a direct comparison between SAR measured velocities and ground truth data. This study focuses on three representative test configurations, summarized in Table 1. The shaker was set to simulate various amplitudes and types of vibrational signals, including single-frequency sinusoidal oscillations and amplitude-modulated waveforms. In the context of civil engineering, the amplitude of structural vibrations can vary considerably depending on the structural type. For long-span bridges, typical displacements range from 0.1 mm to 5 mm, corresponding to radial velocities of approximately 1–10 mm/s or lower. To replicate these conditions, the test campaign was designed to progressively study vibrations beginning with well-defined, high-amplitude motions to those of lower-amplitude more relevant to SHM of bridges. The maximum target velocities for Tests 1, 2, and 3 were 95.5 mm/s, 10.8 mm/s, and 3.1 mm/s, respectively, corresponding to peak vertical displacements of 24.1 mm, 1.1 mm, and 0.5 mm.

To refine the analysis, the SAR measured velocity time histories were fitted using a model based on the superposition of multiple sinusoidal components. First, the SAR velocity spectra were upsampled by a factor of four, and dominant frequencies were identified from the FFT. For Tests 1 and 2, the frequency corresponding to the primary peak was selected, while for Test 3, being amplitude modulated, the three most dominant frequency components were extracted. These extracted frequencies were then used to fit sinusoidal models by optimizing amplitude and phase only. This procedure allowed for the reconstruction of refined, high-resolution velocity time histories.

### 3.2 SAR acquisitions

Satellite data were collected by the Umbra X-band SAR constellation, capable of high-resolution spotlight-mode imaging. Spotlight acquisition was selected to maximize the collection time, and therefore the azimuth resolution.

Commonly, SAR providers deliver Multi-Look Complex (MLC) images, which are generated by averaging multiple looks in the azimuth and/or range directions from the same observation in order to reduce speckle noise. While this averaging improves image interpretability, it also reduces the effective resolution (due to lower acquisition time) and suppresses the micro-motion effects (i.e., paired echoes), that are critical to this study. To preserve these effects, images were provided by Umbra in the form of Single-Look Complex (SLC) products, containing a single, unaveraged observation in both range and azimuth directions. These were processed using the polar format algorithm.

The three SAR images were acquired using sensors operating at a central frequency of 9.6 GHz, corresponding to a wavelength of  $\lambda = 31$  mm. The main characteristics of the SAR acquisitions used in the three tests are summarized in Table 1.

### 3.3 Evaluation of the performance

The ground-measured radial velocities served as a validation benchmark to quantify the performance of SPOT in reconstructing the time history of radial velocity of the target, during the SAR acquisition. To achieve this, the accuracy was evaluated according to the following metrics:

- Root Mean Square of the Error ( $RMSE$ ), computed in the time domain by comparing the SAR-reconstructed and ground-measured velocities at matching timestamps.
- Frequency error ( $\epsilon_f$ ), evaluated as the residual between the true frequency and the frequency measured with m-m SAR, corresponding to the highest peak of the FFT;
- Correlation in time ( $\rho_t$ ) and frequency ( $\rho_f$ ) domains.

Table 1. Test configurations. The table reports: type of signal tested (Signal type), principal frequency of vibration ( $f$ ), maximum ground vertical displacement ( $d_{max}$ ), maximum radial velocity value ( $v_{r,max}$ ), SAR sensor name (Sensor), Pulse Repetition Frequency (PRF), acquisition duration ( $t_a$ ), incidence angle ( $\theta$ ), platform velocity ( $v_p$ ), slant-range distance ( $R$ ), range resolution ( $\Delta x$ ), and azimuth resolution ( $\Delta x$ ).

## 4 RESULTS AND DISCUSSION

This section highlights the results of the SPOT m-m measurement technique, as well as the performance evaluation through the comparison with ground data. The comparison is performed both graphically (see Figure 4.1, Figure 4.2, Figure 4.3) and numerically (Table 2), using error metrics such as  $RMSE$ , frequency error, and Pearson's correlation coefficients in time and frequency domains. Results focus on Tests 1, 2, and 3 as representative cases for varying vibration conditions. Each test was processed using the workflow described in Section 2, with extraction parameters summarized in Table 2.

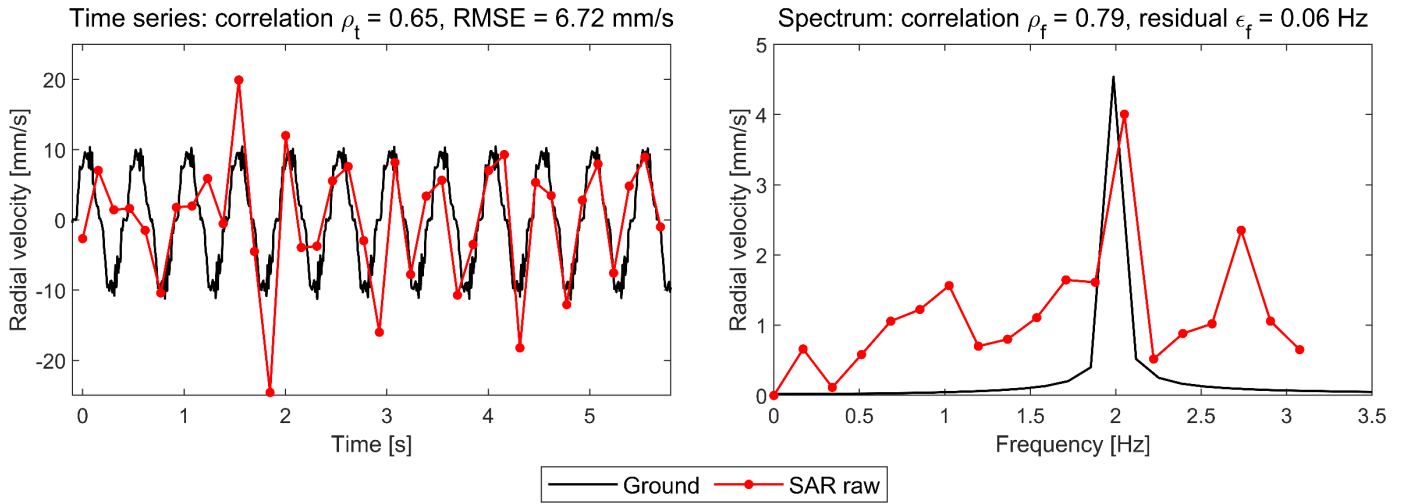

Table 2. Metric results. The table reports for each test: maximum radial velocity value ( $v_{r,max}$ ), acquisition duration ( $t_a$ ), aperture fraction ( $\alpha$ ), overlap ratio ( $\Omega$ ), number of sub-apertures ( $N$ ), sampling frequency ( $f_s$ ), frequency resolution ( $\Delta f$ ),  $RMSE$  and  $RMSE$  relative to max velocity value ( $RMSE\%$ ), frequency residual error ( $\epsilon_f$ ), correlations in time ( $\rho_t$ ) and frequency ( $\rho_f$ ) domains for the raw m-m SAR signal.

Quantity	Test	1	2	3
$v_{r,max}$	[mm/s]	95.5	10.8	3.1
$t_a$	[s]	6.04	5.95	14.70

Test 1:  $\alpha = 7.6\%$ ,  $\Omega = 35.0\%$ ,  $N = 19$ ,  $f_s = 3.23$  Hz,  $t_{\text{sap}} = 0.46$  s,  $\Delta f = 0.18$  Hz

Test 2:  $\alpha = 4.3\%$ ,  $\Omega = 40.0\%$ ,  $N = 38$ ,  $f_s = 6.49$  Hz,  $t_{\text{sap}} = 0.27$  s,  $\Delta f = 0.18$  Hz

Test 3:  $\alpha = 4.5\%$ ,  $\Omega = 49.0\%$ ,  $N = 42$ ,  $f_s = 2.92$  Hz,  $t_{\text{sap}} = 0.66$  s,  $\Delta f = 0.07$  Hz

Figure 4.4. Upsampled SAR FFT spectra compared to ground truths. Plots shows the most dominant frequencies extracted.

Figure 4.5. Test 1: results of model fitting on the SAR measurement, using a frequency of 1.02 Hz.

Figure 4.6. Test 2: results of model fitting on the SAR measurement, using a frequency of 2.01 Hz.

Figure 4.7. Test 3: results of model fitting on the SAR measurement, using frequencies of 0.80 Hz, 0.99 Hz, 1.16 Hz.

#### 4.1 Test 1 – High-velocity, single-frequency vibration

Test 1, presented in Figure 4.1, features the simplest case, with a low single-frequency oscillation (1 Hz) and relatively high vibration velocity ( $v_{r,max} = 95.5$  mm/s). The parameters to obtain the best extraction possible were an aperture fraction  $\alpha = 7.6\%$  and overlap ratio  $\Omega = 43\%$ , resulting in a sub-aperture duration of  $t_{sap} = 0.39$  s and sampling rate of  $f_s = 3.23$  (well above the Nyquist rate for the frequency of interest, 1 Hz). The limited acquisition time led to a spectral resolution of  $\Delta f = 0.18$  Hz. The extracted signal closely matches the ground truth in both time and frequency domains, proved by high Pearson's correlation coefficients, with  $\rho_t = 0.89$  and  $\rho_f = 0.98$  for time and frequency, respectively.

The dominant vibration frequency is accurately identified with frequency residual error of  $\epsilon_f = 0.03$  Hz (lower than the frequency resolution), as well as a correct estimation of the amplitude of the peak in the frequency spectrum. The RMSE in the extraction of the velocity time history is 30.4 mm/s (corresponding to a 31.8% relative to the true peak velocity value).

#### 4.2 Test 2 – Mid-velocity, single-frequency vibration

Test 2, shown in Figure 4.2, presents another constant frequency extraction, however with a frequency of 2 Hz and a vibration amplitude reduced by an order of magnitude to  $v_{r,max} = 10.8$  mm/s, making it a more challenging case. Here, the aperture fraction  $\alpha$  was decreased to 4.3%, and the overlap ratio  $\Omega$  set to 40%, resulting in a sub-aperture duration  $t_{sap}$  of 0.27 seconds and a sampling rate  $f_s$  of 6.49 Hz.

The main frequency component is correctly identified, being the error  $\epsilon_f = 0.06$  Hz (lower than the resolution  $\Delta f = 0.18$  Hz). Some local discrepancies appear in the time-domain signal, including underestimation and overestimation of peak values. Despite the lower absolute RMSE (6.7 mm/s), the relative error is 62.0% due to the lower ground truth amplitude. The time-domain correlation decreases significantly due to the impact of measurement noise, with  $\rho_t = 0.65$ , while frequency domain correlation remains satisfactory at  $\rho_f = 0.79$ . The spectrum also shows minor spurious peaks at 1 Hz and 2.7 Hz.

#### 4.3 Test 3 – Low-velocity, amplitude-modulated vibration

Test 3, represented in Figure 4.3, involved a more complex amplitude-modulated signal with significantly lower velocity magnitude of  $v_{r,max} = 3.1$  mm/s, which is more representative of vibrations from long span bridges or viaducts. An aperture fraction  $\alpha$  of 4.5% and an overlap ratio  $\Omega = 49\%$  were used. This configuration resulted in a sub-aperture duration of 0.66 seconds and a sampling frequency of  $f_s = 2.92$  Hz. In this case spectral resolution was finer, of 0.07 Hz, thanks to the longer acquisition time.

Despite the reduced signal energy, the algorithm extracts the carrier frequency, with a low residual error of  $\epsilon_f = 0.02$  Hz (within the frequency resolution  $\Delta f = 0.07$  Hz) and a frequency domain correlation  $\rho_f = 0.71$  – both comparable to Test 2. Time domain correlation is satisfactory at  $\rho_t = 0.66$ , while the RMSE for this extraction is 1.2 mm/s, with a relative error of 38.7%, the latter being more comparable to Test 1. This suggests that the dominant frequency of vibration has an impact on the quality of the extraction.

#### 4.4 SAR data fitting

Fitting the SAR-extracted data significantly improved the quality of the time-domain signal, both visually and quantitatively. As shown in Figures 4.5, 4.6, and 4.7, temporal resolution was enhanced through model-based fitting without altering the extraction parameters  $\alpha$  or  $\Omega$ . For each test, the dominant frequency components were identified from the upsampled FFT (upsampling factor = 4), and a sum of sinusoids with those frequencies was then fitted to the SAR data by optimizing only amplitude and phase. Results are as follows:

- *Test 1:* From the upsampled FFT, a frequency of 1.02 Hz was extracted. A single sinusoid was fitted, yielding an RMSE improvement from 30.34 to 17.34 mm/s, and a time-domain correlation increase from 0.89 to 0.97.
- *Test 2:* The extracted frequency was 2.01 Hz. After fitting, RMSE dropped from 6.72 to 1.58 mm/s, and  $\rho_t$  improved from 0.79 to 0.98.
- *Test 3:* Multiple dominant frequencies were identified at 0.80, 0.99, and 1.16 Hz. Fitting a sum of three sinusoids led to an RMSE reduction from 1.20 to 0.72 mm/s, and a correlation increase from 0.76 to 0.86.

These results demonstrate that using prior knowledge about the expected oscillatory behavior can significantly enhance the extraction quality. By narrowing the solution space to plausible signal shapes, fitting allows more accurate recovery of the target vibration profile.

### 5 CONCLUSIONS

This paper presented a feasibility study on the use of single-pass SAR images for extracting vibration characteristics from oscillating ground targets via the Sub-Pixel Offset Tracking (SPOT) micro-motion measurement technique. The algorithm was validated through a series of experimental tests, involving an isolated moving Corner Reflector (CR). The performance of the technique was assessed against synchronously acquired ground truth data.

Results demonstrate that SPOT can accurately reconstruct vibration-based information, capturing the dominant frequencies of motion with frequency errors well under the spectral resolution, even under varying conditions of signal amplitude, frequency, and complexity. The algorithm is also able to reconstruct the time histories of radial velocity with correlation values ranging from 0.65 to 0.98 (for the worst case, and best extraction case, respectively) and relative errors RMSE% from 31.8% to 62.0%. For high-velocity, single-frequency oscillations, SPOT achieves excellent correlation with ground truth in both time and frequency domains, respectively at 0.88 and 0.95, with relative RMSE values below 32%. When applied to more challenging low-velocity and amplitude-modulated cases, the method still proves effective in detecting the carrier frequency (with frequency correlations spanning 0.71 to 0.79) and producing meaningful velocity profiles, although the quality declines as vibration velocity decreases, and as frequency content becomes more complex.

Using prior knowledge about the expected oscillatory behavior can significantly enhance the extraction quality. Results from model fitting feature a significant reduction in RMSE and an improvement in correlation, even for the lowest velocity amplitude modulated case, improving from 1.20 mm/s to 0.72 mm/s (with a correlation increase from 0.66 to 0.86).

Limitations concerning m-m SAR measurements are primarily attributed to SAR acquisition constraints, such as short acquisition time, noise and image clutter. Alternative processing strategies could be explored to overcome these issues, particularly those using the phase information rather than the reflectivity. Additionally, the noise-affected velocity profile, in combination with limited acquisition durations, limits the application of m-m SAR for time domain modal extractions, to reconstruct not only the natural frequency but possibly the modeshapes and damping coefficients. On the other hand, the algorithm proves to be quite effective for extracting the frequency spectrum.

Despite these challenges, the study confirms that SAR m-m measurement opens new possibilities for remote vibration-based SHM. Future work will focus on refining the methodology by optimizing the extraction parameters, integrating phase-domain information, improving noise suppression models, and validating the algorithm on real-world bridge structures.

## ACKNOWLEDGMENTS

The study presented was funded by: the European Space Agency under the projects “Bridge Monitoring Based on Single Pass SAR Images” and “EO4Security- Innovative SAR Processing Methodologies For Security Applications-Topic B2: Micro-Doppler Processing”, the ReLUIS Interuniversity Consortium under the agreement DPC-ReLUIS 2020-2022 and DPC-ReLUIS 2024-2026 WP 6 “Monitoring and satellite data”, and the European Union- Next Generation EU, Mission 4 Component 2 - CUP E53D23003560006.

The authors would also like to acknowledge the collaboration of Umbra for providing satellite images, the Glasgow City Council for authorizing on-site tests., and the University of Trento and the University of Strathclyde for helping with the tests.

**ABSTRACT:** The data-driven approach to vibration-based Structural Health Monitoring aims to detect anomalies in the monitored modal properties. A key step in this framework is compensating for the normal variability in the data, which is due to the strong influence of environmental and operational variables on the structure's dynamic behavior. The decision-making process is then formulated as a binary classification problem, supported by an appropriate alarm threshold to distinguish between normal and anomalous structural conditions. The threshold is typically set on the statistical distribution of the novelty index computed during the training phase, often assuming a Gaussian distribution of the data. However, anomaly detection requires a more refined modeling of the distribution tails. The present paper investigates the use of Extreme Value Theory for threshold setting, focusing on the Block Maxima sampling technique and the Generalized Extreme Value distribution. A comparison with conventional approaches demonstrates the significant accuracy achievable through the extreme value theory. The natural frequency time histories of the KW51 bridge are used as benchmark data to highlight the method's effectiveness in improving the reliability of early damage detection.

**KEY WORDS:** Data-driven Structural Health Monitoring; Novelty detection; Threshold setting; Environmental and operational variables; Extreme Value Theory.

## 1 INTRODUCTION

The remote and automated evaluation of the structural conditions through Structural Health Monitoring (SHM) is crucial in the modern management of civil engineering assets. SHM enables a transition from the traditional scheduled maintenance approaches to proactive strategies that exploit the early damage identification, thereby enhancing safety and reducing long-term maintenance costs [1]. In the context of SHM, damage detection is the first step of damage identification, and it is commonly approached through data-driven methodologies. In this framework, the damage detection problem is cast as a novelty detection one [2], [3]. This strategy involves extracting damage-sensitive features (DSFs) from sensor data through automatic Operational Modal Analysis (OMA) techniques, which are further analyzed to detect deviations from a baseline condition. As such, damage detection is framed as a binary classification problem, aiming to distinguish the anomalous structural behavior, caused by either progressive degradation or sudden events, from the normal operating state [4].

In vibration-based SHM the modal properties or other related parameters are often selected as DSFs. Several applications reported in the literature consider the natural frequencies as DSFs because they can be easily obtained from measurements of the ambient vibration response of structures by a few, appropriately located sensors. Even if natural frequencies are relatively easy to monitor and informative for the first level damage detection, they are also very sensitive to the influence of environmental and operational variables (EOVs), such as temperature changes over time. An accurate damage detection therefore requires the application of appropriate compensation techniques to isolate the changes in the structural behavior due

to damage or degradation phenomena from environmental and operational effects on the selected DSFs [5], and, as a consequence, enhance the reliability of the SHM outcomes. Such a compensation relies on setting data normalization models developed with reference to data collected in a training phase.

After the data normalization stage, the DSFs are transformed into novelty indexes (NIs), which are scalar indicators used to quantify how much a given observation deviates from the expected behavior. In order to assess whether the observed structural response should be considered anomalous, appropriate threshold values must be set, so that if the NIs overcome the threshold a warning can be issued. This is, therefore, another key step in the implementation of reliable modal based SHM strategies, in addition to the previously mentioned compensation of environmental and operational influence on DSFs (Figure 1).

A critical aspect in threshold setting is related to the need of defining it in an unsupervised context, that is to say, by using only data from the reference (nominally, healthy) condition of the structure. In the common practice, a Gaussian distribution for NIs is often assumed for the sake of threshold setting. However, this assumption is frequently inadequate for the novelty detection tasks [1]. As a result, setting the threshold based on a predefined data distribution can be misleading. Moreover, this approach does not take into account that detecting rare, extreme deviations is the focus of any SHM strategy, and, as such, an appropriate data-driven threshold setting approach should rely on the careful analysis of the tails of NI distribution.

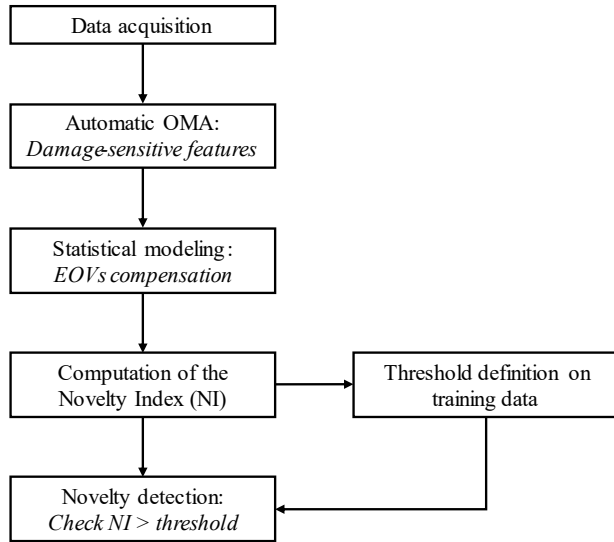

Figure 1. Flowchart of a typical data-driven SHM framework.

The Extreme Value Theory (EVT) represents a suitable alternative to the approaches based on the assumption of a Gaussian data distribution, as it focuses on the tail of the distribution – where anomalies are most likely to occur – thereby enabling a more precise threshold estimation [6].

This paper discusses the problem of the appropriate alarm threshold setting in the context of modal-based damage detection. A comparative assessment of different threshold setting strategies is presented by processing a benchmark dataset available in the literature. The analysis starts from the computation of NIs from natural frequency time histories through the combination of Gaussian Mixture Model (GMM) and Mahalanobis Squared Distance (MSD) to mitigate the influence of EOVs [7]. Afterwards, an EVT-based approach is applied for threshold setting. It resorts on the Block Maxima (BM) method to identify extreme observations and to model them according to the Generalized Extreme Value (GEV) distribution [8]. The effectiveness of the proposed approach in enhancing the robustness of novelty detection in modal-based SHM systems is demonstrated through quantitative comparisons with standard threshold setting methods.

The paper is structured as follows: after the introduction, Section 2 describes the methodological framework, detailing both the compensation strategy for data normalization with respect to the EOV influence and the computation of the NI time series. Moreover, Section 2 also outlines the EVT-based procedure for threshold setting. Section 3 presents the applicative case study and the characteristics of the benchmark dataset, followed by the analysis and discussion of results. The key findings of the study are finally summarized in the conclusions.

## 2 METHODOLOGY

### 2.1 Multivariate modeling of damage sensitive features under EOV influences

The present section describes the approach adopted for the compensation of EOV effects on DSFs and the computation of the NI. In this context, the matrix  $\mathbf{X} \in \mathbb{R}^{n \times m}$  represents the training dataset, holding  $n$  observations of the natural frequencies of  $m$  vibration modes. These are experimentally

collected under varying environmental and operational conditions at the beginning of the monitoring period or, more generally, in a reference monitoring period.

GMM is herein applied to represent  $\mathbf{X}$  as a finite mixture of multivariate Gaussian distributions. The objective of this data processing stage is the effective modeling of the dominant feature clusters associated with the reference states of the monitored structure. The mixture density function is formally defined as:

$$f_{mix}(\mathbf{x}) = \sum_{q=1}^Q \eta_q f_q(\mathbf{x}|\boldsymbol{\mu}_q, \boldsymbol{\Sigma}_q) \quad (1)$$

Here,  $f_q(\mathbf{x}|\boldsymbol{\mu}_q, \boldsymbol{\Sigma}_q)$  denotes the multivariate Gaussian probability density function of the  $q$ -th component, fully characterized by the mean vector  $\boldsymbol{\mu}_q$ , the covariance matrix  $\boldsymbol{\Sigma}_q$ , and the mixture weight  $\eta_q$ . The model parameters are obtained by the Maximum Likelihood Estimation (MLE) method, where the maximization of the likelihood function is achieved by the Expectation-Maximization (EM) algorithm [9].

The optimal number of components  $Q$  in Equation (1) is determined by minimizing the Bayesian Information Criterion (BIC), a standard model selection metric that penalizes model complexity to prevent overfitting [7]. This probabilistic framework supports the implementation of a robust anomaly detection methodology by leveraging the different components of the mixture model while inherently accounting for the influence of EOVs.

In order to obtain the NI time series for anomaly detection, the MSD is adopted as a multivariate metric to measure the distance between the observed DSFs and the GMM components. It incorporates both variable scales and correlations [10], and, given the generic test observation  $\mathbf{z}$ , its MSD relative to each GMM component can be computed as follows:

$$MSD_q(\mathbf{z}) = (\mathbf{z} - \boldsymbol{\mu}_q) \boldsymbol{\Sigma}_q^{-1} (\mathbf{z} - \boldsymbol{\mu}_q)^T \quad (2)$$

where  $\boldsymbol{\mu}_q$  and  $\boldsymbol{\Sigma}_q$  denote the mean vector and covariance matrix of the  $q$ -th GMM component, respectively. The NI corresponding to the generic test observation  $\mathbf{z}$  is then given by the minimum distance across all components:

$$NI(\mathbf{z}) = \min\{MSD_q(\mathbf{z})\} \quad (3)$$

Following the above-described approach, if a new observation is consistent with the reference structural condition, it will be close to one of the GMM components computed in the reference training period, and it will yield a low NI value. Conversely, if the structure has transitioned to a damaged state, the new observations will significantly diverge from all the GMM components in the training stage, resulting in larger NI values with respect to the undamaged condition.

### 2.2 Threshold setting methods for Novelty Detection

In the context of novelty detection, the EVT-based approach provides a robust statistical framework for threshold determination. This method is grounded in the theorem stating that the distribution of extreme values can converge only to one of three canonical forms: Gumbel, Weibull, or Fréchet distributions. To simplify the process, the GEV distribution is

employed, as it unifies all three types within a single parametric family. The GEV distribution is expressed as follows [8]:

$$G(Y) = \exp \left\{ - \left[ 1 + \xi \left( \frac{Y - \lambda}{\sigma} \right) \right]^{-\frac{1}{\xi}} \right\} \quad (4)$$

where  $\xi$ ,  $\sigma$  and  $\lambda$  are the shape, scale, and location parameters, respectively. It is defined on the set of maxima  $Y$ , satisfying the condition  $1 + \xi(Y - \lambda)/\sigma > 0$ , with  $\lambda$  and  $\xi$  real-valued parameters, and  $\sigma > 0$ . The unknown parameters are estimated by using the MLE method.

In order to define the population of extreme values to be fitted by the GEV distribution, the BM method is employed. Thus, the NI time series in the training period is divided into non-overlapping blocks of equal length, and the maximum value is selected in each block. Assuming that the structure is initially undamaged (null hypothesis), and selecting a significance level  $\alpha$ , the threshold can be defined as the corresponding quantile of the fitted distribution [8]:

$$t = \begin{cases} \lambda - \frac{\sigma}{\xi} [1 - \{-\log(1 - \alpha)\}^{-\xi}], & \xi \neq 0 \\ \lambda - \sigma \log\{-\log(1 - \alpha)\}, & \xi = 0 \end{cases} \quad (5)$$

In addition to the previously described approach based on EVT, in this study also a more conventional method for threshold setting is considered for the purpose of comparative assessment. It consists in setting a predefined False Alarm Rate (FAR), interpreted as the tolerable proportion of false alarms in the training data. The threshold  $t$  is then calculated as the cut-off value that satisfies [11]:

$$\frac{\text{number of false alarms } (t)}{n} = FAR \quad (6)$$

Another widely adopted strategy for threshold setting is based on the assumption of Gaussian distribution of the DSFs and the use of MSD as the novelty index. Under these assumptions, the NI follows a  $\chi^2$  distribution, and the threshold can be directly obtained as the quantile of the distribution at the significance level  $\alpha$  [7].

For the sake of the comparative performance assessment of the considered threshold setting approaches, the following parameters are computed: the number of false positives (FPs), the number of false negatives (FNs), and the Youden index. The latter, derived from the Receiver Operating Characteristic (ROC) curve, provides a measure of the balance between sensitivity (the true positive rate) and specificity (the true negative rate) and results in a single value that reflects the overall diagnostic performance of the considered approach [12].

### 3 ANALYSIS OF THE BENCHMARK DATASET

The data collected from the SHM system installed on the KW51 bridge in Belgium are processed for the objectives of the present study. The KW51 bridge is a steel bowstring railway bridge located in Leuven, Belgium (Figure 2). A detailed 15-month monitoring program was conducted between late 2018 and early 2020 to capture the dynamic behavior of the bridge under operational conditions [13]. Acceleration data collected during this period were processed using Operational Modal

Analysis techniques [14], allowing the identification of the first 14 natural frequencies of the bridge.

Figure 2. KW51 bridge in Leuven, Belgium [13].

During the monitoring period, the bridge was retrofitted to correct a construction defect identified during inspection. The intervention involved strengthening the connection between the diagonals, arches, and bridge deck by welding a steel box around each original bolted joint. Specifically, the bridge was monitored before the retrofit intervention between October 2<sup>nd</sup>, 2018, and May 15<sup>th</sup>, 2019, and after that in the period between September 27<sup>th</sup>, 2019, and January 15<sup>th</sup>, 2020.

In the application of the data processing and threshold setting approaches described in Section 2, the natural frequency time series corresponding to modes 1, 2, 7, 8, 10, 12, and 14 were excluded from the analysis due to significant data gaps that prevented successful monitoring of these modes. This was made in agreement with similar considerations reported in [13]. Thus, only the natural frequency time series of modes 3, 4, 5, 6, 9, 11, and 13 were considered for the present analysis. Minor data gaps in these time series were filled by linear interpolation.

In addition to mode selection, since the retrofit intervention introduced a significant shift in the considered natural frequency time histories, the difference in the average value of corresponding natural frequencies before and after the intervention was intentionally reduced to make more challenging the appropriate alarm threshold setting as a result of a reduced change in the observed structural behavior. Specifically, the frequency scatter was scaled down to 25% of its original value to avoid a straightforward or even trivial novelty detection (Table 1).

Table 1. Reduced scatter between average frequency before and after the retrofitting.

Mode	Frequency scatter	
	Original	Reduced
3	0.53%	0.13%
4	1.17%	0.29%
5	0.33%	0.08%
6	2.07%	0.52%
9	0.76%	0.19%
11	2.02%	0.51%
13	1.44%	0.36%

Indeed, without this correction, the frequency shift due to retrofit results in an overly obvious differentiation between pre- and post-intervention states, thereby undermining the relevance of the novelty detection process and threshold setting procedure.

A detailed inspection of the collected natural frequency time histories also reveals some sharp increases in frequency values in the first monitoring period (Figure 3). A detailed investigation about the occurrence of these particular patterns is reported in [13], where the correlation between the natural frequencies of the bridge and the measured temperature has been evaluated. That study showed that those singular patterns occur when the temperature falls below 0 °C. Indeed, before the retrofit intervention, the observed structural behavior is characterized by a bilinear trend in the frequency-temperature relationship, with a knee-point around 0 °C. The interpretation of this phenomenon has been guided by insights gained from similar previously analyzed case study where a similar relationship was observed and attributed to the freezing of the asphalt layer [15]. Further investigations specifically focused on the KW51 case study, also supported by finite element model updating, confirmed that the observed singularities in the natural frequency patterns were associated with the freezing of the porphyry ballast layer beneath the railway tracks.

Excluding the period during which the intervention took place, the dataset employed in this study comprises 6287 observations of the seven selected natural frequencies of the bridge, 3977 of which were collected before the retrofit

intervention, while the remaining 2310 were gathered after the completion of the works.

In the context of the present study, the first 3579 samples collected before the retrofit – approximately corresponding to 90% of the available observations in the same period – have been used to train the GMM and to define threshold values for the subsequent comparative analyses. The remaining 10% of the dataset collected before the structural intervention has been used as a validation set, in order to check that no structural changes are detected before the onset of the retrofit. The whole natural frequency time series collected after the retrofit intervention are instead employed as the test data (Figure 3) to assess the accuracy of the different novelty detection strategies.

The trained GMM has been specifically designed to model the variability induced by EOVs, including the effects of freezing conditions observed between late January and early February 2019. The optimal number of GMM components has been selected as discussed in Section 2.1, resulting in a five-component GMM, which has been identified as the appropriate representation of the training dataset. Once the model of the operational variability of natural frequencies has been established, the NI time series has been computed according to Equations (2) and (3). The resulting NI values, shown in Figure 4, demonstrate the model's capability to effectively account for the influence of EOVs. Specifically, the NIs computed over the training data exhibit a consistent and stable behavior, indicating that the model successfully captures the normal variability of data, even under freezing conditions. Moreover, the NIs

Figure 3. Time histories of the seven selected natural frequencies and partitioning of the dataset into training, validation and testing sets.

Figure 4. NIs time series during the entire monitoring period.

calculated on the validation set remain aligned with those obtained during the training period, thus confirming the generalization capability of the considered model.

In contrast with these results, a marked upward shift in the NI trend can be observed when data collected after the retrofit intervention are considered, clearly suggesting the transition to a different structural state. This result confirms the effectiveness of the proposed approach in distinguishing between the normal environmental and operational variability of the selected DSFs and that associated to the occurrence of changes in the structure as a result of damage or, as in the present case, of a retrofit intervention. In the context of the novelty detection framework, an alarm threshold has been established based on the NIs computed from the training data. To this aim, a combination of the BM method and the GEV distribution fitting has been applied, as further illustrated hereafter.

The training NI time series has been divided into consecutive, non-overlapping blocks, and the maximum value from each block has been extracted to collect a set of extreme values. The choice of the number of blocks plays a critical role in the process [8]. In this work, the number of blocks has set equal to 300.

Figure 5 shows the comparison between the empirical cumulative distribution function (CDF) of the extracted maxima and the CDF of the fitted GEV distribution. The close agreement between the two curves indicates that the GEV distribution effectively describes the statistical variability of the observed maxima.

Figure 5. GEV distribution modeling: comparison between empirical CDF and fitted GEV distribution.

The fitted GEV model has been exploited to determine the alarm threshold corresponding to a significance level  $\alpha$  of 0.05, as per Equation (5). Figure 7a illustrates the application of the determined threshold for novelty detection analysis of the full dataset, highlighting the occurrences of misclassification. During the training and validation periods, corresponding to the structural condition before the retrofit intervention, only a few isolated points exceeded the threshold, indicating a low false positives rate and, therefore, a high specificity of the proposed approach in characterizing the structural behavior in this state. Notably, after the retrofit intervention, only a very limited number of observations remained under the threshold. This demonstrates also the high sensitivity of the method in detecting the transition to a new structural condition, as it

successfully identifies nearly all test data points, referring to the structural response after the retrofit intervention, as anomalous.

For the comparative assessment of the effectiveness of the method for threshold setting based on the GEV distribution, threshold values are also determined by means of the previously mentioned alternative procedures. The related results are presented in Figures 7b and 7c.

Table 2 summarizes the resulting threshold values, along with the corresponding number of misclassifications. Setting a fixed cut-off threshold is the most straightforward approach for the present task. For the considered application, a fixed cut-off threshold has been defined by setting the FAR to 0.05, meaning that up to 5% of the training data points are tolerated as FPs, in agreement with Equation (6).

As a second alternative approach, a threshold has been set based on the assumption of normal distribution of the natural frequencies in the training stage. As a result, the NIs derived through the MSD are expected to follow a  $\chi_m^2$  distribution, with  $m = 7$  degrees of freedom (with  $m$  corresponding to the number of modes considered). From this distribution, a threshold corresponding to a given significance level  $\alpha$  has been determined.

The analysis of the results reported in Table 2 indicates that, although the threshold values obtained as the 95% cut-off value or through the  $\chi^2$  CDF achieve a zero false negative rate – meaning that all observations in the testing stage are correctly classified as anomalous –, they still suffer from a relatively high number of FPs, which can jeopardize the reliability and practicality of the monitoring system (Figure 7b and 7c). On the other hand, the EVT-based method for threshold setting yields a small number of FPs as well as a small number of FNs. While this method might appear less conservative, it establishes a threshold that better approximates the optimal balance between FPs and FNs. This can be demonstrated by looking at the coordinates associated with the various thresholding strategies when they are plotted on the ROC curve (Figure 6).

Table 2. Number of misclassifications for the different threshold setting procedures.

Approach	Threshold	FPs	FNs
BM-GEV	21.2	24	29
Cut-off	12.4	199	0
$\chi^2$ CDF	14.1	120	0

Figure 6. ROC curve and points corresponding to different threshold setting approaches.

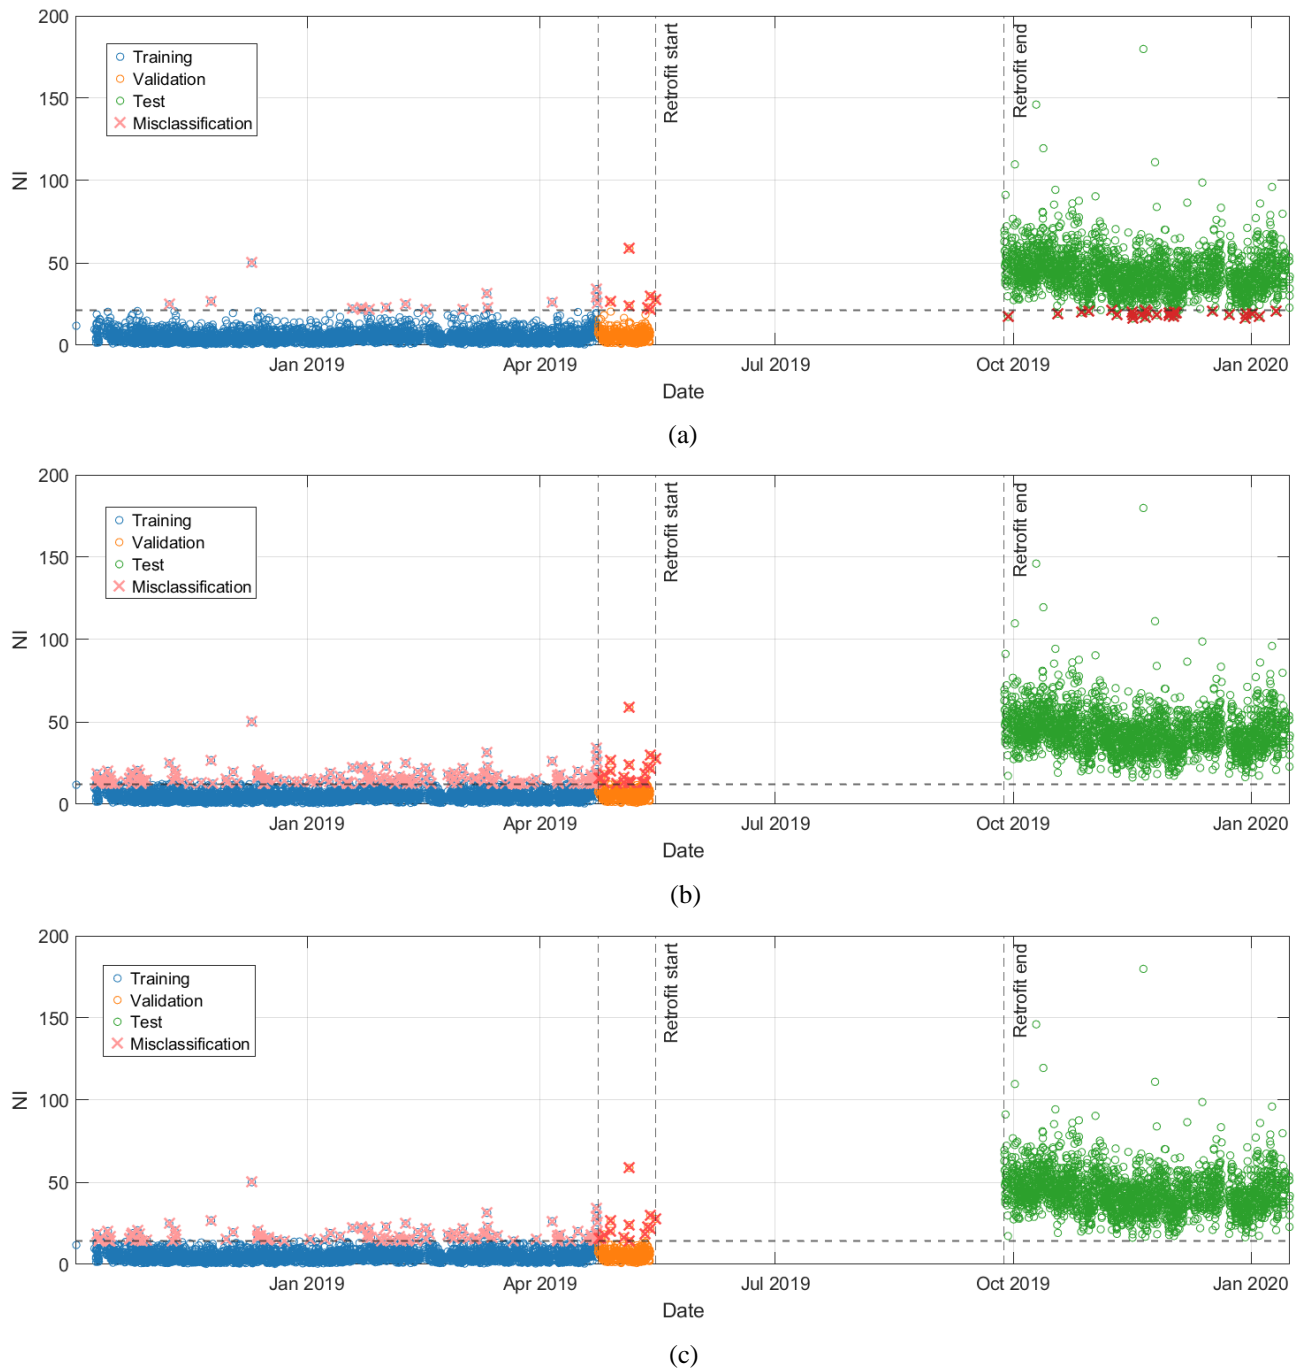

Figure 7. Novelty detection according to: EVT-based threshold (a), 95% cut-off threshold (b), and  $\chi^2$  distribution-based threshold (c).

Indeed, the proximity of a point to the top-left corner of the ROC space – representing a low false positive rate and a high true positive rate – serves as a qualitative measure of the model classification performance. In addition, the distance of each threshold point from the bisector (corresponding to the line of no-discrimination) quantified by the Youden index provides a quantitative measure for the selection of the most effective threshold value.

The Youden index values have been computed for each threshold setting method, and they are reported in Table 3. The results indicate that the threshold derived through the BM-GEV method lies very close to the optimum, corresponding to the maximum Youden index. Furthermore, it outperforms the other

considered approaches, confirming an excellent balance between sensitivity and specificity.

Table 3. Youden index values corresponding to different thresholds values.

Approach	Youden index
Max	0.987
BM-GEV	0.981
Cut-off	0.950
$\chi^2$ CDF	0.970

Figure 8. NIs time series during the entire monitoring period, considering the post-retrofitting condition as the healthy state for model training and validation, and EVT threshold-based novelty detection.

The analysis presented thus far follows the chronological order of data acquisition, corresponding to the subdivision of the dataset into training, validation, and testing sets. Since the retrofitting was intended to correct a construction defect, it led to an improvement in the structural condition of the bridge. As such, the post-retrofitting state can be regarded as the actual healthy condition.

An additional analysis is conducted by applying the proposed methodology using post-retrofitting data for model training and validation, and subsequently testing the model on pre-retrofitting observations. Once again, the novelty analysis results (Figure 8) confirm the model's ability to compensate for EOVs effects and demonstrate strong generalization performance, as evidenced by the NIs of validation data aligning closely with the training trend. The distinct structural condition characterizing the pre-retrofitting period is clearly revealed. Furthermore, a noticeable spike in the NIs time series during the freezing period highlights the presence of a transient condition within the pre-retrofitting state. In this case as well, applying EVT-based threshold yields an excellent balance between FPs (0.5%) and FNs (0.1%).

## CONCLUSIONS

The present study has focused on the comparative performance assessment of different methods for determining a reliable threshold for anomaly detection to be applied in the context of data-driven, modal-based SHM. The natural frequency time series of the KW51 bridge served as the benchmark dataset for the performance assessment. It has been processed using a method that combines GMM and MSD to compute the NI time series and compensate the normal variability of the selected DSFs due to changing environmental and operational conditions. An approach based on EVT has been applied and compared with alternative approaches for threshold setting. The EVT-based approach started from the identification of a set of maxima in the NI time series at the training stage according to the BM method; the GEV distribution was afterwards fitted to the collected maxima and used to define the alarm threshold. Comparing the performance of the EVT-based method with other approaches for threshold setting has shown that, for the considered dataset, the BM-GEV approach appears to be the most precise, with an optimal balance between FPs and FNs, as confirmed by the value of the Youden index derived from the ROC curve.

**ABSTRACT:** Structural monitoring is crucial for extending the service life of civil structures. Vibration-based monitoring is widely employed across various applications, leveraging both traditional and innovative sensing technologies. Among these, video-based methods have emerged as a promising and cost-effective approach for evaluating structural displacements at critical points. This paper presents a novel vision-based procedure enabling accurate three-dimensional structural displacement measurement using only a single camera. The method applies to assessing dynamic effects on bridges subjected to dynamic loads. The algorithm extracts displacements by tracking predefined targets over time. Special attention is given to reconstructing small 3D displacements from videos that inherently capture two-dimensional projections of the scene. The procedure is validated through experiments on a steel frame in a controlled environment, comparing displacement time histories with imposed vibrations from a shaking table. The originality of this work lies in achieving accurate 3D measurements with minimal equipment, offering a practical and innovative solution for structural health monitoring.

**KEY WORDS:** Vision-based monitoring; Structural vibrations; Displacement tracking; Laboratory tests; Experimental validation.

## 1 INTRODUCTION

Structural Health Monitoring (SHM) is a crucial component of modern infrastructure management, offering valuable insights into the condition of structures and helping prevent catastrophic failures while extending their service life. SHM utilizes a combination of sensors, data analysis methods, and computational models to evaluate the performance and safety of civil infrastructure such as bridges, buildings, dams, and other critical structures. The main objective of SHM is to detect changes in the structural integrity or behaviour of a structure, often before visible damage occurs, ensuring continued safety, preventing collapses, and reducing maintenance and repair costs.

SHM systems typically employ a range of sensors to monitor structural responses, such as strain, displacement, and acceleration. These sensors, including accelerometers, strain gauges, displacement transducers, and fibre optic sensors, generate reliable data but they often offer limited spatial coverage and necessitate the installation of dense sensor networks, requiring the structure to be accessible. This can pose challenges during extreme events or when access is restricted, such as during periods of heavy traffic, in remote locations, or unsafe structures. A significant advancement in SHM has been the integration of contactless technologies, which enable the installation of sensors without the need for extensive cabling and, therefore, without interrupting the operation of the structure [1, 2, 3].

These contactless systems allow for easier deployment, even in hard-to-reach or remote areas. With that premise, non-contact monitoring has become increasingly popular. Contactless technologies for civil monitoring encompass a range of methods, including global navigation satellite systems (GNSS) [4, 5], satellite remote sensing [6, 7], terrestrial radar interferometry [8], and vision-based techniques [9]. Among these, vision-based techniques stand out as the only remote sensing approach that can reduce dependence on expensive industrial products [10]. Indeed, these methods have shown

considerable promise even when using consumer-grade devices such as standard video cameras or smartphones [11, 12]. This progress is largely attributed to the development of low-cost technologies that provide high resolution and high frame rates, enabling accurate monitoring of large-scale structures in both static and dynamic fields.

These technologies use video feeds to track structural displacements, vibrations, and deformations, providing a flexible, cost-effective alternative to traditional methods and potentially eliminating the need for direct contact with the structure. The primary objective of such a system is to automatically and reliably transform video data into actionable insights. The fundamental concept behind vision-based monitoring is simple: a video of the structure being monitored is recorded, and the individual frames are analyzed, either in real-time or afterward, to extract motion data. This process generates displacement time histories, which can be further used to calculate strains, velocities, and accelerations. Vision-based methods offer several technical advantages, such as directly measuring displacements, which eliminates the need for the double integration of accelerations. Additionally, a single camera sensor can provide distributed monitoring, enabling the extraction of displacement data from multiple points on the structure within one video recording.

Beyond these technical benefits, the vision-based approach allows for substantial cost savings and significantly reduced setup efforts compared to traditional monitoring systems. Due to these advantages, vision-based techniques have garnered increasing attention in civil engineering research. Recent studies, including those by [13, 14, 15, 16], extensively review vision-based applications, including tests on bridges [17, 18, 19], and footbridges, [20, 21, 22].

A vision-based monitoring campaign and set up requires careful consideration and pre-planning, tailored to the specific structure being monitored. In civil engineering, two-dimensional measurements are typically favored because of their practicality and effectiveness. These measurements are

commonly employed to monitor vertical and transverse vibrations of bridges, as well as the horizontal displacements of buildings and towers. In vision-based applications, a-priori estimating the expected displacements of the structure is crucial for selecting the right camera parameters and determining the optimal camera-to-structure distance, ensuring accurate detection of displacements. While a single camera is usually sufficient for detecting in-plane movements, capturing the full 3D motion of all relevant points can be challenging. Typically, this requires the use of multiple synchronized cameras, each focusing on different parts of the structure. Differently, the proposed procedure enables the reconstruction of 3D motion using just a single camera. This approach simplifies the installation, eliminates the need for video synchronization and the geometrical merging required in stereovision.

In addition to the camera(s), it is essential to identify the sections of the structure to be monitored. In this regard, it is possible to choose intrinsic notable elements of the structure itself [15, 23], such as prominent details, corners, holes, or bolts, or install artificial high-contrast targets on the sections of interest. The first option does not require access to the structure, avoiding traffic disruption, but the second option generally provides more accurate results.

While highly effective in many applications, vision-based monitoring is featured by critical aspects that cannot be overlooked. A key limitation is the sensitivity to environmental conditions, such as vibrations of the camera or its support due to user intervention or wind, non-uniform air refraction caused by temperature differences between the camera and the monitored object, ambient light condition, weather, and visibility, all of which can affect data accuracy. Literature on the assessment of environmental uncertainties in vision-based monitoring includes theoretical analyses and laboratory testing [16, 24], but outdoor experiments are still limited.

The accuracy of measurements relies not only on the camera technical specifications (hardware) but also on video post-processing (software), which includes challenging tasks such as camera calibration, target tracking and pixel-to-metric conversion. This paper presents a vision-based approach for accurately assessing the condition of civil structures and infrastructure, with particular focus on the transformation of image units into real-world units, which is crucial in large-scale civil constructions where perspective distortions can significantly affect measurement accuracy. Aiming to propose a reliable and validated vision-based method for real-world applications, this study evaluates the procedure in a controlled environment, focusing on detecting the dynamic displacement of a laboratory steel frame subjected to controlled shaking. For validation purposes, the vision-based results are compared to reference displacements, highlighting the potential of this method for accurate monitoring.

The paper is organized as follows: Section 2 outlines the procedure framework, detailing each step of the proposed method, from the setup of the monitoring campaign to the post-processing of the recorded video. Section 3 presents the experimental test, specifically designed to assess the performance of the procedure across different camera-to-structure distances. Finally, Section 4 addresses conclusions and future perspectives.

## 2 PROCEDURE FRAMEWORK

The proposed vision-based procedure aims to determine the actual dynamic displacement of a structure within its reference system, effectively filtering out camera vibrations and ensuring independence from the camera position and orientation.

The vision-based procedure relies on different transformation of coordinates. To provide clarity, the reference systems involved are described progressively as follows:

1. The 2D image reference system ( $\pi$ ), which is related to camera sensor reference system by means of the focal length ( $f$ ) and optical center ( $o$ ) in a camera pinhole model. Specifically, the image reference system can be scaled and mirrored (with respect to the optical center) in order to obtain the sensor reference system. The image coordinates of this system are denoted as  $\eta$  and  $\xi$ .
2. The 3D real-world reference system ( $W$ ) located in the optical centre, which represents millimeter displacements, derived from pixel displacements via a three-dimensional mapping process. One axis of the system points in the viewing direction of the camera, along the optical axis. The remaining axes define the plane orthogonal to the optical axis, representing the front side of the camera.
3. The structure reference system defined by the coordinates ( $x, y, z$ ), which uniquely defines displacements along the main directions where structural motion occurs, ensuring that the results are independent of the camera pose.

The extraction of displacements within the image-plane ( $\pi$ ) is straightforward and it is carried out by comparing image coordinates ( $\eta, \xi$ ) across sequential frames. However, deriving the displacement time series in the structure reference system requires careful consideration of several key aspects.

These include the precise calibration of camera intrinsic parameters, accurate detection and frame-by-frame tracking of the target position within the image plane, establishing the correspondence between 2-D points in the image coordinate system ( $\pi$ ) and their corresponding 3-D points in the real-world coordinate system ( $W$ ) to account for potential perspective effects, roto-translating the results to align with the motion axes of the structure being analyzed, and filtering out unintended camera shaking to ensure measurement reliability.

To this end, a brief overview of the procedure is provided as follows:

- Stage 1: Monitoring set-up.
- Stage 2: Calibration of the camera.
- Stage 3: Post-processing of the recorded video, with the detection and the tracking of specific features.
- Stage 4: Perspective-3-Points method to establish the relationship between 2-D coordinates in the image-plane ( $\pi$ ) and their corresponding 3-D points in the real-world ( $W$ ).
- Stage 5: Transformation from real-world ( $W$ ) to structure ( $x, y, z$ ) reference system.
- Stage 6: Filtering of camera unintended vibrations.

### 2.1 Stage 1: Monitoring set-up

A vision-based monitoring system requires careful pre-planning based on the specific characteristics of the structure under observation. First and foremost, it is essential to identify the sections of the structure to be monitored, with each selected section being associated with distinguishing features to be

tracked. These may either be intrinsic, notable characteristics of the structure itself or artificial high-contrast targets placed in areas of interest, yielding more accurate results at the expense of the need to directly access the structure. Specifically, the procedure is designed for high-contrast artificial targets featuring a checkerboard pattern.

Additionally, it is crucial to estimate the expected structural displacements, as the magnitude of these displacements helps determine the necessary level of accuracy. This, in turn, guides the selection of the camera specifications, including the camera-to-structure distance, which depends on factors such as obstacles or finding a stable vantage point; the optical lenses with an appropriate range of focal length ( $f$ ) to ensure the desired field of view at that distance; and the frame rate, selected to adequately sample the expected vibration frequencies. For civil structures such as bridges and buildings, dominant modal frequencies typically lie below 10 Hz, indicating that frame rates of 30 frames per second (FPS) are generally adequate. This allows for the utilization of consumer-grade cameras, which is increasingly feasible thanks to recent technological advancements.

## 2.2 Stage 2: Calibration of camera parameters

Calibrating camera parameters is a crucial step for understanding how the sensor captures and processes visual data. In the current procedure, the calibration is performed according to the diffused approach proposed in [25]. This involves determining several parameters, including mm-to-pixel transformation factor (from sensor to image reference system), focal length ( $f$ ), and lens distortion coefficients (which account for geometric distortions introduced by the lens). Calibration outcomes will be employed in Stage 4 for the derivation of the relationship between 2-D points in the image-plane ( $\pi$ ) and their corresponding 3-D points in the real-world ( $W$ ).

## 2.3 Stage 3: Post-processing of the recorded video

Video post-processing is composed of three basic steps: definition of the Regions of Interest (ROIs), feature detection and feature tracking.

ROIs are defined in the first frame of the video as areas surrounding specific targets located on the structure or on the ground. Targets on the structure are key points of interest for dynamic characterization, while targets on the ground are used for camera vibration filtering. In the application case study, checkerboard targets are adopted.

The definition of a ROI for each target allows to narrow the operational area within the video frames, where the features of the targets are detected, thus accelerating the automated analysis. The defined ROIs are managed as matrices of pixels, where each pixel is characterized by its 2-D coordinates (expressed in pixels relative to the frame upper-left corner) and a unique RGB intensity value.

The next step involves the detection of sparse feature points, also known as key points, which characterize the digital representation of each target. A key point is generally a small region of the image characterized by unique and invariant features, described by a matrix or a vector that encodes its characteristics. A wide variety of key point types have been proposed in the literature, along with specific algorithms for

Figure 1. Feature detection via Harris function.

detecting and describing them [15]. In the presented procedure, the Harris-Stephens algorithm [26] is used to detect the internal corners of each checkerboard target (see Figure 1 for an illustrative example). A corner represents the intersection of two edges, where an edge is characterized by a sharp change in image brightness. In addition to their distinctiveness due to RGB intensity contrast, corners exhibit geometric invariance properties, making them robust features for various applications. Their stability under transformations such as translation, rotation, and changes in scale or illumination enhances their suitability for tasks like detection and tracking.

Once the checkerboard corners are identified in the initial frames of the video, their locations in the subsequent frames are tracked with the Kanade-Lucas-Tomasi algorithm [27, 28], a well-established technique for visual tracking applications. In this process, the movement of the key points is determined through optical flow estimation. The output of this stage consists of a time series of coordinates in pixel units, for each corner of every checkerboard target.

It should be carefully considered that the obtained displacement time series  $\eta$  and  $\xi$  solely represent the motion of the features within the image-plane ( $\pi$ ). To determine the actual displacements of the structure, additional analysis is required, such as establishing the relationship between 2-D points in the image-plane ( $\pi$ ) and their corresponding 3-D points in the real-world ( $W$ ), mapping the movements to the real-world coordinate system and accounting for any unintended camera shaking.

## 2.4 Stage 4: Perspective-3-Points method to relate the 2-D image-plane coordinates to 3-D the real-world position

The mapping of the observed 2-D image-plane ( $\pi$ ) coordinates into their actual 3-D real-world positions can be obtained by solving the so-called Perspective- $n$ -Point (PnP) problem for the target corner coordinates at each frame. This implies to determine the 3D position and orientation of the camera based on a set of  $n$  2D image points and their known corresponding 3D world coordinates. This is a fundamental problem that was first explored in the photogrammetry literature and later extended to the field of computer vision. The P3P method is a specific case of the PnP problem, where  $n = 3$ , namely the camera pose is computed according to the correspondence between 3 points.

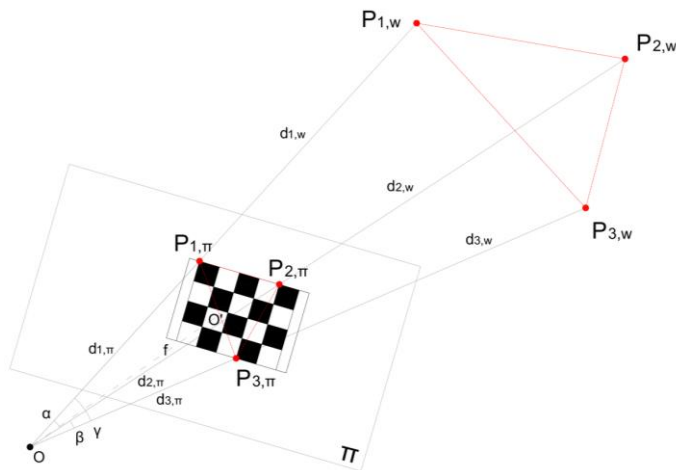

Figure 2. Geometric interpretation of the P3P method.

The solution of the P3P framework used here has its origins in the studies of Grunert [29], and for nearly two centuries it has remained relevant in various research and applications. In this paper, the  $P_nP$  method is used to define the position and orientation of both targets on a structure and the camera. The position of targets on the structure is determined by assuming the camera is not moving while the structure undergoes movement; the motion of the camera is obtained using a fixed target placed outside the shaking structure.

With reference to Figure 2, the intuitive procedure for solving the P3P problem is grounded in the resolution of the law of cosines, which is fundamental for calculating distances and angles in both the image-plane ( $\pi$ ) and the real-world ( $W$ ). The geometric interpretation of Figure 2 refers to a single triplet of checkboard corners, but it can be extended to every possible combination of corners. The law of cosines is first employed for the computation of the angles between the line of sight and the corners in the real-world system. In this phase, the results of Stage 2 and Stage 3 are exploited, namely the calibration outcomes and the coordinate time series of the corners. Then, the law of cosines is re-employed to compute the actual distances between the optical center and the corners of the physical target. This has been the subject of several studies due to the non-linear nature of the problem [30]. Here, the solution of Finsterwalder [31] is used for its high accuracy, as it does not involve any numerical approximations.

For each target, the P3P method is applied to every combination of triplets of corners, resulting in the distance between the optical center and each corner in real-world multiple times. Finally, the distance values related to the same corner are averaged to enhance the accuracy of the estimates. The procedure is repeated for each video frame, associated to a time instant through the frame rate, to obtain the target position at each time step. In this way, the reconstruction of the target displacement with respect to the camera optical center over time is carried out.

This approach is an alternative to the common approach relying on the simple scale factor for unit conversion. The latter only provides accurate results when the camera-to-target line of sight is perpendicular to the target plane. The proposed approach is more flexible, and it can adjust for perspective distortions caused by varying angles between the camera and

multiple targets. This is particularly common when monitoring civil structures due to their large scale and/or the presence of unavoidable restrictions on camera positioning.

## 2.5 Stage 5: Coordinate transformation to the structure reference system

At this stage, a transformation of coordinates into the structure reference system is proposed to ensure a rapid and clear interpretation of the structural behaviour. If the target is positioned in such a way that it aligns as closely as possible with the directions of the main structural movements, two axes of the structure reference system are considered to be parallel to the target directions, and the third one is perpendicular to the target plane. Once this reference alignment is established, a matrix-based change of basis is applied for coordinate transformation.

This involves roto-translating the real-world reference system  $W$  into the structure reference frame. The process includes both rotation and translation operations to account for the differences in orientation and position between the two coordinate systems. The core of the transformation is the least-square fitting of a plane to the coordinates of the checkboard corner in the real-world reference system. This transformation allows the representation of displacements in the structure reference system, which is independent of the location and orientation of the camera.

## 2.6 Stage 6: Filtering of camera unintended vibrations

Up to this stage, the procedure provides the relative displacements between the camera and each target, expressed in the world coordinate system. However, these displacement time series can be affected by camera shaking, which can arise from external factors such as wind or unintended user interactions. To obtain accurate estimates of absolute displacements, it is essential to account for and eliminate these camera-induced contributions. This is achieved by using reference targets placed on the ground in stable positions. These targets are assumed to remain stationary throughout the observation period. Consequently, any apparent displacement they exhibit in the world coordinate system reflects movement of the camera, rather than motion of the targets themselves.

The same tracking procedure outlined in the previous stages can be applied to the ground-based targets to quantify their apparent displacements. The absolute displacements of the targets on the structure can therefore be obtained by subtracting the apparent displacements of the ground-based targets from the relative displacements of the targets on the structure.

In laboratory settings, the camera can often be stably fixed, and the environment is controlled (e.g., no wind), which reduces the need for this correction. In the field, maintaining comparable stability is more challenging, making this filtering step essential. However, since this study focuses specifically on laboratory conditions, field-related considerations are not addressed further.

## 3 PROCEDURE ASSESSMENT PERFORMED UNDER CONTROLLED CONDITIONS

In this Section, the validation of the procedure described in Section 2 is performed through a laboratory test. The aim is to evaluate the performance of the designed vision-based monitoring procedure and to assess its potential applicability in

outdoor scenarios. The test involves the monitoring under controlled conditions of a scale steel frame subjected to excitation from a shaking table (see Figure 3). High-contrast artificial targets with a checkerboard pattern, measuring 250 mm by 250 mm, have been used. Two of them are connected to the base and the top floor of the frame, while a third one is located on the laboratory floor to identify potential camera movements.

The video-monitoring system consists of a Panasonic Lumix GH6 camera and Samsung S23 smartphone recording video in 4K and 8K resolution at 50 and 30 frames per second (FPS), respectively. The results presented below are based on videos captured by the camera, which has a lower resolution compared to the smartphone, making it more sensitive to the noise. Three different scenarios are considered by varying the location of the camera sensor. The distance between the camera and the steel frame for the three examined scenarios is listed in Table 1, measured using a laser meter. In both the scenarios, the angle of incidence between the line of sight and the target plane is nearly zero, implying an almost frontal view of the scene.

Several input excitations have been applied to the frame base during the tests. The results presented in the following refer to the Irpinia earthquake ground motion excitation [32], recorded on November 23, 1980, and reproduced by the shaking table along the  $x$ -axis of the structure, which is nearly horizontal to the recorded scene.

The accuracy of the vision-based monitoring system is assessed by comparing the estimated dynamic displacements with reference time histories. For the target at the base of the frame, the reference displacements are those imposed by the actuator of the shaking table. To validate the vision-based displacement for the target at the top of the frame, a Linear Variable Displacement Transducer (LVDT) is specifically positioned near the target for this purpose. The adopted LVDT measures displacements within the range [0, 100 mm], with sensitivity of 80 mV/V, excitation voltage equal to 10 V, and sampling frequency set at 200 Hz.

### 3.1 Results

The results of the monitoring conducted during the experimental test are discussed in this Section. Since the vision-based results for the target at the top of the frame exhibit similar accuracy, the following focuses on presenting the results for the target at the base of the frame.

The displacements of the frame base target in the 2-D image coordinate system, expressed in pixels and identified as detailed in Section 2.3, are shown in Figure 4 and Figure 5 for scenarios 1 and 2, respectively (similar conclusions can be drawn for scenario 3).

It can be observed that the vertical component of the motion,  $\xi$ , is approximately zero in both scenarios, since the imposed motion is horizontal to the structure and the camera is perpendicular to the target plane, implying no perspective effects. The difference between the amplitude of the horizontal displacement,  $\eta$ , in the two example scenarios is related to the distance between the camera and the frame, which is about 2 m for scenario 1 and 10 m for scenario 2, implying different pixel coverage on the examined target, as indicated in Table 1.

In this regard, it is specified that the target  $\eta$ -displacement time history in pixels (for example, Figure 5 for scenario 2) is

Figure 3. Laboratory experiment framework.

Table 1. Monitoring scenarios.

ID	Measured distance [m]	Target area [10 <sup>3</sup> pxl <sup>2</sup> ]

calculated by averaging the results obtained by separately tracking the motion of the corners of the checkerboard target (see Figure 6, which shows the motion of four out of sixteen monitored corners, specifically the outer ones: points 1, 4, 13, 16 with numbering following Figure 1), a step that allows for an increase in the accuracy. Indeed, this approach minimizes errors from individual tracking by leveraging multiple data for a more reliable measurement.

Afterwards, following the procedure indicated in Section 2.4, Section 2.5, and Section 2.6, pixel displacements related to the image system are converted into 3D real-world displacements, projected into the structure reference system, and cleared from uncontrolled camera shaking, measured by evaluating the apparent motion of the fixed ground-based target. The vision-based dynamic displacement along the  $x$ -direction in the structure coordinate system, expressed in millimeters, is represented in Figure 7 and Figure 8 for scenarios 1 and 2, respectively, along with a comparison to the corresponding reference displacement. In this, the reference is the known displacement time history set by the shaking table, which demonstrates excellent validation of vision-based results for all the scenarios.

As discussed in Section 2.4, a key aspect in determining the three-dimensional mapping between image and real-world systems is the evaluation of the distance between the optical center and the monitored target, determined by means of the P3P method. This method allows the calculation of the distances between the camera and any triplet of checkerboard corners within each frame, after which the time-varying

distance between the target centroid and the camera is evaluated by averaging the triplet estimates.

The variation of the estimated camera-to-target distance along time is investigated in Figure 9, related to scenario 2. The estimation error is less than 1 mm, which is very small compared to the actual distance of 10.9 m. However, this error

is larger than the small change in the real distance caused by the maximum allowed horizontal displacement (about 10 mm). This explains why accuracy decreases as the distance camera-to-scene increases. The camera-to-target distance from the P3P method, averaged over time, is shown in Table 2. P3P-based estimates (Table 2) are in close agreement with the distances measured on-site using a meter laser (Table 1), with relative errors of 0.1, 0.4, and 0.2 % for scenarios 1, 2, and 3.

As a metric in evaluating the reliability of the method, Table 2 also presents the standard deviation  $\sigma_{(0-5)s}$  of the vision-based displacement time series in the first 5 seconds of the tests. During this interval, no excitation is transmitted by the shaking table, so the standard deviation reflects the signal noise and can be considered a measure of the accuracy. The obtained  $\sigma_{(0-5)s}$  is of the order of one-hundredth of mm for scenario 1, denoting a very high accuracy. It reduces to about one-tenth of mm for scenarios 2 and 3, highlighting the impact of the target-to-camera distance on vision-based results.

To further quantify the noise, the standard deviation  $\sigma_{(5-25)s}$  of the difference between reference- and vision-based displacement time histories is calculated for the time interval between 5 and 25 seconds, as reported in Table 2. The standard deviation of the error ranges between 0.1 and 0.4 mm including the three scenarios. Considering that the maximum displacement experienced by the examined (base) target is approximately 10 mm, the accuracy of the measurements is deemed satisfactorily high, with a standard deviation-to-amplitude ratio below 4%, even for the more distant case scenario, indicating reliable measurement accuracy.

Finally, a comparison of the results is presented to assess the accuracy of the P3P method in relation to the scale factor, a simpler and more widely used method in the literature. Scenario 1 is selected as an example, characterized by minimal uncertainty resulting from the (reduced) camera-to-target distance, allowing the error to be entirely attributed to the method employed. The scale factor is calculated as the ratio between the target side in metric units (250 mm) and its side in image units (432 pixel, based on the target area shown in Table 1), resulting in a value of 0.58 mm/pixel.

Using the scale factor method, the horizontal displacement  $\eta$  detected in the image system is simply scaled by the scale factor to obtain the physical displacement  $x$ . Thus, the peak absolute displacement of 16.83 pixels (see Figure 4) multiplied by the scale factor returns a physical value of 9.76 mm. As represented in Figure 7, the maximum absolute displacement detected by the P3P method is 9.30 mm, while the reference (i.e., imposed) value is 9.48 mm. This leads to relative errors with the reference peak displacement of 2.95 % for the scale factor approach and 1.90 % for the P3P method. Peak displacements obtained by the two methods for the other scenarios are shown in Table 3, leading to relative errors as indicated in Table 4. These results demonstrate a generally better performance of the P3P-based designed method compared to the scale factor approach. This indicates that the scale factor, which is designed for frontal views of small-scale objects, performs less effectively than P3P in its intended context. The discrepancy between the two methods is expected to become even more pronounced in the presence of inclinations in the line of sight relative to the structural displacement. These findings highlight the critical need for pixel-to-mm 3D mapping in real-world

case studies, underscoring the significance of the present research.

#### 4 CONCLUSIONS

This study proposes a vision-based approach for structural displacement monitoring, suitable for both dynamic and static conditions. It is a cost-effective, non-intrusive alternative to traditional sensing technologies. The approach involves the use of consumer-grade cameras and checkboard targets to be installed on the structure.

The reconstruction of the monitored target displacement is facilitated by computer vision algorithms, which detect the checkerboard corners in digital images and track their movement across consecutive frames. The proposed approach implements the Perspective-Three-Point (P3P) algorithm to establish a correspondence between the 2D image coordinates and the 3D world reference system coordinates. The flexibility of this approach makes it particularly suitable for a wide range of camera positions and orientations relative to the monitored structure. Additionally, unintended camera vibrations can be filtered out by tracking one or more targets placed externally to the structure, assumed to be stationary.

The methodology has been validated through a laboratory test on a steel frame excited by a shaking table. Specifically, performed tests focused on evaluating the impact of the camera-structure distance, or alternatively, the target area in the images to account for potential zoom variations, on the accuracy of the displacement estimates. The analysis considered two parameters: the standard deviation of the estimated displacements in the initial seconds of the test (where no excitation was applied) and the standard deviation of the difference between the estimated displacements and the reference values during the remaining part of the test. The first parameter represents the signal noise, whose order of magnitude increases from one-hundredth of a millimeter to one-tenth of a millimeter as the camera-target distance increases from 1.85 m to 25.21 m. Despite this variation, the second parameter, which measures the mean error of the displacement time series relative to the reference displacements, remains satisfactory in all the scenarios, with a standard deviation-to-amplitude ratio around 4 % in the greater structure-to-camera distance scenario.

In comparison, the scale factor approach, a simpler and more widely used method in the literature, was also considered. However, the P3P-based method demonstrated better accuracy in capturing displacement under laboratory conditions, suggesting that the scale factor may not be suitable for outdoor scenarios, which may involve non-frontal views and varying orientations of the targets. Additionally, the scale factor estimation requires user intervention, making it unsuitable for automated procedures.

These preliminary results underscore the potential of this vision-based approach for structural monitoring applications, paving the way for its broader adoption in civil engineering structures and infrastructure. Future research will focus on integrating these initial findings with further tests, particularly examining the effects of the inclination between the line of sight and the target, and refining the displacement accuracy.

**ABSTRACT:** The integrity management of bridges is crucial for ensuring public safety and economic stability. In practice, Structural Health Monitoring data recorded during bridge operation is increasingly used to guide maintenance decisions. However, incorporating structural damage information more effectively can lead to optimal strategies for integrity management. In this study, we employ Bayesian Model Updating to develop a more reliable structural model. The updated finite element model is then used to train a variational autoencoder-based surrogate model for damage detection, localization, and severity estimation. The variational autoencoder model establishes a link between damage-related features and the modal properties derived from SHM data. Damage information supports maintenance decision-making through a predefined decision rule.

**KEY WORDS:** Structural health monitoring, damage detection, surrogate models, structural integrity management, maintenance decision.

## 1 INTRODUCTION

Bridges and viaducts are fundamental components of transportation networks, ensuring connectivity and economic stability. However, their structural integrity is continuously challenged by aging, increasing traffic loads, and environmental stressors. Effective bridge health management can benefit from continuous monitoring and strategies to detect potential damage and mitigate the risks before they compromise safety.

Structural Health Monitoring (SHM) has emerged as a crucial tool for assessing bridge conditions in real-time, providing early detection of structural anomalies. The design and implementation of SHM systems for bridge integrity management were proposed in the study by Limongelli et al. [1]. SHM system provides continuous information about structural properties such as natural frequencies, damping ratios, and mode shapes. However, directly labeling the obtained modal properties as belonging to either damaged or undamaged states from data collected on real-world structures is challenging. This difficulty arises because the changes in modal features can also result from various factors not related to damage, such as environmental conditions, operational variability, or sensor noise. While some studies explored damage detection and localization through the modal properties [2], a fundamental part of damage detection strategies entails the use of physics-based models, which provide a basis for understanding the overall structural behavior under varying conditions. By integrating SHM data into physics-based formulations, the models are updated to represent the actual bridge conditions, enhancing structural integrity management, improving maintenance planning, and decision-making. However, the computational cost of updating a finite element model in real-time can be very high. Surrogate models provide a computationally efficient alternative to complex physics-based simulations.

In this paper, an approach based on Bayesian Model Updating (BMU) using Transitional Monte Carlo Markov Chain is implemented to update the structural model of a bridge using measured data. This approach refines the bridge model through the incorporation of modal properties extracted from SHM data, by reducing the discrepancy between measured and calculated modal properties. Thanks to the systematic updates of the structural parameters, the model accurately represents the bridge's current state. The high-fidelity and calibrated FE model is then used for training a surrogate model. Namely, the FE model is used to simulate several damage scenarios and generate the relevant response of the bridge, thus providing the necessary training data for the surrogate models. Several surrogate modeling approaches have been explored in the literature, with the most used ones including Kriging models, artificial neural network (ANN)-based surrogate models, and reduced order models [2], [3], [4], [5]. In this paper, a Variational Autoencoder (VAE) architecture is adopted to effectively capture complex, high-dimensional patterns in the structural response data. Unlike the other autoencoders, VAE provides a probabilistic latent representation, allowing better generalization, which is particularly valuable for long-term SHM tasks [6]. Furthermore, the use of fully connected layers in classifiers and regression blocks enables the estimation of damage severity and location directly from the latent space.

## 2 METHODOLOGY

The framework proposed in this paper integrates SHM information, a Bayesian finite element (FE) model updating approach, and surrogate modelling techniques to efficiently localize and quantify damage. A BMU framework is first employed to calibrate a high-fidelity FE model using SHM data, refining the model parameters to closely reflect the real structural behavior. Using the calibrated FE model, various damage scenarios are simulated to generate labeled datasets of

modal responses. These datasets are then used to train a Variational AutoEncoder (VAE)-based surrogate model, which learns a latent representation of the relationship between modal features and damage states. Subsequently, the trained VAE model is utilized to obtain fast and scalable predictions of damage scenarios during online monitoring, bypassing the computational burden of running FE simulations in real time. This integrated approach bridges the gap between accurate physics-based modeling and the practical demands of efficient damage diagnosis in SHM systems. The overall architecture of this framework, including the surrogate model construction and its application for decision support, is illustrated in Figure 1.

After being trained, the surrogate model is capable of mapping newly acquired experimental modal features to damage location and severity, providing damage scenario indicators that can be used for decision support. This hybrid approach combines physics-based model updating for data generation with data-driven surrogate modeling for inference. It ensures a computationally efficient yet robust damage detection system for bridges.

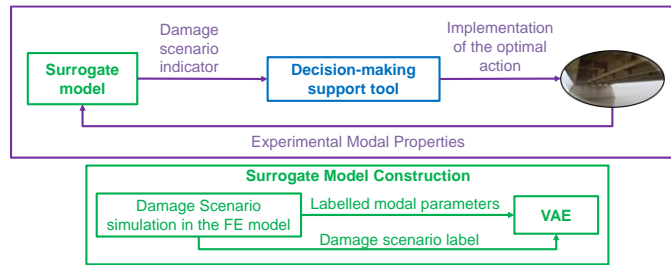

Figure 1: General workflow for online damage detection.

## 2.1 FE calibration and simulation of damage scenarios

Bayesian Model Updating (BMU) is employed to calibrate the FE model of the bridge using measured modal properties. The overall BMU workflow is indicated in Figure 2 that illustrates the step-by-step process of refining model parameters, from prior assumptions to the convergence of posterior distributions. The process aims to reduce discrepancies between experimental and simulated dynamic characteristics by updating uncertain model parameters, thereby enhancing the accuracy and predictive capabilities of the model. In this study, BMU is performed using Transitional Markov Chain Monte Carlo (TMCMC). TMCMC is a sampling-based Bayesian inference method that allows efficient estimation of the posterior distribution of model parameters, even in high-dimensional or nonlinear problems [7], [8].

### 2.1.1 Parameter Selection and Prior Definition

Parameters with high sensitivity to modal responses are selected for updating, specifically, the vertical stiffnesses of the girders. Each parameter  $\theta$  is assigned a prior distribution  $\pi(\theta)$ , representing the initial uncertainty in its value based on engineering knowledge.

### 2.1.2 Likelihood Function Construction

The likelihood function  $L(D|\theta)$  of data  $D$  quantifies the agreement between simulated and measured modal data, including both natural frequencies and mode shapes. Mode

shape similarity is evaluated using the Modal Assurance Criterion (MAC). The likelihood is defined as indicated in Eq. 1.

$$L(D|\theta) = \exp \left( -\frac{1}{2} \sum_i w_i \left( \frac{f_{m,i} - f_{s,i}}{\sigma_i} \right)^2 - \frac{1}{2} \sum_j w_j \log(1 - \text{MAC}_j) \right) \quad (1)$$

where  $f_{m,i}$  and  $f_{s,i}$  are measured and simulated frequencies,  $\sigma_i$  represents uncertainty, and  $w_i, w_j$  are weighting factors.

### 2.1.3 Transitional Sampling via TMCMC

TMCMC introduces a sequence of intermediate, tempered distributions shown in Eq. 2.

$$\pi_\beta(\theta|D) \propto \pi(\theta)L(D|\theta)^\beta \quad (2)$$

where  $\beta \in [0,1]$  gradually increases from 0 (prior only) to 1 (full posterior). At each state, samples are reweighted and resampled based on their likelihood, allowing efficient exploration of the parameter space. The process continues until the convergence is achieved.

### 2.1.4 Posterior Sampling and Model Updating

During the TMCMC process, the FE model is continuously evaluated as parameter samples are drawn and updated through each intermediate distribution. At every step, the simulated modal properties are compared with experimental data to assess the quality of the current model approximation. The iterative approach allows progressive refinement of the model, ensuring that the final set of posterior samples yields a calibrated model that reliably captures the dominant dynamic behavior of the structure. Despite the minor residual discrepancies (e.g. in higher modes), the updated model serves as a high-fidelity basis for generating synthetic damage scenarios, which provide the labeled data needed to train the surrogate model described in the following sections.

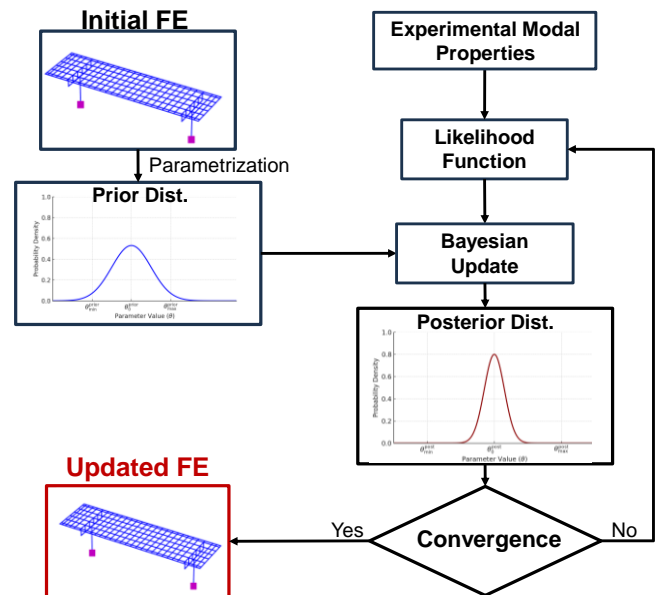

Figure 2: Bayesian Model Update diagram

In this study, vertical stiffnesses were chosen as updating parameters due to their high sensitivity to vertical and torsional modes identified in the experimental data. A total of 8 stiffness

parameters (one per each girder) were assigned uniform prior distributions with  $\pm 50\%$  bounds from nominal values. TCMC was implemented with 50 intermediate  $\beta$  steps and 1000 samples per step. Convergence was evaluated using the coefficient of variation of the likelihood, with a threshold of 5% at each stage.

## 2.2 Surrogate model

The calibrated FE model is used to generate labelled dataset for several damage scenarios, which constitute the training set for the surrogate model. In this work, a Variational Autoencoder (VAE) is employed to learn a latent representation of modal properties across the various damage scenarios. The model is trained on synthetic modal data representing damage states of increasing severity and is developed for real-time estimation of damage location and severity based on updated modal properties. While this structure supports unsupervised feature learning, it has incorporated supervised outputs, providing reconstructed modal properties and predicted damage features.

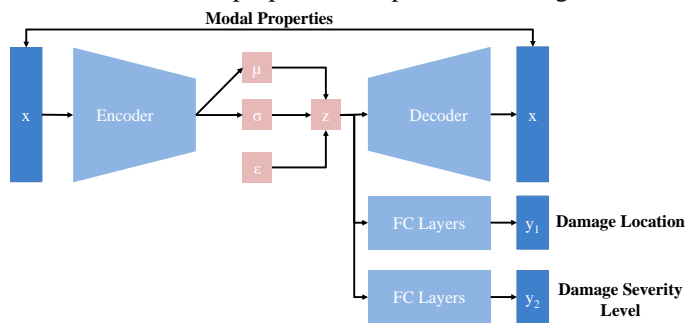

Figure 3: VAE architecture

The VAE consists of an encoder, which maps the modal properties ( $\mathbf{x}$ ) to a latent space ( $\mu, \sigma, \epsilon, z$ ), and a decoder, which reconstructs the modal properties while ensuring regularization through a Kullback-Leibler (KL) divergence term. This term, commonly used in VAE architecture, encourages the latent variables to follow a normal distribution and helps the model learn meaningful and general features [9]. In addition to the conventional VAE architecture, two fully connected layers (FC Layers) are incorporated as a part of supervised feature learning: one serves as a classifier for identifying the location of damage  $y_1$ , and the other functions as a regressor to estimate damage severity levels  $y_2$ , as illustrated in Figure 3.

The input to train the surrogate model comprises modal frequencies and normalized mode shapes, extracted from modal analysis. The encoder consists of three fully connected layers with Rectified Linear Unit (ReLU) as a nonlinear activation function mapping the input to a latent space of dimension 32. The ReLU is widely used for its simplicity and effectiveness in preventing vanishing gradients. Two separate fully connected layers use the mean and log variance of the latent distribution to establish a relationship between the latent features and the damage locations and severity levels. The decoder follows a symmetric structure to reconstruct the input. Additionally, two parallel output layers predict damage locations and severity. Similar to the approach proposed by Yessoufou and Zhu [10], who employed a convolutional neural

network-LSTM with distinct loss functions for damage classification and severity estimation, the proposed architecture treats damage location as a classification problem supervised with cross-entropy loss, while damage severity estimation is formulated as a regression task that predicts severity levels between 0 and 1 and is optimized using mean squared error.

The model is trained using a weighted loss function combining:

1. Reconstruction Loss: Mean Absolute Error (MAE) between input and reconstructed modal properties.
2. KL Divergence Loss: Enforcing latent space regularization.
3. Classification Loss: Cross-entropy loss for damage location prediction.
4. Regression Loss: Mean Squared Error (MSE) for damage severity estimation.

A cyclical KL annealing strategy is implemented, gradually increasing the weight of the KL term to improve latent space disentanglement [11]. To enhance the training performance, several incremental analyses were conducted, based on which the Adam optimizer was selected [12]. Additionally, the initial learning rate was set to 0.001 and configured to adaptively decrease throughout different phases of training to maintain stable convergence and improved generalization.

## 2.3 Decision-Making approach

A concept for a decision-making approach is proposed in Figure 4, drawing inspiration from existing SHM-informed response protocols proposed by Çelebi [13].

At the core of this approach lies a threshold-based logic that interprets the results produced by the VAE model. The VAE model identifies the most likely damaged locations and estimates the damage severity. For each identified component as the location of damage, the damage severity is evaluated individually through a decision-making layer that maps severity levels to specific actions. These outputs are contextualized through a decision-making layer that maps each damage severity level to a specific action. Namely, the outputs of the VAE (relevant to damage location and severity) are evaluated against predefined thresholds. The exceedance of a threshold triggers a specific action (continued monitoring, issuing a warning, or initiating a repair procedure). These layered interpretations add practical value to the detection results and allow for automatic mapping of evolving damage states into operational decisions. Exemplary actions are depicted in Figure 4. The VAE model provides two key outputs, which are the damage location and the damage severity. Each damaged component is associated with an evaluated damage severity ( $k_{red}$ ) and a warning indicator. Green indicates normal condition, yellow suggests the need for inspection, and red prompts immediate repair or closing bridge suggestions, depending on severity. The goal of this approach is to support a straightforward integration of SHM-informed, rule-based maintenance strategies into bridge integrity management, ensuring that timely and proportional interventions are triggered as the condition of the structure evolves. The definition of the threshold is a critical aspect of this approach and must be carried out based on reliability analysis for specific limit states defined for the bridge.

### 3 CASE STUDY

The procedure described in the previous section has been applied to a continuously monitored bridge located in northern Italy. The bridge consists of 15 spans, 11 of which are instrumented with acceleration sensors. Each monitored span is equipped with 5 to 6 acceleration sensors on the deck, strategically placed to capture the bridge's dynamic response under operational conditions.

Figure 4: Decision-making framework based on damage level threshold

To identify the modal parameters from recorded responses, an online automatic Stochastic Subspace Identification (SSI) method has been developed. To ensure robust tracking of modal properties over time, a post-processing step involving modal clustering is employed. The identified modal properties are clustered using a hierarchical clustering algorithm based on a predefined Modal Assurance Criterion (MAC) and frequency similarity threshold. This process helps distinguish consistent modes from spurious ones, reducing uncertainties in the estimated modal parameters.

The approach follows the clustering methodology detailed in previous works by Magalhães et al. [14] which has demonstrated its effectiveness on SSI-based modal tracking in bridge monitoring applications.

A detailed finite element model of the bridge was built using the OpenSees software [15], and calibrated by applying the Bayesian model updating process. During the BMU, vertical bending stiffnesses were selected as updating parameters, based on their higher sensitivity. This choice was made since the experimental mode shapes of the selected bridge are predominantly in the vertical direction, including vertical and torsional modes. These stiffness parameters were iteratively updated using the Transitional Markov Chain Monte Carlo (TMCMC) algorithm described in section 2.1. The resulting frequencies and MAC values before and after the BMU are indicated in Table 1. The mode shapes obtained from experimental data and the updated FE model are shown in Figure 5 and Figure 6, respectively.

After updating, the FE model showed improved agreement with the experimental modal properties. The first and second modes reached MAC values of 99.8% and 94.2%, respectively.

However, the third mode retained a relatively low MAC value of 36.1%, which indicates limited consistency. This discrepancy is attributed to reduced sensitivity of vertical stiffness to higher terms not captured by the selected parameters.

Despite this, the updated FE model provides a sufficiently accurate representation of the bridge's dominant dynamic behavior, and it is used exclusively to generate synthetic damage scenarios for training the surrogate model. Since both training and test datasets are generated from the calibrated model, the surrogate model's performance reflects the behavior encoded in the updated FE model, while remaining independent of direct comparisons with experimental data.

Table 1: Modal properties comparison

	Experimental	FE Model before BMU	FE Model after BMU	
Mode Number	Frequency (Hz)	Frequency (Hz)	Frequency (Hz)	MAC value (%)
1	1.56	1.70	1.75	99.8
2	2.50	1.82	2.42	94.2
3	3.63	3.42	3.76	36.1

### 3.1 Construction of the surrogate model and damage identification

The proposed damage identification framework is applied to a single span to demonstrate its effectiveness in damage detection and integrity assessment. The Variational Autoencoder (VAE) model was trained and applied using numerically simulated data representing various damage scenarios with different damage locations and severity. To generate the training dataset for the VAE model, damage was simulated in the FE model through the reduction in vertical rotational stiffness. For each damage scenario, the FE modal properties were obtained by dividing the span into 20 parts and applying the reductions to the corresponding vertical rotational stiffnesses.

Damage severity levels were defined as reductions ranging from 10% to 70% in the corresponding vertical rotational stiffness values. For each segment and each severity level, a separate damage scenario was created. In total, 140 damage scenarios were generated (20 segments  $\times$  7 severities). Table 2 summarizes the segments and the associated severity levels considered in the training data generation. To enhance the robustness of model learning, random noise was artificially added to the modal properties during the training data generation process. During the training phase, the surrogate model was trained using the labeled modal properties (natural frequencies and normalized mode shapes) corresponding to the various considered damage scenarios. The structural model was modified for each damage scenario, and a modal analysis was performed to obtain corresponding modal properties, enabling the VAE to learn patterns associated with different damage levels and locations. After the generation of the training dataset, it was divided into 80% and 20% portions, with 80% used to train the model, remaining 20% used to test the model, providing an unseen dataset to objectively evaluate the model's learning performance.

It is acknowledged that the damage scenarios used in this study are synthetically generated and not validated against experimental damage. While the applied stiffness reduction levels serve to explore the sensitivity and robustness of the surrogate model, such values may not reflect the typical damage progression in real-world structures. These scenarios are intended to span a wide range of conditions, including rare or extreme cases.

Table 2: Summary of the damage scenarios

Damage Scenario	Segment No	Reduction Factors
DS1	1	From 0.1 to 0.7
DS2	2	From 0.1 to 0.7
DS3	3	From 0.1 to 0.7
...	...	...
DS20	20	From 0.1 to 0.7

### 3.2 Damage identification

The capability of the surrogate model to identify damage was tested using unseen test data, that is, samples of modal parameters corresponding to the considered damage scenarios, not used in the training phase. Results are represented by the confusion matrix in Figure 7. The confusion matrix compares the true and predicted damage locations, where diagonal

elements represent correct predictions and off-diagonal elements indicate misclassification in the test datasets.

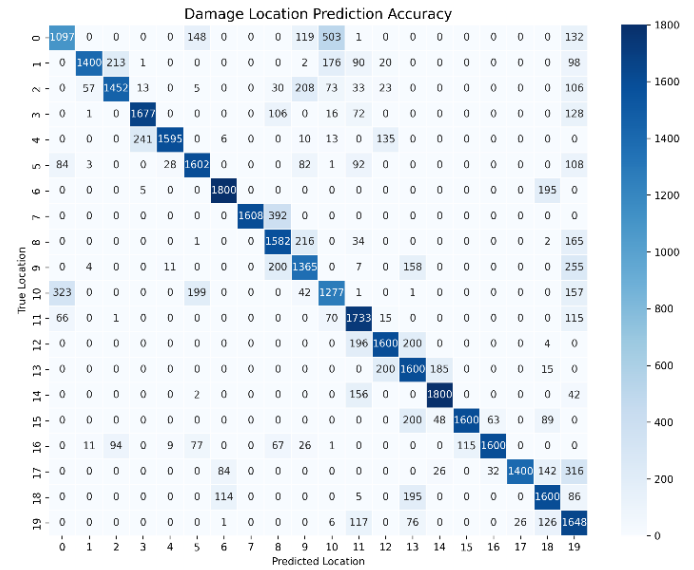

Figure 7: Confusion matrix for damage locations

In Figure 7, predicted and simulated (ground truth) damage locations are represented along the  $x$  and  $y$  axes by the element indices in the FE model. The diagonal elements of the matrix indicate the number of samples for which the damage location was correctly identified.

It is important to note that both training and testing datasets for the surrogate model were generated from the updated FE model, which was calibrated using experimental model properties. Although the updated model still presents some discrepancies, particularly in higher modes, the surrogate model operates entirely within the dynamic response space defined by the updated model. To enhance the robustness of the algorithm, artificial noise was introduced into synthetic modal data during both training and testing. This ensures that the model is not overfitted to idealized cases and can generalize across realistic measurement uncertainty, while maintaining consistency with the physical behavior captured by the updated FE model.

The model was tested on scenarios involving progressive damage evolution, effectively capturing and tracking the increasing severity over time. The data for the evolving damage severity was gathered from the unseen test dataset to indicate the model's performance in this context. The results are presented in Figure 8 where the vertical axis represents stiffness reduction factors. The predicted damage severity follows this predefined discretization to ensure the consistency between training and testing data. Additionally, Figure 8 illustrates the damage detection results over an evolving damage scenario, highlighting how the proposed framework translates predicted damage severity levels into actionable maintenance decisions. Each step in Figure 8 corresponds to a synthetic damage state generated by reducing the stiffness in the model. These steps represent hypothetical damage progression sequences, used to demonstrate the ability of the VAE model to track increasing severity.

Figure 8: Damage level identification results

### 3.3 Decision Making

For the considered case study, the thresholds that trigger different management actions for each bridge component have been defined in terms of the stiffness reduction factor,  $k_{red}$ , and are reported in Table 3. To these thresholds correspond the damage scenarios considered for the training of the VAE model.

Table 3: Thresholds for stiffness reduction

$k_{red}$	Maintenance management action
0.1	normal condition
0.2	structural inspection
0.3	component repair
0.4	cautionary bridge closing

It is also worth mentioning that the maintenance actions proposed here are not intended to restore the load-bearing capacity but rather to compensate for localized stiffness reductions that may affect the bridge's dynamic behavior and long-term serviceability. The decision framework relies on stiffness reduction as a measurable proxy for damage progression, which triggers maintenance interventions aimed at preserving structural performance and reducing the risk of further deterioration. This approach reflects a conservative, condition-based strategy focused on sustaining system stiffness and structural continuity, even before reaching strength-based limit states.

## 4 CONCLUSION

This paper presents an online damage identification approach based on a Variational Autoencoder surrogate model. The proposed methodology combines model-based data generation with surrogate modelling to enhance the efficiency of the real-time data-driven damage identification without reducing accuracy.

To support timely maintenance decisions, a concept for a structured decision-making framework is proposed. The framework maps the structural condition into specific management actions. This structured, rule-based approach enables scalable, real-time decision support under varying operational scenarios.

Future work will explore the integration of stochastic deterioration models into the Finite Element model to refine long-term maintenance strategies, providing a more effective approach to bridge infrastructure management. The

investigation of threshold values consistent with pre-defined limit states of the bridge will be a further research step.

**ABSTRACT:** Structural health monitoring (SHM) is essential for ensuring bridge safety and longevity. Under dynamic loads, such as train traffic, acceleration data from sensors offers valuable insights into the condition of the structure. Vehicle bridge interaction models required to predict the acceleration time histories involve numerous parameters for rail traffic. Also, model-based methods have a trade-off between high-fidelity, computationally intensive, and less accurate models. To overcome these limitations, this study introduces a deep learning (DL) algorithm to identify changes in the bridge. However, large datasets resulting from high-frequency sampling and long observation periods pose computational challenges as the train passes over the bridge. To address this, down sampling is employed, reducing data complexity while preserving essential features of the signal. The approach is demonstrated using acceleration data recorded at a node point of a railway truss bridge during train passage. An Autoencoder is employed, compressing high-dimensional data into a low-dimensional latent space, and a deep neural network (DNN) is applied to the latent space, incorporating a measurement loss function to estimate the system parameters. This framework ensures computational efficiency and data integrity, enabling precise system parameter estimation and showcasing its effectiveness in real-life bridge SHM.

**KEY WORDS:** Data compression; Autoencoder; Deep neural network; Deep learning; Railway steel truss bridge; Structural health monitoring.

## 1 INTRODUCTION

Structural health monitoring (SHM) has advanced significantly with the development of sensing technologies and data collection capabilities [1],[2]. It plays a crucial role in ensuring the safety, durability, and reliability of critical structures, particularly railway bridges that experience continuous dynamic loading [3],[4]. Accurately estimating structural parameters such as cross-sectional area, damping coefficients, and stiffness properties is fundamental for detecting structural degradation, damage progression, and potential failures [5],[6]. Traditional methods, including finite element model (FEM)-based approaches, rely on high-fidelity models and experimental calibration, which are computationally expensive and susceptible to modeling inaccuracies [7],[8],[9]. These challenges necessitate data-driven approaches that leverage machine learning (ML) techniques for efficient and accurate structural assessment [10],[11].

Neural networks, a part of ML techniques, have emerged as powerful tools in SHM, enabling automated inspection processes and addressing the growing complexity of intelligent monitoring systems. Their primary advantages include automatic feature extraction, effectiveness in handling noisy datasets, and accurate modeling of nonlinear relationships [12]. Nevertheless, conventional artificial neural networks (ANNs) frequently encounter issues such as convergence to local minima, susceptibility to overfitting, and limited ability for deeper feature extraction due to shallow network architectures [13]. Recent advancements in deep learning (DL) have introduced data-driven SHM approaches, wherein structural parameters are inferred directly from measured vibration signals [14],[15] to overcome the above mentioned challenges.

Such DL frameworks effectively capture complex nonlinear relationships inherent in multi-sensor datasets, making them particularly suitable for classification and regression tasks [16]. Nevertheless, standalone DL models share several limitations commonly observed with traditional ANNs, including high computational efficiency, overfitting, and convergence issues, highlighting the need for hybrid DL methodologies [17]. Over the past decade, several hybrid DL approaches have been developed for bridge damage detection and condition assessment. One promising approach is the Autoencoder, which is known for its ability to perform dimensionality reduction and data compression effectively.

To highlight a few instances, an unsupervised Autoencoder approach proposed in [18] achieved real-time bridge damage detection directly from raw acceleration data, although it was limited to single-sensor applications without the capability for damage localization or quantification. In another study [19], a hybrid methodology combining statistical modeling, neural networks, and deep support vector domain description demonstrated effective real-time damage detection with minimal false alarms; however, this method lacked localization capability, exhibited reduced performance with multi-sensor datasets, and has not been tested on full-scale structures. [20] introduced an Autoencoder-based method emphasizing the relationships among natural frequencies and mode shapes. Further extending this concept, [21] proposed a deep sparse Autoencoder specifically used for structural damage detection using these vibration characteristics. [22] developed a two-level hybrid learning framework, employing unsupervised learning for preliminary damage detection followed by supervised validation, demonstrating its efficacy through

numerical simulations of concrete beams and experimental validation using laboratory frames. Additionally, [23] introduced an unsupervised deep neural network (DNN) method combining a deep Autoencoder with a one-class support vector machine (SVM), eliminating the reliance on extensive labeled datasets by utilizing only intact structural data.

While prior research has explored hybrid DL models involving Autoencoders for data compression, most studies have primarily addressed laboratory-scale experiments or relied on supervised learning methods. In contrast, this study introduces an integrated framework combining unsupervised Autoencoder-based compression and a supervised DNN model to effectively handle on-field acceleration signals coming in the form of latent space representation from the Autoencoder. The proposed Autoencoder-DNN framework is computationally efficient and provides an effective compression strategy that preserves the important structural characteristics of real-world acceleration data by extracting relevant features, facilitating accurate and reliable estimation of structural parameters in railway steel truss bridge members.

The methodology presented herein constitutes the preliminary phase of a comprehensive, multi-stage investigation to extend parameter estimation from an individual joint (node point considered in this study) to the entire railway steel truss bridge structure. By demonstrating the effectiveness and robustness of the developed approach through this single-node case study, the present work lays a solid foundation for data-driven SHM of complex infrastructure with relevance to railway bridge systems.

The structure of this paper is as follows: **Section 2** details the bridge type and instrumentation scheme. **Section 3** explains data collection and segmentation. **Section 4** presents the proposed methodology, including the Autoencoder and the DNN model. **Section 5** discusses the results, focusing on model accuracy, anomaly detection, and computational efficiency. Finally, **Section 6** concludes the key findings and explores potential directions for future research.

## 2 BRIDGE DETAILS AND INSTRUMENTATION SCHEME

The Pamban Bridge is a railway steel truss bridge linking Rameswaram on Pamban Island to mainland India, as shown in Figure 1. Commissioned in 1914, it was India's first sea bridge. Although most spans are conventional I-plate girders on concrete piers, the bridge features a notable double-leaf bascule section that pivots to let ships and barges pass. This movable portion, designed by Scherzer, is counterbalanced and pivots around a horizontal axis, with the superstructure rolling atop the track girder. Each leaf consists of a rigid jaw-and-tongue system to transfer shear without moments and is further subdivided into north and south trusses [24].

Since the bridge endures harsh marine conditions, corrosion is a significant concern, making it essential to evaluate any loss of cross-sectional area for structural assessments. A total of 40 uniaxial accelerometers have been installed at various bottom nodes in biaxial mode on the bridge's Mandapam and Pamban truss segments in both the north and south directions, as shown in Figure 2.

Figure 1. Orientation of the Pamban bridge.

Figure 2. Location of accelerometers on the bridge.

## 3 DATA COLLECTION AND SEGMENTATION

The acceleration data used in this study was collected from a bottom node marked with a red box in Figure 2, where two uniaxial accelerometers were installed in biaxial mode. Measurements were taken in both the x and y directions, with the x direction corresponding to the direction of train movement and the y direction representing the direction of gravity. When detecting a train pass event, the DAQ system continuously recorded acceleration data for 480 seconds, which was sufficient to cover the train passage with an ample margin before and after the event.

The sampling frequency of the acceleration was set at 600 Hz, resulting in 288,000 data points for each recording session. After analyzing acceleration signals from 150 train passages for each direction, it was observed that the train-induced vibrations predominantly occupied the initial segment of the recorded signal. At the same time, the remaining portion primarily consisted of ambient noise. Based on this observation, a consistent segmentation approach was adopted, wherein the first 1,60,000 data points were extracted from each recording for further analysis. This segmentation ensured the retention of train-induced dynamic responses while excluding prolonged noise periods, thereby reducing the number of data points in the subsequent processing stages.

## 4 METHODOLOGY

This study adopts a multi-step methodology comprising data pre-processing and data compression to improve the performance, scalability and computational efficiency of the Autoencoder-DNN framework for parameter estimation. The overall flowchart is presented in Figure 3, which outlines the

key steps involved. Each step is further detailed in the following sections, explaining the implemented approach.

Figure 3. Flowchart depicting the methodology.

#### 4.1 Data Preprocessing

After obtaining the train pass signals, the time-domain data was converted into the frequency domain using the fast Fourier transform (FFT). This transformation was essential to facilitate efficient data processing, as the large dataset in the time domain posed computational challenges for subsequent analyses,

notably when applying the DNN model. The FFT utilizes the symmetric property of real-valued signals, reducing the adequate number of data points by half while retaining the qualities of the original signal, which optimizes storage and computational requirements. The amplitude spectrum of the transformed signal was carefully examined, revealing that frequency components beyond 100 Hz have acceleration amplitudes  $1/4^{\text{th}}$  less than the maximum amplitude. Therefore, a frequency threshold of 100 Hz was adopted to truncate the signal, effectively eliminating higher-frequency content while retaining the dominant spectral content. This transformation approach introducing symmetry and frequency truncation has resulted in a reduced dataset of approximately 26,666 data points. Figure 4 illustrates the process, where the time-domain acceleration signal is converted to the frequency domain and truncated up to 100 Hz. This significant reduction enhanced computational efficiency and preserved the essential dynamic characteristics of the train-induced vibrations. However, despite the reduction, the large dimensionality of the dataset still posed computational challenges, particularly concerning memory requirements and the convergence efficiency of the DNN model.

#### 4.2 Data Compression Using Autoencoder

To mitigate computational challenges, a data compression technique based on an Autoencoder is implemented. The Autoencoder used in this study consists of two key components: an encoder, which compresses the input data into a lower-dimensional latent space, and a decoder, which reconstructs the data from this compressed representation. Figure 5 illustrates the step-by-step application of the Autoencoder, detailing the transformation process at each stage.

Since acceleration signals exhibit distinct dynamic characteristics in the x and y directions, separate Autoencoders are implemented for each direction. The Autoencoders applied in both directions maintain an identical architecture, layer structure, and activation functions, as shown in Figure 5, but they are trained independently to capture the unique frequency and amplitude variations inherent to each direction. This ensures that the learned representations accurately reflect the direction-specific vibration behavior while preserving consistency in the latent space size.

Figure 4. Data preprocessing workflow.

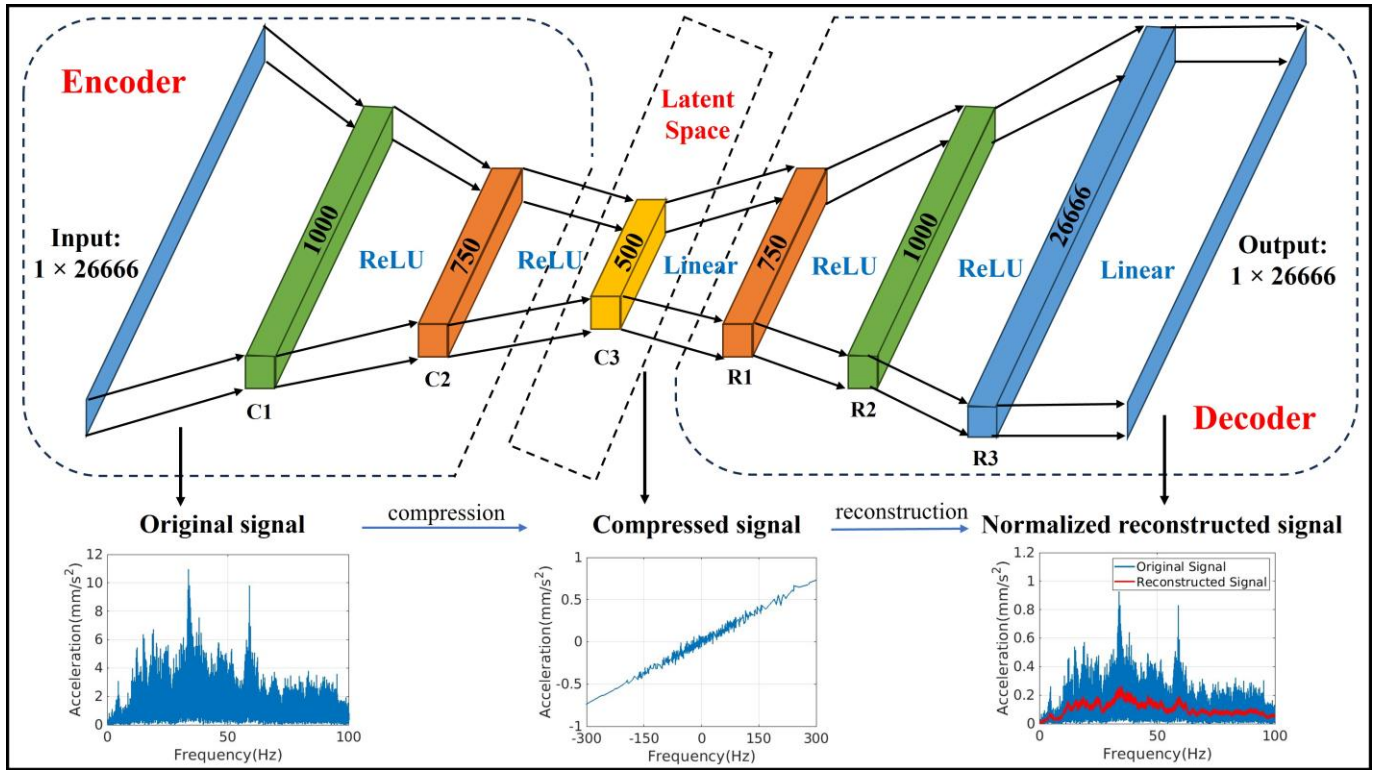

Figure 5. The architecture of the Autoencoder.

#### 4.2.1 Encoder network

It consists of three layers labeled C1 to C3. The ReLU activation function is applied in layers C1 and C2, while the linear activation function is used in layer C3. As described in the previous section, the network takes preprocessed input data of size  $1 \times 26666$  for one train pass. However, since the autoencoder is trained on data from 112 (75% of 150 train passes) train passes, the input data size becomes  $1 \times 26666 \times 112$  for each direction. The data is progressively compressed through each layer, reducing its dimensionality from  $1 \times 26666 \times 112$  in the input layer to  $1 \times 1000 \times 112$  in C1,  $1 \times 750 \times 112$  in C2, and finally to  $1 \times 500 \times 112$  in C3, which represents the latent space.

#### 4.2.2 Decoder network

The decoder network consists of three layers, labeled R1 to R3, designed to restore the compressed latent space to its original dimension. The ReLU activation function is applied in layers R1 and R2, while the linear activation function is used in the final layer R3. The input to the reconstruction network is the latent space representation of size  $1 \times 500 \times 112$ . The data is gradually reconstructed through each layer, expanding from  $1 \times 750 \times 112$  in R1, then to  $1 \times 1000 \times 112$  in R2, and ultimately restored to its original size of  $1 \times 26666 \times 112$  in R3 at the output layer.

#### 4.2.3 Dropout Regularization

To prevent overfitting and enhance the generalization capability of the Autoencoder model, dropout regularization is applied to each layer except the latent space layer. A 10% dropout rate is used, randomly deactivating 10% of the neurons to zero during each training iteration.

#### 4.2.4 Loss function

The Autoencoder is trained using the mean squared error (MSE) loss function, which measures the reconstruction error between the original input data and the reconstructed output. The MSE loss is defined as:

$$L_{MSE} = \frac{1}{N} \sum_{i=1}^N (x_i - \hat{x}_i)^2 \quad (1)$$

where  $x_i$  represents the original input data,  $\hat{x}_i$  represents the reconstructed output, and  $N$  is the total number of train passes. The loss function is minimized during training, ensuring that the reconstructed signal closely approximates the characteristics of the input signal. This optimization enables the Autoencoder to retain essential features of the input data, making the compressed representation more computationally efficient.

#### 4.2.5 Optimization

The Adam optimizer employed to train the Autoencoder is widely recognized for its effectiveness in various applications. It is well-suited for non-stationary objectives and problems with noisy or sparse gradients [25]. The optimization is performed over 30 epochs, minimizing the MSE loss to improve reconstruction accuracy while retaining the essential features of the input data.

#### 4.3 Integration with DNN Model

Integrating the compressed latent space representations of the frequency-domain acceleration data with the DNN model helps in parameter estimation. Figure 6 illustrates the step-by-step application of the DNN model.

Figure 6. The architecture of the DNN model.

#### 4.3.1 Input to DNN model

The compressed latent space representations of the frequency-domain acceleration data in both the x and y directions are integrated within the DNN model to estimate the cross-sectional area of the truss members. Since acceleration responses exhibit distinct dynamic characteristics in different directions, the compressed x and y components are concatenated to form a combined  $500 \times 2$  input vector for each train pass.

This combined representation allows the DNN model to capture the full structural behavior influenced by both directional responses. The combined  $500 \times 2 \times 112$  input vector for all train passes is passed into the DNN model for training, enabling the model to learn the system's dynamics across multiple loading conditions.

#### 4.3.2 DNN architecture

As mentioned earlier, the DNN model receives compressed latent space representations of the acceleration data from the Autoencoder, presented in a concatenated format that includes data from both directions. After conducting hyperparameter tuning using the grid search method, Table 1 displays the final values of the parameters used in the DNN model.

Table 1. DNN model parameters and their values.

Parameter	Value
Hidden Layers	3
Hidden Neurons	64
Output Neurons	5
Hidden Activation	Leaky ReLU
Dropout Layer	0
Learning Rate	0.001
Optimizer	ADAM
Epochs	20000

The final output layer estimates the cross-sectional area of the truss members connected, which is highlighted by a red color line in Figure 6. The network effectively learns the mapping from the compressed input to the target output while integrating the measurement loss function to improve accuracy.

#### 4.3.3 Measurement loss function

The DNN model incorporates a measurement loss to improve the accuracy of the estimated area. This loss minimizes the difference between the true cross-sectional area (provided in Table 2) and the predicted area obtained from the DNN model using the MSE loss function defined as:

$$L_{MSE} = \frac{1}{N} \sum_{i=1}^N \sum_{j=1}^5 \left( (x_{true}^j)^i - (x_{predicted}^j)^i \right)^2 \quad (2)$$

where  $x_{true}^j$  is the true value of the  $j^{\text{th}}$  parameter of the system to be estimated – the cross-sectional area and  $x_{predicted}^j$  is the corresponding predicted value from the DNN model.

Table 2. The table shows the true values of the cross-sectional area.

Parameter	Value (mm <sup>2</sup> )
Element 1 (E1)	24400
Element 2 (E2)	12178
Element 3 (E3)	15800
Element 4 (E4)	20100
Element 5 (E5)	8700

#### 4.4 Hypothesis for Estimating Cross-Sectional Area from a Single Node Response

The study focuses on a single node among those where bi-axial accelerations are recorded. This node is structurally connected to five truss elements, each assumed to have known lengths ( $L_1, L_2, L_3, L_4$ , and  $L_5$ ) and elastic modulus, while the cross-sectional areas ( $A_1, A_2, A_3, A_4$ , and  $A_5$ ) are unknown and to be estimated. The arrangement of the members is as shown in Figure 7. The assumption that all five truss elements are fixed at the other end is not true in the actual truss structure. However, this assumption allows checking of the algorithm in a smaller setting.

Figure 7. Schematic of the monitored truss node with five connected members. The bi-axial accelerometer is positioned at the node to record dynamic responses during train passages.

The mass matrix is formulated based on the shape functions that approximate the displacement. The consistent element mass matrix formulated in global coordinates for member AB is given by:

$$[M_{AB}] = \frac{\rho AL}{6} \begin{bmatrix} 2c^2 & 2cs & c^2 & cs \\ 2cs & 2s^2 & cs & s^2 \\ c^2 & cs & 2c^2 & 2cs \\ cs & s^2 & 2cs & 2s^2 \end{bmatrix} \quad (1)$$

where  $c$  and  $s$  denote  $\cos(\theta)$  and  $\sin(\theta)$ , respectively,  $\theta$  is the counter-clockwise angle measured with respect to the positive  $x$ -axis,  $\rho$  is the density of the material,  $A$  is the cross-sectional area, and  $L$  is the length of the element.

Meanwhile, the stiffness matrix is derived under the assumption of linear elastic behaviour. The stiffness matrix used in global coordinates for member AB is given by:

$$[K_{AB}] = \frac{EA}{L} \begin{bmatrix} c^2 & cs & -c^2 & -cs \\ cs & s^2 & -cs & -s^2 \\ -c^2 & -cs & c^2 & cs \\ -cs & -s^2 & cs & s^2 \end{bmatrix} \quad (2)$$

where  $E$  is Young's modulus,  $A$  is the cross-sectional area, and  $L$  is the element length.

Similarly, the global mass and stiffness matrices for all five connected truss elements are formulated and subsequently condensed by applying suitable boundary conditions according to the idealization results in a  $2 \times 2$  system of equations relating

the translational degrees of freedom at the monitored node to the forces acting on the node due to the train. During a train passage, this node undergoes dynamic displacement, and the bi-axial accelerometer captures its response along the train movement ( $x$ -direction) and gravity direction ( $y$ -direction).

Given that the displacement ( $u_x$  and  $u_y$ ) and acceleration ( $a_x$  and  $a_y$ ) responses are known, and the excitation is indirectly inferred from the train passage characteristics ( $f_x$  and  $f_y$ ), the cross-sectional areas, which influence the mass and stiffness of each member, leave a unique imprint on the node's dynamic response as reflected in:

$$\begin{bmatrix} K_{11} & K_{12} \\ K_{21} & K_{22} \end{bmatrix} \begin{Bmatrix} u_x \\ u_y \end{Bmatrix} + \begin{bmatrix} M_{11} & M_{12} \\ M_{21} & M_{22} \end{bmatrix} \begin{Bmatrix} a_x \\ a_y \end{Bmatrix} = \begin{Bmatrix} f_x \\ f_y \end{Bmatrix} \quad (3)$$

where  $K_{11} = \frac{EA_1}{L_1} + \frac{EA_2}{L_2} + \frac{EA_3c_2^2}{L_3} + \frac{EA_5c_1^2}{L_5}$ ;  $K_{12} = K_{21} = \frac{EA_3c_2s_2}{L_3} - \frac{EA_5c_1s_1}{L_5}$ ;  $K_{22} = \frac{EA_3s_2^2}{L_3} + \frac{EA_4}{L_4} + \frac{EA_5s_1^2}{L_5}$  and  $M_{11} = \frac{\rho A_1 L_1}{3} + \frac{\rho A_2 L_2}{3} + \frac{\rho A_3 L_3 c_2^2}{3} + \frac{\rho A_5 L_5 c_1^2}{3}$ ;  $M_{12} = M_{21} = \frac{\rho A_3 L_3 c_2 s_2}{3} - \frac{\rho A_5 L_5 c_1 s_1}{3}$ ;  $M_{22} = \frac{\rho A_3 L_3 s_2^2}{3} + \frac{\rho A_4 L_4}{3} + \frac{\rho A_5 L_5 s_1^2}{3}$ , are respective components of the effective stiffness and mass matrices. Here,  $c_1$  and  $s_1$  denote  $\cos(\theta_1)$  and  $\sin(\theta_1)$ ,  $c_2$  and  $s_2$  denote  $\cos(\theta_2)$  and  $\sin(\theta_2)$ , respectively, and  $\theta$  is the counter-clockwise angle measured with respect to the positive  $x$ -axis.

Equation (3) represents a possible relation between the acceleration and the cross-sectional area of connected elements. The proposed framework finds this relationship between the measured acceleration and cross-sectional areas in a data-driven manner.

## 5 RESULTS AND DISCUSSIONS

This section presents the performance evaluation of the Autoencoder-DNN framework, focusing on data compression, reconstruction errors, system parameter estimation, computational efficiency, and anomaly detection. The model is trained and tested using 150 train pass datasets for each direction, with a 75%–25% train-test split, ensuring the model generalizes well to unseen data.

### 5.1 Autoencoder Performance and Reconstruction Loss Behavior

The Autoencoder uses a validation set of a split ratio of 75%–25% instead of the test set during training to monitor the reconstruction loss and ensure that the model generalizes effectively to unseen data. This is important, as the loss terms for the autoencoder should remain consistent across the training and validation sets to facilitate accurate compression and reconstruction.

Figure 8 illustrates the training and validation loss curves, showing a smooth and stable convergence of order  $10^{-3}$ , which indicates that the latent space representation effectively captures the dominant structural features of the train-induced vibrations. The final loss values confirm that the compression process does not introduce significant deviations, making the latent representation reliable for subsequent DNN-based analysis.

Figure 8. Comparison of loss in the training set and in the validation set.

Additionally, the method takes approximately 240 seconds to compress the acceleration data into the latent space for both directions, highlighting its effectiveness in data compression and computational speed.

## 5.2 DNN Model Parameter Estimation

Once the Autoencoder compresses the frequency domain acceleration data into the latent space, the DNN model is trained using 75% of the dataset and subsequently tested on the remaining 25% of unseen data. The primary objective of the DNN model is to estimate the cross-sectional area of the truss members by minimizing the measurement loss function. Figure 9 illustrates that during the training process, the MSE loss consistently decreases as the number of epochs increases, leading to stable convergence of the estimated parameters.

Once stable convergence is achieved, while observing the parameter values in the training dataset, it is noticed that the cross-sectional area of the truss members converges to their true values. To interpret this result physically, for an idealized truss structure without structural damage, the cross-sectional area values should remain constant across all train passes. Figure 10 shows the area estimation of element (E2) for five train passes. It can be observed that the cross-sectional area is converging to its true value (reported in Table 2). Similarly, for all the train passes and for all the truss members considered, the results across the entire training dataset confirm that the estimated area values closely align with the expected true values.

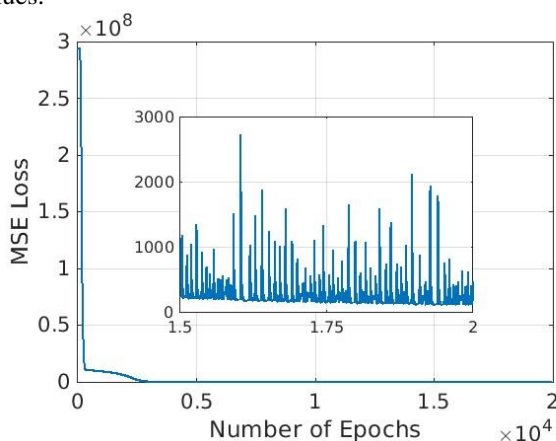

Figure 9. Convergence of measurement loss at each epoch.

Figure 10. The cross-sectional area of element (E2) using the training data.

### 5.2.1 Performance Evaluation of the DNN Model on the Test Data

Once the DNN model is trained, its performance is evaluated using the test data. Figure 11 illustrates the values of the cross-sectional area obtained from the DNN model for all the test datasets. The coefficient of variation (CoV) is computed for the estimated cross-sectional area for all the truss members and tabulated in Table 3. It is observed that the CoV values for all the truss members are less and identical. This uniformity in CoV shows that the DNN model exhibits consistent relative variability in its predictions across different members. Such behavior indicates stable model performance under test conditions, with no bias or irregularity in estimating cross-sectional area. However, this observation also highlights the need for further analysis to ensure that the model is sufficiently sensitive to localized structural variations, and hence, the model is tested through false data simulating sensor fault, noise, and anomalies, as explained in the next section.

Table 3. The table shows the coefficient of variation of the predicted cross-sectional area under test data.

Parameter	Coefficient of Variation (%)
Element 1	0.18
Element 2	0.18
Element 3	0.18
Element 4	0.18
Element 5	0.18

Figure 11. The cross-sectional area of the truss members for the test data.

Figure 12. Illustration of the false data for the DNN model, showing (a) the time-domain acceleration signal, (b) its frequency-domain representation, (c) the latent space obtained from the Autoencoder, and (d) a comparison between the normalized reconstructed false data and original data, highlighting their differences.

### 5.3 Computational Efficiency

The DNN model employed in this study took approximately 100 seconds to estimate parameters involving 150 train passages in both directions, emphasizing the model's effectiveness in balancing accuracy and computational speed in parameter estimation.

### 5.4 Anomaly Detection Through False Data Injection

To evaluate the robustness of the Autoencoder-DNN framework and its ability to detect inconsistencies in the input data, three false datasets are used in this study. These false data are provided to check whether the proposed framework can detect potential structural anomalies, sensor noise, or environmental influences, which introduce variations in the acceleration response in the on-field conditions. To be specific, the first false data replaces the train pass signal with data collected from a different node point, the second exhibits a faulty sensor that fails to capture the correct train pass signal, and the third represents an anomaly where the sensor is unable to record any valid data—potentially caused by false triggers. Figure 12 illustrates the procedure followed for preparing these false datasets prior to their input into the DNN model. It sequentially presents (a) the acceleration signal in the time

domain, (b) its corresponding frequency-domain representation, (c) the latent-space representation obtained from the Autoencoder, and (d) a comparison between the reconstructed false data and original data from the trained Autoencoder, clearly highlighting differences between the two signals. When the latent space of the false data was passed onto the DNN model, the predicted cross-sectional area for all the truss members exhibited notable deviations, as shown in Table 4. It is observed that the percentage deviation of the cross-sectional area for all the truss members exhibits the same percentage change for the different false datasets, regardless of the specific member location. For false data 1, 2, and 3, the percentage deviation is approximately 4.30%, 1.10%, and 3.30%, respectively. The statistically significant percentage change across members highlights the framework's ability to detect gross inconsistencies in the input signals, though it also indicates a need for future enhancement to improve sensitivity to localize anomalies. It may be that localization would occur when multiple nodes are used. Thus, the proposed framework provides the identification of faulty sensor readings, environmental influences, or potential structural changes. However, the classification of the signal remains a challenge.

Table 4. The table shows the percentage deviation of the predicted cross-sectional area values with respect to the true cross-sectional area values for the false data.

Parameter	Percentage deviation from the true cross-sectional area value (%)		
	False data 1	False data 2	False data 3
Element 1	4.30	1.10	3.30
Element 2	4.30	1.10	3.30
Element 3	4.30	1.10	3.30
Element 4	4.30	1.10	3.30
Element 5	4.30	1.10	3.30

## 6 CONCLUSION

This study introduced an Autoencoder-DNN framework for data-driven structural parameter estimation using train-induced vibration responses. The Autoencoder effectively compressed high-dimensional acceleration data in the frequency domain into a lower-dimensional latent space, preserving critical structural features while significantly enhancing computational efficiency. The DNN model, trained on the compressed latent representation, allows for accurate estimation of the cross-sectional area of the truss members connected to the node point considered in this study. The model exhibited stable performance on test datasets, with low prediction errors and consistent coefficients of variation, indicating reliable and uniform estimation capabilities. Furthermore, the framework effectively detected inconsistencies when introduced with false datasets simulating sensor faults, noise, and anomalies. In all cases, uniform deviations in the estimated cross-sectional area confirmed the model's robustness in identifying global anomalies in the input data.

Overall, the proposed framework offers an Autoencoder-based compression, supervised DNN model, and automated anomaly detection, making it a scalable and computationally efficient tool for large-scale truss structures in real-world applications. Future work will focus on improving the framework's sensitivity to localize damage and integrating the full-scale truss bridge model and extended datasets to further examine the framework's generalization capability.

## ACKNOWLEDGMENTS

The authors thank Southern Railways for funding this work and allowing the utilization of the collected data for analysis.

**ABSTRACT:** This study uses novel image processing techniques to explore the effects of Cement Replacement Materials (CRM) like silica fume and fly ash on concrete's microstructure and durability. Cylindrical concrete specimens were prepared with mixed ratios of 1:2:4 and 1:3:6, incorporating water-cement (W/C) ratios of 0.4, 0.5, and 0.6 and CRM levels of 0%, 15%, and 25%. Images captured at various cylinder heights were analyzed using rectangle and nearest neighboring methods to quantify aggregate distribution and air void characteristics, including area, size, and spacing. Validation against manual measurements showed an error rate of less than 1.9%, underscoring the accuracy of these techniques. Results indicated that increasing CRM content reduced air void proportion and size, indicating improved durability. Additionally, CRM increased concrete homogeneity, with 25% of CRM samples exhibiting the lowest coefficient of variation (Cv) values (0.29–0.37), compared to higher Cv values (0.41–0.57) in non-CRM mixes. These findings highlight CRM's potential to enhance concrete mix design for better structural performance and sustainability in construction applications.

**KEY WORDS:** CRM, Concrete, Image Processing

## 1 INTRODUCTION

Concrete holds significant importance in civil infrastructure construction due to its favorable properties such as durability, strength, adaptability, and ease of availability. Concrete consists mainly of cement, aggregates, and water, making it a composite material. The cement paste, formed by mixing water with hydraulic cement, acts as a binding agent in concrete formulations. Cement is the most expensive component within the concrete matrix. Moreover, the escalating global demand for cement production contributes to the upward trend in environmental CO<sub>2</sub> levels [1]. To reduce both the economic and ecological impacts associated with cement production, the incorporation of cement replacement materials (CRMs) has gained prominence, leveraging waste materials like silica fumes (SF) and fly ash (FA) as viable alternatives to conventional cement [2, 3]. CRM can significantly affect the rheology of the mortar, which refers to its flow properties [4, 5]. FA particles are fine and spherical and act as ball bearings, reducing internal friction between cement particles and making the mix more workable in the concrete mixture [6]. SF particles are extremely fine with a high surface area, which enables them to fill the spaces between cement particles and create a dense matrix. This results in increased viscosity and reduced flowability in the concrete [7]. Therefore, aggregate distributions and air void content in concrete are affected by CRM due to the changes it induces in the rheological and microstructural properties of the concrete [8].

The distribution of aggregates and air voids in concrete offers valuable insights into the concrete sedimentation behavior, directly impacting its stability, structural serviceability, durability performance, and resistance to cracks [9, 10, 11]. Concrete petrographic analysis (ASTM C856) [12] is a commonly utilized method for assessing many concrete aspects, e.g., size and distribution of aggregates, porosity

levels, and bughole formations etc. [13]. Typically, concrete petrography entails the micro-structural examination of concrete components on a polished concrete section using imaging methods such as optical microscopy [14] or scanning electron microscopy [15]. In the past, human experts have conducted petrographic analysis by visually inspecting bugholes and aggregate distribution in cut sections of hardened concrete to evaluate its stability [16]. Determination of the size of aggregate particles has traditionally been done through mechanical sieving or manual clippers, but these methods are susceptible to human bias, errors, monotony, and inefficiency. Hence, there is a growing need for automated techniques and alternative methods to assess concrete stability.

In recent years, digital image processing has emerged as a widely employed tool in structural health monitoring (SHM) of concrete structures. [17]. Numerous studies have leveraged image processing techniques for the distribution analysis of aggregates within concrete. Aggregate size, area, and distribution within the concrete mixture are assessed to investigate the stability of self-compacting concrete [18]. Characteristics and distribution of coarse aggregate were computed in [19] by segmenting the concrete image into the background (cement paste) and foreground (aggregates). Characteristics and distribution of coarse aggregate are evaluated in [20] by an image analysis method using cross-sectional images. The consistency between 3D and 2D parameters is assessed, and a comparison of the ratio of mortar-to-coarse aggregate area with the mortar-to-coarse aggregate volume is presented. The aggregate distribution analysis in asphalt concrete was carried out by examining the aggregates' segmented images obtained through X-ray computed tomography in [21]. An aggregate classification approach that considers mesoscale angularity is proposed in [22].

This paper presents image processing-inspired techniques for assessing the impact of CRM on the concrete characteristics i.e., aggregate distribution, air void formation, and mixture homogeneity and segregation. To ameliorate this, concrete cylinders of different mix design ratios and percentages of SF and FA cut at the top and bottom sections were imaged to capture the internal concrete characteristics. Then, the images were annotated with pixel-level labels to facilitate quantitative analysis. Image processing-based methods are presented for aggregate and air void analysis to understand the impact of different CRM ratios in a concrete mixture. Subsequently, indicators for assessing concrete homogeneity are introduced by integrating aggregate size, roundness, and inter-aggregate distances. The study provides valuable insights into the segregation of aggregates and air void proportions within the concrete mixes and provides a comprehensive understanding of the sedimentation behavior induced by CRM.

## 2 DATABASE

### 2.1 Preparing Concrete Mixtures:

Two distinct designs of concrete were chosen, each with different proportions of cement, fine aggregates, and coarse aggregates for casting. These proportions were specified as

1:3:6 and 1:2:4. Mixes were formulated using different W/C ratios (0.4, 0.5, and 0.6) under the standards set by ASTM C 94 [23] and ACI 318 [24], since the variability in the water/cement (W/C) ratio plays a significant role in influencing the workability and distribution of aggregates within concrete. A total of six mix designs were included in the cast samples. Fly ash (FA) and silica fume (SF) were employed as Cement Replacement Materials (CRM) at varying replacement percentages of 0%, 15%, and 25% to assess their impact on the distribution of aggregate and air voids within the concrete mixtures. Two batches of 18 concrete cylinders were produced using the mix design ratios outlined in Table 1, and were allowed to cure for 14 and 28 days, respectively. These cylindrical samples were 300 mm in height (H) and 150 mm in diameter (D). They were then cut into three slices at 1/3rd and 2/3rd sections (approximately 100 mm from the bottom and top) using a stone cutting saw. The cutting procedure for acquiring concrete slices is depicted in Figure 4. Due to the fine materials accumulation on the bottom face of the third slice, and the top face of the first slice had minimal or no aggregate information and were thus excluded from imaging. This left four faces for imaging to generate the dataset.

Table 1. Detail of the samples with Mix Ratios

Sr. No.	Mix Ratio	W/C Ratio	FA %	SF %	Proportions in kg/m <sup>3</sup>

The image acquisition setup was organized in a closed room, depicting an experimental arrangement for capturing digital images of concrete specimens, as shown in Figure 1. To ensure high-quality images for effective processing, measures were taken to maintain a consistent environment and minimize external influences such as light variations, noise, and shadows. Black sheets were used to cover all entry points for light, and two 30-W LED bulbs provided controlled illumination from a

specific angle, resulting in a light intensity of 2000 lux. A digital camera (Nikon DSLR 3300) with a resolution of 24 megapixels and ISO value set at 1000 was employed to capture 192 high-resolution slice images, each measuring 6000→4000 pixels. A constant distance was maintained by mounting the camera on a stand at a distance of 600 mm from the surface of the sample. The image acquisition setup, for example slice image, is illustrated in Figure 1.

Figure 1. Preparation of Concrete Mixtures (Top Left), Casting and Cutting of Samples (Top Right), Image Acquisition (Bottom Left), Image Labeling (Bottom Right).

## 2.2 Casting and Cutting of Samples

Two batches of 18 concrete cylinders were produced using the mixed design ratios outlined in Table 1, and were allowed to cure for 14 and 28 days, respectively. These cylindrical samples were 300 mm in height (H) and 150 mm in diameter (D). They were then cut into three slices at 1/3rd and 2/3rd sections (approximately 100 mm from the bottom and top) using a stone cutting saw. The cutting procedure for acquiring concrete slices is depicted in Figure 2. Due to the fine materials accumulation on the bottom face of the third slice, the top face of the first slice had minimal or no aggregate information and was thus excluded from imaging. This left four faces for imaging to generate the dataset.

Figure 2. Cutting the concrete cylinders into three slices at top and bottom sections

## 2.3 Image Labeling

Each image was meticulously labeled at the pixel level to distinguish between non-aggregate suspension (e.g., air voids, sand-cement matrix) and aggregate pixels. Similarly, for air void analysis, image pixels were labeled as either air void pixels or non-air void suspension pixels (e.g., aggregates, sand-cement matrix). Binary images were generated for aggregates and air voids, respectively.

Figure 3. High-resolution images of concrete slices: The top left is the original image, the top right is the background removed image, the bottom left is the Aggregate ground truth and the bottom right is the Air void ground truth image

Figure 3 shows a concrete cylinder slice with background, the processed image with the background removed, and the corresponding ground truth images for aggregates and air voids. White pixels in these images indicate the presence of aggregates and air voids as per the ground truth labels. Among all the labeled pixels across 144 slice images, 41.3% were labeled as aggregate pixels and 58.7% as non-aggregate pixels. Similarly, 0.25% of labeled pixels were labeled as air void pixels, with 99.75% classified as suspension pixels. Among all the labeled images, 1.8% of the particles were found to be connected. On average, each connected component consisted of approximately 13 pixels. These connected components were separated with a Marker-controlled watershed transformation algorithm [25] enabling detailed analysis and quantification of characteristics of each aggregate and air void in concrete samples.

The aggregates and air voids proportions can significantly influence the rheology, stability, mechanical characteristics, durability, and cost-effectiveness of concrete. These proportions can be determined from annotated images. The overall area occupied by aggregates and air voids in a concrete cylinder was determined by counting the white pixels, representing aggregates and air voids, and then multiplying it by the unit pixel size. Then this pixel size is converted to 0.044 mm. To validate this method, the aggregate and air void characteristics were compared with measurements obtained manually and using AutoCAD [26]. For manual area measurement of aggregates and air voids, a transparent graph paper with a 1 mm square grid was placed on the cylinder surface to count squares covering aggregates and air voids, as illustrated in Figure 4. The numbers of squares fully and partially covering aggregates and air voids were counted and then finally summed to determine the area of aggregate and air void, respectively. The aggregate mean size and roundness

values were manually verified against a vernier caliper, as illustrated in Figure 4. In AutoCAD [26], the raster images were first scaled according to the standard diameter of the cylinder. Subsequently, the boundaries of the aggregates and air voids were then traced, and certain boundary points were marked to form polygons, as depicted in Figure 4. With the help of a built-in command, the area of these polygons was calculated based on the coordinates of the boundary points. This approach differs from the pixel-based method, enabling a meaningful comparison between the two techniques. The areas of these polygons were then summed to determine the total aggregate and air void area, respectively. A comparison of aggregate and air void characteristics measured using the proposed image processing method, manual measurements, and AutoCAD is presented in Table 2. The results demonstrate significant consistency, confirming the effectiveness of the proposed image processing method in precisely identifying characteristics of aggregates and air voids.

Table 2. Comparison of the computed areas

Parameters	Mix Ratio	Proposed Method	AutoCAD	Visual Inspection	Percentage Error
Aggregate Area (mm <sup>2</sup> )	01:02:04	9335.35	9297.12	9411.25	0.81
	01:03:06	10058.42	10083.88	10171.5	1.11
Aggregate Mean Size (mm)	01:02:04	14.84	14.53	14.75	0.61
	01:03:06	15.36	15.64	15.5	0.9
Aggregate Mean Roundness	01:02:04	1.73	1.81	1.75	1.14
	01:03:06	1.52	1.43	1.5	1.33
Air-voids Area (mm <sup>2</sup> )	01:02:04	5.19	5.31	5.25	1.14
	01:03:06	9.68	10.12	9.5	1.89
Air-voids Mean Size (mm)	01:02:04	2.53	2.42	2.5	1.2
	01:03:06	2.77	2.87	2.75	0.73

#### 2.4 Aggregate and Air Void Characteristics:

An object's characteristics, like size, shape, and orientation, can tell much about its concrete composition. Quantifying these characteristics can lead to size and distribution uniformity analysis, which in turn facilitates the examination of concrete mixture's consolidation, workability, compatibility, interlocking, and bonding. The Feret rectangle technique [27] was utilized in this study to measure the characteristics of the coarse aggregate and voids from the image. This technique entails drawing rectangles that enclose each object with the minimum area possible, according to their Feret diameter as depicted in Figure 5. The Feret diameter represents the greatest distance between points along the object's perimeter. To compute this, we iterated through pairs of points on the boundary line, calculating their Euclidean distances and

identifying the greatest distance as the Feret diameter. Subsequently, around each object, a rectangle was drawn, with its length corresponding to the Feret diameter and its width perpendicular to this direction. The orientation of these rectangles was optimized to minimize their area while encompassing the object. The dimensions, i.e., length and width of each Feret rectangle, were then determined and recorded as the corresponding object's length and width. The length of the object was considered as its size, and the mean aggregate size was calculated as the average of all aggregate sizes measured in the image. The roundness values of coarse aggregates were assessed by computing the ratio of the rectangle's longer side to its shorter side. A roundness value of one signifies a square-shaped rectangle. As the roundness increases, the shape of the object becomes more elongated.

### 3 RESULTS AND DISCUSSION

#### 3.1 Aggregate Proportion

The proportion of aggregate in the concrete mixture is an essential factor in analyzing the structural health of a member and can be calculated using the image processing methodologies discussed previously. As presented in Table 1, in this study, two mix ratios, 1:2:4 and 1:3:6, were employed. These mix ratios denote the proportions of cement, fine aggregates (sand), and coarse aggregates in 1 m<sup>3</sup> volume of concrete. Initially, the proportion of coarse aggregates in the cylinder was quantified using the aggregate volume ratio (AVR) parameter. AVR represents the ratio of coarse aggregate volume to the total volume of a cylinder, as given by Eq. 1,

$$AVR = \frac{\text{Coarse Aggregate Volume}}{\text{Cement} + \text{Sand} + \text{Coarse}} \quad (1)$$

According to Eq. 1, the mix ratios of 1:2:4 and 1:3:6 correspond to AVR values of 0.57 and 0.60, respectively. The AVR values were then compared with the proportions of aggregates obtained from 2D cross-sectional images of the

cylinder. By analyzing concrete cross-sectional images and computing areas of aggregate, the proportion of aggregates in 2D images was quantified using the aggregate area ratio (AAR), given as Eq. 2,

$$AAR = \frac{\text{Area of Aggregate in Image}}{\text{total cross sectional area of cylinder}} \quad (2)$$

Here, the total cross-sectional area of the cylinder refers to the area encompassed by all pixels within the cylinder boundary. Figure 6 illustrates the AAR values obtained from the cross-sectional images for the two mix ratios across different CRM ratios. An observable trend emerges where an increase in the CRM ratio corresponds to a reduction in the variation of deducted AAR values. This may be because the incorporation of CRM results in a more uniform distribution of aggregates in concrete compared to normal concrete. It is noticeable that the calculated AAR values exhibit deviation from the AVR values. The disparity in AAR values may arise from several factors. Segregation can occur during mixing, transporting, and casting of concrete, leading to a nonuniform distribution of aggregates within concrete. These factors directly influence the calculated AAR values.

Figure 6. Box-Plots showing variation of calculated AAR values for the two mix designs with varying CRM ratios.

### 3.2 Aggregate Size

In segregation, the coarser aggregate particles tend to settle down, and the finer aggregate particles remain at the top. The sizes of aggregates at the bottom and top regions of concrete cylinders were analyzed (as detailed in Section 2.2) to assess the impact of different proportions of W/C ratio and CRM on segregation. Analysis of aggregate size involves examining cross-sectional images of the concrete cylinder at the top region (comprising the bottom face of the first slice and top face of the second slice) and the bottom region (comprising the bottom face of the second slice and top face of the third slice). The difference in aggregate mean size between these regions

indicates the extent of segregation and is shown in Figure 7 for different CRM Ratios. Within each mix ratio (1:2:4 and 1:3:6), generally, there is a slight increase in the difference in mean aggregate size with an increase in W/C ratio, which indicates the occurrence of segregation. This occurs because higher water content increases the mobility and fluidity of the concrete mix, making it more susceptible to segregation during handling, transportation, or placement. Excessive water can cause coarser particles to settle, increasing the size disparity between the aggregates.

Figure 7. Mean size of coarse aggregates at bottom and top regions of the concrete cylinders bottom and top regions.

### 3.3 Aggregates Roundness

The roundness of aggregates significantly influences segregation in concrete. Less rounded aggregates have irregular shapes with sharp edges and corners. When these less-rounded particles come in contact, they interlock, creating a bridging effect in the concrete mix. This bridging effect minimizes the risk of segregation for the less-rounded particles. On the other hand, more rounded aggregates have a uniform shape, making

them less prone to interlocking and bridging. This can result in a higher likelihood of particle movement and segregation within the mix. The more rounded shape reduces the frictional forces between particles, allowing them to move more freely and potentially separate from one another. The mean roundness values of aggregates in the top and bottom regions of the concrete cylinders are calculated using a specified method. Figure 8 represents the analysis results of aggregate mean roundness values at the bottom and top regions of a concrete cylinder with 0%, 15%, and 25% CRM, respectively.

Figure 8. Mean roundness values of coarse aggregate at bottom and top regions of the concrete cylinders.

### 3.4 Distance Between Aggregates

The examination of the distribution of aggregates in the bottom and top regions of concrete specimens can provide valuable information about the concrete sedimentation behavior. To examine the effect of CRM and W/C ratios on the distribution of aggregates, the distance between centroids of coarse aggregate particles was determined by the nearest neighbor image analysis method. The frequencies of these distances for different range groups are then determined for each section. Figure 9 shows the frequencies of distances between the aggregate for the specified range groups at different CRM and W/C ratios. The frequencies of distances between coarse aggregates are shown separately for the bottom and top regions of the concrete cylinder specimens. Most aggregate distributions fall within the 10 mm- 20 mm distance

range in all specimens. Notably, the 0% and 25% CRM cylinders exhibit a high frequency within the range of 10 mm-20 mm spacing distances, indicating closer aggregate spacing compared to the 15% CRM specimens. Figure 13 also reveals that the frequency of distances between 10mm and 20mm is higher in the bottom region, suggesting a more compact arrangement of aggregates at the bottom. Additionally, the frequency of distances within the range of 30 mm- 40 mm and 40 mm- 50 mm is lower in the bottom region compared to the top region. This difference can be attributed to the settlement of heavier aggregate particles, which results in closer spacing of aggregates within the 10 mm- 20 mm range, consequently reducing the maximum spacing between aggregates, typically in the 30 mm- 50 mm range.

Figure 9. Frequency of distances between centriods of coarse aggregate particles; Top Cylinder Region (First row), Bottom Cylinder Region (Second row)

### 3.5 Air Void Proportion

Assessing the air void proportion within a concrete mixture is a crucial step for achieving the desired balance between durability and mechanical properties, and it can be determined using the image analysis techniques described above. The air void proportion in the 2D cylinder images was quantified through the area air void ratio (AAVR) parameter, which is calculated as Eq 3.

$$AAVR = \frac{\text{area of air void in image}}{\text{total cross sectional area of cylinder}} \quad (3)$$

Here, the total cross-sectional area of the cylinder slice refers to the area encompassed by all the pixels contained within the boundary of the Concrete cylinder. Figure 10 displays the AAVR values computed from the images of concrete cylinder

specimens for the two mix ratios with varying CRM ratios. Across varying W/C ratios and concrete mix ratios, a consistent trend emerges. Generally, as the percentage of CRM increases from 0% to 15% and 25%, the proportion of air voids tends to decrease. This suggests that incorporating CRM, such as FA or SF, can reduce the formation of air voids in concrete. This reduction in AAVR values can be attributed to the pozzolanic properties of FA and SF, which enhance the workability and cohesion of the concrete mix, reducing the likelihood of entrapped air and thus decreasing the number of air voids. These findings offer valuable insights into optimizing concrete mix designs with CRM to minimize air voids. It's also worth noting that the W/C ratio effects the influence of CRM on air void proportion, as the two factors interact to shape the entrapped air content, highlighting the importance of considering both factors when optimizing concrete mix designs for specific applications.

Figure 10. Influence of CRM on the area air void ratios

### 3.6 Air Void Size

The size of air voids significantly impacts concrete properties. Smaller air voids enhance the concrete's resistance to freeze-thaw cycles, enhancing durability. Larger air voids, on the other hand, can weaken the concrete's mechanical properties, making it more vulnerable to cracking and deterioration in challenging environmental conditions. Achieving the right balance in air void size is crucial in optimizing concrete for specific applications, ensuring a combination of strength, durability, and long-term performance. To understand the effect of different CRM and

W/C ratios on the size of air voids, the mean size of air voids in the concrete cylinder sections was calculated by the method discussed. The influence of CRM on the size of air voids can be observed by comparing the air voids' mean sizes at different CRM percentages, as shown in Figure 11. It can be seen that as the percentage of CRM in the mix increases, the mean size of air voids tends to decrease. For instance, in the 1:3:6 mix with a W/C ratio of 0.4, the air voids mean size is 1.97 mm when there is no CRM (0% CRM), whereas with 15% CRM, it reduces to 1.71 mm. The air void mean size further decreases to 1.55 mm with 25% CRM.

Figure 11. Influence of CRM on the mean size of air voids

#### 4 CONCLUSION

This study explored advanced image processing techniques to investigate the impact of CRM (Silica Fume and Fly Ash) on air void characteristics and aggregate distribution in concrete. Techniques such as the Feret rectangle method and nearest neighbor analysis provided detailed insights into the size, shape, and spatial distribution of aggregates. The following main conclusions can be drawn from the results of the study:

- The analysis of aggregate proportion, quantified through Aggregate Area Ratio (AAR), revealed a close correlation with Aggregate Volume Ratio (AVR) values. This correlation underscores the accuracy and effectiveness of the employed image processing methods in predicting the aggregate proportion.
- The incorporation of CRM led to a notable reduction in both the proportion and size of air voids. This decrease enhances concrete durability by improving resistance to freeze-thaw cycles and reducing cracking risks.
- Increasing CRM content significantly reduces segregation tendencies, leading to a more uniform aggregate distribution across the concrete mix. This improvement is evidenced by lower Cv values, indicating improved homogeneity.
- CRM improved the homogeneity of aggregates by providing more consistent results in terms of aggregate areas, sizes, and roundness, particularly in specimens with higher CRM content. Kurtosis analysis further showed fewer outliers, indicating a more even distribution of aggregates.

• The image processing techniques, including the Feret rectangle method and nearest neighbor analysis, showed an error rate of less than 1.90%, confirming their reliability and accuracy in predicting aggregate and air void properties.

This study primarily addressed rounded and angular aggregates. However, closely positioned elongated or flaky aggregates or irregular shapes aggregates may overlap, potentially leading algorithms to inaccurately identify them as a single aggregate. This could affect the analysis of parameters such as area, length, and roundness. While manual labeling ensures accuracy, it is labor-intensive and subjective, limiting scalability for large-scale or rapid analysis needs. In future work, we plan to use deep learning-based image processing methods, i.e., DeepLabv3+, UNET, and vision transformers, to

segment and quantify aggregate and air void characteristics. Additionally, we aim to validate the effect of different CRM ratios on homogeneity by analyzing the distribution of aggregates and air voids at various sections of other structural members in real-world applications.

**ABSTRACT:** Traditional fatigue assessment in metals is based on load sequences either measured or assumed, S-N (Wöhler) curves and the application of linearized damage accumulation rules. This requires a large amount of experimental effort to obtain materials data to be used for prognostics of which the result is often unsatisfactory. Furthermore, such assessment is mainly based on stress and strain as the loading parameters applied. However, materials fatigue degradation is a more complex process, far from being linear and not limited to stress and strain only. Material's degradation is an issue. Without knowing a material's prior loading history its degree of degradation can neither be assessed nor monitored on this basis. However, monitoring a material's degree of degradation is a prerequisite to preserve a structure's health over its Residual Useful Life (RUL). Available Non-Destructive Testing (NDT) techniques can be of a significant help. This paper shows how a metallic material's non-linear fatigue behaviour can be visualized in a 3D plot characterizing the loading applied as an input parameter, the NDT parameter recorded as a material response and the relative fatigue life, hence the degree of degradation, as a resulting parameter respectively. It is shown how this resulting 3D viewing plane can be used to determine a material's degree of fatigue degradation at virtually any stage of its operational life and it is demonstrated how this information can be used for a monitoring system in the sense of Structural Health Monitoring (SHM) to further track a structure's RUL in a much more precise way than traditionally done so far.

**KEY WORDS:** Monitoring, non-linear fatigue degradation, Residual Useful Life, metallic materials

## 1 INTRODUCTION

Degradation of materials due to fatigue is a concern scientifically elaborated on since around 150 years. Its traditional assessment is based on load sequences either measured or assumed, S-N (Wöhler) curves and the application of linearized damage accumulation rules. The approaches being applied to experimentally determine a material's fatigue degradation and to get this analytically and/or numerically evaluated has been described in a variety of textbooks (i.e. [1-3]). Although the principles described in those textbooks might be applicable to a variety of materials, these principles have been mainly developed and used so far best with metallic materials. The effort to get the respective materials characterized and data generated is relatively high. To sufficiently cover such materials' fatigue data a set of around 25 fatigue experiments needs to be performed at different loading levels, a significant effort in terms of time and cost. An attempt to optimize this effort has been achieved by collecting and evaluating materials' data for cyclic loading nearly 40 years ago [4,5]. This data has been based on stress and strain as the loading parameters, being the most relevantly used in engineering design today. A major application of this data is within the context of local strain approaches, where the fatigue life of a service loaded notched component is determined with the help of a notch-strain-relationship as proposed by Neuber and others [1-3]. Materials' fatigue data determined on unnotched specimens are therefore the basis to perform a fatigue life evaluation of notched components under service loading. This article will therefore focus on the material's fatigue response and how this could be monitored with

advanced sensing beyond the traditional parameters of stress and strain.

To further enhance the process of materials fatigue data generation in terms of time and cost Short Time Evaluation Procedures (STEP) have been developed, along which the material's stress-strain and S-N behaviour can be determined down to a single fatigue experiment only [6-8]. The logic of those STEP approaches in its earlier form and being applied here is shown in Figure 1. This is based on three fatigue experiments, where two are traditional Constant Amplitude tests (CAT) and one is a Load or a Strain Increase Test (LIT or SIT) respectively, all tests performed on unnotched specimens. A LIT or SIT is a fatigue test, where the specimen is loaded at a constant stress (LIT) or strain (SIT) amplitude for a defined number of time or loading cycles, starting at a small stress/strain amplitude within the material's full elastic range behaviour and then increasing the stress or strain stepwise while keeping the duration of each step in terms of either time or number of cycles constant.

What is determined from the LIT or SIT is a relationship between the load applied (i.e. stress or total strain) versus a respective material response. In traditional terms, this material response is often plastic strain, being one of the mechanisms associated with fatigue in metals. Morrow [9] was possibly one of the first who determined such a relationship in terms of the strain hardening exponent  $n'$  of a metallic material's stress versus plastic strain relationship proposed as

$$\varepsilon_{a,p} = \varepsilon_f' \cdot \left( \frac{\sigma_a}{\sigma_f'} \right)^{1/n'} \quad (1)$$

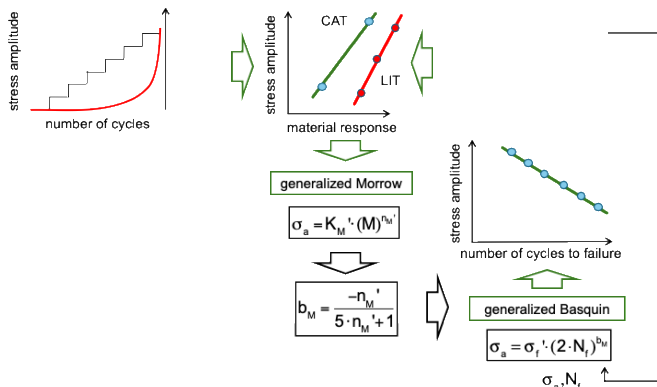

Figure 1 Logic of a STEP approach for the quick determination of an S-N curve

where  $\varepsilon_{a,p}$  represents the plastic strain amplitude,  $\sigma_a$  the applied stress amplitude, and  $\varepsilon_f'$  and  $\sigma_f'$  are constants referred to as the cyclic ductility and strength respectively similar to the true fracture ductility and strength under tensile monotonic loading. Morrow also used the two latter constants to describe a material's strain-life curve in the form of

$$\varepsilon_{a,t} = \frac{\sigma_f'}{E} (2N_f)^b + \varepsilon_f' (2N_f)^c \quad (2)$$

where  $\varepsilon_{a,t}$  is the total strain amplitude as an addition of elastic and plastic strain,  $E$  Young's modulus,  $N_f$  the number of cycles to failure and  $b$  and  $c$  the slopes of the life curves for elastic and plastic strain when being plotted in a double logarithmic scale respectively. What Morrow further did was to establish a relationship between the slopes  $b$  and  $c$  on the one side and the strain hardening exponent  $n'$  on the other resulting in

$$c = \frac{-1}{1+5n'} \text{ and } b = \frac{-n'}{1+5n'} \quad (3)$$

allowing a fatigue life (S-N) curve to be determined from a material's strain hardening response in the end. This relationship has also been used in the STEP procedures mentioned above in a slightly modified way, differentiating between the elastic and the plastic material behaviour.

Sensing and hence monitoring of a material's behaviour today can go far beyond monitoring stress and strain only. Non-Destructive Testing (NDT) has opened a large gamut of options considered in the past with respect to fatigue life evaluation and hence, residual life assessment of engineering structures, of which the potential has only been explored to a limited extent in the past. However, where this has been considered is in the context of STEP and here with respect to what has been considered as the 'material response' shown in the diagram in Figure 1. Examples presented in [6-8] and in various other publications do include techniques such as infrared thermography, electrical resistance and eddy current measurement. In this paper the case of thermography is presented and how this can be used for characterizing a metallic material's fatigue degradation behaviour. The information obtained is intended to be used for monitoring existing engineering structures, for which the degree of fatigue degradation due to a missing crack observation is unknown but where through monitoring an improved Residual Useful Life

(RUL) assessment of the metallic engineering structures is in need.

## 2 THERMOGRAPHY INSPECTION OPTIONS

Thermography is an electromagnetic NDT technique, along which a specimen is viewed with an infrared (IR) camera. The camera used here has been a thermoIMAGER TIM 450 from Micro-Epsilon, which is based on a bolometer-based pixelized image of 382 x 288 pixels with a sensitivity of  $\geq 40$  mK each. A view of such a set-up as well as a resulting image is seen in Figure 2. Temperatures are continuously recorded on the unnotched specimens in a fatigue test in the three zones indicated as  $T_1$  to  $T_3$ . From the data recorded a temperature difference  $\Delta T$  is then determined in accordance with the following equation:

$$\Delta T = T_3 - \frac{T_1 + T_2}{2} \quad (4)$$

Figure 2 Thermographic monitoring on unnotched specimen under fatigue loading: View of the specimen through thermographic camera including measurement points (left), experimental set-up (right)

## 3 THERMOGRAPHY BASED FATIGUE DATA

Metallic materials' data for cyclic loading are traditionally determined under either stress or strain control and are represented in terms of stress-strain relationships and the number of loading cycles up to failure (S-N curves). This data may be used for fatigue life evaluation of engineering structures under cyclic service loading, where mainly linearized damage accumulation rules such as proposed by Palmgren [10] and Miner [11] are applied. Results obtained often show a certain randomness (scatter) and the reasons for this can be sought in non-linearities a material provides. A question therefore arises what additional material response information could be retrieved in case of data being recorded with an NDT technique. In the case shown here, unnotched specimens made of the unalloyed steel C45E (1.1191 or SAE 1045) have been fatigue loaded as CATs at different stress and strain amplitudes and a LIT and SIT respectively and this under stress as well as strain control and at partially different loading frequencies. The full test set-up is shown in Figure 3.

Three CATs were performed under stress control at amplitudes of 320, 340 and 360 MPa and resulting fatigue lives of 109 408, 14 957 and 16 294 cycles respectively were obtained. The reason why the fatigue life of the test run at  $\sigma_a =$

360 MPa is higher than the fatigue life for the test run at  $\sigma_a = 340$  MPa is due to scatter in the fatigue life and the proximity of the stress amplitudes. The  $\varepsilon_{a,t} - N$  curve shown in Figure 4 that the experimental results show a typical fatigue behaviour. In addition, a LIT was performed starting at a stress amplitude of 100 MPa and being increased by 20 MPa always after 9 000 cycles until it reached a stress amplitude of 380 MPa. All of those tests were operated at a loading frequency of 5 Hz. These experiments were part of a master thesis performed [12].

Figure 3 Test setup for recording thermographic data along fatigue experiments on unnotched specimens: 1) test frame, 2) clamped specimen, 3) IR camera

In addition, two CATs and a SIT were performed on the same material but now under a sinusoidal function in strain control mode and considering a constant average strain rate of 1.0 %/sec or a maximum strain rate of 1.57 %/sec respectively. The strain amplitudes for the CATs were  $\varepsilon_{a,t} = 1.0$  % and  $\varepsilon_{a,t} = 0.3$  % respectively while the SIT started at a strain amplitude of  $\varepsilon_{a,t} = 0.1$  % and was increased by 0.02 % after every step of 2 000 cycles until it fully failed at a strain amplitude of  $\varepsilon_{a,t} = 0.42$  %. The fatigue lives of the two CATs up to full fracture was 600 and 14 600 loading cycles respectively.

Based on this data STEP as described before was applied to determine the S-N data. Figure 4 shows the results in terms of the stress vs. plastic strain relationship as well as the strain-life curve. The exponent  $n'$  from Eq. 1 turned out to be -0.122 which allowed the exponents for the  $\varepsilon_{a,t} - N$  curve to be determined according to Eq.s 3. Coefficients  $\sigma_f'$  and  $\varepsilon_f'$  were determined from the results of the two strain-controlled CATs through averaging. The resulting  $\varepsilon_{a,t} - N$  curve very well matches the remaining experimental results used for validation.

A summary of the thermographic recordings is provided in Figure 5. It shows the relationship of the temperature difference  $\Delta T$  due to fatigue loading versus a normalized fatigue life. This normalization has been determined on the fatigue life of each of the experiments shown here. This can also be considered as the degree of degradation, specifically for the CATs, where the Palmgren-Miner rule applies per se. Why this has also been done for the LIT and the SIT is for reasons of comparison with some further explanation later. What can be seen at this stage is that the stress levels match fairly well between the stress-controlled CATs and the LIT. When looking at the strain-controlled tests the SIT generates higher temperature differences when compared with a CAT at the same strain level.

What is also to be observed from Figure 5 is, that the temperature difference  $\Delta T$  seems higher for the stress-controlled experiments than it is for the strain-controlled tests. However, it has to be kept in mind, that the loading frequency for the stress-controlled tests was always 5 Hz while the strain-controlled tests were done at a constant maximum strain rate of 1.57 %/sec and the loading frequency hence varied between 0.25 and 2.5 Hz only. Following these results, it might be worth to explore, which loading parameters do have an influence on the temperature difference  $\Delta T$ . The reason why the temperature drops after each loading step in the SIT is due to the fact that loading is briefly interrupted and the new loading step is started with a gradual increase of the load applied. This effect has not been further considered in the evaluation.

Figure 4 Results of fatigue tests performed presented as a stress vs. plastic strain relationship (top) and  $\varepsilon_{a,t} - N$  curve (bottom) both in a double logarithmic scale

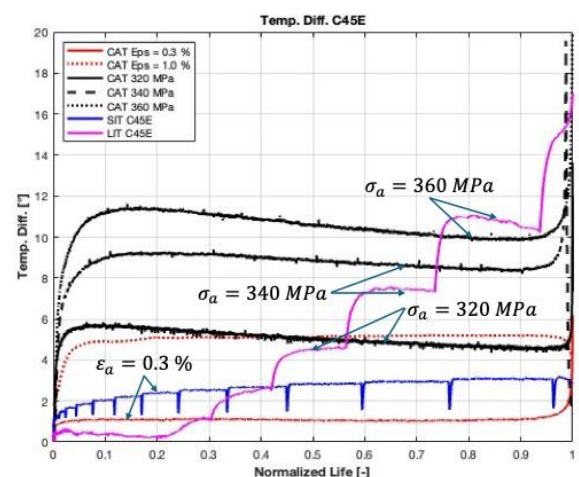

Figure 5 Development of temperature difference in three CATs and one LIT over normalized life of the CATs obtained under stress-controlled fatigue loading

All the experiments presented here were analysed with respect to stress amplitude and maximum strain rate vs.  $\Delta T$  and the result obtained is shown in Figure 6. It can be seen that as long as no plastic deformation occurs  $\Delta T$  remains marginal. Hence, any significant influence on  $\Delta T$  is governed by loading parameters in the plastic deformation region. The relationship between plastic strain and  $\Delta T$  can be linearized but this depends on the loading conditions (i.e. stress- or strain-controlled) and only when those are similar, a single function can be drawn, as to be seen from the fatigue test data shown in Figure 7.

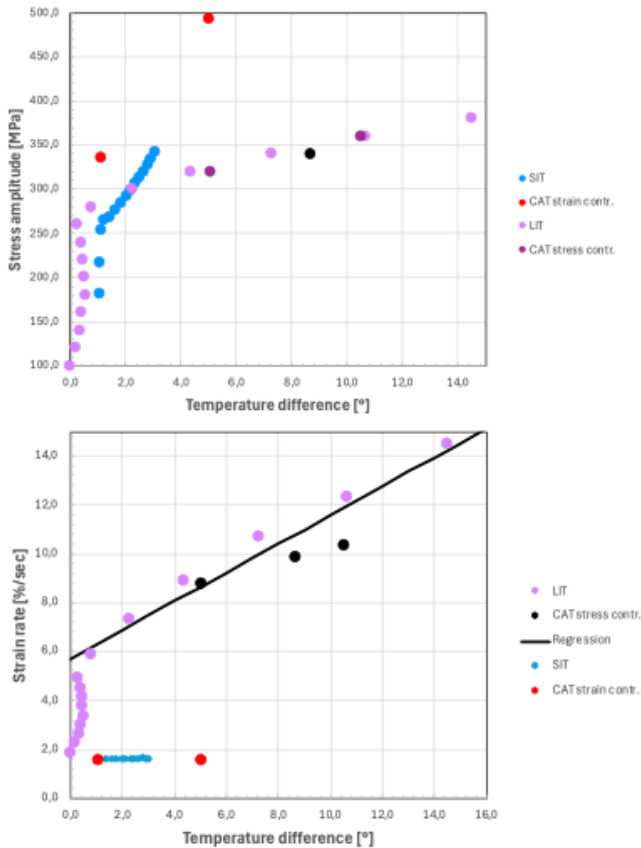

Figure 6 Stress vs.  $\Delta T$  (top) and strain rate vs.  $\Delta T$  (bottom) for all CATs, LIT and SIT performed

Figure 7 Plastic strain vs.  $\Delta T$  for all CATs, LIT and SIT performed

Energy is another parameter worth to be considered in that regard where the Smith-Watson-Topper (SWT) parameter [13] also known as the Neuber-parameter is widely used in the field of fatigue life evaluation of notched components and which is defined as:

$$P_{SWT} = \sqrt{\sigma \cdot \varepsilon_t \cdot E} \quad (5)$$

where  $\sigma$  represents the stress,  $\varepsilon_t$  the total strain and  $E$  Young's modulus respectively. If the fatigue results of this parameter are plotted versus  $\Delta T$  a result as shown in Figure 8 is obtained. The figure shows a lot of similarities to Figure 6 (top) and Figure 7 which is not much of a surprise. However, also in the case of energy no consistency in the thermographic material response can be observed. What can already be concluded here is that stress-controlled loading conditions can be better monitored with thermography than strain-controlled conditions can.

A question that might arise is, what would happen if a fatigue test could be performed where the energy applied could be permanently kept constant (controlled). First of all, this is a fairly complex fatigue test, which can be performed and has been specified as Neuber-controlled but which requires stress and strain to be controlled at the same time [14]. This could lead to some consistency between loading and the material's thermographic response and hence way of further validation. However, when looking plastic deformation in the roots of notched components, those plastic zones are mainly strain-controlled due to the elastic field around this plastic zone. Furthermore, energy conditions change along the life cycle of a material due to hardening and softening conditions resulting from the loading history.

Figure 8 Energy expressed in terms of the Smith-Watson-Topper parameter vs.  $\Delta T$  for all CATs, LIT and SIT performed

As a consequence of all having been presented so far, the plastic strain rate as well as the stress range above the yield strength looks to be mainly influential on  $\Delta T$ . As such a thermography-related loading parameter  $P_T$  is defined as to the following:

$$P_T = \varepsilon_{a,p} \cdot \omega \cdot (\sigma_a - \sigma_y) \quad (6)$$

where  $\varepsilon_{a,p}$  is the plastic strain amplitude,  $\omega$  the circular frequency of the loading,  $\sigma_a$  the stress amplitude and  $\sigma_y$  the yield stress respectively, the latter determined as 255 MPa from the upper diagram in Figure 6. Plotting all the experimental results as  $P$  vs.  $\Delta T$  leads to the diagram shown as Figure 9, which allows a concise relationship to be determined in linear or close to linear format.

Figure 9 Loading parameter  $P_T$  vs. temperature difference  $\Delta T$  for all CATs, LIT and SIT performed

Since the temperature difference  $\Delta T$  recorded is a material response, its possible non-linear behaviour raises certainly the question what of a material's non-linear behaviour it represents and if the consideration of such non-linearity might better cover a metallic material's non-linear fatigue degradation than this has been possible to be covered in the past. To get this shown a 3D plot has been generated representing temperature difference  $\Delta T$  recorded (z-axis) versus the enforcement applied represented by the parameter  $P_T$  (y-axis) and the fatigue life for the CATs in a normalized form (x-axis). What the latter axis therefore represents is nothing else than the degree of degradation.

Such a result is shown in Figure 10 for the five CATs (stress and strain controlled) as well as the LIT and the SIT. In the case of the CATs the temperature increases immediately at the beginning since in all cases yield is passed and plastic deformation has occurred. Once plastified, the temperature increase looks fairly constant over the lifetime of the specimens until final fracture occurs. The strain-controlled tests show less of a temperature increase when compared to the stress-controlled tests. Principally they align well with the parameter  $P_T$  defined in Eq. 6. Furthermore, these test results can serve as a basis to generate a plane as shown in Figure 11 characterizing the material's fatigue as well as monitoring behaviour, which is discussed later.

When looking at the results from the LIT and the SIT a fairly different behaviour is observed. While the SIT due to its constant strain rate shows a relatively continuous behaviour with slight temperature increases observed due to the slight increases in strain amplitudes and loading in terms of the parameter  $P_T$ , the LIT and the way it has been performed shows a fundamentally different behaviour with significant changes in temperature due to the significant changes from loading step to loading step. However, the results of both tests fairly well align

in the plane described by the CAT results keeping potential scatter in materials' data in mind. It might therefore be worth considering such planes as a material's characteristic along which the results of any loading sequence might move. Further proof of those assumptions with more complex loading sequences might be advisable for the future.

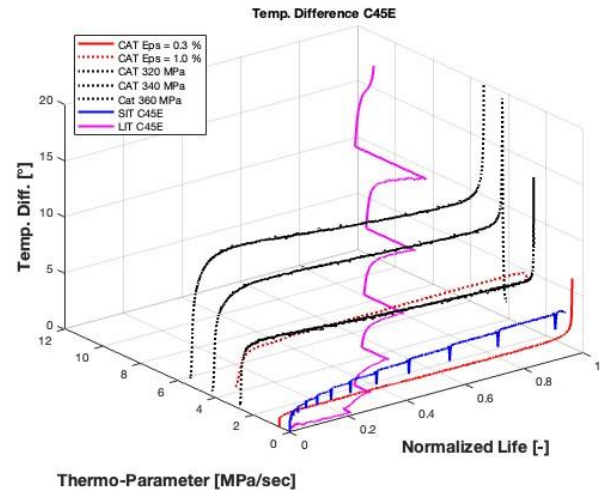

Figure 10 Development of temperature difference  $\Delta T$  in dependence of power rate applied and normalized fatigue life of CATs and comparison with the same relationship obtained from LIT and SIT

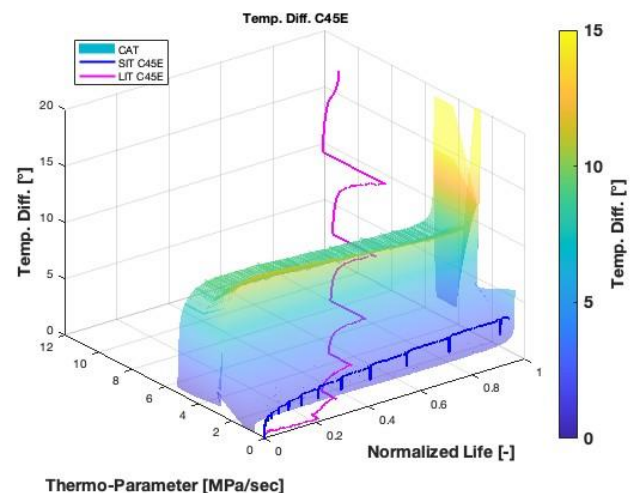

Figure 11 Topography of temperature difference  $\Delta T$  vs. power rate  $P$  and normalized life relationship for CATs and compared with similar results obtained from LIT and SIT

Since the stress, strain and loading frequency are the controlled and hence known input values related to the material's loading and  $\Delta T$  the material response monitored, the remaining unknown value is just the normalized life or in other words, the degree of degradation when talking in terms of the Palmgren-Miner rule, at least related to CATs. To get this degree of degradation obtained it has been assumed that the Palmgren-Miner rule applies for CATs and that as such the amount of degradation can therefore be calculated for each of the loading blocks or even loading cycles of the LIT and the

SIT. This leads to a description of the degradation development being very much different, as can be seen from Figure 12. The degradation process for the SIT and specifically for the LIT looks very much slower and the estimated fatigue life looks to be expired before plastic deformation even starts off in the case of the LIT. This contradicting result might be another proof of the lack of precision when applying Palmgren-Miner's rule. A conclusion is therefore, that monitoring the temperature emitted from a loaded structure might be the better information to determine a structure's degree of degradation than performing a Palmgren-Miner evaluation in traditional terms.

Figure 12 Development of temperature difference  $\Delta T$  over the CATs' normalized fatigue life and determining the respective fatigue life of the LIT and SIT through application of the Palmgren-Miner rule

#### 4 TEMPERATURE DIFFERENCE FOR MONITORING

SHM is based on using a material's response information to assess a structure's degree of degradation. Hence, the material's information provided through a diagram as shown in Figure 11 might therefore be a valuable tool to assess the structure as well as the monitoring principle being considered. A temperature difference resulting from a load applied on a structure and monitored through SHM could be principally used to be referenced to a diagram as shown in Figure 11. Assuming the respective value monitored on the structure could be determined as a single value on such a reference diagram, the degree of the structure's degradation could be easily determined. However, if such a value turns up more than once on the plane of the reference diagram, a conflict arises, which needs to be solved through more information to be retrieved. A help might be to mark the respective value positions on the diagram, which might even be described as isobars. Based on those isobars the appropriate solution needs to be found, which might be possible either through a variation (differentiation) in the direction of the power rate  $P_T$  and/or the normalized fatigue life.

As for the specific case of using thermography as the monitoring principle and the material as shown here, the situation in getting useful information from such a differentiation becomes tricky. The plane described in Figure

11 is mainly flat in the direction of the normalized life of the CATs. It looks like the material characterized becomes immediately plastified and this condition stays until fracture occurs towards the end of the tests. Thermography as a monitoring technique therefore clearly demonstrates, that it can identify plastic deformation but obviously not its contribution to fatigue degradation in the end. Also, the plane's inclination in the direction of the power rate  $P_T$  is fairly constant. Hence, the variation of loading parameters along the monitoring process might not provide the information to sufficiently identify the degree of material degradation.

However, the principle of a 3D plot as shown here in Figures 10 and 11 might be a useful instrument to collect and visualize data monitored as a combination of load, loading frequency and temperature on either a real structure or an unnotched specimen - of course of the same type of material. A summarized dataset shows in such a 3D plot if the data do represent a plane and which uncertainties might exist, to get this plane described or in other words how scattered the data recorded might be. Based on such scattered data allowance criteria might then be defined. Maybe that a longer-term monitoring on a structure to be assessed generating a larger database and combined with some advanced statistical evaluation might help to identify an appropriate location on the plane of the 3D plot and hence determine the degree of the structure's degradation. However, this requires further evaluation, which has not been performed so far.

In the context of the thermographic data presented here another aspect might be worth to be discussed. Thermography looks to be a method to allow plastic deformation in metals to be monitored well. This could make it interesting to identify plastic deformation in stress concentrated areas such as in notches. However, one needs to keep in mind, that fatigue loaded plastic zones in stress concentrated areas of notches are loaded in a strain-controlled mode. The reason for this is due to the elastic deformation occurring around the plastic zone. Hence, if those plastic zones might be monitored with thermography one should not be astonished if the signal might be weak, as concluded from results shown in Figures 5 and 6.

#### 5 CONCLUSIONS

The results presented here are far from claiming to be holistic. They are rather an additional extraction of data having been recorded along tests to establish S-N curves in accordance with the STEP approach. However, what proves to be interesting is to find out if an NDT method considered might be useful in terms of SHM and this in view of monitoring a material's and even a structure's degree of degradation with respect to fatigue. Compared to state-of-the-art approaches where monitoring is just possible in terms of detecting loads, strains and cracks, monitoring based on thermography at least allows plastic deformation to be identified additionally, a precursor to fatigue cracking.

While it has been shown here that loading, plastic deformation and of course also cracking can be measured through a temperature difference  $\Delta T$ , further parameters inherent in thermography signals might be worth to be explored. This may be achieved through higher sampling rates of the thermographic data and might allow the signal recorded to be better evaluated in terms of time domain information

including phase. Further extensions could be made in view of active thermography.

Generalizing the approach made here to virtually any monitoring and hence NDT technology to be considered for SHM could be a means to assess the NDT technology's potential with respect to SHM. A further step could be to differentiate the 3D plane obtained and shown in Figure 11 either in terms of the power parameter  $P_T$  or the normalized fatigue life. This would lead to a new 3D plot that would either characterize the material's sensitivity with respect to the loading or the fatigue life. In case of the fatigue life such differentiation might be a more sensitive parameter in identifying the degree of degradation and this also with respect to monitoring. However, this requires the 3D plane not to be as flat as in the case shown here, since a differentiation of this plane leading to a 3D gradient plot otherwise just scatters around zero. Such flatness of the 3D plane and scattering around zero in the 3D gradient plot might therefore also be an indication that the monitoring technique is possibly not suitable for monitoring a material's fatigue degradation in the pre-cracked stage.

The topography of the 3D plot shown in Figure 11 is also an indication of the non-linearity the monitoring parameter exhibits and this with respect to a potential non-linearity in the material. Hence, if the 3D plot is relatively 'flat' and constant in its height, this could mean that linearization of fatigue degradation for the respective material and hence the traditional Palmgren-Miner rule would be better applicable when compared to materials where such a topography of the 3D plane might be more uneven. However, in the case here it at least shows for the LIT and the SIT that irrespective of the smooth surface the predictions are not very consistent and the material response recorded might not work very well in combination with the Palmgren-Miner rule (c.f. Figure 12). Further corrections might therefore have to be done to get this improved. Or formulated inversely as a question: Would a 'wavy' or possibly more 'spiky' 3D plane characterize a monitoring technology as a more relevant technology for monitoring fatigue degradation? Furthermore, could a 'spiky' 3D plane possibly be used to enhance a component's fatigue life under service loading evaluation since it better covers the material's non-linearities in fatigue degradation than the Palmgren-Miner rule is able to do? Answers to these questions might be obtained through a further random load fatigue assessment.

Should any if not all of those questions be answered positively, then the diagrams as shown in Figures 10 and 11 might become future displays of materials' data for cyclic loading, representing a clear extension when compared to the traditional stress-strain and S-N curves provided in handbooks such as [4,5] in the past. Interesting additional questions in that regard are also if the 'life path' of a randomly loaded material follows the topography spanned by the CAT results. In case of a match every data recorded could be virtually added to the database, allowing the material's information to continuously grow.

What has been shown here with the SIT results is, that the temperature difference  $\Delta T$  mainly stays or marginally increases on an isobar during each loading step when the strain is increased from one strain level to another. However, what

happens with this path when the strain levels are decreased is still an open question to be answered.

The large amount of data being recorded might also become an interesting source for statistical evaluations. Monitoring an engineering structure under service loading with a thermographic camera combined with other loading parameters might provide an interesting data sample for a further statistical evaluation of which the statistical patterns might be correlated with patterns to be found in the material's general reference database.

The approach presented here intends to show how far thermography might be applicable in the context of SHM. At present the monitoring principle has been proven for a laboratory environment only. The major sensing device is the IR camera which has to stay as an external device. An interesting next step to explore would be to perform the same type of fatigue experiment but with larger, more complex, notched components and to see how well the fatigue behaviour in the notches could be monitored. A constraint might be the strain-controlled mode and the resolution of the IR camera system as well as the component's shape for which corrections might have to be made regarding the signals to be processed. Another aspect to be explored is the influence of the component's surface preparation. It is very likely that a quantitative validation of a component as is might not lead to satisfying results and that coatings might have to be removed and/or treated such that comparable conditions are achieved. This is an important step that has to be proven before considering any in field monitoring in terms of general applications. Potential first applications could be seen for fatigue loaded components being visually easily accessible and highly loaded, preferably considering a load spectrum to be 'sharp', hence, with a large number of high loads. Again, a potential application could be in the field of testing of fatigue loaded components and assessment of their degradation processes in a laboratory environment. Another field would be rotating machinery where the rotating rod is just fixed with bearings, but all other parts are visually easily accessible. However, a new challenge might arise between the rotating frequency of the machinery versus the frame rate of the IR camera.

A solution to all those challenges could be temperature sensors, that could be directly adapted onto the structure to be monitored but this is far from being realized at present. However, the approach presented here is not limited thermographic monitoring only. Eddy current or other electromagnetic sensors being commercially available are sensors that can already be attached in situ and where the 3D plot can be generated as the source of reference. In that case, civil infrastructure could be an interesting application field.

All what has been described here is related to passive thermography only. What active thermography would provide is an additional chapter being beyond the scope of this article.

A further challenge comes if those monitoring approaches might be applied in the field where a thermographic camera records a structure in service under general environmental conditions. In that case all environmental influences will have to be compensated such that only the true difference due to degradation becomes apparent in the thermographic analysis.

As such passive thermography in SHM of mechanically loaded structures is still limited to fundamental explorations that may provide the appropriate parameters to be considered for a more generalized application in structural life cycle management.

**ABSTRACT:** Structural health monitoring (SHM) is a well-established practice to ensure safety and reliability of civil structures. With the increasing demand for environmentally responsible construction practices and the need to reduce the carbon footprint of construction projects, sustainable materials, such as clay, are gaining attention. Clay-printed structures introduce a novel domain to SHM that requires adaptations of established SHM strategies. Research on SHM strategies devised for clay-printed structures remains scarce, leaving a critical gap in understanding the long-term performance of clay-printed structures. Serving as a foundation for developing SHM strategies for clay-printed structures, this paper proposes a methodology to experimentally determine the structural behavior of clay-printed structures, including buckling, shrinkage, and load-bearing capacity, while identifying key factors critical for developing SHM strategies. The methodology proposed in this study incorporates condition assessment, constraint definition, design optimization, prototyping, and SHM strategy definition. The methodology is implemented for a wall component to experimentally determine shrinkage. Based on the structural behavior of the wall component, an SHM strategy is proposed that essentially consists of selecting appropriate SHM techniques, defining sensor placement, and establishing decision-making criteria. The results demonstrate the feasibility of constructing structurally stable clay-printed structures and provide key insights into SHM strategies for clay-printed structures, advancing sustainable construction practices.

**KEY WORDS:** Additive manufacturing; clay printing, structural health monitoring, sustainable construction.

### 1 INTRODUCTION

Digital fabrication techniques, particularly 3D printing (3DP), have witnessed increasing adoption across various industries in recent years [1]. The construction sector has been adopting 3DP technologies over the past two decades, scaling up 3DP processes to meet the demands of large-scale building projects and enabling environmentally responsible construction practices. The trend towards using 3DP in construction has encouraged research on automating construction processes, owing to well-developed digital-based construction methods as well as research on 3DP materials, such as concrete and clay [2].

Data on the long-term performance of 3D-printed structures and on the internal state of 3D-printed materials is essential for understanding relationships between 3DP processes, materials and geometries [3]. By monitoring structural aspects, such as buckling, shrinkage, and load-bearing capacity, the long-term performance of 3D-printed structures may be determined and assessed. Consequently, structural health monitoring (SHM) may facilitate data recording and analysis to monitor the long-term performance of 3DP structures. However, SHM methodologies tailored to 3D-printed structures, particularly clay-printed structures, barely exist [4].

Generally, embedded sensors may enhance monitoring of structural and material behavior of clay-printed structures. In 3DP applications, embedded sensors have been largely deployed for concrete printing and in a lesser extent for clay printing [5]. Since sensing in concrete printing is more mature compared to sensing in clay printing [6], synergies between concrete and clay printing may be exploited to monitor structural parameters (e.g., strain and deformation) and

material parameters (e.g., temperature and moisture content) of clay-printed structures. For example, lead zirconate titanate piezoelectric sensors, utilizing electro-mechanical impedance techniques, provide real-time insights into the stability of stacked layers and help assess potential structural weaknesses during printing [7]. Strain gauges and linear variable displacement transducers are used to evaluate buckling characteristics in complex 3D-printed walls under compressive loading [8]. Similarly, fiber Bragg grating sensors embedded in clay capture internal strain changes and allow measuring critical parameters, such as temperature and pressure variations [9]. However, current sensing techniques lack a systematic approach, hindering the development of SHM methodologies for clay-printed structures.

Latest studies in clay printing have primarily relied on visual inspection of in-situ tests, with limited emphasis on systematic evaluation techniques [10]. Moreover, sensor placement in clay-printed structures has been determined by trial-and-error testing rather than structured investigation. Hence, research on SHM methodologies specifically tailored to clay-printed structures remains limited. Thus, by deploying a generalized experimental testing methodology, SHM strategies may be defined to assess the behavior and improve the understanding of long-term performance of clay-printed structures. For example, shrinkage, which may cause structural instabilities [11], could be assessed by monitoring temperature and moisture content during the drying process to minimize desiccation cracks.

In this paper, a methodology for defining an SHM strategy for clay-printed structures is proposed. The methodology considers structural and material behavior, comprising

condition assessment, constraint definition, design optimization, prototyping, and, finally, SHM strategy definition.

The reminder of this paper is structured as follows. First, an overview of the proposed methodology is presented. The methodology is implemented by experimental testing to derive an SHM strategy. Next, the effectiveness of the SHM strategy is validated by embedding sensors to monitor moisture content. Finally, the paper concludes with a summary and a concluding synthesis of the key findings.

## 2 METHODOLOGY

The methodology is devised to propose a scientifically sound SHM strategy and it consists of five phases, condition assessment, constraint definition, design optimization, prototyping, and SHM strategy definition (Figure 1). In the first phase (*condition assessment*), initial conditions are determined to identify climate conditions, material characteristics, available equipment, and software applications. Climate conditions, such as temperature and humidity of the environment, provide insights for designing clay mixtures and for assessing drying processes. Clay mixtures are designed by mixing clay, aggregates, binders, and water, to achieve a material that is extrudable by the equipment (i.e., clay printer). The material characteristics of the clay mixtures are determined by material testing to assess extrudability, buildability, small-scale shrinkage, and cracking behavior based on established testing methods. For each material test, four specimens are tested. Specifically, in this study, shrinkage and cracking are assessed by non-standardized testing, where customized cylindrical specimens are printed and evaluated.

In the second phase (*constraint definition*), constraints are defined by identifying and categorizing limitations based on the initial conditions, including structural, fabrication, and sensing constraints. The structural constraints are based on the flowability, strength, buildability, and shrinkage performance of the material. The fabrication constraints (e.g., layer height, built height, overhang angle, and bridging length) are determined through process parameter tests [12-15]. For each process parameter test, two specimens are tested. The sensing constraints include sensor size and sensor type restrictions, which affect design decisions in the next phase.

In the third phase (*design optimization*), design variables are identified and optimized based on the structural constraints, the fabrication constraints, and the sensing constraints. Through parametric design, infill patterns and connections are optimized

for material reduction and structural integrity based on the structural constraints. The print path is then refined based on print speed and fabrication constraints, taking into account the process parameters previously defined to ensure the manufacturability of the optimized structure while considering the sensing constraints. The design process utilizes software applications for parametric design options, enabling efficient parameter adjustments without redesigning the workflow. In this study, the software application *Rhino 8* [16] is used for the parametric design, primarily motivated by the integrated visual programming tool *Grasshopper 3D*.

In the fourth phase (*prototyping*), physical prototypes are developed and evaluated to refine the design and to ensure structural integrity and manufacturability. The prototypes are fabricated to define the SHM strategy with emphasis on sensor positioning, with one prototype produced per clay mixture. The prototypes facilitate assessing changes in observable parameters (e.g., moisture content and drying direction), the respective structural behavior (e.g., shrinkage and desiccation cracking), and the related material testing (e.g., small-scale shrinkage tests).

In the fifth phase (*SHM strategy definition*), the SHM strategy is defined, based on the experimentally assessed structural behavior (e.g., shrinkage and desiccation cracking). The SHM strategy considers interactions observed between structural behavior and parametric design, when defining sensor type and sensor positions. For example, monitoring shrinkage includes selecting sensor types to observe temperature and moisture content and providing criteria for systematically determining sensor positions. The criteria determine sensor positions based on potential failure scenarios, ensuring comprehensive coverage of critical structural vulnerabilities, particularly those caused by desiccation cracks. Finally, a feedback loop facilitates adjusting the parametric design to fit the defined SHM strategy, where sensors are embedded into clay-printed prototypes to validate the SHM strategy. In the following section, the implementation of the methodology is presented.

## 3 EXPERIMENTAL TESTING

The methodology is implemented by experimental testing to derive the SHM strategy. The following subsections are structured in compliance with the aforementioned phases of the methodology, shown in Figure 1.

Figure 1. General workflow for determination of SHM strategies in clay printing.

### 3.1 Condition assessment and constraints definition

The tests are conducted in a laboratory container of the Institute of Digital and Autonomous Construction. The container is maintained at a constant temperature of 23 °C. The robotic system is a 3D Potterbot Scara v4, equipped with a linear ram extruder and 3.5 l extrusion tubes that can print plastic clays. As shown in Figure 2, material tests are performed on a designated testing area, while process parameter tests are conducted on a separate levelling board. The levelling board ensures a flat printing surface and enhances adhesion due to its rough texture.

Figure 2. Experimental setup of the clay printer and print area in the laboratory container.

Clay mixtures are designed using two clay types, “clay A” representing a raw clay and “clay B” representing a milled clay. Quartz sand is added to the mixtures to increase stability and reduce shrinkage, and a starch binder is added to improve mechanical behavior. The residual moisture in the sand is below 0.3 %, with a grain size ranging from 0.062 mm to 0.3 mm. The binder, Optapix S 51, consists of modified starch with a bulk density of 0.5 kg/m<sup>3</sup>. The physical properties and the chemical composition of clay and sand are listed in Table 1.

Table 1. Physical properties and chemical composition for clay types and sand (percentages in M-%).

	Clay A	Clay B	Quartz sand
Density [g/cm <sup>3</sup> ]	2.65	2.65	1.3 ± 0.3
Drying shrinkage [%]	4.0	6.0	-
SiO <sub>2</sub> [%]	75.0	71.0	92.1
Al <sub>2</sub> O <sub>3</sub> [%]	19.8	24.0	2.7
TiO <sub>2</sub> [%]	1.4	2.0	0.0
Fe <sub>2</sub> O <sub>3</sub> [%]	0.9	1.0	0.1
CaO [%]	0.2	0.0	0.9
MgO [%]	0.3	0.0	0.2
K <sub>2</sub> O [%]	2.2	3.0	1.5
Na <sub>2</sub> O [%]	0.1	0.0	0.2

A detailed testing workflow is created (Figure 3), comprising material composition, material parameters, and process parameters. First, material composition tests are conducted for each mixture, to determine and evaluate viable ratios of clay, sand, binder, and water. The material composition tests consist of a simple extrusion test, where the consistency and extrudability of the clay mixtures are evaluated. Results achieved from the material composition tests, 19 viable clay mixtures are obtained.

Second, the material parameters of the viable clay mixtures are evaluated, including flowability, wet strength, buildability, and shrinkage. The tests to determine the flowability, strength, and buildability consist of a cylinder drop test according to [12] and a shape retention test according to [13]. For the (non-standardized) shrinkage test, customized cylindrical specimens are printed and observed for horizontal shrinkage, vertical shrinkage, and cracking behavior. The cylindrical specimens have a diameter of 150 mm and a height of 200 mm. As a result of the material parameter evaluation, 6 viable mixtures are selected from the previous 19 mixtures previously achieved.

Third, the process parameters are determined for each mixture via extrusion line tests, failure tests, double cone tests, and bridging tests, in compliance with [14] and [15]. The process parameters are utilized to determine the fabrication constraints for designing wall components. A clay content of

Figure 3. Material testing workflow.

Table 2. Material testing clay mixture proportions.

Name	Clay [M-%]	Sand [M-%]	Water [M-%]	Binder [M-%]
A_25.0C_36.0W_1.0B	32.9	29.0	15.1	0.8
B_25.0C_38.0W_1.0B	32.6	28.6	15.6	0.8

Table 3. Process parameters defined for design considerations.

Parameter	A_25.0C_36.0W_1.0B	B_25.0C_38.0W_1.0B
Layer height for 11 mm layer width	4.5 mm	4.0 mm
Maximum build height	243 mm	356 mm
Maximum inward angle	30.0°	27.5°
Maximum outward angle	27.5°	27.5°
Bridging length, adjacent layer spacing > 0 mm	40 mm	20 mm
Bridging length, adjacent layer spacing < 0 mm	80 mm	80 mm

25 % of the dry volume is observed to offer an optimal balance between shrinkage and stability, resulting in a suitable choice for prototyping applications. Therefore, two clay mixtures A\_25.0C\_36.0W\_1.0B and B\_25.0C\_38.0W\_1.0B are selected for prototyping; material composition is detailed in Table 2. The corresponding process parameters are listed in Table 3.

### 3.2 Design optimization

The design optimization includes design variable adjustments of infill patterns, segmentation, and connection design. The infill is optimized by reducing the total material volume and print speed. Through a curved geometry, the material is reduced while retaining stability. Intersection width of adjacent curves are increased to accommodate the sensor width. The process parameters defined in the fabrication constraints regarding overhang angle and build height influence segmentation and connection design. Additional factors, including layer height, determine the toolpath configuration. Furthermore, by defining toolpaths as continuous paths, print times are reduced as retraction points and non-printing moves are minimized.

### 3.3 Prototyping

Two prototype specimens of a wall component, prototype A (fabricated with the mixture using clay A) and prototype B (fabricated with the mixture using clay B), are devised respectively. Buckling, overhang angles, and surface quality are visually assessed immediately after fabrication. Following the fabrication, the prototypes are evaluated during and after the drying process on shrinkage and cracking.

The prototypes are observed to be printable with no failures or significant buckling of either the contour or the infill. Observations during the drying process reveal non-uniform drying patterns in the two prototype specimens. The drying process showcases a directional gradient, characterized by drying progressing from the top to bottom and from the exterior surfaces toward the interior infill.

Moisture content assessment, conducted after a six-day drying period, reveals variations between the prototype specimens. Figure 4 shows the moisture retention behaviors of the two prototype specimens. Prototype A demonstrates faster drying rate, with faster moisture dissipation across the specimen. Conversely, prototype B exhibits a slower drying

rate, as evidenced by a darker discoloration of the infill and contours, indicating retained moisture.

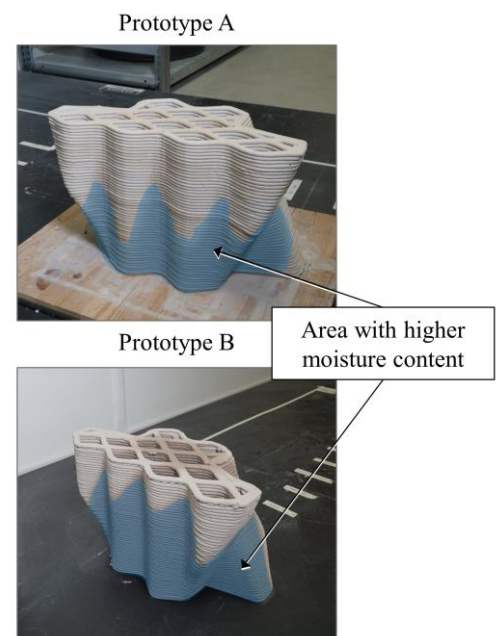

Figure 4. Prototype moisture content observed after a six-day drying period.

Desiccation cracks are documented during the drying process. On the one hand, prototype A develops multiple desiccation cracks (Figure 5). The first cracks appear after day four, primarily centered in the midline region advancing from bottom to top, with a final length of 226 mm and width of 2 mm. Further cracks appear in the midline and front region in days six and eight and increase in length during the following days, with a final length of 223 mm and 95 mm and a final width of 1 mm, respectively. The crack at the midline region may represent a protentional weak point due to the location, length, and width of the crack. On the other hand, prototype B exhibits significantly reduced desiccation cracks with only a single crack forming after eight days at the midline region observed to advance from bottom to top. The location of the crack is similar to the position observed in the first crack of prototype

A. However, the crack length and width are less severe, with a 140 mm in length and less than 1 mm in width.

Upon drying, shrinkage is evaluated by measuring the dimensions of the dry specimens and comparison with the initial dimensions. The measurements include the length on long side, length on short side, width, and height of each prototype specimen. Uneven shrinkage of the prototype is observed across the two specimens after two weeks of drying. For prototype A, a horizontal shrinkage of 5.34 % and a vertical shrinkage of 0.64 % is observed on average. Comparatively, for prototype B, a horizontal shrinkage is 6.76 % and a vertical shrinkage is 2.2 % is observed on average. The prototype A shows strong adhesion to the leveling board, resulting in reduced shrinkage at the base. In contrast, a free shrinkage at base of prototype B is noticeable due to low adhesion to the smooth bed plate. However, the prototype specimens are inaccurate for shrinkage material characterization due to the complexity of the geometry.

The difference in the shrinkage behavior of both prototypes may be attributed to the drying rate and to local errors, such as air bubbles in the extruded material, during printing. An increase in water content leads to increased shrinkage, as observed in the shrinkage evaluation, where prototype A showed less shrinkage than prototype B. Typically, increased shrinkage and faster drying processes are associated with increased desiccation cracking. However, errors during printing may cause additional cracking due to induced internal stresses, as observed by the strong adhesion to the leveling board showcased by prototype A. Special attention should be paid to the printing setup and drying rate to minimize desiccation cracking.

To define the SHM strategy, a second prototype iteration is conducted, where moisture sensors are embedded. Considering the shrinkage behavior exhibited by prototype B, the mixture using clay B is selected for the second prototype iteration (prototype B2). The prototype B2 serves to assess the effectiveness of the monitoring system and to refine the sensor

positioning that will be relevant to the SHM strategy to be proposed.

### 3.4 Sensor integration for SHM strategy definition

As a basis to define the SHM strategy, which will be proposed in the following section, sensor integration of varying sensor types and positions is investigated. A validation test is conducted to assess the performance of resistive and capacitive moisture sensors, as well as the effect of sensor positions. Resistive and capacitive moisture sensors are typically used to measure soil moisture content using different sensing principles. Therefore, by deploying both sensor types to monitor drying processes in clay printing, the sensitivity of the sensors for detecting changes in moisture content may be compared to assess performance. As shown in Figure 6, two sensor systems are used to monitor prototype B2,

- (i) sensor system I, a **commercial sensor system** consisting of a resistive moisture sensor typically used for discrete soil monitoring, and
- (ii) sensor system II, a **custom-made SHM system** consisting of a moisture sensor node (containing three capacitive moisture sensors) and an environmental sensor node for continuous monitoring of clay moisture content and the surrounding environment.

The resistive and capacitive moisture sensors are positioned at different embedment depths and distributed on the exterior and interior surfaces of prototype B2 to monitor the drying process following the observed drying gradient during the prototyping phase.

On the one hand, sensor system I is designed to measure soil moisture by outputting a value of resistance between the two probes. On the other hand, sensor system II is designed for recording real-time data of the prototype moisture content and the environmental conditions in the laboratory. The moisture sensor node of sensor system II comprises the three embedded capacitive moisture sensors v2.0 that are connected via cables to an Arduino ESP32 microcontroller to record moisture content by detecting changes in capacitance. The capacitive

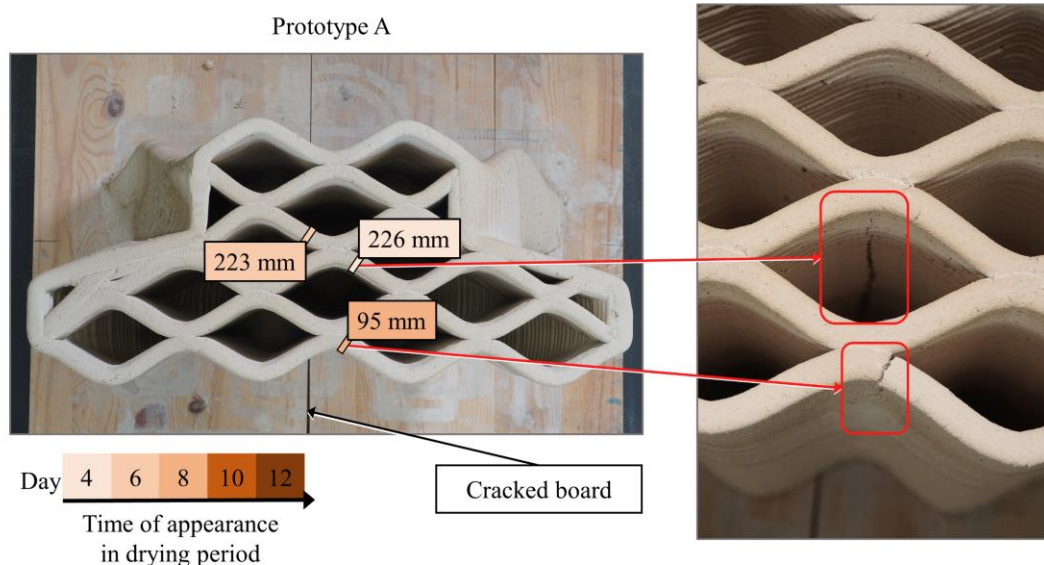

Figure 5. Desiccation cracks in prototype A.

sensors are embedded at a depth of two-thirds of the sensor length. The environmental sensor node consists of an Si7021 temperature and humidity sensor connected to a microcontroller for recording environmental conditions. The data recorded by both sensor nodes is transmitted via a cable connection to a base station (i.e. Raspberry Pi microcomputer) that serves as a datalogger for data management and storage. It should be noted that the capacitive moisture sensors are calibrated in both dry and fresh clay conditions using the pre-calibrated sensor system I as benchmark.

The positioning of the embedded moisture sensors of both sensor systems is determined by the respective geometric constraints. The resistive sensor of sensor system I consists of two probes, each 180 mm in length and spaced 30 mm apart. The capacitive soil moisture sensors of sensor system II measure 98 mm in length, 23 mm in width, and 4 mm in thickness. Considering a layer width of 11 mm, the sensors are embedded vertically at overlying points within the structure to minimize any impact on structural stability. Furthermore, to evaluate the effect of the sensor positions, three embedment depths are defined (Figure 7). The capacitive sensors of the moisture sensor node of sensor system II are positioned following the printing process, where Sensor 1 (printing time  $t = 60$  min) and Sensor 2 ( $t = 112$  min) are fully embedded during printing, while Sensor 3 ( $t = 147$  min) is partially embedded. The probes of the resistive sensor (Sensor 4) of sensor system I are also partially embedded at  $t = 147$  min. Due to the length of the probes of Sensor 4, Sensor 2, and Sensor 4 record moisture content at approximately the same height. A special consideration is given to the capacitive sensors, where a permeable membrane is wrapped around the sensing elements of the sensors that are in contact with clay to facilitate local moisture evaporation. Sensor cables are routed through the infill gaps, which serve as cable channels, and are connected to the microcontroller after the printing process.

Figure 6. Components of sensor system I (blue) and sensor system II (green).

Prototype B2 is monitored over 10 days, and the moisture content is recorded continuously by sensor system II, while sensor system I is read manually three times daily. No structural instabilities or sensor-induced cracking are observed during this period.

The environmental data (Figure 8) shows humidity levels ranging from 15 % to 40 % and temperatures between 18.1 °C and 23.8 °C. The declining moisture content in the structure

(Figure 9) corresponds with these environmental changes. Capacitive sensors (Sensors 1-3) exhibit a stabilization phase of approximately 25 h, due to the membrane barrier. The fully embedded sensors (Sensor 1 and 2) reveal nearly identical trends, while partially embedded sensor 3 shows higher initial moisture levels during the first 160 h.

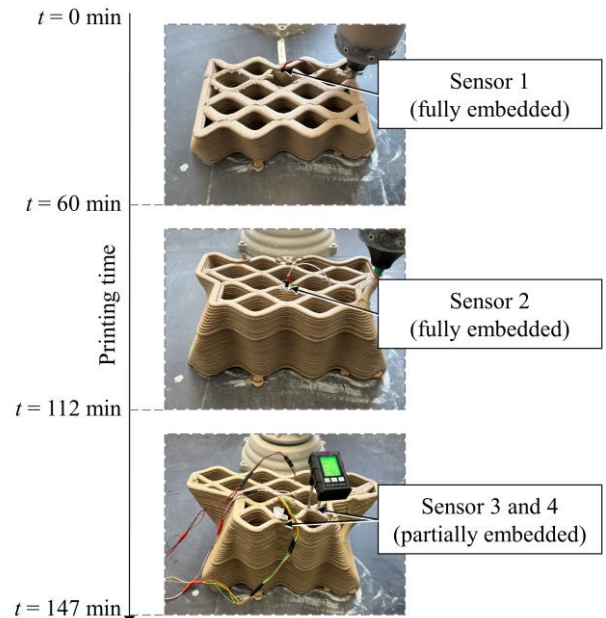

Figure 7. Embedded sensor integration during the printing process.

Figure 8. Environmental sensor readings.

Furthermore, as observed from Figure 9, the resistive sensor (Sensor 4) showcases higher values of moisture content compared to the capacitive sensors in the first 195 h of measurement, followed by a sharp drop of moisture content. Although a similar moisture content trend was expected between Sensor 2 and Sensor 4, the values observed for Sensor 4 indicate that the resistance-based sensing principle is not as sensitive to the change of moisture content compared to capacitive-based sensing principle. By observing the cumulative soil moisture loss over time (Figure 10), a total moisture loss ranging from 43 % to 48 % is observed. The measured cumulative moisture loss from Sensor 1 and Sensor 3 are comparable, while Sensor 2 deviates slightly in an acceptable range. In contrast, Sensor 4 deviates significantly, further indicating limited accuracy and responsiveness.

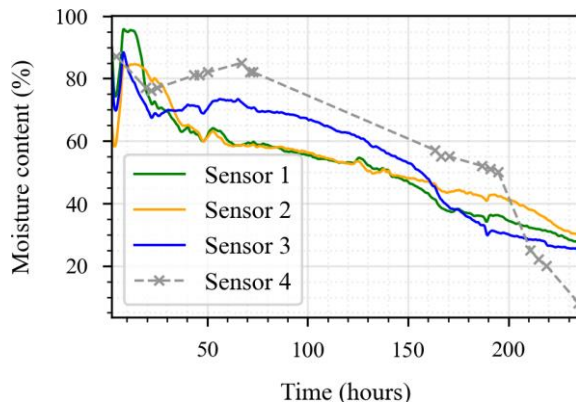

Figure 9. Moisture sensor readings (sensors are calibrated for dry mixture = 0%, wet mixture = 100%).

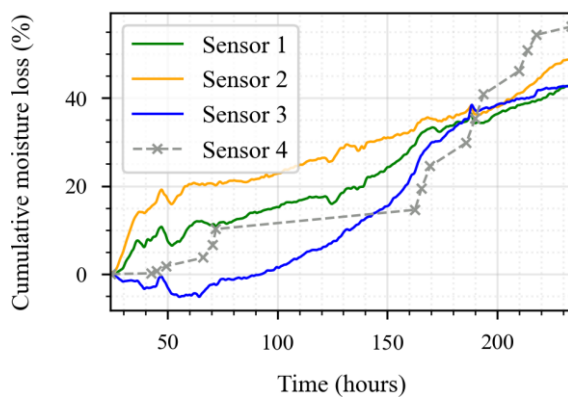

Figure 10. Cumulative moisture loss over time (starting at  $t = 25$  h).

## 4 DISCUSSION AND SHM STRATEGY DEFINITION

In this section, the results of the sensor integration are discussed as a basis for the SHM strategy definition, subsequently proposed in this section.

### 4.1 General discussion of the results

The moisture sensors have demonstrated varying accuracy. Fully embedded sensors have shown nearly identical values, while the partially embedded sensors have tended to record higher moisture levels. Following initial surface water loss, the sensor readings have aligned with the visual observations, reflecting the drying conditions of prototype B2. The absolute moisture readings have been inconsistent between sensor types and absolute measurement results have not been quantified by means of measuring the component weight over time. However, the recorded trends of capacitive soil moisture sensors have correlated with the expected structural performance and visual assessments, suggesting the suitability of capacitive measuring for relative monitoring. The permeable membranes have delayed the moisture penetration causing additional time for sensor stabilization. Capacitive changes have been detected by the embedded sensors with varying accuracy, depending on sensor type and position; however, measurements of capacitive moisture sensors have successfully captured the drying gradient within prototype B2. The environmental conditions have significantly influenced the

drying process, with accelerated moisture loss observed under lower humidity and elevated temperature.

Overall, the findings underline the applicability of moisture sensors for monitoring moisture loss in additively manufactured clay structures and form the basis for developing a tailored SHM strategy.

### 4.2 SHM strategy

Defining the SHM strategy for clay-printed structures requires careful selection and placement of sensors tailored to specific monitoring objectives. Clay moisture and environmental conditions must be assessed to evaluate structural integrity, while visual inspections aid in optimizing sensor placement. Different sensor types serve distinct monitoring purposes: Moisture sensors enable tracking of drying behavior, whereas stability sensors, such as strain gauges, allow detecting buckling and shrinkage, and provide long-term data on internal stress states. In this study, both capacitive and resistive moisture sensors have proven capable of capturing drying behavior in the conducted experiments. However, resistive sensors are more susceptible to corrosion and exhibit a high sensitivity to increased ion concentrations, such as salt, which are prominent in clay. Salts decrease the resistance between sensor nodes and, therefore, the sensors read comparatively increased moisture values. Capacitive sensors, by contrast, have shown greater reliability and resolution, rendering capacitive sensors a more promising choice for continued application in SHM strategies. Sensor placement should follow the observed (or expected) drying gradients, to enable accurate assessment of moisture migration and identification of zones prone to cracking. Due to the evolving geometry and temporal variability inherent to additive manufacturing, a fundamental decision must be made regarding the embedding time, i.e. whether the sensors are integrated during or after the printing process. Embedded wired sensors introduce challenges, including the risk of crack formation at cable transition points caused by clay shrinkage. The cracks may compromise structural stability or facilitate moisture ingress. Although infill gaps can serve as routing channels for sensor cabling, the geometrical complexity of 3D-printed components poses significant limitations for scaling wired sensor networks.

Therefore, wireless monitoring solutions are a prerequisite for scalable SHM in clay-printed structures. However, the physical properties of clay pose substantial challenges for embedded wireless communication. The high dielectric constant and moisture retention of clay lead to significant attenuation of high-frequency radio waves, thereby impairing signal transmission. Elevated moisture content intensifies the effect by increasing material conductivity and absorbing radio frequency (RF) energy, causing reduced transmission efficiency. Additionally, multipath interference, owing to RF signal reflection and scattering within the heterogeneous internal structure of clay, may lead to signal distortion and data loss. To ensure reliable wireless sensing, careful selection of operating frequencies and the implementation of adaptive communication protocols are required, to account for the variable electromagnetic properties of clay throughout the drying process. Furthermore, current technological limitations constrain the deployment of SHM systems: Low-cost capacitive sensors often lack the required accuracy, standard resistive sensors remain prone to corrosion, and both exhibit

limited sensitivity to gradual moisture changes. When implementing SHM strategies for clay-printed structures, attention must be paid to the aforementioned constraints by enhancing sensor robustness, measurement precision, and wireless operability. Particular attention should as well be given to the development of embedded, miniaturized wireless sensors capable of long-term, real-time data acquisition in the challenging environment of clay-printed structures.

## 5 SUMMARY AND CONCLUSIONS

With the increased attention on clay printing in research and practice, SHM strategies need to be tailored to fit clay-printing technologies. In this study, an SHM strategy has been proposed, and the structural properties of clay-printed structures, including buckling, shrinkage, and load-bearing capacity, have been experimentally determined. Prototyping and sensor placement validation have demonstrated the feasibility of constructing structurally stable clay-printed structures and provided key insights into material behavior (i.e., shrinkage) for deriving sensor positioning strategies.

The methodology proposed in this study has provided a structured approach to understanding clay as a 3DP material, incorporating both material characterization and an SHM strategy. The experimental results have demonstrated that effective sensor placement can be obtained through systematic analysis of material behavior, particularly focusing on drying patterns and potential fault locations. Moreover, the study has addressed relationships between small-scale laboratory tests and larger prototypes, establishing crucial scalability considerations for SHM sensor networks of large-scale structures. In summary, the findings contribute to advancing the field of sustainable construction by demonstrating the viability of clay printing based on a sound SHM strategy. Future research may include quantifying sensor results in respect to shrinkage and extending the SHM strategy from cable-based to wireless systems.

## ACKNOWLEDGMENTS

Financial support provided by the German Research Foundation (DFG) through grants SM 281/22-1 and SM 281/31-1 as well as by Hamburg University of Technology via the I<sup>3</sup> program under the junior project *Digitalization of Earth Printing to Advance Climate-Informed Engineering* is gratefully acknowledged. The authors express their gratitude to Goerg & Schneider GmbH & Co. KG for supplying the clay material. **ABSTRACT:** Structural Health Monitoring (SHM) is employed to provide insights and conservation guidelines for Icelandic turf houses through periodic and continuous monitoring of hygrothermal and geometrical parameters. The turf houses are unique vernacular structures that were the primary dwelling form in Iceland from settlement (~ 874 A.D.) through the 20th century. These structures, now maintained predominantly by the National Museum of Iceland, represent a cultural legacy but suffer from limited research on their materials, structural behavior, and long-term maintenance requirements.

Key conservation challenges include water leakage, differential settlement, and geometrical distortion, highlighting the need to understand the hygrothermal performance of the turf roofs and the structural behavior of the timber frames carrying the roofs. To address these issues, a remote and unobtrusive SHM system was designed, tailored to the constraints of heritage buildings.

This paper provides a one-year overview of monitoring at two sites: Keldur farm in southern Iceland and Laufás in the north. The study details the monitoring strategy, system design, installation, and operation, presenting results such as 3D point scans, hygrothermal data, and comparative analyses between the two sites. Findings from the study contribute to understanding the behavior of Icelandic turf houses, offering insights for their long-term conservation and ongoing management.

**KEY WORDS:** Hygrothermal and geometrical monitoring, museum artifact, monitoring in remote locations, vernacular structures

### 1 INTRODUCTION AND MOTIVATION

Turf houses represent the vernacular architecture of Iceland. The tradition spans from the 9th-20th centuries, surviving far longer than turf architecture traditions in most other countries. Turf was historically an ideal building material in Iceland due to its ready availability, its excellent insulation properties, its ability to protect against wind and precipitation, and the lack of available timber in Iceland (Zöega et al 2023). It was used to build different types of houses, churches, stables, sheds, raised roads, and boundary walls by members of all social classes (Hafsteinsson and Jóhannesdóttir, 2024; Zoega et al 2023, Ágústsson, 2000).

The turf house developed alongside the inhabitants, serving as the main form of residence for most of the country's history. This declined rapidly into the 20th century as they were largely replaced by timber and concrete houses. By the 1950s, only 716 turf houses were registered, representing 3.6% of all residences in the country (Hagstofa Íslands, 1997). Most turf houses were either abandoned to decay or deliberately destroyed (Hafsteinsson and Jóhannesdóttir, 2024). The few remaining turf houses generally represent wealthy or influential farms that have been taken under the protection of the National Museum of Iceland through their Historic Buildings Collection, including Laufás and Keldur, monitored and presented in this paper (see Figure 1). There are also a handful of smaller houses under private ownership or owned by other institutions.

These surviving turf houses no longer function as homes, instead operating as museums intended to conserve this unique aspect of Iceland's cultural heritage. As no one lives in them, the buildings must be monitored and repaired to ensure their continued survival and operation. This can pose difficulties as the museums are not open year-round and funding is limited.

Damage is therefore not always immediately noticed and necessary repairs must be identified and prioritized. There are also few experts remaining who are experienced enough to undertake these repairs. While research has been done on traditional building methods and the cultural and historical importance of the turf tradition, little to no research has been done on the structural behavior of the buildings themselves, the properties of turf as a building material, or on the additional materials often used in turf roofs, leaving a large gap in the field of study.

This project seeks to fill this gap in research by studying the structural behavior and monitoring the structural health of several turf houses in the Historic Buildings Collection of the National Museum, including Laufás and Keldur. This research seeks to create a remote monitoring system that the museum can use to more effectively identify and prioritize repairs and keep track of the condition of the turf houses in their collection, many of which are very remote and far from the museum's headquarters in the capital region. This will be done through an interdisciplinary approach combining structural engineering, museology, and conservation studies. This comprises creating a monitoring strategy, 3D scan analysis, monitoring fluctuations in temperature and moisture in the turf roofs, modelling the hygrothermal behavior of turf, literary research, and interviews with experts actively working in the field. This paper provides a one-year overview of the monitoring process.

### 2 TURF HOUSES: LAUFÁS AND KELDUR

#### 2.1 Development of turf houses

The Icelandic turf tradition began with the settlement in the 9<sup>th</sup> century and can be divided into three main developmental

stages (National Museum of Iceland, 2011). The so-called Viking-Age longhouse represents the first stage of the turf tradition, featuring a long building made of turf, timber, and stone (Stefánsson, 2013 Abrecht, 2018). This first stage existed with relatively few changes until the 13<sup>th</sup> and 14<sup>th</sup> centuries, with the gradual emergence of the passageway farmhouse.

The passageway farmhouse represents the second stage of development. This did not replace the longhouse, and both forms as well as combinations of the two existed. The passageway farmhouse layout featured a long hall or passageway with individual rooms added to the sides and rear of the building (National Museum of Iceland, 2011).

The third and final stage of the turf tradition, the gabled farmhouse, emerged in the late 18<sup>th</sup> and early 19<sup>th</sup> centuries. The gabled farmhouse features individual but interconnected rooms, typically facing the front yard, with wooden gables and individual turf roofs (Abrecht, 2018). This is the version of the turf house that people are most familiar with today and serves as a physical representation of this aspect of Icelandic cultural heritage (Stefánsson, 2013).

Spanning over 10 centuries, the turf tradition represents the primary dwelling for Icelanders throughout its history. By the mid-20<sup>th</sup> century, the tradition had largely been abandoned, and a shift from residential buildings to museum buildings began to take place, largely under the supervision of the National Museum. Once representing a long-standing housing tradition, turf houses today serve a different function as museums to educate and conserve both the architectural tradition, but also cultural and social aspects of the nation's history.

Figure 1: Location of the monitored houses presented in this paper.

## 2.2 Turf roofs

The roofs of turf houses are mainly composed of turf blocks that rest on the top of an interior timber frame, as the turf walls themselves are typically not load-bearing (National Museum of Iceland, 2011, Zoega et al., 2023). There are two main roof types depending on the interior lining, either slate or thatch (Icelandic: hellupök eða tróðpök) (Ágústsson, 2000). Different types of turf can be used, and there are multiple ways of laying a turf roof (Sigurðardóttir, 2008). Additional materials and methods have also been introduced, particularly from the late 19th century onwards. The materials and methods were used based on material availability, the layout of the house itself, and decisions made by the craftsmen. This leaves much room for variation, and different layering can be found between locations

and within the same house, depending on the intended use of the specific room or building.

Figure 2: Example of dried birch twigs carried by purlins and rafters (thatched roof).

Turf roofs typically need to be steep to support moisture runoff and thick for insulation purposes and to allow absorption. If the top layer of turf in a roof is compromised, leaks are likely to occur (Zoega et al 2023, Sigurðardóttir, 2021). The problem of leaking with turf houses is not new, and people in the past dealt with this issue in a number of resourceful and creative ways. Layers of stone, brush, and straw were added in some places to support the turf, which can be seen in Figure 5. When corrugated iron and tar paper arrived in Iceland in the latter half of the 19th century, people almost instantly began adding these materials to their houses as a waterproofing layer in the roofs, examples of which can be seen in Figure 3 (Stefánsson, 2020, Hafsteinsson, 2024).

Figure 3: Examples of corrugated steel in turf roofs. A fishing net has also been added likely because the turf slides on the corrugated steel.

As turf houses began to transform from dwellings to buildings in a museum collection, their maintenance and upkeep changed as well. As the buildings were no longer lived in, the constant cycle of coexistence and repairs shifted. One of the biggest changes has been the roof itself; historically, the roof could be up to 1 meter thick, which promoted absorption and the correct conditions for the grass on the outermost layer to survive and hold itself up (Sigurðsson, 2025).

In the latter part of the 20th century, the roofs of many turf houses were significantly thinned, and a waterproofing layer of PVC or plastic was added as an attempt to prevent leaks and improve the aesthetics of the buildings, see examples in Figure 4 (Stefánsson, 2013). All turf houses in the Historic Buildings Collection of the National Museum have thinned roofs with PVC or plastic membrane, and many also have corrugated iron.

When constructing a turf roof today, the ideal thickness ranges from 40-70 cm (Sigurðsson, 2025). We have not yet seen a roof with this thickness in any of the buildings we are monitoring. Additionally, many of the roofs have holes or chunks of turf missing.

Figure 4: Examples of plastic membranes in turf roofs. Left: membrane visible from the inside. Right: membrane visible from the outside.

When the turf becomes too thin, it is unable to support itself and becomes more prone to damage from the elements. All additional roofing materials used in the past and in the present have been a response to problems, but these new materials have often had unexpected or unintended consequences, which is part of the focus of this study (Stefánsson, 2013).

Figure 5: Typical cross-section of a turf roof.

Figure 5 shows a typical cross-section of a turf roof. As mentioned, the thickness of the different material layers can vary greatly from house to house and even within one house.

A: The turf layer itself can be divided into three sections: 1) the outermost layer is living grass serving as the first water barrier and provides possibilities for runoff from the roof, 2) root mesh serving as stabilizing layer that prevents the turf from sliding (this layer also has moisture absorption and insulation capabilities), and 3) the innermost layer is soil without roots, used to even out the surface for turf laying. B: The next layer, as discussed previously, was added when new materials arrived, such as corrugated steel and plastic membranes. These materials make it more challenging to keep the turf in place

since they are slippery. C: Various materials have been used under the membrane and turf depending on the time of construction and the local availability of materials. Natural stone slates, dried birch twigs and dried turf (Icelandic: nærtorf), are common materials. Some of them, like birch and turf, have some insulation properties, whereas stone is a poor insulator. D: These materials rest on purlins. E: The purlins are carried by a wooden rafter which is part of the structural frame carrying the whole roof.

### 2.3 Timber frame

The structural system of the turf houses is a timber frame which carries the roof, see for example Figure 6. The foundations for the frame are stone blocks resting on the ground. Each column in the frame is resting on individual blocks which are not connected to each other. Two columns are connected to each other by joists perpendicular to the walls. Parallel to the wall, columns are connected by beams. Sometimes the rafters only rest on the columns and sometimes the rafters are connected to beams between the columns. The walls, built by turf or stone, only carry their self-weight and do not support the roof.

All elements of the structural system are made from natural materials, that is timber and stone, making them susceptible to temperature and moisture fluctuations. Furthermore, the foundations, stones placed on the earthen floors, can suffer from differential settlements. However, the characteristics of the movements of the timber frames have not been studied in a structural context and are therefore not fully understood.

Figure 6: Structural system in the kitchen in Keldur.

### 2.4 Laufás

Laufás was a prosperous manor farm that also served as a priest's residence, see Figure 7. It is in Eyjafjörður in the North of Iceland. Its history dates back to at least the early 11th century, though the present buildings reflect 19th century building traditions (National Museum of Iceland, *Húsasafn*, Stefánsson, 2013). The farm entered the National Museum's collection in 1948 and has since undergone extensive renovations and repairs.

The farm consists of 12 interconnected houses and is approximately 29 meters long and 28 meters wide (Hafsteinsson, 2008). It is representative of the gabled farmhouse with older elements of a passageway farmhouse, and the roof falls under the thatched category as the inner lining is

turf. The room being monitored is called *dúnhús*, or down house, referencing the valuable down from eider ducks that was once an important source of income for the farm. The down house is on the western side of the farm facing the yard, with a door and three windows facing the yard.

Figure 7: Laufás in Eyjafjörður.

### 2.5 Keldur

Keldur was a prominent farm in the South of Iceland with a rich history dating back to the 12th century, see Figure 8. It is the largest turf farm in the south and is mentioned in several of the famous Icelandic sagas. The present buildings were primarily rebuilt in the 19th century, and the farm entered the National Museum's collection in 1946.

Keldur also represents a gabled-farmhouse with earlier elements of the passageway-farmhouse, but the roof is representative of the slate category. The inner layer of the roof is entirely slate, with an interior plastic membrane and turf as the outermost layer. Both the *skáli*, or longhouse, and the *eldhús*, or kitchen are monitored in Keldur.

Figure 8: Keldur in Rangárvellir.

### 2.6 Comparing Keldur and Laufás

The two farms are representative of turf building traditions in their respective regions. Laufás provides a classic example of the turf houses built in the north, with more turf used in the building and roof, and visible turf blocks in the walls. Keldur represents the turf building traditions in the south of Iceland, with more stone used in the building and roof and a grass covering on the top of the houses. These differences can be seen in Figure 7 and Figure 8, and relate to differences in climate in the north and south of the country.

The climate in the north of Iceland is more stable, with longer cold and dry periods providing better conditions for turf houses. This results in the northern turf houses having more turf and needing to be repaired and rebuilt less frequently. Historic records suggest that turf houses in the north lasted significantly longer before needing major rebuilding or repairs than those in the south, with one source reporting turf houses in the north lasted for 50-60 years, while those in the south lasted 10-20 years (Bald, 1897).

The climate in the south of Iceland fluctuates more in regard to both temperature and precipitation. Additionally, parts of the south do not have the same access to large amounts of good quality turf as in the north, and it is much more common to have higher amounts of stone in the buildings and the roofs.

The walls in Laufás are made from turf and rest upon a stone base. Different patterns of turf blocks can be seen from the interior and exterior of the building. The inner-most layer of the roof in the down house of Laufás is dried turf. In Keldur, the walls are layered with both turf and stone. The inner-most layer of the roof in the kitchen of Keldur is made of stone slates. It is not possible to see distinct patterns of turf blocks in the walls, and the exterior of the houses is grass.

## 3 MONITORING STRATEGIES, SYSTEM DESIGN, AND INSTALLATION

This project began in part as a response to reports from those working in close contact with the museum buildings. Issues with leaking roofs, moving timber frames and turf walls, losing turf from the roofs, and complications with the plastic membranes were reported. In order to research these issues, an unobtrusive monitoring system that could be utilized in a museum environment was employed. As these buildings are all active museums, any visible signs of research or monitoring must be limited, and museum activities and visitor access cannot be hindered.

Two monitoring strategies have been employed in the course of the research, targeting the pre-selected rooms at each location. One is continuous monitoring of the hygrothermal parameters in the turf roofs through sensors that were installed in both the exterior and interior layers of the roofs. The second is a periodic monitoring strategy where 3D scans are taken using LiDAR with an Artec Ray scanner. These scans are planned 3-4 times per year. Comparisons between the point clouds are planned in the open software CloudCompare.

### 3.1 Differential settlement and geometrical distortion

LiDAR scanning has been used to help monitor the structural health and behavior of buildings, bridges, roads, tunnels, and other forms of civil infrastructure (Kaartinen et al., 2022). LiDAR has also been implemented in the cultural heritage sector for a variety of purposes, including to detect and identify damage and degradation in wooden components of historic buildings (Liu et al., 2024) and documenting and assessing deformation (Yaagoubi and Miky, 2018).

LiDAR scanning was selected as a method in this study as a way to better understand the behavior of the interior timber frames of the turf houses. The reported displacements in the timber frames can impact the roof and the walls, which can lead

to accelerated decay and degradation, putting the overall health of the building at greater risk.

Some of these displacements can be seen with the naked eye, including tilt in passageways, halls, and door frames, warped wood, and compacted or deteriorating turf. Although this can cause strain on parts of the building, strain monitoring is not a feasible method, as the structural frames may be undergoing rigid body movement and displacement without deformation. While we know that movement is occurring, it is still unknown exactly why and how this movement happens. LiDAR scans and the subsequent point clouds that are created will be compared in CloudCompare. This will enable a greater understanding of the movement of the timber frames, particularly if the movement is related to the decay of the timber, seasonal fluctuations, or changes in weather.

Figure 9: Artec Ray scanner in operation in the kitchen of Keldur.

### 3.2 Turf monitoring

The hygrothermal behavior of turf is relatively unknown despite its usage in buildings for centuries and across the world. Turf is known for its insulation properties and its ability to absorb moisture, but the specifics are lacking. The usage of sensors in the indoor and outdoor climate of the turf roofs is a way to better understand the moisture and thermal characteristics of the turf.

Research into the hygrothermal properties and behavior of different earthen building materials has covered many types of materials, including earthen bricks (Cagnon et al., 2014), light-earth construction materials (Colinart et al., 2020), and various soil types (Kehrer and Pallin, 2017). A 2019 literary review provides a detailed overview on the research into hygrothermal properties of earthen construction materials, noting renewed interest in their sustainable building qualities and ability to support comfortable living environments, but turf and the turf tradition is not included (Giada et al., 2019). Therefore, research is needed to address this gap.

As mentioned earlier, the monitoring system needed to be unobtrusive and operable in remote locations. To that end, wireless sensors with Bluetooth connection to gateways that can connect and send the data to the cloud were chosen.

The first monitoring system was installed in Keldur. A monitoring system from SensorPush was chosen. The

SensorPush sensors are small, battery-operated devices with no wires, see left picture in Figure 10, making them ideal for this project. They measure air temperature and relative humidity. Eight sensors were installed in pairs, the inner laying on the plastic membrane and the outer very close to the surface of the turf. Two additional sensors were installed to measure the indoor and outdoor climate. In Keldur the thickness of the turf is approximately 10-12 cm. Figure 11 shows the monitored locations on the south side of the roof, one very close to the ridge, one close to the inside of the outer wall, and one in the valley where the gable house meets the longhouse.

In Keldur a service house is located close to the turf house making it possible to run an ethernet cable into the turf house for direct connection with the gateway. However, since the gateway was located inside the house and the sensors were installed inside the turf from the outside, it was challenging to connect to them through the turf. However, the installation was successful. Shortly after installation all the humidity sensors read a constant 100% RH and that did not change. Even though the moisture sensors did not survive the wet and cold Icelandic summer the temperature sensors kept operating until October 2024 when all sensors were unresponsive.

Figure 10: Left: Air temperature and humidity sensor from SensorPush. Middle: Soil moisture and temperature sensor from HOBO. Right: Air temperature sensor from HOBO.

Figure 11: Sensor locations on south side of roof in Keldur.

The next monitoring system was installed in Laufás. This time sensors for soil monitoring were chosen, see the middle picture in Figure 10. The sensors are from the MX series from HOBO. They have a robust casing, and the logger is connected to the sensors with wires, so the logger does not have to be buried into the turf. This makes the sensor more likely to survive harsh weather conditions, but it also makes it more visible.

Two pairs of sensors were installed in Laufás. Like in Keldur, the inner sensors were close to the plastic membrane and the outer sensors were near the surface. In Laufás the thickness of the turf was approximately 25-30 cm. The sensors were installed on the north side of the down house, close to the rear

gable wall, one upper location and one lower, which can be seen in Figure 12.

Figure 12: Sensor locations in down house roof in Laufás.

In Laufás an internet connection is established by SimCard WiFi Router which is then connected to the gateway. The gateway communicates with the dataloggers via Bluetooth. In Laufás the dataloggers were installed inside the house and the wires run through a small hole in the gable avoiding the problem with poor Bluetooth connectability through the turf. This was possible since the loggers were connected with wires to the sensors which were installed in the turf.

## 4 OPERATION AND SITE VISITS

### 4.1 Laufás

In October 2024, a research team undertook the first visit to Laufás to examine the building, photograph conditions, install sensors, and take the first round of 3D scans in the down house. Several issues were noticed with the roof, including holes, missing pieces of turf on the top layer, and degradation of the inner and outer layers of the turf roof, resulting in the plastic membrane showing. The back wall of the down house also had considerably higher moisture. The sensors were installed in the roof of the down house and the 3D scanning was performed.

The second trip to Laufás was taken in February 2025. Some small-scale repairs had been done to parts of the turf walls, but there were still holes in the roof of the down house. The back wall also had visibly more moisture than the other three walls. The sensors were still in place and actively logging data, and the second set of 3D scans were taken.

### 4.2 Keldur

Sensors were installed in the roof of Keldur in May 2024. The sensors were installed on the north and south side of the long-house. Several of the sensors went offline, so a second trip was taken in October 2024 to attempt to reconnect to the sensors. This was unsuccessful, and six out of ten sensors remained offline, unable to log data. This was thought to be related to the extreme weather conditions, as the sensors were unable to cope with the high amount of rain. Scans were not taken on either trip, as the 3D scanner is shared between departments at the National Museum and had been rented out.

Due to the remote location of Keldur, poor weather and road conditions prevented a return trip in the winter of 2024. The third trip took place in February 2025, where the kitchen was scanned. An additional trip is planned for the spring of 2025 to

take the next round of scans and install new sensors that can withstand the outdoor climate.

## 5 RESULTS FROM STUDY HOUSES

In this section current results from the monitoring strategies are presented.

### 5.1 Laufás

The down house in Laufás has been 3D scanned twice, once in October 2024 and again in February 2025. Comparative analysis of the scans is ongoing. Renderings of the scans are shown in Figure 13.

Figure 13: Renderings of 3D scans of the down house in Laufás.

Figure 14 shows the time series for temperature at Laufás. The blue shows the temperature measurements from the nearest weather station, Végeirsstaðir, approximately 12 km from Laufás. The orange shows the air temperature as measured outside by the monitoring system and the green shows the air temperature measurements from inside the house. The turf temperature close to the surface is shown in red and the turf temperature 20-24 cm deeper is shown in purple. The two monitored sections are shown, one upper and one lower, see Figure 12.

The temperature in the turf shows less fluctuations than the air temperature outside and inside the house. The difference between the outer and inner sensor is remarkably low, only 1-3°C, as shown in the lowest plot in Figure 14.

Figure 15 shows the turf moisture measurements in Laufás. In this first analysis the manufacturer calibration of the moisture sensor was used. That can have an effect on the absolute values but does not affect the trends. The moisture is plotted together with rainfall measurements from the weather station in Akureyri, 20 km from Laufás. Heavier rain can be correlated with higher moisture content.

Generally higher moisture content is measured in the lower location than in the upper location. This observation is consistent with that rainfall and moisture within the turf seeps downwards.

Figure 14: Temperature measurements in Laufás. Note: Weather refers to temperature from nearest weather station, Végeirsstaðir.

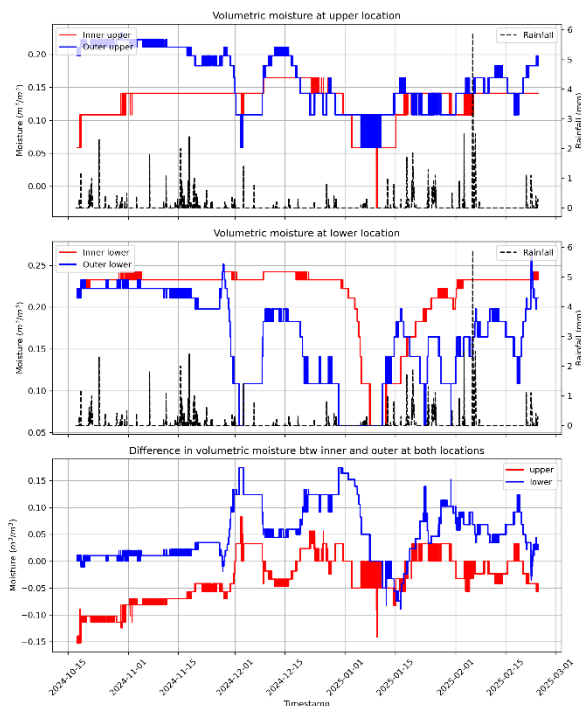

Figure 15: Turf moisture measurements in Laufás. Note: Rainfall measurements from weather station in Akureyri.

Moreover, the inner sensor at the upper location is drier than the outer sensor, also consistent with expected behavior. However, at the lower location the outer sensor is drier than the

inner. More investigation is necessary to fully explain this observation.

## 5.2 Keldur

Figure 16 shows the time series for temperature at Keldur. The blue shows the temperature measurements from the nearest weather station, Sámstaðir, approximately 5 km from Keldur. The orange shows the air temperature as measured outside by the monitoring system and the green shows the air temperature measurements from inside the house. The turf temperature close to the surface is shown in red and the turf temperature 10-12 cm deeper is shown in purple. Two cross sections are represented, one close to the ridge and the other in the valley.

In general, the temperature close to the surface (red) fluctuates more than the temperature deeper in the turf close to the plastic (purple). The temperature inside is more stable than outside. Close to the ridge the temperature increases significantly, even higher than the air temperature. This is most likely because this part of the roof is facing south and highly affected by the sun radiation.

In the valley, which has more shadow, the outer sensor measures higher temperatures than the inner. The lowest plot in the figure shows the temperature difference between the outer and inner sensor at both locations. The temperature difference is higher at the ridge than at the valley, showing that the surface of the turf is very prone to temperature fluctuations. It even indicates that the turf, albeit thin, exhibits good insulation properties and/or high thermal inertia.

Note that for less extreme temperatures, between 5°C and 10°C, the difference between the outer and inner measurements is not as pronounced.

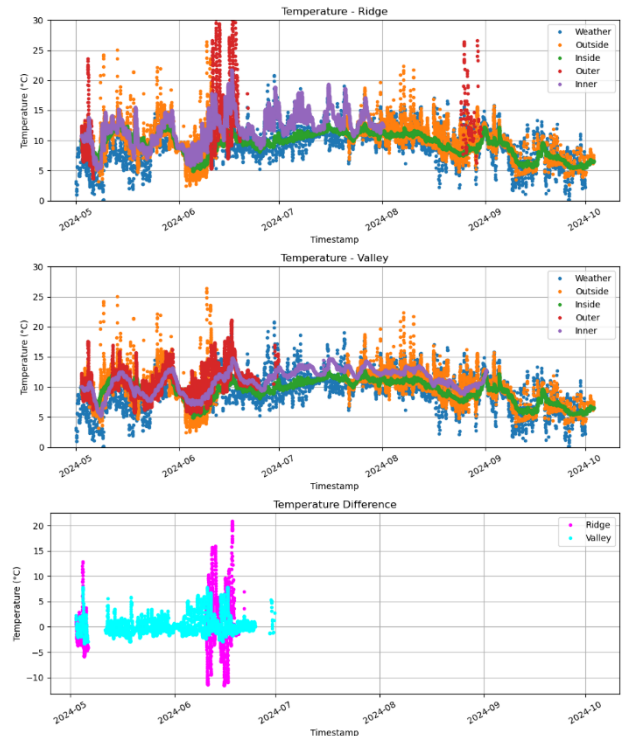

Figure 16: Temperature measurements in Keldur. Note: Weather refers to temperature from nearest weather station, Sámstaðir.

## 6 CONCLUSION

The implementation of this structural health monitoring system combines different methods and approaches to better understand the Icelandic turf buildings whose structural behavior has not been studied. One year into the monitoring reveals several details about working with these technologies in museum buildings and in the Icelandic weather conditions. Early results provide information on the buildings, but additional scans and continued monitoring with the sensors is necessary to provide a more complete picture.

The Artec Ray scanner had some difficulties operating in cold temperatures. While the interior temperature of the turf houses was just above the minimum operating temperature, some scans were incomplete and needed to be repeated.

Additional sets of 3D scans are necessary to perform a comparative analysis of potential displacement in the timber frames.

The first installation of sensors at Keldur revealed that the SensorPush sensors struggled to operate in wet conditions, resulting in a 100% RH reading before all sensors stopped logging data. Additionally, there were difficulties in getting the Bluetooth connection to work through the turf roofs.

These obstacles in the first round of sensors led to the selection of the HOBO sensors that were installed in Laufás. These sensors are better able to withstand harsh weather conditions and can connect to the gateway. Laufás has cellular reception, making it possible to send the data to the cloud. Multiple sensors can operate on the cellular internet with good reliability.

New sensors will be installed at Keldur this spring. Since Keldur has ethernet connection, good uploading capabilities are available. However, it is important that sensors in remote locations have internal memory in case the system goes offline.

The data from the sensors at Keldur shows that the turf roofs can get quite warm in the summer, well above the outdoor temperature. Smoother temperature readings by the inner sensors at Keldur also show the insulation capabilities of the turf. This difference is not as visible in Laufás, possibly because the sensors in Laufás are located on the north side and have only been monitoring during the wintertime.

Moisture content of the turf roof is correlated with the rainfall. The cross-section closer to the ridge is drier than the cross-section further down. At the upper location the outer sensor measures higher moisture content than the inner sensor. This is not the case at the lower location.

Monitoring of these two houses and more are planned for the next few years providing insights into long-term continuous monitoring strategies at remote locations.

**ABSTRACT:** Durability is a critical factor in the long-term performance of concrete structures. Ensuring adequate surface quality – and thus extending the service life of concrete elements – relies significantly on proper curing during the hydration phase. To assess and monitor the effectiveness of the curing process, suitable testing methods are essential. Among these, gas permeability testing provides valuable insights into the porosity of the concrete, which directly affects its durability. This study investigates the influence of various curing methods on gas permeability using both laboratory and field testing. The results demonstrate that insufficient curing leads to higher gas permeability in the near-surface zone of concrete. Concrete specimens and structural components made from identical mix designs but subjected to different curing conditions are analyzed and compared. The findings also take into account the influence of concrete composition and environmental conditions on surface quality. Based on these insights, the study offers recommendations for a reliable evaluation of curing effectiveness through gas permeability as an indicator of surface integrity.

**KEY WORDS:** concrete curing; non-destructive testing; gas permeability testing; durability; quality control.

### 1 INTRODUCTION

The results of this study provide a differentiated understanding of how curing quality and external climatic influences interact to affect the permeability and thus the long-term performance of concrete structures. By isolating the effects of curing and environmental conditions, it becomes possible to derive targeted recommendations for construction practice and quality assurance, especially under conditions where optimal curing cannot be ensured. In particular, gas permeability is examined as a practical and sensitive indicator for the assessment of curing effectiveness and surface concrete quality, as highlighted in various previous studies [1–5, 7, 8, 10].

Several works have investigated the applicability of gas permeability as a diagnostic tool in both laboratory and field conditions [3, 4, 10, 11]. Moreover, the significance of environmental parameters during curing and their long-term implications for concrete performance has been documented [5, 6, 7, 9]. This study contributes to this ongoing research by systematically quantifying these influences under controlled yet variable conditions and by using a standardized testing approach (Permeator AC+), thereby ensuring comparability and reproducibility of the findings.

The remainder of this paper is structured as follows: Section 2 outlines the concrete material and details the specimen preparation, climatic conditioning, and measurement procedures. Section 3 presents the results of gas permeability testing under the different environmental scenarios. In Section 4, the results are discussed with regard to the interaction between curing quality and environmental exposure. Finally, Section 5 summarizes the key findings, draws practical implications, and suggests directions for future research.

**Objective:** This study involved a series of tests aimed at systematically quantifying the influence of time, temperature,

and relative humidity on the permeability of concrete. Three different concrete structures were examined under controlled climatic conditions. The resulting data make it possible to analyze the interactions between thermal effects, moisture ingress, and temporal changes in the diffusion behavior of concrete, thereby contributing to a deeper understanding of the long-term durability of concrete under varying environmental conditions.

**Relevance:** The study evaluated whether curing quality of concrete can still be clearly detected through gas permeability measurements, even under fluctuating environmental conditions. For this purpose, concrete specimens were exposed to different combinations of temperature and humidity, then analyzed for their gas permeability. The aim was to determine how variable environmental parameters influence the effectiveness of the curing process, allowing conclusions to be drawn about the durability of the concrete.

**Methodology and Approach:** Within the scope of this study, concrete specimens were systematically exposed to different temperature and relative humidity conditions in a climate chamber. The curing performance was assessed by measuring gas permeability, a reliable indicator of concrete tightness and therefore durability. For quantitative determination of gas permeability, the Permeator AC+ device was used, enabling standardized and reproducible measurements. The collected data provide a foundation for analyzing the relationships between specific climatic conditions and the diffusion properties of concrete.

This methodological approach ultimately allows for an assessment of how successful concrete curing is under varying environmental conditions, and which parameters significantly affect gas permeability a key criterion for assessing the durability of concrete.

As part of a study, nine identical concrete test specimens were initially produced to serve as the base material for examining curing quality. The specimens were divided into three equally sized groups of three units each to apply different curing methods. The curing was carried out as (a) optimal curing (b) neutral/no special conditions and (c) bad curing.

This approach enables a comparison of three different levels of curing quality derived from the same raw material.

Subsequently, all nine specimens were exposed to various environmental conditions in a climate chamber. Variable temperatures and relative humidity levels were simulated to evaluate the impact of these parameters on gas permeability. Gas permeability was measured using a Permeator AC+, ensuring precise and standardized determination of the concrete's diffusion properties.

This systematic investigation makes it possible to analyze in detail the influence of curing quality in conjunction with varying environmental conditions on the durability and impermeability of concrete.

## 2 CONCRETE MATERIAL

For the present investigation, nine concrete test specimens with dimensions of 15 cm × 15 cm × 15 cm each were produced. All specimens were made from the same batch of concrete to ensure a consistent starting point and to allow for isolated examination of the curing process. After demolding, the specimens were divided into three groups of three and subjected to different curing conditions. These differentiated curing procedures enabled a systematic investigation of how varying curing quality affects gas permeability and, consequently, the durability of the concrete.

### 2.1 Concrete Composition

All specimens were fabricated from a single concrete batch prepared in accordance with concrete type B3 as specified in ÖNORM B 4710-1. The binder used was a Portland composite cement of type CEM II/A-M (S-L) 42.5 N according to DIN EN 197-1. This cement contains, in addition to Portland clinker, ground granulated blast-furnace slag (S) and limestone (L) as main components, with a combined proportion of 6 to 20 m-%. The strength class 42.5 indicates a standardized strength between at least 42.5 MPa and at most 62.5 MPa after 28 days, while the "N" denotes normal early strength development. Table 1 summarizes the concrete mixture.

Table 1. Main Parameters of the Investigated Concrete Mixture (According to [8]).

Concrete parameter	value	unit
w/b	0.55	-
Slump-value	F52	-
Grain-size	22	mm
Air-content	3-5.5	%
Cement	CEM-II/A-M(S-L)	-

After demolding, the specimens were divided into three groups of three and subsequently subjected to different curing treatments. This systematic variation of curing conditions enabled precise analysis of how different curing qualities affect gas permeability and thus the durability of the concrete. The choice of concrete type in accordance with ÖNORM B 4710-1

and the use of composite cement aimed at a practice-oriented assessment of the interaction between curing, environmental conditions, and permeability characteristics.

### 2.2 Curing of the Specimens

The specimens were demolded 24 hours after production and then divided into three groups of three. Each group was subjected to the following differentiated curing procedures:

- **Good curing:** Immediately after demolding, the specimens were completely wrapped in foil to prevent moisture loss. For the first seven days, the specimens were stored at a temperature of  $20 \pm 2$  °C, a relative humidity of  $\geq 80\%$ , and no air flow due to the sealed foil environment. Afterward, they remained wrapped for an additional six days under the same conditions to ensure continued moist curing and optimal hydration.
- **No curing:** The second group received no further treatment after demolding and was stored under ambient laboratory conditions to simulate natural drying. The specimens were exposed to a temperature of  $20 \pm 2$  °C, a relative humidity of approximately  $50 \pm 5\%$ , and free air circulation. These conditions served as a reference for unprotected, natural drying in indoor environments.
- **Poor curing:** The third group was deliberately subjected to suboptimal curing conditions by being placed on a windowsill exposed to natural indoor light and airflow. This setup simulated increased drying conditions, resulting in accelerated surface moisture loss. The environmental conditions during this period were approximately  $25 \pm 3$  °C, relative humidity of  $40 \pm 10\%$ , and moderate to high air movement due to occasional ventilation and solar exposure. These conditions represent inadequate curing typical of poorly protected elements during early-age concrete exposure.

This methodological differentiation allowed for a systematic investigation of how different curing qualities influence gas permeability and, consequently, the durability of the concrete.

## 3 TIME-DEPENDENT TESTING

The concrete specimens were examined for gas permeability at 7, 14, 28, and 56 days after demolding. The  $k_T$  value was determined on four defined surfaces of each specimen: the troweled top surface, the bottom formwork surface, and two lateral formwork surfaces.

**Climate Chamber Testing:** The previously defined environmental conditions (temperature, relative humidity, and air flow) were maintained consistently in the climate chamber throughout the entire storage period, in accordance with the respective curing method. The specimens were removed from the chamber at the predefined testing ages, tested, and then returned to their respective environments. The remaining specimens continued to be stored under the assigned climatic conditions until their next scheduled testing.

Figure 1. Change in  $k_T$  value over time..

Figure 1 illustrates a clear differentiation between the  $k_T$  values of the three different curing methods. The optimally cured specimens consistently show the lowest permeability values, while those with poor curing exhibit the highest. Furthermore, a marked increase in the  $k_T$  values is observed across all curing types over the observation period from 7 to 56 days. The distinctions between the individual curing classes remain, which can be attributed to continued surface drying of the concrete.

#### 4 CLIMATE CHAMBER TESTING

To further explore the effects of environmental conditions, additional tests were conducted in a climate chamber to assess their influence on the gas permeability of the concrete specimens. Each group was stored for 12 hours under varying combinations of temperature and relative humidity, as shown in Table 1. Subsequently, the  $k_T$  values were re-measured on the same surfaces as described in Chapter 3 (troweled top surface, bottom surface, and two sides).

Table 2. Climate chamber testing under different humidity and temperature conditions.

		Temperature in °C			
		25	30	35	40
Relative air moisture in %	60	x	x	x	x
	70	x	x	x	x
	80	x	x	x	x
	90	x	x	x	x

In addition to gas permeability, concrete moisture content was also measured at the same locations using a concrete moisture meter (Type: Tramex). This parallel measurement enables a more detailed analysis of the relationship between moisture content and the diffusion characteristics of concrete, and helps identify possible interactions between environmental conditions and concrete durability.

##### 4.1 Influence of Temperature on Gas Permeability

The results show that the overall impact of temperature on measured gas permeability is relatively minor. However, the

effect is most apparent in the optimally cured specimens. In general, a slight but noticeable increase in gas permeability with rising temperature can be observed (see Figure 2).

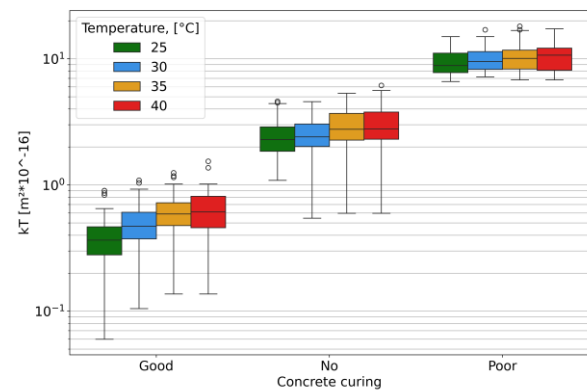

Figure 2. Gas permeability at different temperatures, grouped by curing method, for the corresponding relative humidity see Table 2.

This suggests that higher temperatures may accelerate surface drying, thereby enhancing the diffusion capacity for gases. Although this effect is present across all curing qualities, its magnitude varies significantly depending on the initial curing quality.

##### 4.2 Influence of Relative Humidity on Gas Permeability

As shown in Figure 3, relative humidity has only a minimal influence on the gas permeability of the concrete specimens examined. Across the studied range of relative humidity, the measured permeability values show little to no significant change.

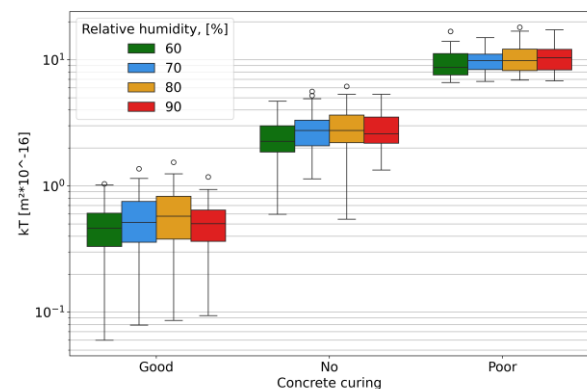

Figure 3. Gas permeability at varying relative humidity, grouped by curing method, for the corresponding temperature see Table 2.

##### 4.3 Influence of Relative Humidity on Concrete Moisture

Changes in relative humidity have a direct impact on measured concrete moisture. The data show a clear correlation: as relative humidity increases, so does the moisture content in the concrete. However, despite this relationship between environmental humidity and concrete moisture, the measured gas permeability remains almost unaffected.

#### 4.4 Comparison of Gas Permeability and Concrete Moisture

As illustrated in Figure 4, there is a clear inverse correlation between concrete moisture and gas permeability. Higher surface moisture levels correspond to lower  $k_T$  values, indicating reduced gas permeability—typically a sign of better curing quality. Conversely, lower surface moisture is associated with higher  $k_T$  values, suggesting insufficient curing and increased gas permeability.

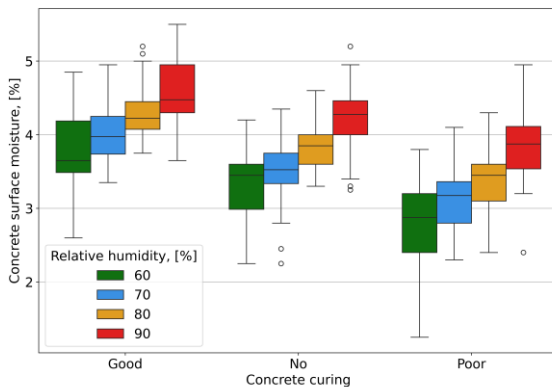

Figure 4. Moisture content of the material (in mass-%) as a function of curing conditions and different ambient humidity levels.

#### 4.5 Corrected $k_T$ Value

Referencing Torrent & Bueno et al. [12]: “Effect of surface moisture on air-permeability  $k_T$  and its correction”, it is well-established that moisture within concrete pores impedes gas flow and significantly affects gas permeability readings. While laboratory samples are often pre-conditioned through controlled drying, on-site measurements are typically performed under prevailing natural moisture conditions.

According to Swiss Standard SIA 262/1-E:2019, air permeability testing (Torrent method) on construction sites is only permitted if the concrete surface moisture ( $m$ ), as measured by electrical impedance, does not exceed 5.5%.

In this study, 50 data sets from five independent investigations were analyzed, showing a strong relationship between gas permeability ( $k_T$ ) and concrete moisture ( $m$ ). In 84% of the cases ( $R = 0.95$ ), this relationship could be described using an exponential function of the form:

$$k_T = k_{T_0} \cdot e^{d \cdot m} \quad (1)$$

with  $d$  typically ranging between 1.0 and 2.0 (median: 1.45). Based on these results, a practical correction method is proposed to mathematically adjust gas permeability measurements for moisture effects. For moisture levels between 4.5% and 5.5%, the correction is of minor practical relevance. However, incorporating such a correction into future versions of relevant standards is conceivable.

## 5 CONCLUSIONS

The presented research investigated the impact of various curing methods under otherwise nearly identical conditions.

The findings demonstrate that both the type and duration of curing significantly influence the gas permeability of concrete – and, by extension, the long-term durability of the structure. Therefore, gas permeability measurements can serve as an indirect indicator of curing quality.

This approach is notable for its straightforward and non-destructive application, suitable for both laboratory settings and on-site evaluations. The analysis of the collected data is efficient and uncomplicated. Existing recommendations, such as the representation of permeability values per test area according to Swiss Standard SIA 262/1:2019 [13], offer a useful framework for assessing surface quality.

However, since gas permeability is affected not only by curing conditions but also by concrete composition and other factors, it does not allow for a direct measurement of curing quality. One potential solution is to define a permeability threshold during the planning phase as a minimum standard for concrete performance. This threshold could be derived from reference measurements on similar concrete elements with the same composition. Implementing such a method would require extensive research to establish a statistically reliable dataset for defining acceptable limits.

A follow-up research project is currently underway, focusing on gas permeability testing of concrete structures with varying properties and exposed to different climatic conditions. Simultaneously, reference values are being gathered from test specimens with identical formulations and optimal curing to support the evaluation of site-specific results. While this approach shows promise, further research is essential to fully validate its effectiveness and reliability.

#### Summary of key findings:

- Laboratory investigations have confirmed that gas permeability measurement is a reliable and effective method for assessing the curing quality of concrete.
- A clear distinction in the permeability coefficient was observed between specimens with “good” curing and those with either “poor” or no curing. However, since gas permeability is also influenced by the specific concrete composition, it is not possible to define universal threshold values for curing quality evaluation.
- Inadequate curing leads to increased gas permeability and is also associated with a reduction in compressive strength compared to optimally cured concrete.
- Tests conducted on actual construction sites demonstrated that direct gas permeability measurements on structural elements yield valid insights into the quality of curing.
- Environmental conditions, such as wind, temperature, and humidity, significantly affect on-site measurements. These influences can either improve or impair concrete quality and must therefore be taken into account when choosing measurement locations, scheduling testing, and interpreting curing effectiveness.
- For field assessments, it is recommended – according to Swiss standard SIA 262/1:2019 – that at least six

individual  $k_T$  measurements be performed per testing area to ensure reliable results.

**ABSTRACT:** The research team, comprising international and local experts, has been studying heritage adobe buildings in Uzbekistan for several years. A few field studies were conducted at the heritage sites of Uzbekistan and Karakalpakstan: Toprak-Kala, Chadra Hauli, Ulli Hovli, and many others. As the first step of the comprehensive research strategy, laser scanning was used to generate accurate digital twins of the heritage structures. A non-destructive ambient vibration study of selected structures was conducted in the second step. This in-situ testing measures resonant frequencies and mechanical properties at very small excitations, which is insufficient for accurate numerical modeling. This study was conducted to address this shortcoming. A few adobe structures constructed of pakhsa were selected. Since the pakhsa is made of clay, which is available in the vicinity of the construction site, the exact georeferencing of each structure was considered. A few cylindrical samples were bored out from the walls of the structures and tested at the University of California, Berkeley. The samples were instrumented with strain gages, and they were investigated in compression and split tests. As a result of this study, Young's modulus, Poisson's ratio, and the strength of each test specimen were measured. These parameters will be used to generate more accurate numerical models of the structures and assess the advantages of reinforcement strategies for heritage structures.

**KEY WORDS:** Adobe heritage structures; structural health monitoring; pakhsa; numerical modeling; laser scanning.

## 1 GENERAL GUIDELINES

Buildings made of adobe materials are very common throughout the world. They represent a very affordable way of construction, utilizing local materials. In addition, the adobe buildings are environmentally friendly because their construction uses natural, renewable materials and energy-efficient construction methods. As a result, this construction has a smaller carbon footprint compared to conventional construction. In addition, the adobe buildings naturally retain heat inside longer during winter and preserve a cooler room environment on hot summer days.

The adobe construction is very common in Central Asian countries and is considered one of the traditional construction techniques in these regions. Adobe buildings can last a very long time. For example, the adobe structures of Toprak-Kala (Uzbekistan) are dated to the 2<sup>nd</sup> and 3<sup>rd</sup> centuries CE (Common Era). They still have an adequate structural health condition, as evaluated in a laser scanning study [1]. A recent discovery of previously unknown ancient cities, Tashbulak and Tugunbulak (Uzbekistan), revealed that these cities have adobe buildings dated to the 6<sup>th</sup>–11<sup>th</sup> century CE [2]. Another recent example is the four-story-tall Chadra Hauli in Uzbekistan, constructed in 1871 and still in excellent structural shape, as studied by using a laser scanner [3]. More than 200 Adobe buildings of more recent construction have been studied in rural areas of Tajikistan [4]. All of these structures are good representatives of pakhsa construction.

## 2 COMPREHENSIVE SHM APPROACH AND OBJECTIVES OF THIS PAPER

### 2.1 SHM of adobe buildings with performance prediction

A comprehensive approach is undertaken for the structural evaluation of the heritage structures and the prediction of their performance under various loading conditions. The structural evaluation and assessment are conducted using laser scanning technology to capture the current condition of heritage monuments in 3D accurately, as shown in Figure 1.

Figure 1. 3D point cloud of a heritage building collected by a laser scanner [3].

Based on the analysis of the point clouds collected by the laser scanner, all anomalies of the monuments are identified and studied in detail. Based on the 3D geometry captured by the laser scanner, an accurate finite element is created to investigate its structural performance under various loading conditions, as presented in Figure 2.

Figure 2. A finite element model of a heritage building was generated from the point cloud.

The finite element model requires input of the material properties of adobe to generate a realistic model. This information is difficult to obtain, as it relates to destructive testing, which is not permitted for heritage structures. Even if the collection of the sample is permitted, the benefits of the sample testing need to be investigated to optimize the sample set and the sample collection methods. This paper focuses on the development of a sample collecting procedure, a procedure for the preparation of collected samples for testing, and a procedure for testing to measure major material properties of the samples. These procedures are developed by investigating two buildings constructed of the same material as the heritage building, pakhsa. It is worth noting that there are a few standards focused on testing adobe samples, see [9], as a representative example. Still, their scope is very limited and does not provide any adequate guidance on reliable procedures for measuring the Young's modulus and Poisson's ratio.

## 2.2 Material properties of adobe: A brief review of the previous work

Adobe represents a man-made construction material that utilizes the raw earth material usually available close to the construction site. Hence, its mechanical characteristics depend on many parameters. These parameters can be as follows: the quality of earth material available for construction, the curing time of the clay before forming it into a wall or a brick, the way the clay was placed into the walls, bonding aggregates added to the earth material (if any), the quality of the craftsmanship work, the curing process after forming the wall, and many others. After the completion of construction, the mechanical properties can be affected by moisture. Therefore, there is substantial variability in the mechanical properties of adobe materials used in or taken from structures worldwide [5]. The mechanical properties are estimated by testing samples taken from adobe walls or created during construction (which is very rare). The samples can be collected in the form of cubes,

prisms, and cylinders, and the test results also depend on the shape of the test specimen [6]. For example, based on a comparative analysis of test results for cylinders [7] and [8], the Young's modulus of the adobe material varies by a factor of ten.

## 3 TESTING ADOBE CYLINDERS

### 3.1 General description of samples

The samples were collected from existing buildings at specific locations away from structurally critical areas. Two buildings were included in this study. One building was located in the Sabzovot region of Tashkent, Uzbekistan, and was estimated to be at least 60 years old. The second set of samples was collected from Sukok of the Tashkent Region. In both cases, the samples were bored out from the walls as presented in Figure 3.

Figure 3. Sample collection.

The hole in the wall after taking the bored cylinder out is presented in Figure 4.

Figure 4. Adobe wall after specimen collection

Since the specimens could break inside the bore during the boring process, their length varied from specimen to specimen, as shown in Figure 5. For consistency, only long specimens were used in the study, and the short ones were discarded. The long specimens were cut to a shorter length to maintain a similar length-to-diameter ratio.

Figure 5. Collected specimens before cutting them to the same length and selecting the best ones

The length and the diameter of each specimen are summarized in Table 1.

Table 1. Overall dimensions of adobe cylinders.

No	Length, mm	Diameter, mm	Geo-location
1	102	33	Sabzabot
2	110	52	Sabzabot
3	96	52	Sabzabot
4	105	52	Sabzabot
5	103	42	Sukok
6	104	44	Sukok
7	103	44	Sukok
8	103	43	Sukok

It is worth noting that the quality of the adobe material from these two geo-locations was noticeably different. The samples from Sabzovot were of a lighter color and were dense and uniform, whereas the samples from Sukok were of a darker color and had a few large voids, as shown in Figure 6. This difference played a significant role in the overall strength of the collected test specimens.

Figure 6. Adobe wall after specimen collection

### 3.2 Density results

The weight of each specimen was measured, and based on the calculated volume, the density was estimated as summarized in Table 2.

Table 2. Summary of density estimates.

No	Weight, g	Density, kg/m <sup>3</sup>	Average
1	148.4	1701.0	1541.0
2	343.4	1470.0	
3	303.6	1489.1	
4	335.3	1503.7	
5	218.9	1534.0	1468.5
6	219.3	1386.8	
7	217.8	1390.7	
8	233.7	1562.4	

As presented in the table above, the average density of specimens from Sabzovot was slightly greater than that of the specimens from Sukok.

### 3.3 Compression test: specimen preparation

As mentioned earlier, the specimens varied in length. All of them were cut to maintain the same length-to-diameter ratio. Since the specimens were quite brittle, they were cut in a special device, as shown in Figure 7.

Figure 7. Adobe specimen in a cutting device

To distribute the forces at the ends of the samples, the adobe specimens were sulfur-capped for the compression test as presented in Figure 8.

Figure 8. Adobe specimens with sulfur caps

Finally, the adobe specimens were instrumented by bi-axial strain gages as presented in Figure 9. The legs of the gage were

aligned with the longitudinal direction and the circumferential direction, respectively. A 40-mm long strain gage was used in this study.

Figure 9. Adobe specimen with bi-axial strain gage.

### 3.4 Compression test: strength

To measure the Young's modulus, Poisson's ratio, and strength of the specimens, they were tested using a compression test machine, as shown in Figure 10.

Figure 10. Adobe specimen in the compression test machine.

The compression load was applied at a constant rate of 25 N/s. A plot for Specimen No. 3 from the Sabzobot's geo-location showing the change of stress over time is presented in Figure 11.

Figure 11. Force vs. time plot for Specimen No. 3.

As shown in the plot above, the stress steadily increases to the peak value, and there is a sharp decline in the compression stress capacity right after the peak value. A similar result was obtained for Specimen No. 4, as depicted in Figure 12. The peak load values were very close to each other, as summarized in Table 3. The table also shows the air humidity for each specimen on the day of testing.

Figure 12. Stress vs. time plot for Specimen No. 4.

Table 3. Summary of compression strength (Sabzobot).

No	Peak load, N	Peak stress, MPa	Humidity, %
3	5911	2.78	30.0
4	6605	3.11	32.0

The results for the Sukok geo-location revealed different results. The strength capacity of the two tested specimens varied significantly, as presented in Figure 13 and Figure 14. The results are summarized in Table 4.

Figure 13. Stress vs. time plot for Specimen No. 6.

Figure 14. Stress vs. time plot for Specimen No. 7.

Table 4. Summary of compression strength (Sukok).

No	Peak load, N	Peak stress, MPa	Humidity, %
6	2456	1.16	32.0
7	1312	0.62	32.0

The larger variability in the test results was expected because the Sabzobot samples were more homogeneous than the Sukok samples, which had a few relatively large voids.

### 3.5 Compression test: Young modulus

Several approaches to measuring Young's modulus in compression for cylinder-shaped specimens have been previously proposed and utilized [6-8]. One of the primary objectives of this paper was to utilize existing methods and select the most suitable one for achieving consistency in data reduction; therefore, the following all three approaches were employed and evaluated. First, a slope of a secant line between the start and end of the linear portion of the stress-strain curve was used to estimate Young's modulus [6]. In this paper, the modulus based on this approach is denoted by  $E_{LR}$ . Second, the Young's modulus calculation was based on the slope of a secant line between 5 and 50% of the peak stress [8].  $E_{05-50}$  denotes the modulus based on this approach. Third, a slope of the secant between 33.3 and 66.6% of the peak stress was used for estimating Young's modulus [7].  $E_{33-66}$  denotes the modulus based on this approach. All three procedures were employed in this paper, and their results were compared to one another.

As mentioned earlier, a bis-axial strain gage was installed on each test sample. The longitudinal leg of the strain gauge was used to estimate Young's modulus. A plot showing stress ( $\sigma$ ) versus longitudinal strain ( $\epsilon$ ) for Specimen No. 3 is presented in Figure 15. The plot also displays the result of the linear regression, which was generated during the testing period, starting from loading and ending when the strain gage came out of the test specimen due to the gage's failure. It is worth noting that the latter point was very close to that when the peak stress occurs. The Young's modulus obtained from the linear regression ( $E_{LR}$ ) is also presented in the same plot. It is worth noting that the R-squared value of the linear regression is close to unity, indicating a good fit. It can also be observed visually that the stress-strain curve can be closely approximated with a straight line. To reduce the noise of the recorded data, which can be visually observed in Figure 14 and Figure 14, a running average over seven points was used to filter out the noise for the Young's modulus calculations.

Figure 15. Stress vs. longitudinal strain plot for Specimen No. 3: Young's modulus from linear regression.

The results of the two other above-mentioned approaches for estimating Young's modulus are presented in Figure 16.

Figure 16. Stress vs. longitudinal strain plot for Specimen No. 3: two estimates of Young's modulus.

Similar results for Specimen No. 4 are presented in Figure 17 and Figure 18. As can be observed from the plots, the moment when the strain gage stopped working is very close to the moment when the maximum stress occurred.

Figure 17. Stress vs. longitudinal strain plot for Specimen No. 4: Young's modulus from linear regression.

Figure 18. Stress vs. longitudinal strain plot for Specimen No. 4: two estimates of Young's modulus.

The results for the set collected from the Sabzobot geo-location show relatively large variation in the estimation of the Young's modulus, as summarized in Table 5. The variability of  $E_{05-50}$  is significantly greater than that of the other two modules. It depends on the overall trend of the stress-strain curve:  $E_{05-50}$  is less than  $E_{33-66}$  when the curve opens upwards (concave up), and  $E_{05-50}$  is greater than  $E_{33-66}$  when it opens downwards

(concave down). It is worth noting that the results for  $E_{33-66}$  in both cases are closer to those for  $E_{LR}$ , although slightly lower.

Table 5. Summary of estimations of Young's modulus (Sabzovot).

No	$E_{LR}$ , MPa ( $R^2$ )	$E_{05-50}$ , MPa	$E_{33-66}$ , MPa
3	1320.8 (0.97)	1040.8	1246.2
4	1460.9 (0.98)	1753.3	1354.8

The same calculation approaches were used for the sample set from the Sukok geo-location, and the results are summarized in Table 6. The stress-strain curves for Specimen 6, along with the respective values of Young's modulus, are presented in Figure 19 and Figure 20. It is worth noting that Specimen 7 data was very inconsistent with all other test results, and as such, it was considered an outlier.

Table 6. Summary of estimations of Young's modulus (Sukok).

No	$E_{LR}$ , MPa ( $R^2$ )	$E_{05-50}$ , MPa	$E_{33-66}$ , MPa
6	1258.5 (0.99)	1198.9	1361.6
7	671.9 (0.95)	547.3	1003.8

Figure 19. Stress vs. longitudinal strain plot for Specimen No. 6: Young's modulus from linear regression.

Figure 20. Stress vs. longitudinal strain plot for Specimen No. 6: two estimates of Young's modulus.

### 3.6 Compression test: Poisson's ratio

While the results for Young's modulus were reported for many locations worldwide [5], very limited information is available for the estimates of Poisson's ratio. This is especially true for the region of Central Asia. Therefore, one of the primary

objectives of this paper was to address this issue and to have a complete set of mechanical properties of some adobe buildings. For this purpose, a strain gage was installed to read the circumferential strain ( $\epsilon$ ) of the adobe cylinders.

Poisson's ratio ( $\nu$ ) was obtained by using the following expression:

$$\nu = -\epsilon/\epsilon \quad (1)$$

The results for Specimen No. 3 are presented in Figure 21. In this plot, only a portion of the data was used to ensure that both longitudinal and circumferential strain gages yield reasonable data. The portion of the plot in red corresponds to the data when the stress was between 33.3% and 66.6% of the maximum stress. The plot shows that the general trend of the change of Poisson's ratio with stress is very close to linear. In the red portion of the data, the values vary from 0.12 to 0.16 with an average of 0.14.

Figure 21. Stress vs. Poisson's ratio ( $\nu$ ) plot for Specimen No. 3: Sabzovot.

The respective results for Specimen No. 4 are shown in Figure 22. The plot shows that the general trend of the change of Poisson's ratio with stress is nonlinear. In the red portion of the data, the values vary from 0.12 to 0.18 with an average of 0.16.

Figure 22. Stress vs. Poisson's ratio ( $\nu$ ) plot for Specimen No. 4: Sabzovot.

The test results for the specimens collected from Sukok geo-location are presented in Figure 23 and Figure 24. Specimen No. 6 (see Figure 23) yields stable results in the red portion of the data, where the value changes from 0.22 to 0.24 with an average of 0.23.

Specimen No. 7 was considered an outlier, and the results shown in Figure 24 serve as further evidence of this conclusion.

Figure 23. Stress vs. Poisson's ratio ( $\nu$ ) plot for Specimen No. 6: Sukok.

Figure 24. Stress vs. Poisson's ratio ( $\nu$ ) plot for Specimen No. 7: Sukok.

#### 4 DISCUSSION AND CONCLUSIONS

The results discussed in the paper show that the testing of adobe specimens can be challenging. It greatly depends on the procedures followed during specimen collection, handling from the collection site to the test site, and preparation for the test. In addition, it depends on the overall quality of the adobe wall from which the specimens are collected. The quality of the adobe wall is controlled by following parameters: the quality of earth material available at the construction site, the curing time of the clay before forming it into a wall or a brick, the way the clay was placed into the walls, bonding aggregates added to the earth material (if any), the quality of the craftsmanship work, the curing process after forming the wall, and many others.

Several cylinder-shaped samples were collected from two geo-locations in Uzbekistan. The density of all specimens was determined before the tests. Since some of the collected samples did not have a uniform and homogeneous structure, a total of eight samples (out of eleven total) were used in the density estimation. The compression tests were performed on four of them to estimate the following mechanical parameters: compression strength, Young's modulus, and Poisson's ratio. Based on previous studies, three approaches for calculating Young's modulus were employed. The correlation between the previously published results (only corresponding to cylinder-shaped specimens from the literature) and the results obtained in this study was as follows.

The comparison of the results of this paper to the previously published results on compressive strength of cylindrical

specimens is presented in Figure 25. As shown in the plot, the samples from Sabzobot geo-location were the greatest of all.

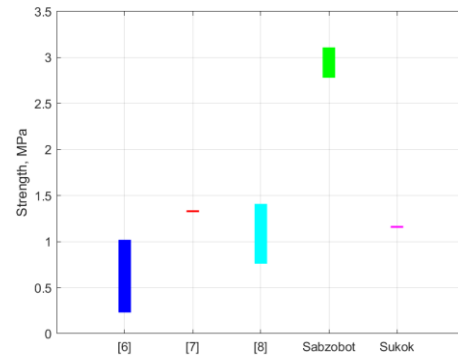

Figure 25. Compression strength results for Sabzovot and Sukok geo-locations compared to previously published [6], [7], and [8].

When comparing the Sabzovot and Sukok sets to [6], the compression strength of the adobe samples was slightly greater: the lowest value (excluding the outlier) is 1.16 MPa, versus 1.02 MPa [6]. Young's modulus was significantly lower: 1,461 MPa is the largest value obtained in this work, excluding the outlier, compared to 7,609 MPa reported earlier [6]. When compared to [7], the compression strength of adobe samples was slightly lower: the lowest value (excluding the outlier) is 1.16 MPa versus 1.33 MPa [7]. Young's modulus obtained in this study was significantly greater: 1,461 MPa is the largest value (excluding the outlier) versus 802 MPa reported earlier [7]. When compared to [8], the compression strength of adobe samples was slightly lower: the lowest value (excluding the outlier) is 1.16 MPa versus 1.71 MPa [7]. Young's modulus obtained in this study was significantly greater: 1,461 MPa was the largest value (excluding the outlier) versus 92 MPa published earlier [8].

The study showed that  $E_{0.5-50}$  depends on the direction of the overall curvature of the stress-strain curve and, as such, can have much larger variation. At the same time,  $E_{LR}$  and  $E_{33-66}$  yielded more similar results.

No literature references were found with respect to the experimental estimation of Poisson's ratio for adobe cylinders. The results of this study showed that Poisson's ratio is most likely stress-dependent, and for stress between 33.3% and 66.6% of the maximum stress, it can vary from about 0.12 to 0.24.

The results of this study will be used in finite element modelling of Chadra Hauily (Khorezm Region, Uzbekistan). The finite element mesh of the monument was generated by a laser scanner [3]; only the mechanical parameters of adobe were missing to generate a realistic model. This study fulfilled this need. The team is working on collecting more samples from other geo-locations to develop an extensive database of pakhsa properties in Central Asia.

It is worth noting that only a few test results are discussed here as representative examples. The research group is working on collecting more samples from other adobe buildings, including heritage buildings.

**ABSTRACT:** The bridge system composed of Los Grillos, Puente Nuevo, and Chorro Blanco, located along the roadway connecting Sogamoso and Aguazul, near the municipality of Pajarito (Colombia), is founded on an active large-scale landslide in shale bedrock. This mass movement exhibits variable displacement rates depending on rainfall frequency over time. On August 20, 2023, the Los Grillos Bridge collapsed as a result of cumulative ground displacements that compromised its foundations and piers. Between July and December 2024, an integrated monitoring system was implemented, combining observations from an Automated Total Station (ATS), distance measurements using LiDAR, and tilt data obtained from inclinometers. The primary objective of this system is to establish correlations and track both ground and structural displacements, thereby supporting local stakeholders and decision-makers in the operational management of the remaining bridges still in service for civilian traffic. This paper presents the principal findings and illustrates how the integration of data from multiple sensor technologies enhanced the understanding of differential behavior between the ground and the structures. The analysis includes the collapsed bridge as well as the two remaining bridges in the affected area, providing timely and valuable information to support safe roadway operations.

**KEY WORDS:** Structural monitoring, Los Grillos Bridge, wireless sensors, landslide monitoring, Lidar ATS infrastructure monitoring, risk management.

## 1 INTRODUCTION AND GENERAL OVERVIEW

In Colombia, geological conditions present a wide range of engineering challenges, primarily due to the geodynamic behavior of the territory, which is heavily influenced by the presence of the Andes Mountain range across much of the country. These complex environments increase the risks that directly or indirectly affect social activities in these regions. Such risks may stem from seismic hazards, mass movements, among other factors, and have a direct impact on the design and construction of resilient and sustainable infrastructure.

In general terms and considering the current state of development in the country, one of the economic sectors most affected by geological conditions is freight transportation. Road corridors such as the one stretching from Sogamoso, Boyacá to Aguazul, Casanare—the focus of this study—are characterized by steep topography and high-mountain road networks, facing ongoing challenges in terms of mobility and connectivity.

Roadways with steep slopes, sharp curves, and unstable soils increase vulnerability to landslides, subsidence, and other impacts triggered by climatic phenomena such as heavy rainfall and thermal variability, including segments that traverse páramo ecosystems. These environmental factors significantly affect road safety, increase logistical costs, and prolong the time required for the transport of goods and personnel.

In the area located at station PR81 of the Sogamoso–Aguazul corridor, also known as the Cusiana Transversal, mass movement processes and geomorphological activity have been observed for more than two years and continue to occur to this day. These processes affect both the upper and lower zones of the surrounding slopes.

Figure 1. General location and panoramic view of the study area.

Given these geological conditions, a 666-meter-long viaduct was constructed, consisting of three consecutive bridges named Los Grillos (with a span of 261 meters), Nuevo (105 meters), and Chorro Blanco (300 meters from abutment to abutment).

Due to persistent landslides in the area, these structures are currently partially or completely out of service because of multiple evident structural pathologies. In the case of the Nuevo and Chorro Blanco bridges, significant deterioration has been observed, while the Los Grillos Bridge experienced a collapse of the structure.

Based on these geotechnical and structural conditions, and with the primary goal of providing continuous monitoring through an early warning system, two complementary monitoring systems were implemented.

The first system involved tracking three-dimensional displacements using automated readings of topographic prisms and virtual points with a GMS robotic LiDAR station (Geotech Monitoring Station).

The second system focused on structural monitoring of relative displacements and rotations through the use of triaxial inclinometers and wireless laser distance meters.

Figure 2. General overview of monitoring systems in sector PR81

In the face of these challenges, engineering plays a critical role in mitigating risks associated with road infrastructure and enhancing regional connectivity.

The application of advanced techniques for slope stabilization, pavement reinforcement, and geotechnical monitoring through automated methods contributes significantly to improving the safety and operational reliability of road corridors.

## 2 GEOLOGY AND GEOTECHNICAL INSTABILITY OF THE AREA

The study area is located between the municipalities of Sogamoso and Pajarito, in the department of Boyacá, Colombia. Hydrologically, the region where the monitoring points are situated is primarily influenced by the Cusiana River and the Chorro Blanco stream.

According to Sheet No. 192 of the regional geological map corresponding to the surroundings of Lake Tota, Department of Boyacá, Colombia, at a 1:100.000 scale [1], the sector known as PR81 lies within a geological unit referred to as the Macanal Shale Formation (Kilm), as shown in Figure 3.

This unit is predominantly composed of black shales interbedded with thin sandstone layers, which is indicative of a deep marine sedimentary environment typical of the Lower Cretaceous.

This paleoenvironmental interpretation is supported by field evidence, particularly the abundant presence of ammonite fossils, which serve as index fossils for this geological era.

The shales of this formation are fine-grained, rich in organic matter, and exhibit well-developed foliation, making them particularly susceptible to weathering processes and deformation under load or saturation conditions. These geomechanical characteristics significantly affect slope stability, subsoil behavior beneath structures, and the design of foundations or roadways that traverse such materials—factors that may account for the various active geotechnical processes currently observed in the area.

Figure 3. Regional geological map of the study area PR81 [1]

For years, the area has exhibited significant and progressive mass movement processes, particularly near the Chorro Blanco stream and along the slopes leading to the Cusiana River channel. This suggests that torrential flows from these tributaries may act as a triggering factor for the landslides and fissures observed on the slopes.

Figure 4. Evidence of geomorphological processes in sector PR81

### 3 STRUCTURAL COLLAPSE EVENT OF 2023 AT LOS GRILLOS BRIDGE

Due to the previously mentioned geodynamic conditions, among the three structures that comprise the viaduct, the Los Grillos Bridge exhibited the most significant deterioration. This was primarily attributed to its structural typology in conjunction with the landslides occurring in the area.

Since late 2022, multiple structural pathologies had been identified, raising concerns about the bridge's stability [2], with clear evidence of progressive structural degradation.

In 2023, following a series of seismic events with magnitudes ranging from 0.70 to 6.10, a collapse occurred on August 20 in a central section of the Los Grillos Bridge deck, located at the midpoint of the main span. This failure may have been influenced by a combination of factors, including material fatigue and cumulative effects of regional seismic activity.

The occurrence of these events underscores the critical importance of implementing continuous monitoring systems at the earliest signs of deterioration, integrating both geotechnical and structural data to enable comprehensive assessments and timely interventions.

Figure 5. Evidence of mass wasting processes near the foundations of the PR81 corridor bridges

Figure 6. Los Grillos bridge structural collapse.

### 4 IMPLEMENTED MONITORING SOLUTIONS

Considering the geotechnical challenges of the area, specific contingency measures were established to mitigate the risks faced by both the local population and construction personnel. Among these measures, a dual early warning system was implemented to monitor the displacement behavior of both the bridge superstructures and the surrounding slopes.

This dual system consisted of an automated total station based on LiDAR GMS technology, which conducted three-dimensional tracking of thirty (30) topographic prisms strategically installed in various sectors within the area of analysis.

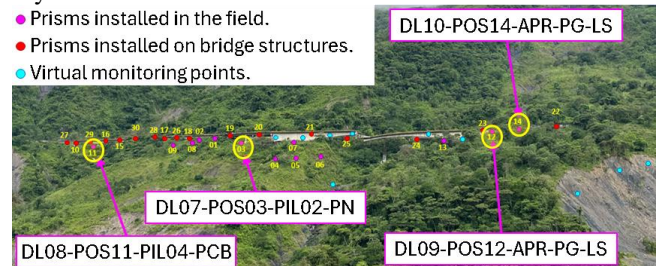

Figure 7. General location of measurement targets with GMS

Additionally, thirty-six (36) wireless sensors were installed. Of these, twenty-four (24) are triaxial clinometers used to monitor tilting at strategic locations on the viaduct bridges. The remaining twelve (12) sensors are laser distance meters equipped with triaxial clinometric sensors, designed to monitor relative displacements and inclinations.

These devices were mounted on poles located near exposed surfaces of the bridges, where topographic prisms were also installed to provide redundant data, monitored by the robotic GMS station.

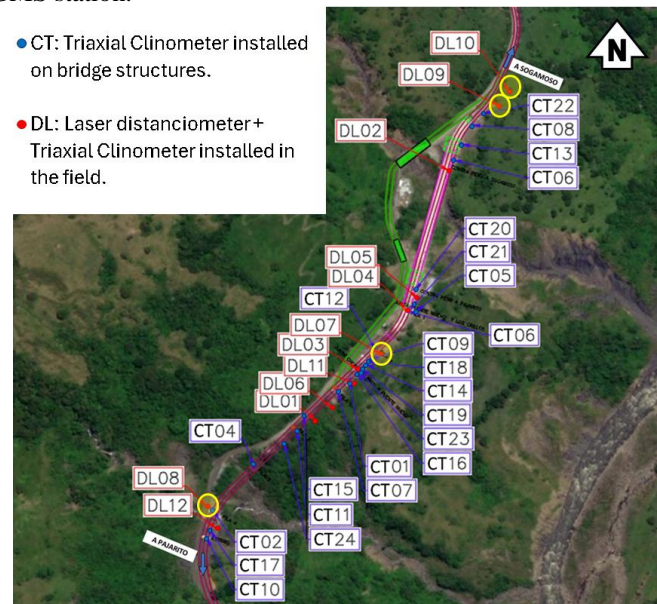

Figure 8. General location of wireless sensors

#### 4.1 Description of robotic lidar gms technology

This type of system consists of a state-of-the-art robotic total station capable of performing high-precision measurements of three-dimensional displacements on selected targets.

These targets may include both physical reference points, such as topographic prisms installed throughout the monitored area, and virtual points defined by pixel positions on images of exposed slopes or structural surfaces, using advanced image processing techniques.

This methodology enables continuous acquisition, processing, and analysis of displacement data within the area of interest. The resulting information facilitates the identification of incipient or progressive movements, as well as the establishment of behavioral trends in the short, medium, and long term.

Figure 9. GMS Technology Implemented in Sector PR81

#### 4.2 Description of clinometric sensors and laser distance meters

This type of system enables the monitoring of displacements (via laser distance meters) and inclinations (via clinometers) at specific points on the structures.

Regarding the measurement of relative displacements, the laser distance meters project a light beam that allows for the measurement of the distance between the sensor location and a target surface, with high precision and under adverse environmental conditions.

On the other hand, the triaxial clinometers allow for the tracking of inclination angles, primarily along the two orthogonal axes, X and Y.

From this clinometric data, the displacement associated with the observed inclination can be calculated using trigonometric relationships.

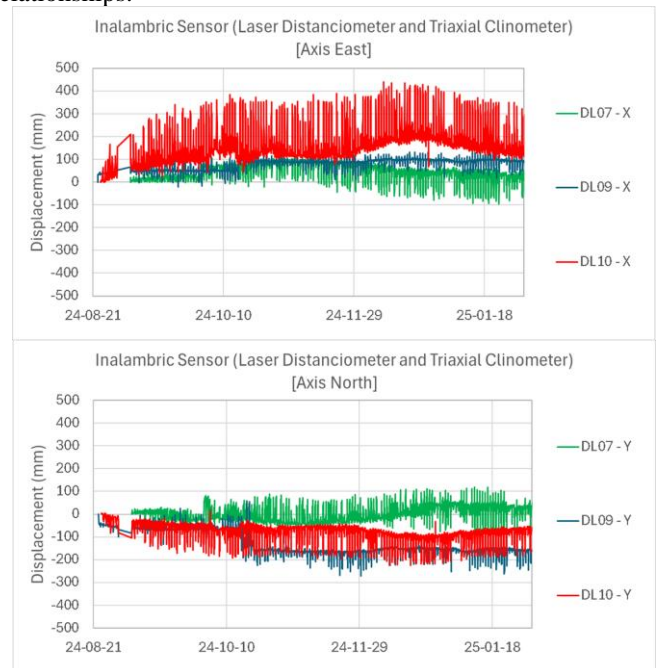

Figure 10. Sensor Technology Implemented in Sector PR81

### 5 RESULTS OBTAINED DURING THE GMS AND CLINOMETER MONITORING PERIOD

After nearly seven months of monitoring, primarily transient trends were observed in the study area PR81, both in the displacements recorded by the GMS equipment and in the inclinations measured by the triaxial clinometers.

It is important to note that, since the monitoring points reported movement data in their local axes ( $X'$ - $Y'$ ), the recorded values were transformed into local North-East coordinates. This transformation was performed through an orthogonal axis rotation (see Figure 11), as expressed in Equation 1.

Figure 11. Diagram of orthogonal axis rotation

$$\begin{bmatrix} X \text{ (ESTE)} \\ Y \text{ (NORTE)} \end{bmatrix} = \begin{bmatrix} \cos(\theta) & -\sin(\theta) \\ \sin(\theta) & \cos(\theta) \end{bmatrix} \begin{bmatrix} x' \\ y' \end{bmatrix} \quad (1)$$

For each clinometer and laser distance meter, it was necessary to establish reference lines parallel to the bridge structures, as the instruments were installed following this alignment. Once these lines were defined, the angle between the local measurement axes and the global reference axes ( $X$ - $Y$ ), aligned with true north, was determined (Figure 12). By applying Equation 1, it was possible to transform the displacements recorded in local coordinates into the global coordinate system.

It is noted that, in the case of data obtained from the GMS (Geodetic Monitoring System), this transformation is performed automatically by the equipment, based on the predefined global axes and the relative orientation of each prism with respect to the measuring station, as determined by the laser projection

Figure 12. Axis diagram for the sensor DL02

Once the measurement results were transformed into global axes, it was possible to perform a comparative evaluation of the trends identified through both monitoring approaches (sensors and GMS).

As a summary, the data obtained for the following monitoring points are presented:

- Zone 1: Pile of Chorro Blanco Bridge (Prism PR11 – Sensor DL08).
- Zone 2: Pile of Nuevo Bridge (Prism PR03 – Sensor DL07).
- Zone 3: Sogamoso Abutment of Los Grillos Bridge (Prism PR12 – Sensor DL09).
- Zone 4: Sogamoso Abutment of Los Grillos Bridge (Prism PR14 – Sensor DL10).

For Zones 1 and 2, based on the data obtained from the dual monitoring system (GMS and sensor network), an initially positive incremental trend is observed along the X-axis (East), which subsequently tends to stabilize.

Similarly, although with an opposite pattern, the Y-axis (North) shows an initially negative incremental trend, also followed by a stabilization phase.

The global displacements recorded along both axes remain below 20 cm in magnitude, which aligns with field observations and with the presence of geomorphological indicators of slow-moving processes.

These behavioral patterns suggest a process of progressive deformation, followed by a decrease in displacement rates (as evidenced toward the end of the monitoring period), possibly associated with the seasonal transition from wet (winter) to dry (summer) periods.

Figure 13. Location and historical record of horizontal displacements for Sector 1

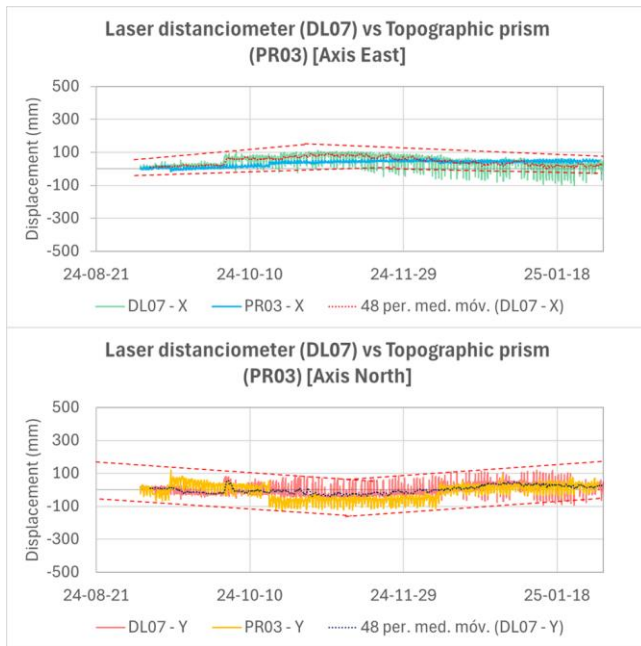

Figure 14. Location and historical record of horizontal displacements for Sector 2

On the other hand, for Zones 3 and 4, based on the information obtained during the monitoring period, mainly incremental displacement trends were identified, with more pronounced movement along the X-axis (East).

In contrast, the behavior along the Y-axis (North) tends to be more stable, exhibiting only minor variations.

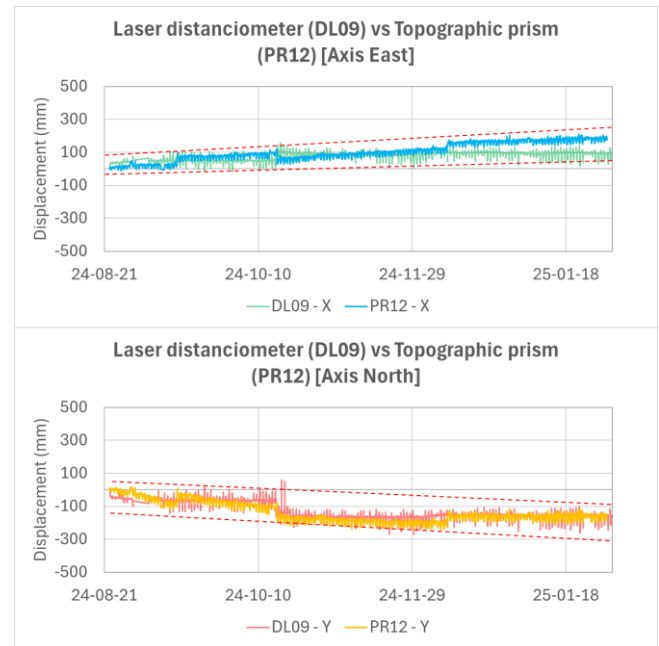

Figure 15. Location and historical record of horizontal displacements for Sector 3

The recorded displacements remained below 20 cm along the X-axis and below 25 cm along the Y-axis, values that are consistent with field observations and the documented surface morphological evolution in the area.

This behavior suggests a more active movement dynamic in the X-direction (East), possibly associated with the slope geometry, the orientation of the fracturing system, or the direction of the principal stress in the ground.

Figure 16. Location and historical record of horizontal displacements for Sector 4

### 5.1 Principal displacement directions identified

Regarding the displacement directions derived from the wireless sensors, it was observed that, as expected, movements recorded by devices installed directly on the ground exhibit greater magnitudes compared to those mounted on concrete structures.

This difference is primarily attributed to the foundation conditions of the structures, which tend to dissipate part of the deformation, as well as to the geological characteristics of the adjacent slopes, which favor greater displacement in the superficial soil layers.

Similarly, displacement behavior is also evident in the topographic prisms installed both on structural elements and on natural slopes. It is worth noting that, due to the specific conditions of the project, a higher density of prisms was installed in comparison to the wireless sensors deployed on the slopes.

This wider spatial distribution of topographic targets provides broader coverage of the monitored area, enabling a more detailed characterization of displacement patterns, particularly in critical zones of the terrain.

Figure 17. Principal Displacement Directions Identified Based on Measurements from Wireless Sensors

When comparing the results obtained from both monitoring systems, notable similarities are observed in the behavior of the monitored elements previously presented in this document.

These similarities suggest a degree of informational redundancy between the two systems.

The predominant displacement trends appear to be strongly influenced by the geomorphological characteristics of the area, which are generally aligned with the direction of the ongoing mass movement process occurring near the bridge foundation structures.

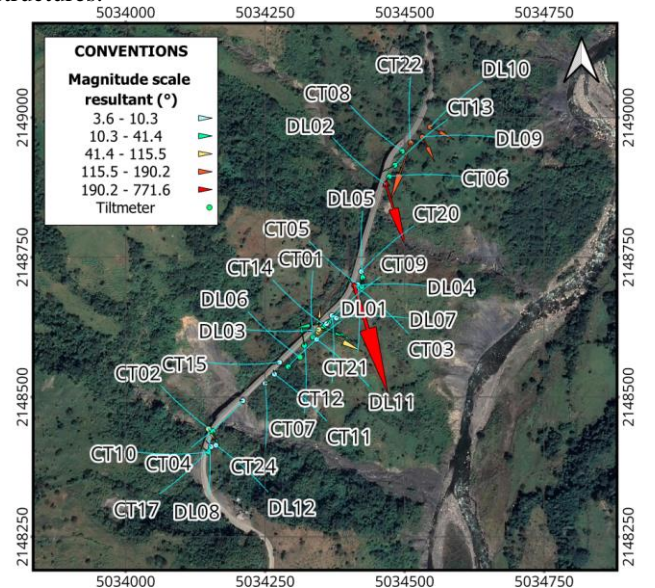

Figure 18. Principal Displacement Directions Identified Based on Measurements from topographic prism

The largest displacement magnitudes are concentrated around the abutment areas of the Los Grillos Bridge. It is important to highlight that, despite these observed similarities, the two monitoring systems are based on fundamentally different methodologies, each with its own limitations and advantages.

The convergence of results enhances the reliability of the data and supports the use of a hybrid monitoring strategy to improve interpretation, redundancy, and validation of both structural and geotechnical behavior over time.

## 6 DISCUSSION OF MAIN RESULTS

Based on the results obtained, an approximate correspondence can be identified between the displacement trends recorded by the wireless sensors (inclinometers) and those measured by the topographic prisms.

Likewise, a satisfactory agreement is observed in terms of the displacement magnitudes captured by both technologies.

It is important to highlight that the differences in magnitude can be attributed to the specific accuracy characteristics of each system. In this regard, the inclinometer-based methodology, being directly installed on the ground or the structural body, offers greater sensitivity and precision for detecting angular variations and relative displacements. It has been shown that, based on properly supervised studies conducted on buildings over 50 meters high, high-precision inclinometers provide optimal performance in the continuous monitoring of sub-millimetric displacements [3].

In contrast, monitoring through topographic prisms is subject to factors such as the distance between the GMS station and the target prisms, as well as atmospheric and visibility conditions, which may reduce its accuracy in detecting small-magnitude displacements. The precision of data obtained through geodetic equipment is mainly influenced by the atmospheric conditions along the measurement path. For example, in the case of a slope monitored in Austria, a variation of 1°C or 3.6 mbar resulted in measurement deviations of up to 10 mm over a 1 km measurement range [4]. Therefore, it becomes essential that the data acquisition system incorporates algorithms capable of applying atmospheric corrections in its operation, as is the case with the equipment used for monitoring sector PR81.

## 7 CONCLUSIONS

The results obtained through the implementation of a dual monitoring system—comprising wireless sensors (triaxial inclinometers and laser distance meters) and topographic prisms connected to the GMS (Geodetic Monitoring System)—provide a reliable and complementary framework for evaluating structural and geotechnical behavior in critical sections of the road corridor.

The identified displacement directions and magnitudes show an acceptable level of agreement between both monitoring methodologies, particularly in the analyzed sectors, which highlight the robustness and validity of the combined approach.

It was observed that the sensors installed directly on the ground recorded greater displacement magnitudes, which are consistent with local geotechnical conditions, slope geomorphology, and the foundation characteristics of the structures.

Additionally, although topographic prisms are more susceptible to external factors such as visibility and atmospheric conditions, they offer broader spatial coverage due to their higher installation density.

The convergence in displacement trends detected by both systems reinforces the reliability of monitoring data and enables a more comprehensive interpretation of the structural behavior in response to ongoing mass movement processes, especially in the vicinity of the Los Grillos Bridge.

This confirms the importance of integrating advanced sensor technologies with traditional geodetic monitoring methods to strengthen decision-making processes related to the design, maintenance, and risk management of critical infrastructure.

## ACKNOWLEDGMENTS

The authors express their sincere gratitude to all professionals, technicians, and the entire team who carried out the installation using high-access equipment in a complex geological setting. Special recognition is given to Alejandro Navarro and Cristhian Melo, whose work stood out for its passion and outstanding quality.

**ABSTRACT:** There are several ways to incorporate SHM data into the structural assessment of existing bridges. Beyond conventional model calibration, SHM can improve environmental effects and load estimates, thereby reducing the model uncertainty. However, the measurement data itself is also affected by epistemic uncertainty. This paper investigates the influence of selected data quality characteristics on the recalculation of prestressed concrete bridges, focusing on the example of coupling joints. A research bridge serves as a case study, equipped with temperature sensors recording data since February 2024 until today. A numerical FE model of the bridge provides a solid basis for simulations. A sensitivity analysis was carried out to identify the key parameters influencing the results. This includes the effect of the temperature gradient on the fatigue stress of the coupling joint. The study demonstrates the impact of representativeness and coverage of measurements in a spatial and temporal context on the estimated remaining service life of the structure. It highlights the importance of the correct selection of the sensor number and placement, and of the data collection period length. The results confirm the suitability of the proposed methodology for the systematic evaluation of monitoring concepts. However, further research is needed to derive specific recommendations for the design of monitoring systems for coupling joints. This work contributes to optimized SHM-based bridge recalculation by providing a basis for assessing the quality of monitoring concepts and its influence on structural analysis.

**KEY WORDS:** Sensitivity analysis; Measurement uncertainty; Fatigue; Coupling joints; Temperature monitoring.

## 1 INTRODUCTION

A large number of bridges on Germany's federal highways were built in the 1960s and 1970s (see Figure 1) and have been exposed for more than 55 years to heavy traffic and other loads, for which they were not initially designed. About 47 % of these bridges are prestressed concrete bridges [1]. In addition to durability and overloading issues, fatigue is an important concern for many of these structures [2].

Figure 1. Bridge age along German federal highways, [1].

Long-span prestressed concrete bridges are typically constructed by concreting in sections (see Figure 2). Each section is prestressed as a partial structure to avoid the accumulation of frictional losses over the length of the superstructure. Each new section is prestressed against the previous one. The tendons are connected at the coupling joints by coupler anchors. One half of the fixed coupler anchor is embedded in the concrete of the previous section and serves as the end anchorage during the construction of this section. The

other half of the anchor is located in the new section (see Figure 2). The tendons are then connected by tying the tendons of the next section to the coupler anchor already embedded in the concrete [3].

Figure 2. Section-by-section construction of a prestressed concrete bridge and a historical construction detail of a coupling joint, [4].

The first case of fatigue failure to coupler joints – and the only known fatigue failure to date – occurred in 1976 in the bridge “Hochstraße Prinzenallee” in Düsseldorf, Germany. This incident led to extensive theoretical and experimental research

[5; 6] as well as to the complementation of the technical rules for coupling joints in Germany. These regulations include the calculation of fatigue resistance, the more precise assessment of internal forces, and new design regulations. As a result of these regulations, it can generally be assumed that the coupling joints constructed from 1979 have no fatigue deficits [7]. The following causes of damage in coupling joints (vertical cracks and fatigue of tendons) were identified [3; 8; 9]:

- Concrete tensile strength in the joint is negligible;
- Neglect of temperature gradient over the height in the design stage;
- Position close to the points of contraflexure, where the temperature effects, and the scattering of the dead loads are important factors to consider;
- Non-linear strain distribution due to sectional prestressing;
- Internal stress states due to hydration heat;
- Increased prestressing losses in the coupling joint because of creep, shrinkage, and prestressing steel relaxation (CSR) due to the larger geometry of the couplers;
- Reduced fatigue strength of the tendons in the coupling joint due to fretting corrosion;
- Uneven distribution of tendons across the cross-section.

Consequently, infrastructure operators have routinely carried out recalculations of existing bridges based on advanced standards and guidelines. The recalculation guideline for existing road bridges [10] plays a key role in this context. After the introduction of this guideline in 2011, the results of the first recalculations were systematically evaluated in a research project on behalf of the Federal Highway and Transport Research Institute [11]. In this study, 43 % of the 126 investigated prestressed structures showed a calculational fatigue deficit at the coupling joints. This makes the fatigue verification of coupling joints the second most frequent failure mechanism that leads to calculational deficits. The recent evaluation of recalculations [7] took into account the first supplement to the recalculation guideline from 2015 [12]. The coupling joint fatigue was recalculated for 63 bridges, of which 33 showed deficits. In 37 % of the recalculations with coupling joint deficits, the fatigue resistance was exceeded by more than 50 % [7], see Figure 3.

Figure 3. Fatigue deficits for coupling joints according to the German recalculation guideline after 2015, [7].

These calculational deficits do not necessarily indicate actual structural damage. However, they often lead to expensive external post-tensioning or even to a premature demolition of a bridge before the end of its intended service life. To improve

the assumptions about the actual impacts and resistances, the use of monitoring data is a powerful tool. The objective of monitoring is to reduce epistemic uncertainty, which arises from incomplete knowledge and can be reduced by increasing the amount of information or improving the model quality. In contrast, aleatory uncertainty – reflecting inherent randomness such as signal noise – is considered irreducible and is typically modeled stochastically [13–15]. In structural safety assessment, conservative assumptions are generally applied. Therefore, reducing epistemic uncertainty through monitoring data is expected to have a beneficial effect on the estimated load-bearing capacity and the predicted service life of the structure. This is especially true for bridges with high traffic volumes that exhibit considerable temporal variations in load, where incorporating measured daily temperature and traffic loads can yield more accurate results [16].

However, monitoring methods applied in practice are highly heterogeneous, with no standardized guidelines for the design of measurement systems, data evaluation, or data integration in the measurement-based recalculation. Standards for data quality requirements and quantifiable quality indicators are also missing. Consequently, monitoring concepts are often based on empirical knowledge, and the assessment of data quality remains subjective. The quality of the monitoring concept directly influences the quality of the resulting monitoring data, which in turn affects the reliability of structural condition assessments. Therefore, it is essential to consider both the data quality and the quality of the monitoring concept itself.

This paper presents a systematic methodology for the evaluation of an existing temperature monitoring concept, with regard to selected quality characteristics and their impact on the recalculation results using coupling joints as an example.

## 2 TEMPERATURE MONITORING FOR BRIDGE ASSESSMENT

The relationship between the bending moment  $M$  and the prestressing steel stress  $\sigma_P$  is described by the moment-stress diagram. The normal force, prestressing force, geometry of the cross section, material stiffness and tendon distribution influence the position and shape of the moment-stress curve, which is shown in Figure 4. It consists of three sections [17]:

- Linear-elastic behavior in uncracked state (Mode I)
- Transition area with concrete tensile strength  $f_{ct} = 0 \text{ N/mm}^2$
- Distinct cracked state (Mode II).

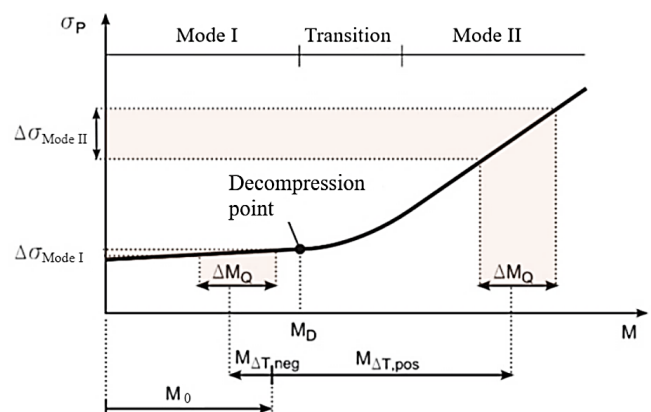

Figure 4. Moment-stress diagram for prestressing steel, [3].

In addition to the alternating moment  $\Delta M_Q$  due to traffic impact, the so-called base moment  $M_0$  has a substantial influence on the stress range  $\Delta \sigma_p$ . The base moment  $M_0$  is caused by the following components: dead weight of the structure, statically indeterminate part of the prestressing, losses due to CSR, redistributions from the construction to the final state, settlements as well as temperature loads. As long as the structure remains in Mode I, the stress range  $\Delta \sigma_{\text{Mode I}}$  is relatively low. However, once the decompression point is exceeded ( $M > M_D$ ) and the upper stress enters Mode II, fatigue-relevant stress ranges  $\Delta \sigma_{\text{Mode II}}$  are expected. The stress range  $\Delta \sigma_p$  in Mode II is considerably higher than in Mode I, despite the same impact through  $\Delta M_Q$ . The increase in the base moment  $M_0$  required for the Mode II can be caused, for example, by large vertical temperature gradients  $M_{\Delta T, \text{pos}}$  or prestressing losses [8]. For coupling joints, the moment component induced by temperature gradients is decisive in comparison to permanent loads, as they are typically located close to the points of contraflexure (points of zero bending moment). For older existing structures, variations of the base moment depend primarily on the temperature gradient, as redistributions, settlements and CSR are already completed [9].

For the reasons stated above, fatigue calculation of prestressed concrete bridges requires, in addition to the stress range  $\Delta \sigma$  in the prestressing steel from the traffic load  $\Delta M_Q$ , the knowledge of the magnitude of the base moment  $M_0$ . Therefore, the stress range monitoring in coupling joints is usually combined with temperature measurements. The temperature load  $M_{\Delta T}$  is a non-stationary variable influenced by environmental factors. While solar radiation and air temperature determine the general thermal input, wind speed and humidity affect the rate of heat exchange between the structure and the surrounding air. Additionally, the geographical orientation of the structure, height above ground, pavement thickness and other factors affect the temperature load [16].

Figure 5. Temperature field components, [16].

The temperature field of a bridge cross-section can be divided into three components (Figure 5): (1) *The constant component*  $T$  induces no internal forces or stresses if the deformation of the structure is not impeded. (2) *The linear component*  $\Delta T_v$  causes a curvature that creates a constraining moment if the deflection is impeded. This component results in internal forces and therefore stresses in the cross-section. Only this component is considered in fatigue recalculations of coupling joints. (3) *The non-linear component*  $T_E$  is usually neglected in calculations of stresses [18].

In order to capture the linear temperature gradient over the entire cross-section, it is necessary to suitably distribute temperature sensors over the cross-section and to choose an appropriate monitoring period [16]. According to [2; 19], a measurement period of a whole year is sufficient to determine the structure-specific temperature load in the coupling joint. However, for Germany, the measurement period can be reduced to 3 to 6 months during the summer months (May to August), as both the highest positive and negative temperature gradients occur during this period [18]. Winter months are unsuitable for monitoring due to the low intensity of solar radiation. High gradients are especially observed when a cool, cloudy period is followed by a sunny day [9]. In [20] on the basis of measurements on a bridge and in [18] on the basis of simulation calculations, it was determined that the greatest temperature changes over the cross-sectional height occur in

Figure 6. Illustration of the openLAB bridge including the standard cross-sections (Graphic: Fabian Collin, Max Herbers).

the slab, which requires a denser arrangement of temperature sensors in this area than in the webs.

The following section presents the existing measurement concept for recording temperature effects on a demonstrator structure – the openLAB research bridge located in Germany.

### 3 CASE STUDY: RESEARCH BRIDGE OPENLAB

#### 3.1 The structure and its coupling joint

The reference structure openLAB is a 45-meter-long and 4.5-meter-wide prestressed concrete bridge located in Bautzen, Germany. Constructed as part of the research project IDA-KI, it serves as a large-scale demonstrator for advancing structural health monitoring (SHM) and digital twin technologies. The bridge comprises three 15-meter spans, each meticulously designed to address specific research objectives [21].

Spans 1 and 2 consist of three precast elements (PE) with T-shaped cross-sections, which are transversely connected by a cast-in-place concrete layer, see Figure 5. Span 1 has been designed to replicate typical structural deficiencies of early tensioning methods, such as coupling joint problems, stress corrosion cracking, and areas with reduced shear capacity. Span 2 represents state-of-the-art construction methods and integrates innovative “smart tendons” which are equipped with integrated distributed fiber optic sensors [22]. Span 3 showcases a prefabricated construction system that eliminates the need for cast-in-place concrete. This system employs hollow precast elements that are transversely coupled by grouting joints, enabling the PE to be fully loadable immediately after installation.

All PEs are prestressed with strands that have an immediate bond. In addition, PE 1.1 and 2.1 are post-tensioned (see Figure 6 and Figure 7). The structural system features monolithic connections between the superstructure and substructure at axes 10 and 20. At axis 30, a connection between spans 2 and 3 with ultra-high-performance fiber-reinforced cementitious composite material (UHPFRC) is planned. However, the connection will be implemented at a later stage, after the first load tests planned for May 2025. Currently, span 3 remains statically decoupled from the other two spans.

The coupling joint under investigation is situated in PE 1.1, at the estimated point of contraflexure. The PE was constructed in multiple stages. Initially, a 4-meter segment of the element was fabricated and partially post-tensioned. Subsequently, the remaining 11-meter segment was cast, which also included the partial prestressing of the second tendon. The connection between the first and second tendons was achieved using a fixed coupler, certified under European Technical Assessment No. 13/0839. The first tendon was anchored in a manner consistent with the use of an anchor head for stressing anchors. In addition to a stress anchor, the coupler head provides a projecting ring collar with slots. The prestressing steel strands of the second tendon were placed in the slots and secured with a tensioning belt. Following this, the strands in immediate bond were prestressed, and the tendons in subsequent bond were tensioned to their final prestressing force. Finally, the tendon ducts were grouted to ensure proper bonding and corrosion protection of the prestressing steel.

#### 3.2 Temperature monitoring of openLAB

A comprehensive monitoring system has been installed at the openLAB since “hour zero” – the beginning of the construction phase. This monitoring system integrates global and local measurement techniques, providing detailed insights into the bridge’s structural behavior and environmental influences. Acceleration, inclination, and displacement sensors are employed to assess global structural behavior. Concurrently, environmental parameters such as air temperature, relative humidity, solar radiation, and precipitation are continuously recorded to account for external influences. Local measurements, in contrast, target areas susceptible to structural damage. These include strain gauges on reinforcement bars, distributed fiber optic sensors (DFOS) embedded in the concrete, and linear displacement transducers to monitor crack widths, e.g., in the coupling joint.

The component temperature is measured using temperature sensors, which were embedded into the PE 1.1 near the coupling joint during the construction phase. There are three temperature sensors (PT100) distributed over the height (see Figure 7). These sensors have been continuously recording data at 10-minute intervals since February 2024 until today.

To assess the influence of temperature measurement uncertainty on the recalculation results for the coupling joint, temperature data recorded by the component temperature sensors between January 31, 2024, and February 28, 2025, at 10-minute intervals, was used to calculate the linear temperature gradient. A reference dataset – Test No. 0.1 – was defined by using the full observation period (January 2024 to February 2025), a sampling interval of 10 minutes, and the complete sensor configuration including all three temperature sensors:  $T_{top}$ ,  $T_{middle}$ , and  $T_{bottom}$ .

Figure 7. Installed temperature sensors embedded in the PE 1.1 of openLAB; all measures are given in cm.

The linear temperature gradient  $\Delta T_{M,y}$ , which induces a bending moment  $M_y$  in the coupling joint under consideration, is calculated using the following equation [23]:

$$\Delta T_{M,y} = \frac{h}{I_y} \cdot \sum_{i=1}^n T_i \cdot S_{y,i} \quad (1)$$

In this formulation,  $h$  denotes the total cross-sectional height,  $I_y$  is the second moment of area about the  $y$ -axis,  $T_i$  represents the temperature at a specific sub-area of the cross-section, and  $S_{y,i}$  is the first moment of area of the respective sub-area. The cross-section is conceptually discretized into  $n$  small sub-areas. The temperature values between the fixed-position sensors ( $T_{top}$ ,  $T_{middle}$ , and  $T_{bottom}$ ) are linearly interpolated or extrapolated to estimate the temperature distribution throughout the height of the cross-section. This approach is not limited to the number of available sensors but rather assumes a continuous distribution of temperature across the section.

### 3.3 Fatigue simulation

The residual fatigue life is predicted based on the accumulated fatigue damage  $D$ . Failure occurs at  $D = 1$ . The fatigue damage is calculated according to Miner's rule [24]:

$$D = \sum_{i=1}^m D_i = \sum_{i=1}^m \frac{n(\Delta\sigma_i)}{N(\Delta\sigma_i)} \leq 1 \quad (2)$$

The damage at a load level  $i$  is derived from the ratio of applied load cycles  $n$  to bearable load cycles  $N$ . The load cycles until failure are obtained from the S-N curve (Wöhler curve) according to the stress range  $\Delta\sigma_i$ . The progression of fatigue damage is simplified through extrapolation of the frequency of calculated stress ranges  $\Delta\sigma_i$  from varying traffic and temperature loads.

For traffic loads, the fatigue load model FLM 4, as defined by EN 1991-2, was applied. It consists of five standardized truck types which represent the characteristics of heavyweight traffic in Europe. To achieve relevant stress states up to the ultimate limit state with reasonable testing effort, only 25 % of Load Model 1 according to EN 1991-2 was considered for the design of the openLAB. Consequently, FLM 4 was appropriately scaled to ensure realistic stress amplitudes. Relevant load positions for the truck types were determined using influence lines.

For temperature loads, both the temperature gradients from the recalculation guideline and the temperature gradients from structural monitoring are considered (see Section 4.1).

The annual damage contribution  $D_{year}$  is calculated as the sum of partial damages  $D_{\Delta T,i}$ , incurred during the passage of a standard vehicle of type  $i$  under the simultaneous action of the temperature gradient  $\Delta T$ . The index  $i = 1 \dots 5$  covers the five vehicle types according to the FLM 4. Only high temperature gradients combined with heavy traffic lead to fatigue damage. The partial damage is weighted according to the relative frequency of individual vehicle types  $p_i$  in the annual traffic volume  $N_{obs}$  and the annual probability of occurrence of the temperature gradient  $\lambda_{T,\Delta T}$ :

$$D_{year} = N_{obs} \cdot \sum_{\Delta T=\min \Delta T}^{\max \Delta T} \left[ \sum_{i=1}^5 p_i \cdot \lambda_{T,\Delta T} \cdot D_{\Delta T,i} \right] \quad (3)$$

The calculation of internal forces in the cross-section of the coupling joint was performed using a linear-elastic finite element (FE) model developed in SOFiStiK (version 2024). Given the complete decoupling of spans 1 and 2 from span 3, the structural model was simplified to a two-span system. The

T-beams were modeled using beam elements with six degrees of freedom per node (three translations and three rotations). In the transverse direction, the three parallel beam axes were coupled using plate elements (see Figure 8).

Figure 8: FE-Model of openLAB.

To accurately represent the load-bearing behavior of the integral structure, the abutment wall at axis 10 and the columns at axis 20 were modeled and rigidly coupled with the superstructure. Shell elements (abutment wall) and beam elements (columns) were used to idealize the substructures. At axis 30, the superstructure is supported on the substructure via a hinged connection. Thus, the pier wall at the support point was simplified using equivalent, linear-elastic springs. The tendons were integrated into the FE model according to their position in the construction plans. Prestressing forces were calculated internally by SOFiStiK and automatically applied to the intersected beam elements.

The structure was erected in various consecutive construction stages, which include the following: (1) manufacturing of the PEs in the factory; (2) construction of the substructures using cast-in-place concrete construction; (3) installation of PEs on temporary supports; and (4) production of the cast-in-place concrete layer for force-fit connection of PEs. The redistribution effects associated with this construction method, resulting from creep and shrinkage after the completion of the cast-in-place concrete addition, were accounted for in the FE model through different construction phases.

The calculation of the stress amplitudes  $\Delta\sigma_i$  were performed for the relevant cross-section also in SOFiStiK, considering the non-linear stress-strain relationships of concrete and steel.

## 4 IMPACT OF DATA QUALITY ON FATIGUE ASSESSMENT

### 4.1 Methodology

The collected measurement data only represents a sample from a total population. In this paper, three quality indicators were identified for the description of this property of measurement data at different levels: representativeness, coverage, and completeness. These quality indicators (for definition see Table 1) were originally presented by [25] for atmospheric measurements and adopted in the draft of VDI Guideline 3786 Sheet 1 [26]. These characteristics are adapted for the bridge monitoring and applied to the monitoring data of openLAB.

Completeness can be easily calculated as a percentage of the actual measurement data points relative to the expected measurement data points. This quality characteristic can be used to identify potential failures in the measurement system. In contrast, the other two quality characteristics – coverage and

representativeness – cannot be described with a simple formula and should already be considered when designing the measurement system. Therefore, the two characteristics – coverage and representativeness – are the subject of the following considerations.

Table 1. Quality characteristic for data of atmospheric measurements, [25; 26].

Quality characteristics	Definition according to [25; 26]
Representativeness	The ability of a series of observations to provide an unbiased estimate of a parameter of a specified statistical population.
Coverage	Spatial and/or temporal distribution of measurement locations in the area under investigation.
Completeness	The extent to which the information provided enables the data user to draw conclusions in accordance with the goal and scope definition.

Table 2 provides an overview of the definitions of these quality characteristics for bridge monitoring. Spatial representativeness refers to the areas of the bridge structure where sensors are installed. The temporal representativeness describes the period during which the data is collected. Spatial coverage describes the number of sensors distributed within the representative area of the structure and whether sufficient metrological redundancy is achieved. Temporal coverage refers to the sampling frequency of the measurements.

Table 2. Quality characteristics for bridge monitoring concepts.

Quality characteristics	Definition for bridge monitoring
Representativeness	Spatial: Local distribution of sensors
	Temporal: Period of data collection
Coverage	Spatial: Sensor density
	Temporal: Sampling frequency

Insufficient monitoring data completeness affects the coverage, which in turn affects the representativeness of the data. Furthermore, incorrect selection of monitoring areas and periods can render the monitoring results unusable for the intended use case, even if coverage and completeness are high. To address this problem, this paper presents a methodology using the openLAB research bridge as a case study. This methodology can be applied to identify sufficient representativeness and coverage of monitoring data.

The spatial representativeness is investigated by varying the local distribution of the sensors in the upper and lower area of the cross-section. To assess the temporal representativeness, the observation period for the temperature measurements at openLAB was systematically varied between two days and a whole year. Spatial coverage was analyzed by altering the number of sensors, while temporal coverage was assessed by applying different sampling frequencies. A total of four test

series were conducted in which only one of these three boundary conditions – observation period, sampling interval, sensor density, or local sensor distribution, – was varied at a time, while the others were held constant. This methodology corresponds to the one-at-a-time sensitivity analysis. The definition of the investigated test series is shown in Table 3.

Table 3. Definition of investigated test series.

No.	Description	Specification
0.0	Recalculation guideline	-
0.1	Reference measurement	12 months; 3 sensors
1.2	April – September	6 months; 3 sensors
1.3	May – August	4 months; 3 sensors
1.4	May – July	3 months; 3 sensors
1.5	June – July	2 months; 3 sensors
1.6	June	1 month; 3 sensors
1.7	08.07. – 09.07.2024	2 days; 3 sensors
2.2	0.00028 Hz (every hour)	12 months; 3 sensors
2.3	0.00002 Hz (every 12 hours)	12 months; 3 sensors
2.4	0.00001 Hz (every 24 hours)	12 months; 3 sensors
3.2	Upper and lower sensor	12 months; 2 sensors
4.2	Upper and middle sensor	12 months; 2 sensors
4.3	Middle and lower sensor	12 months; 2 sensors

Test Series 1 examines the impact of the temporal representativeness by shortening the observation period to six months (April - September 2024), four months (May - August 2024), three months (May - July 2024), two months (June - July 2024), one month (June 2024), and finally two days (July 8 - 9, 2024). The two-day period was selected according to the criteria that a cloudy day was followed by a sunny day [9]. This ensured a strong increase in air temperature and solar radiation within the observation period (Figure 9), which is expected to lead to high temperature gradients in the structure.

Figure 9. Meteorological data for the location Bautzen, Germany for the period from July 1<sup>st</sup> to July 15<sup>th</sup> 2024, [27].

Test Series 2 investigates the influence of the temporal coverage, i.e., sampling interval, by increasing it from the reference value of 10 minutes to 60 minutes, 720 minutes, and 1440 minutes.

Test Series 3 examines the effect of spatial coverage. In addition to the reference case using all three sensors ( $T_{top}$ ,  $T_{middle}$ ,  $T_{bottom}$ ), this scenario considers only two sensors:

$T_{top}$  and  $T_{bottom}$ . Due to the limited number of installed sensors, only one variation of spatial coverage was possible.

Test Series 4 addresses the spatial representativeness in two scenarios with two sensors each:  $T_{top}$  and  $T_{middle}$ , and  $T_{middle}$  and  $T_{bottom}$ , with the objective of concentrating the sensors primarily at the bottom or top of the cross-section.

The probability distributions for the temperature gradients were determined according to the methodology presented in Section 3.2. The results of the parameter study for the calculation of the linear temperature gradient  $\Delta T_{M,y}$  are illustrated in Figure 10. The linear temperature gradient determined for the openLAB is presented as a histogram of relative frequency  $f$  over  $\Delta T_{M,y}$  for each test case. The reference case exhibits an approximately normal distribution, whereas, for example, Test 1.7 (observation period from July 8 to July 9, 2024) shows a notable deviation from normality due to the limited number of temperature readings. Other histograms reveal distributions with varying degrees of positive or negative skewness when compared to the reference distribution.

In the next step of the analysis, these histograms derived from real-world temperature measurements will be used to estimate the remaining service life of the openLAB structure according to the Section 3.3.

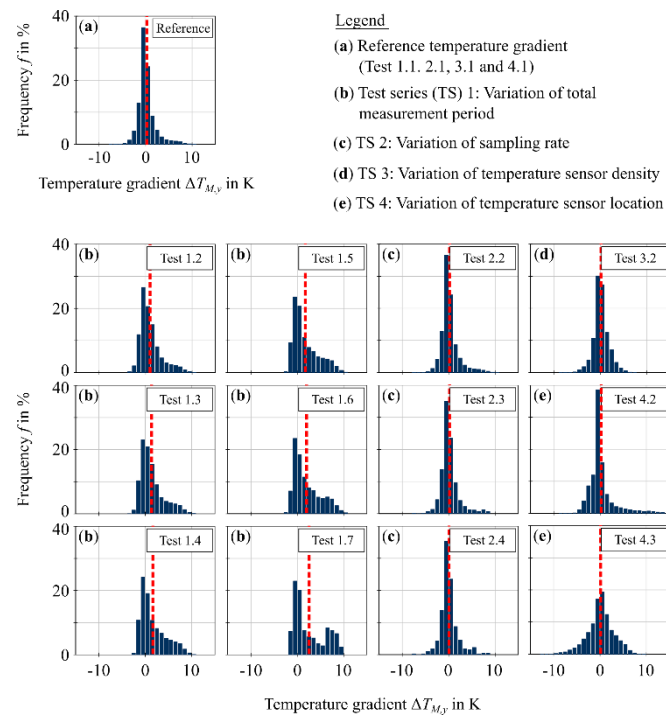

Figure 10. Parameter study on the influence of temperature measurement uncertainty on the linear temperature gradient. (a) Reference distribution; (b) Test series 1: Variation of total measurement period; (c) Test series 2: Variation of sampling rate; (d) Test series 3: Variation of temperature sensor density; (e) Test series 4: Variation of temperature sensor location.

In the German recalculation guideline [10], the temperature gradients are calculated in accordance with the reference standards DIN FB 101 and Eurocode DIN 1991-1-5. In addition, probabilities of occurrence for temperature gradients

are specified for the calculation with the fatigue load model FLM 4. The guideline states temperature gradients to be applied according to the probability of occurrence and the cross-sectional shape of the bridge (box girder, T-beam, or slab) for a pavement thickness of 50 mm. The probabilities of occurrence for the temperature gradients were determined based on extensive investigations in [16]. For this purpose, hourly weather data were collected over eight years for three typical bridge cross-sections and evaluated statistically. The distribution and the daily course of the temperature load given in the German recalculation guideline were derived from this data. This standardized probability distribution is compared to the bridge-specific measurements of openLAB in Section 4.2. This comparison enables a quantification of the uncertainty in  $\Delta T_{M,y}$  and its impact on the total service life assessment of the openLAB bridge.

## 4.2 Results

The results of the temperature gradient evaluation and the recalculation of the total service life for the coupling joint fatigue are summarized in Table 4. The first column corresponds to the test number. Test No. 0.0 represents the normative distribution given in the recalculation guideline, while No. 0.1 corresponds to the reference distribution, for which the entire temperature data set was utilized. The second and third columns contain the mean values  $\mu$  and the values of the standard deviation  $\sigma$  of the temperature gradients  $\Delta T$  in Kelvin. The third column provides the total service life in years for the respective data set about fatigue in the coupling joint. The last column shows the relative deviation of the service life compared to the reference distribution No. 0.1 in percent.

Table 4. Results of fatigue calculation.

No.	$\mu$ of $\Delta T$ in Kelvin	$\sigma$ of $\Delta T$ in Kelvin	Absolute service life in years	Relative deviation of service life in %
0.0	1.800	$\pm 2.619$	1077.583 (recalculation guideline)	+ 7.69
0.1	0.198	$\pm 1.887$	<b>1000.634 (reference)</b>	-
1.2	0.983	$\pm 2.289$	1051.303	+ 5.06
1.3	1.357	$\pm 2.463$	1075.903	+ 7.52
1.4	1.625	$\pm 2.698$	1092.141	+ 9.14
1.5	1.720	$\pm 2.731$	1098.567	+ 9.79
1.6	2.013	$\pm 2.873$	1117.958	+ 11.72
1.7	2.546	$\pm 3.334$	1147.002	+ 14.63
2.2	0.198	$\pm 1.887$	1000.509	- 0.01
2.3	0.176	$\pm 1.954$	998.609	- 0.20
2.4	0.082	$\pm 1.926$	992.569	- 0.08
3.2	0.184	$\pm 1.633$	1001.866	+ 0.12
4.2	0.220	$\pm 2.820$	989.575	- 1.11
4.3	0.146	$\pm 2.839$	985.031	- 1.56

Overall, the variations in the measured data result in only minor deviations in the service life, which was determined to be approximately 1045 years on average for all test series. The service life that was calculated on the basis of the reference configuration gave a result of approximately 1001 years. Relative values range from -1.56 % to +14.63 %. This observation indicates that the impact of the temperature

measurement uncertainty may not be a relevant factor for this structure with a relatively moderate influence on the fatigue of the coupling joint. The identification of relevant influence factors on the fatigue of the openLAB bridge will be systematically investigated in the further course of this study using a sensitivity analysis. It will enable a comparison of temperature influences with other relevant factors such as variation of traffic loads, prestressing losses or material properties.

It can be seen that the probability distribution of the temperature gradients from the recalculation guideline No. 0.0 leads to a slight overestimation of service life (+ 7.69 %) compared to the reference distribution No. 1.1 based on the complete measurement temperature data. In test series 1.2 to 1.7, in which the recording period becomes progressively shorter, there is a shift in the mean value towards high gradients and an increase in the standard deviation. Contrary to the expectation that this temperature gradient distribution would result in a reduced service life of the bridge, it continues to increase. This finding contradicts the information available in the literature (e.g. [9; 18; 20]), where the more frequent occurrence of positive temperature gradients (i.e., shorter measurement period in the summer months) normally leads to shorter service life. This unusual observation can be attributed to the initial stress state of the structure. Prestressing generates high negative bending moments in the coupling joint of the openLAB bridge (see Figure 11).

Figure 11. Moment-stress diagram for coupling joint of openLAB with moment impacts caused by applied temperature gradients.

The most extreme temperature gradients  $\Delta T$  determined from all test series in Figure 10 are  $-12.5$  K and  $+15.5$  K. The range of base moments  $M_0$  resulting from all measured temperature gradients between these values is represented as a purple section on the curve in Figure 11. The moments that lead to cracks in the cross-section  $M_D$  (exceeding the decompression point) are marked with blue arrows.  $M_{D,top}$  represents the base moment that causes the cross-section to crack at the top of the bridge cross-section.  $M_{D,bottom}$  represents the base moment that leads to cracking at the bottom edge. It can be seen that the calculated positive temperature gradients are not high enough to cause cracking at the bottom edge. Consequently, negative temperature gradients result in higher stress ranges in the prestressing steel and, therefore, greater partial fatigue damage

$D_{\Delta T,i}$  compared to positive temperature gradients of the same absolute magnitude. This explains why the positive gradients have a positive effect on the load-bearing capacity of the structure. In this case, the coupling joint tends to crack at the upper edge of the cross-section instead of cracking at the bottom edge, as is the case with conventional prestressed bridges [5].

The variation of sampling frequency (Test No. 2.2 – 2.4), sensor density (Test No. 3.2), and local distribution of sensors (Test No. 4.2 and 4.3) have a considerably lower influence on the service life span than the period of data collection (Test No. 1.1 – 1.7). Consequently, a reduced frequency of measurements, may suffice to reliably estimate the actual temperature distribution. A lower sampling frequency reduces the amount of data collected. The impact of variations in local distribution cannot be reliably assessed in this particular case due to the limited number of sensors available. To obtain reliable results, additional temperature sensors are required, particularly within the slab of the openLAB bridge and in the edge areas of the component, where the largest gradients occur. The installation and operation of additional sensors in the openLAB is carried out in April 2025. The same evaluation methodology will be applied again with the new data generated by additional sensors to prove the representativeness and coverage of the enhanced monitoring concept.

## 5 CONCLUSIONS AND OUTLOOK

This study provides a methodological approach for the systematic evaluation of the monitoring concept quality applied to a bridge structure. The fatigue recalculation of the coupling joint was utilized as an example for the implementation of the sensitivity analysis concerning the temperature data. It is based on a single case study of a research bridge, which limits the statistical significance of the results. It should be mentioned that the research bridge used in this study has considerably smaller dimensions and a different structural design compared to typical prestressed concrete bridges. Consequently, the findings cannot be directly generalized to conventional prestressed bridges. The primary focus of this work is the methodology itself, which requires further testing and validation on real-world, full-scale bridges. The introduced methodology can be applied to other sensor types and failure mechanisms.

The presented evaluation of temperature data indicates that, in this particular case study, the temporal representativeness expressed by the varied period of data collection has the most impact on the fatigue calculation of the coupling joint. The lower temporal coverage expressed by the lower sampling frequency does not notably affect the results of the recalculation. Spatial coverage and spatial representativeness could not be properly evaluated in this case study due to the limited number of sensors. It is not yet possible to derive universally applicable recommendations for the design of measurement systems for coupling joints based solely on this case study. Further investigations with a greater number of sensors are required to achieve this objective.

In addition to temperature monitoring, concrete strain or prestressing steel strain ranges are usually recorded at coupling joints. To determine an appropriate holistic monitoring concept for this specific structure, investigations are also required for

these measurements. The load tests that will be performed on the openLAB bridge in 2025 can be used to validate and update the existing FE model. The appropriate estimation of the base moment  $M_0$  and the determination of the moment-stress curve, which describes the transition of the coupling joint from Mode I to Mode II, play a key role in this context.

In summary, further research on the quality of monitoring concepts has the potential to refine existing monitoring approaches and to provide a more accurate assessment of impacts at coupling joints of prestressed concrete bridges. The quality control of monitoring concepts and data should be incorporated as a key component in relevant standards and regulations. This not only facilitates a more reliable condition assessment but also supports a potential extension of the service life of bridge structures.

## ACKNOWLEDGMENTS

This research was funded by the Federal Ministry for Digital and Transport within the research project ANYTWIN (Standardizing Monitoring Based Safety Assessments of Bridges and the Integration into Digital Twins, grant number: 01F2248B) and by the German Research Foundation (DFG) as part of the Priority Program 2388 (SPP 2388) "Hundred plus – Extending the Lifetime of Complex Engineering Structures through Intelligent Digitalization" (project number: 501808860). email: paul.thurlow@geo-instruments.com Sergio Estrada@geo-instruments.com

**ABSTRACT:** Spanning across Freeway 101, several rail roads and the LA river, the 6th Street Viaduct replacement project is one of the largest bridge projects in the City of Los Angeles. The original bridge was built in 1932 and became a backdrop to the film industry. The iconic bridge was demolished following the decision to replace it with the existing 6th Street Viaduct due to the structure becoming seismically vulnerable. At 3,060-ft-long and 100-ft-wide, the redevelopment of the new bridge – designed by Michael Maltzan, – includes 10 network arch spans, with a total of 388 hangers supporting the bridge deck. The bridge spans 101 Highway, the Los Angeles River. The hanger installation and stressing for the bridge was a complex procedure that would need careful attention to detail for loading the hangars before removal of formwork and for fine tuning the final load criteria. There were 18 load sequences per arch. The instrumentation and monitoring of the hangars while loading required a novel approach that started two years in advance of the works with development of a bespoke system, calibration and acceptance. During installation and works many lessons were learnt by all parties involved. The close working relationship with a desire to succeed between the site team and designers was as fascinating as the technical brilliance applied by all to deliver this section of the project in a safe manner, within the schedule and to the specification.

**KEY WORDS:** Bridge; structural monitoring; strain gauges, load verification, dataloggers, hangers

## 1. Introduction

The 6<sup>th</sup> Street Viaduct replaced the original, beloved bridge in 1932, which had been deteriorating for decades due to alkali silica reaction. This condition is caused by an aggregate in the concrete that drew in moisture and caused cracks. After repeated attempts to retrofit the old bridge the decision was made that it needed to be replaced. In 2012, after much outreach and consultation with the community, the Los Angeles Bureau of Engineering held an international design competition to select a design for the new viaduct. Michael Maltzan Architects, a local Los Angeles firm, and HNTB, were the winners with the design, called "The Ribbon of Light".

In 2016 the bridge was demolished completely, and construction on the new Sixth Street Viaduct began. Funded by the Federal Highway Transportation Administration, the California Department of Transportation, and the City of Los Angeles, the \$588 million Sixth Street Viaduct Replacement Project was led by the Los Angeles Bureau of Engineering under City Engineer Gary Lee Moore in partnership with the LA Bureau of Contract Administration.

The new Sixth Street Viaduct consists of 10 pairs of arches that range in heights from 30 feet to 60 feet tall. Each arch has a 9-degree outward cant, 10-foot width, and requires 260 cubic yards of concrete. Arches had to be poured at a rate of 4 vertical feet per hour for a total of 12-14 hours per arch due to the formwork and intricate support system.

The arches join into a Y-shaped column, and in total, the 23 columns and 2 abutments of the bridge use triple friction pendulum bearings for seismic base isolation. These bearings allow movement up to 30 inches in any lateral direction, not only ensuring earthquake survival, but making the Sixth Street Viaduct one of the largest base-isolated structures in the world. Generally, construction developed from east to west and was led by contractor Skanska-Stacy and Witbeck Inc. Arches were poured without cables in place, then cables 2 3/4 in. in diameter were added and tightened to create a network-tied arch structure.

## 2. Development of a Custom Load Verification System.

Following an extensive series of interviews with manufacturers specializing in conventional load verification technologies, the contractor—Stacy Witbeck Skanska Joint Venture (JV)—engaged Geo Instruments to develop a bespoke load verification system tailored to the unique constraints of the Sixth Street Viaduct project. A key requirement was that instrumentation could not be integrated during strand manufacturing due to the complexity of the process. The system needed to be repeatable, allow for self-performed installation by the JV team following training, and support real-time data acquisition both on the bridge deck and remotely for review and approval by the design team based in Canada. Load measurements were required to achieve accuracy within 2 % of the target load for each loading cycle.

Traditional strand loading methods typically employ in-strand tensiometers or vibration-based devices. However, the project's emphasis on repeatability and operational simplicity led to the selection of vibrating wire strain gauges—recognized for their reliability and proven performance in structural load measurement.

Vibrating wire strain gauges operate by tensioning a steel wire between two fixed anchors within a stainless-steel housing. Electromagnetic coils induce oscillation in the wire via a brief voltage or swept frequency excitation. The wire vibrates at its resonant frequency, generating a sinusoidal alternating current. This frequency is captured by a readout unit or data logger equipped with a vibrating wire interface and converted into engineering units of strain. Changes in structural force alter the wire's tension, thereby shifting its resonant frequency. The square of the frequency change is directly proportional to the change in strain.

These gauges are cost-effective, durable, and compact, with the capability to record data at intervals as short as one second. For this application, low-profile vibrating wire strain gauges manufactured by Geosense (UK) were selected. The

chosen model had a maximum strain capacity of 3000  $\mu\epsilon$  which was deemed suitable for the expected load range.

To ensure consistent and accurate strain measurements, each vibrating wire strain gauge was mounted on a custom-engineered aluminum clamp designed to securely interface with the prestressing strands. The clamp assembly was developed to prevent slippage or misalignment during strand elongation, thereby preserving measurement integrity. A secondary carrier clamp, positioned above the primary clamp, housed the strain gauge and enabled reuse across multiple strands without compromising performance or structural integrity. The prototype assembly was presented to the client for review and approval.

Figure 3. Prototype strain gauge assembly.

## 3. Load Verification Tests.

An opportunity to conduct a destructive test on a single strand was utilized to validate the design. The initial test setup included two strain gauges mounted on opposite sides (top and bottom) of the test strand. The gauges were configured to record data at five-second intervals. The testing facility prepared and rigged the test frame to simulate loading conditions representative of field operations, in such a way that

there were not any incremental load stops to verify the load and strain alignment. The test was too fast, and load profiles generated on the test machine did not mimic the anticipated loading sequence anticipated on site. The initial destructive test provided limited insight into the load recording capabilities of the test frame. Unfortunately, the load data output was incompatible with standard data analysis platforms such as Microsoft Excel, which hindered post-processing and review. Following this session, and in consultation with the client, it was agreed to proceed with a single strain gauge per strand for subsequent tests. This decision was based on the observation that strand bending was negligible due to the strand's diameter and length, and that dual-gauge setups would unnecessarily slow down field operations.

The second test session comprised a series of ten proving tests, each requiring the strand to withstand a load of one million pounds prior to failure. Strain gauges were mounted at the mid-span of each strand, and data was recorded at two-second intervals. The resulting strain measurements demonstrated strong consistency and alignment with expected values, thereby validating the reliability of the system and increasing confidence in its field performance.

Despite the successful strain data acquisition, the load recording methodology employed by the testing facility remained a limitation. The format of the load data continued to be incompatible with standard analytical tools, presenting challenges for integration and review by the project team

Figure 3. Testing hanger strands to destruction.

The third round of testing was conducted at the strand manufacturer's facility, enabling a more controlled environment and allowing tests to be performed at loading rates that closely matched field conditions. This controlled setup facilitated more accurate correlation between applied load and strain gauge measurements.

Following these tests, the client reviewed the results and verified the accuracy of the instrumentation system. Based on the successful performance and alignment with project requirements, the client approved the methodology and proceeded with the procurement and fabrication of the full instrumentation system.

#### 4. Field Work.

During the planning phase, the decision was made to utilize Campbell Scientific CR6 data loggers, equipped with the necessary number of multiplexers to accommodate strain gauge readings. The CR6 model was selected primarily for its integrated Wi-Fi capability, which enables real-time data visualization, an essential feature for the loading team during operations. Each arch structure required instrumentation of approximately 18 to 22 strands, with the optimal placement for the data loggers initially identified as the base of the arches, housed within secure enclosures.

Figure 4. Strain Gauge assembly and logger setup.

Strain gauge cables were procured based on the measured distances to the midpoints of each strand, with additional length included to ensure connectivity to the central logger. However, due to significant incidents of theft and equipment damage during the early stages of construction, the client mandated the relocation of the logger enclosures to the top of the arches. To accommodate this change in routing and cable length, pigtail with M12 connectors were added to both the loggers and multiplexers. Each pigtail was uniquely numbered to correspond with its respective strand, streamlining the installation process.

Although relocating the data loggers to elevated positions introduced logistical challenges—particularly related to working at height—the use of modular connectors proved to be a significant advantage. These connectors simplified installation and maintenance, especially under constrained site conditions.

To ensure all stakeholders were aligned with the revised installation procedures and loading protocols, the client organized a pre-installation workshop. This session brought together the site personnel, design team, and representatives from Geo Instruments to review the updated methods, including bracket installation, strain gauge handling, and the specific loading cycles planned for each arch. This collaborative approach helped streamline field operations and ensured consistency across the instrumentation process.

Figure 5. Typical Load sequence of strands per arch.

The pre-installation workshops proved instrumental in resolving potential installation issues and allowed the team to simulate and troubleshoot scenarios that could arise during field operations. As is common with large-scale infrastructure projects, the introduction of a novel instrumentation method attracted attention from a wide range of stakeholders. In anticipation of this, the first week of loading operations was dedicated to comprehensive onsite training. This included verification of installation procedures, validation of data flow, and execution of trial runs to ensure system readiness.

Figure 6. View of typical strand hanging operation

During installation, each strand was secured to the top of the arch using custom holders, aligned with corresponding lower brackets, pinned, and subsequently tensioned. The strain gauge was connected to the strand and set to 1000 Hz manually using a GK404 VW readout to accommodate the expected loading tension. The strain gauges were factory calibrated in bulk to avoid any errors in this process. Given the length of the strands (up to 40 feet) significant initial curvature was observed prior to loading which forced a revision of the strain gauge loading

sequence to avoid strain gauge bending. A bedding-in phase was necessary to allow the strand to settle and align properly before the verification load was applied. A proving load of 10 tons was established as a baseline across the project to confirm system integrity. Operational loads for individual strands varied between 48 and 100 tons, depending on their location and structural role within the arch system. The contractor's jacking system consisted of a custom hydraulic setup featuring a yoke-style configuration designed to sit directly over each strand. This system included integrated load readouts and was operated via a tablet interface that displayed calculated load values derived from strain measurements at 30-second intervals.

Figure 7. Contractors strand loading system

Typical strain gauge readings, acquired through up to eight Campbell Scientific CR6 Wi-Fi data loggers with two number 32 channel multiplexers each, installed on the arches were recorded at one-second intervals per gauge and converted to load. During each loading sequence, the supervising engineer plotted the strain gauge load data against the hydraulic jacking system's load readings. These plots were reviewed and verified in real time by the City Engineer. Each strand's loading cycle was individually signed checked and signed off to ensure compliance with the performance criteria.

Figure 8. Hangar required load with applied load site plots

The data from the strain gauges was sent via modem and Wi-Fi to the Geo Instruments servers and in-house visualization software – Quickview.

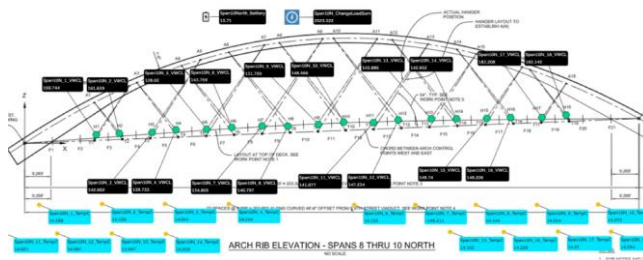

Figure 9. QuickView visualization platform

This software portal allowed the designers and contractors not on the bridge to view the loading sequence, one minute behind the actual site work. The data points on the site view showed digits, load and temperature for each strain gauge as well as the accumulative total load of the arch. Data was viewed and downloaded by consultant Ramboll for design verification and quality control reporting.

Figure 10. Sequence of strand installation.

### Temperature Effects and Adaptive Stressing Strategy

Temperature played a significant role in data interpretation and reduction throughout the project. Fortunately, the early phases of construction coincided with an unusually overcast period in Los Angeles, resulting in minimal temperature variation during the typical eight-hour workday. To further mitigate thermal effects, each strain gauge was wrapped in a heat-shielding material. While clamp-on heat shields were initially considered, they proved impractical for field use due to their bulk and handling complexity. Although the City of Los Angeles initially considered retaining the strain gauges for long-term monitoring post-commissioning, this plan was ultimately removed from the project scope during execution.

In the final three months of arch construction, weather conditions shifted unexpectedly, with unseasonably high temperatures becoming a concern. The combination of

intense solar radiation, the elevated position of the arches, the increased number of arches complete and the thermal mass of the concrete structure caused the bridge to act as a heat sink. This thermal buildup peaked during the same hours scheduled for hanger stressing, raising concerns about data reliability and structural behavior under elevated temperatures.

Rather than attributing delays or complications to any single party, the site team collaborated closely with the designers to analyze the data and identify the root cause of the discrepancies. With eight arches remaining to be instrumented, the team reviewed the sun trajectory and its impact on different arch segments. It became evident that larger arches and their associated strands were heating more rapidly and retaining heat longer than smaller ones, skewing strain readings throughout the day.

Figure 11. Temperature of strands on arch

To address this, the stressing schedule was revised. Work shifts were rescheduled to occur between midnight and 5:00 a.m., when ambient temperatures were more stable and thermal effects on the instrumentation were minimized. This proactive adjustment allowed the team to complete the stressing operations on schedule and within specification.

### 5. Conclusion.

All projects provide great feedback what went well and what could be improved on, it's how instrumentation and structural health monitoring evolves. In hindsight, the initial testing of the strain gauges should have been run under temperature variations, but as discussed, the testing locations were not suitably equipped up for long testing load cycles. The very fast load cycles in the testing locations and the ability to capture data in format that was compatible with instrumentation loggers turned out to be an issue. Such is the rarity of these large-scale tests; it would require some investment from all parties to get suitable outputs.

Figure 12. View of one completed arch.

The success of the Sixth Street Viaduct instrumentation program was driven by collaborative efforts, continuous feedback, and iterative improvement cycles among all stakeholders on site. The designer's clear articulation of data requirements, particularly the need for rapid and reliable access, guided the development of a robust instrumentation system, including the selection of strain gauges, bracket assemblies, and data loggers.

The site team played a critical role in refining installation procedures. Their feedback on bracket mounting techniques, bolt torque specifications, pre-connection verification methods, and data visualization strategies on the bridge deck significantly enhanced the practicality and reliability of the system.

Credit is due to the Los Angeles Bureau of Engineering for its foresight in supporting this novel testing approach. During early project meetings, concerns were raised regarding the lack of precedent for using this technique on large-scale strand bridges. Nevertheless, the Bureau's commitment to innovation enabled the development of a comprehensive and technically sound solution that instilled confidence across the project team.

The Sixth Street Viaduct replacement officially opened in June 2023, on schedule. It has since become an iconic structure within Los Angeles, earning multiple international awards for its design and construction excellence.

### Acknowledgments.

The authors would like to express their sincere gratitude to all those who contributed to the successful completion of this project. Special thanks are extended to the Stacey Witbeck Skanska Joint Venture and the management team: Emily Melkesian, Lee Pelton, and Robert Walent.

We acknowledge Geosense UK, particularly Tim and Martin Clegg, for their support, Tobias Petschke and his talented design team at Ramboll for their engineering insight. The authors further recognize the contributions of Geo Instruments and the Los Angeles Bureau of Engineering and HNTB for their collaboration and site support.

**ABSTRACT:** The Nova Scotia Department of Public Works (NSDPW), based on their observations and research, believe that the simplified method of analysis of timber bridges included in the Canadian Highway Bridge Design Code (CHBDC) yields excessively conservative load ratings for typical timber girder bridges in the province. With over 2000 such bridges in their inventory, this study looks to improve conservative load ratings by developing more realistic live load distribution factors for timber bridges based on load testing and analytical work.

NSDPW engaged SHM Canada to conduct load testing of selected timber bridges and to develop a new regime of realistic live load distribution factors derived from the test data. Six timber bridges of various characteristics were selected for this study to cover as wide a range of bridge configurations as possible in the provincial inventory. The collected displacement and strain measurement data were analyzed and used to calibrate a large number of analytical models and followed by statistical and mathematical formulation of the proposed simplified method. The new method incorporates distribution factors specifically developed for timber bridges, by taking into consideration various parameters such as span length, girder spacing, and mechanical properties of the girders, to offer a fast, reliable, and cost-effective approach for evaluation and management of the province's timber bridge inventory.

**KEY WORDS:** Timber Bridge, Live load distribution factor, Load testing, Displacement transducer, SMA.

## 1 INTRODUCTION

The Nova Scotia Department of Public Works (NSDPW) inventory of bridges includes over 2000 timber bridges. These bridges are key components of the province's transportation infrastructure and are critical links on the local and collector roads. The majority of these bridges are short-span structures that have been in service for over 50 years [1].

Because of the size and importance of this inventory, substantial resources are dedicated for the inspection and load rating of these timber bridges. Currently, NSDPW uses the simplified method of analysis given in the latest editions of CAN/CSA-S6, the Canadian Highway Bridge Design Code (CHBDC/ the Code), for the load rating of in-service bridges and for the design of new timber bridges.

Based on their experience and research, NSDPW hypothesizes that load ratings determined through the CHBDC simplified methods are overly conservative for the types of timber bridges commonly found in the province. Comparison of results yielded by the CAN/CSA-S6-14 and -19 simplified methods to the results yielded by the preceding version (S6-06) show that the newer versions are relatively more conservative. This study has shown that even the simplified method in the 2006 edition of the Code yields more conservative load ratings for timber bridges than do the rigorous methods of analysis, [1-4]. Historically, NSDPW has used rigorous methods for analysis of its timber bridges. The application of these methods, however, is time-consuming and resource-intensive and would be too onerous to apply for the evaluation of NSDPW's timber bridge inventory. The overly conservative simplified methods, which have primarily been developed for steel and concrete bridges, also have a significant financial impact on the

province. The primary objective of this study, therefore, is to develop an easy to use, and efficient method of evaluation specifically for timber bridges.

SHM Canada Consulting Limited (SHM Canada) was engaged by NSDPW to carry out load testing of six preselected timber bridges, representing a significant portion of the inventory, and to develop new live load distribution factors for timber bridges in the Province of Nova Scotia that would offer a time- and cost-effective alternative to the more sophisticated analysis methods. The accuracy and efficacy of these factors will be critical to the continued safe operation of Nova Scotia's transportation infrastructure and for effective management of resources.

## 2 LITERATURE REVIEW

The current standard for the design and evaluation of bridges in Canada is CAN/CSA S6:19. Methods of calculation of live load distribution in CHBDC and its predecessor, the Ontario Highway Bridge Design Code (OHBDC), have been revised multiple times since 1983. These methods are categorized as either Simplified Methods of Analysis (SMAs) or Refined Methods of Analysis (RMAs).

RMAs emerged as the increasing availability and enhanced capabilities of computers in the 1980s and 1990s encouraged engineers to attempt more complex forms of analysis and to model bridges with a large number of structural elements. These methods are generally highly accurate but require significant modelling time [1], [5]. More time-efficient simplified methods are therefore required for analysis of large inventories of simpler structures (e.g. the NSDPW inventory of over 2000 timber bridges in Nova Scotia).

Finite Element Method (FEM), Semi-Continuum Analysis (SCA), Orthotropic Plate Theory, Grillage analogy, Folded plate theory... are some of the recognized RMAs in CHBDC, [1-4], however, only FEM and SCA were used in this study.

The Finite Element Method (FEM) is a powerful tool for analyzing simple to complex structures. The main challenge of this method remains a long modelling time [1] [5].

The semi-continuum analysis (SCA) method is useful for modelling timber bridges as it closely represents their structural configuration with slab on girder elements. The timber deck is modelled as a plate element supported on stringers, which are, in turn, modelled as line elements. The models generated by these methods are close to the reality of the nature of the bridge components and thus lead to more accurate results [1] [3] [4].

SMAs rely on the beam analogy, an equivalent-beam method in use since the 1930s, for longitudinal distribution of loads along the bridge, by calculating the maximum contribution of a single girder (or a unit width of a slab-type bridge) in resisting imposed loads. In all SMAs, transverse distribution of the longitudinal load effects is a result of multiplying a fraction coefficient provided by the formulas in the codes. Span length is a key parameter in deriving simplified method equations, as longer span length results in better transverse load distribution. Tighter spacing between girders leads to effective loads sharing among more number of girders across the width of the bridge, resulting in lower distribution factor values, [1-4], [8], [9].

As the Commentary for the current edition specifies, the CHBDC SMA equation should always produce load effects that are greater than those calculated using RMAs, as the RMAs used to develop the SMA equation are based on the most critical condition permitted by the Code [9]. In general, using RMA result in higher load rating values than those calculated from the three editions of the Code (06, 14, and 19). Using SMA will therefore lead to conservative designs and yield lower load ratings for the existing bridges.

The majority of the constants in the formulation of the CHBDC simplified method were derived from work by Smith, while the recent formulation of SMA in CAN/CSA-S6:19 benefits significantly from the work done by Théoret and Massicotte, [1]. These studies, however, relied primarily on analysis of concrete and steel bridges. Timber bridges differ considerably from the most concrete and steel bridges in their structural configuration, and the mechanical properties of timber are markedly different from those of concrete or steel.

The non-linear behavior of the girders beyond the proportionality limit, and before the point of failure, can result in redistribution of the load effects. The technical committee of the OHBDC, therefore, offered an 8% reduction in the live load moment effect due to the redistribution of the moment effect based on a number of analytical studies of bridges with a concrete slab-on-steel-girder design. This reduction was offered only for the evaluation of existing bridges, and not for the design of new bridges. Although it is recognized as applicable to other bridge types, it has not been investigated extensively for those bridge types [8].

Fanous et al. carried out extensive research on development of live load distribution factors for glued-laminated timber girder bridges with glued-laminated timber deck panels. With a verified numerical model created in ANSYS 11 based on four in-service bridges, more than 100 hypothetical bridge models

were produced and live load distribution factor's relation was obtained for various bridge parameters, such as span length, girder spacing, and bridge width. It was shown that the AASHTO LRFD Bridge Design Specifications are conservative compared to the results obtained from field tests and numerical models [10].

An analytical and experimental study of six sawn timber bridges showed that asphalt, which tends to be neglected in both SMAs and RMAs, contributes to better live load sharing between timber stringers. This conclusion was based on the finding that stringers in field tests contributed a 17% smaller value of load sharing than predicted through rigorous analysis using SECAN/SCA. This study also found that analytical results for deflection were 20% larger than values obtained in the field, suggesting a larger modulus of elasticity than assumed in the Code recommendation for that timber species [11].

A more recent study sponsored by NSDPW carried out analysis of timber bridges with multiple editions of CHBDC (CAN/CSA-S6-88 through CAN/CSA-S6-14). This project was aimed at understanding the evolution of the simplified method in CAN/CSA-S6 over time and to compare results of the simplified method with more rigorous analysis using SCA. The study employed SECAN4 software and a scaled-down laboratory mode of the timber bridge. The results showed that the load effects calculated using revised versions of the code had increased over time by up to 30% [1]. NSDPW currently recognizes a rate of increase of 22%. CAN/CSA-S6-06 was found to produce the most accurate results of the versions studied but still yielded more conservative load ratings than those determined from the rigorous analyses. The study recommended the use of the simplified method in CAN/CSA-S6-06 as a first step in evaluation. Where this analysis yields a live load capacity factor (LLCF) falling within the range of 0.7–1.0, as is the case for approximately 60% of bridges in the NSDPW inventory, a more rigorous method may yield a higher load rating [1].

### 3 INSPECTION AND LOAD TESTING

#### 3.1 Bridge Inspection Program

Prior to field load testing, detailed hands-on inspection of the six test bridges was carried out in accordance with CAN/CSA S6:19 [4]. The primary objective of these inspections was to identify any defects or deficiencies with the potential to affect load testing results.

The inspection program comprised three main components:

- Detailed visual inspection of the bridge superstructure and timber substructure where applicable;
- Non-destructive testing (NDT), including sounding and Stress Wave Timer (SWT) testing; and
- Timber grading.

Detailed measurements were taken with adequate detail to produce elevation and section sketches in AutoCAD format. The overall condition rating of the six bridges as determined during the inspection program is given in Table 1.

Table 1. Condition Rating of Six Test Bridges

Bridge ID	Overall Current Bridge Condition Rating
HFX 061	Good
COL 098	Fair, near to Good
HFX 334	Fair, near to Good
HFX 322	Good
HFX 325	Fair
HFX 099	Fair

### 3.2 Load Testing Program

Girder deflection under load from a static truck with a known weight was measured by displacement sensors under each girder of the bridge and by strain gauges installed at select locations. The quality of this data was improved by incorporating an array of strategically placed high-precision sensors in the load testing program.

#### 3.2.1 Data Acquisition System

All displacement sensors and strain transducers were connected to a data logger which acquired data at a speed of 3 Hz. Two 16-channel analog input modules were used to connect displacement transducers and strain transducers. The data acquisition system was housed in the monitoring vehicle located on site and powered by a high-capacity inverter. In order to avoid disruptions in power supply, the system was equipped with a rechargeable 12 V back-up battery.

#### 3.2.2 Displacement Transducers

In selecting the most appropriate type of displacement transducer, three main factors, under-bridge clearance; minimum environmental disturbance; and ease of installation, calibration, and removal of sensors; were considered in the selection of the draw wire displacement transducers. Under-bridge clearance varied between 1.2 m and 3 m, and special adjustable steel cable system was designed to facilitate easy installation.

#### 3.2.3 Strain Transducers

Strain measurements were recorded using strain transducers with a gauge length of 75 mm. The selected strain transducers provide improved accuracy in comparison to bonded foil-type strain gauges. Special mounting brackets were developed to eliminate the effect caused by local variations/imperfections in timber during installation of the transducers.

#### 3.2.4 Installation

For each bridge, draw-wire sensors were installed at mid-span on the soffit of all timber girders. Additional displacement sensors were installed near the supports on bridges where appropriate. Small steel plates were attached to the soffit of each timber girder with wood screws. Matching steel plates with high-power magnets attached to the displacement sensors allowed a quick, secure, and efficient installation and retrieval.

A custom-built sensor installations system, which incorporates a thin aircraft cable, was developed and fabricated to accommodate the varying distance between girder soffits and the stream bed. The draw-wire of the sensor was pulled down approximately 50% of the sensor range and attached to the thin aircraft cable, which was adjusted in the field to make up the

remainder of the distance to the stream bed. The aircraft cable was attached to steel hooks that were screwed on to a square timber beam supported on steel stools and ladders resting on the stream bed thus minimizing disturbance to the riverbed. The test setup for the bridge, HFX 099, is shown in Figure 1 below.

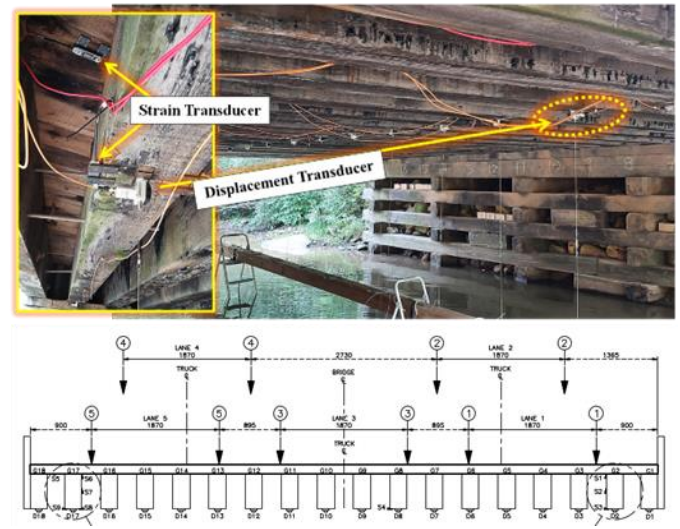

Figure 1. Test setup for HFX 099

Strain transducers were installed on selected timber girders, in close proximity to the draw-wire sensors as possible, in order to correlate strain measurements to the displacement measurements. On select bridges, strain transducers were installed on the deck soffit to determine load sharing characteristics of the timber deck.

#### 3.2.5 Test Vehicle

Bridges were tested using a single-unit tandem axle truck loaded near the legal maximum capacity (25880 kg). The truck was pre-weighed prior to commencing the load testing. A summary of the test vehicle axle loads and axle spacing is presented in Table 2 below for the bridge, HFX 322.

Table 2. Test Vehicle Axle Weight and Spacing

Front Axle Weight (kg)	Twin Rear Axle Weight (kg)	Axle Spacing (mm)	
		First to Second	Second to Third
7930	17950	4150	1360

#### 3.2.6 Load Testing Procedure

After all sensors were installed and tested for functionality, traffic control was implemented to close the bridge to all vehicular traffic. The load testing procedure consisted of the following steps:

- Demarcate travel lanes for each test run.
- Demarcate equally spaced lines at predetermined intervals depending on span length of the bridge.
- Record baseline readings of bridge prior to commencing load testing.
- Move the test truck to align with first travel lane and position centre point of second axles over the first stop as shown in Figure 2.

- Wait for one minute or longer for bridge to stabilize and then record data for 3 minutes.
- Review collected data to confirm consistency. If data were found to be inconsistent, repeat test before moving to the next load position.
- Move truck to next stop and repeat procedure at each transverse line.
- Collect data at end of each test and determine if any residual deflections remain in girders after removal of test truck from bridge.
- Move test truck to align with next travel Lane and repeat steps above until all travel lanes are completed.
- Once testing was complete in all lanes, confirm consistency of testing data by computing summation of girder deflections for similar stop points of different test lanes.
- Collect data for moving test truck over bridge in order to detect dynamic load effects.

Figure 2. Test Vehicle at COL 098

### 3.2.7 Load Testing Data Results

Collected data for each bridge was reviewed and processed prior to commencing data analysis. Maximum deflection values for each bridge are presented in Table 3. All bridges were well below the maximum deflection criteria of  $L/360$ .

Table 3. Summary of Load Testing Results

Bridge ID	Clear Span (m)	Maximum Recorded Deflection (mm)	Deflection-to-span Ratio
HFX 061	7.9	15.2	1/520
COL 098	6.7	11.3	1/591
HFX 334	5.1	9.4	1/543
HFX 322	6.2	8.5	1/729
HFX 325	3.9	8.8	1/443
HFX 099	8.4	14.1	1/596

## 4 DATA ANALYSIS AND DEVELOPMENT OF LOAD DISTRIBUTION FACTORS

Following the load testing phase, field-recorded data were processed to be used for validation of the computer models.

### 4.1 Data Processing and Preliminary Analysis

Data collected during the load testing were processed in this phase. For each bridge, data collected at each position of the

test truck were averaged. Initial recorded values from the gauges were then deducted from these averages. In bridges where displacement sensors were installed at the end of the girders, settlement of the abutments was noted. An average settlement of 3 mm was recorded for the tested bridges and was considered in the model calibration process. Data recorded after the truck was moved off the bridges showed that abutments rebounded to their original condition.

### 4.2 Material Properties of Timber

Material properties of timber are different in three orthogonal directions. Figure 3 shows a typical view of principal axes of wood relative to the direction of the wood grains.

Figure 3. Principal axes of wood material, [12]

Material properties of timber also vary by species. According to the standard drawings for bridges in the province from 1959 and 2001, Douglas fir and hemlock have been extensively used as the material for stringers, and deck elements, respectively. Both are classified as soft [13], [14]. Multiple resources were consulted to determine a range of values for the material properties of these species [1], [11], [12], [15]. The wood material properties used in the initial analysis discussed in this section are presented in Table 4.

Table 4. Material properties of wood species used in Nova Scotia timber bridges.

Property (MPa)	Douglas Fir	Hemlock
Longitudinal ( $E_L$ )	1.06+E4	1.09+E4
Radial ( $E_R$ )	6.26+E2	4.85+E2
Tangential ( $E_T$ )	6.26+E2	4.85+E2
Longitudinal-Radial ( $G_{LR}$ )	7.53+E2	3.82+E2
Longitudinal-Tangential ( $G_{LT}$ )	7.53+E2	3.82+E2
Radial-Tangential ( $G_{RT}$ )	7.42+E1	3.27+E1
Modulus of Elasticity ( $E$ )		
Modulus of Rigidity ( $G$ )		

In an initial attempt to validate the girders' mechanical properties in the longitudinal direction, the recorded Strain-Displacement (converted to Moment-Displacement) values were compared with the equivalent results generated by an analytical MATLAB code, developed by Hoseinpour et al. and modified for the current study, [16]. This code uses the typical equations of the Strength of Material to calculate displacement diagrams for the timber beams to be compared and calibrated with the field-recorded displacement data. Strain-Displacement data from slow-speed dynamic load test were the key factors in carrying out the validation process. Figure 4 presents an

example of the analytical investigation of wood material properties where equivalent moments were determined using the recorded strain values for HFX 099, which has a clear span length of 8.40 m.

The resulting Moment-Displacement diagram was compared with the diagram generated by MATLAB for different span lengths and moduli of elasticity. Analysis showed that the closest relationship between the field data model and the analytical model is achieved by increasing the clear span length of the bridge by 3.5% (to account for the bearing span length) and by using a longitudinal modulus of elasticity of 1.0E4 MPa for the girders.

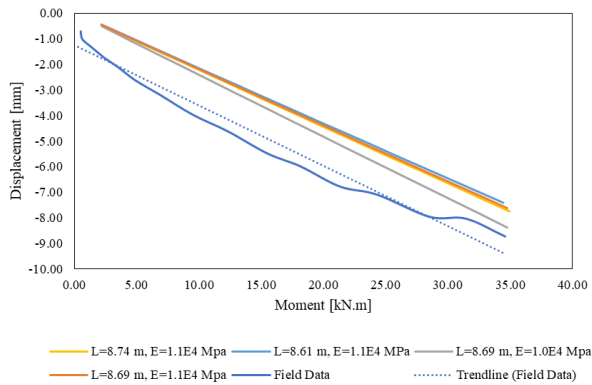

Figure 4. ST 3 on HFX 099

The final step in the process of validating material properties was examination of the values obtained with the 3D numerical model in midas Civil, and the generation of the deflection diagrams for comparison with the field recorded data. Due to the uncertainty associated with wood as an orthotropic material, multiple trials were performed to complete the validation of the wood material properties.

#### 4.3 Analysis Methods

Multiple methods were employed in analysis of the bridges under study, including the simplified methods of the codes CAN/CSA S6-06 and S6:19/14. Two different clauses of the SMAs in the newer versions of the Code were used where the method described in C5.6.6, generally applies to slab-on-girder bridges, and the simplified method outlined in C5.6.7, applies specifically to non-skewed timber bridges. Semi-Continuum Method of Analysis (SECAN4 in conjunction with CBridge) and Finite Element Analysis Method (midas Civil Software) were used for rigorous analysis and for evaluation of SMA results, which were then calibrated based on the field test data. The components of the modelled bridges via FEM were assigned appropriate element types, i.e., beam and plate elements for modelling girders and timber decks respectively, and appropriate links were created between them to represent nailed connections. In all analysis methods the timber bridges were assumed to act as a simple span beam.

The CHBDC standard loading truck was used in the analytical process, and the test truck “Test Vehicle” was used in the calibration of the computer models. A 3-D of the finite element model is shown in Figure 5.

Figure 5. A FEM model of a skew bridge with truck load

The outcome of the final step of the calibration of the FEM models for two of the six bridges under investigation is presented in Figure 6 and Figure 7 below. The figures show the deflection profile across the bridge deck at the test vehicle stop that induced the maximum displacement under reference axle.

The small difference between experimental diagrams and numerical model can be attributed to the effect of other factors (e.g. abutment settlement, condition of the bridges, and presence of asphalt) which were taken into account while developing the distribution equations.

Figure 6. COL 098 – Lane 1: Transverse deflection profile

Figure 7. HFX 334 – Lane 5: Transverse deflection profile

#### 4.3.1 Comparison of Results

The results obtained by the mentioned methods are summarized in the Table 5 and Table 6, representing moment and shear effects respectively. Multi-lane reduction factor is multiplied in the results obtained by rigorous analysis as this factor is inherent in the code formulation. In both tables, all load factors have been excluded from the results; only net values of the maximum distributed effects are displayed.

#### 4.4 Loading Characteristics of the Hypothetical Models

The single unit truck of S6:19 (CL3\_625) was selected as the effective live loading on the hypothetical bridges shown in Figure 8, [4]. The selected truck was used to achieve uniform

loading and to eliminate any effect of additional axle loads. For the majority of timber bridges in Nova Scotia, given their defined range of span lengths, CL3\_625 is the governing truck for determining load effects.

CHBDC specifies that the minimum distance between the truck wheels and curb, railing, or barrier wall shall be 0.60 m. Standard drawings for Nova Scotia bridges include a typical barrier width of 0.30 m [13], [14], and are therefore in compliance with the Code. Some of the bridges studied, however, have a barrier measuring only 0.1 m. Therefore, a minimum 0.6 m distance from the edge of the bridge was used to establish the transverse location of the loading truck. To achieve maximum load effect, the truck wheels were also aligned directly over the nearest girder while maintaining a clearance of 0.6 m from the bridge edge.

Table 5. Moment effects comparison (all values are in kN-m).

Bridge	S6-06	S6:19/14, C5.6.7	S6:19/14, C5.6.6	SCA (SECAN)	FEM (MIDAS)
HFX322	41.76	53.89	44.58	46.92	47.95
HFX325	31.56	40.49	36.68	29.80	30.92
HFX334	30.32	38.91	33.51	31.53	30.50
HFX099	70.26	90.31	71.00	60.27	53.53
COL098	51.11	65.44	53.80	47.18	44.46
HFX061	57.86	82.77	58.49	62.56	60.40

Table 6. Shear effects comparison (all values are in kN).

Bridge	S6-06	S6:19/14, C5.6.7	S6:19/14, C5.6.6	SCA (SECAN)	FEM (MIDAS)
HFX322	47.27	59.19	46.61	57.43	55.58* (76.94)
HFX325	52.42	65.65	51.70	64.36	52.75* (78.48)
HFX334	43.72	52.17	41.09	61.41	48.20* (67.14)
HFX099	54.45	69.19	54.49	55.10	61.13* (82.69)
COL098	52.12	65.08	51.25	67.61	56.52* (72.85)
HFX061	50.77	66.59	49.35	80.31	68.34* (91.93)

\* These values represent shear effects when wheel load footprints are modelled as patch loads. The values shown in parentheses represent shear effects, when wheel loads are represented as point loads, representing an average increase of 1.35 over the patch load effects.

Figure 8. CL3 625 Single unit truck used in the hypothetical models, Source: CHBDC [4]

#### 4.5 Characteristics of the Hypothetical Models

Having the FEM models calibrated based on span length and material properties, 101 hypothetical bridges were created and used to generate the mass data required for statistical analysis. Typical values of the parameters of Nova Scotia timber bridge inventory, such as girder spacing and span length were considered when generation the models.

#### 4.6 Development of Moment Distribution Factor

Distribution of the moment effect between girders is known to be related to the girders' displacement. Based on the Theory of Timoshenko, however, it is critical to differentiate between displacement imposed on the girder by work moment and displacement imposed by shear effects. Lower maximum distribution factors indicate better distribution of load effects between girders.

##### 4.6.1 Parametric Analysis of Moment Distribution Factor

After the maximum distribution factor of each hypothetical bridge was obtained, those values were plotted against variable parameters, and relationships between distributions factors and each parameter was determined. Span length, for instance, which is a key factor in bridge analysis, appeared to have a negative linear relationship with the moment distribution factor, as shown in Figure 9 below.

Figure 9. Span length in relation to the distribution factor

Girder spacing was also found to have a positive linear relationship with the distribution factors (Figure 10 below).

Figure 10. Girder spacing in relation to distribution factors

R-squared values showed that the spacing of girders correlates more strongly with the bridge distribution factor than do other parameters. The number and geometry of girders and

other parameters, however, did not play an important role in determining distribution factors and were tried to be imported to the equations as modification factors.

#### 4.6.2 Development of the Moment Distribution Factor Equation

The Moment distribution factor was formulated using MATLAB; in which the bridge's parameters were combined in different forms, i.e. separate linear combination and multiplication or division of parameters to different powers, to achieve highest correlation. The highest R-squared value (0.96) was found to belong to the simple linear summation of span length and girder spacing shown in Equation 1 below.

$$F_T = S/4.562 - L/394 + 0.051 \quad (1)$$

$$F_{T-min} = S/4.182 + 0.016$$

S: average girder spacing, center to center (metres)

L: bearing span length (metres)

When  $F_T > F_{T-min}$ :  $F_{T-modified} = F_T^2 / F_{T-min}$

When  $F_T \leq F_{T-min}$ :  $F_{T-modified} = F_{T-min}$

In cases where  $F_T$  is larger than  $F_{T-min}$ , a correction is required to account for the effect of different girder sizes. Therefore, the value obtained by the above equation shall be multiplied by the ratio of  $F_T / F_{T-min}$  as shown in the step 3 of Equation 1. Based on calibration process described in Section 4.2, the recommended bearing span length for timber bridges is 1.035 times of the measured clear span length.

#### 4.6.3 Effect of Skew Angle ( $\psi$ ) on Distribution Factors

Skew angle and span length are two important parameters used to determine skew effect in CHBDC. Bridge width, which was the dominant factor in the past editions of the code, plays an insignificant role in the current edition (S6:19).

Maximum moment effect is reduced in skewed bridges due to the decrease in the effective span length. Shear effect is subject to increase in the obtuse corner of skewed bridges, as a result of decreasing stiffness of the girders at the points on the axle line toward the acute edge and a corresponding reduction in load carrying of the far girders, [9].

The Mohr circle concept was employed to generate deck material properties for bridges with different skew angles. Analysis of the hypothetical skewed models also demonstrated that shear effects are increased, and moment effects are decreased in skewed bridges. The results for skewed bridges were close to those obtained by multiplying the CHBDC skew equation with the results of non-skewed bridges. The CHBDC skew effect equation should therefore be used to magnify shear effects and reduce moment effects. The shear modification coefficient determined from the CHBDC skew effect equation is denoted as  $F_S$  in relevant formulations.

$$F_S = 1.2 - (2.0/(\epsilon + 10)) \quad (2)$$

$\epsilon = (L/S) \tan \psi$  for  $\psi \leq 45$

L = Bearing span length

S = Girder spacing

#### 4.6.4 Effect of Girder Dimension on Distribution Factors

Mechanical properties of different girder sizes for each bridge configuration showed low correlation with the obtained

moment distribution factors and made it difficult to find a simple formulation to determine the effect of girder dimension. Given its partial correlation with the distribution factors, the effect of the mechanical properties of the girders is reflected in the original expression with  $F_{T-min}$  and the proposed increase in the moment distribution factors.

#### 4.6.5 Effect of Multiple Traveling Lanes on the Distribution Factors

Nova Scotia timber bridges are typically limited to two travelling lanes. Deflection diagrams showed that the effect of a single truck on one side of a wide bridge has an uplift effect on the far girders at the opposite side. Having three trucks on the specified lanes of the timber bridges would therefore lower distribution factor values; therefore, only two-lane bridges were considered in the modelling process. To account for multilane effect, the Number of Lanes factor,  $F_L$ , was included in Equation 4, with the values displayed in Table 7 below.

Table 8. Number of Lanes factor ( $F_L$ )

Single Lane Bridge	Two-Lane Bridge
1.00	1.21

The Code's statistical factor to account for multi-lane effects is still applicable and is presented in the current research as well. Per sections 3 and 14 of the Code, respectively, the modification factor is 0.90 for design of a two-lane bridge, and 0.85 for evaluation. This factor is denoted by  $R_L$  in Equation 3.

#### 4.6.6 Effect of Bridge Condition on the Distribution Factors

Live load testing results in conjunction with inspection findings and analytical modelling suggest that the bridge condition may affect the load distribution factor. In some cases, field-validated loading responses of the bridge structures differed from those expected based on the calibrated FE model. In order to align the FE model with recorded field data, the condition rating of the bridges under investigation was considered (See Section 3.1). The values provided in Table 9 below were assigned as the factor  $F_C$  to reflect the overall condition of the bridges in the load distribution formulation, Equation 4.

Table 9. Bridge Condition factor ( $F_C$ )

Good	Fair to Good	Fair
1.00	1.12	1.20

None of the bridges included in the current study were rated in lower than Fair condition. Local decays in bridges in Poor condition has the potential to significantly affect the load distribution factor. No  $F_C$  factor, therefore, is provided for evaluation of bridges rated at Poor condition and it has to be concluded based on professional judgment.

#### 4.6.7 Effect of Asphalt Surface on the Distribution Factors

Asphalt pavement of varying thickness was found on four of the six bridges in the current study. Thicker asphalt would result in better load distribution and therefore lower load distribution factors. The effect of asphalt surface is designated as  $F_A$  in Equation 3 and Table 10. Linear interpolation shall be used to find an equivalent factor for different asphalt thickness.

Table 10. Asphalt surface factor ( $F_A$ )

90 mm	150 mm	250 mm
1.08	1.15	1.25

A gravel surface, in contrast to an asphalt surface, is inconsistent in thickness/distribution over the bridge deck and has low elastic properties. Furthermore, only one of the bridges under investigation had a gravel surface, and it appeared to be loose and uneven near the edge of the bridge. Therefore, the contribution of a gravel surface to the load distribution, could not be evaluated in this study, and  $F_A$ , shall be assumed as 1.0.

#### 4.6.8 Generalized Moment Distribution Factor Equation

Equation 3 below presents the overall distribution factors for moment effects. This equation includes coefficients that account for the effects of other parameters, as discussed earlier in this chapter.

$$F_M = F_{T-modified} F_L F_C R_L / F_A F_S \quad (3)$$

$F_{T-modified}$  = Moment distribution factor

$F_S$  = Skew angle coefficient

$F_L$  = Multiple lane effect factor

$R_L$  = Statistical multilane coefficient

$F_C$  = Bridge condition factor

$F_A$  = Asphalt effect factor

#### 4.7 Shear Distribution Factor

Shear distribution factor was obtained by dividing the maximum contribution of the girders by the maximum shear effect of the same loading on a single beam with the same span length, where the single beam was analyzed using CBridge. In order to produce maximum shear in a simple beam, the heavy truck axles must be located as near as possible to the supports where, due to the minimum deflection of the girder, the girder closest to the wheel load absorbs much of the shear effect. Shear distribution does not, therefore, follow the same pattern as the moment distribution, and a separate distribution factor is required.

##### 4.7.1 Parametric Analysis of Shear Distribution Factor

Like the moment distribution factor, shear distribution factors showed a stronger correlation with girder spacing than with span length. In general, weaker correlations (i.e. R-squared values) were established between the shear distribution factor and variable parameters of the timber bridges than between the moment distribution factor and those parameters.

##### 4.7.2 Development of the Shear Distribution Factor Equation

The shear distribution factor in the 2019 version of the Code is only a function of girder spacing, magnified by a modification factor. Using this factor in the current study yielded an R-squared value well below the expected value.

MATLAB was used to combine the effects of different parameters and to develop a formulation for the shear distribution. Multiple trials, however, failed to yield correlations (i.e. acceptable R-squared values) that would suggest sufficient accuracy for these formulas.

A method similar to that used for determination of the moment distribution factor, was therefore applied to generate a

modification coefficient to account for the shear distribution factor. As shown in Equation 4, the shear distribution factor was obtained by modifying the moment distribution factor, the use of which can produce shear effects having an acceptable correlation with an R-Squared value of 0.71.

$$F_v = F_S^2 F_M / (1.35 \gamma_v \gamma_{lv}) \quad (4)$$

Where,  $F_S$  is the skew angle factor, and the shear modification factor  $\gamma_v$  is obtained from the following equation:

$$\gamma_v = S/2.532 - L/134 + 0.247 \quad (5)$$

The correction factor,  $\gamma_{lv}$ , of the shear effect for two-lane bridges is equal to 1.14. See Equation 1 and 3 for the notations.

In an attempt to create maximum load effects, the longitudinal wheel line of the loading truck was aligned over the girder closest to the bridge edge, while respecting the minimum 600 mm clearance. This was the governing case specifically for determining the shear effects.

Considering the low potential for transverse load distribution at the end of the bridges' span it would be safe to assume that the loaded girder absorbs the entire wheel load on the support.

On the other hand, analyzing the standard truck of CL-625 on a short span bridge has the potential of eliminating the effect of the heavier axle load in the shear analysis as it remains off the bridge span in the critical shear loading case. As a result, there is always a possibility to disregard the heavier axle loads with wide spacing in the shear analysis, where they have no potential to be transversally distributed when acting on the support. Therefore, the minimum unfactored shear effect shall be taken as the largest of the wheel load of the loading truck divided by the patch load correction of 1.35.

#### 4.8 Comparison of the results of the developed SMA to the loading tests and CHBDC results

Table 11 presents distribution factors obtained from live load tests, different versions of the Code, and the developed SMA in this study to validate the results of newly developed formulations.

Table 11. Comparison of the moment distribution factor derived using new formulation with other methods

(2) S6-14/ S6:19 C5.6.6

(3) S6-06

(4) Live Load Test

(5) Developed SMA

This comparison established a close relationship between the live load test results and the results of the developed SMA here. Compared to the results obtained with CHBDC S6-14 and S6:19, C5.6.7, both live load tests and the new SMA show a decrease of between 17.4% and 34.5% in moment distribution factors across all timber bridges studied, which is consistent with NSDPW's hypothesis that the Code-specified analysis method for timber bridges leads to more conservative design and evaluation criteria.

## 5 CONCLUSION

Results of this study show that the current SMAs in the Canadian bridge codes are overly conservative, and the congruence of analytical and load test results supports the hypothesis that the newly developed equations are sufficiently accurate for the simplified analysis of typical timber bridges in Nova Scotia. The equations presented in this report can be used for both design and evaluation purposes, using appropriate factors and subject to the following parametric limitations:

- Span range: 3 m to 15 m.
- Girder spacing: 350 mm to 800 mm.
- Girder width: 150 mm to 300 mm.
- Girder depth: 250 mm to 800 mm.
- Girder spacing: Uniform or with less than 10% variation.
- Skew angle: Less than 45°

Bridges with characteristics outside the above ranges will require additional study.

## ACKNOWLEDGMENTS

The authors would like to acknowledge Nova Scotia Department of Public Works for initiating this study and their active support during all stages of its completion. The authors also acknowledge Dr. Baidar Bakht, P. Eng., for his help in determining load sharing factors for the six timber bridges evaluated during this study.

**ABSTRACT:** Structural engineers, particularly bridge engineers, rarely have the opportunity to test full-scale bridges to failure due to the high costs involved. Such experiments are typically conducted on scaled-down specimens in controlled settings, which can introduce challenges in accurately correlating results to real-world full-scale behavior. In 2019, a unique opportunity arose when the Steinavötn bridge in southern Iceland was irreparably damaged by flooding. Built in 1964, the 102-meter-long reinforced concrete continuous beam bridge had two abutments and five piers and was part of Iceland's national road system, connecting the ring road around the island. One of its piers suffered scour damage beyond repair, leading to the decision to demolish the structure. Before its demolition, a measurement campaign was conducted using long-gauge fiber-optic sensors to capture the bridge's response to ultimate loading. This study presents the findings from the measurement campaign and bridge modelling, providing valuable insights into the ultimate load behavior of a full-scale bridge and advancing the understanding of structural performance under extreme conditions.

**KEY WORDS:** Full-scale testing, Bridge modelling, Continuous beam bridge, Long-gauge fiber-optic sensors, Reinforced concrete.

## 1 INTRODUCTION

In 2017, a unique opportunity arose when the Steinavötn bridge in southern Iceland was irreparably damaged by flooding. Built in 1964, the 102-meter-long reinforced concrete continuous beam bridge had two abutments and five piers (Figure 1) and was part of Iceland's national road system, connecting the ring road around the island. One of its piers suffered scour damage beyond repair, leading to the decision to demolish the structure. Before its demolition, extensive load testing and vibration measurements were conducted on it during the summer of 2019. These tests were carried out as a collaborative effort involving the Icelandic Road and Coastal Administration (IRCA), Reykjavik University, ETH Zurich, and Osmos Monitoring Group. Various sensors were used during the measurements, including force gauges, displacement sensors, accelerometers, and different types of strain sensors. The bridge response was recorded under various load scenarios, such as excitation from natural environmental vibrations, controlled traffic loads on the bridge, impact loads, and gradually increasing vertical loads on one bridge span far into the non-linear regime.

The events leading up to and the causes of the bridge's destruction have been examined in a master's thesis written at the University of Iceland [1]. A bachelor's thesis at Reykjavik University documented the setup of the load tests on the bridge and the data collection process. It presented results from material tests on concrete and reinforcement steel. Furthermore, preliminary numerical computational models of the bridge were developed, deflections were calculated, and the load-bearing capacity was compared with measurement data as well as with design calculations [2]. The dynamic behavior of the bridge has also been analyzed based on vibration data by a research group at Reykjavik University and the Technical

University of Denmark [3], [4]. A comparison between non-linear beam-truss models with different boundary conditions was conducted at the University of Iceland [5].

Structural engineers, particularly bridge engineers, rarely have the opportunity to test full-scale bridges to failure due to the high costs involved. Such experiments are typically conducted on scaled-down specimens in controlled settings, which can introduce challenges in accurately correlating results to real-world full-scale behavior. It is therefore important to seize the opportunity and conduct full-scale experiments to improve knowledge and understanding of structural behavior as well as validating numerical models. Data analysis methods and numerical models developed in these rare settings provide valuable insights into structural behavior, numerical modelling, and structural health monitoring methods.

In this paper insights from data measured by the long-gauge fiber-optic strain sensors and LVDT displacement sensors during the ultimate load test at Steinavötn bridge are presented.

## 2 THE STEINAVÖTN BRIDGE

### 2.1 Description of the bridge

The Steinavötn Bridge on National Road 1 was built by the IRCA in 1964 and was located in the Suðursveit region of Southeast Iceland, south of Vatnajökull, about 61 km west of Höfn in Hornafjörður. The bridge was a 102-m-long concrete beam bridge, single-lane and with six spans. The bridge was an important link in completing the ring road, and 10 years after its construction, the road was fully connected [6]. Figure 1 shows the bridge over Steinavötn.

The span from the abutment to the first intermediate pier was 14 m on both sides and the inner spans were 18.5 m (see Figure 2). The intermediate piers rested on timber piles that went approximately five meters into the ground.

Figure 2. A view of the Steinavötn bridge from the ICRA's drawing set.

### 2.2 Bridge cross-section

The bridge superstructure had two different cross-sections. Four meters on either side of every pier, the cross-section was a hollow box girder shown in Figure 3. The remaining 10.5 m and 6 m in the inner and outer spans, respectively, were double T-beams illustrated in Figure 4. The bridge deck was monolithically cast and reinforced with the piers.

Figure 3. Bridge cross-section at pier. Hollow box girder. Measurements in cm. From the ICRA's drawing set.

Figure 4. Bridge cross-section at midspan. Double T-beam. Measurements in mm. From the ICRA's drawing set.

### 2.3 Materials

Three concrete samples were extracted from the bridge using core drilling, taken from its longitudinal beams. The cylindrical samples had a diameter of 100 mm and an initial length of 270 mm, which was reduced to 200 mm by BM Vallá ehf. concrete plant, who also leveled the ends with additional concrete. The

compressive strength was tested in collaboration with Mannvit hf. consulting firm following the ÍST EN 12390-3:2009 standard, applying an axial load increasing at 0.6 MPa/sec until failure. The average compressive strength was 37.7 MPa [2].

Ultra-sonic measurements were performed on the side beams of the superstructure to determine the dynamic modulus of elasticity of the concrete. The average dynamic modulus of elasticity was 39 GPa [7]. Note that the dynamic modulus can be approximately 20-30% higher than the static one [8]. According to Eurocode EC2, the static modulus of elasticity for concrete strength 37.7 MPa is 33 GPa [9]. This is 15% of the measured dynamic modulus.

Three samples were taken from the longitudinal reinforcement and three from the shear reinforcement of the bridge. The steel strength was determined through tensile testing in collaboration with Mannvit, following the ÍST EN ISO 15630-1:2019 standard, with a 200 mm anchorage length at each end for proper grip. Due to challenges regarding the equipment, only the yield and ultimate strength were recorded [2].

Table 1 shows the material properties that were recorded and the values used in the subsequent analysis.

Table 1. Material properties.

	Measurements			
	Compr. strength [MPa]	Dyn. E [GPa]	Yield stress [MPa]	Ultim. stress [MPa]
Concrete	37.7	39	-	-
Steel stirrup	-	-	290	439
Steel longit.	-	-	405	758
	Used in analysis			
	$f_{ck}$ [MPa]	$f_{yk}/f_{uk}$ [MPa]	$E_c$ [GPa]	$E_s$ [GPa]
Concrete	38	-	33	-
Steel	-	400/760	-	210

### 2.4 Bridge after scour damage

In September 2017, there was a large increase in water in the river, resulting in scouring at intermediate pier 2, measured from the western end of the bridge. The settlement of the pier was measured at about 200 mm, but it also deviated and tilted by 70 mm/1000 mm, or 7%, from the vertical [1]. Figure 5 shows how the bridge pier has subsided. Cracks could be seen on the bridge superstructure above the seats of intermediate piers 1 and 3, which extended 5 m into the water. Since the bridge piers were cast and reinforced with the bridge deck, rotation of a pier therefore caused rotation of the bridge deck. Crack formations above the intermediate piers strongly indicated that floating elements had formed at these locations. After a site visit by the Icelandic Road Administration and stress tests in early October 2017, the bridge was deemed unusable [10]. Subsequently, a temporary bridge was built to allow traffic to reopen, and in September 2021, a new double-lane bridge over Steinavötn was inaugurated.

Figure 5. The intermediate pillar of the bridge has sunk [10].

### 3 BRIDGE TESTS

This section offers a comprehensive overview of the monitoring experiments conducted on the old Steinavötn bridge during the summer and fall of 2019, prior to its demolition. The IRCA chose to utilize the bridge as an educational and research resource prior to its demolition and commenced comprehensive experiments on it in collaboration with various Icelandic and international partners. Multiple experiments were carried out on the bridge, measuring acceleration, deflection, strain, and static loading.

#### 3.1 Short overview of tests

Figure 6 illustrates a side view of the Steinavötn bridge, highlighting the test span subjected to various structural analyses. The bridge, spanning the Steinavötn river, is depicted with five piers (labeled Pier 1 through Pier 5) and six spans (Span 1 through Span 6).

Notably, Figure 6 identifies "plastic hinge" locations in Span 1 and Span 3, indicating potential areas of structural weakness. The bridge is further divided into "Damaged Structure" and "Undamaged Structure". A note points to a pier damaged during a flood in September 2017, contributing to the "Damaged Structure" classification.

Researchers from ETH Zürich used single-axis accelerometers to measure the vertical acceleration response of the Steinavötn bridge within the test span. They installed sensors during the summer to monitor long-term ambient background vibrations and conducted damage detection experiments in September.

The OSMOS Group employed Fiber Bragg Grating sensors, including OSMOS Optical Strands, a Thermal Probe, and the OSMOS Expert Data Acquisition System, to measure strain in real-time within the test span. The sensors were installed on the bridge beams in July 2019. The sensors recorded mostly strain, but also some temperature data, evaluated through remote activation, until the ultimate load test in September 2019. The sensors were uninstalled prior to the bridge demolition.

Reykjavik University conducted two measurement campaigns on the bridge, utilizing five 3-axial accelerometers and two LVDT displacement sensors within the test span. The data from those measurements have been used to analyze the response of the bridge, and more details and results can be found in [3].

In September 2019, IRCA and Reykjavik University jointly performed a shear capacity test on the test span of the bridge, monitoring both strain and displacement.

Figure 6. Side view of the Steinavötn bridge illustrating the test span (between Piers 4 and 5) used for structural analysis, including shear capacity testing.

#### 3.2 Detailed description of incremental point load test

The purpose of this test is to assess the structural integrity and load capacity of the bridge component, specifically related to the Steinavötn bridge's shear capacity. The steel structures supporting the hydraulic jacks were designed to withstand a minimum bearing capacity of 3000 kN, considering steel availability and on-site assembly. According to a 2018 master's thesis [1], the Steinavötn bridge's local shear capacity is approximately 2200 kN. The experiment aims to validate these calculations and ensure the safety and reliability of the bridge structure under realistic loads.

Figure 7 depicts the test setup designed to evaluate the load-bearing capacity of the bridge structure. The setup utilizes two hydraulic jacks, each capable of applying a maximum force of 200 tons, which is distributed through 300x300 mm plates onto the bridge deck. These jacks are supported by a 5-meter-long HEA1000 beam, which transfers the load to HEB100 columns. The columns, in turn, are bolted to lower HEA1000 beams, which are restrained by two HEB300 beams and connected to piles via  $\phi 25$  mm rebars. Each rebar pair is clamped to a single pile using UNP100 profiles and M20 bolts. Each pile group consists of four piles, approximately 11 meters deep.

Figure 7. Test Setup

The test analyzed in this paper was performed on the 17<sup>th</sup> of September 2019. Loads were applied using the hydraulic jacks in steps, starting at approximately 500 kN and reaching approximately 2300 kN. The load as measured by the load cells is shown in Figure 8.

Figure 8. Displacement and force measurements during incremental point load test.

#### 4 FIBER-OPTIC AND DISPLACEMENT SENSORS

Before the load tests were conducted, long-gauge fiber-optic strain sensors from the technology company OSMOS were installed on the bridge in axial, parallel, and crossed topologies; see Figure 9. During the incremental point load test, an LVDT sensor was placed under each T-beam in the center of the tested span.

##### 4.1 Long-gauge fiber-optic strain sensors

Fiber-optic sensors emerged several decades after the invention of electrical strain gauges. Fiber-optic sensors are primarily made of silica, an inert material resistant to chemical exposure, and electromagnetic interference [11]. This makes silica highly suitable for measurements in harsh environments like concrete. The fiber optic serves both as the sensor and the transmission medium for the measurement. Depending on its configuration, a fiber-optic sensor can measure strain, tilt, acceleration, movement, temperature, humidity, corrosion, and more [12]. Additionally, multiple types of sensors can be linked together and transmit measurements through the same medium. Moreover, signals can be transmitted over long distances (several kilometers) without requiring electrical power [11], [13].

Figure 9. Long-gauge fiber-optic strain sensor locations on the south side of the monitored span. Note: sensor locations are the same on the north side of the span except lower sensors in parallel topologies over piers are not present.

Discrete strain gauges are either short (approximately 10–100 mm) or long (250–10,000 mm) [13]. Short- and long-gauge sensors provide similar results in homogeneous materials. Common construction materials, particularly concrete, are far

from homogeneous, as they are characterized by aggregates, cracks, and pores [14]. The properties of concrete are thus discontinuous, and while short strain gauges can provide accurate information about localized strains, it is nearly impossible to accurately represent the overall strain state of a concrete structure with short gauge sensors. However, long gauge strain sensors measure the average strain over their gauge length, offering a better overview of the behavior in heterogeneous materials. In other words, it is often less relevant to know the strain in the individual components of concrete (cement paste, aggregates, phase boundaries) but far more relevant to measure the overall behavior and response of the material referred to as concrete. Further discussion on the accuracy and applicability of long-gauge fiber-optic strain sensors can be found in the literature, f.ex. [15], [16], [17].

Parallel strain sensors provide information about the average curvature of the cross-section [13], specifically,

$$\kappa = \frac{\varepsilon_1 - \varepsilon_2}{h} \quad (1)$$

where:

$\kappa$  is the average curvature of the cross-section in  $\mu\text{ε}/\text{mm}$

$\varepsilon_1$  is the axial strain measured by the lower sensor in a parallel topology in  $\mu\text{ε}$

$\varepsilon_2$  is the axial strain measured by the upper sensor in a parallel topology in  $\mu\text{ε}$

$h$  is the distance between the two sensors in mm

Crossed strain sensors are intended to measure the average shear strain over the height of the cross [13], specifically,

$$\gamma = \frac{\varepsilon_1 - \varepsilon_2}{2 \cos(\alpha) \sin(\alpha)} \quad (2)$$

where:

$\gamma$  is the average shear strain in  $\mu\text{rad}$

$\varepsilon_1$  is the axial strain measured by sensor 1 in the crossed topology in  $\mu\text{ε}$

$\varepsilon_2$  is the axial strain measured by sensor 2 in the crossed topology in  $\mu\text{ε}$

$\alpha$  is the angle between the sensors in the cross

The curvature over the east pier and shear under the load, as measured by the parallel and crossed sensors respectively, are shown in Figure 10 and Figure 11.

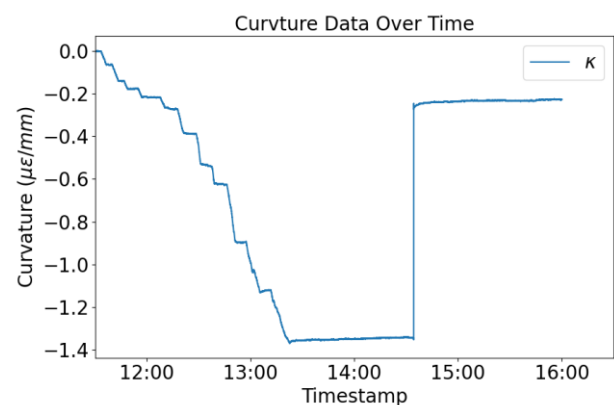

Figure 10. Average curvature over east pier during the incremental point load test.

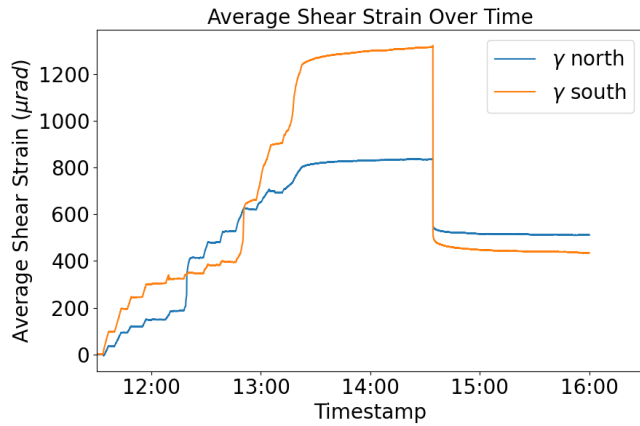

Figure 11. Average shear strain under the load during the incremental point load test.

#### 4.2 LVDT displacement sensors

Linear Variable Differential Transformers (LVDT) are known for their precision, dependability, and adaptability in measuring linear displacement [18]. The measurements from the middle of the span during the incremental point load test are shown in Figure 8 along with the load measurements.

### 5 LINEAR APPROXIMATIONS

Linear approximations for deformation at midspan, curvature and shear strain are provided in the following sections. These linear approximations become increasingly inaccurate as the load increases, more cracks form, and the structural behavior becomes more nonlinear.

#### 5.1 Deformation

The deformation is estimated using handbook equations for deformation of beams with different boundary conditions [19]. The true behavior of the span is somewhere between these two as the boundary conditions are stiffer than for the simply supported beam and softer than the fixed-fixed beam. Thus, the true deformation is a weighted average of the two equations.

Simply supported beam:

$$\Delta_x = \frac{Pbx}{6EI} (l^2 - b^2 - x^2) \quad (3)$$

Beam with fixed-fixed supports:

$$\Delta_x = \frac{Pb^2x^2}{6EI} (3al - 3ax - bx) \quad (4)$$

where:

$\Delta_x$  is the deformation at location  $x$  in mm.

$P$  is the load in N

$a$  is the location of the load from the left support in mm

$b$  is the location of the load from the right support in mm

$l$  is the total length of the span,  $l = a + b$ , in mm

$E$  is the elastic modulus in MPa

$I$  is the moment of inertia of the cross-section in mm<sup>4</sup>

#### 5.2 Curvature

When assuming linear behavior the curvature in the cross-section is

$$\kappa = \frac{M}{EI} \cdot 10^6 \quad (5)$$

where:

$\kappa$  is the average curvature in  $\mu\text{e}/\text{mm}$

$M$  is moment in the section in Nmm

$E$  is the elastic modulus in MPa

$I$  is the moment of inertia of the cross-section in mm<sup>4</sup>

#### 5.3 Shear

When assuming that the material behaves within the linear elastic range, the shear stress in a hollow box cross-section can be expressed as:

$$\gamma = \frac{VA\bar{y}}{2GI} \cdot 10^6 \quad (6)$$

where:

$\gamma$  is the average shear strain in  $\mu\text{rad}$

$V$  is the shear force acting on the section in N,

$A$  is the area above the point where the stress is calculated in mm<sup>2</sup>,

$\bar{y}$  is the distance from the centroid of  $A$  to the centroid of the cross-section in mm

$G$  is the shear modulus in MPa

$I$  is the moment of inertia of the cross-section in mm<sup>4</sup>

$t$  is the thickness of the web (total thickness  $2t$ ) in mm

### 6 NONLINEAR NUMERICAL MODELS

#### 6.1 OpenSees

OpenSees (Open System for Earthquake Engineering Simulation) is a software framework for developing applications in earthquake engineering using finite element methods [20]. It is designed to simulate the behavior of structural and geotechnical systems subjected to earthquakes. The flexibility of OpenSees allows researchers and engineers to create customized models that can accurately reflect the unique characteristics of various materials and structural configurations. This capability makes it an invaluable tool in assessing the performance of structures during seismic events and informing design improvements.

The Beam Truss Model (BTM) proposed by Lu and Panagiotou [21] and Lu et al. [22] is a design-oriented analysis method used to model reinforced concrete (RC) structures, efficiently computing the force and deformation capacity of RC components. It represents a wall component as an assemblage of horizontal, vertical, and inclined line elements with a beam formulation and a fiber section, capturing nonlinear out-of-plane flexural resistance and its coupling with axial and in-plane flexural/shear resistance. This method makes it possible to get a more accurate picture of how the structure will behave under different loads, which makes design predictions more reliable. The BTM also makes it easier to include advanced material models, which helps engineers better understand how the different parts of reinforced concrete structures interact with each other.

There is a biaxial truss element in OpenSees called Truss2. It is meant to consider biaxial effects in a uniaxial element when it is used with the ConcretewBeta material. The ConcretewBeta material is a uniaxial concrete material model in OpenSees that considers the effect of normal tensile strain on the compressive behavior of concrete, using a tri-linear compressive stress-strain envelope to model strength degradation in tension. This interaction allows for a more accurate representation of how

concrete structures respond under various loading conditions, particularly when subjected to simultaneous axial and lateral forces. By utilizing the Truss2 element with the ConcretewBeta material, engineers can better predict potential failure mechanisms and optimize the design of reinforced concrete elements for enhanced safety and performance.

## 6.2 OpenSees model of Steinavötn bridge

In this study, the test span of the Steinavötn bridge was modeled utilizing OpenSees with the BTM approach. The span was discretized into 60 units along its length. As illustrated in Figure 12, the blue lines, parallel to the bridge's longitudinal axis, were modeled as longitudinal elements. These dispBeamColumn elements are particularly suited for capturing nonlinear material and geometric behavior. Thirteen dispBeamColumn elements with fiber sections were used, totaling 780 elements. The fiber sections incorporated Steel02 material for rebar and Concrete04 material for concrete. Hollow boxed girder and double T-beam sections have been considered with different fiber sections at the bottom of the cross-section (this distinction is not visible in Figure 12). This fine discretization allowed for a detailed representation of the nonlinear material behavior under the incremental point load test. The red lines, representing the transverse elements of the deck, were modeled. In contrast, elasticBeamColumn elements model beams and columns with linear elastic material properties. Twelve elasticBeamColumn elements were used per cross-section, totaling 732 elements. The piers, located on both sides, were modeled with two elasticBeamColumn elements each, bringing the total number of elasticBeamColumn elements to 736. These elasticBeamColumn elements considered only the concrete's Young's modulus, assuming linear elastic behavior. The green lines, representing the diagonal elements of the triple-layer grid structure (Truss2 elements), a key component of the Beam-Truss model, totaled 1440 elements, incorporating the ConcretewBeta material to model the concrete's tensile and compressive response. The total number of elements used in the OpenSees model was 2952. Fixed boundary conditions, denoted by magenta squares in Figure 12, were applied at the base of the piers to simulate the support constraints.

Figure 12. OpenSees model of the Steinavötn bridge with applied loads, highlighting the structural discretization.

Information on deformation is extracted directly from the midspan of the model. For evaluation of the curvature and shear, strains are extracted at the sensor locations, and the curvature and shear strain are calculated using Equations (1) and (2).

## 7 RESULTS

The results from measurements, linear approximations, and nonlinear numerical modelling are presented in Figure 13 to Figure 15. The results are presented as force-response diagrams highlighting the nonlinearity of the bridge behavior at high loads. The measurement results are shown in yellow and red, with measurements on the north side of the bridge in yellow and on the south side in red, the linear approximations in dot-dashed gray, and the nonlinear OpenSees results in dashed black.

The load-displacement at midspan is reported in Figure 13. The measurements fall between the linear approximations of the fixed beam and the simply supported beam, as was expected. The weighted average is calculated by combining 30% of the response from the fixed beam and 70% from the simply supported beam. However, the measured displacement is never truly linear. The nonlinear model has the same slope as the simply supported beam and starts to deviate from that line when the load reaches approximately 1500 kN. The model appears to have more capacity than the real structure.

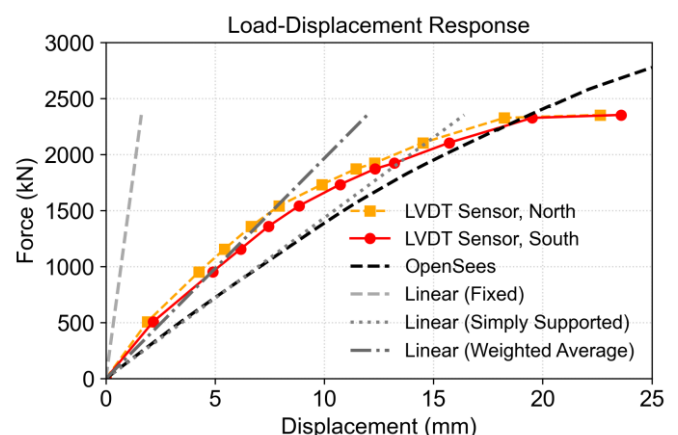

Figure 13. Load-displacement diagram. Results from measurements, linear approximations, and nonlinear numerical modelling at midspan.

The load-curvature at the east pier is shown in Figure 14. The curvature is calculated from strain measurements and nonlinear numerical modelling strains using Equation (1). The linear approximation is calculated using Equation (5). The measured curvature exhibits linear behavior very close to the linear approximation until the load reaches approximately 1500 kN. The nonlinear numerical model changes stiffness (slope) when the load reaches 500 kN and then again when the load reaches 1500 kN. The nonlinear numerical model shows less stiffness than the measurements. This is reasonable since the numerical model is a single span supported by piers, not including the adjacent spans that will increase stiffness. However, despite this minor difference in stiffness, the model successfully models the measured behavior.

The load-shear strain relationship close to the east pier is shown in Figure 15. The average shear strain from fiber-optic strain measurements in crossed topologies on the north and south side of the bridge is calculated using Equation (2). The same equation is used to calculate the simulated shear strain using strains from the Truss2 element in the OpenSees model. Note that  $\alpha = 45^\circ$  in the model whereas  $\alpha = 39^\circ$  for the fiber-optic strain sensors.

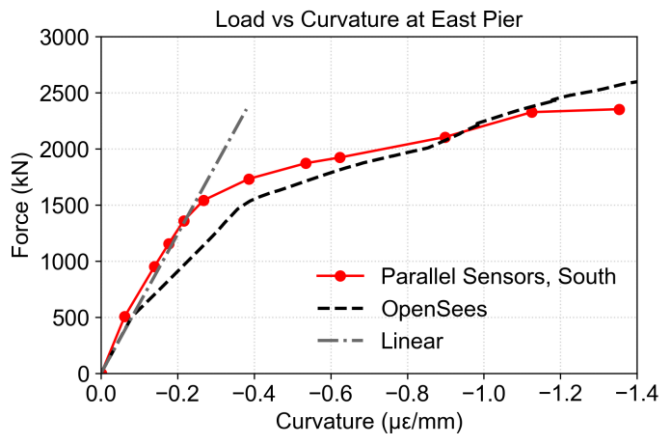

Figure 14. Load-Curvature diagram. Results from measurements, linear approximations, and nonlinear numerical modelling at the east pier.

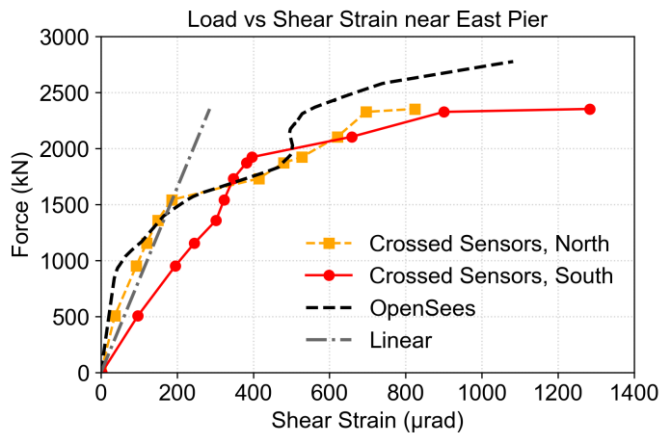

Figure 15. Load-Shear Strain diagram. Results from measurements, linear approximations, and nonlinear numerical modelling near the east pier.

In the incremental point load test the load is applied directly above the crossed fiber-optic strain sensors. The internal shear diagram for the bridge thus has a sharp discontinuity exactly at the sensor location. Additionally, according to St. Venant's principle the strain field directly under the force is heavily perturbed. However, despite these circumstances the average measured strain on the north side is in good agreement with the linear approximation until the load reaches 1500 kN. On the south side the stiffness seems to be less than on the north side and the stiffness changes before the load reaches 1500 kN. More detailed analysis is needed to explain the difference between the response on the north and south side of the bridge.

The nonlinear numerical model shows stiffer behavior under low loads than the fiber-optic measurements and changes stiffness when the load reaches 1000 kN. Generally, the numerical results are in good agreement with measurements on the north side of the bridge.

## 8 DISCUSSION

Simple linear approximations are able to describe the linear behavior of this concrete structure. When the load reaches 1500 kN, a nonlinear response is observed in all studied parameters. The load-displacement behavior at midspan demonstrates that measured displacements fall between the linear approximations of a fixed and simply supported beam, with an estimated weighted response of 30% fixed and 70% simply supported. While the nonlinear numerical model captures the general trend, it predicts a higher load capacity than observed in measurements.

The load-curvature relationship at the east pier exhibits good agreement between measurements and the linear approximation up to approximately 1500 kN. The nonlinear numerical model changes stiffness at 500 kN and 1500 kN and generally shows less stiffness than measured values. This difference is attributed to the model's exclusion of adjacent spans, which would otherwise contribute to the bridge's overall stiffness. Nonetheless, the nonlinear model successfully replicates the measured strain behavior at sensor locations, validating its reliability.

An important factor to keep in mind is that Equation (1) is based on the assumption that plain sections remain plain and that the strain distribution over the height of the cross-section is linear. This assumption is true in the linear elastic range of the materials, demonstrated by the excellent agreement between the linear approximation and the measurements. However, after the materials enter the nonlinear regime, plain sections do not necessarily remain plain and the assumption that the strain varies linearly between the two parallel sensors is not necessarily correct. In other words, the slope of the line between the two strain measurements in the parallel sensor topology does not necessarily accurately describe the curvature of the cross-section when the bridge starts to behave nonlinearly. The fact that the curvature obtained by this method from the strain measurements and the nonlinear model are similar demonstrates that nonlinear model successfully simulates the strains at the sensor locations.

The load-shear strain relationship near the east pier reveals a strong correlation between measured strains and the linear approximation up to 1500 kN on the north side. However, the south side exhibits lower stiffness and an earlier stiffness change, necessitating further investigation to understand these discrepancies. The nonlinear numerical model shows higher stiffness at low loads and a change in stiffness at 1000 kN but aligns well with measurements on the north side. Strains as simulated by the nonlinear OpenSees model are similar to the measurements from strain sensors, resulting in curvature and shear strain with similar behavior. This result highlights the strength of the Truss2 elements in OpenSees in conjunction with crossed fiber-optic sensors.

## 9 CONCLUSION

This paper presents the Steinavötn bridge that was damaged during flooding in 2017. Subsequently, before demolition, the bridge was instrumented with long-gauge fiber-optic strain sensors and LVDT sensors, and tests carried out far into the nonlinear regime. This paper presents the load-response behavior of the bridge under the incremental point load test using the fiber-optic and LVDT measurements, linear approximations, and nonlinear numerical modeling in OpenSees.

The analyzed parameters were displacement at midspan, curvature at the east pier and shear strain near the east pier (under the load). All analyzed parameters exhibit linear behavior up to an approximate load of 1500 kN. The results highlight the bridge's nonlinear response at high loads and provide valuable insights into its structural behavior.

More in depth analysis of the nonlinear strain field from the OpenSees model is necessary to evaluate the error caused by the linear assumptions made in the data analysis of the sensor and numerical data. Overall, the nonlinear numerical model effectively captures key aspects of the bridge's nonlinear response, despite minor discrepancies in stiffness predictions.

Future research should focus on refining the numerical model, exploring differences between the north and south side responses, and evaluating the effects of adjacent spans to enhance predictive accuracy.

**ABSTRACT:** This study addresses the need for high-fidelity system identification in Digital Twin (DT) applications for Structural Health Monitoring (SHM). As infrastructure ages, its material properties may degrade due to various factors, including damage, corrosion, and fatigue. Accurate assessment of material properties is critical for ensuring safety and reliability. High-fidelity identification enables the detection of localized damages that traditional methods may not detect, directly impacting maintenance strategies and public safety. In this work, we present a formulation of the optimization problem that minimizes errors between observed and simulated displacements by varying material properties. Additionally, we utilize adjoint-based sensitivity analysis, combined with regularization techniques such as Vertex Morphing, to enhance the efficiency and robustness of the optimization process. Our case studies, which include detailed analyses of 2D and 3D structures using real-world data, demonstrate the effectiveness of our methods in accurately inferring material properties and revealing structural integrity. By implementing this advanced methodology, practitioners can achieve timely and accurate assessments of structural integrity, leading to better-informed decision-making regarding maintenance and safety protocols. This research contributes to the ongoing advancement of Digital Twin technology, promoting safer and more efficient infrastructure management.

**KEYWORDS:** High-fidelity Digital Twin, Inverse Problems, Regularization, Adjoint sensitivity analysis.

## 1 INTRODUCTION

Throughout the lifecycle of structures, their material properties can deteriorate due to various factors, including damage, corrosion, and fatigue. Advances in sensor technology and numerical simulation techniques now enable the creation of Digital Twins (DT) — dynamic digital representations of complex structures. DT can be defined as follows [7-10]:

*“A set of virtual information constructs that mimic the structure, context, and behavior of an individual/unique physical asset, or a group of physical assets, is dynamically updated with data from its physical twin throughout its life cycle and informs decisions that realize value.”*

A key component in developing DT is system identification, which involves evaluating the current state of material properties and identifying areas of weakness. This process often requires solving inverse problems through appropriate parameterization, typically framed as an optimization challenge. The formulation steps of the system identification problem can be outlined as follows:

1. *System Description:* Analyze all available information about physical objects and numerical models, including documentation, numerical models, or data from the design phase, for instance, testing data from wind tunnels or experiments with material samples.

2. *State Information:* Collect and analyze available sensor data, measurements, load tests, and visual inspections to inform the assessment.

3. *Definition of Optimization Problem:* Define the objective function that incorporates the available measured data and select system parameters to minimize the errors between measured and computed data points.

Figure 1 illustrates the “twinning” process schematically. In real-world applications, the structure can be used under various conditions. A digital model can predict performance and provide feedback about the structure, indicating whether it requires maintenance or can be safely used further. To enhance the feedback provided by the digital model, the system identification process aligns the real and virtual worlds.

Figure 1. Twinning real and digital worlds.

In system identification, various fidelities can be applied, which can be categorized into two main types: analysis and identification, as shown in Figure 2. Low-fidelity analysis is represented by simplified finite element (FE) models, such as using beam elements to describe the structure. In contrast, high-fidelity models incorporate detailed geometry, complex material laws, and other intricate characteristics.

Similarly, low-fidelity identification involves a limited number of parameters that typically reflect the overall structural behavior of the system. Low-fidelity system identification is well solved using artificial neural networks. For instance, in [14], the identification parameters are the coordinates of the damaged regions and the stiffness reduction factor. This setup allows for the localization of damage, but it is limited to a single region. In [16], the three-floor structure is studied, where each floor has its own set of global identification parameters, which describe the structure's properties. As a result the damage localization is limited to the floor.

In high-fidelity identification, however, many system parameters need to be determined, for example, a unique set for each finite element in the model. Consequently, while low-fidelity identification can indicate an average weakening in the structure, high-fidelity identification can localize many damaged regions with different shapes and damage intensity. In this work, we focus on high-fidelity FE models and high-fidelity identification as the most challenging case. However, the proposed methodology can also be applied to other fidelity cases.

Figure 2. Fidelity levels in the FE model and system identification.

An adjoint analysis is an essential component of solving high-fidelity system identification problems with many parameters. The adjoint-based technique for localizing damages in structures using displacement and strain measurements is presented in [1]. A combination of several sensor approaches would also appear highly promising in future applications [11], including risk measures and uncertainty quantification [12]. Additionally, recent research has demonstrated the potential for restoring the temperature field based on displacement and strain measurements [13].

Frequent updates between numerical and physical assets are an essential property of the digital twin in practical applications. Live monitoring requires a fast solution to the system identification problem to analyze and update the system. In [3], the authors studied the possible computational cost reduction using various optimization algorithms.

This study addresses the minimization problem associated with identifying material properties within numerical models. The cost function is formulated based on the aggregated errors between observed and simulated displacements across multiple locations. To enhance the robustness of the minimization process, we employ various smoothing and filtering techniques, including the Vertex Morphing approach, which helps regularize the optimization problem.

We present both 2D and 3D structural case studies, where one of the cases are represented by a testing bridge “Concerto”. Our examples utilize real-world data alongside numerical simulations to demonstrate the effectiveness of our methods in accurately inferring material properties and revealing structural integrity. This work contributes to the ongoing advancement of Digital Twin technology for effective structural health monitoring, ultimately promoting safer and more reliable infrastructure.

## 2 METHODOLOGY

The system identification of material properties, such as damage, can be formulated as an optimization problem involving unknown material parameters  $\mathbf{p} = [p_1, p_2, \dots, p_n]$ . Depending on the applied material model, the unknown material parameters can be Young's modulus, Poisson's ratio, or other, at each of the elements in the finite element model (FEM). Figure 3 illustrates the components of generalized system identification, which includes a digital twin and the optimization problem.

The digital twin comprises a physical object, measured data, and a numerical model. The key components of the optimization process are material parameters, a regularization technique, an optimization algorithm, and the formulation of the objective function, which incorporates the available measured data. The following sections describe details of each component and its challenges.

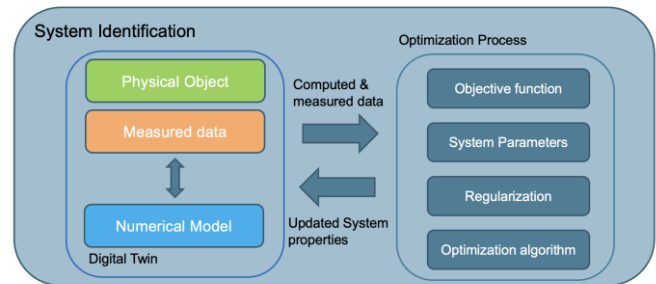

Figure 3. System identification process.

### 2.1 Objective function

One of the key components in setting up the optimization process is defining the objective function. Based on the available data, the generalized objective function can be formulated as a weighted sum of the errors between measured and computed quantities. Given  $l$  number of the different sensor types and  $n$  given load cases  $\mathbf{F}_i, i = 1..n$ ;  $n \cdot l$  corresponding measurements at  $m$  measuring points of their respective data  $\varphi$ . The variable  $\varphi$  can represent different quantities based on the sensor type, for instance, displacement, strain, temperature, acceleration and etc. The generalized objective (cost) function is formulated as:

$$J(\mathbf{p}, \boldsymbol{\varphi}(\mathbf{p})) = \sum_{k=1}^l \sum_{i=1}^n \sum_{j=1}^m \Phi(\omega_{kij}, \boldsymbol{\varphi}_{kij}^{md}, \mathbf{I}_{kij}^d \boldsymbol{\varphi}_{ki}(\mathbf{p}), \mathbf{p}) \quad (1)$$

where  $\omega_{kij}$  are the measurement weights;  $\mathbf{I}_{kij}^d$  are interpolation matrices that are used to obtain the computed value from the finite element mesh at the measurement locations.  $\Phi(\omega_{kij}, \boldsymbol{\varphi}_{kij}^{md}, \mathbf{I}_{kij}^d \boldsymbol{\varphi}_{ki}(\mathbf{p}))$  is a weighted aggregation function, for instance, weighted square sum:

$$\Phi = \frac{1}{2} \omega_{kij} [\boldsymbol{\varphi}_{kij}^{md} - \mathbf{I}_{kij}^d \boldsymbol{\varphi}_{ki}(\mathbf{p})]^2 \quad (2)$$

In case, only one load case is considered with one sensor type with displacement measurements, and the material parameter of interest is Young's modulus, then the objective function defined in Equation (1) simplifies to:

$$J(\mathbf{u}(\mathbf{E})) = \frac{1}{2} \sum_{j=1}^m \omega_j (\mathbf{u}_j^{md} - \mathbf{I}_j^d \mathbf{u}(\mathbf{E}))^2 \quad (3)$$

## 2.2 Sensitivity analysis

An important step in the optimization process for identifying material parameters is computing the derivative of the objective function with respect to the material parameters. Considering the objective function introduced in Equation (3), we can apply the chain rule:

$$\frac{dJ}{d\mathbf{E}} = \frac{\partial J}{\partial \mathbf{E}} + \frac{\partial J}{\partial \mathbf{u}} \frac{d\mathbf{u}}{d\mathbf{E}} \quad (4)$$

where  $\frac{\partial J}{\partial \mathbf{E}} = 0$  because  $J$  does not depend directly on  $\mathbf{E}$ , Equation (4) can be further developed:

$$\frac{dJ}{d\mathbf{E}} = \frac{\partial J}{\partial \mathbf{u}} \frac{d\mathbf{u}}{d\mathbf{E}} = - \left( \sum_{j=1}^m \omega_j (\mathbf{u}_j^{md} - \mathbf{I}_j^d \mathbf{u}) \right) \frac{d\mathbf{u}}{d\mathbf{E}} \quad (5)$$

In general,  $\frac{dJ}{d\mathbf{E}}$  can be computed using either the finite difference approach or the adjoint approach. Due to a large number of material parameters to identify, the adjoint approach is preferred because it is computationally more efficient by avoiding the direct computation of  $\frac{d\mathbf{u}}{d\mathbf{E}}$ . Adjoint approach requires first solving a primal problem, which is depicted in Equation (6) in the residual form, where  $\mathbf{K}$  is the stiffness matrix,  $\mathbf{u}$  is the displacement vector, and  $\mathbf{F}$  is the load vector:

$$\mathbf{R} = \mathbf{K}\mathbf{u} - \mathbf{F} \quad (6)$$

Then, the adjoint problem is solved for  $\boldsymbol{\lambda}$  Lagrange multipliers:

$$\left( \frac{\partial \mathbf{R}}{\partial \mathbf{u}} \right)^T \boldsymbol{\lambda} = - \left( \frac{\partial J}{\partial \mathbf{u}} \right)^T \quad (7)$$

and the Lagrange multipliers are used in a post-processing step to compute the final sensitivities:

$$\frac{dJ}{d\mathbf{E}} = \frac{\partial J}{\partial \mathbf{E}} + \boldsymbol{\lambda}^T \frac{\partial \mathbf{R}}{\partial \mathbf{E}} \quad (8)$$

We would like to note that the Equation (7) is independent of the choice of the material parameter. Hence, the adjoint approach can be used for various material parameters and Young's modulus  $\mathbf{E}$  has been used as an example. A lot of performance and implementation optimization can be achieved by solving the adjoint system, because  $\left( \frac{\partial \mathbf{R}}{\partial \mathbf{u}} \right)^T = \mathbf{K}^T$  and  $\mathbf{K}$  is symmetric, hence we can re-use the existing left-hand side of

the primal problem and only have to change the right-hand side (i.e. pseudo-load) to obtain  $\boldsymbol{\lambda}$ .

## 2.3 Regularization

Similarly to node-based shape and topology optimization, to avoid high-frequency noisy results, we need to apply appropriate regularization techniques [2]. Therefore, one option is to subject the raw gradients to smoothing using filters. In [1], the authors reviewed various gradient smoothing techniques for material identification problems, such as simple element averaging, weak Laplacian smoothing, and pseudo-Laplacian smoothing, where the last one has been chosen as a better technique. In [3], the authors apply an explicit filter called Vertex Morphing to smooth material gradients. In the context of Vertex Morphing, thus, the physical material properties, for instance, Young's Modulus  $\mathbf{E}$  are indirectly controlled by an unsmoothed control field  $\mathbf{p}$  and a kernel (or filter) function  $\mathcal{F}$ , for example, on the surface  $\Gamma$  with surface coordinates  $(\xi, \eta, \zeta)$ :

$$(\xi_0, \eta_0, \zeta_0) = \int_{\Gamma} \mathcal{F}(\xi - \xi_0, \eta - \eta_0, \zeta - \zeta_0) \mathbf{s}(\xi, \eta, \zeta) d\Gamma \quad (9)$$

After discretization of the structural geometry  $\mathbf{E} = [E_1, E_2, \dots, E_n]$  and control function  $\mathbf{s} = [s_1, s_2, \dots, s_n]$  by standard techniques such as the finite element method, Vertex Morphing appears as:

$$\mathbf{E} = \mathbf{A}\mathbf{s} \quad (10)$$

Where  $\mathbf{E}$  is Young's modulus of elements, and they are arranged sequentially.  $\mathbf{A}$  is the filter operator matrix, and  $\mathbf{s}$  is the vector of discrete control field parameters, again arranged sequentially. The most straightforward approach is to add control parameters to every element.

The entries  $A_{ij}$  of the filter matrix  $\mathbf{A}$  reflect the filter effect as the interaction between two different centers of the elements  $i$  and  $j$ , their center's spatial position vectors  $\mathbf{x}_i$  and  $\mathbf{x}_j$ , and their Euclidean distance  $\|\mathbf{x}_i - \mathbf{x}_j\|$ . For the case of the Gauss distribution as kernel function and approximating integration by summation, it holds:

$$A_{ij} = \mathcal{F}(\mathbf{x}_i, \mathbf{x}_j) / \text{sum} \quad (11)$$

$$\text{sum} = \sum_j \mathcal{F}(\mathbf{x}_i, \mathbf{x}_j)$$

$$\mathcal{F}(\mathbf{x}_i, \mathbf{x}_j) = \begin{cases} e^{-\|\mathbf{x}_i - \mathbf{x}_j\|^2 / 2r^2}, & \|\mathbf{x}_i - \mathbf{x}_j\| \leq r \\ 0.0, & \|\mathbf{x}_i - \mathbf{x}_j\| > r \end{cases} \quad (12)$$

and  $r$  is the filter radius. By changing the filter radius, one can adjust the filtering intensity.

## 2.4 Generalized workflow

Figure 4 shows the generalized workflow of the optimization process for system identification. Every optimization iteration, we need to evaluate objective function value and its gradients. Then, we apply Vertex Morphing (or other filtering technique) on the computed gradients and compute the control parameter update using optimization algorithm. Then, we apply one more time Vertex Morphing on the computed control parameter update to compute new model parameters state. This process continues till the convergence criteria are met or maximum number of optimization iterations are reached.

Figure 4. Generalized system identification workflow as an optimization process.

Relevant optimization convergence criteria for system identification are:

1. Relative reduction of objective function:

$$\frac{J(\mathbf{p}^i)}{J(\mathbf{p}^0)} \leq \varepsilon \quad (13)$$

2. Absolute reduction of objective function:

$$J(\mathbf{p}^0) - J(\mathbf{p}^i) \geq \varepsilon \quad (14)$$

3. Maximum sensor error:

$$\max_j \text{abs}(\mathbf{u}_j^{md} - \mathbf{L}_j^d \mathbf{u}(\mathbf{p})) \leq \varepsilon \quad (15)$$

In general, a lot of standard techniques from optimization theory can be apply to solve system identification problems, including convergence criteria, optimization algorithms, aggregation techniques, variable scaling, line search techniques and globalization strategies.

### 3 CHALLENGES IN SYSTEM IDENTIFICATION

In this section main challenges of the method are summarized.

#### 3.1 Modeling the objective function

The choice of the objective can play a crucial role in system identification because various types of measured data have to be combined. That require a proper scaling of the measured information to keep the objective function dimensionless and it allows to find a “correct” solution. Additionally, in minimization of the sum of the errors, the component with the highest error would have the highest contribution to the search direction. The sensor with highest error may change in the sequential optimization iterations leading to zig-zagging behavior. In [1], authors reviewed few weighting strategies to combine strains and displacements. In case of Equation (3), these techniques compute weights for displacements as follows:

1. *local weighting*:

$$\omega_j = (\mathbf{u}_j^{md})^{-2}$$

This method may lead to an ‘over-emphasis’ of small displacements, that are in regions of marginal interest.

2. *average weighting*:

$$\omega_j = \left[ \frac{\sum_{j=1}^m |\mathbf{u}_j^{md}|}{m} \right]^{-2}$$

This method may lead to an ‘under-emphasis’ of small displacements that may occur in important regions.

3. *max weighting*:

$$\omega_j = \left[ \max_j |\mathbf{u}_j^{md}| \right]^{-2}$$

This method may lead to an ‘under-emphasis’ of smaller displacements that can occur in important regions;

4. *local/max weighting*:

$$\omega_j = \max \left[ \varepsilon \max_j |\mathbf{u}_j^{md}|, |\mathbf{u}_j^{md}| \right]^{-2}$$

where  $\varepsilon = [0.01, 0.1]$ . This method works best of all, as it combines local weighting with a max-bound minimum for local values.

The weights for strain components (or other measured values) can be computed in a similar manner.

#### 3.2 Large design space

In our approach, we aim to identify the material parameters for each element individually. As a result, there are various spatial distributions of material properties that can produce similar or identical deformations under a fixed load case. This type of optimization problem is known as “multimodal,” meaning it has multiple optimal solutions with the same objective function values. Consequently, engineering expertise is necessary to “narrow” down the design space. For example, if the material is expected to weaken over time, we can impose an upper limit on Young’s modulus to prevent stiffening of the structure, as illustrated in Figure 5.

Figure 5. Results of the system identification problem with (right) and without (middle) stiffening in the material.

To improve the convergence of the system identification process, authors in [4] suggest using a zoom-in approach, where they start with a limited number of design variables and then gradually reparametrize the problem to zoom into the damaged region by switching from low-fidelity identification to high-fidelity. This approach improves the robustness of the method by better finding the weak areas globally and afterward identifying damages on a smaller scale.

#### 3.3 Discrete gradients

To localize damage effectively, it is necessary to consider many material parameters, such as modifying Young’s modulus for each element. This results in a large number of parameters and the need for gradient-based optimization algorithms. Consequently, adjoint analysis is essential. Section 2.2 discusses the use of adjoint analysis to compute the gradients of the objective function.

The gradients obtained through adjoint methods can be discrete and noisy, which may lead to high-frequency solutions. To address this issue, regularization techniques are required. One such technique is Vertex Morphing, which is introduced in Section 2.3. Figure 6 illustrates the effect of Vertex Morphing.

Figure 6. Young's Modulus distribution: top – without, bottom – with Vertex Morphing.

### 3.4 Optimization algorithm

The difference between classical mathematical optimization problem and system identification problem is that evaluation of the objective value typically requires solving the FEM-based structure analysis. Therefore, robust and efficient optimization algorithms are required with minimal functional and gradient evaluations. In [3], the authors compare various optimization algorithms and their performance. It has been shown that a significant amount of computational cost can be avoided by selecting a well-suited algorithm.

Figure 7 shows the performance of the various algorithms. 2D Plate with a hole (Section 4.1) has been used as a benchmark to study the performance. The tested algorithms are: SciPy Broyden-Fletcher-Goldfarb-Shanno (BFGS), SciPy Limited memory Broyden-Fletcher-Goldfarb-Shanno bounded algorithm (L-BFGS-B), SciPy conjugate gradient algorithm (CG), SciPy Trust-Region Constrained Algorithm (TRC), PyRol the steepest descent method with back-tracking line search, PyRol Lin-More trust region algorithm (LM-TR) and Kratos Nesterov accelerated gradient method with Quasi-Newton Barzilai-Borwein correction line search (NAG-QNBB).

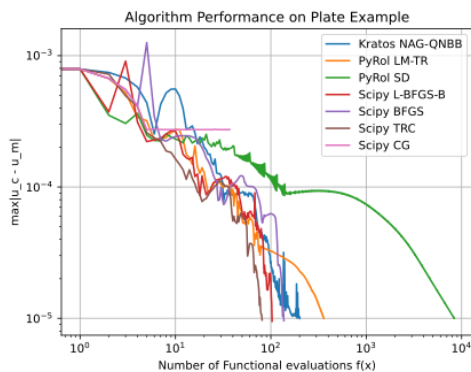

Figure 7. Convergence rate of the tested algorithms [3].

## 4 NUMERICAL EXAMPLES

This section demonstrates two examples of the system identification process. A simple 2D plate with a hole example is a numerical benchmark from [3], which is introduced to help the reader better understand the introduced methodology. The second example demonstrates the usability of the method on a real-world structure, and its measured performance is shown. The measured data were obtained from [5].

### 4.1 2D Plate with a hole

The FE model of the 2D plate with a hole is shown in Figure 8, where the left side is fixed, and the distributed force is applied on the right side. Figure 9 (left) shows displacements of the damaged model and the mapped displacements to the sensors. These displacements are used as “measured” displacements to identify the given damage. The virtual sensor is modeled as a point with  $x$ - and  $y$ - spatial coordinates, and the measured value is associated with its location. The damaged material is visible in Figure 9 (right).

Figure 8. FEM model [3].

Figure 9. Measured displacements (left) and predefined damage (right) [3].

The objective function is defined similarly to Equation (3), and it is based on the measured and computed displacements in the  $x$ -direction:

$$J(\mathbf{u}(\mathbf{E})) = \frac{1}{2} \sum_{j=1}^m \omega_j \left( u_{x_j}^{md} - u_{x_j}(\mathbf{E}) \right)^2 \quad (16)$$

The filtering radius is chosen to be constant, and  $r = 5$ , covering approximately 4 FE elements. The optimization process stops when the maximum error in the sensor reaches  $10^{-5}$ , Equation (15).

Figure 10 shows the found damaged areas using the system identification process. Due to the applied filtering, the found damage areas have smoothed boundaries in contrast to the ideal predefined damage model (Figure 9).

Figure 10. Found damaged areas using the NAG-QNBB algorithm [3]

#### 4.2 Concerto bridge

For the long-term evaluation of innovative Structural Health Monitoring (SHM) techniques, the experimental plate girder bridge "Concerto" was constructed in 2005. The bridge measures 17.5 m in total length, 4.0 m in width, and 0.8 m in height [5, 6]. Figure 11 shows the support positions (A, B), the ground anchors (C), the transducers (C, D), and the cantilever arm (E). In the lower part of Figure 11, the instrumentation and reference point signalization are depicted.

Figure 11. Experimental Bridge "Concerto". Upper part: indication of support (A, B), ground anchor (C), Deformation transducer positions (C and D), and cantilever arm (E). Lower part: instruments (UAV, laser scanner, and transducer) and signalization of reference points [5].

Figure 12 shows the deformation of the bridge under the load from photogrammetric measurements. For more details on the measurement techniques, an interested reader is referred to [5]. In this study, we utilized data obtained through photogrammetric measurements. However, data from other measurement techniques can also be applied. We chose photogrammetric measurements because they provide continuous data, in contrast to the limited number of points obtained from tachymetry and transducer measurements. It is important to note that laser scanner measurements exhibit a gap between 12.5 meters and 15 meters.

Figure 12. According to photogrammetric measurements, the deformation of "Concerto" under load is seen from the top. Lowered areas are colored in red, elevated areas in green, and no elevation change in black [5].

A finite element (FE) model has been created to model the bridge, as shown in Figure 13. This model consists of 77,000 small-displacement 3D elements that represent the concrete domain (depicted in gray), 800 truss elements representing the tendons (shown in blue), and 107 small-displacement 3D elements that represent the elastomers (illustrated in yellow). The load is applied to the red surfaces.

Figure 13. FE-model of the Concerto bridge: concrete part (gray), steel tendons (blue), elastomers (yellow), applied force (red).

To utilize the measured data, we create a series of virtual sensors positioned along the x-axis at the midpoint of the bridge. Figure 14 illustrates the locations of these virtual sensors, represented as spheres, along with their corresponding values (displacement in the z-direction) that have been derived from the measured data.

The objective function is defined similar to Equation (3) and it is based on the photogrammetric measurements and computed displacements in the z-direction:

$$J(\mathbf{u}(\mathbf{E})) = \frac{1}{2} \sum_{j=1}^m \omega_j \left( u_{z_j}^{md} - u_{z_j}(\mathbf{E}) \right)^2 \quad (17)$$

There are three various material domains to identify in the model. The largest domain is concrete, where we set the valid Young's modules range to  $E = [1e9, 1e11] Pa$  and as the initial parameter  $E^0 = 3e10 Pa$ . In this model, we set the upper boundary higher than the initial value because we want to keep large identification freedom. The second material domain is steel tendons, with parameter ranges  $E = [1e10, 1e12] Pa$  and  $E^0 = 2.1e11 Pa$ . The last model part is elastomers, which model the rubber supports with unknown material properties. We set  $E = [1e6, 1e8] Pa$  and  $E^0 = 1e7 Pa$ . All material

parameters are identified through a single system identification process.

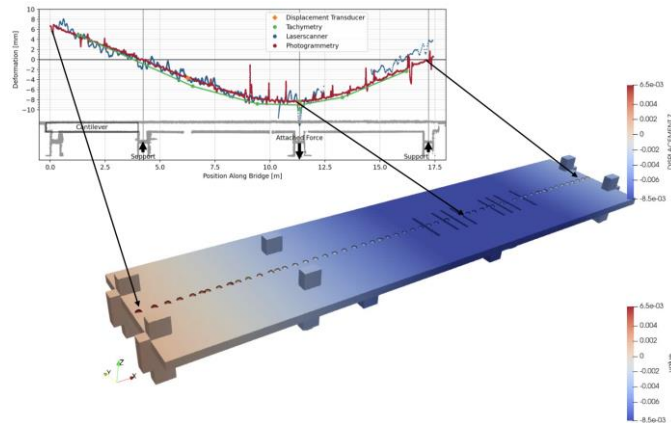

Figure 14. Applying the measured data to its numerical model: measured data at the center line (top graph), virtual sensors with mapped data (small circles).

Figure 15-18 shows the final Young's modulus of the materials. The results show that steel tendons are not damaged, and the elastomer material converges to  $1e8 Pa$ . In Figure 16, we highlight the areas with damaged concrete and provide photos of these areas. Figure 17 shows the graph comparing the measured and computed displacement at the middle line before and after system identification.

Figure 15. Young's modulus of steel tendons shows no damage.

Figure 16. Young's modulus of elastomers converged to upper bound ( $1e8$ ).

The optimization process took 30 optimization iterations to reduce the objective function by 98.9 %. Further optimization iterations lead to overfitting the parameters (see Figure 19), where the material parameters converge to unphysical values, while the reduction of the cost function stays at similar level 99.1 %.

Figure 17. Top: Young's modulus of concrete. Bottom: Pictures of the current state of the bridge in the weakened regions.

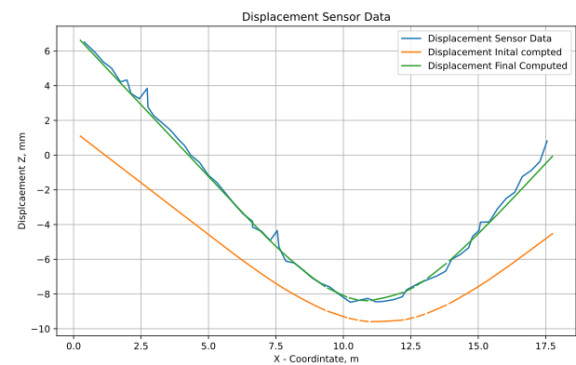

Figure 18. Comparing z-displacements along the x-axis in the middle of the bridge: measured data (green), initial computed data (orange), final computed data (blue).

Figure 19. Overfitted material parameters. Young's modulus of concrete reaches upper and lower bounds.

## 5 DISCUSSIONS

In this study, we explored the system identification process for structural health monitoring using adjoint-based optimization techniques. Our findings highlight the effectiveness of employing high-fidelity Digital Twin models to accurately infer material properties and detect weaknesses in structures. The method has been applied to the "Concerto" bridge with real-world measured displacement. We have found damaged areas that are confirmed by visual inspection of the real state of the bridge.

However, the results are not without limitations. One significant challenge is the dependence on sensor configuration, which can strongly affect the accuracy of the identified material properties. Additionally, the multimodal

nature of the optimization problem complicates finding a “true” solution during the identification process, as multiple identified states can yield similar results. Another significant challenge is the convergence criteria, which, on one hand, should stop the optimization process before overfitting the material parameters, and on the other hand, shouldn’t stop it too early before all damaged regions are found.

## 6 OUTLOOK

Moving forward, we recommend several directions for future work:

- 1) How can we identify the crucial measured locations / optimal sensor placement?
- 2) How to load the structure? How many load scenarios are required to identify all damaged regions?
- 3) How can we include the probability of sensor failure and inaccurate measurement?
- 4) How can we check which damage can be found by a given sensor configuration on the structure?
- 5) How to circumvent the overfitting of the data?

**ABSTRACT:** High fidelity finite element model updating plays a critical role in ensuring the accuracy and reliability of structural models for complex infrastructure systems. This study focuses on the application of a cooperative game theory model to update high fidelity finite element model of a pedestrian suspension bridge. By treating the model updating process as a cooperative game model, game theory provides a novel framework for distributing and balancing multiple objectives inherent in this process. The proposed approach is compared with conventional finite element model updating methods to assess its efficiency, accuracy, and robustness. Key performance indicators, such as the reduction in discrepancy between experimental and numerical modal parameters and computational efficiency are evaluated. The cooperative game theory framework is shown to enable an optimized and balanced resolution of conflicting requirements in high fidelity model updating, resulting in improved alignment with observed structural behavior. The primary objective of this research is to demonstrate the potential of game theory as an innovative and effective tool for solving optimization problems in high fidelity FE model updating. The findings are expected to contribute to advancements in structural health monitoring by providing a robust methodology for enhancing the reliability of numerical models.

**KEY WORDS:** High Fidelity Finite Element Model Updating; Cooperative Game Theory; Structural Optimization; Structural Health Monitoring, Dynamic parameters

## 1 INTRODUCTION

High-fidelity numerical modelling has become essential in modern structural engineering for simulating complex physical behavior with a high degree of accuracy. High-fidelity finite element (FE) models are characterized by detailed geometric definitions, fine mesh discretization, and many physically meaningful parameters. These models enable precise structural simulations but also significantly increase computational effort and sensitivity to modelling assumptions. Despite their accuracy, high-fidelity FE models often fail to perfectly represent real structural behavior due to uncertainties in boundary conditions, material properties, and idealizations made during the modelling process. To reduce these discrepancies, the Finite Element Model Updating (FEMU) procedure is employed. FEMU involves adjusting selected model parameters based on experimental data—typically obtained from static tests, dynamic modal analysis, or continuous structural health monitoring—to improve correlation between the numerical model and the actual structural behavior [1]. The updating process becomes particularly challenging for high-fidelity models, where computational demands are high, and the solution space is large. In such cases, effective and reliable optimization strategies are critical. FEMU methods can be broadly classified into direct (non-iterative) and indirect (iterative) approaches [2]. Direct methods update the numerical model by modifying mass or stiffness matrices in a single step but may lack physical

interpretability [3][4]. In contrast, indirect (iterative) methods adjust physical parameters through successive approximations until numerical predictions align with experimental data [5]. One of the most widely used formulations is the Maximum Likelihood Method, which treats FEMU as an optimization problem (Eq. (4)) aimed at minimizing the difference between predicted and measured structural responses (Eq. (1)-(3)) [6].

$$r_t^f(\theta) = |\Delta f_t| = \left| \frac{f_t^{num} - f_t^{exp}}{f_t^{exp}} \right| \quad (1)$$

$$\text{MAC}(\phi_t^{exp}, \phi_t^{num}) = \frac{|(\phi_t^{num})^T \phi_t^{exp}|^2}{((\phi_t^{num})^T (\phi_t^{num})) \cdot ((\phi_t^{exp})^T (\phi_t^{exp}))} \quad (2)$$

$$r_t^m(\theta) = \sqrt{\left( \frac{(1 - \sqrt{\text{MAC}})^2}{\text{MAC}} \right)} \quad (3)$$

These residuals are then combined into a single-objective function (Eq. (4)) using weighting factors:

$$F(\theta) = \sum_{t=1}^{n_r} w_t F_t(\theta)^2 \quad (4)$$

$$F(\theta) = (\sum_{t=1}^{n_f} w_t^f r_t^f(\theta)^2 + \sum_{t=1}^{n_m} w_t^m r_t^m(\theta)^2),$$

$$\theta_l < \theta < \theta_u$$

This discrepancy is mathematically expressed using residuals based on modal parameters—most commonly natural

frequencies (Eq. (1)) and mode shapes (Eq. (3)). The residuals are defined as: optimization problem into a cooperative game structure, enabling a more robust and adaptive solution process suitable for updating complex and high-fidelity FE models.

The performance of this approach is highly dependent on the proper selection of the weighting factors and, which balance the influence of different types of residuals. However, determining these weights is non-trivial—typically requiring trial-and-error procedures, sensitivity analyses, and expert judgment [7–11]. This process is especially inefficient and unreliable when applied to high-fidelity FEMU, where each function evaluation involves high computational cost. To overcome these limitations, this paper proposes a novel formulation of the single-objective FEMU problem using Cooperative Game Theory (CGT). In the proposed approach, each residual is modelled as a player in a cooperative game. Instead of manually assigning weights, the optimization seeks a compromise solution by introducing a weighted objective function and a super-criterion that captures collective performance. This eliminates the need for manual tuning of weighting factors and enables a more automated and adaptive updating process. The optimization is performed using the Harmony Search (HS) algorithm—a population-based metaheuristic known for its balance between exploration and exploitation, and for its computational efficiency in solving nonlinear problems [12]. The proposed CGT-based method is applied to the updating of a high-fidelity finite element model of a pedestrian suspension bridge, providing a relevant and demanding benchmark for testing performance. The results are compared to those obtained using conventional optimization algorithms, highlighting the benefits of the proposed approach in terms of accuracy, robustness, and efficiency.

The paper is structured as follows. Section 2 introduces the cooperative game theory model applied to single-objective optimization in the context of high-fidelity finite element model updating (FEMU). Section 3 describes the case study structure, including numerical modelling and experimental testing that define the target structural behavior. Section 4 presents the FEMU process, including sensitivity analysis and comparison between conventional and game theory-based optimization. Section 5 discusses the results, and Section 6 provides concluding remarks based on the findings.

## 2 COOPERATIVE GAME THEORY MODEL FOR HIGH FIDELITY FINITE ELEMENT MODEL UPDATING

Game theory (GT) is a mathematical framework used to model decision-making, conflict, and cooperation among multiple agents, or "players" [13]. Recent trends in optimization highlight the transformation of classical optimization problems into game-theoretic formulations [14]. Within this framework, the fundamental components include players, strategies, utility, information, and equilibrium [15]. In the context of optimization, objective functions can be interpreted as players, with their design variables acting as strategies, and their respective function values as utilities [16]. Cooperative game models are particularly suitable for complex engineering problems, where conflicting objectives need to be aligned into a compromise solution through a negotiation model or a super-criterion [17]. This study applies the cooperative game theory (CGT) approach to high-fidelity finite element model updating

(FEMU)—a process characterized by computationally intensive models and the need for precise alignment with experimental data. CGT has been successfully combined with various soft computing techniques in the literature: Dhingra and Rao [18] integrated CGT with fuzzy set theory; Xie et al. [19] developed a four-step GT-based multi-objective method; Monfared et al. [20] formulated Pareto-optimal equilibrium (POE) points via two-player games; and Cheng and Li [21] incorporated genetic algorithms into the CGT framework. Annamdas and Rao [22] proposed a modified CGT model using Particle Swarm Optimization (PSO), which is adapted in this work for single-objective optimization.

### 2.1 Single-Objective optimization using Cooperative Game Theory

To update high-fidelity FEM models without explicitly analysing the impact of weighting factors, this study uses a single-objective optimization approach based on the CGT model introduced by Annamdas and Rao [22]. In this adapted method, Harmony Search (HS) is used instead of PSO to reduce computational cost [23]. The procedure includes four main steps:

- definition of the objective function;
- minimization, maximization, and normalization of objective function residuals;
- formulation of a weighted objective function;
- optimization of the weighted objective function.

Initially, the HS algorithm is used to minimize the objective function and obtain optimal residual values -  $f_t(\theta_t^*)$ . Next, maximization via HS yields the worst-case residuals -  $f_t(\theta_t^{**})$ . These results are used to normalize the residuals:

$$f_{nt}(\theta) = \frac{f_t(\theta) - f_t(\theta_t^*)}{f_t(\theta_t^{**}) - f_t(\theta_t^*)} \quad (5)$$

The normalized values are then used to define a weighted objective function:

$$F_{w,t} = K_1 f_{n1}(\theta) + K_2 f_{n2}(\theta) + \dots + K_{k-1} f_{n(k-1)}(\theta) + (1 - K_1 - K_2 - \dots - K_{k-1}) f_{nk}(\theta) \quad (6)$$

with the constraints

$$0 \leq K_t \leq 1, \sum_{t=1}^k K_t = 1 \quad (7)$$

To ensure that residuals are as far as possible from their worst-case values, a super-criterion is introduced:

$$SC = \prod_{t=1}^k [1 - f_{nt}(\theta)] \quad (8)$$

The final optimization problem is thus defined as:

$$F_{w,t}(\Phi) = FK - SC, \quad \Phi = [\theta_1 \ \theta_2 \ \dots \ \theta_n \ K_1 \ K_2 \ \dots \ K_{k-1}]^T \quad (9)$$

Minimizing  $F_{w,t}(\Phi)$  yields the optimal set of design parameters and weighting factors, effectively enhancing the correlation between the high-fidelity FEM predictions and experimental observations.

### 3 CASE STUDY ON REAL STRUCTURE

Suspension bridges, though efficient for spanning long distances and visually striking, are prone to damage mechanisms such as corrosion and fatigue, especially in their main cables and hangers. Due to limitations in traditional local damage detection methods, global vibration-based approaches combined with high-fidelity finite element model updating (FEMU) have proven to be a promising solution for monitoring such complex structures.

#### 3.1 Description of the structure

To evaluate the proposed model updating methodology presented in the previous section, a pedestrian suspension bridge over the Drava River in Osijek (Figure 1.) was selected as the case study. Constructed in 1980, the bridge features a single span of 209.5 m, suspended by a parabolic cable anchored behind 24 m high steel pylons.

Figure 1. a) View on the bridge from the right bank b) Longitudinal section and the ground plane of the bridge

The 5 m wide pedestrian deck is composed of 50 prefabricated concrete slabs of three different types, characterized by reinforced longitudinal and transverse ribs. The slabs are supported by inclined hangers ( $\phi$  21 mm) on one side and longitudinally movable connections ( $\phi$  28 mm) on the other, allowing for limited displacement and load redistribution.

Figure 2. Cross section of the bridge (all dimensions are in millimetres)

The structural system includes two  $\phi$  61 mm pre-tensioned cables on each side, anchored at the base of the pylons to reduce deck deformations and mitigate vibrations (Figure 2.). During

the 1990s war, the bridge sustained damage to its hangers and several slabs. It was subsequently rehabilitated to its original state. In 2009, an asphalt layer was added and the slab connections repaired. Further rehabilitation work in 2022 included replacement of upper cable connections, reprofiling of slab beams, sealing of joints, corrosion protection renewal, and repair of the handrail. This real-world example, with its complex structural behavior and history of interventions, provides an ideal scenario for applying and validating advanced model updating techniques within a structural health monitoring context.

#### 3.2 Initial numerical model

An initial finite element (FE) model of the pedestrian suspension bridge was developed using ANSYS software, consisting of 20,787 elements (Figure 3.). The structural components were modelled as follows: main and transverse beams, handrails, and rigid joints with BEAM188 elements; concrete slabs with SHELL181 elements; cables and hangers with LINK180 elements; and interconnections via COMBIN14 spring-damper elements. Boundary conditions were applied to restrict translations at anchor points and pylons in all directions.

Figure 3. Initial numerical model of pedestrian suspension bridge over Drava River a) 3D view b) y-z plane c) x-z plane d) x-y plane

Material properties and cross-sectional dimensions were assigned based on project documentation, and initial tensile forces in cable elements were derived from previous experimental measurements. Hangers were grouped into four categories based on mean axial force values and standard deviations (ranging from 30.4 kN to 52.1 kN), while the upper main cables were divided into four groups with forces between 4744 kN and 4852 kN. The lower main cables were assigned a prestress force of 1300 kN. A numerical modal analysis was performed to extract natural frequencies and mode shapes (Figure 4).

$$\begin{array}{lll} \phi_1^{num} - \text{torsional} & \phi_2^{num} - \text{vertical} & \phi_3^{num} - \text{torsional} \\ f_1^{num} = 0.335 \text{ Hz} & f_2^{num} = 0.428 \text{ Hz} & f_3^{num} = 0.641 \text{ Hz} \end{array}$$

Figure 4. First three numerically determined natural frequencies ( $f_t^{num}$ ) and mode shapes ( $\phi_t^{num}$ ) of pedestrian suspension bridge over Drava River ( $t=1, \dots, 3$ )

These results served as a reference for subsequent model updating and were compared with experimentally obtained modal parameters to assess the model's initial accuracy.

### 3.3 Experimental campaign

A comprehensive experimental campaign was conducted to identify the dynamic properties of the pedestrian suspension bridge and its key structural components. The investigation included determination of axial forces in all hangers (Figure 5.) and main anchor cables, natural frequencies of the down main cables and pylons, as well as dynamic parameters of characteristic edge and span slabs.

Figure 5. Calculated force values in the hangers on the upstream and downstream side of the bridge

Global dynamic properties of the entire bridge were determined under ambient excitation from pedestrian walking. Axial forces in the hangers were determined using the resonant vibration method [24] by measuring the natural frequency of each hanger following a manual excitation. These frequencies were correlated to tensile force using string vibration theory [25]. The results showed highest force values in the mid-span hangers and noticeable deviations between upstream and downstream pairs. A similar procedure was used to determine force magnitudes in the main anchorage cables on both banks, with calculated values showing good agreement with historical measurements and design data. Dynamic testing of the down main cables and pylons was performed using impulse excitation with a rubber hammer. Natural frequencies were identified using frequency domain decomposition based on acceleration measurements in orthogonal directions. To assess local behavior, dynamic parameters of a representative edge slab and a central span slab (Figure 6.) were identified through ambient vibration testing induced by random pedestrian walking [26].

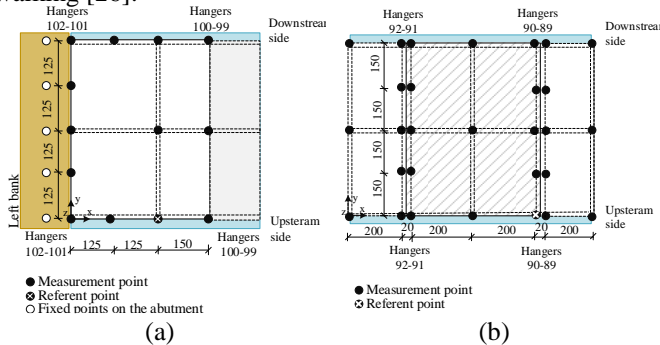

Figure 6. Arrangement of the measurement points on characteristic slab (a) edge (b) span

Acceleration responses were recorded at 13 and 29 measurement points, respectively, and modal properties were extracted using FDD. For global structural identification, vertical excitation due to pedestrian traffic was used to excite the entire structure. Acceleration was measured at 100 nodes (50 upstream and 50 downstream) in two directions, resulting in 200 degrees of freedom. Natural frequencies, mode shapes, and damping ratios (Figure 7.) were extracted using Enhanced Frequency Domain Decomposition (EFDD).

$$\phi_1^{exp} - \text{Torsional} / X; f_1^{exp} = 0.337 \pm 0.011 \text{ Hz}; \zeta_1^{exp} = 3.83 \pm 1.23$$

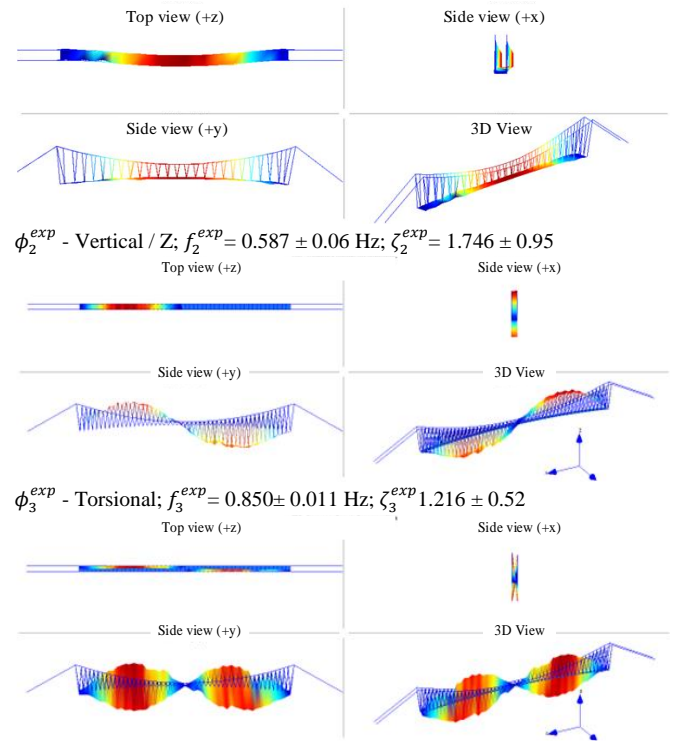

Figure 7. First three experimentally determined natural frequency ( $f_t^{exp}$ ), damping ratio ( $\zeta_t^{exp}$ ) with their standard deviation ( $\sigma_t^f, \sigma_t^z$ ) and mode shapes ( $\phi_t^{num}$ ) of pedestrian suspension bridge over Drava River ( $t=1, \dots, 3$ )

The analysis revealed distinct global mode shapes consistent with the expected behavior of a suspension bridge, providing essential input for finite element model updating (FEMU). These experimentally obtained dynamic parameters form the basis for calibrating and validating the numerical model, as described in the following chapter.

### 3.4 Comparison of Numerical and Experimental Results

A comparison between the initial numerical model and experimental results was conducted to evaluate model accuracy. Natural frequencies and mode shapes were compared using relative differences and the MAC coefficient (Table 1.). While the initial model showed acceptable agreement, some deviations indicated the need for refinement. To improve accuracy, finite element model updating (FEMU) was performed using two approaches: a conventional multi-objective (MO) optimization method and a Cooperative Game Theory (CGT)-based method.

Table 1. Comparison of the pedestrian suspension bridge modal parameters predicted by initial numerical model and its actual modal parameters based on the absolute relative difference between the natural frequency values ( $\Delta f_t$ ) and modal assurance criterion MAC ( $\phi_t^{exp}, \phi_t^{num}$ )

Mode shape t	$f_t^{num}$ [Hz]	$f_t^{exp}$ [Hz]	$ \Delta f_t $ [%]	MAC ( $\phi_t^{exp}, \phi_t^{num}$ ) [/]
1	0.335	0.337	0.597%	0.995
2	0.569	0.587	3.163%	0.967

#### 4 FINITE ELEMENT MODEL UPDATING

##### 4.1 Sensitivity Analysis

To identify the most influential parameters for the model updating process, a sensitivity analysis was performed using the ratio of modal strain energy (MSE) associated with each physical parameter to the total MSE of the structure. Initially, 17 parameters were considered, but based on the analysis results (Figure 8.), 13 were selected for updating. The selected parameters include material properties (e.g., Young's modulus of concrete and handrails), connection stiffnesses, and cable pretension forces (down main cables, hangers, and upper main cables).

Figure 8. Results of sensitivity analysis performed on the pedestrian suspension bridge finite element model for initial selected ( $\theta_{1,...,17}$ ) 17 updating parameters

To ensure physical feasibility, each parameter was constrained within predefined lower and upper bounds. Following parameter selection, the optimization problem was structured by partitioning the residuals of natural frequencies and mode shapes. Using a sorting-based approach [14], the influence of each parameter was quantified, and two strategy spaces were defined: for natural frequency,  $S_f = \{\theta_1, \theta_2, \theta_3, \theta_4, \theta_5, \theta_6, \theta_7, \theta_8, \theta_9, \theta_{11}\}$  and for mode shape,  $S_{ms} = \{\theta_{10}, \theta_{12}, \theta_{13}\}$ . This

selection guided the subsequent model updating process to achieve more accurate and efficient calibration of the FE model.

##### 4.2 Solution of the MO FEMU problem based on the conventional optimization method

To assess the computational efficiency of the proposed CGT-based model for high-fidelity FEMU of complex structures, a benchmark analysis was conducted using a conventional multi-objective optimization method since previous research [23] has confirmed its effectiveness and accuracy. The Harmony Search (HS) algorithm was adopted for this comparison. The optimization process was implemented by coupling ANSYS for FE analysis with MATLAB for optimization. Key HS parameters were population size (PS = 50), maximum iterations ( $I_{max} = 100$ ), objective function tolerance ( $10^{-4}$ ), pitch adjustment rate (PAR = 0.3), and harmony memory consideration rate (HMCR = 0.9). The resulting Pareto front of the two objective function residuals is shown in Figure 9, highlighting the “knee point” as the most balanced solution. This optimal solution corresponds to a set of updated model parameters that improved the accuracy of the numerical model. The total computational time required to reach this solution using HS was approximately 192,783 seconds, providing a reference for evaluating the performance of the CGT approach.

##### 4.3 Solution of the FEMU problem based on the CGT model

Following its proven efficiency and accuracy on a laboratory-scale bridge model, the Cooperative Game Theory (CGT) model was applied to solve the high-fidelity FEMU problem of a complex pedestrian suspension bridge. The optimization began from an initial strategy vector  $\theta_{initial\_PSBO}^0 = [1 \ 1 \ 1 \ 1 \ 1 \ 1 \ 1 \ 1 \ 1 \ 1 \ 1 \ 1 \ 1 \ 1 \ 1 \ 1 \ 1 \ 1]$  and iterations were carried out until the convergence criterion  $\xi = 0.001$  was met. Cooperation weights were set symmetrically  $w_{11} = w_{22} = w_{12} = w_{21} = 0.5$  based on the established rules. Upon convergence, the optimal parameter set  $\theta_{CGT\_PSBO}^* = [0.9997 \ 0.8917 \ 1.0585 \ 1.0305 \ 0.8686 \ 1.2281 \ 1.7530 \ 1.0488 \ 0.8219 \ 1.0221 \ 1.0086 \ 0.9969 \ 1.0020]$  showed strong alignment with physical properties, leading to significantly improved correlation with experimental data. The CGT model completed the optimization in 89,758 seconds, demonstrating both computational efficiency and robustness in handling the multi-objective FEMU problem for a real-world, large-scale structure.

#### 5 DISCUSSION

To evaluate the performance of the proposed Cooperative Game Theory (CGT) method for multi-objective finite element model updating (FEMU), a comparative analysis was conducted against a conventional Harmony Search (HS) multi-objective optimization approach. Two main criteria were considered: solution accuracy and computational time. As illustrated in Figure 9, the solution obtained using the CGT method closely matches the optimal solution (“knee point”) identified by the conventional HS method. Importantly, this level of accuracy was achieved with significantly lower computational effort. The CGT model required 89,758 seconds, compared to 192,780 seconds for the HS algorithm—demonstrating a reduction in computational time of over 50%, without compromising result quality. This efficiency is

achieved through the direct identification of the knee point using game theory principles, eliminating the need to compute the entire Pareto front, as required in conventional methods.

Figure 9. Comparison of the “knee” point obtained based on the Pareto front (conventional method) with the position of the optimal solution obtained using CGT model

Furthermore, Table 2 and Table 3 presents the updated natural frequencies and MAC values for both methods. The CGT approach (Table 3.) yields comparable accuracy in terms of relative frequency differences and mode shape correlation (MAC factors), confirming its robustness and suitability for high-fidelity FEMU of complex structures such as suspension bridges.

Table 2. Correlation between experimental and updated natural frequencies and mode shapes using conventional HS

Mode t	$f_t^{exp}$ [Hz]	$f_t^{upd,HS}$ [Hz]	$\Delta f_t^{HS}$ [%]	$MAC_t^{HS}$ [/]
1	0.337	0.335	-0.46	0.997
2	0.587	0.596	1.53	0.985
3	0.850	0.842	-0.94	0.984

12	3.037	3.054	0.56	0.964
13	3.313	3.258	-1.65	0.993

Table 3. Correlation between experimental and updated natural frequencies and mode shapes using CGT model

Mode t	$f_t^{exp}$ [Hz]	$f_t^{upd,CGT}$ [Hz]	$\Delta f_t^{CGT}$ [%]	$MAC_t^{CGT}$ [/]
1	0.337	0.334	-0.89	0.997
2	0.587	0.597	1.70	0.984
3	0.850	0.843	-0.82	0.984
4	1.013	1.025	1.18	0.954
5	1.150	1.141	-0.78	0.987
6	1.400	1.384	-1.14	0.982
7	1.663	1.635	-1.68	0.957
8	1.925	1.898	-1.40	0.971
9	2.188	2.223	1.60	0.996
10	2.475	2.425	-2.02	0.987
11	2.737	2.692	-1.64	0.993
12	3.037	3.042	0.16	0.964
13	3.313	3.269	-1.33	0.992

These results validate the CGT method as a computationally efficient and accurate alternative to traditional optimization

approaches for model updating in structural engineering applications.

## 6 CONCLUSION

This research presents a novel and efficient framework for high-fidelity finite element model updating (FEMU) by leveraging the principles of Cooperative Game Theory (CGT). The proposed approach was applied to a real-world pedestrian suspension bridge, providing a rigorous testbed to evaluate the effectiveness of the method in handling the complexity and precision demands of high-fidelity finite element analysis. Key contributions and findings include:

- By formulating FEMU as a cooperative game, the method enables a targeted and efficient resolution of conflicting objectives, such as matching both natural frequencies and mode shapes, without the need to compute the entire Pareto front. This aspect is especially beneficial in complex, high-fidelity models with many interdependent parameters.
- Compared to the conventional Harmony Search (HS) method, the CGT approach achieved equivalent or better accuracy with a reduction in computational time of over 50%. This demonstrates that high-fidelity analysis does not necessarily come at the cost of efficiency when advanced optimization strategies are applied.
- The CGT-based method improved the correlation between the numerical and experimental modal parameters, confirming its suitability for high-fidelity finite element analysis where accuracy and detail are critical. The updated model captured the structural behavior of the bridge with remarkable precision, addressing discrepancies in natural frequencies and mode shapes.
- The method was validated using extensive experimental data from a real suspension bridge, including local and global dynamic characteristics. The updated model reflects the true structural behavior with a high level of fidelity, even in the presence of structural uncertainties and historical modifications.

In summary, the CGT-based FEMU framework proves to be a robust, accurate, and computationally efficient solution tailored to the needs of high-fidelity finite element analysis. Its adaptability and performance make it a promising tool for advancing structural health monitoring in complex and intelligent infrastructure systems.

**ABSTRACT:** Structural Health Monitoring of bridges is being used increasingly to ensure safe operation of bridges. Non-iterative and mechanics-based algorithms that were developed in the past to find the material property of a bridge or the live load moving over the bridge use the static strain response of the bridge. However, the field strain measurement of these response quantities has both static and dynamic components. To apply these non-iterative methods for live load or material property estimation, it is important to decouple the static components of the strain from its dynamic components. Hence, in the current study, the dynamic components of the bridge strain response are filtered to extract the static components using a low-pass filter. The adequacy of filtering is then measured based on the probability of the static maximum axial strain and average shear strain contained in the probabilistically determined dynamic response corresponding to different road roughness. The idea of relating the cutoff frequency to the bridge natural frequency is investigated. It is concluded that using a cutoff frequency of half the bridge natural frequency, one can sufficiently filter out the dynamic components under any case of vehicle speed, road roughness, and bridge natural frequency.

**KEY WORDS:** System identification; Dynamic response filtering; Monte Carlo simulation; Vehicle bridge interaction; Low-pass filter.

## 1 INTRODUCTION

Bridges play a critical role in a country's development. The bridges built in the past are deteriorating due to degradation from the environment and varying operational conditions. Although the current method of visual inspection is simple in procedure, it has some disadvantages when dealing with many bridges. It is time-consuming and subjective. Hence, structural health monitoring (SHM) is emerging as a viable alternative. SHM uses technology to access the current state of the bridge. The current state of the bridge here refers to either the current stiffness or the strength of the bridge. The strength is determined by non-destructive testing, like the rebound hammer and ultrasonic pulse velocity. In contrast, stiffness is determined by knowing the material parameters, boundary conditions, geometric parameters, and live load spectrum.

In the present study, the focus is on determining the current stiffness of the bridge. This can be computed by finding the current material properties and geometrical quantities like the moment of inertia and the cross-sectional area. To do so, the usual approach is to minimize the error between the measured response and the computed response using an optimization algorithm. But this involves computational costs, the problem being ill-posed, and other disadvantages. So, a mechanics-based non-iterative algorithm was proposed [1] to estimate the material property. This method has been proven effective for quasi-static loading conditions, neglecting vehicle-bridge interaction (VBI) dynamics. However, when it comes to realistic traffic scenarios and road roughness profiles, VBI is present and leads to a deviation of the measured response from the actual static response. So, one needs to filter out the dynamic components to arrive closer to the static response.

Now, the input to the material parameter estimation algorithm can be given in two ways. Either a known vehicle load will move over the bridge, as in [1] or the vehicle load also needs to be found using some appropriate measured response quantity [2]. The latter is more advantageous than the former in the case of continuous monitoring. So, identifying the moving load is also focused on. In general, moving load identification literature again involves optimization-based algorithms with the above-mentioned disadvantages. The numerous vehicles and bridge parameters must be known or optimized to find the axle loads. Such an approach increases the uncertainty involved in fixing the parameter values or ill-posed problem and hence reduces the accuracy of the identification. Instead, an algorithm for load estimation in a railway bridge was proposed by [2], which uses a composite strain response for estimating the moving load. An important property of this composite response is that it remains constant over a period for a single vehicle to pass over the bridge. But once again, the field-measured value of this composite strain response quantity can potentially include the dynamic components due to VBI and does not remain constant.

To overcome the above-mentioned difficulties, one of the approaches followed is to filter out the dynamic components from the measured response to get the static response. Few works on filtering can be found in the literature. For instance, in [3], a digital filtering technique was employed to obtain the static bridge response from the dynamic weigh-in-motion data. A low-pass filter of frequency ranging from 0.25 Hz to 1.0 Hz was used. But later it was shown that no proper criteria can be found for cutoff frequency, and a new technique called the equivalent digital filtering technique (EDFT) was proposed [4]. This uses the pseudo-static response of the bridge and the fact

that the dynamic response (pseudo-static response + dynamic effects) and the static response in the frequency domain are approximately equal at 0 Hz. It was shown to be highly accurate in estimating static vehicle weight on dynamic response untainted by other miscellaneous vibrations. [5] used an 11-point and 21-point moving average low-pass filter to improve the accuracy of identified moving loads by eliminating the noise effect. It was found that the percentage errors were significantly reduced, and hence filtering was highly recommended. [6] used a low-pass filter to filter out the dynamic components from the identified bridge influence lines. In [7], the noise and dynamic components are removed to get static strains for moving load identification. It was found that when the cutoff frequency is equal to six to eight times the fundamental frequency of the train load, the peaks of the second derivative of the strain measurements can be identified. Recently, [8] used a low-pass filter to isolate the bridge response from the vehicle dynamics and other excitation sources (the asphalt roughness). The acceleration signal from a vehicle moving at 140 km/h was filtered to obtain the static response for identification of the bridge's elastic modulus using the correlation method. A cutoff frequency of 0.5 Hz, much less than the vehicle's first natural frequency of 2 Hz, was used. It was shown that proper filtering could adequately filter out the vehicle dynamics and other excitations. Now, even though many studies on filtering are available, there are not many studies that extensively deal with measuring the efficacy of filtering algorithms for various vehicle bridge parameters.

Hence, in the present study, a methodology to filter out the dynamic components from the measured strain response is developed. A numerical simulation is performed by modeling the vehicle bridge interaction dynamics. Using a half-car model and a classical Euler-Bernoulli beam model, the dynamic characteristics of the bridge strain response are obtained. Then, using a low-pass filter based on a cutoff frequency, the high frequency components are filtered out. The degree of closeness of the static response is measured using a probabilistic measure. The working of the proposed method is checked for the practical range of vehicle and bridge parameters.

In this paper, the methodology adopted in the study is explained in Section 2, followed by the implementation details of VBI modelling, code validation, numerical data taken in the study, and modal convergence in Section 3. The investigation relating the cutoff frequency to the bridge natural frequency and the effect of various VBI parameters is illustrated in Section 4. Finally, the study is summarized, and the findings from the study are listed in Section 5.

## 2 METHODOLOGY

The Fast Fourier Transform (FFT) of the bridge response was computed to understand its various frequency components. The FFT of the mid-span bridge acceleration response and the bridge mid-span axial strain response is shown in Figure 1. It is observed that the dynamic components are predominant in the acceleration FFT, whereas the static components are predominant in the strain FFT. Hence, it can be observed that when one uses strain response, the feasibility of getting the static response is much higher than that of using the acceleration response. So, through a threshold frequency called

“cutoff frequency”, one can segregate the static and dynamic components. First, the dynamic analysis is performed using a half-car vehicle model. The dynamic responses of concern in the study are the maximum mid-span axial strain and the mean of the sum of shear forces at the quarter span and the three-quarter span. The reason for choosing them is because of their applicability in non-mechanics-based SHM algorithms. The maximum mid-span axial strain is used in finding the material property of the bridge [1] and the average shear strain is used in estimating the moving load [2]. A Monte Carlo simulation of 1000 random trials is performed to account for the random nature of road roughness. Assuming a typical population standard deviation of 2 to 3 micro-strain, a 95% confidence interval yields an estimated margin of error of approximately 0.1–0.2 micro-strain. The best fit distribution and the maximum likelihood estimate parameters for the filtered dynamic response are then found using the Kolmogorov–Smirnov (KS) test in MATLAB. The adequacy of filtering is then measured using the value of the probability for the filtered signal to contain the static response. A bound of  $\pm 1$  micro-strain is considered as a tolerance value for the static response, since it is the least resolution one can achieve in the field for electrical strain gauges.

## 3 IMPLEMENTATION DETAILS

### 3.1 Vehicle Bridge Interaction Modeling

The vehicle is modeled using a half-car model (HCM) as shown in Figure 2. The bridge is modeled as a simply supported Euler-Bernoulli beam. In HCM, four degrees of freedom are considered – vertical displacement ( $z_v$ ) and pitching rotation

( $\theta_v$ ) of the vehicle's center of gravity (CG), vertical displacement of the front ( $z_{tf}$ ) and rear tires ( $z_{tr}$ ). The vehicle's sprung mass is represented by  $M_v$ , pitching moment of inertia as  $I_v$ , front and rear suspension stiffness  $k_{sf}$  and  $k_{sr}$  and front and rear suspension damping as  $c_{sf}$  and  $c_{sr}$  respectively. The axle spacing between the two axles is ' $s$ ' and the distances of CG from the front axle and the rear axle are denoted by  $s_1$  and  $s_2$ . The displacements of the bridge at the contact points corresponding to the front and rear tires are  $u_{cf}$  and  $u_{cr}$  respectively. The road roughness profile at the contact points is represented by  $r_{cf}$  and  $r_{cr}$ . The equation of motion for the vehicle's bouncing motion can be given by taking vertical force equilibrium as,

$$M_v \ddot{z}_v + c_{sf} (\dot{z}_v + \dot{\theta}_v s_1 - \dot{z}_{tf}) + k_{sf} (z_v + \theta_v s_1 - z_{tf}) + c_{sr} (\dot{z}_v - \dot{\theta}_v s_2 - \dot{z}_{tr}) + k_{sr} (z_v - \theta_v s_2 - z_{tr}) = 0 \quad (1)$$

Figure 2. Half car model.

The equation of motion for the vehicle's pitching motion can be found by taking moment equilibrium about the vehicle's CG axis as:

$$I_v \ddot{\theta}_v + c_{sf} (\dot{z}_v + \dot{\theta}_v s_1 - \dot{z}_{tf}) s_1 + k_{sf} (z_v + \theta_v s_1 - z_{tf}) s_1 - c_{sr} (\dot{z}_v - \dot{\theta}_v s_2 - \dot{z}_{tr}) s_2 - k_{sr} (z_v - \theta_v s_2 - z_{tr}) s_2 = 0 \quad (2)$$

The equation of motion for the vertical displacements of the front and rear tires can be found as:

$$m_{tf} \ddot{z}_{tf} - c_{sf} (\dot{z}_v + \dot{\theta}_v s_1 - \dot{z}_{tf}) - k_{sf} (z_v + \theta_v s_1 - z_{tf}) + c_{tf} (\dot{z}_{tf} - \dot{u}_{cf} - v r'_{cf}) + k_{tf} (z_{tf} - u_{cf} - r_{cf}) = 0 \quad (3)$$

$$m_{tr} \ddot{z}_{tr} - c_{sr} (\dot{z}_v - \dot{\theta}_v s_2 - \dot{z}_{tr}) - k_{sr} (z_v - \theta_v s_2 - z_{tr}) + c_{tr} (\dot{z}_{tr} - \dot{u}_{cr} - v r'_{cr}) + k_{tr} (z_{tr} - u_{cr} - r_{cr}) = 0 \quad (4)$$

Finally, the bridge's flexural vibration equation is given by,

$$EI u^{iv}(x, t) + m \ddot{u}(x, t) + c \dot{u}(x, t) = \left[ -\frac{M_v g}{2} - m_{tf} g + c_{tf} (\dot{z}_{tf} - \dot{u}_{cf} - v r'_{cf}) + k_{tf} (z_{tf} - u_{cf} - r_{cf}) \right] \delta(x - vt) + \left[ -\frac{M_v g}{2} - m_{tr} g + c_{tr} (\dot{z}_{tr} - \dot{u}_{cr} - v r'_{cr}) + k_{tr} (z_{tr} - u_{cr} - r_{cr}) \right] \delta(x - (vt - s)) \quad (5)$$

Using the modal superposition technique, the displacement  $u(x, t)$  can be represented using,

$$u(x, t) = \sum_{n=1}^N q_n(t) \varphi_n(x) \quad (6)$$

where  $q_n(t)$  is the modal coordinate and  $\varphi_n(x)$  represents the  $n^{\text{th}}$  mode shape of the simply supported beam, and  $N$  represents the total number of modes used. Now, substituting Equation (6) in Equations (1), (2), (3), (4), and (5), and then using the modal orthogonality principle, the vehicle bridge interaction system can be represented in a matrix form as follows:

$$[M]\{\ddot{X}\} + [C]\{\dot{X}\} + [K]\{X\} = \{R\} \quad (7)$$

where  $[M]$ ,  $[C]$  and  $[K]$  represent the mass, damping, and stiffness matrix of the VBI system of size  $(N + 4) \times (N + 4)$ .  $\{R\}$  represents the force vector and  $\{\ddot{X}\}$ ,  $\{\dot{X}\}$  and  $\{X\}$  represents the acceleration, velocity, and displacement vector, respectively, of size  $(N + 4) \times 1$ . This equation is coded in MATLAB and solved using Newmark's technique (constant acceleration). In this study, road roughness is modeled as a random process with a normal distribution. The wavelength characteristics are characterized using the spectral density of the profile height. The power spectral density coefficients from [10] are adopted to represent various classes of road roughness. A typical roughness profile is shown in Figure 3.

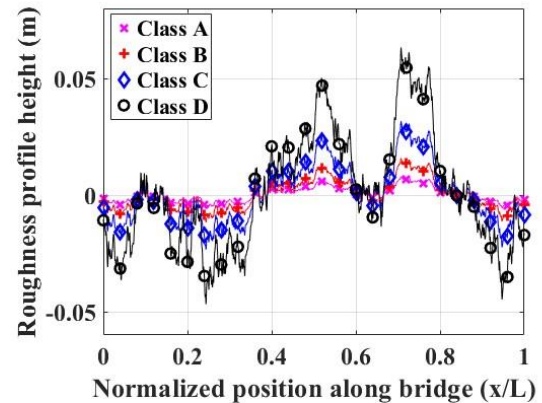

Figure 3. A typical roughness profile.

### 3.2 Validation of the HCM code

The code for vehicle bridge interaction is validated using data from the literature [9]. The values of the VBI parameters taken are as follows.

Vehicle:  $M_v = 1794.4$  kg;  $m_{tf} = 87.15$  kg;  $m_{tr} = 140.4$  kg;  $s_1 = 1.271$  m;  $s_2 = 1.713$  m;  $I_v = 3443.03$  kgm<sup>2</sup>;  $k_{sf} = 66.824$  kN/m;  $k_{sr} = 18.615$  kN/m;  $k_{tf} = k_{tr} = 101.12$  kN/m;  $c_{tf} = c_{tr} = 0$  Ns/m;  $c_{sf} = 1190$  Ns/m;  $c_{sr} = 1000$  Ns/m;  $v = 40$  km/h; Bridge:  $m = 20000$  kg/m;  $L = 100$  m;  $E = 207$  GPa;  $I = 0.174$  m<sup>4</sup>; Roughness: Smooth. The mid-span displacement of the bridge obtained using the developed code matched well with that from the literature, as shown in Figure 4.

### 3.3 Numerical data taken in the study

The half-car vehicle model values are taken from the representative vehicle data set from TruckMaker software. For the bridge, the values of a typical 50m span prestressed box

girder for three lane traffic are considered. And, for road roughness, the parameter values were taken from [10], [11] and [12]. The numerical values are given below.

Vehicle:  $M_v = 22700$  kg;  $m_{tf} = m_{tr} = 1500$  kg;  $I_v = 71,761.1$  kg/m<sup>2</sup>;  $s_1 = 3.133$  m;  $s_2 = 1.667$  m;  $k_{sf} = 25000$  N/m;  $k_{sr} = 30000$  N/m;  $k_{tf} = k_{tr} = 1.273 \times 10^6$  N/m;  $c_{tf} = c_{tr} = 6000$  Ns/m. Bridge:  $m = 11880$  kg/m;  $L = 50$  m;  $A = 4.87$  m<sup>2</sup>;  $I = 4.923$  m<sup>4</sup>;  $E = 31.62$  GPa;  $\nu = 0.2$ ;  $f_{b1} = 2.31$  Hz

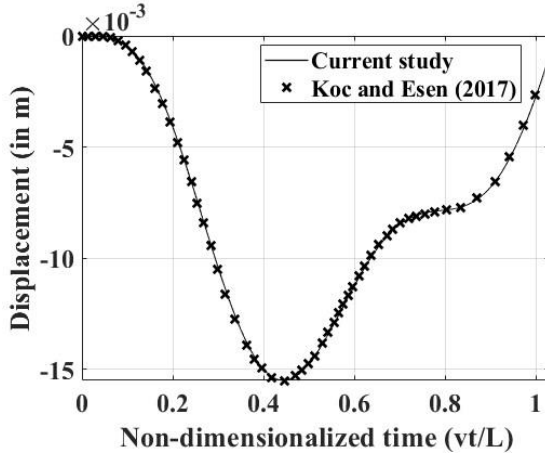

Figure 4. Validation of HCM code.

### 3.4 Modal Convergence study

As the method uses modal superposition, the minimum number of modes required to accurately represent the results are found using a convergence study. Towards this, absolute ( $\delta_{abs}$ ) and relative ( $\delta_{rel}$ ) convergence is checked wherein the definition used is,

$$\delta_{abs} = \| \epsilon_{N=N_{max}} - \epsilon_{N=1} \| \quad (8)$$

$$\delta_{rel} = \| \frac{\epsilon_{N=N_{max}} - \epsilon_{N=1}}{\epsilon_{N=N_{max}}} \| \times 100\% \quad (9)$$

where  $N$  represents the number of modes used;  $N_{max}$  represents the maximum number of modes used;  $\epsilon$  represents the maximum strain value at the given number of modes. The tolerance limit was kept at 0.01 micro-strain for absolute convergence and 0.01% for relative convergence. The convergence study was performed for various vehicle speeds ranging from 20 km/h to 120 km/h and for four roughness classes as per [10]. The minimum number of modes required to achieve convergence of the maximum axial strain response is shown in Table 1 and Table 2 respectively. It was found that 53 modes were adequate to satisfy the tolerance. Hence, further in the study, 60 modes were considered for all the computations.

Table 1. Modal convergence study based on absolute convergence for maximum axial strain at L/2.

Roughness Class	Speed (in km/h)					
	20	40	60	80	100	120
Class A	31	27	17	23	11	27
Class B	29	19	11	23	13	27
Class C	27	11	11	21	11	29
Class D	27	11	13	11	29	15

## 4 RESULTS

### 4.1 Filtered and Unfiltered response

To demonstrate the filtering process, as a reasonable estimate, a cutoff frequency of half the bridge's natural frequency is taken. The dynamic response of the bridge is simulated for 1000 random trials of road roughness. Assuming the velocity to be 50 km/h and road roughness as class D, the maximum midspan axial strain and average shear strain sum of the unfiltered and filtered signals are shown in Figure 5 and Figure 6 respectively.

Table 2. Modal convergence study based on relative convergence for maximum axial strain at L/2.

Roughness Class	Speed (in km/h)					
	20	40	60	80	100	120
Class A	31	29	17	31	15	29
Class B	31	31	17	31	31	31
Class C	29	19	13	31	29	31
Class D	29	11	31	17	29	15

Figure 5. Monte Carlo simulation of (a) unfiltered and (b) filtered dynamic response of 1000 random trials for maximum axial strain at L/2 (dashed line represents the static response).

Figure 6. Monte Carlo simulation of (a) unfiltered and (b) filtered dynamic response of 1000 random trials for average shear strain sum at L/4 and 3L/4 (dashed line represents the static response).

The histogram plot for the maximum axial strain and average shear strain sum for 1000 trials is shown in Figure 7(a) and Figure 7(b) respectively. One can observe that filtering makes the unfiltered response come closer to the static response. This observation was not much in the case of the average shear strain sum. Various probability distributions that can sufficiently fit the filtered histogram data were checked using the maximum log likelihood values in MATLAB. The plot of various distributions fitting the histogram data is shown in Figure 8.

A Kolmogorov-Smirnov (KS) test is used to check whether two samples come from the same distribution or not. Here, one sample is from the Monte-Carlo simulation data, and the other sample is from the fitting distribution (Normal, Lognormal, Logistic, Weibull, Gamma, etc.). The null hypothesis is that both come from the same distribution, and the alternative hypothesis is that both come from different distributions. A p-value of 0.05 is used to denote the significance level for the null hypothesis to be true. The distribution that gives the highest p-value and the log likelihood value is chosen as the best fit distribution, and its probability density value at the static response is calculated.

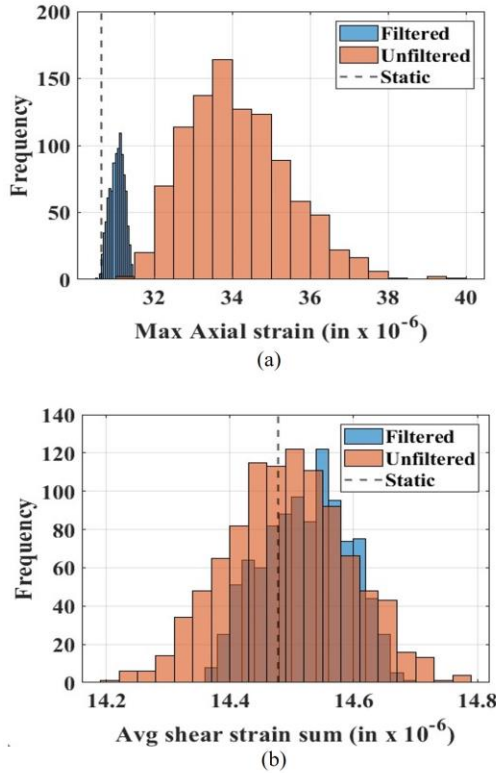

Figure 7. Histogram plot for the (a) Maximum axial strain (b) Average shear strain sum data.

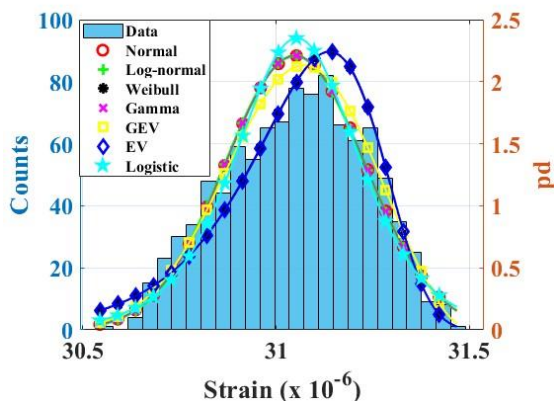

Figure 8. Best fit probability distribution for strain data.

The maximum likelihood estimates (MLE) parameters, KS test results, and their corresponding p-value for various distributions are shown in Table 3 and Table 4. One can observe that for the unfiltered response, the Generalized

Extreme Value (GEV) distribution has passed the test with the highest p-value of 0.9104. For the case of filtered response, all the distributions tested gave the pass results, but again, GEV has the highest p-value of 0.7167. Hence, the probability that the GEV distribution contains the static response  $\pm 1$  micro-strain for the filtered and unfiltered response will be 1.0000 and 0.0086, respectively.

#### 4.2 Study of static response probability for different cutoff frequency coefficients

The cutoff frequency was taken as a multiple of the bridge's natural frequency. This multiple will be referred to as the cutoff frequency coefficient. The range of coefficients from 0.2 to 1.5 was studied. The variation of the probability value of the static response for this range of coefficients is shown in Figure 9(a) and Figure 9(b) for a given vehicle speed of 50 km/h and road roughness class D. For the case of axial strain in Figure 9(a), it is observed that the probability value becomes zero at very low cutoff frequency (here for 0.1 and 0.15). This implies that there are not enough frequency components in the filtered response to represent the static value. Hence, the distribution of the filtered response will lie much farther away from the static response. A typical histogram plot for this case is shown in Figure 10(a) and Figure 10(b) for a cutoff frequency of  $0.15f_{b1}$ . One can observe that the filtered values are much lower than the static value. For all the values after 0.1, the probability becomes greater than 0. This means that the probability of static response lying in  $\pm 1$  micro-strain bound of the filtered response is greater than that of the unfiltered response. This demonstrates the effect of filtering. The maximum effect is observed at the one with the highest probability value. i.e., in this case, for a cutoff frequency of  $0.45 f_{b1}$ . For the case of shear strain sum shown in Figure 9(b), the static response probability becomes almost close to 1.0 for all the cutoff coefficients above 0.1. This is because, for shear strain sum, the average value was taken. Even for the case without filtering, one can achieve a response value closer to the static value, as evident from Figure 7(b). Hence, filtering doesn't have much of an effect in this case.

Table 3. Maximum Likelihood Estimates, KS Test results, and probability values to contain the static response for various distributions of unfiltered responses.

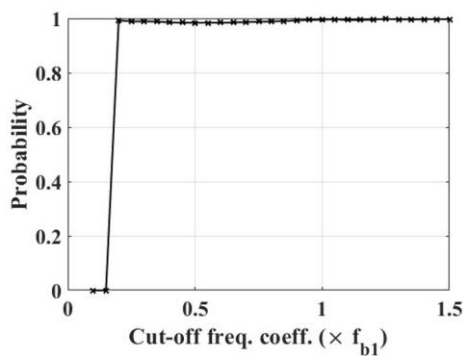

Distribution	MLE parameter	KS test	p-value	Probability
Normal	$\mu=34.13$ $\sigma = 1.311$	Pass	0.1768	0.0282
Log-normal	$\mu=3.527$ $\sigma = 0.038$	Pass	0.3078	0.0240
Weibull	$a=34.79$ $b = 23.82$	Fail	$9.8e-6$	0.0773
Gamma	$\alpha=686.3$ $\beta = 0.049$	Pass	0.2580	0.0253
GEV	$\mu=-0.1005$ $\sigma = 1.146$ $\xi = 33.57$	Pass	0.9104	0.0086
EV	$\mu=34.82$ $\sigma = 1.494$	Fail	$4.6e-7$	0.0815
Logistic	$\mu=34.07$ $\beta = 0.750$	Pass	0.3078	0.0351

Table 4. Maximum Likelihood Estimates, KS Test results, and probability values to contain the static response for various distributions of filtered response.

Distribution	MLE parameter	KS test	p-value	Probab ility
Normal	$\mu=31.05$ $\sigma=0.18$	Pass	0.5295	0.9994
Log-normal	$\mu=3.435$ $\sigma=0.006$	Pass	0.4938	0.9994
Weibull	$a=31.14$ $b=189.7$	Pass	0.2355	0.9999
Gamma	$\alpha=29566$ $\beta=0.0011$	Pass	0.5295	0.9994
GEV	$\mu=-0.368$ $\sigma=0.187$ $\xi=30.99$	Pass	0.7167	1.0000
EV	$\mu=31.14$ $\sigma=0.164$	Pass	0.2145	0.9999
Logistic	$\mu=31.03$ $\beta=0.106$	Pass	0.2355	0.9959

### 4.3 Effect of vehicle speed

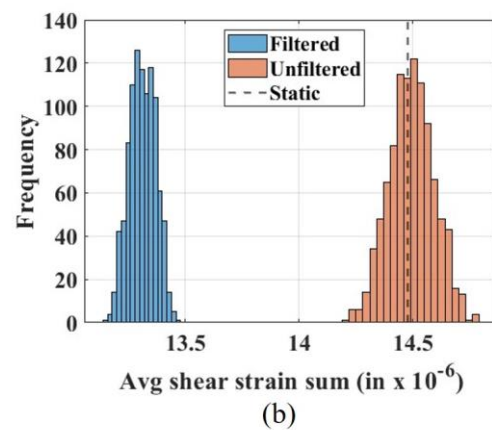

The effect of vehicle speed is studied by taking speed values as 10 km/h, 25 km/h, 50 km/h, and 100 km/h. The road roughness and bridge natural frequency were kept constant at class D and 2.31 Hz. The static response probability values for different cutoff frequencies are shown in Figure 11 for maximum mid-

span axial strain and in Figure 12 for the average shear strain sum. We can observe that the minimum cutoff required to attain a probability value of 1.0 increases with increasing speed. For instance, the minimum cutoff coefficients for speed values of 10, 25, 50, and 100 km/h are  $0.1f_{b1}$ ,  $0.15f_{b1}$ ,  $0.25f_{b1}$ , and  $0.4f_{b1}$ , respectively. This is because of the shifting of the driving frequency with the increase in speed. Also, the region from  $0.45 f_{b1}$  to  $0.75 f_{b1}$  has the probability value of 1.0 in all the cases and is hence recommended.

For shear strain sum, the effect of speed is observed in Figure 12. Again, the effect of driving frequency on the minimum cutoff coefficient can be observed. Also, after the minimum cutoff, at all the cutoff coefficients, the static response probability is maintained at 1.0, which was not observed in the axial strain case. This is because of the same advantage of taking the average value in the case of shear strain sum, as explained previously.

(a)

(b)

Figure 10. Histogram plot for filtered and unfiltered response corresponding to cutoff frequency of  $0.15f_{b1}$  for (a) Maximum axial strain at L/2 (b) Average shear strain sum at L/4 and 3L/4.

Figure 11. Effect of vehicle speed (a)  $v=10$  km/h (b)  $v=25$  km/h (c)  $v=50$  km/h (d)  $v=100$  km/h – Maximum axial strain at L/2 for  $f_{b1} = 2.31$  Hz and roughness class D.

#### 4.4 Effect of road roughness

The effect of road roughness is studied by varying the road roughness from class A (Very Good) to class D (Poor). The vehicle velocity is kept constant at 50 km/h, and the natural frequency is at 2.31 Hz. The static response probability values for different cutoff frequencies are shown in Figure 13 and Figure 14 for maximum mid-span axial strain and average shear strain sum, respectively. It can be observed that for low roughness classes, the probability is 1.0 even at higher cutoff frequencies. As the roughness class increases, the static response probability decreases. This is because a higher degree of roughness corresponds to increased dynamic noise in the signal and hence a decrease in the static response probability value. For the case of the average shear strain sum in Figure 14, there was not much observation. The probability value reaches 1.0 for all the cutoff coefficients above 0.15.

Figure 12. Effect of vehicle speed (a)  $v=10$  km/h (b)  $v=25$  km/h (c)  $v=50$  km/h (d)  $v=100$  km/h – Average shear strain sum at L/4 and 3L/4 for  $f_{b1} = 2.31$  Hz and roughness class D.

Figure 13. Effect of road roughness (a) Class A (b) Class B (c) Class C (d) Class D – Maximum axial strain at L/2 for  $f_{b1} = 2.31$  Hz and  $v=50$  km/h.

#### 4.5 Effect of bridge natural frequency

Finally, the effect of various bridge natural frequencies is studied. The natural frequency of the bridge is varied by changing the value of the flexural rigidity of the bridge. Four values of natural frequency – 2.31 Hz, 5 Hz, 7.5 Hz, and 10 Hz were studied, corresponding to four EI values – 157 GNm<sup>2</sup>, 753 GNm<sup>2</sup>, 1693 GNm<sup>2</sup>, and 3008 GNm<sup>2</sup>.

Figure 14. Effect of road roughness (a) Class A (b) Class B (c) Class C (d) Class D – Average shear strain sum at L/4 and 3L/4 for  $f_{b1} = 2.31$  Hz and  $v=50$  km/h.

Figure 15. Effect of bridge natural frequency (a)  $f_{b1} = 2.31$  Hz (b)  $f_{b1} = 5$  Hz (c)  $f_{b1} = 7.5$  Hz (d)  $f_{b1} = 10$  Hz – Maximum axial strain at  $L/2$  for  $v = 50$  km/h and roughness class D.

For all the coefficients between  $0.25 f_{b1}$  to  $0.7 f_{b1}$ , the static response probability for the case of maximum axial strain is 1.0, irrespective of different natural frequencies, as shown in Figure 15. Also, it can be observed that for a given case of a cutoff frequency closer to the bridge's natural frequency, the static response probability depends upon the relative distance between the driving frequency and the bridge's natural frequency. If this difference is high, the probability value becomes 1.0; otherwise, the value reduces. The figure for the average shear strain sum is shown in Figure 16. As observed previously, the probability value for most of the cutoff coefficients is 1.0.

Figure 16. Effect of bridge natural frequency (a)  $f_{b1} = 2.31$  Hz (b)  $f_{b1} = 5$  Hz (c)  $f_{b1} = 7.5$  Hz (d)  $f_{b1} = 10$  Hz – Average shear strain sum at  $L/4$  and  $3L/4$  for  $v = 50$  km/h and roughness class D.

## 5 CONCLUSION

The idea of cutting off the higher frequencies from the bridge strain response to get the static response of the bridge is

investigated. A half-car vehicle bridge interaction model was used to simulate the motion of a moving vehicle. Newmark's constant integration scheme was used to solve the program in MATLAB.

A Monte Carlo simulation of 1000 trials is performed for random values of road roughness. A low-pass Butterworth filter is used to cut off higher frequencies. Contrary to the literature studies wherein the cutoff frequency was related to the driving frequency, in this study, it is related to the bridge's natural frequency. A detailed study on the influence of the cutoff frequency so that the filtered signal contains the static response  $\pm 1$  micro-strain is undertaken. And finally, the effect of VBI parameters – vehicle speed, road roughness, and natural frequency was studied. From the study, the following is inferred:

- The cutoff frequency of 0.5 times the bridge natural frequency seems to have the highest probability of containing the static strain response across different vehicle speeds, road roughness, and natural frequency of the bridge.
- The higher the vehicle speed, the higher is the driving frequency, and hence the cutoff frequency to contain the static response increases.
- The higher the road roughness, the higher the dynamic noise in the response, and hence, the static response probability decreases for a given cutoff frequency.
- Both the driving frequency and the bridge natural frequency determine the cutoff frequency, which would contain the static strain response.

Further efforts are required to validate the study using field data.

**ABSTRACT:** This paper presents key results on the laboratory testing of old girders removed from a flood-damaged bridge located near Ljubljana, Slovenia. The structure was widened in 1989 to accommodate pedestrians and cyclists by integrating prefabricated prestressed reinforced concrete T-girders. To assess the structural behaviour of the bridge, six girders were subjected to a rigorous testing program involving bending and shear tests in a laboratory setting. The tests were performed on girders with static lengths of 12.20 meters and 9.90 meters. The program aimed to evaluate the structural performance of the girders. Preliminary results indicate satisfactory structural behaviour of the prestressed T-girders under the applied loads, with insights into their performance under both bending and shear stresses. This study contributes valuable data for assessing the long-term behaviour of bridges. The outcomes are particularly relevant for optimising resource allocation in bridge rehabilitation projects and ensuring safety and functionality in transportation networks.

**KEY WORDS:** laboratory testing, prestressed girders, assessment, load test, operational modal analysis, damage, acoustic emission

### 1 INTRODUCTION

Bridges are a key component of transport infrastructure, ensuring connectivity and traffic flow at both regional and national levels. However, as they age, they become susceptible to damage due to material degradation, traffic loads, and extreme weather events. Regular condition assessment through visual inspections and different structural monitoring systems is therefore essential to ensure the safety of both the structures and their users.

Bridge replacement typically entails significant financial costs, long execution times, and considerable logistical challenges. Consequently, it is crucial to leverage all available knowledge to accurately assess the actual safety and remaining service life of existing bridges. In this context, experimental data plays a vital role, as it provides direct insight into the structural behaviour [1, 2, 3].

This paper presents the ReNos project, a research initiative by the Slovenian National Building and Civil Engineering Institute (ZAG), which involved laboratory testing of prestressed concrete girders recovered from an existing bridge structure that had been exposed to flooding. The main objectives of the research were: (i) to determine the actual load-bearing behaviour and (ii) to monitor damage development using various sensor types, and (iii) to develop a protocol for potential reuse of the girders.

First, the bridge and the girders are described, including the entire process of the adapted demolition and transportation of the girders to the laboratory. This is followed by a description of the experimental program, preliminary results, and the future work plan.

### 2 DESCRIPTION OF THE BRIDGE, GIRDERS, AND DISASSEMBLY PROCESS

#### 2.1 Bridge and girders

The five-span bridge with a total length of 52.6 m and width of 8.2 m was located on a state road near Ljubljana, Slovenia. The original superstructure consisted of a ribbed reinforced concrete slab with brick inserts, supported by thin walls.

In 1989, the bridge was widened on both sides to accommodate pedestrian and cyclist traffic. The extension incorporates prefabricated prestressed concrete T-girders supported by additional wall piers aligned with the existing substructure. These girders were connected transversely by a cast-in-place reinforced concrete slab. The extended bridge from the upper stream side is shown in Figure 1.

Figure 1. Existing bridge before the collapse (downstream).

Following the catastrophic 2023 floods in Slovenia, the bridge partially collapsed, as shown in Figure 2 from the downstream side. While the intermediate supports were damaged, an inspection confirmed that the longitudinal girders remained in good condition. In agreement with the infrastructure manager and demolition contractor, selected girders were salvaged for laboratory testing (Figure 3).

Figure 2. Partly collapsed bridge after floods (upstream).

Figure 3. Lifting the girders with cranes.

## 2.2 Disassembly process

The process of disassembling the girders proved to be highly challenging. Nevertheless, all stakeholders involved, including the infrastructure management authority and the demolition contractor, demonstrated a commendable level of flexibility by adapting the demolition procedure to enable the safe recovery of the girders for further purposes, such as experimental testing or potential reuse.

The girder disassembly process comprised the following key steps: identification of reusable elements; preparation of the demolition method by the contractor; cutting of the concrete slab between the girders; removal of the edge girders; lifting of the girders using cranes; transportation of the girders; and placement at designated storage or testing locations.

## 3 EXPERIMENTAL PROGRAM AND TEST SETUP

The investigation program was based on the testing of six girders, focusing on the following parameters: the influence of girder length (span lengths of 9.9 m and 12.2 m), the influence of the load application point (shear/flexural test), the influence

of the presence of a reinforced concrete (RC) slab on the girder (girders with and without slabs), and the impact of pre-existing damage to the girder.

In addition, supporting activities were carried out, including visual inspections of the girders, destructive and non-destructive testing of the girder materials/aggregates and laser scanning of specimens.

The test setup is presented in Figure 4. The girder was simply supported, with a pinned support at one end and a roller support at the other side. Both supports were rigidly anchored to the laboratory's strong floor. Lateral stability of the girder was ensured using a rigid steel frame. The load was applied by means of a hydraulic actuator, which was clamped into the steel reaction frame.

Figure 4. Experimental setup at ZAG's Laboratory for Structures.

The essential instrumentation for each test included a force transducer, displacement transducers, strain measurement devices (extensometers, strain gauges, digital image correlation (DIC) system, optical sensors), accelerometers, and acoustic emission sensors.

The testing procedure for the static cyclic tests was generally divided into two stages. The first stage was load-controlled, while the second stage was displacement-controlled. Each stage comprised several phases, defined either by force levels (in the first stage) or displacement increments (in the second stage). The load, whether force- or displacement-controlled, was progressively increased until the girder failed.

## 4 PRELIMINARY TEST RESULTS

Due to the limited scope of the paper, in the following, the preliminary results of only the flexural test on the B4 girder is presented. This girder, with a span length of 9.9 m, was loaded at mid-span during the test. It was tested without the top RC slab and had no pre-existing damage prior to the testing.

### 4.1 Flexural behaviour of girder

The flexural behaviour of the girder is represented by the hysteretic curve, which shows the relationship between applied force and mid-span displacement, as illustrated in Figure 5. The triangles indicate the state at initial cracking and the state just before failure. The labels S1, S2, and S3 denote engineering-

defined states employed for damage detection accelerometers, as described in Section 4.2.

Figure 5. Hysteretic response of the girder at the middle.

The initial cracks appeared during the second loading phase, forming in the load application area with an initial width of approximately 0.1 mm (Figure 6). Cracking began at an applied force of 246.1 kN and a corresponding displacement of 10 mm. These cracks closed completely upon unloading. As the loading progressed through subsequent phases, the cracks widened and propagated, increasing both in number and extent. Inclined (shear) cracks also began to appear in supports' region.

Figure 6. Damage state at the peak of the cycle when the first cracks appeared.

Figure 7. Damaged girder in the failure stage.

In the phase immediately preceding failure, the maximum observed crack width reached 4.5 mm, with a residual width of 3.0 mm after unloading. In the following phase at displacement of 22,4 mm and force 497 kN, the girder experienced flexural

failure, accompanied by the rupture of the prestressing tendons in the load application zone (Figure 7).

#### 4.2 Monitoring of damage with accelerometers

The damage of the girder at the end of individual loading cycles was monitored using 18 DEWESoft 3-axial MEMS accelerometers [4], placed on the top flange. This part of the experimental program aimed to evaluate the limits of acceleration-based monitoring systems to detect structural damage based on changes in the specimens' dynamic characteristics.

Damage progression was monitored through ambient vibration measurements conducted after each load cycle on fully unloaded girders, ensuring consistent initial boundary conditions. The specimen's dynamic properties, including natural frequencies, mode shapes, and damping ratios, were identified using Operational Modal Analysis (OMA) performed with the DEWESoft ARTEMIS OMA software [5].

This study presents and discusses the changes in natural frequencies of the first two vertical bending modes, shown in Table 1. A schematic illustration of the corresponding mode shapes is provided in Figure 8.

Table 1. Change in mode shape natural frequencies during experimental phases.

B4	$f_1$ [Hz]	$f_2$ [Hz]	$\Delta f_1$ [%]	$\Delta f_2$ [%]
Reference	12.4	45.8	\	\
S1: after crack phase	12.0	45.2	-3.2	-1.3
S2: after yield phase	10.3	43.8	-16.9	-4.4
S3: near collapse	8.0	40.8	-35.5	-10.9

The reference natural frequencies of the first and second vertical bending modes amounted to 12.38 Hz and 45.81 Hz, respectively. As damage accumulates during load cycles, the girder's stiffness diminishes, which is reflected in the corresponding reduction of natural frequencies in Table 1. A reduction of 3% to 36% in the first natural frequency was observed as the damage evolved from cracking (S1) to near-collapse limit state (S3). Smaller decrease was obtained for the second vertical bending mode (1% to 11%), which is due to the applied load causing more damage near mid-span, where the amplitude of the second mode is nearly zero (see Figure 8b).

Figure 8. First (a) and second (b) vertical bending modes of B4 girder.

Initial findings indicate that acceleration-based monitoring can be used to detect structural damage in a controlled environment.

### 4.3 Monitoring of damage with acoustic emission

During the load test, the evolution and propagation of damage were also assessed using acoustic emission methods (AEM). Three Physical Acoustic Corporation type PK6I sensors were mounted half height of the girder's web. Physical Acoustic Corporation AEWin for Sensor Highway Smart Monitor Ver. E5.00 software was used to record the acoustic emission parameters and the load. The threshold was set to 40 dB.

General acoustic emission activity, represented by the amplitude of each hit, the applied load, are time-dependent and presented in Figure 9. Nevertheless, The AE activity, i.e. damage evolution during loading and unloading phases, is visible. In addition, the b-value and the damage parameter as used by Vidya Sagar and Raghu Prasad [6] and Elbatanouny et al. [7] in similar investigations were calculated to evaluate the damage evaluation. The decrease of b-value and the increase of damage parameter with increased load are clearly visible.

Figure 9: Load and amplitude of individual hits, and b-value and damage parameter as a measure of damage evolution and propagation.

Figure 10: Maximum loads (Max - blue), and number of hits (N - purple), total energy (Sum - red) and mean count (Mean - green) of the hits for individual phases (P1, P2, P3), cycles (C1, C2) and stages (loading L and unloading U).

As an example of a more detailed analysis the number of hits, total energy and mean counts of the first three phases are presented in Figure 10. Each phase consists of two cycles of loading and unloading. A significant difference in AE activity between different phases, cycles within individual phases and

loading/unloading stage was recorded. A more detailed analysis is foreseen. It must be noted that some data of the phase 3, cycle 1, loading stage (marked L\* on graph), was unfortunately lost.

## 5 CONCLUSION

The experimental investigation carried out within the ZAG's research project ReNos provides valuable insights into the structural behaviour and bearing capacity of prestressed concrete bridge girders recovered from a flood-affected structure. Preliminary results demonstrate that acceleration-based monitoring systems as well as acoustic emission can identify the progression of damage and help identify critical states in the girder's response. This confirms that such systems are suitable for structural health monitoring applications.

Additionally, the study highlights that, with coordinated stakeholder involvement, dismantling procedures can be executed in a way that preserves structural components for further testing and potential reuse.

Future work will focus on the analysis of remaining test results taking into account the main objective of the study: (1) to determine the actual load-bearing behaviour and compare it with the original design assumptions, (2) to monitor damage development using various sensor types, and (3) to develop a protocol for the potential reuse of the girders in line with circular economy principles.

Acoustic emission techniques can clearly detect and monitor damage evaluation, but a more detailed analysis of the results is needed.

## ACKNOWLEDGMENTS

The research was funded by the Slovenian Research Agency (ARIS) through the research programme No. P2-0273 and the infrastructure programme No. Z2-7431. Additional support was provided by the European projects CIRCUIT and BIM4CE. The authors sincerely acknowledge all individuals and institutions involved in various phases of the research.

**ABSTRACT:** Unusual gaps at the ends of bridge girders can occur due to the displacement of abutments or insufficient initial gaps during construction. However, when such irregularities arise, it is difficult to estimate the cause through visual inspection alone. As analyses on the causes of these gaps and their expansion are needed, investigations into appropriate remedial measures have become important. For these analyses, we developed a device called the Expansion-Gap Measurement System (EGMS), which enables the causes of unusual gaps to be estimated based on continuous monitoring for temperature-related changes in gap distance. By capturing seasonal variations in gap distance, the system allows us to estimate the progression in abutment movement and the causes of damage. This paper presents the case study of a simple bridge made with H-shaped steel girders with unusual gaps where the EGMS was installed for approximately three years to investigate the causes of a gap. It was found that during the high-temperature summer months, the gap closed completely, whereas in winter, the gap remained. Furthermore, it was confirmed that the abutment saw no lateral movement during the winter, indicating the minimal progression of displacement. Based on these findings, the cause of the unusual gap was attributed to either an error in the abutment's initial placement during construction or to previous lateral displacement of the abutment.

**KEY WORDS:** Unusual expansion gap; Expansion-Gap Measurement System; Long-term monitoring; Girder bridge.

### 1 INTRODUCTION

At bridge girder ends, cases where the main girder is in contact with the abutment have been frequently observed [1]. This phenomenon is a type of damage known as 'an unusual gap', which occurs when there is insufficient clearance to accommodate the temperature-related expansion and contraction of the main girder. As a result, unexpected and harmful axial forces develop in the main girder. Additionally, it is suspected that some form of horizontal displacement is occurring in the substructure.

The horizontal displacement of the substructure can arise from various causes, and in some cases, it may continue over time. If such displacement persists, the restoration of the gap will be done by cutting off the end of the main girder to shorten, but it may lead to the recurrence of the unusual gap. Therefore, it is crucial to identify the cause of the substructure's horizontal displacement, to assess its persistence, and to formulate an appropriate repair strategy for the unusual gap.

However, identification of the cause of horizontal displacement in the substructure is not straightforward. When such displacement is suspected, typical approaches to determine the cause are to investigate the ground and foundation conditions. This process often requires geological investigations, such as boring surveys, but it can be costly. Generally, it is difficult to estimate the cause of horizontal displacement solely through visual inspections.

To address this issue, the authors have developed the Expansion-Gap Measurement System (EGMS) for girders [2]. This system continuously measures the gap distance and the temperature of the main girder, enabling the cause of horizontal

displacement in the substructure to be estimated. The details of the EGMS are described in Chapter 2.

In this study, in order to verify the effectiveness of the EGMS, we installed the system on a simple steel girder bridge composed of H-shaped steel where an unusual gap had been observed. Over the course of approximately three years, we used the EGMS to determine the cause of the unusual gap.

### 2 OVERVIEW OF THE EXPANSION-GAP MEASUREMENT SYSTEM (EGMS) FOR GIRDERS

#### 2.1 Configuration of the EGMS

The EGMS for girders primarily consists of linear displacement sensors and thermometer installed at the gap section. Figure 1 provides an overview of the EGMS. The linear displacement sensors are placed on the upper and lower sections of the main girder to continuously measure the gap distance at each location. These sensors can detect changes in the gap distance caused by the temperature-induced expansion and contraction of the main girder. Additionally, the thermometer attached to the main girder provides data for calculations on the theoretical expansion/contraction amount and the corresponding gap distance.

The collected data is stored in a data logger for retrieval approximately once every two months. Since the data logger supports wireless data transfer, data can be collected from the bridge deck even if the data logger is installed underneath the main girder. The system is powered by either a solar battery or an 12V deep-cycle battery. A DC/DC converter is used to adjust the voltage to 5V, which is required for the linear displacement sensors and other components. The data logger,

Figure 1. Overview of the EGMS.

battery, and DC/DC converter are housed in a compact, insulated box (approximately  $15 \times 25 \times 20$  cm) for protection.

Additionally, to verify the system's performance in cold environments, an operational test was conducted at  $-35^\circ\text{C}$  [3]. The system was confirmed to function properly even at extremely low temperatures.

The system is designed to determine the cause of unusual gaps simply and efficiently, without relying on large-scale equipment. As described above, it is composed of readily available devices.

## 2.2 Causes of Deformations Determined by the EGMS

In the EGMS, the gap distance at both the upper and lower sections of the main girder at each support, together with the temperature of the main girder, are continuously measured. Since the system records the temperature of the main girder, the theoretical gap distance at each support can be calculated (Figure 2(a)). At the same time, the EGMS measures the actual gap distance at the upper and lower sections of the main girder, allowing for a comparison between the theoretical and actual gap distance.

For example, in the case of a simple girder, if the gap distance becomes 0 mm during summer, when the main girder temperature is high, and recovers in winter, when the temperature is low (Figure 2(b)), then it can be assumed that the abutments remain stationary and that the gap reduction is stable due to an initially insufficient clearance between the abutments. In such a case, cutting off the end of the main girder would prevent further reductions in gap distance.

On the other hand, if one of the abutments (fixed bearing) undergoes horizontal displacement and continuously pushes the superstructure, the gap distance at the movable bearing remains 0 mm regardless of temperature changes (Figure 2(c)).

Additionally, if tilting occurs, a difference in the gap distance between the upper and lower sections of the main girder can be expected. In this scenario, since the horizontal displacement of the abutment is ongoing, cutting off the end of the main girder would lead to another reduction in the gap distance. Therefore, measures to stop the horizontal displacement of the abutment

Figure 2. Example of theoretical and actual gap distance of a simple girder.

are necessary.

Although based on a classical approach, the Expansion-Gap Measurement System for girders enables the determination of the cause of unusual gaps by analyzing the horizontal displacement of the substructure. Furthermore, it facilitates the development of an appropriate repair strategy.

## 3 OVERVIEW OF EGMS INSTALLATION

### 3.1 Bridge Covered by the Study

Figure 3 provides an overview of the bridge investigated in this study. The target bridge is a simply supported non-composite H-shaped steel girder bridge in Hokkaido, Japan, with a total length of 14.6 meters. Each of the four main girders has the dimensions of  $H800 \times 300 \times 14 \times 26$  mm. The deck is a 19 cm-thick reinforced concrete slab with a 70 mm-thick asphalt pavement. The abutments are of the reversed T type and are

Figure 3. Overview of the target bridge.

constructed of concrete. The foundation consists of six steel pipe piles each with a diameter of 600 mm and a length of 14 meters. The lowest winter temperature in the region where the bridge is located is approximately  $-30^{\circ}\text{C}$  [4].

Regarding the ground conditions, the soil to a depth of 4 m below the road surface consists of a gravel layer with an N-value of approximately 10. Below this, from the depth of 4 to 18 m, clay layers with N-values ranging from 2 to 11 are distributed. Beneath the clay layers, a sandy layer with an N-value of 30 or higher (bearing layer) is present. According to the design drawings, the pile foundation reaches the bearing layer.

The bridge was completed in 1971, but a periodic inspection in 2012 found the gap at both abutments to be 0 mm. However, there were no indications of lateral movement, and the cause of the unusual gap remained unknown, posing challenges to the selection of appropriate remedial measures.

### 3.2 Installation Status of the EGMS

Figure 4 illustrates the installation locations of the EGMS for girders. The linear displacement sensors were installed at both the upper and lower sections of the girder ends on the north-side main girder (the G4 girder), with one sensor placed at each location. These sensors exhibited a measurement range of 50 mm, with an accuracy of  $\pm 0.3\%$  at full scale. Figure 5 shows the installation of the linear displacement sensors. Additionally, a thermometer was installed on the web of the G4 girder to measure the temperature of the main girder. Various devices, including the data logger, were installed on the bearing seat surfaces of each abutment.

The measurement interval for the gap distance and the temperature was set to 30 minutes. Continuous measurements were conducted from September 30, 2021, to October 21, 2024.

Figure 4. EGMS installation locations.

Figure 5. Installation status of the linear displacement sensors.

## 4 MEASUREMENT RESULTS AND DISCUSSION

### 4.1 Gap Distance Measurement at the Fixed Bearing

Figure 6 shows the measured gap distance at the A1 abutment, which serves as the fixed bearing. The gap distance is displayed with the initial measurement value set to 0 mm. Figure 6 also includes the temperature of the main girder for reference.

At the fixed bearing, the variation in gap distance was minimal, remaining within the range of  $\pm 0.7$  mm. Since the bearing at the fixed support has a 2 mm clearance, it is presumed that movement within this range occurred at the bearing. This confirms that the fixed bearing is functioning properly.

On the other hand, a difference in gap distance between the upper and lower sections of the main girder was observed over time. This discrepancy suggests that the abutment may have tilted. Therefore, a more detailed investigation of this issue is conducted in Section 4.5.

### 4.2 Gap Distance Measured at the Movable Bearing

Figure 7 shows the measured gap distance at the A2 abutment, which serves as the movable bearing. As for the A1 side, the gap size is displayed with the initial measurement value set to 0 mm. The temperature of the main girder is shown as a blue line, while the theoretical gap distance, calculated based on the girder temperature, is indicated in gray.

At the movable bearing, significant variations in the gap distance are observed in response to temperature changes. During the winter, when temperatures were low, the main girder contracted, and the measured gap distance closely

Figure 6. Variation in clearance (A1 abutment).

Figure 7. Variation in clearance (A2 abutment).

matched the theoretical gap distance. In the summer, when the temperatures were high, the gap distance decreased. However, the gap reduction was less than the theoretical value. Onsite inspection confirmed that the main girder was in contact with the abutment parapet. A more detailed investigation into the gap distance behavior during warmer periods is discussed in Section 4.6.

### 4.3 Temperature Measurements

To verify the accuracy of the temperatures measured by the thermometer installed on the main girder, a comparison was made with the temperatures recorded by thermometer at a nearby station of the Japan Meteorological Agency's Automated Meteorological Data Acquisition System (AMeDAS) [4]. Figure 8 presents this comparison. The bridge and the AMeDAS thermometer are approximately 15 km apart.

As shown in Figure 8, the temperature measured by the thermometer on the main girder closely approximates the temperature recorded at the AMeDAS station. However, the temperature variations observed on the main girder are smaller than those recorded by AMeDAS. This is likely due to the fact that the main girder is made of steel, which takes time to

Figure 8. Comparison of temperatures measured at the main girder with those measured by nearby thermometer.

Figure 9. Battery voltage variation (A1 abutment).

respond to changes in ambient temperature. Since the measured values were generally consistent with the nearby temperature data, the measurement results are considered valid.

### 4.4 Transition of Battery Voltage

The battery used for the displacement sensors may experience voltage drops at low temperatures. Since the displacement sensors output data based on voltage, a drop in input voltage makes accurate displacement measurements difficult. Therefore, the battery voltage was also monitored. Figure 9 shows the changes in the voltage of the battery installed in the system at the A1 abutment.

The battery voltage decreases due to system operation, so periodic replacements were planned. However, at the end of 2021, the battery voltage dropped sharply, causing the system to shut down. This was attributed to power consumption by the system and to the cold temperatures. Therefore, from 2022 onward, the battery was replaced approximately every two months to prevent system shutdowns.

Except for the period at the end of 2021, the battery voltage remained above 10 volts. Since the 5 volts that is required to operate the displacement sensors and other components was maintained, the gap measurements obtained by the system were

Figure 10. Variation in the difference of clearance between the upper and lower parts of the main girder.

confirmed to be accurate. Additionally, by replacing the battery regularly, it was confirmed that this system can be applied even in cold environments where temperatures drop below  $-20^{\circ}\text{C}$ .

#### 4.5 Evaluation of the Abutment Inclination using the Difference Between the Upper and Lower Displacement Sensors

To investigate the cause of the difference in gap distance between the upper and lower segments of the main girder at the fixed bearing over time, Figure 10 illustrates the transition of that difference for each abutment.

As shown in Figure 10a, at the A1 abutment (the fixed bearing), the difference became negative and that negative difference continued to increase over time. It is noted that the difference fluctuated significantly during the cold winter season, likely due to girder deflection caused by snow accumulation and the impact of snow removal. In contrast, the change in the difference at the A2 abutment (the movable bearing) remained minimal.

Referring to Figure 6, while the lower gap distance of the main girder remained around 0 mm, the upper gap distance showed a decreasing trend. This indicates that the increase in negative difference is caused by a decrease in the upper gap distance. Since the lower gap distance remained unchanged while the upper gap distance decreased, it is assumed that the A1 abutment is tilting toward the main girder. Therefore, it is presumed that the cause of the unusual gap lies in the A1 abutment.

However, since the decrease in the upper gap measurement was approximately 0.5 mm over three years, it is considered to have no immediate impact on the safety of the bridge.

#### 4.6 Determination of Damage Causes Using the Correlation Between Temperature and Gap Distance

To examine in detail the condition of girder gaps during periods of rising temperatures, Figure 11 shows graphs for each linear displacement gauge, with temperature on the horizontal axis and gap displacement on the vertical axis. To show the transition of gap distance, data points are color-coded by year,

and the theoretical gap distance is represented in gray.

At the A1 abutment (the fixed bearing) (Figures 11a and 11b), the gap distance fluctuates within the range of  $\pm 0.4$  mm regardless of temperature. Additionally, while the gap distance of the lower segment of the girder changes linearly with temperature, no distinct trend is observed in the upper segment. This is likely because the lower segment primarily undergoes thermal expansion and contraction due to the steel material of the girder, whereas the upper segment is constrained by the concrete deck, which has a different specific heat capacity. However, since the overall variation in displacement is small, it is confirmed that the A1 abutment is functioning as a fixed bearing.

At the A2 abutment (the movable bearing), it is observed that the gap distance increases as the temperature decreases. However, when the temperature exceeds  $15^{\circ}\text{C}$ , the decrease in displacement plateaus. The difference between the theoretical and measured gap distances increases, and at  $30^{\circ}\text{C}$ , this discrepancy reaches approximately 2 mm.

Since gap distance is maintained during periods of temperature decrease at the A2 abutment, it is unlikely that the abutment is consistently leaning against the girder. In contrast, as noted in Section 4.5, a slight tilt was observed at the A1 abutment. This suggests that one possible cause of the unusual gap is the gradual tilting of the A1 abutment after the bridge was completed. However, since no significant inclination is visible on the front of the abutment, another potential cause could be past abutment movement or an insufficient distance between abutments during construction.

In any case, since no ongoing horizontal displacement of the abutments was detected and the average annual tilt of the upper part of the A1 abutment is approximately 0.1 mm, cutting off the girder ends is expected to be effective in preventing axial force from being input into the main girder.

## 5 CONCLUSION

We have presented a case study in which the authors utilized their Expansion-Gap Measurement System (EGMS) for girders to identify the cause of unusual girder gaps in a simple steel

Figure 11. Relationship between temperature variation and clearance.

girder bridge composed of H-shaped steel. The following findings were obtained.

- (1) The EGMS enables the long-term monitoring of girder gap variations.
- (2) In the investigated bridge, the A1 abutment was found to be tilting toward the main girder, suggesting that the cause of the unusual gap lies in the A1 abutment.
- (3) As the temperature rises, the gap displacement at the A2 abutment decreases, and when the girder temperature reaches 30°C, the difference between the theoretical and measured gap distance is approximately 2 mm. Since the tilt of the A1 abutment on this bridge is gradual, cutting off the girder ends is considered effective to prevent axial force from acting on the main girder.

## ACKNOWLEDGMENTS

We would like to express my appreciation to the Hokkaido Regional Development Bureau for kindly providing the field for this study. We would also like to extend my gratitude to Mr. Takuya Nitta of Nihon Kasetsu Co., Ltd. for his assistance in the installation and adjustment of the equipment.

**ABSTRACT:** This paper presents a comprehensive monitoring study of the dynamic sensitivity of the Solkan footbridge in Slovenia, with a focus on its response to user-induced actions. An extensive ambient vibration measurement campaign was carried out, during which 26 triaxial accelerometers were strategically deployed along the bridge to capture its modal characteristics in all three spatial directions. The structure's dynamic response was monitored under both regular pedestrian traffic and elevated loading conditions during a local marathon event, allowing for the assessment of its behaviour across a broad spectrum of real-world scenarios. Preliminary measurements revealed reduced pedestrian comfort, primarily due to resonance effects resulting from bridge–user interaction. The study highlights the importance of field-based dynamic assessments in diagnosing performance issues and informing mitigation strategies. The findings contribute to the advancement of resilient and dynamically efficient design and maintenance practices for pedestrian bridges.

**KEY WORDS:** Modal model validation; Footbridges; Ambient vibrations; Dynamic sensitivity; User-induced excitation.

### 1 INTRODUCTION

Pedestrian footbridges are particularly challenging structures to design due to their pronounced susceptibility to dynamic issues resulting from bridge–user interaction [1]. These interactions can lead to serviceability concerns such as excessive vibrations, which in turn affect user comfort and, in some cases, may even raise long-term durability concerns [2] [3]. Addressing these challenges requires going beyond conventional static checks and incorporating advanced dynamic analyses aimed at identifying and mitigating resonance-related problems [4].

Current standards and guidelines provide recommendations for the frequency ranges typically excited by pedestrians and runners and require dynamic analysis when a bridge's natural frequencies fall within these ranges [5-8]. The critical frequency range for vertical vibrations is between 1.5 and 3.5 Hz, while for horizontal vibrations, it is between 0.5 and 1.5 Hz [5]. According to Sétra guidelines [6], resonance risks are particularly high for vertical vibration frequencies between 1.7 and 2.1 Hz, and for horizontal vibration frequencies between 0.5 and 1.1 Hz. To prevent resonance, the fundamental frequencies of footbridges should ideally exceed these ranges. However, achieving this is often challenging in lightweight and flexible structures, such as suspension or cable-stayed footbridges. Therefore, detailed dynamic assessments are essential to ensure acceptable levels of pedestrian comfort. For instance, Eurocode [7,8] mandates dynamic analysis for footbridges with predominant vertical frequency below 5 Hz and horizontal frequency below 2.5 Hz.

Given the complexity of structural dynamic response, post-construction measurements are crucial to verify performance in real-world conditions. Ambient vibration testing, combined with operational modal analysis (OMA), offers a non-invasive and effective means of identifying a bridge's dynamic characteristics [2]. These data can be used to calibrate

numerical models and support robust methodologies for evaluating and improving dynamic performance.

In addition to typical service conditions, there is growing recognition of the need to monitor the structural response of footbridges under extreme user-generated actions, such as dense crowds, synchronized movements, or dynamic events like running or jumping. Long-term dynamic structural health monitoring (SHM) enables the detection of changes in modal properties, transient amplification effects, and possible structural degradation under such rare but critical loading scenarios. Integrating SHM strategies into bridge management enhances safety, informs maintenance decisions, and supports the development of resilient infrastructure that can withstand both everyday usage and exceptional dynamic demands.

This paper investigates the dynamic behaviour of a pedestrian footbridge spanning the Soča River in Slovenia, which has shown reduced pedestrian comfort during regular use. The bridge's dynamic response and its sensitivity to user-induced excitation are evaluated through an experimental monitoring campaign utilising strategically placed triaxial accelerometers [9].

### 2 METHODOLOGY

#### 2.1 Bridge description

The Solkan footbridge is a single-span cable-stayed suspension structure crossing the Soča River in Slovenia with total span 120.0 m (see Fig. 1). It features an open-section steel deck suspended from two main parabolic steel cables anchored on both riverbanks. The main cables are supported by two steel A-shaped pylons mounted on reinforced concrete abutments. Vertical hangers, spaced at 6.0-meter intervals, connect the deck to the main cables. The deck is additionally laterally and longitudinally stabilised by a parabolic cable anchored to the abutments, along with four straight bracing cables attached at one-quarter of the span length from each end. The deck is

supported at both ends by four elastomeric bearings, two of which allow for longitudinal movement to accommodate thermal expansion.

The material of the pylons is S235 steel according to EN-1993-1-1, while the material of all deck members is S355 steel. The cables are constructed with high-strength steel ropes with tension strength  $f_u = 1500$  MPa and modulus of elasticity  $E = 165$  GPa. The cross-section and material characteristics of the bridge are summarized in Figure 1. Footbridge over the Soča River (Slovenia).

Table 1.

Figure 1. Footbridge over the Soča River (Slovenia).

Table 1. Characteristics of footbridge's structural parts (FLC – Full Coil Rope, OSS – Open Spiral Strands,  $D$  - Outside diameter,  $t_w$  - Wall thickness)

Element	Property	Material
Main cables	FLC, $D = 72$ mm	High-strength steel
Hangers	FLC, $D = 16$ mm	High-strength steel
Stabilising parabolic cables	FLC, $D = 60$ mm	High-strength steel
Stabilising straight cables	FLC, $D = 38$ mm	High-strength steel
Connecting cables	OSS, $D = 12$ mm	High-strength steel
Pylon (legs)	Circular hollow section, $D/t_w = 355/10$ mm	S235
Pylon (traverse)	Hollow circular section, $D/t_w = 254/10$ mm	S235
Long. girders	IPE400	S355
Trans. girders	IPE270	S355
Bracing diagonals	IPE200	S355

## 2.2 Concept of investigation

The experimental campaign aimed at investigating the bridge's dynamic characteristics and its sensitivity to user-induced loads was conducted in November 2024. The measurements included:

- ambient vibration measurements,
- controlled pedestrian loading tests to assess its dynamic performance under user-induced excitation,
- monitoring of the bridge's response during a marathon event, to evaluate its behaviour under dense, real-world extreme pedestrian traffic.

Under controlled pedestrian loadings, the program included pedestrian sweeps, running, and synchronized marching tests with both small and large groups. This methodology allowed for evaluating the structure's general susceptibility to user-induced excitations.

Overall, the investigation was guided by two primary objectives:

- identification of the structure's modal properties,
- evaluation of the bridge's dynamic sensitivity to user-induced excitation.

## 3 MODAL MODELS

### 3.1 Monitoring setup

The footbridge's reference modal model was established based on experimental data obtained through ambient vibration measurements. For this purpose, the acceleration response of the bridge was recorded at multiple control points distributed across the structure. In total, 26 accelerometers were used in the campaign. Measurements were taken in all three global directions at each control point, with a sampling rate of 500 Hz. The sample of the measured acceleration signals consists of 1 hour of ambient vibration data. A representative control point with a tri-axial accelerometer is depicted in Figure 2.

Figure 2. Representative control point.

The measuring system was composed of twelve MonoDAQ-E-gMeter MEMS accelerometers and fourteen IOLITEi-3xMEMS-ACC accelerometers, both connected with EtherCAT cables to an industrial PC running the DewesoftX acquisition system. Both types of sensors are triaxial accelerometers, featuring low-noise performance (96 dB dynamic range and  $25 \mu\text{g}/\sqrt{\text{Hz}}$  spectral noise density), integrated data acquisition, and EtherCAT connectivity. The MonoDAQ-E-gMeters were mounted on aluminium plates and were attached to the deck's transverse girders via magnets, while the IOLITEi-3xMEMS-ACC were attached to steel tripods and were placed directly on the bridge deck.

Data acquisition and initial processing were carried out using DewesoftX software, which enabled signal recording, real-time analysis, and visualization. The collected data were subsequently exported for further analysis in FlexPro, Simcenter Testlab (LMS Test.Lab), and Dewesoft Artemis OMA, supporting both time- and frequency-domain evaluations.

### 3.2 Experimental modal models of the footbridge

Based on data collected during ambient vibration monitoring, the modal models of the footbridge were extracted using methods belonging to two main methodological groups that are strongly oriented towards OMA, namely [9]:

- Frequency Domain Decomposition (FDD),
- Stochastic Subspace Identification (SSI).

Accordingly, the following approaches were compared: Enhanced Frequency Domain Decomposition (EFDD), Curve-fit Frequency Domain Decomposition (CFDD), Unweighted Principal Component (SSI-UPC), and Extended Unweighted Principal Component (SSI-UPCX). Figure 3 presents an example of data recorded in the mid-span of the footbridge during ambient vibration testing, shown in the time-frequency domain. The experimental modal models were validated using the Modal Assurance Criterion (Eq. 1), with the AutoMAC matrix employed for this purpose [10].

$$MAC_{ij}(\psi_i^A, \psi_j^B) = \frac{(\{\psi_i^A\}^T \{\psi_j^B\})^2}{(\{\psi_i^A\}^T \{\psi_i^A\})(\{\psi_j^B\}^T \{\psi_j^B\})} \quad (1)$$

The modal models obtained from different identification techniques are summarized in Table 2. Figure 4 illustrates the 3D AutoMAC matrix for the SSI approach, and Figure 5 provides a comparison of the damping ratio estimates across the various methods.

Figure 3. Acceleration and frequency time histories for ambient vibration (mid-span, vertical direction).

Figure 4. AutoMAC matrix for SSI OMA.

Table 2. Natural frequencies of the footbridge obtained with different OMA techniques.

Mode*	Frequency [Hz]			
	FDD	CFDD	EFDD	SSI
1V	0.574	0.570	0.569	0.571
2V	0.764	0.764	0.765	0.770
3H	0.847	0.843	0.843	0.844
4V	1.052	1.054	1.054	1.053
5H	1.096	1.096	1.097	1.098
6T	1.145	1.144	1.145	1.142
7V	1.743	1.740	1.741	1.735
8T	1.819	1.804	1.804	1.818
9V	2.202	2.196	2.201	2.194

## 4 SENSITIVITY OF THE BRIDGE TO USER-INDUCED EXCITATION

### 4.1 Controlled pedestrian loading tests

The primary objective of the field tests involving pedestrians and runners was to evaluate the footbridge's susceptibility to resonance effects. Therefore, a series of experiments was carried out, during which various dynamic scenarios were considered, including walking and synchronized group movement, to identify critical excitation frequencies and assess the resulting vibration levels in different structural locations. The responses were evaluated using acceleration and frequency time histories obtained from Short-Time Fourier Transform (STFT) analysis with a window size of 0.54 s and 50% overlap.

Based on dynamic responses, a series of resonant frequencies induced by various human activities were observed. In the random walk case, the dominant response frequency in the horizontal direction was 0.84 Hz (see Fig. 6b). This resonance was exciting by walking-induced dynamic loading at a frequency of 1.64 Hz in the vertical direction, as shown in Fig. 6a. This suggests that the excitation falls within the resonance range of the first horizontal mode, which also contributes to the vertical response, particularly evident in the 7V mode (see Tab. 2). The excitation frequency (1.64 Hz) corresponds to approximately 95% of the mode's natural frequency (1.74 Hz). This is a significant observation, as both the 1.64 Hz and 0.84 Hz components originate from the same pedestrian passage, corresponding to the vertical and horizontal components of the walking-induced forces, respectively.

Figure 6. Acceleration and frequency time histories for random walking (mid-span) for vertical (a) and (b) horizontal direction.

Figure 7. Acceleration and frequency time histories for marching group of people (mid-span, vertical direction).

Figure 8 presents the time-domain response recorded during the user-induced frequency sweep, ranging from 1.50 to 3.50 Hz. This was performed by three volunteers moving in synchrony, guided by a preprogrammed metronome recording. MP3 files with impulse sounds have been generated (intended to synchronize volunteers' stomping on the bridge). Each file contains a sweep of frequencies from 1.5 Hz to 3.5 Hz, in 0.1 Hz increments (i.e., 1.5, 1.6, 1.7, ..., 3.5 Hz), with smooth transitions between frequencies (no pauses) and an approximate total duration of 385 seconds.

The Short-Time Fourier Transform (STFT) analysis, represented in terms of normalized Power Spectral Density ( $PSD_{norm}$ ), revealed that several natural frequencies were excited over the course of the experiment, indicating a dynamic interaction between the excitation and the structure's modal characteristics. Notably, the most prominent response occurred in the frequency range between 0.8 and 1.70 Hz, which corresponds to the range of several resonant frequencies of the structure (3H to 7V, see Table 2). This suggests that the system exhibits a strong sensitivity to excitation near these frequencies. The largest amplification occurred at a frequency of approximately 1.2 Hz, which is close to the first torsional mode of the footbridge (6T). A clear amplification of the response in the range of resonant frequencies confirms the effectiveness of the frequency sweep in exciting the relevant modal behaviour.

Figure 8. Acceleration and frequency time histories for user-induced frequency sweep (mid-span, vertical direction).

#### 4.2 Footbridge's response during a marathon event

The monitoring campaign also included continuous data acquisition during a marathon, allowing for the assessment of

the structure's dynamic behavior under dense pedestrian loading. Figure 9 presents the time-domain response recorded during the marathon at mid-span in the horizontal direction. STFT analysis revealed that several natural frequencies were excited during this large-scale social event, which represents an extreme loading scenario. This indicates a dynamic interaction between the excitation and the modal characteristics of the structure. The most significant response was observed at a frequency of approximately 1.10 Hz in the horizontal direction.

Figure 9. Acceleration and frequency time histories for marathon (mid-span, horizontal direction).

## 5 CONCLUSIONS

Based on the presented study, several key conclusions were drawn. Within the frequency range of 0–2.50 Hz, nine vibration modes were successfully identified. Among them, two modes belonged to the commonly recognized critical set for footbridges, including one vertical (1.74 Hz) and one horizontal mode (0.84 Hz), which suggests sensitivity of the bridge to user-induced excitation. Notably, both modes were excited by a single pedestrian passage, making the response particularly concerning. This is further amplified by the fact that the random walk scenario, responsible for triggering both modes, is the most frequent type of loading expected during regular bridge use. A high level of consistency was achieved across all developed modal models, with a mean error of less than 2%, confirming the reliability of the applied identification techniques.

The analysis of dynamic responses revealed a dominant resonant frequency of 1.64 Hz under both random walking and marching activities, indicating a strong excitation associated with the vertical component of pedestrian loading. Additionally, during random walking, a significant response was observed at 0.84 Hz, which corresponds to the horizontal component of the same excitation. These results demonstrate that human-induced vibrations can simultaneously activate multiple modal components of the structure. Furthermore, during the marathon event, extreme horizontal vibrations were recorded, to the extent that participants were unable to continue running across the footbridge. This highlights the severity of the dynamic response under real, large-scale crowd loading. The use of user-induced frequency sweeps during experimental testing proved to be an effective method for capturing a wide range of vibration modes and natural frequencies.

These findings underscore the importance of considering both vertical and horizontal components of pedestrian-induced

loading in the dynamic analysis, design, and safety assessment of footbridges. The observed variation in identified modal parameters across different load scenarios highlights the need to account for uncertainty in vibration-based evaluations. Future research should address this aspect more systematically by following established best practices in pedestrian bridge monitoring and incorporating statistical methods to quantify confidence levels in the extracted modal data.

## ACKNOWLEDGMENTS

The authors would like to acknowledge the support of the Municipality of Nova Gorica (Slovenia), Rok Mesar from the company Dewesoft (Slovenia), and Prof. Chiara Bedon, Marco Fasan and Michele Dilella from the University of Trieste (Italy) in the execution of the field measurements. The first and second authors would like to acknowledge the support of the Slovenian Research Agency, obtained through Research core funding No. P2-0273 and Infrastructure funding IO-0032.

**ABSTRACT:** A new subway line is under construction in Prague, Czechia. The drilling and construction potentially affect the structural health of buildings and infrastructure in the zone of influence. As part of geotechnical monitoring for the Metro Line D construction, subsidence is monitored through satellite interferometry (InSAR). Measurements from TerraSAR-X/PAZ are analysed using a customised PS-InSAR algorithm to capture evolving deformation patterns during construction. In addition, several add-on methods have been developed to provide targeted trend analysis and geotechnically relevant metrics. The retrospective “passportization stage” has been followed by standard monitoring stages with adaptive stage duration and frequency of satellite acquisitions. The nonlinear characteristics of displacement trends present challenges for InSAR. Particularly in X-band data, phase unwrapping errors compromise spatial interpretation, elevate noise levels, and diminish the reliability of results. Issues are addressed by tailored enhancements to the InSAR methodology, including advanced time series segmentation considering statistically significant differences in displacement velocities or noise levels. Validation confirms strong agreement between displacement trends measured through InSAR and conventional geotechnical methods.

**KEY WORDS:** InSAR; Subway; Subsidence; Structural health.

## 1 INTRODUCTION

### 1.1 *MT-InSAR as a tool to monitor tunnel drilling impacts in an urban environment*

Urban tunnelling projects, particularly those involving mechanised excavation methods such as Tunnel Boring Machines (TBMs), are known to induce subsidence ground deformations that can compromise the structural integrity of buildings and infrastructures above the tunnel alignment. Monitoring and assessing these effects is crucial for mitigating risk in densely built environments. Interferometric Synthetic Aperture Radar (InSAR), particularly advanced multi-temporal techniques (MT-InSAR), has emerged as a reliable and cost-effective method for monitoring such deformations with millimetric precision over extensive spatial and temporal scales.

Recent studies have demonstrated the efficacy of InSAR in tracking surface displacements due to tunnelling activities in various urban contexts. For example, [1] utilised InSAR to monitor tunnel-induced ground movements and demonstrated its value in complementing conventional geotechnical instrumentation during tunnelling operations in Turin, Italy. Similarly, [2] applied InSAR to assess accumulated settlement related to highway tunnel construction in Genoa, Italy. The [3] showcased a novel integration of MT-InSAR and the relative stiffness method to assess structural damage during the London Crossrail project, highlighting the role of soil-structure interaction in deformation modelling. These approaches allow for better estimation of tensile strains and more accurate prediction of damage potential compared to greenfield assumptions.

The [4] emphasised the integration of InSAR in all phases of tunnelling—from planning to post-construction monitoring—noting its advantage in detecting both anticipated and unexpected deformations across large urban sectors. Meanwhile, [5] applied retrospective PSI analysis in East London during the Lee Tunnel construction, revealing previously undetected geotechnical anomalies and advocating for InSAR's role in early risk identification.

Beyond deformation detection, translating InSAR-derived ground displacement data into actionable insights for building vulnerability assessment is gaining traction. Damage level on buildings and infrastructure caused by subsidence depends on the asset's position in the subsidence bowl, displacement direction and magnitude [6]. The [7] and [8] successfully derived empirical fragility curves by correlating InSAR-derived displacements with in-situ damage surveys, enabling probabilistic assessments of structural risk across extensive building inventories. These methods have proven especially pertinent in older urban centres, where subsidence impacts are compounded by complex underground networks and historical constructions, such as in Madrid [9] and Pistoia [6].

### 1.2 *MT-InSAR supporting geotechnical monitoring during subway construction in Prague*

In this context, the present study describes the operational use of MT-InSAR as a component supporting complex geotechnical monitoring during the construction of the Prague D line subway. Spatially dense and temporally resolved deformation data from MT-InSAR complement traditional operational monitoring techniques, providing additional

insights about the extent and chronology of tunnelling-related hazards.

A new subway line is under construction in Prague, Czechia, traversing from the city's peripheral regions to its central districts through geologically complex and challenging conditions. The influence of subway construction potentially affects the structural health of buildings and infrastructure in the zone of influence, which is being monitored by standard geotechnical and geodetic techniques, including precise levelling. A network of more than 900 static measurement points has been established in the zone of influence between planned stations Pankrac and Olbrachtova by the client. Measurements identify deformation trajectories reaching or exceeding pre-established hazard warning levels to allow early and timely mitigation during construction.

InSAR complements the monitoring in two ways:

- Stage 0: Provision of passportization status documenting the level of (in)stability within and beyond the zone of influence before the construction started as of April 2022.
- Stage 1-8: Regular monitoring during construction with variable monitoring interval lengths (6 – 12 months) and satellite data acquisition frequency (11 – 33 days). The InSAR monitoring set-up has been designed to be efficient and cover periods with the highest expected deformation rates and measurement frequencies.

As of the end of 2024, the fifth monitoring stage has been completed, with stages 6-8 planned for 2025-2026 (refer to Figure 1). The overall size of the core area of interest (AOI) along the zone of influence is approximately 0.5 km<sup>2</sup>. InSAR monitoring covers the area of the AOI extended by a 0.5 km wide buffer.

Figure 1: Passportization (Stage 0) and subsequent monitoring stages (up to Stage 5). The average frequency of TSX imagery acquisition is indicated below the graph. From 2025 on, additional stages follow up after Stage 5.

## 2 SATELLITE DATA

TerraSAR-X data (X-band, wavelength 3.08 cm) in StripMap mode (spatial resolution 3x3 m) are being used for InSAR monitoring. The images cover the monitoring period 2016-2024, and their total number is 129.

As a supplementary dataset, freely available Sentinel-1 (C-band, wavelength 5.6 cm) data were processed for the same area of interest from three tracks (ascending 146 (looking from West) and descending 22 and 95 (looking from East)). The look angle is flatter than that of TerraSAR-X and, therefore, more sensitive to the horizontal (East-West) displacements. Sentinel-1 images were processed from 2015 to the end of 2024, amounting to 430-450 images per track. An overview of satellite datasets is listed in Table 1.

Digital terrain models (DTMs) and digital surface models (DSMs) obtained from open data sources [10] were used to

estimate the location of each PS point (ground, facade, roof, etc.) and to determine its height above ground.

Table 1. Baseline and supplementary satellite datasets.

Satellite/mode / track	Images used	Inc angle [deg]	Spatial resolution [m]
TerraSAR-X / SM / D2	129	22	3x3
Sentinel-1 / IW / D95	441	32	20x5
Sentinel-1 / IW / D22	436	44	20x5
Sentinel-1 / IW / A146	429	39	20x5

## 3 METHODOLOGY

### 3.1 MT-InSAR analysis

The InSAR processing was performed using the persistent scatterers algorithm (PS-InSAR) in the SARproZ(c) software, which is tailored for infrastructure monitoring. For Sentinel-1, all pixels within the area of interest were processed to reach the highest possible point density. In contrast, for TerraSAR-X, point selection was based on local amplitude maxima to streamline the processing timeline. A reference point was selected in another stable part of the city to avoid being influenced by the construction works.

Subsequently, proprietary post-processing techniques have been employed to enhance results from the standard PS-InSAR algorithm. In particular, the detection of temporally coherent targets and time series segmentation has been used to retain a higher density of candidate PS measurement points.

The time series of each PS point was segmented into intervals with constant velocity and noise, and abrupt movements were excluded within a single segment. The segmentation method is data-driven, based on statistical tests to compare principal values for subsequent segments (such as velocity and noise). The segmentation enables us to more accurately estimate the quality of the time series for PS points experiencing highly non-linear displacement. In conventional InSAR workflows, the estimated reliability expressed by coherence “averaged” over the whole monitoring period is low for these points, resulting in their discarding in the candidate selection phase. For each segment, displacement noise was estimated, and if it was too high, that segment was considered unreliable. However, if a point is reliable for at least part of the monitoring period, it can be interpreted for that period. The tolerable noise level was calculated based on statistical simulations, considering ambiguous fundamentals of InSAR, and depends on the SAR wavelength and the length of a segment. Generally, the allowed noise level is around 2.8 mm for TSX for long segments, and slightly lower for shorter segments. This is particularly important in areas with ongoing construction work, where a point may become unreliable for shorter periods and then regain reliability. These periods may repeat frequently. The

segmentation is performed for each PS point individually; therefore, the segments vary between points.

With special attention, the displacement velocity in the last reliable segment (i.e. the most recent displacement velocity) is estimated, together with its standard deviation, at the end of each monitoring stage.

### 3.2 Estimation of horizontal component

The TSX dataset, featuring a steep incidence angle in the area of interest, is particularly suitable for detecting displacements with a dominant vertical component. In addition, due to suspicions of displacements with strong horizontal components in certain zones of the drilling influence zone, the Sentinel-1 dataset has been employed. Measurements from opposite ascending and descending orbits feature flatter incidence angles and are more sensitive to horizontal displacements in the East-West direction. Standard decomposition using a custom grid size was implemented to convert displacement rates from the LOS (radar line-of-sight) to vertical and horizontal deformation components. Sentinel-1 measurements at the end of Stage 3 and Stage 5 from their most recent reliable displacement rates (in mm/year) were used. This option turned out to be less noisy compared to processing options utilising stage-wise or cumulative displacements (in mm).

### 3.3 Estimation of buildings affected by geotechnical hazard

Geotechnical hazards and the structural health of buildings can be assessed using PS-InSAR results through various methodologies. For the pilot demonstration of technology utility for the D line subway in Prague, we focused on testing existing approaches, their customisation, and developing a new one.

The [11] combined PS-InSAR with damage surveys to develop empirical building fragility curves. The approach focuses on monitoring settlement-induced damage through parameters summarily ranked as SRI (Subsidence-Related Intensity), such as differential settlement and relative rotation (deflection ratio), calculated from a cloud of PS points for building polygonal footprints or their immediate vicinity. Ancillary metrics (length, width, buffer) are computed from the polygonal geometry. SRI proxies the potential damage risk for different classes of building construction materials.

The [9] employ PS-InSAR to monitor deformation in urban environments, particularly in historical city centres, where underground activities may induce ground subsidence. Their method applies novel classification indices, including deformation velocity, dispersion, and acceleration indices, as a proxy for assessing the structural health of buildings.

To complement the above methodologies for specific types of buildings in dense residential urban stock (tall and with a small footprint area), we developed an additional index to indicate the potential tilt of the building. It is based on the correlation between the estimated height of a PS point (above ground) and the estimated displacement velocity. Figure 2 displays the simple model of the situation.

Supposing the correlation exceeds the threshold and the difference between the highest and lowest PS points in the footprint exceeds the set value, then the rate between the displacement velocity and height is estimated and converted to tilt angle, assuming that the differential displacements are horizontal (East-West direction). In our case, the tunnel's

orientation is ideal for InSAR, as the expected East-West displacements are most sensitive to this technique.

Figure 2: Illustration of the relation between the measured line-of-sight displacement and height for a tilted building.

To estimate the tilt angle, the least squares method accounting for errors in both x and y axes (i.e., height and displacement velocity) was used [12], as both values were estimated from the original InSAR data. Practically, the stochastic model is not precise as it does not consider the relation between the estimated height and displacement velocity. This is because the relationship is not straightforward, as the height is calculated from all the SAR data, while the displacement velocity is not. Moreover, outliers were excluded from the adjustment. Finally, the tilt angle was confirmed only if it was higher than its standard deviation; the tilt angles are overall smaller than, e.g., 2.5 times the standard deviation.

The correlation method can only be used for X-band data. Sentinel-1 data have a high standard deviation in height, which leads to a too-high standard deviation of the estimated tilt angle.

### 3.4 Cross-validation

Total displacements measured converted to vertical direction were compared with geodetically measured settlements for a set of buildings in the zone of influence.

## 4 RESULTS

At the end of each monitoring stage, results with a standardised structure and formatting are delivered to the construction monitoring committee. These include maps of ground displacements in LOS from the baseline TSX dataset complemented by additional metrics derived by analysis of segmented deformation time series (refer to Figure 3):

- Displacement rates – average, last reliable velocity (mm/yr)
- Stage-wise and cumulative displacement (mm)
- Acceleration
- Classification of displacement trend typology
- Classification of reflecting target type

In total, more than 4,000 temporally coherent PS measurement points are being detected for each monitoring stage in the core AOI from the TerraSAR-X dataset, and over 22,000 measurement points for the extended AOI.

Figure 3. Example of PS points' displacement time series from a building affected by repeated drilling-induced settlements and injecting-induced uplifts in the meantime.

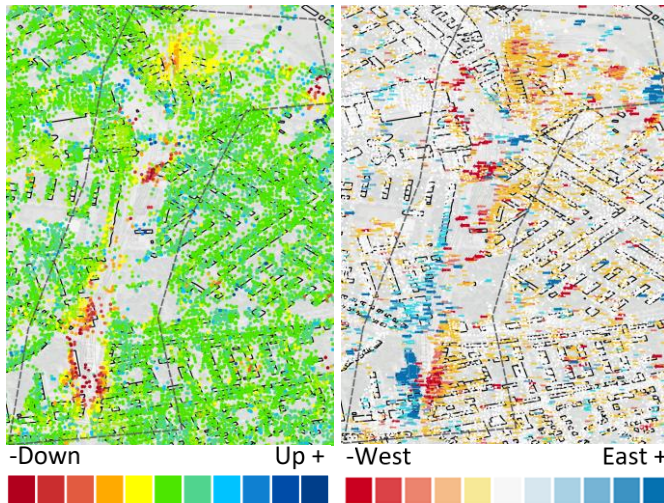

Figure 4. Ground displacement velocity (from at least a 1-year-long reliable time-series segment) in the core AOI from the Sentinel-1 dataset decomposed from LOS to (a) vertical and (b) East-West direction, which is roughly perpendicular to the subway drilling axis (please note: displacement velocity magnitude could not be disclosed).

Validation revealed discrepancies between InSAR displacements from TSX converted to vertical direction and geodetic measurements by levelling. These discrepancies in measured settlements amounted up to 3-4 mm over a comparable measurement period for a line of tall buildings at the east side of the settlement zone, while being negligible in other areas. After a thorough analysis, we can attribute these discrepancies to the influence of horizontal displacements – the buildings are slightly leaning away from the satellite in LOS. These displacements increase the displacement magnitude in the LOS and subsequently in the vertical direction, if projected without considering the horizontal component. Furthermore, the horizontal component estimated from InSAR for tall multi-storey buildings is higher than the magnitude measured trigonometrically at the buildings' foot or first storey level. As a result of tilting, the horizontal displacement is more pronounced at the rooftop level, where most of the PS measurements are located, than at the ground.

After realising the occurrence of horizontal displacements (accompanied by building tilting), the ground displacements map from the TSX has been complemented by MT-InSAR analysis of the Sentinel-1 dataset, followed by decomposition

of LOS velocities into vertical and horizontal displacement components for selected monitoring stages. These results (refer to Figure 4) confirm the existence of horizontal displacements and show the extent and heterogeneity of the phenomena.

The methodology of [8] was found helpful in detecting differential settlements for larger buildings as an indicator of potential damage risk. Buildings need to have enough PS points detected within the building footprint. Furthermore, the distance between PS points with minimum and maximum deformations, which is used to calculate the deflection angle, needs to be sufficiently long. The method is applicable to buildings regardless of their height; however, the deflection angle is estimated more reliably for buildings elongated parallel to the settlement sloping gradient vector.

Similarly, [9] provides a means for more complex assessment by considering aggregated displacement velocities complemented with their acceleration and spatial dispersion within a building polygon. This is an indicative proxy metric for building tilting regardless of height; however, buildings must have enough PS points within the footprint.

The correlation-based tilting indicator supplemented the above techniques by pointing to tilts of high buildings with relatively small footprints, which are common in the residential urban fabric.

## 5 CONCLUSIONS

During its operational execution, InSAR proved to provide highly valuable and complementary insights into the spatial and temporal context of settlement phenomena during Prague's Metro D line construction.

The most pronounced advantages and benefits of InSAR identified by its practical and operational application are listed below:

- High density of measurements that allows more precise delineation of the zone of influence.
- Delineation of the real extent of the zone of influence. Assessment of specific drilling-induced trend patterns in measurement time series and their spatial distribution reveals that this extent is larger in some areas compared to the projected zone of influence.
- Delineation of additional settlement zones within and beyond the core AOI. The geotechnical and hydrogeological interpretation indicates their association with groundwater withdrawal in the aquifers.
- Differentiation between drilling-induced settlement and subsidence caused by other drivers. This may turn instrumental for assessment and passportization of damages and as evidence in potential legal disputes.

Furthermore, results showcase that:

- The use of the temporally coherent targets variant of the PSI algorithm is instrumental in maintaining a high density of measurements during different monitoring stages.
- TSX data are indispensable to obtaining the highest measurement density, allowing detailed settlements and uplift impact assessment at the level of individual buildings.
- TSX measurements from single track suffer from biased displacement rate magnitude in LOS when buildings tilt

in a direction parallel to LOS. The bias is propagated in a vertical direction after simple reprojection.

- The monitoring should be complemented by InSAR measurements from ascending and descending paths of Sentinel-1 and their decomposition to map the extent of the horizontal deformation field.
- Appropriate geotechnical methodologies and metrics need to be selected, customised, and combined to indicate risk and tilting for a broader spectrum of different building sizes and heights. The reflective position of the PS measurement point (on the roof, facade, or from the ground) needs to be estimated and considered.

## ACKNOWLEDGMENTS

We would like to express our sincere gratitude to Jakub Bohátka and Jiří Bárta from SG Geotechnika, a.s. for their invaluable assistance with validation, geotechnically oriented insights, and interpretation, which contributed to the quality of the InSAR outputs.

## DISCLAIMER

Detailed results and scales of vertical or horizontal displacement velocities could not be disclosed due to their sensitive nature.

**ABSTRACT:** Dams are used worldwide to, e.g., manage flooding, generate energy, or secure the freshwater supply. They play an essential role in the local economy. However, an operational or structural failure also poses a significant threat to the environment and the local economy. Therefore, it is vital to ensure their structural health and functionality.

In this study, we present the ground surface deformation of the Parapeiros-Peios Dam during the later stages of its construction, first filling, and shortly afterwards. Since data services, such as the European Ground Motion Service, surfaced and provide freely available ground motion datasets, one might think that in-house processing of SAR data for surface deformation monitoring of critical infrastructure is obsolete. In order to explore the advantages of in-house processing, we compare ground motion datasets generated by Fraunhofer IOSB and the European Ground Motion Service based on advanced differential synthetic aperture radar interferometry techniques. The dataset consists of sets of measuring points, their mean deformation velocity, and the associated displacement time series. Based on the mean velocity maps, we present a spatial analysis of the observed deformation patterns. In addition, we analyzed the temporal deformation pattern of individual measuring points by employing the Persistent Scatterer Deformation Pattern Analysis Tool (PSDefoPAT<sup>®</sup>). This tool can be used to fully automatically identify the statistically best fitting model to describe the temporal deformation pattern of a persistent or distributed scatterer (i.e., linear, quadratic, piecewise linear, or periodic) and provides insight into the dynamics of the surface deformation. It can aid with the analysis of changes in the structural health of the dam.

**KEYWORDS:** Embankment Dam; Persistent Scatterer Interferometry; European Ground Motion Service; Deformation PSDefoPAT<sup>®</sup>.

## 1 INTRODUCTION

Dams are large engineering structures used for centuries to stop the surface water flow. They have at least two components: a dam body and a reservoir. The dam body is used to either redirect or impound surface water. The impounded water creates an artificial lake, which is referred to as a reservoir. The main purposes of these structures are storing water for irrigation or human consumption, energy generation, flood control, fish farming, and storing tailings. Thus, they have a significant influence on the local economy. They can have a positive impact on the region, but a failure of the dam body or an operational failure can also be detrimental to the local economy, human settlements, and the environment. Therefore, it is essential to ensure their structural health and functionality [1]. Depending on the construction type of the dam body, the set of parameters that need to be monitored varies. In the case of an embankment dam, which is the most common type used worldwide, the International Commission on Large Dams (ICOLD) stipulates monitoring structural deformations, movements, and temperature of the dam body, as well as uplift pressure, seepage, drainage rates and the chemical composition of the seepage water [2,3].

This study will focus on the surface deformation of embankment dams. Those dams are subject to numerous loads during their lifetime, which can result in the deformation or displacement of the entire or parts of the dam body [4]. Recent studies have demonstrated that Synthetic Aperture Radar Interferometry (InSAR) techniques, such as Persistent Scatterer

Interferometry (PSI), can be used to map and analyze the surface deformation of dams for short phases of their lifetime [5,6].

In this study, we map and analyze the deformation of the Parapeiros-Peios dam during the time of the first filling of its reservoir and shortly after. The dam is located in southern Greece on the Peloponnese Peninsula. Its construction finished in early 2019, and the reservoir filling process started in September 2019. We acquired two different datasets of the area of interest. The first dataset, Dataset A, consists of 119 Sentinel-1 (S1) Synthetic Aperture Radar (SAR) images and was processed in-house. The second dataset, Dataset B, was obtained from the European Ground Motion Service (EGMS), which provides ground surface deformation measurements for most European countries based on S1 SAR images and advanced DInSAR processing. Dataset B covers the time from January 2019 to December 2023. Since data services, such as the EGMS, are freely available, one might think that in-house processing of SAR data for surface deformation monitoring of critical infrastructure is obsolete. However, the EGMS does not provide customized datasets for specific events or time spans and is delayed by at least three quarters of a year. In order to explore the advantages of in-house processing, we compare our own results with those generated by the EGMS regarding the observable spatial and temporal deformation patterns. Both datasets provide maps with the mean deformation velocities and displacement time series for individual measuring points (MP). The mean deformation velocity maps were used to

analyze the spatial deformation pattern of the Parapeiros-Peios dam, while the individual displacement time series were analyzed using the Persistent Scatterer Deformation Pattern Analysis Tool (PSDefoPAT<sup>®</sup>) developed at Fraunhofer IOSB, which automatically assigns each time series a best-fitting model [7]. The estimated time series models offer information on the temporal deformation pattern, which is not directly visible in the mean deformation velocity maps.

This paper is structured into five sections. The Parapeiros-Peios dam and the data used to monitor it are described in Section 2. Section 3 provides an overview of the methods used to analyze the data. The results are presented and discussed in Section 4, and finally, our conclusion is presented in Section 5.

## 2 PARAPEIROS-PEIROS DAM

The Parapeiros-Peios dam is located in the municipality of Patras in the northwest of the Peloponnese Peninsula (Greece). It consists of an embankment dam, a diversion dam, and a reservoir. The total capacity of its reservoir is 44 million m<sup>3</sup> of water. The impounded water is intended to supply more than 2 million people in three regions (Patras, Erymanthos, and Dytiki Achaia) with fresh water. While the diversion dam reroutes the Peiros River, the embankment dam impounds the water of the Peiros and Parapeiros rivers. In detail, the dam is about 75 m high and 900 m long. Its construction finished in early 2019, and the filling process of the reservoir started in September 2019 [8,9] and is estimated to take about three years.

The first reservoir filling is particularly interesting, since the construction is subject to all the loads it was built to withstand for the first time. The dam body is expected to deform as a consequence. At this point, only the most significant deformation phenomena will be mentioned. A detailed description of the many deformation phenomena was provided by Evers [10]. The deformation phenomena can be sorted into three patterns:

- (1) subsidence,
- (2) uplift and
- (3) horizontal displacement.

The building and foundation materials of the dam body are compressed by the weight of the construction, resulting in partial or complete subsidence of the dam body. The dead load

of the increasing amount of impounded water only fosters this process [11]. Moreover, collapse compression on the upstream shoulder can add to the subsidence rates. A partial uplift of the dam body can be caused by a decrease in the effective stress in the upstream shoulder resulting from the increasing water load during the filling process. The third deformation category is the horizontal displacement of the entire or parts of the dam body. The cause for horizontal displacement is the increased lateral tension within the dam body during the filling process [4].

Two advanced DInSAR datasets were used to analyze the spatial and temporal deformation of the Parapeiros-Peios dam. The goal is to explore whether it is obsolete to process SAR images in-house for surface deformation monitoring of critical infrastructure such as dams, since ground motion datasets are freely available and updated regularly.

Dataset A consists of 119 S1 SAR images recorded with a descending acquisition geometry and Interferometric Wide Swath mode. The time series extends from September 2019 to November 2022, which corresponds to the time of the first filling of the reservoir. The images depict the area surrounding the Parapeiros-Peios dam, allowing for the mapping and analysis of the deformation of the dam body and the surrounding slopes. Dataset B is a ground motion dataset of the same area provided by the EGMS. The EGMS provides ground motion measurements at a millimeter scale using persistent scatterer (PS) and distributed scatterer (DS) techniques. The service was first made available at the beginning of 2022 and documented in its first edition the ground motion of most European countries from 2015 to 2020 based on all available S1 images from this time span. The dataset is regularly updated, always considering S1 images of the past five years [12]. The new dataset is made available in the following fall. For this study, a dataset covering the period from January 2019 to December 2023 was used, which corresponds to the time immediately preceding the first filling, the first filling itself, and approximately two years afterward. The chronology of the datasets and the time of the construction and commission phase of the Parapeiros-Peios dam they cover are illustrated in Figure 1. The goal is to explore whether

## 3 METHODS

### 3.1 Persistent Scatterer Interferometry (PSI)

InSAR and PSI are techniques used to map surface deformation

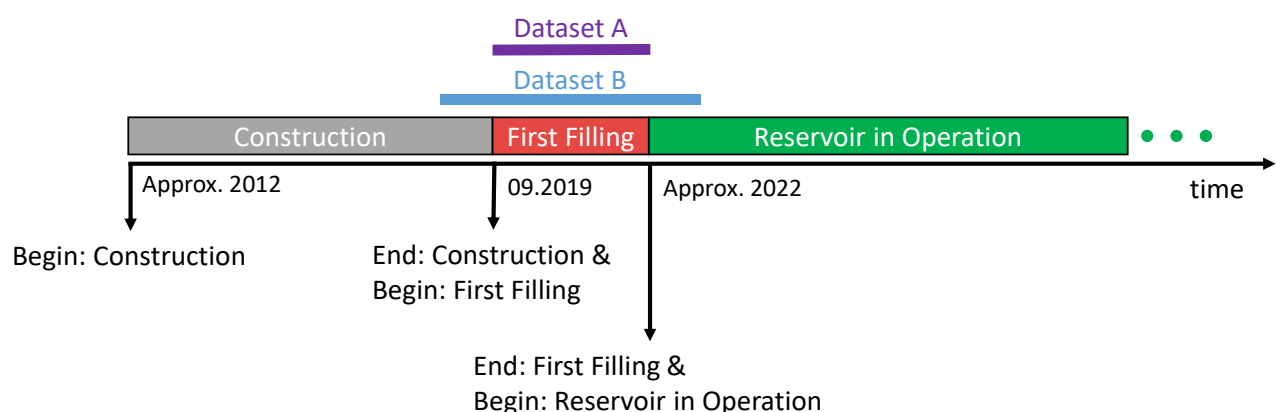

Figure 1. Timeline of the construction and commission phase of the Parapeiros-Peios dam and the Datasets A (S1 images processed by Fraunhofer IOSB) and B (provided by EGMS).

Figure 2. Workflow of PSDefoPAT<sup>®</sup> [7].

over a wide area. In contrast to InSAR, PSI uses a time series of SAR images to identify pixels with a low noise level to reduce the influence that phase decorrelation and the atmospheric phase delay have on the deformation estimates. The algorithms that implemented this concept were developed by, e.g., Ferretti and Hooper [13, 14]. An adapted version of the StaMPS PSI algorithm, which can be used in a Windows-based framework, was used in this study to process Dataset A.

As stated previously, Dataset B was obtained from the EGMS. Processing the S1 SAR images for the EGMS with advanced DInSAR algorithms was carried out by four different companies, e-GEOS, TRE Altamira, NORCE, and GAF, who each have their own well-established processing chains. DSs were not taken into consideration for all regions processed in the EGMS. The type of scatterer, PS or DS, is indicated by the attribute field “mp\_type” in the downloaded EGMS datasets [15]. In the case of the northwestern region of the Peloponnese Peninsula, no MPs marked as DS were identified in the EGMS dataset. The service distributes several InSAR products at different processing levels: (1) Level 2a (L2a), (2) Level 2b (L2b), and (3) Level 3 (L3). The L2a datasets are precise InSAR displacement measurements in the line-of-sight (LOS) of the sensor. The displacements are relative values calculated with a local reference point. The L2b displacements were calibrated with a Global Navigation Satellite System (GNSS) model and are no longer relative measurements. L2b datasets in ascending and descending geometry were used to calculate the horizontal and vertical displacements for the L3 datasets [12]. For this study, we used an L2a dataset.

In addition to an analysis of the spatial deformation pattern, based on mean deformation velocity maps, both datasets were processed with the Fraunhofer IOSB tool PSDefoPAT<sup>®</sup> [7] to analyze temporal deformation patterns. PSDefoPAT<sup>®</sup> extracts

relevant information on the temporal deformation patterns not directly visible in the typically presented mean deformation velocity maps.

### 3.2 Persistent Scatterer Deformation Pattern Analysis Tool (PSDefoPAT<sup>®</sup>)

The tool PSDefoPAT<sup>®</sup> was developed at Fraunhofer IOSB to ease the analysis of the individual displacement time series of a large set of PS [7]. Most PSI algorithms provide a map of the mean velocity of each PS found in the area of interest and the associated displacement time series for each PS. The advantage of the mean velocity maps is that areas of active deformation are easily recognizable. Also, their spatial expansion and the direction of the deformation in the LOS of the sensors are provided. However, the mean velocity is calculated assuming the deformation is linear. More complex deformation patterns are not considered, such as a periodically varying surface deformation or an accelerating or decelerating deformation pattern. Thus, information on the dynamic nature of the deformation is completely lost to the analyst. PSDefoPAT<sup>®</sup> estimates the best-fitting model to describe the deformation pattern of each PS over time and thus provides information on the dynamic nature of the deformation. PSDefoPAT<sup>®</sup> separates the long-term trend, periodic, and noise components of each displacement time series in six steps. The order of these steps is illustrated in Figure 2. The displacement time series is first denoised using wavelet transformation. Afterward, the periodogram of the remaining time series is calculated, and a Fisher’s g-test is conducted to determine whether or not the time series has a significant seasonal component. If the time series has such a component, the seasonal and trend components are estimated in one step.

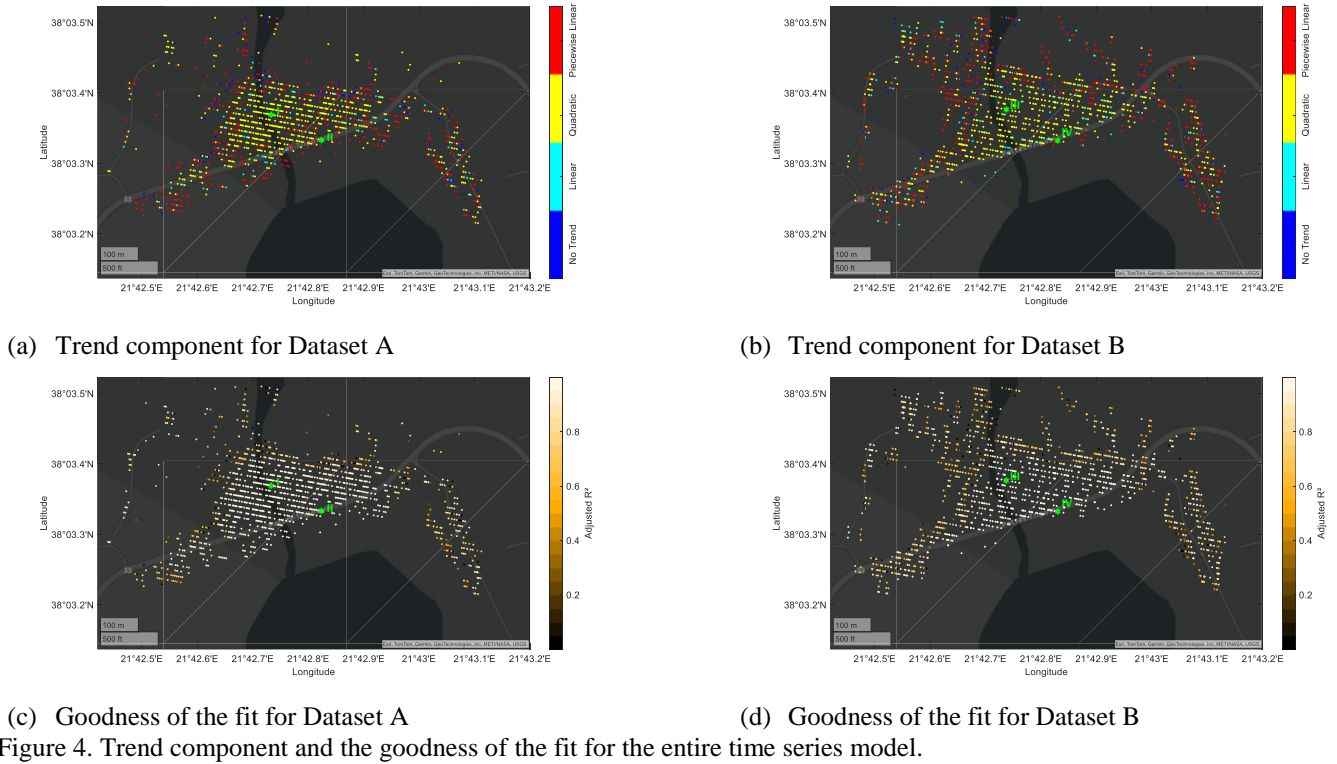

(a) Dataset A

(b) Dataset B

Figure 3. Mean deformation velocity for MPs on the dam body of the Parapeiros-Peios dam in Greece.

Valid time series models are (1) purely seasonal, (2) seasonal with a linear trend, and (3) seasonal with a quadratic trend. Only the trend component is estimated if the time series has no significant seasonal component. Applicable models for the trend component are (1) linear, (2) piecewise linear, and (3) quadratic time series models. Before the different models are estimated, the time series is segmented using a top-down segmentation algorithm to provide change points for a piecewise linear model. Lastly, the best-fitting model is determined using the Bayesian Information Criterion (BIC) and the value for the adjusted coefficient of determination  $R^2_{adj}$ . Both parameters provide information on the goodness of the fit, taking into consideration the complexity of the model and, therefore, preventing overfitting [7]. PSDefoPAT<sup>®</sup> automatically generates four plots by default to visualize its results. The plots indicate: (1) the type of trend component, whether or not the time series features a periodic component, (3) the amplitude of the periodic component, and (4) the goodness of fit for the entire time series model. A practical example of these plots is presented in Figure 4 and Figure 5, which visualize the results for the Parapeiros-Peiros dam. With these plots the temporal deformation pattern, not directly visible in the typically presented mean deformation maps, of the MPs in the AOI can be analyzed. For example, MPs effected by a periodic behavior can be easily spotted.

#### 4 RESULTS AND INTERPRETATION

In the following section the results generated with PSDefoPAT<sup>®</sup> for Dataset A processed by Fraunhofer IOSB and Dataset B obtained from the EGMS are presented and the fit of exemplarily displacement time series and the estimated time series models of individual MPs are discussed.

The mean deformation velocities for the measuring points (MP) in Dataset A and Dataset B located on the dam body of the Parapeiros-Peiros dam are presented in Figure 3. The color map ranges from red, indicating a deformation velocity larger than 20 mm/y in the direction towards the sensor, to blue, indicating a deformation velocity larger than -20 mm/y in the direction away from the sensor. Both images show that the mean deformation velocity on the dam body varies along the downstream shoulder, with more -20 mm/y at the crown and close to zero at the toe of the dam body. This is a typical spatial deformation pattern observed for embankment dams [16]. In order to analyze the temporal deformation pattern, the displacement time series of Dataset A and Dataset B were processed with PSDefoPAT<sup>®</sup>. The results are visualized in Figure 4 and Figure 5. Figure 4 (a) showing Dataset A and (b) Dataset B indicate whether the processed displacement time series exhibit a linear (cyan), quadratic (yellow), piecewise linear (red) trend, or no trend (blue). In both cases, the majority of MPs at the center of the downstream shoulder of the dam body exhibit a quadratic trend, and MPs located closer to the edges or adjacent to the dam exhibit a piecewise linear trend. This pattern is mirrored in Figure 4 (c) and Figure 4 (d), which present a measure for the goodness-of-fit in the form of the adjusted coefficient of determination  $R^2_{adj}$  for the estimated time series model for Dataset A and B, respectively. The estimated time series model for MPs at the center of the dam body fit the displacement time series better than those estimated for MPs at the edge of the dam body, for both Datasets.

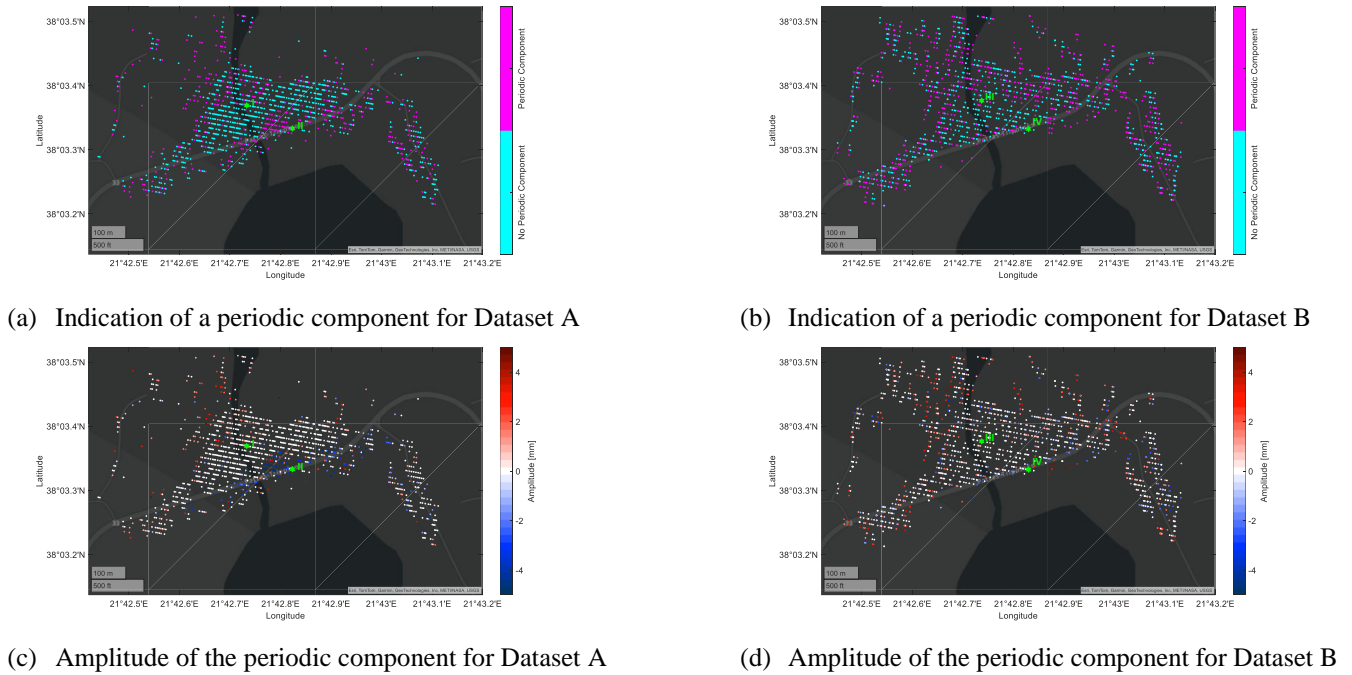

Figure 5. Periodic component and the corresponding amplitude of the periodic component.

Figure 5 indicates whether the estimated time series model includes a periodic component (magenta) or not (cyan), along with the corresponding amplitude of the periodic component. While the estimated time series models for Dataset A, see Figure 5 (a) and Figure 5 (c), show that only some MPs exhibit a periodic behavior, in the case of Dataset B, see Figure 5 (b) and Figure 5 (d), significantly more MPs exhibit periodic behavior. This may be due to the different time spans that Dataset A and Dataset B cover. In order to investigate the displacement time series and estimated time series models further, we examined four exemplary MPs located at the downstream shoulder (MP I and MP III) and crown (MP II and MP IV) of the dam body for both datasets. The MPs are marked in green in Figure 4 and Figure 5. The selected MPs for both datasets are not identical, however, they were picked as closely together as possible to ensure comparability. Their displacement time series (black dots), overall estimated time series model (green), and the lower and upper error margins

(red) are presented in Figure 6 and Figure 7. The estimated parameters for the time series models are also summarized in Table 1. Figure 6 displays the displacement time series for MP I and MP III, which are located on the downstream shoulder of the dam body. Both estimated time series models exhibit a quadratic trend. While the linear coefficients of both models are similar, with  $-11.1 \text{ mm/y}$  for MP I and  $-10.1 \text{ mm/y}$  for MP III, the scaling parameter of quadratic time series model differs. The scaling parameter is estimated to be  $-1 \text{ mm}^2/\text{y}^2$  for MP I and  $-0.5 \text{ mm}^2/\text{y}^2$  for MP III. A smaller value for the scaling parameter leads to a wider opening for the parabola, approximating the displacement time series. This difference in the scaling parameter might be influenced by the slightly different time spans that Dataset A and Dataset B cover. While Dataset A covers only the time of the first filling of the freshwater reservoir, Dataset B covers a short time before the first filling and about a year afterwards.

Table 1. Model parameters and estimated mean velocity of the selected MPs.

	Mean Velocity	Best-Fitting Model	$R^2_{\text{adj}}$
Downstream Crown:			
Dataset A	$-25.1 \text{ mm/a}$	$d = -29.7 \text{ mm/a} \cdot t + 2 \text{ mm}^2/\text{a}^2 \cdot t^2 - 4.6 \cdot \sin(\frac{2\pi}{798.3d}(t - 391.9 \text{ d}))$	0.99
Dataset B	$-28.1 \text{ mm/a}$	$d = -26.6 \text{ mm/a} \cdot t - 0.3 \text{ mm}^2/\text{a}^2 \cdot t^2 - 1.6 \cdot \sin(\frac{2\pi}{519.9d}(t - 119.4 \text{ d}))$	0.99
Downstream Shoulder:			
Dataset A	$-16.1 \text{ mm/a}$	$d = -11.14 \text{ mm/a} \cdot t - 1.0 \cdot t^2 \text{ mm}^2/\text{a}^2$	0.99
Dataset B	$-17 \text{ mm/a}$	$d = -10.1 \text{ mm/a} \cdot t - 0.5 \text{ mm}^2/\text{a}^2 \cdot t^2$	0.99

(a) MP I in Dataset A

(b) MP III in Dataset B

Figure 6. The displacement time series (black dots), overall estimated time series model (green), and the lower and upper error margins (red) for MP I and MP III, which are located on the downstream shoulder of the Parapeiros-Peiros dam.

The estimated time series model of MP II and MP IV, which are located on the downstream side of the crown, are presented in Figure 7. Again, both displacement time series are approximated by a quadratic model for the trend component. The values of the linear coefficient are significantly higher than those estimated for MP I and MP III. The coefficients were estimated to be  $-29.7$  mm/y for MP II and  $-28.1$  mm/y for MP IV. The observed varying deformation rates from the crown of the dam body, along its shoulder to the toe, are common for embankment dams [16]. Additionally, both time series models have a periodic component. However, the estimated amplitude and cycle length of the periodic component for MP II and MP IV diverge from one another. The amplitude is  $-4.6$  mm for MP II and  $-1.6$  mm for MP IV, and the corresponding cycle lengths are 798.3 d and 519.9 d, respectively. These differences are again possibly influenced by the varying time span the datasets cover. Two events of quick water level rise in the reservoir occurred during the filling process [17]. The first one occurred in late 2020 and the second one in late 2021, both time spans are marked in purple in Figure 6 and Figure 7. The displacement time series of MP II diverges significantly from the quadratic during this time, see Figure 6(a). The displacement time series of MP IV also diverges from its trend during this time, see Figure 7(b). However, the periodic component is not as prominent as in the time series model of MP II. This might be due to the more

extended time span that the displacement time series of MP IV covers. The displacement time series includes data from 2022 and 2023, in addition to 2020 and 2021. The events of accelerated water level rise from fall and winter 2020 and 2021 did not repeat in the same severity at the end of 2022 and 2023. Therefore, the displacements due to these events have been smoothed over in the longer displacement time series and thus have led to different estimations for the periodic component of MP IV in comparison to MP II.

Based on the analysis of the mean deformation velocity maps, presented in Figure 3, the spatial deformation pattern of both datasets for the Parapeiros-Peiros dam are very similar. Using PSDefoPAT<sup>®</sup> in post-processing to analyze the temporal deformation pattern reveals that short-term temporal deformation patterns are not only smoothed over in the mean deformation map but also in cases where longer time series, such as Dataset B, are used. Highlighting the advantage of customizing the dataset to a specific time span that needs to be examined. For infrastructure monitoring, both long-term trends and short-term events are of interest. Thus, in-house processing of SAR images for surface deformation monitoring is still necessary.

(a) MP II in Dataset A

(b) MP IV in Dataset B

## 5 SUMMARY

In this study, we examined the surface deformation of the Parapeiros-Peios dam during its first filling and shortly after, based on two datasets. The first dataset consists of 119 S1 SAR images and was processed in-house. The second dataset was downloaded from the EGMS. The observable spatial and temporal deformation patterns of both datasets were compared to explore the necessity for in-house advanced DInSAR processing for surface deformation monitoring of critical infrastructure, such as a newly built dam. An analysis of the spatial deformation patterns based on the mean deformation velocity maps showed good agreement between both datasets and that the highest deformation rates can be observed at the crown of the dam body, which agrees with the spatial deformation pattern typically observed in embankment dams [15]. The analysis of observable temporal deformation patterns, not directly visible in the mean velocity maps, was aided by the post-processing tool PSDefoPAT<sup>®</sup> developed by Fraunhofer IOSB. The tool extracts relevant information on the temporal deformation pattern of advanced DInSAR datasets by automatically determining the best-fitting time series model for each displacement time series of the dataset. In the case of the two datasets examined in this study, it was revealed that short-term displacement events are not only smoothed out in the mean deformation velocity maps but also in cases where longer time series are examined, e.g., Dataset B. Both long-term displacement trends and short-term events of diverging displacements are important to document and analyze in infrastructure monitoring. Pointing out a disadvantage of using the EGMS for infrastructure monitoring, which always examines a time span of five years. Another disadvantage is the time delay in providing the data, which is currently at a minimum of three-quarters of a year. Both of these aspects led us to the conclusion that the possibility of customizing the dataset to the deformation phenomena in question and the timelier fashion of processing still render in-house processing of SAR images for surface deformation monitoring of infrastructure necessary.

**ABSTRACT:** Remote sensing, in particular multi-temporal Synthetic Aperture Radar interferometry (MT-INSAR), is becoming an operational technique for landslide and subsidence monitoring, and it shows significant potential as an effective tool for bridge monitoring as well. In this case study, the possibilities of MT-INSAR-based structural health monitoring were demonstrated on a motorway bridge in Austria. The bridge is a perfect test object to compare the achieved accuracy due to the availability and good coverage of TerraSAR-X and Sentinel-1 data in combination with an in-situ deformation monitoring system. Due to the overlapping period of one year, a statistical evaluation of the obtained deformations along the bridge could be made. Another topic addressed in this contribution is the modelling of typical bridge deformation patterns, which are primarily caused by thermal expansion of the bridge. To detect critical displacement patterns, it is therefore necessary to separate the thermal component from the critical one. After completing this step, we applied and evaluated newly developed algorithms that detect changes in bridge deformation patterns and raise alarms when necessary. Furthermore, an interesting comparison was made between processed Sentinel-1 time series as provided by the Copernicus Land Monitoring Service via the European Ground Motion Service (EGMS) and the custom processing of the area of interest exclusively, utilizing site-specific temperature data.

**KEY WORDS:** Bridges, InSAR, MT-InSAR, Structural Health Monitoring, Sentinel, TerraSAR-X, thermal displacement.

## 1 INTRODUCTION

The transport infrastructure and its structures must be functionally intact, provide reliable performance and guarantee the safety of road users. Above all, this requires high standards for engineering structures such as bridges in terms of resistance to impacts, durability and sufficient fulfilment of requirements on structural safety. Other important aspects include low maintenance costs, few service interventions and cost-efficient operation over the entire life cycle.

In addition, the tasks of infrastructure operators with regard to their facilities have shifted from new construction to the maintenance and repair of existing structures or their replacement with new ones. The combination of an ageing infrastructure with limited financial resources makes this a very challenging task. For example, 50% of Austrian/German/Swiss motorways are now over 40 years old and most bridges are about to undergo major maintenance.

As of today, the condition of bridges is mainly determined by on-site inspections (visual inspections and close on examination). The main advantage of this method is the use of experienced personnel with knowledge of the historical development of the structural condition. Bridge monitoring systems with sensors are only used in special cases. A comprehensive, sensor-based examination of all structures is currently too time-consuming and costly to be used across the entire transport network.

### 1.1 InSAR for bridges

Remote sensing, particularly multi-temporal synthetic aperture radar interferometry (MT-INSAR), has a strong potential to be utilized for bridge monitoring. In this context,

the advantages of MT-INSAR are the large spatial and the dense temporal coverage (4-12 days, in the case of the Sentinel-1 constellation) of SAR data, the possibility of retrospective bridge monitoring and the fact that many bridges can be semiautomatically monitored at the same time. Furthermore, MT-INSAR techniques allow for the monitoring of slow movements that are often not apparent in visual inspections. But it is precisely the slowly occurring deformation patterns that play a major role in the assessment of the structural health of bridges. This could be shown by retrospective InSAR-based measurements of the bridge in Genoa (Italy) [1] after its collapse. First signs of critical deformation were identified several months/years in advance. However, [2] analyzed the same data sets as in [1] with two independent MT-INSAR methods and found no pre-collapse displacements in their consistent results, leading them to deeply disagree with the findings of [1]. In the reply, the importance of innovative research in the emerging field of InSAR applications to civil engineering structures is highlighted.

### 1.2 Motivation

The main focus of the study is to demonstrate the case study of the accuracy of the vertical deformation measurement of bridges based on MT-InSAR processing using Sentinel-1 and TerraSAR-X data. This was achieved by direct comparison with in-situ measurements for a selected motorway bridge in Austria. Although several such studies have been carried out [3], there is still a need to include more examples to increase their statistical significance. The conceptual basis of a flagging system to distinguish between normal bridge movement behavior resulting from environmental conditions and

abnormal behavior that may indicate structural damage is described here. Accurate bridge temperature is an important issue for this task. Therefore, different data sources on environmental conditions have been investigated and their influence has been analyzed.

### 1.3 Description of the chosen bridge and its in-situ measurement system

The bridge structure G46 is an integral bridge on the A2 Süd Autobahn of Austria, located in the south of Graz consisting of two identical structures, each carrying one traffic direction. It was built in 1969 and has a steel structure: a box girder with an orthotropic deck. The bridge is designed as a single-span composite frame, where the reinforced concrete columns support a steel beam with a span of 88 meters. It rests on non-inspectable lead bearings, presenting a challenge for direct inspection and assessment. Shortly after the completion, a sloping on the longitudinal beams was noticeable. A hydrostatic leveling monitoring system was installed in 2015 to monitor the structural integrity over time. Together with geodetic measurements, there was a confirmation of this sloping that is particularly relevant in the northern beam. A second monitoring system was then installed in 2018 which was complemented in 2020 with a redundant hydrostatic leveling system.

Hydrostatic levelling is a monitoring system used to measure relative displacements in the vertical direction. By interconnecting different liquid vessels, it is possible to use fluid pressure sensors to measure the movements of these vessels and the structures that these are attached to. This allows for very precise measurements over long distances and obstacles, that provides the relative vertical position between the sensors with accuracy under the millimetric scale.

RED Bernard installed two independent hydrostatic levelling systems each in one of the independent structures. These are installed in the abutment and the midspan of the bridge, which provides data about the displacement of the center of the bridge, taking the abutments as fixed points. An overview of the bridge and the sensors installed is shown in Figure 1.

Figure 1. Highway bridge selected for the case study with schematic layout of the measurement system.

### 1.4 InSAR Data

One of the aims of the study was to compare the results obtained using different satellites and different processing methods. Both Sentinel-1 (C-band) and TerraSAR-X (X-band) data were used for this purpose. Sentinel-1 data was processed

specifically for the area of interest, but the centrally processed level 2a data from the EGMS platform [4] was also employed. Knowledge of the local temperature can improve the accuracy of custom processing. To evaluate this effect, processing was carried out separately using different temperature sources. Those used included global meteorological models, such as ERA5 [5], estimated structure temperature through Virtual Sensing [7][8], based on raster weather data from the GeoSphere data hub [6], and in situ temperature measurements from sensors installed on the bridge surface. TerraSAR-X data was available only from a single orbit and for a limited amount of images/acquisition dates, while Sentinel-1 data is available long-term and from three orbits. For a fair and direct comparison, it was decided to use only one ascending Sentinel-1 orbit (ASC146) for an initial comparison of the quality and quantity of data points. A large stack of data was processed for Sentinel-1 and the final (short) monitoring period was then cropped. An overview of the data used, including time frame, spatial resolution and orbit direction, is given in Table 1.

Table 1. Overview of satellite data used

Satellite (mode)	Sentinel-1 (Interferometric Wide Swath)	TerraSAR-X (StripMap)
Image no.	135	25
Timeline	08/20-08/23	05/22-03/23
Spatial resolution	5x20 m	3x3 m
Orbit direction	Ascending 146	Ascending

## 2 METHODOLOGY

### 2.1 Processing of the Sentinel and TerraSAR-X data

MT-InSAR processing was performed in SARproZ(c) software, independently for Sentinel-1 and TerraSAR-X data, listed in Table 1. Topography signal was subtracted using Copernicus DEM [9] and temperature effects were estimated based on in-situ measured, Virtual Sensing or ERA5 temperatures.

After thermal effect subtraction, Sentinel-1 time series (each point individually) were divided into segments with linear displacement and for each temporal segment, the noise level was estimated and segments with too high noise level were indicated as unreliable. Points which are not reliable for at least 3 years were discarded. After the segmentation, the thermal effects were re-added to the data, which was necessary for a direct comparison with the bridge deformations based on the EGMS and with the in-situ measurement, since in both of them the temperature effect is not compensated.

For TerraSAR-X data, the segmentation could not be performed because of too short timeline. As a quality criteria, interferometric temporal coherence was used, and points with coherence lower than a threshold of 0.8 were discarded. Unfortunately, the separation of thermal and permanent displacement was erroneous at the bridge center due to the short timeline: the minimum recommended timeline to reliably separate the permanent and thermal displacement is around 1.5 years [10].

It shall be noted that in spite of the fact that Sentinel-1 and EGMS resources are calculated using the same satellite data, the processing methodology slightly differs, as well as the criteria for point dropping.

MT-InSAR displacement time series were converted from SAR line of sight direction to vertical direction geometrically, based on the assumption that the displacement is purely vertical. If some points move in a horizontal direction, such a conversion gives incorrect results.

## 2.2 Clustering of the persistent scatterer (PS) Points on the bridge

The PS points for each of the three configurations (EGMS, Sentinel, TerraSAR-X) were first filtered to contain only points on the bridge based on their geo-location. As expected, the number of obtained PS points varied widely ranging from 34 (EGMS Figure 2a), 86 (Sentinel Figure 2b) up to 368 (TerraSAR-X, Figure 2c). To calculate the vertical deformations of the bridge with respect to its longitudinal coordinate, the PS points were clustered into 7 groups, which were distributed evenly along the bridge axis as shown in Figure 2.

Figure 2. PS Points with the background form OpenStreetMap (OSM), a) EGMS, b) Sentinel-1, c) TerraSAR-X

A time history of the deformation for each cluster was obtained as an average of these points, corresponding to the bridge deflection for that area. This approach is based on the

assumption that the points in this area move together, which is approximately true for a bridge deck, neglects however the effects of torsion along the bridge axis. This has been additionally testified with TerraSAR-X data, as there are enough PS points to divide each area further into three clusters across the width of the bridge. If the bridge had been subject to torsional deformations, it would have been visible, but none were observed.

Once the clustering was complete, the PS points were reselected based on the correlation matrix, which is a table showing the correlation coefficients between all PS points within a zone. The correlation coefficient is a statistical measure that expresses the extent to which two PS points are related. It ranges from -1 to +1, where +1 is a perfect positive correlation, -1 is a perfect negative correlation and 0 means no predictable relationship between the points. We estimated, that to classify a PS point as correlated with the others, it must be correlated with at least 1/3 of all points with a threshold of 0.5. It should be noted that this approach is case sensitive and must be carefully adapted when used for other bridges.

This step would be particularly important for bridges with many PS points underneath, as it would help to distinguish which points were on the bridge. In this case there is mostly water, where no PS points are present. Nevertheless, the use of this criteria helped to discard single points without any correlation to the others, which could be caused by the reflection of a non-structural element with some additional movement that does not reflect the deformation of the bridge.

The next step was to calculate a median value for each cluster based on the selected data points, including time series. This greatly reduced the noise of the PS points, removed the outliers and produced a smooth time series as can be seen in Figure 3.

Figure 3. Calculation of the time – series for a cluster in the mid span for EGMS data.

## 2.3 Normal bridge deformation patterns

A critical task for MT-InSAR bridge monitoring and damage identification is the recognition of normal bridge deformation patterns resulting from environmental influences. This movement must subsequently be subtracted from the measured deformations to obtain a clear pattern. This step is not required when using the SARproZ(c) software mentioned above, as the estimation (and subtraction) can be performed within MT-

InSAR processing. However, it is essential for EGMS data or other MT-InSAR processing algorithms that do not automatically include it.

There are two common approaches to achieve this: data-driven and model-based. Both are effective in achieving the goal, but each has some advantages and limitations. Mostly, the first one is used and only when the time series is not long enough, the model-based one is employed.

In this study, we combined these approaches by identifying the normal bridge deformation pattern from the data and cross-checking it with an adapted finite element (FE) model. In this way, a link can be established between the single PS point approach and the whole bridge deformation shape. This approach requires two steps, which are described below.

The first step is to relate the deformation values calculated for each zone, as described in the previous section, to the structural temperature. If the data set is too short (less than 1.5 years), as may easily happens with commercial data (such as TerraSAR-X), this can be done with EGMS data (Figure 4). The structural temperature can be obtained either from in-situ measurements, if available, or by using the Virtual Sensing method developed by AIT [7][8]. If none of the above is accessible, the air temperature can be used, but a lower accuracy has to be accepted.

In the second step, a simple FE model was created, although only limited information about the cross-section geometry was available. In case of the examined integral bridge the longitudinal extension was restrained on both sides by very stiff elastic spring elements. To verify the temperature induced deformations, a uniform temperature was applied to the model and the deformations in vertical and horizontal directions were extracted for the same zones as defined for MT-InSAR processing. This was valuable for the decomposition of the Line of sight (LOS) deformation described in the next chapter and for the plausibility validation of the MT-InSAR results.

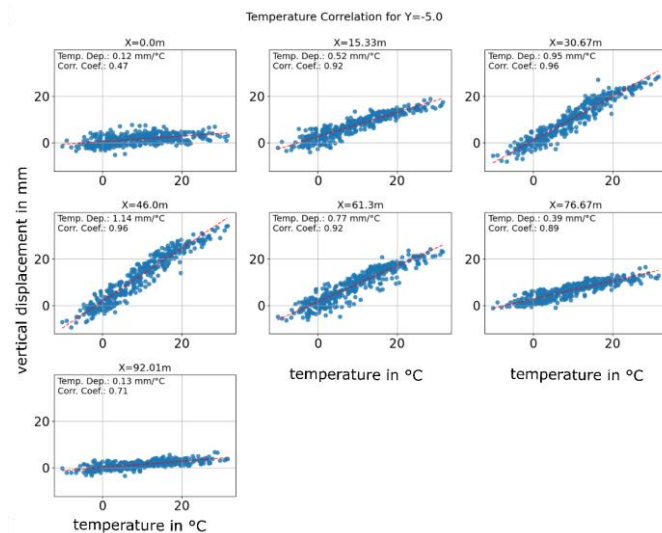

Figure 4. Thermal bridge deformation for each cluster based on EGMS.

In this way, not only the influence of temperature on the movement of each PS point was identified, but also the bridge deformation shape. The latter can be used to validate the

deformation over the entire length of the bridge if enough PS points are available.

## 2.4 LOS decomposition

The decomposition of  $d_{los}$  into  $d_{vertical}$  requires in general either both ascending and descending orbits or prior knowledge of the horizontal bridge movement based on normal bridge deformation patterns [3]. The analysis described in the previous section has shown that the temperature induced movement of the bridge is almost exclusively in the vertical direction. Therefore, the decomposition of  $d_{LOS}$  into  $d_{vertical}$ , which is of interest in this case, can be simplified to equation (1).

$$d_{vertical} = \frac{d_{LOS}}{\cos(\alpha_{incidence})} \quad (1)$$

## 2.5 Flagging system

In this study, we developed a method to detect abnormal bridge deflection. The purpose of this system is to identify bridges that require additional on-site inspection, rather than immediately triggering an alarm or leading to bridge closure based solely on MT-InSAR results. This approach ensures that potential structural issues are carefully evaluated before taking further action.

The flagging system was based on a data-driven approach in order to be flexibly adaptable to different types of bridges. The proposed system is designed to distinguish different classes of bridge displacement behaviors based on the time series of  $d_{vertical}$ :

- no trend or breakpoint,
- linear trend,
- one or more breakpoints,
- accelerating trend (i.e. at least one breakpoint and two different downward trend slopes  $\beta_{t2} < \beta_{t1}$ , where  $t_2 > t_1$  and  $\beta_{t1}, \beta_{t2} < 0$ ).  $\beta_{t1}, \beta_{t2}$  denote the slopes of the model segments before and after the breakpoint.

A data-driven approach assumes that normal bridge deformation patterns can be derived from the deformation time series as described in section 2.3. However, this may not always be the case as MT-InSAR time series may be too short to assume a pattern to be stable. In this study, only the Sentinel-1 time series was used as the displacement time series derived from TerraSAR-X was too short. Additionally, the flagging system provides for the possibility of applying user-specified thresholds on linear trends and total displacement. In order to minimise noise the PS points were grouped according in seven segments along the length of the bridge.

## 3 RESULTS

### 3.1 Influence of the temperature accuracy on MT-InSAR results

For data-driven methods to estimate/subtract temperature effects, temperatures at the acquisition times are necessary and their accuracy directly influences the (temporal) noise of the final time series of each point, and in some cases (especially those with shorter timeline), also other results, such as the displacement or estimated thermal dilation coefficient.

Results achieved using in-situ and Virtual Sensing temperatures are comparable, as the average differences between these two temperature sets is 0.7 degrees and the

maximum difference is 3.1 degrees (acquisition time for this data is 5PM UTC).

The differences between Virtual Sensing and ERA5 temperatures, on the other hand, (compared in a different processing not considered here), are much higher: average of 2.5 degrees and maximum 5.2 degrees (even if the acquisition time for this case was 5AM UTC).

If the number of images is high enough and the monitoring period long enough to provide numerical stability of separation between linear and thermal displacement components (at least 1.5 years according to [10]), the temperature inaccuracies (if not systematic in time) influence only the noise, i.e. the estimated point quality, which may slightly influence point density.

If temperature accuracy is lower but the number of points is high enough to provide for statistical processing, and the thermal dilation is also significant, higher accuracy can be achieved by temperature refinement procedure [10].

### 3.2 Comparison with in-situ measurements

To compare the accuracy of the three data sets considered, the recalculated values of vertical bridge deformation in the mid-span (zone 4) were compared with the in-situ measurement. A period of time from May 2022 to April 2023 was selected, which was common to all data sets. The direct comparison is shown visually in Figure 5, where green dots represent the in-situ measurements, while the red curve shows EGMS, black Terra-SAR-X and blue custom processed Sentinel-1 data. The normal bridge deformation patterns were not removed from either the reference in-situ or the InSAR data. If it was already subtracted during the MT-InSAR processing, it was added afterwards for the purpose of this comparison.

Figure 5. Comparison between the reference measurement (green dots), EGMS (red line), TSX (black line) and Sentinel (blue line) for the central segment of the bridge

The differences between each InSAR data set (EGMS, Sentinel-1 and TSX) and the reference were statistically analyzed and the resulting standard deviations are shown in Table 2. To compare the InSAR data with the reference measurements, first the mean value is calculated for all the Persistent Scatterer (PS) points belonging to the cluster associated with the location of the reference measurement. This mean value represents the average displacement derived from

the InSAR dataset for that area. Next, any offset between the two datasets is removed to align both to the same baseline. Once aligned, the mean value obtained from the selected InSAR cluster is then subtracted from the corresponding reference measurement. This difference reflects the deviation between the two datasets at the reference location. Finally, the standard deviation of these differences is calculated to quantify variability and assess consistency between InSAR-derived values and reference data.

Table 2. Comparison with in-situ measurement

data set	Std. deviation in mm
EGMS	3.8
Sentinel	2.1
TSX	1.7

The bridge deformations from the in-situ measurement are only given for the mid-span, so only these values were available for comparison. Therefore, a FE model of the bridge was used to perform a plausibility check on the deformed bridge shape that results from the MT-InSAR analysis. First, it was slightly updated to match the deformation in the center of the span by adjusting the stiffness of the constraining springs at the bridge abutments. Next, several TerraSAR-X acquisition times were selected and structural temperatures were calculated for each date and time. These temperatures were then applied to the FE model and the resulting bridge deformations were extracted and plotted as a solid line in Figure 6. Equivalent bridge shapes resulting from the TerraSAR-X data were plotted with the dashed line and the in-situ measurements with a point. The colors were kept the same for each date to enhance visual comparison. Not only does the mid-span deformation match very well between the FE model, reference measurement and MT-InSAR, but also the shape over the entire length of the bridge is similar. This demonstrates very high quality of the bridge deformation measurement obtained by MT-InSAR processing.

Figure 6. Comparison of the bridge shape according to FE Model (solid line), TSX (dashed) and reference (dots)

Once the direct comparison of the three datasets was complete, the analysis was repeated for the remaining two Sentinel-1 orbits. To obtain the total vertical deformation for each zone, the average of the results from each orbit was calculated after interpolation between acquisition times. In this way a combined EGMS and Sentinel-1 solution was obtained.

In addition, a combination of Sentinel-1 and TerraSAR-X data was derived for a total of four orbits. All three options for zone 4 (mid-span) were again compared with the reference measurement and the resulting standard deviations are shown in Table 3.

Table 3 Comparison with in-situ measurement for all available orbits

data set	Std. deviation in mm
EGMS	1.7
Sentinel-1	1.4
Sentinel-1 + TSX	1.3

The use of multiple orbits greatly improved accuracy, especially for EGMS. It is also evident that locally processed Sentinel-1 data can give better results than centrally processed EGMS, although both are based on exactly the same radar data. This is particularly true for the single orbit approach shown in Table 2. A novel combination of Sentinel-1 and TerraSAR-X data could improve the quality even more, but as the standard deviation is already very small, it does not bring that much improvement. It is expected that for bridges with scarce Sentinel-1 coverage the enhancement would be much more significant.

### 3.3 Flagging system

The developed algorithm for the flagging system was then applied to the processed data for each zone. This step allowed us to automatically evaluate potential anomalies in the bridge deflection and determine if the bridge may require further field inspection.

Figure 7 and Figure 8 show linear displacement rates up to 0.6 mm per year. Displacement rates of this magnitude were deemed too small to flag any of the anomalous behaviors listed in section 2.5. Breakpoints along the time series were detected, e.g., in zone 5, however, the overall displacement trend along the time series is close to zero. Overall, no flags were raised for any of the bridge segments.

Figure 7 Overview of annual displacement rates for each of the seven bridge segments. OSM is used as background map.

Figure 8 Displacement time series for four segments with fitted trend lines and 95% confidence intervals of the fitted lines.

## 4 CONCLUSIONS

While MT-InSAR bridge monitoring has certain limitations, it also offers unique advantages. One key advantage is its ability to provide retrospective monitoring when historical data are available, with Sentinel-1 data being available globally from 2015. However, due to its limited spatial resolution, Sentinel-1 data typically provides reliable results only for larger structures. For higher point density and improved accuracy, high-resolution satellite data from sources such as TerraSAR-X or Cosmo-SkyMed are required.

In this study, deformations from in-situ measurements of a highway bridge in Austria were compared with three different InSAR datasets: EGMS, processed Sentinel-1 and TerraSAR-X. As can be expected the number of PS points on the bridge is significantly higher for X-band radar compared to C-band. Nevertheless, the result show, that for the investigated bridge a remarkable accuracy, with standard deviations lower than 2 mm, can be achieved with all three datasets, especially if all available Sentinel-1 orbits are taken into consideration. This result not only highlights the great potential of MT-InSAR-based monitoring for detecting bridge deformations with high accuracy, but also raises the question whether expensive X-band data is required for bridge monitoring or often the freely available Sentinel-1 data is sufficient for this purpose.

To accurately assess actual bridge displacements and distinguish them from normal deformation patterns, thermal effects are estimated and subtracted from the MT-InSAR results. This correction helps to refine the analysis, ensuring that detected displacements more accurately reflect structural behavior rather than temperature-induced variations.

Finally, by implementing the flagging system, an automated method for identifying potentially problematic bridges was developed and demonstrated. However, it is important to emphasize that this approach is not intended to replace on-site inspections. Rather, it serves as a complementary tool that provides additional information to assist in the assessment of bridges that may require further investigation.

**ABSTRACT:** Resilient high-voltage grids are essential for ensuring energy supply and preventing. However, climate change, the energy transition and the required expansion of electricity grids pose growing challenges for infrastructure operators in the energy sector. In Austria, landslides in alpine regions and decreasing groundwater levels in flat areas represent significant potential risks to power pylons. The Austrian Power Grid AG (APG), which operates the Austrian transmission grid, faces growing demands to detect damage at an early stage and to guarantee grid security amid changing climatic conditions. Satellite-based Interferometric Synthetic Aperture Radar (InSAR) potentially provides millimeter-precise, area-wide monitoring of ground motion and structural deformations. Periodic InSAR data updates (e.g. semi-annually) enable a complete and continuous analysis of all single structures such as power pylons and thus facilitate an assessment of the structural integrity of the entire grid. This allows the early identification of risks such as landslides or structural changes and the implementation of predictive maintenance. This paper highlights previous experiences and future potentials of integrating the InSAR technology into APG's workflows and risk management, which contributes to sustainable planning and increased grid stability in an increasingly complex system.

**KEY WORDS:** Wide-area InSAR; Power Grids; Monitoring; Predictive maintenance.

## 1 INTRODUCTION

The Austrian Power Grid AG (APG) plays a central role in Austria's energy infrastructure. As the operator of the Austrian electricity transmission network, APG is responsible for ensuring a continuous and reliable power supply. A critical factor in maintaining efficient and secure grid operations is the early detection of potential disruptions or structural changes in the transmission infrastructure.

APG manages an extensive network of power lines, substations and more than 12.000 power pylons in Austria, that require regular monitoring. Identifying ground movements, structural deformations, and other potential risk factors is essential to minimize unplanned outages and enhance operational security. In this context, a feasibility study is being conducted to evaluate the integration of satellite-based InSAR technology into APG's monitoring strategy, aiming to enhance early-warning capabilities and risk mitigation.

## 2 BASICS OF INSAR TECHNOLOGY

Synthetic Aperture Radar (SAR) satellites use radar signals to generate high-resolution images of the Earth's surface, independent of weather conditions or daylight. The principle is based on transmitting microwave pulses, which are reflected by the Earth's surface or manmade objects and received by the satellite. These signals are processed to create detailed images through complex signal processing techniques.

### 2.1 Reflection of Radar Waves

The reflection of radar waves follows the physical principles of electromagnetic wave propagation. The strength of the reflected signal depends on two main factors:

- **Geometry of the Reflector:** When incoming radar waves are reflected at an appropriate angle, a significant portion of the signal returns to the satellite. Smooth, metallic surfaces or structural elements enhance reflection.
- **Material Properties of the Surface:** Materials with high electrical conductivity, such as metals, reflect radar waves effectively, whereas natural surfaces like vegetation or snow scatter waves in various directions, reducing the returned signal strength.

### 2.2 Different Frequency Bands for Various Applications

SAR satellites operate at different frequency bands to serve specific applications:

- **L-Band (1-2 GHz):** Commonly used for agricultural and forestry monitoring due to its ability to penetrate vegetation.
- **C-Band (4-8 GHz):** Frequently used by Earth observation satellites like Sentinel-1, offering a balance between resolution and penetration depth.
- **X-Band (8-12 GHz):** Employed in high-resolution applications such as infrastructure monitoring and military surveillance, providing high spatial resolution but limited penetration capability.

### 2.3 Orbit and Imaging Geometry

SAR satellites typically follow a polar or sun-synchronous orbit, capturing data in both ascending (ASC) and descending (DSC) imaging geometries. In the ascending geometry, the satellite moves from the South Pole toward the North Pole, while in the descending geometry, it moves from the North Pole toward the South Pole. A schematic representation of the flight

directions can be seen in Figure 1. This configuration allows for continuous monitoring of the Earth's surface.

Figure 1. Ascending (ASC) and descending (DSC) geometry [2].

#### 2.4 Line of Sight (LOS) and Incidence Angle

The SAR system's viewing direction (azimuth angle) is typically oriented sideways ( $90^\circ$  to the flight path). In the ASC geometry, the satellite looks eastward, while in the DSC geometry, it looks westward. The incidence angle is the angle between the vertical and the incoming radar beam, varying depending on the satellite system and terrain conditions. A larger incidence angle occurs further from the nadir (directly below the satellite), affecting shadowing, measurement accuracy, and displacement detection.

Since SAR images capture displacements along the LOS, movements perpendicular to this direction remain partially undetected. This limitation can be mitigated through multi-orbit analysis (see chapter 2.6) or integration with ground-based data sources.

#### 2.5 From SAR to InSAR

As SAR satellites repeatedly capture images of the same area over time, they provide insights into surface changes. Each SAR acquisition records two essential parameters: (a) Amplitude, representing the energy of the reflected signal, and (b) Phase, related to the distance between the sensor and the target.

Figure 2. Schematic representation of how InSAR (interferometric SAR) works. The phase shift ( $\Delta r = R_2 - R_1$ ) results from the phase information ( $R$ ) of two or more images of the same area at different times or different positions [2].

Interferometric SAR (InSAR) compares phase differences between two or more SAR images to detect changes in distance

between the satellite and the Earth's surface along the LOS-vector. [1] This technique enables millimeter-accurate measurements of slow ground movements, such as landslides, earthquakes, and subsidence. Figure 2 shows the phase calculation that is performed for each individual measurement pixel.

#### 2.6 Displacement Vectors and 2D Decomposition

InSAR primarily measures displacement along the LOS. To derive vertical or horizontal displacement components, a 2D decomposition technique is applied using data from both ASC and DSC imaging geometries. This method allows for estimating movement in the east-west and vertical directions, while north-south displacement remains largely undetectable or at least underestimated and requires complementary data sources, such as GNSS measurements.

### 3 DATA PROCESSING

#### 3.1 SqueeSAR® Analysis

In this study, the applied SAR data was processed using the multi-interferogram technique known as SqueeSAR® [1]. SqueeSAR®, a patented method developed by TRE ALTAMIRA, improves the reliability of InSAR measurements in heterogeneous environments by reducing phase decorrelation in areas with vegetation or urban structures. It combines Persistent Scatterers (PS) and Distributed Scatterers (DS) to achieve a high spatial density of measurement points.

To ensure high precision and accuracy, SqueeSAR® requires a dataset of at least 15 to 20 SAR images acquired over the same area using the same acquisition mode and geometry. By combining PS, which are stable and well-defined radar reflectors, with DS, which represent diffuse scattering signals, SqueeSAR® can extract reliable movement data even in areas with low signal stability. This enables comprehensive monitoring of ground deformations.

#### 3.2 Precision and Accuracy

Precision and accuracy are crucial in measurement science:

- Precision refers to the consistency of repeated measurements. A measurement series is precise if repeated observations under the same conditions yield similar values, regardless of their deviation from the true value.
- Accuracy describes how close a measurement is to the actual (true) value, meaning a measurement is accurate if systematic errors are minimal.

#### 3.3 Determining Precision in InSAR Data

The precision of InSAR results is influenced by:

- Measurement Point Locations: The geolocation accuracy of measurement points depends on the SAR coordinates and the derived height from the InSAR analysis. Higher resolution sensors improve geocoding precision.
- Displacement Time Series: The standard deviation ( $\sigma$ ) of individual measurements quantifies the variation around the mean displacement rate. Lower  $\sigma$  values indicate higher precision, while higher values suggest greater measurement variability.

For a dataset of at least 30 SAR images covering a two-year period, measurement points within 1 km of a reference point typically exhibit a standard deviation of less than 1 mm/year. The average standard deviation for a single measurement is usually  $\pm 5$  mm. While InSAR precision is statistically derived, measurement accuracy is usually validated with ground-based reference data, such as geodetic surveys, achieving accuracy in the sub-millimeter range [1].

### 3.4 MatchSAR® - Transformation of InSAR measurements into objects

MatchSAR® is an advanced algorithm developed by AUGMENTERRA in collaboration with TRE ALTAMIRA. It transforms millions of InSAR measurement points across Austria by aligning them with physical structures such as buildings, power pylons, dams, roads, and railways.

The transformation process consists of several key steps. First, a spatial analysis and quality control of all available InSAR measurement points are conducted to ensure accurate attribution of ground movements to the corresponding structures. Additionally, the algorithm integrates InSAR data with other terrain and structural datasets, creating a comprehensive, multidimensional view of each object. As a result, every object processed by MatchSAR® is assigned a displacement time series covering at least two to three years, enabling in-depth movement analysis (e.g., steady vs. accelerating displacement).

MatchSAR® is a core component of the 'AUGMENTERRA Observer', a Software-as-a-Service (SaaS) platform featuring state-of-the-art 3D visualization. The 'AUGMENTERRA Observer' is accessible via various devices, including PCs, smartphones, and tablets, allowing users to retrieve structural and ground movement data within seconds. By automatically updating measurement data every six months, MatchSAR® ensures continuous tracking of structural movements, significantly reducing manual processing efforts and improving long-term risk assessment capabilities.

## 4 USE CASE: WIDE-AREA MONITORING OF STRUCTURAL MOVEMENTS AT APG

For the APG power pylon monitoring use case, Sentinel-1 data is automatically reprocessed every six months for all locations. Using a three-year moving window, updated measurement data is consistently incorporated into structural stability assessments. This approach ensures up-to-date risk evaluations, with new measurement pixels available every six to twelve days depending on Sentinel-1A/B availability. This guarantees a consistent and up-to-date analysis of structural stability over time. The results are implemented directly into APG's internal GIS using an API solution to ensure maximum availability and up-to-date information. Data access and visualization in the customer interface is displayed in Figure 3. A detailed time series of a moving pylon with an average movement of about 19 mm/year is shown in Figure 4.

Figure 3. Structural movement measurements from InSAR and locations of the APG power pylons, visualized using the 3D WebGIS application 'AUGMENTERRA Observer'.

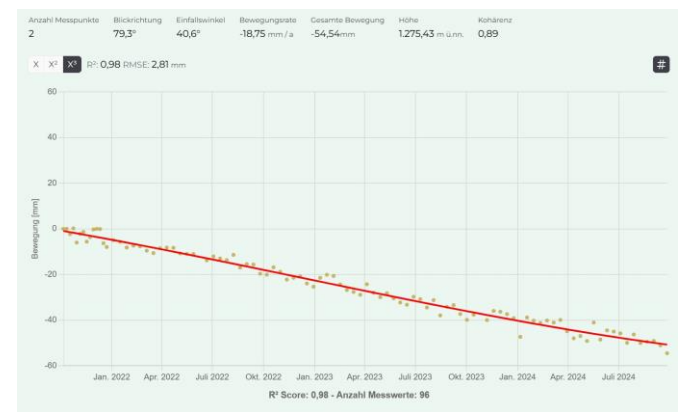

Figure 4. Time series of a power pylon located in Figure 3. The pylon shows an average movement of approx. 19 mm/year in the LOS direction. The movement behavior is homogeneous.

### 4.1 Monitoring Ground Deformation and Stability

One of the primary applications of InSAR for APG is detecting and analyzing ground deformations that could compromise the stability of power pylons. Subsidence, landslides, and soil compaction can lead to shifts in foundation structures, potentially endangering the transmission network. This allows the definition of hotspots that can be subjected to more intensive monitoring. A distinction is made between two main processes:

- Landslide and erosion detection: InSAR can identify gradual slope movements that may threaten pylon stability.
- Subsidence monitoring: Infrastructure near mining areas, groundwater extraction zones, or soft soil regions can be monitored for ground subsidence.

### 4.2 Structural Health Monitoring of Power Pylons

In addition to assessing ground stability, InSAR can also detect internal deformations of transmission pylons. While traditional structural monitoring relies on ground-based sensors, satellite-based InSAR provides:

- Large-scale coverage: Continuous monitoring of the entire power grid, including remote areas.

- Millimeter-level accuracy: Detection of slight tilting or deformation of pylons over time.
- Historical data comparison: Analysis of past SAR images to identify long-term structural trends.

#### 4.3 *Integration with Other Monitoring Technologies*

For optimal monitoring, InSAR data can be combined with:

- Ground-based sensors: Combining InSAR with GPS, inclinometers, and strain gauges enhances measurement reliability.
- Drone and LiDAR surveys: High-resolution aerial surveys provide additional validation of deformation patterns detected via satellite.

#### ACKNOWLEDGMENTS

We extend our gratitude to the Austrian Power Grid team, particularly Alois Ammerer, Christian Laister, and Gabriel Stollhof, for their continued collaboration and trust in our data. Their expertise and insights have played a key role in refining our automated monitoring system to meet the evolving demands of the energy sector.

**ABSTRACT:** With Canada's transportation infrastructure aging, compounded by the effects of climate change, the need to enhance condition assessment through structural health monitoring is increasingly critical to ensure integrity, performance, public safety, and cost-effectiveness. Bridge pier scouring, caused by high river flow and turbulence that erode the surrounding bed material, poses a significant threat to bridge stability and can potentially lead to failure. Conventional scouring inspections are often time-consuming and costly. This paper presents a case study on the Red River Bridge in Winnipeg, Canada, where an innovative, multidisciplinary assessment of bridge stability was performed, including both environmental and structural investigations. The environmental investigation utilized multispectral satellite imagery and optical-band unmanned aerial vehicle (UAV) imagery, combined with large-scale particle image velocimetry (LS-PIV), to assess river flow and turbulence. An anomalous condition near a bridge pier, detected in multispectral satellite imagery, was confirmed by UAV photogrammetry and LS-PIV river current patterns. The structural investigation, detailed in this paper, incorporated Persistent Scatterer Interferometric Synthetic Aperture Radar (PS-InSAR) deformation measurements from satellite imagery, in-situ measurements on the bridge deck, and numerical bridge model predictions. This provided an assessment of the bridge's structural behavior and its potential connection to the condition observed near one of the bridge piers.

**KEY WORDS:** Satellite PS-InSAR; Remote sensing; Bridge deformation; Case study.

### 1 INTRODUCTION

#### 1.1 Background and motivation

Canada's transportation infrastructure, especially its bridges, is facing significant challenges due to aging and environmental stresses. Many bridges across the country are nearing the end of their design life, necessitating substantial investments in maintenance and upgrades [1]. The aging infrastructure is further strained by increasing traffic loads and environmental impacts, such as extreme weather events and temperature fluctuations [2]. These factors accelerate the deterioration of bridges, affecting their safety, performance, and economic viability. The need for innovative solutions to ensure long-term sustainability and reliability is more urgent than ever [3].

Bridge pier scouring is a major issue impacting river bridges. It occurs when fast-flowing water erodes the bed material surrounding bridge piers, leading to instability and potential structural failure [4]. This problem is compounded by climate change, which is causing more frequent and severe flooding events [5]. Such conditions accelerate the scouring process, increasing risks to bridge safety and necessitating advanced monitoring and mitigation strategies [6]. Research has shown that various factors, including water velocity, bed material type, and pier shape influence the extent of scouring [7]. Effective countermeasures, such as pier modifications and protective structures, are essential to mitigate these risks [8].

In response to these challenges, there is a growing need to assess bridge safety and performance through structural health monitoring technologies. Remote Sensing for Structural Health Monitoring (RS-SHM) is an emerging field that uses multispectral and radar satellite remote sensing, combined with

low-footprint in-situ measurements, to monitor bridge structures between routine inspections. This approach, which does not require bridge closure or create traffic disruption, provides early awareness of developing risks and understanding of how environmental changes may affect structural behaviour and safety. By integrating satellite data with in-situ measurements, engineers can gain comprehensive insights into bridge structural behaviour, enabling proactive maintenance and risk management. This approach enhances safety by providing early detection of risks while improving cost-effectiveness through optimized maintenance plans and extended bridge lifespan.

The integration of advanced sensor technologies and cloud-based platforms in SHM systems allows for continuous real-time monitoring of bridge conditions. These systems can detect even minor structural changes, such as vibrations and displacements, which are critical for assessing the health of aging infrastructure. The use of SHM technologies not only improves the accuracy of bridge assessments but also facilitates timely interventions, thereby preventing catastrophic failures and extending the service life of bridges. As Canada continues to face environmental and economic pressures, the adoption of innovative SHM solutions will be crucial in maintaining the integrity and safety of its transportation infrastructure.

Additionally, the implementation of predictive maintenance strategies, supported by SHM data, can significantly reduce maintenance costs and extend the lifespan of bridge structures, which are typically designed for 75 years in Canada. Predictive maintenance involves analyzing data from SHM systems to forecast potential issues before they become critical, allowing for timely and targeted interventions.

This proactive approach enhances safety and optimizes resource allocation, ensuring that inspection, maintenance and rehabilitation efforts are focused on areas with highest risk.

Ultimately, aging transportation infrastructure requires substantial investments to address increasing traffic loads and environmental impacts. Adopting advanced SHM technologies and predictive maintenance strategies offers a promising solution to improve safety, performance, and longevity.

### 1.2 Case study site

The Red River is a shallow meandering river flowing north through the city of Winnipeg in Manitoba, Canada. The 258-m long Red River Bridge, with four lanes of vehicle traffic and one lane of foot traffic, crosses the Red River south of Winnipeg. Figure 1 shows a satellite view of the bridge, with annotations for bridge piers (P1 to P6), and west and east abutments (WA, EA). Piers P3, P4, and P5 are located in the permanent river channel, while Piers P1, P2, and P6 may become inundated at their base during periods of high flow.

From west to east, the bridge structure consists of a total of seven spans, including two simply-supported spans between WA and P2, where the longitudinal movement is fixed at P1, followed by four continuous spans between P2 and P6, where the longitudinal movement is fixed at P4, and a last simply-supported span between P6 and EA, where the longitudinal movement is fixed at the east abutment. This detail will explain the direction and extent of thermal expansion of deck along the bridge length. Ambient temperature data for this site was acquired from a local weather station located at the Winnipeg international airport, as given in Figure 2.

Figure 1. Bridge structure over Red River in Winnipeg, MB.

Figure 2. Ambient air temperature measured at Winnipeg international airport during the bridge monitoring period.

## 2 METHODS

### 2.1 Environmental investigation summary

In 2023-2024, a multimodal RS-SHM environmental investigation (not yet published) was conducted to detect and monitor potential hazards at the Red River Bridge and its surroundings from multispectral satellite imagery and optical-band UAV imagery. Eight Maxar Worldview mono orthoimage scenes acquired during the ice-free spring and summer months of 2022 were evaluated for river flow conditions that may affect the bridge structure stability. UAV photogrammetry of the riverbanks was conducted in November 2023, and two UAV-based Large Scale Particle Image Velocimetry (LS-PIV) collections were acquired in Spring 2024. These investigations did not require bridge closure or disrupt normal traffic, nor did they necessitate unsafe surveying practices. The findings are used to inform the structural investigation in order to verify if a correlation with the monitored bridge deformations do exist.

### 2.2 Georeferencing of SAR satellite imagery

Accurate positioning of SAR satellite imagery data, including the integration of up-to-date elevation data, is essential for precise georeferencing during the PS-InSAR analysis [9]. This process ensures that measurements are correctly aligned with real-world coordinates, which is critical for detecting subtle ground deformations. A reliable Digital Surface Model (DSM) plays a pivotal role in this step by accounting for topographic variations. Inaccuracies in the DSM can lead to misplacement of Persistent Scatterers (PS), introducing errors in phase interpretation and ultimately compromising the reliability of deformation estimates. Furthermore, an accurate DSM supports the separation of topographic and displacement signals, enhances phase unwrapping, and improves the 3D localization of PS, particularly in complex urban or mountainous terrains.

The horizontal coordinate reference frame for this project is the North American Datum of 1983 Canadian Spatial Reference System (NAD 83 CSRS). The horizontal geographical units were projected into planar coordinates in the Universal Transverse Mercator (UTM) system, Zone 14 North with a central meridian of 99° W. The vertical coordinate reference system is the Canadian Geodetic Vertical Datum of 2013 (CGVD-2013).

A stereo pair of 50-cm resolution panchromatic-band Airbus Pleiades 1-B satellite images acquired on 14 June 2021 was used to create a 1-m resolution Digital Surface Model (DSM) of the Red River in the Winnipeg metropolitan area, inclusive of the Red River Bridge. Image selection criteria included clear views of the river surface in the vicinity of the bridge, with no clouds, cloud shadows, or aerosols. The source images of the stereo pair were georeferenced using a sparse RTK survey of tie points (bases of lampposts on the pedestrian walkway of the bridge) on the bridge deck conducted by the University of Manitoba with a DJI D-RTK 2 mobile positioning system, orthorectified using the High Resolution Canadian Digital Elevation Model (HR-CDEM), and used to produce the DSM (Figure 3) and image stack with horizontal coordinates and elevations in the project coordinate reference system described previously. Horizontal and vertical accuracies of a DSM derived from satellite imagery in this manner is estimated at +/- 0.5 m horizontal (CE 90) and +/- 1.5 m vertical (LE90) [10].

Figure 3. Digital surface model created for the Winnipeg bridge and its surroundings.

### 2.3 PS-InSAR satellite measurements

Persistent Scatterer Interferometric Synthetic Aperture Radar (PS-InSAR) is a satellite-based remote sensing technique used to monitor ground deformation over time. It involves analyzing a series of SAR images acquired at different times to measure the motion of stable ground features (or objects), known as persistent scatterers (PS). This method allows the detection of subtle movements and deformations on the Earth's surface or man-made structures by comparing the phase information (e.g., phase change and intensity) of the radar signals across multiple temporal acquisitions. More details on the PS-InSAR technique are available elsewhere [11][12], along with its applications in preventing bridge collapses [13][14].

The technique was applied to two image stacks of SAR satellite imagery (Figure 4) acquired over the Winnipeg metropolitan area from C-band satellites of the RADARSAT Constellation Mission (RCM), including one stack acquired in ascending viewing geometry (i.e., satellite travelling from south pole to north pole, looking to the East) with an incidence angle of  $45^\circ$  and a satellite track heading of  $350^\circ$ , and a second stack acquired in descending viewing geometry (i.e., satellite travelling from north pole to south pole; looking to the West) with an incidence angle of  $42^\circ$  and a satellite track heading of  $190^\circ$ . The bridge heading angle was measured at  $62^\circ$ . The RCM imaging mode was the Spotlight mode with a nominal pixel resolution of  $1 \times 3$  meters (range vs. azimuth). The minimum and maximum satellite revisit times were four days and twelve days, respectively. The image acquisition period covered in this paper spans approximately one year from May 2023 to June 2024. Table 1 provides the details on the two satellite image stacks processed for this study.

Table 1. Features of RCM satellite image stacks.

Look direction	Ascending	Descending
Beam mode	Spotlight	Spotlight
Incidence angle	$45^\circ$	$42^\circ$
Satellite track heading	$350^\circ$	$190^\circ$
Resolution (range x azimuth)	$1 \times 3$ m	$1 \times 3$ m
Swath (range x azimuth)	$20 \times 5$ km	$20 \times 5$ km
Number of scenes	29	55
Stack start date	1 May 2023	2 May 2023
Stack end date	16 June 2024	17 June 2024

Figure 4. Winnipeg metropolitan area showing footprints of the ascending and descending satellite image stacks.

### 2.4 In-situ displacement measurements

Figure 1 above illustrates some structural parameters of the bridge, such as the connection details between girders and piers. Permanent survey positions were identified on the bridge deck for the in-situ measurements using a total station (TS) and GPS. These positions were located on the deck and aligned with abutments, piers and mid-spans. Matching markers were added to the metal handrail beside the pedestrian walkway so that the reflection prism for TS and the GPS Antenna could be precisely mounted on the same positions with good repeatability (within  $\pm 1$  mm error) during the measurement period.

The position measurements using the total station were taken from each abutment. The two sitting positions for the TS were fixed, and their origin coordinates were determined using a real-time kinematic (RTK) global positioning system (GPS). The coordinates of the position marks were determined by moving the 360-degree prism from the WA position to the centre of the bridge when the measurements were conducted from the west abutment, and by moving the prism from the EA position to the centre of the bridge when the measurements were taken from the east abutment.

The measurements using the GPS instrument were conducted using a base station and a rover. The base station was mounted at the WA position, and the rover was moved to all positions from WA to EA. The position measurements from the rover can achieve a horizontal positioning accuracy of 6 millimetres with a signal correction from the base station, while a vertical positioning accuracy of 10 millimetres can be achieved. The RTK correction signal was communicated between the rover and the base using a radio link. To ensure accuracy, data were collected with correction times of 1-2 seconds. The thermal movement of the marked positions on the handrail was measured against temperature during a period of a few months.

### 2.5 Numerical bridge model simulations

Figure 5 shows the finite element model (FEM) of the bridge using the SAP 2000 software, assuming linear elastic material behaviour. It was used to study the dynamic vibrations of the bridge and the ambient temperature dependence of bridge displacements. The bridge's steel girders and concrete slab were modelled using thin shell elements connected by stiff link elements.

The bracing system, brackets, and edge beams supporting the sidewalk were modelled using frame elements. The bridge abutments were modelled using thick shell elements, and the bearings between abutments and girders were modelled with special link elements to allow rotation only or rotation and relative displacement depending on bearing type.

Figure 5. The numerical finite element model of the bridge.

An element size of up to 600 mm was chosen after comparing the results from several mesh sizes for a portion of the bridge. The complete model consists of 85,526 nodes, 2,268 frame elements, 6,912 thick shell elements, 75,133 thin shell elements and 12,704 link elements.

A FEM simulation is a component of a digital twin, but it does not constitute a digital twin on its own. Our work extends beyond the mere simulation by continuously updating and predicting the structure's performance using real-time data. Human intervention plays a crucial role in this process, modifying results by comparing outputs from FEM simulations, remote satellite imagery, and in-situ GPS, and TS.

### 3 RESULTS AND ANALYSES

#### 3.1 Environmental observations

The findings of this case study demonstrate how spatio-temporal environmental information is used to provide context to bridge deformation measurements in an RS-SHM study. Unexpected river turbulences observed in three different datasets (mono ortho satellite imagery, UAV imagery, LS-PIV vectors) acquired over a 2-year period indicate the presence of unexpected river behaviour upstream of Pier P5. The very high-resolution UAV photogrammetry collection provided particularly interesting contextual information for PS-InSAR monitoring, notably that riverbank sediment loss was occurring upstream of the bridge and a persistent pile of woody debris was present at the base of Pier P5 in all LS-PIV video collections but not at any other piers. The LS-PIV results confirmed the presence of a subsurface obstruction to river flow observed in the satellite image stack and revealed an area of unexpectedly high currents near the east bank of the river. These observations are sufficient to indicate that more detailed assessment of pier stability using other methods is required.

#### 3.2 PS-InSAR displacement results

PS-InSAR analysis was conducted independently on each stack of ascending and descending satellite images. The resulting

time series include measurements projected in the one-dimensional line-of-sight (LOS) of the satellite.

Three types of displacement measurements were obtained: (i) displacement linear rate (or velocity) derived from linear regression against time, (ii) displacement thermal sensitivity (or unit thermal displacement) obtained from linear regression against ambient temperature taken at times of image acquisitions, and (iii) cumulative displacements over the acquisition period (one year so far).

Figure 6 illustrates the ascending (top) and descending (bottom) sets of LOS linear displacement rates measured over the bridge deck, where the bridge concrete barriers with steel railings are perfect natural reflectors of SAR energy. However, due to the shallow incidence angle and the satellite look direction, not all sections of the barriers reflected valid persistent scatterers. Most ascending-pass PS concentrated on the north-west barrier while most descending-pass PS concentrated on the south-east barrier, making it challenging for the 2D decomposition analysis (explained next). Nevertheless, the study of these datasets reveals no excessive LOS displacement linear rates observed in the ascending or descending satellite data. Different viewing geometries (i.e., ascending and descending) were specifically selected to allow for a 2D decomposition calculation of the vertical and horizontal (east-west) components of displacement, noting that pole-orbiting satellites are not sensitive to pure north-south movement [11][12].

Figure 6. PS-InSAR LOS displacement linear rates (mm/year) measured over the bridge deck from ascending viewing geometry (top) and descending viewing geometry (bottom).

Figure 7 shows a horizontal grid of nine consecutive bins along the deck centreline, which was used for averaging displacement measurements from each viewing geometry. The bins were used to calculate the average vertical and horizontal components of displacement at the centre of each bin by trigonometry. The size of the bins was carefully selected to get representative values of displacement for each span of the bridge considering the different support conditions at the piers and abutments (free, pinned or fixed). The advantage of large bins is that each bin can contain multiple persistent scatterers from both ascending and descending satellite passes, enabling accurate 2D decomposition. A 2<sup>nd</sup> set of 18 consecutive bins was also created for comparison purposes, where the length of each bin was exactly half that of the 1<sup>st</sup> set (i.e., 14.4 m), with the aim to get a well-distributed set of average displacements, perhaps at the expense of having a few empty bins for either ascending or descending viewing geometry.

Figure 7. 2D decomposition grid over the bridge deck, showing nine regularly-spaced bins. Each bin is 28.8 m long.

Figure 8 illustrates how 1D LOS displacement measurements from two opposite satellite viewing geometries can be combined for a 2D decomposition of the vertical and horizontal components of displacement.

Figure 8. Satellite viewing geometries and 2D decomposition.

Equation 1 was adapted for a bridge-centric coordinate system [15]. If both the vertical and transverse components of displacement can be assumed to be small compared to the longitudinal component, then Equation 1 can reduce to Equation 2. The east-west component of displacement can then be projected onto the longitudinal direction of the bridge for direct comparison with other measurement and prediction methods. Similarly, if both longitudinal and transverse components of displacement can be assumed to be small in comparison to the vertical component, then Equation 1 can reduce to Equation 3, as follows:

$$D_{LOS} = D_V \cos \alpha - D_L \sin \alpha \sin \beta + D_T \sin \alpha \cos \beta \quad (1)$$

$$D_L = -D_{LOS} / (\sin \alpha \sin \beta) \quad \text{if both } D_V \text{ and } D_T \sim 0 \quad (2)$$

$$D_V = D_{LOS} / (\cos \alpha) \quad \text{if both } D_L \text{ and } D_T \sim 0 \quad (3)$$

where  $D_{LOS}$  is the line-of-sight displacement toward the satellite sensor,  $D_V$  is the vertical component in the upward direction,  $D_L$  is the horizontal component in the longitudinal direction of the bridge from west to east,  $D_T$  is the horizontal component in the transverse direction of the bridge,  $\alpha$  is the incidence angle of the satellite LOS, and  $\beta$  is the angle measured clockwise from the satellite track heading to the bridge longitudinal axis.

However, if the vertical and transverse components of displacement are not negligible, Equation 4 should be used to calculate the longitudinal displacement:

$$D_L = \left[ \frac{D_{LOS,d}}{\cos \alpha_d \tan \alpha_a \sin \beta_a} - \frac{D_{LOS,a}}{\sin \alpha_a \sin \beta_a} \right] / \left[ 1 - \frac{\tan \alpha_d \sin \beta_d}{\tan \alpha_a \sin \beta_a} \right] \quad (4)$$

Similarly, if the longitudinal and transverse components of displacement are not negligible, Equation 5 should be used to calculate the vertical displacement:

$$D_V = \left[ \frac{D_{LOS,d}}{\cos \alpha_d} - D_{LOS,a} \frac{\tan \alpha_d \sin \beta_d}{\sin \alpha_a \sin \beta_a} \right] / \left[ 1 - \frac{\tan \alpha_d \sin \beta_d}{\tan \alpha_a \sin \beta_a} \right] \quad (5)$$

where subscripts  $a$  and  $d$  represent the components calculated from the ascending or descending image stacks, respectively.

### 3.3 Comparison between PS-InSAR and other methods

In-situ measurements were conducted on the bridge, as described previously in Section 2.4. The distances from all marks to Mark 1 (located at the west abutment) were calculated, and the distance changes against ambient temperature variation during the measurement period were obtained (Figure 9). It can be seen that both in-situ measurement methods agree well with each other and to the FEM predictions of unit thermal displacement along the bridge, as expected. A small 0.2 mm/°C mean error is observed between the two sets of in-situ measurements and the FEM predictions.

Figure 9. In-situ thermal displacements of bridge along the longitudinal direction compared to FEM predictions. (Notation: F = fixed joint; Exp = expansion joint).

In addition, the bridge unit thermal displacement in the vertical direction was also predicted with the FE model and measured with the total station and GPS instruments, for which the results are presented in Figure 10.

Figure 10. In-situ thermal displacements of bridge along the vertical direction compared to FEM predictions.

It can be observed that both types of field measurements agree well with the FEM predictions of vertical displacement.

Given that the FEM predictions of thermal displacements appear to be valid based on the horizontal and vertical field measurements, the PS-InSAR measurements will be compared to and validated against the FEM predictions in the next figures.

Figure 11 illustrates the average longitudinal thermal displacement measured by the RCM satellites for each set of bins along the bridge deck from West to East, using the detailed Equation 4. The expected movement direction (eastward vs. westward) and extent of thermal displacement are well characterized, with gradually increasing thermal displacements between the two expansion joints (at P2 and P6) and the expected sign reversal on either side of each expansion joint due to opposite directions of thermal movement going away from the pier. The comparison between the thermal displacements obtained from each bin size illustrates excellent agreement between the results of the two bin sizes, except that the smaller bin size returned no data at two locations near P6.

Figure 11. PS-InSAR thermal displacement along the longitudinal direction of bridge compared to FEM predictions.

Similarly, Figure 12 illustrates the PS-InSAR data for the vertical component of thermal displacement calculated along the bridge using Equation 5 for the two sets of bins. The comparison from either set of bins with the FEM predictions shows a good match, where the difference ranges from 0.1 mm/°C to 0.2 mm/°C. These PS-InSAR measurements also compare very well with the field measurements in Figure 10 above.

Overall, the satellite-monitored bridge thermal displacements are observed to be consistent with and very similar to both in-situ measurements and FEM predictions, confirming satellite-based PS-InSAR as a promising SHM tool for displacement measurements.

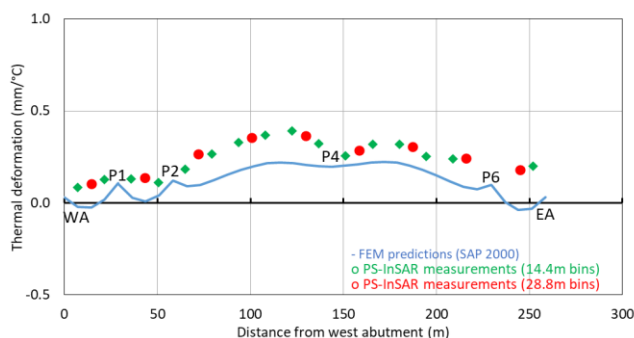

Figure 12. PS-InSAR thermal displacement along the vertical direction of bridge compared to FEM predictions.

### 3.4 Assessment of PS-InSAR calculation method accuracy

As mentioned in the previous section, the PS-InSAR measurements of the longitudinal thermal displacement shown in Figure 11 were calculated using Equation 4. These results show a maximum difference of 0.3 mm/°C at the expansion peaks (P2 and P6) compared with the FEM predictions. This difference is believed to be due to an averaging effect from the relatively large size of the bins used for 2D decomposition, especially around the P2 and P6 discontinuities. Shorter averaging bins would have been desired if the density of the ascending PS on the downstream barrier and the descending PS on the upstream barrier were higher (Figure 6). At P3 and P5, where the averaging effect is negligible, a small difference of 0.2 mm/°C is observed when compared to the FEM predictions.

Table 2 presents standard deviation and point count statistics for the PS results obtained from the 2D decomposition depending on pass direction and bin size. It is shown that the bin size did not have a significant impact on the accuracy of the averaged results, except that the smaller bin size had two empty bins around P6 due to the low density of PS for the ascending pass. The ascending data exhibited slightly higher standard deviations than the descending data, which is likely due to the lower PS density in the ascending pass, which also had fewer images in its stack (29 vs. 55, as shown in Table 1) compared to the descending stack.

Table 2. Standard deviation and point count statistics for PS-InSAR results from ascending and descending passes.

Bin no.	Bin centre distance from WA (m)	Ascending pass		Descending pass	
		St. dev. within each bin (mm/°C)	PS point count in each bin	St. dev. within each bin (mm/°C)	PS point count in each bin
9-bin grid:

9a	237.6	-	0	0.04	13
9b	252.0	0.05	5	0.07	30

This study was fortunate to have access to two stacks of satellite imagery over the bridge from opposing viewing geometries, which allowed the full 2D decomposition of movement for the correct determination of horizontal (east-west) and vertical components of movement. This is convenient when one needs to compare and validate results with field measurements and/or numerical simulations for which displacement results are typically determined in the vertical and horizontal directions.

There are cases where satellite imagery is only available for one viewing geometry (ascending or descending). While it is possible to estimate the horizontal or vertical displacement components by simple trigonometry (Equation 2 or 3, for example), one needs to ensure that the unknown variable is small enough to be safely neglected. Case studies on SAR satellite-monitored highway bridges have been successfully conducted using SAR imagery obtained only from one viewing geometry [16][17].

In this study, however, it was found that the vertical component of displacement could not be neglected. For example, Figure 13 presents the PS-InSAR measurements of unit thermal displacement in the longitudinal direction of the Red River Bridge, which were calculated separately for each viewing geometry using the simplified Equation 2, which comes with the assumption of negligible vertical displacement. The results actually show a poor match with the FEM predictions, especially for the descending set of displacement data, where differences with the FEM predictions of up to 0.8 mm/°C can be observed.

Figure 13. Longitudinal PS-InSAR thermal displacement for either ascending or descending passes compared to FEM predictions, using the inappropriate assumption of negligible vertical displacements. Dotted lines indicate lack of PS data.

The inferior match with the FEM predictions for the descending image stack is unique to this case study and depends on several factors – one of them being the orientation of the bridge with respect to the satellite tracks on the ground. As mentioned earlier, SAR satellites are not sensitive to movement along the satellite track heading (roughly N-S). This is because they are typically right-looking polar-orbiting satellites.

In this study, the angle between the satellite look direction (satellite track heading + 90°) and bridge heading is much larger for the descending stack ( $190^\circ + 90^\circ - 62^\circ = 218^\circ$ ) than it is for the ascending image stack ( $350^\circ + 90^\circ - 62^\circ - 360^\circ = 18^\circ$ ). Consequently, the ratio of vertical movement to the reduced observable longitudinal movement from the descending viewing geometry becomes apparently larger. This confirms the fact that SAR satellites are most sensitive to movement aligned with the look direction of the satellite [11][12].

### 3.5 Interpretation of results based on environmental context

As mentioned in the introduction section, the RS-SHM approach is meant to provide bridge operators with early awareness of developing risks and context to understand how changes in the surrounding environment may affect structural behaviour and safety.

The environmental investigation actually identified such a risk to bridge stability: a subsurface bluff-body obstruction to river flow and unexpectedly high currents near the east bank of the river close to Pier P5 of the bridge. These observations were sufficiently significant and clear to trigger a more detailed structural assessment of bridge stability using other methods.

The structural investigation, indeed, focused on two major aspects of structural behaviour of the bridge. The first aspect included the vibration measurements of bridge piers reported elsewhere [18]. The vibration study identified the fundamental natural vibration frequencies of the bridge piers and will keep monitoring them to detect changes where a reduction of the fundamental natural frequency is expected to indicate the weakening of the pier foundation as a result of scouring. Damping is another indicator but is not being considered.

The second aspect of the structural investigation included the thermal behaviour of the bridge, which was obtained by four different measurements and prediction methods (PS-InSAR, TS, GPS and FEM). The remote PS-InSAR and in-situ measurement methods agreed well with the expected bridge thermal deformation predictions from the bridge FE model.

Given the above, there is currently no evidence or signs of pier scouring at the bridge. However, due to observations from the environmental investigation, the deformations and ambient vibrations of the bridge piers, particularly at Pier 5, will remain under close scrutiny.

## 4 CONCLUSIONS

As part of a case study conducted on the Red River Bridge in Winnipeg, Canada, a structural investigation combining PS-InSAR deformation measurements from satellite imagery, in-situ measurements on the bridge deck, and numerical bridge model predictions was conducted. It provided an assessment of the bridge's structural behaviour with insight obtained from a prior environmental investigation. The following conclusions can be drawn:

1. This case study demonstrated the importance of combining key environmental observations with structural health monitoring data in an RS-SHM approach to provide comprehensive risk assessments for river bridges.
2. The environmental investigation identified unexpected river behaviour, including riverbank sediment loss, flow contraction during high-water periods, and persistent woody debris near Pier P5 of the bridge, suggesting potential risks to bridge stability, thus warranting further assessment of pier stability.
3. PS-InSAR displacement measurements were found to be consistent with in-situ and numerical model predictions, confirming its reliability as a monitoring tool, and have proven effective in this case study for assessing bridge stability and detecting subtle deformations over time.

4. The successful 2D decomposition of PS-InSAR displacement data allowed for accurate determination of both vertical and horizontal components, emphasizing the value of having satellite imagery from two opposing satellite viewing geometries.
5. It was demonstrated that, under some specific conditions, analyzing SAR images from only one viewing geometry might induce measurement inaccuracies if the simplifying assumptions on expected displacements cannot be met.
6. Although no current evidence of scouring was detected, the findings of the environmental investigation highlight the importance of remaining vigilant due to the potential scouring risks observed at Pier P5.

## ACKNOWLEDGMENTS

The PS-InSAR work detailed in this paper has been supported by collaborative research funding from the National Research Council Canada's Artificial Intelligence for Logistics Program with funding from Defence Research and Development Canada's Canadian Safety and Security Program (DRDC/CSSP).

The environmental investigation summarized in this paper was financially supported by the National Research Council Canada's Initiative on Climate Resilient Built Environment.

The authors would also like to acknowledge the Canadian Space Agency for providing the RCM satellite imagery and TRE Altamira for performing the PS-InSAR analysis.

The work related to the in-situ bridge displacement measurements and numerical bridge simulations was conducted by SIMTReC at the University of Manitoba, which was financially supported by the National Research Council Canada and Manitoba Transportation and Infrastructure.

**ABSTRACT:** Extreme weather events that cause flooding endanger people, economic goods, and the environment. Flood protection systems, such as dams, dikes, and levees, defend these valuable assets and therefore their structural health should be monitored. The goal of this project is to investigate the potential of Interferometric Synthetic Aperture Radar (InSAR) satellites for the monitoring of dams and dikes. The ability to monitor flood protection systems depends on the availability of a sufficient number of measurement points. This is influenced by several factors, such as the type of the scanned surface area (e.g. vegetation cover, concrete), the orientation of the dike with respect to the satellite's orbit, the temporal and spatial resolution of the SAR sensor, and the period for which the European Ground Motion Service (EGMS) provides the data. It is also of interest to study the differences between persistent scatterers and distributed scatterers. Furthermore, the correlation between surface subsidence detected by InSAR and the changes in water level, which pinpoint flood events, is also investigated. The use of Corner Reflectors or satellites with higher spatial resolution, are also some of the aspects to be explored in the next steps to investigate how to maximize the potential of InSAR satellites for the monitoring of flood protection systems.

**KEYWORDS:** InSAR, Structural Health Monitoring, Flood Protection, Dike, Levee, Earth dam

## 1 INTRODUCTION

### 1.1 Motivation

The occurrence and intensity of flooding constantly increases due to climate change and more frequent heavy rainfall events. Urban areas, often located near rivers, are threatened in particular by this natural hazard. Therefore, sustainable natural hazard management and structural health monitoring is essential to protect human lives, and their environment. Since the catastrophic floods of 2002 in Austria, a shift towards integrated flood risk management has been observed. In this context, the flood protection measures are complemented by the assessment and monitoring of existing protection structures such as dikes and levees.

Currently the condition of flood protection structures is mostly monitored by means of "close-up inspection" or by conducting geodetic surveys with theodolites along the dams. Only in rare exceptional cases are fully automated total stations with installed prisms or locally referenced Global Navigation Satellite System (GNSS) sensors permanently installed. Initial investigations into the use of drones for surveying dams have also revealed various limitations, turning these methods uneconomical.

The aim of the project "Flood protection monitoring via satellites" (HoSMoS) is to investigate the potential of structural health monitoring by means of satellites for flood protection systems. Based on multitemporal Interferometric Synthetic Aperture Radar (InSAR), long-term deformations on the earth's surface can be monitored under certain conditions [1]. The special feature of this indirect monitoring method is not only the fact that no additional sensors need to be attached to the structure, but depending on the mission, it can also offer the unique possibility to analyze data retrospectively,

e.g. Sentinel-1 data goes back to the year 2015. The accuracies currently achieved with InSAR are sufficient for monitoring trends of mass movements or glacier retreat, for example. There are promising results for the use of this technology in the monitoring of bridges, where the accuracy can be increased significantly by compensating for environmental conditions [2].

The innovation of the HoSMoS project consists of investigating the fundamental applicability of the InSAR technology for flood protection. The aim is to investigate whether monitoring by satellites is possible in principle under the special circumstances that typically prevail at such structures. For example, the influence of natural vegetation, construction materials, the presence of roads and paths and the orientation of linear structures on the satellite monitoring are to be investigated. The accuracy achievable with advanced differential InSAR (DInSAR) products provided by the European Ground Motion Services (EGMS) [3] is to be compared with the requirements for monitoring. Seasonal effects and relevant environmental conditions that require compensation are to be identified.

Remote sensing by satellites promises a great potential for the monitoring of flood protection systems. It would enable the simultaneous monitoring of deformations for many different structures in a large territory, with a higher temporal and spatial resolution than is currently possible. Long-term trends may be recognized through the retrospective evaluation of deformations. The definition of warning thresholds would allow the rapid, systematic identification of potentially critical areas and sections that require closer monitoring or inspection.

## 1.2 Remote sensing with InSAR

The publication of the first differential interferogram related to an earthquake in the United States in the 1990s marked the beginning of exploiting DInSAR to observe surface deformation [4]. Since then, the technique has undergone significant advances, including the development of more refined approaches such as Persistent Scatterer Interferometry (PSI) [5], [6].

The key idea of DInSAR is to combine the phase of at least two SAR images of the same area of interest (AoI) taken at different times and slightly different geometry in an interferometric manner to form an interferogram. The interferometric phase needs to be corrected for the phase contribution induced by the topography of the illuminated scene to extract information on the ground surface displacement that occurred between image acquisitions [1], [4].

SAR images from the Sentinel-1 satellites commissioned by the European Space Agency (ESA), can be processed with InSAR technology to produce displacement maps. They orbit the Earth at an altitude of 693 km, whereby the points on the Earth's surface are flown over in an approximately synchronous polar orbit in two orbital directions, once from south to north (ascending orbit) and once from north to south (descending orbit). The SAR images are taken in a skewed Line of Sight (LOS) with respect to the Earth's surface, see Figure 1, left. The return time to the same orbit is 12 days [2], [7]. Originally, Sentinel-1A and 1B satellites were used together, which doubled the temporal resolution. Unfortunately, satellite 1B has been out of service since December 2021 due to a solar storm. However, Sentinel-1C has been successfully deployed end of 2024 as a replacement.

Figure 1. Left figure: The deformation measurement of the Earth's surface is recorded in so-called scenes during overflight; the direction of measurement is right-looking in the direction of flight of the satellite (= Line of Sight, LOS); right figure: Coherent reflectors (Persistent Scatterers, PS) of the recorded pixels are used as reference values and differential displacements are observed after approx.  $n$  recordings and analyzed, source: [8].

The basic idea of advanced DInSAR techniques, such as Persistent Scatterer Interferometry (PSI) is to identify pixels with low noise in a time series of differential interferograms. Relevant information about the observed deformation of the ground surface is then extracted from the backscattered radar signal of only these pixels, also referred to as Persistent Scatterer (PS). The backscattered signal of these pixels is characterized by the response of a single reflector in the corresponding ground resolution cell, which remains stable over time, as illustrated in Figure 1, right. The radar signal

reflected from the Earth's surface is detected, and the relative phase change of the PS pixels in between image acquisitions can be determined using interference, with the wavelength of  $\lambda = 54$  mm in the case of Sentinel-1 operating in C-band, see Figure 1 right. Displacement rates in the range of a fraction of the wavelength  $\lambda$  can be derived based on the comparison of the phase values of corresponding pixels from different consecutive differential interferograms [5], [6], [8]. With Sentinel-1, the images are taken at a time interval  $\Delta t$  of 6 or 12 days [8]. In principle, no additional man-made reflector is required on site; instead, the already present natural and man-made scatterers can be used, which provide a coherent signal for at least approx. 20 to 25 images. Sentinel-1 satellites acquire SAR images of the Earth's surface in a  $5 \times 20$  m ground resolution cell (Figure 1, left), which slightly limits the spatial resolution. Other satellites, such as TerraSAR-X, can also resolve ground cells down to 1.0 m in High Resolution Spotlight mode. The accuracy of the information obtained from Sentinel-1 data can be further increased by additionally attaching man-made Corner Reflectors (CR) to the Area of Interest (AoI). The CRs also be utilized in landscapes without already established PS for better object assignment [2].

Within the scope of this paper and the HoSMoS project, the focus is on the analysis of ground motion data provided by the EGMS. The EGMS generates fully processed PSI datasets based on Sentinel-1 SAR images for all European Countries supporting the Copernicus Initiative. The datasets are updated yearly using all Sentinel-1 data acquired in the past five years [3], [8].

## 2 MONITORING OF FLOOD PROTECTION SYSTEMS

### 2.1 Overview of satellite-based monitoring in flood protection

Before the potential of satellite-based monitoring of flood protection systems is analyzed, a brief overview of previous research on the topic is given. Comprehensive work was conducted within SAFELevee project organized by the Dutch Research Council (NWO) between 2014 and 2019, focusing on better understanding of the behavior patterns and situations that can lead to a failure of the flood protection structures, establishing an International Levee Performance Database [9], [10]. In this context, InSAR was investigated for the purpose of documenting surface deformations of flood protection systems in the Netherlands as a function of hydrodynamic loading and examine these deformations in relation to failure mechanisms [10]. In addition, the application of PSI was evaluated in several case studies in the Netherlands using SAR data from the high-resolution satellite TerraSAR-X, the medium-resolution satellites ERS-1/2 and Envisat, and the surface deformations were documented [11]. The analysis of the case studies showed that it was possible to document surface deformation with sufficient spatial coverage in all cases. The accuracy of the values depends on the orientation of the flood protection system and its slope. Based on the given temporal sampling rate, the authors see the potential for applying PSI for flood protection not in the area of real-time monitoring, but in an early warning system that indicates unusual deformation behavior.

The evaluation of images of Delft from TerraSAR-X in [12] showed that not only the density of the selected Persistent Scatterer (PS) pixels is sufficient to document surface

deformations, but also that the comparatively narrow temporal sampling rate can be used to observe the expansion and contraction of the flood protection barriers. In addition, it was shown that this short-term deformation pattern correlates with metrological data.

Further studies focused on the flood protection systems along the Mississippi River in the United States. A fully polarimetric L-band SAR mounted on an airplane and the X-band SAR satellite, TerraSAR-X, was investigated in [13] in order to show that weak points can be identified by means of analyzing the backscatter responses of the different polarizations and texture features. The same L-band SAR airborne system was also used in [14] and [15] to examine dike in California for subsidence and seepage in the Sacramento-San Joaquin Delta and the lower Mississippi River. Moreover, the polarimetric SAR (POLSAR) technique was used to detect seepage from multi-polarization images [14].

## 2.2 Conventional monitoring methods in flood protection

To analyze the potential of satellite monitoring methods, it is essential to create a base line for comparison. With this in mind, the currently available methods of monitoring flood protection systems were collected and are briefly systematically analyzed.

### 2.2.1 Geodetic surveying

The most commonly used method of monitoring is traditional geodetic surveying. In this process, selected points on the structure are marked and measured at regular intervals (e.g. monthly or yearly) using a theodolite. The accuracy of this method is approximately  $\pm 1$  mm [16].

### 2.2.2 Hydrostatic settlement cells

A very precise option for monitoring settlements is offered by hydrostatic settlement cells [17]. The principle of this device is based on liquid-level that consists of connected tubes filled with liquid causing liquid-level height difference or pressure differences (when using electronic liquid-level). The difference between two or more measurement points can be determined even over large distance.

### 2.2.3 Magnetic settlement tubes

Another solution for monitoring settlement is provided by magnetic settlement tubes, which allow the simultaneous monitoring of numerous vertically distributed measuring points located inside a dam [18], [19]. For this purpose, a tube is installed in the structure, with magnets placed on the bottom and in the wall at the locations, which are to be measured. A probe equipped with a reed switch is pulled up through the pipe in a controlled manner, starting from the bottom, and is activated each time it reaches a magnet, so that its relative height with respect to the bottom can be measured. The measurement accuracy is approximately  $\pm 3$ -5 mm [20].

### 2.2.4 Inclinometers

Inclinometers can also provide valuable information about geometric changes in a dam [17]. Inclinometers or tilt sensors measure the angular rotation related to the direction of the gravitational force. In principle, inclinometers can be designed for single-axis or for dual-axis measurements. There is a wide variety of different operating principles for inclinometers. The simplest inclinometers use a solid-state pendulum, the

deflection of which can be measured either by inductance or by a potentiometer [21].

### 2.2.5 Piezometers

Piezometers can be used to determine the water or earth pressure inside an earthfill dam, but they must be placed at the intended location already during construction [16], [22]. Tensiometers can also be used for continuous measurement of soil moisture in dams [23].

### 2.2.6 Electrical resistivity tomography

Electrical resistivity tomography (ERT) is a geoelectric method for imaging subsurface structures based on measurements of electrical resistivity at the surface or through electrodes in one or more boreholes. Possible applications of ERT on dams include: the localization of cracks, animal burrows, seepage points and leaks, the monitoring of water saturation, and the determination of geometric dimensions and internal properties [24], [25]. The measurements require extensive preparation and are very expensive. However, ERT also allows automated continuous monitoring of entire dam sections [26].

### 2.2.7 Fiber optic sensors

Fiber optic sensors (FOS) make it possible to measure physical quantities of the external world such as temperature, strain, vibration, magnetic field, etc. along the sensor fiber [27]. In the case of earth dams, they can be used primarily to detect seepage points by measuring the resulting temperature differences [28], [29].

### 2.2.8 Acoustic emissions sensors

Acoustic waves in a test object can be detected by piezoelectric sensors that convert surface displacements (or vibrations) caused by the acoustic emission into electrical signals. This technology can also be used to monitor piping causing seepage failure in dams and dikes [30].

### 2.2.9 GNSS

A second option for satellite-based monitoring of settlements in addition to InSAR is GNSS (Global Navigational Satellite System). The main difference to the InSAR technology is that a receiving device of the GNSS signal must be positioned on the structure to carry out measurements. In order to achieve greater accuracy, an additional reference station is required, the exact location of which is usually determined by classical surveying methods. The main advantage over InSAR is that not only long-term deformations but also dynamic processes can be observed. The two satellite technologies can also be combined. As an example, global positioning system was employed for monitoring of river embankment in [31].

### 2.2.10 Terrestrial laser scanning and Photogrammetry

Another alternative for capturing the geometry of flood protection structures is Terrestrial Laser Scanning (TLS), also referred to as terrestrial topographic Light Detection and Ranging (LiDAR). A TLS device scans its surrounding by means emitting light pulses in raster-like fashion. The distance between the scanner and the object is recorded and, depending on the scanning mode, one or two angles are recorded between the light and the vertical and horizontal axes. The scanning device can also be mounted on Unmanned Aerial Vehicles

(UAVs), i.e. aircraft that can operate autonomously or remotely and do not need to carry a human crew. When the UAV is expanded to form a complete system with recording technology, a control unit, a communication method, etc., it is referred to as an unmanned aerial system (UAS). Among UAS, drones are the most common because they can fly in confined spaces and are able to hover and take off and land vertically [32]. Drones can be equipped with various types of sensors, such as cameras [33] or LiDAR [34]. A study on the achievable accuracy for an earth fill dam showed an accuracy of approximately 1-2 cm for TLS and 2-4 cm for drone-based photogrammetry [35].

### 2.3 Comparison of monitoring methods in flood protection

The satellite monitoring of flood protection is now compared to the conventional methods described above in order to highlight the potential of the latter. In this context, important aspects are not only the spatial (density of measurement points) and the temporal resolution (measuring frequency), but also the accuracy of the measurement as well as required effort in terms of working hours and costs needed for carrying out a measurement and installation of the monitoring system.

Geodetic surveying requires significant effort due to the need of trained personnel to carry out measurements and operate a theodolite in the field. Another consequence of the *modus operandi* of this method is that the spatial and temporal resolution is low. This is noticeable particularly for large structures where scanning the surface's structure with InSAR has significant advantage.

Hose leveling system installation requires more planning and some kind of intervention into the structure as the theodolite surveying method. The very high effort needed to set up the measuring system is compensated with very high measurement accuracy and very high temporal resolution since the measurements can be automatized without the necessity of human supervision. As regards spatial resolution, the installation of this system is limited to a number of measurement cells and length that is bonded to a particular structure.

Electromagnetic settlement tubes require similar effort for setting up the measurement system as the hose leveling, needing a dedicated sensor for one measurement point. The advantage of this measurement system is high level of accuracy. The spatial and temporal resolution are average when compared to other methods.

One receiver device per measurement point is also required when using GNSS. If higher precision measurements are required, an additional reference station has to be in place, making the required effort very high and offering low spatial resolution. On the other hand, displacement monitoring with GNSS provides very high temporal resolution when compared to InSAR measurements.

Laser scanning offers very high spatial resolution stemming from the principle of this method when many measurement points around the TSL device are acquired. However, when aerial vehicles are used to increase scanned area in shorter time the accuracy of this method is compromised. Similar to the geodetic surveying, the measurements have low temporal resolution due to the trained labor that is necessary each time a measurement is taken.

Monitoring inclination is unique in measuring angular changes rather than displacements, which provide a slightly different viewpoint on the health status of the flood protection structure, that is obtained from InSAR data. The inclinometers also provide very high temporal resolution since the device is permanently located at the measurement point. However, the fact that one measurement device is needed for one measurement point limits the spatial resolution and increases the required effort for installation of the measurement system. Water or soil pressure measurements by means of piezometer sensors share the same levels of temporal and spatial resolution as with the inclinometers. The accuracy of this method is high, although the effort required to employ this method is also high since they have to be installed during construction of the dam. The advantage of using this measurement technique is that it offers information that cannot be directly obtained from any InSAR measurements.

Another technique that provides unique insight into health status of a flood protecting structure in comparison to SAR satellites is electrical resistivity tomography (ERT). However, it is very expensive to carry out ERT measurements, which require elaborate preparation. In comparison to other measurement techniques, ERT provides good accuracy and average spatial resolution, but low temporal resolution.

An excellent spatial and temporal resolution with high accuracy is provided by fiber optic sensors. However, in comparison to SAR satellites the installation of the fiber requires rather high amount of effort.

Similarly demanding on effort is acoustic emission method. This measurement technique also allows for high temporal resolution, but rather low spatial resolution and an average accuracy in comparison to the InSAR measurements.

The comparison of InSAR and other monitoring methods for flood protection systems in terms of effort for the operator of the infrastructure, accuracy, spatial and temporal resolution is summarized in Table 1.

## 3 RESULTS

Satellite based monitoring is particularly suitable for types of failure that develop over a longer time period and affect medium or large areas, such as subsidence, tilting or sliding. The accuracies and repeat-pass periods achievable through InSAR measurements are sufficient for monitoring these types of failure and the low cost compared to other monitoring methods makes this method particularly attractive. However, the question that arises based on the basic evaluation is whether and under what conditions a sufficient number of natural reflection points are available on dikes and other flood protection structures to carry out meaningful satellite monitoring.

In the present project analyses are carried out to answer this question, mostly based on selected representative AoIs, but in some cases also considering all flood protection systems in Lower Austria region along Danube River. Occasionally comparable systems abroad, where more suitable data is already available, are analyzed. The various investigations are explained individually and thematically separated below, and the results of each are briefly presented.

Table 1. Comparison of monitoring methods for flood protection systems in terms of measured property, effort, accuracy, measurement point density, and frequency

Method	Measured property	Effort required	Accuracy	Spatial resolution	Temporal resolution
InSAR	Displacement	Low	High	Medium-low	Medium
Geodetic surveying	Displacement	High	Very high ( $\pm 1$ mm)	Low	Low
Hose levelling	Displacement	Very high	Very high ( $\pm 1$ mm)	Low	Very high
Electromagnetic settlement tubes	Displacement	Very high	High ( $\pm 3$ -5 mm)	Medium	Medium
GNSS	Displacement	Very high	High	Low	Very high
TLS / LiDAR	Displacement	High	Medium-high	Very high	Low
Inclinometers	Inclination	High	High	Low	Very high
Piezometers	Pressure	High	High	Low	Very high
ERT	Damaged area	High	Medium	Medium	Low
Fiber optic sensors	Temperature	High	High	Very high	Very high
Acoustic Emission	Flow	High	Medium	Low	Very high

### 3.1 Point density depending on surface type and orientation

The flood protection structures in the Lower Austria region were divided into eight surface type categories based on characteristic locations, or structures in which they are integrated or surrounded. The typical surface types are the following:

- highways and roads,
- buildings (e.g. a house on a dam),
- green areas with asphalt paths,
- green areas with gravel paths,
- green areas without gravel,
- residential areas,
- foreign objects (e.g. electrical poles),
- miscellaneous (everything that does not fit above).

It is noteworthy that majority of the investigated dikes are situated in green areas, amounting to 60 %. The second and third most common surface type groups are highways with roads, and residential areas representing 22 % and 10 % of all analyzed dikes, see Figure 2.

Figure 2. Distribution of surface types on or in the immediate vicinity of the investigated flood protection structures.

Orientation is a characteristic aspect of a flood protection structure since its length is usually significantly longer than the other two dimensions. The orientations of the 155 km of investigated dikes in Lower Austria along the Danube River were analyzed with respect to the cardinal directions. The results show that the dikes are predominantly aligned with the Danube River as evidenced by 43 % of the total dike length being oriented in the east-west direction, which matches the

river's course in this region. In contrast, the shortest dike orientation of is north-south, accounting for only 18 km or 12 % of the total analyzed length, see Figure 3.

Figure 3. Orientation distribution of the 155 km-long flood protection structures in the investigated area with respect to cardinal directions.

Since the LOS direction of the SAR satellite is related to the cardinal direction, the number of available points also depends on the orientation of the observed object, such as dike. Based on the analysis of the investigated dikes, most of the PS points are obtained for dikes that are oriented in north-south direction for all surface types except highways and roads, as can be seen in Figure 4. Therefore, the number of points in the other directions are shown in relation to this most favorable orientation. Exceptionally high numbers of points are also obtained for all cardinal directions in highways and roads. An important finding is that in case of all types of green areas the number of reflection points drops significantly for unfavorable orientations. Particular low number of points is obtained for east-west and northwest-southeast directions, see Figure 4.

The results of the analysis regarding reflection point density with respect to the surface type are unfavorable for the investigated flood protection structures. The green areas, where the most dike sections belong to, have the smallest point density per 100 m. On the other hand, the surface types with the highest density are buildings, residential areas, and highway and roads as can be seen in Figure 5.

The number of available reflection points depend also on the date release of the postprocessed InSAR database. The EGMS database, used in this study, contains three different releases varying in the different time periods (epochs), 2015-2021, 2018-2022, and 2019-2023. Except for the newest data release in “highways and roads” surface type, the number of available measurements points slightly increases with later release time, see Figure 5. This is probably caused by better and more efficient data processing algorithms.

### 3.2 Comparison of persistent and distributed scatterers

Having a high number of reliable reflection points on the object or in the AoI is crucial for drawing reliable conclusions on the state of the flood protection structure. The potentially higher density of reflection points provided by additional distributed scatterers (DS) was examined, in order to investigate if their

inclusion could remedy the situation regarding scarcity of reflection points in green areas and unfavorable orientation of the investigated objects when using PS.

In contrast to PS pixels, DS pixels do not stand out due to a high coherence over a long period. They rather often exhibit a moderate coherence but show a statistically similar behavior as their neighboring pixels, since they often belong to the same object. This statistical similarity can be exploited to improve the signal-to-noise ratio of DS pixels by spatially averaging them. Thus, allowing a joint processing of DS and PS pixels. While PS pixels are often associated with point-wise bright scatters, such as dihedral or trihedral reflectors on buildings or naturally occurring boulders, DS pixels are often found in desert-like areas, areas covered by debris, and on non-cultivated land with short vegetation. [5], [36].

Figure 4. Relative number of points for different surface types with respect to the north-south orientation.

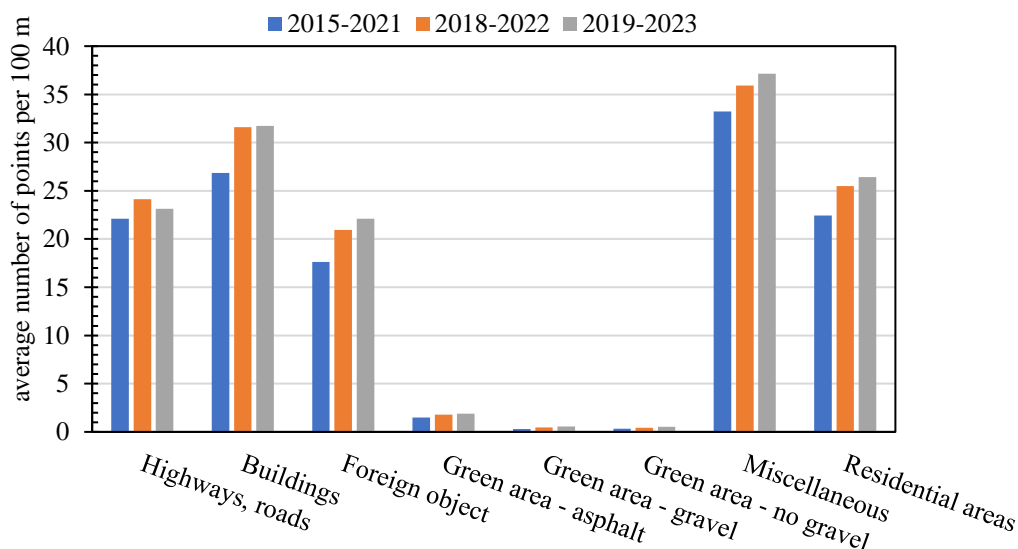

Figure 5. Comparison of the point density for different EGMS database releases and surface types on or in the immediate vicinity of the investigated flood protection structures.

The EGMS data are processed by four consortia using slightly different algorithms. While only the PS points are evaluated in Austria, the DS are also processed in Spain and France, among other countries. Since these are particularly suitable for non-urban areas, it was verified within the project whether a significantly higher number of data points along the dikes can be expected with a joint PS and DS processing.

For this purpose, a dike section in France, approximately 30 km long, was selected and examined. This is located on the La Loire River between Orleans and Jargeau. Analogous to the investigations on the Danube River, all points within 20 m of the dam crest, as illustrated in Figure 6, were considered and statistically evaluated. It was found that the DS points account for only 4.5% of all available points. The added value of such data processing is therefore not very high. A small part of this section with a particularly high density of PS and DS points was discovered and examined more closely. This section is almost free of vegetation, the surroundings are flat and treeless. The embankment section consists of coarse gravel and has a slope of approx. 20° to 30° and is seen from both orbit directions, the orientation is NW-SE. These findings are well in line with the observations obtained in the Vienna and lower Austria area.

### 3.3 Correlation of water level with InSAR measurement

As an example of the potential of using InSAR for flood protection structures in Vienna region was showcased for a lock in Greifenstein during high water periods. The object of interest was the end part of a pier of a lock. Here, three reflection points obtained from EGMS data for a period between the beginning of 2018 and the end of 2022 were analyzed and compared with water level measurement stations in Bärnsdorf and Nussdorf. The data from water level measurement stations shows periodical increases of water level in the Danube River depending on the seasons. In the available time period four prominent peaks marking extraordinary high-water level are visible on 30.05.2019, 04.02.2020, 05.08.2020, and on 19.07.2021. Analysis of the InSAR data revealed a settlement of approximately 8 mm (shown in red) at one reflection point and 12 mm (shown in light and dark green) at the other two points, at the beginning of 2020, see Figure 7 for a visual representation of the mean values and standard deviations. When compared to the water level during this period (shown in blue), it seems plausible that this change was related to the high-water level event on February 4<sup>th</sup>, 2020.

However, this showcase analyzed a rather local effect. Interesting results may be obtained after the analysis of the floodings in September 2024 in central Europe, once the EGMS data for this period becomes available.

## 4 DISCUSSION – FUTURE OUTLOOK

Corner reflectors provide a possibility to introduce a stable measurement point in areas or on structures that are absent of any reflective elements for L, S, C, or X-band waves. The corner reflectors can be also used as a reference to the other natural reflectors, to which they can be related to. The

disadvantage of the corner reflectors is that they require additional effort for installation. On the other hand, the installation is easy, there is no need for maintenance, and the service life is long. The benefit of a corner reflector is that it provides a stable reflection point.

The use of low-cost corner reflectors suited for dikes has been investigated and will also be a focus of future research. To this date, two couples of concrete corners with edge length of 40 cm were installed on a dike along the Danube River. Each couple was oriented in opposite directions so that the corner reflectors face directly to the LOS of the Sentinel-1 satellite descending and ascending flight trajectory, see Figure 8. Thin aluminum plates were glued onto the inner surfaces of one couple of the concrete corner reflectors as shown in Figure 8 a). The other couple of concrete corner reflectors was left untreated, see Figure 8 b). The two couples of low-cost concrete corner reflectors do not reflect enough signal back to the InSAR Sentinel-1A satellite and there would likely be no PS points corresponding to these four corner reflectors in the Sentinel-1 dataset. The reason for this may be small reflective surface or slightly obtuse angle between two neighboring inner surfaces. In addition to the experimental concrete corner reflectors, a standard double-headed corner reflector, shown in Figure 8 c), was installed near a dike next to the Danube River as a reference. The standardized corner reflector works as expected and a new measurement point is recorded by Sentinel-1A and is likely to appear in the EGMS dataset. This will be used as a reference measurement point in the future research.

As already mentioned, the choice of the SAR sensor also influences the monitoring results that can be achieved on the AoI. In addition to the theoretical maximum value of displacement rate, factors such as spatial resolution also play an important role. There are currently at least six SAR satellite missions (e.g. Sentinel-1, RADARSAT, PALSAR-2, TerraSAR-X, COSMO-SkyMed, SAOCOM) that generate SAR images capable of interferometry and at least two other missions (e.g. NASA-ISRO, ROSE-L) that are currently being implemented. The missions differ greatly in the wavelength used, the achievable spatial resolutions, the temporal sampling rate, as well as the general availability and the underlying data policy. In addition, commercial micro-satellite providers (e.g. ICEYE and Capella Space) are also striving for InSAR capability. Hence, it can be assumed that, as already shown in some studies [11], based on multi-resolution, multi-temporal and multi-frequency approaches the combination of InSAR measurements from different SAR constellations will significantly increase the added value of this measurement method.

Next research step is an analysis of the areas in lower Austria and in Vienna region flooded in September 2024. In comparison to correlation of the water level with the settlement of the pier, this research will exploit the full potential of InSAR that is particularly suitable for examining of middle to large areas.

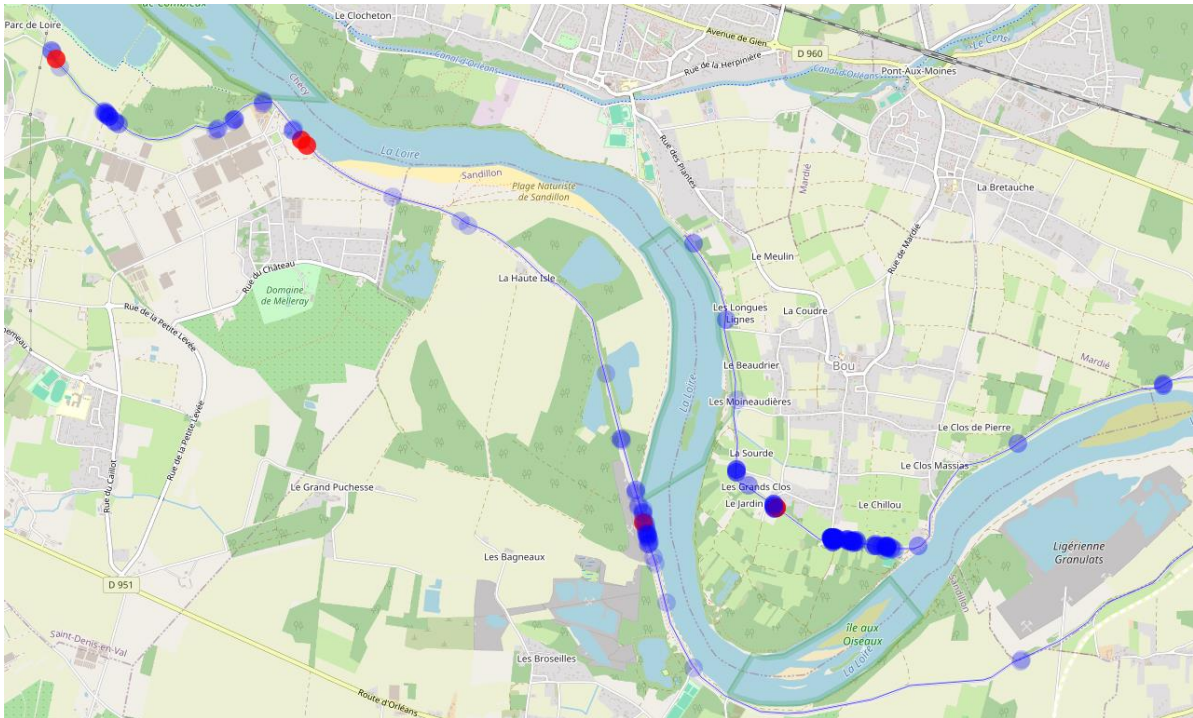

Figure 6. Overview of PS (blue) and DS (red) points along the embankment of the La Loire, France (thin blue solid line).

Figure 7. Settlement records from the EGMS database for three points (marked by red, light and dark green points, referring to the right vertical axis) at the endpoint of a river lock pier in Greifenstein, compared with water levels in the Danube River, as measured at stations in Bärndorf and Nussdorf (light and dark blue solid curves, referring to the left vertical axis), plotted as a function of time. The settlement mean trend lines,  $\mu$ , are indicated by bold dash-dotted lines and their standard deviations,  $\sigma$ , are plotted by thin dashed lines. The dates in blue font near the water level peaks mark high-water events.

Figure 8. Corner reflectors installed on the dike at the Danube River: a) cement corner reflectors with aluminum sheets, b) plain cement experimental corner reflectors, and c) standard double-headed corner reflector.

## 5 CONCLUSION

The present paper provides a brief overview of the potentials of InSAR monitoring of flood protection structures comparing it to conventional monitoring methods. In this context, the EGMS data provide high accuracy of displacement measurements with low required effort. However, the temporal and spatial resolution is limited.

The temporal resolution is dependent on the number of satellites and their repeat-pass periods. Since the return time of the Sentinel-1A to the same orbit is 12 days, the resulting EGMS data is suitable for monitoring slowly occurring changes. With the successful launch of Sentinel-1C in December 2024, the temporal resolution will double in the future. The spatial resolution can be increased by using commercial SAR satellites, which, however, increases required costs effort.

The spatial resolution of the Sentinel-1 satellites, with respect to the measurement point availability, was extensively investigated in this study. The EGMS database was used to examine several aspects of the measurement point availability in selected AoIs. First investigated aspect was number of obtained reflection points based on surface type and orientation. Green areas with gravel, asphalt, and no-gravel which constitute 60% of dike length in the investigated area (Figure 2), have the lowest point density out of all considered surface types (Figure 5). The number of available points is also dependent on orientation of the observed object. In this context, the most points in investigated AoIs are obtained for objects oriented in north-south (Figure 4). Unfortunately, 43 % of dikes in the investigated area along the Danube River are oriented to east-west direction (Figure 3).

The number of available reflection points also depends on the database release. EGMS provide access to three databases of InSAR measurement points, 2015-2021, 2018-2022, and 2019-2023. With the exception of highways and roads the newer the database, the more available points there are for each surface type category (Figure 5).

Since most of the dikes are located in green areas and the distributed scatterers are known to be more suitable for natural landscape, the potential use of DS was examined. To this end, the PS and DS were extracted from EGMS database for approximately 30 km dike section. This analysis showed that only 4.5 % of all available points are DS (Figure 6), rendering usability of the DS points rather low.

The settlement at a pier of a ship lock could be linked with high probability the flood of the Danube River. This case study showcased the potential of InSAR utilizing Sentinel-1 satellites for monitoring the condition of flood protection structures along the Danube River in the aftermath of flood events.

InSAR is an excellent method to monitor surface displacements of large areas in all-weather conditions, providing useful insights on the structural health of infrastructure assets. This study shows the potential of this method for monitoring dikes along Danube River, but also highlights the limitations, stemming from the low number of available reflection points. Therefore, future research will focus on increasing the number of available reflection points, by employing low-cost, highly-available corner reflectors, and investigating the availability of InSAR data from other existing or upcoming InSAR satellite missions.

## ACKNOWLEDGMENTS

The authors and partners of this research project are grateful for support from the Austrian Research Promotion Agency (Forschungsförderungsgesellschaft; FFG). Without its funding and support it would not be possible to conduct this research. Furthermore, we would also like to acknowledge the support from the Danube Flood Control Agency (DHK) during this research.

email: [vera.costantini@nhazca.com](mailto:vera.costantini@nhazca.com)

**ABSTRACT:** This paper presents ISABHEL (Integrated SATellite and ground-based monitoring for Bridge HHealth Lifetime assessment) project, which demonstrates an integrated approach to Structural Health Monitoring (SHM) by combining satellite InSAR data, contact sensors, Photomonitoring™, and Finite Element Modeling (FEM). The system is implemented on two bridges over the Po River in Turin, Italy: the Amedeo VIII and the Regina Margherita bridges. Each technology complements the others, providing a comprehensive understanding of bridge behavior. The InSAR analysis using high-resolution COSMO-SkyMed data revealed slight asymmetric deformation in the Regina Margherita Bridge, with the western lane exhibiting higher deformation rates. Contact sensors were strategically designed to be positioned based on each bridge's specific vulnerabilities, with the Amedeo VIII bridge focused on static monitoring and the Regina Margherita bridge on dynamic monitoring. The calibrated FEM models will enable prediction of structural behavior and establish critical thresholds. A web platform integrating all data sources will provide real-time visualization and alerts. This paper presents the initial results of this ongoing project funded by ESA, which will be completed in the next months.

**KEY WORDS:** Bridges; InSAR; Contact Sensors; Photomonitoring; Finite Element Modeling; Data Integration; 5G Communication

## 1 INTRODUCTION

The bridge infrastructure across Europe is aging, with many structures approaching or exceeding their design lifetime. This aging infrastructure requires consistent monitoring to ensure safety, optimize maintenance schedules, and extend its operational life. Traditional monitoring methods often rely on periodic visual inspections, which may miss early signs of deterioration and are labor-intensive [1]. Modern Structural Health Monitoring (SHM) approaches offer continuous data collection, but often focus on a single technology, providing only a partial view of the structure's condition [2]. The ISABHEL (Integrated SATellite and ground-based monitoring for Bridge HHealth Lifetime assessment) project, funded by the European Space Agency (ESA), and with the support of the Municipality of Turin, demonstrates an innovative approach to bridge monitoring by integrating multiple technologies: satellite Interferometric Synthetic Aperture Radar (InSAR), contact sensors, Photomonitoring™, and Finite Element Modeling (FEM). This integration leverages the strengths of each technology to create a comprehensive monitoring system capable of detecting various deterioration mechanisms at different scales.

The project focuses on two river bridges in Turin, Italy: Amedeo VIII bridge and Regina Margherita bridge (Figure 1). These structures were selected due to their strategic importance, different structural characteristics, and potential vulnerability to scouring phenomena. Additionally, the Regina Margherita Bridge may be affected by slope movements on the nearby hillside.

The project aims to demonstrate how multi-technology integration can provide a more comprehensive understanding of bridge health and support evidence-based maintenance decisions.

Figure 1. Location of bridges under study

## 2 PROJECT OVERVIEW AND METHODOLOGY

### 2.1 Case studies in Turin

The Amedeo VIII bridge is a reinforced concrete structure with post-tensioned cables added during a retrofit intervention in recent years. The bridge also features Gerber saddles (i.e. half-joints) which were strengthened during the same renovation (Figure 2).

The Regina Margherita bridge is a reinforced concrete structure with prestressed cables. It consists of two parallel carriageways that can be treated as separate bridges (Figure 3).

Both bridges are subject to potential scouring phenomena due to their superficial foundations. The Regina Margherita Bridge, moreover, is potentially subject to phenomena induced by slope movements on the hillside, which are difficult to perceive by on-site measurements but could be easily identified by satellite measurements over an extended area.

Figure 2: Overview of Amedeo VIII bridge

Figure 3: Overview of Regina Margherita Bridge

The Amedeo VIII and Regina Margherita bridges are examples of modern infrastructures, built respectively in 1933 and between 1970-1972, constructed in reinforced concrete, and that experience substantial daily traffic (2,164 and 2,715 vehicles per day, respectively). Notably, the Regina Margherita bridge falls within Class 1 (High) attention level as per current Guidelines. The project, conceived on these typologies of infrastructures, represents an important chance to develop reliable procedures that can be applied to a significant number of similar infrastructures, which are very common on the Italian territory.

This aspect is even more important since, in the last years, significant attention has been focused on the monitoring and safety assessment of bridges, due to the recent problems that occurred on some infrastructures because of maintenance problems [1]. As evidenced by the publication by the Ministry of Infrastructure and Transport, of the document "*Linee Guida per la Classificazione e Gestione del Rischio, la Valutazione della Sicurezza ed il Monitoraggio dei Ponti Esistenti*," in April 2020, surveillance and monitoring of bridge infrastructures should be provided especially for bridges ranked in the high attention class, which need continuous update of the structural model.

## 2.2 Integrated monitoring approach

In this project a comprehensive, multi-technology approach to bridge monitoring is adopted, ensuring a detailed and accurate assessment of structural health. At the core of this methodology is the integration of satellite-based and ground-based technologies, allowing for a continuous and complementary evaluation of deformation patterns and structural behavior.

The satellite-based component is represented by Interferometric SAR analysis (InSAR), which relies on high-resolution COSMO-SkyMed data to provide both historical deformation analysis and long-term monitoring of millimeter-scale displacements across the entire area of interest. This technology provides important information on long-term deformation trends and enables the detection of anomalies that might indicate structural degradation.

To complement the satellite data, a network of contact sensors is installed on the bridges, providing real-time measurements of key structural parameters. These sensors include biaxial inclinometers, triaxial accelerometers, strain gauges, displacement transducers and temperature probes, all of which contribute to acquiring data on both the static and dynamic behavior of the structures. The data collected from these sensors is transmitted via 5G technology, ensuring fast and reliable communication with the central monitoring system.

In addition to sensor-based measurements, the project incorporates an advanced Photomonitoring system. Camera installations near the bridges capture regular image sequences, which are then processed using Digital Image Correlation (DIC) and Change Detection (CD) techniques. These methods allow for the identification of visual modifications in the structure over time, facilitating the detection of potential issues such as cracks, material degradation, or unusual displacements. To further enhance the monitoring capabilities, Finite Element Modeling (FEM) is employed to create digital twins of the bridges. These virtual models are continuously updated and calibrated using real-world data obtained from satellite observations, contact sensors, and Photomonitoring. By simulating different loading conditions and environmental factors, FEM enables predictive analysis of structural performance.

All collected data is integrated into a centralized web-based platform, which serves as the primary interface for monitoring and analysis. This platform not only visualizes the structural health status in real time but also tracks changes over time and issues alerts when predefined thresholds are exceeded. By providing an intuitive and comprehensive overview of bridge conditions, the system facilitates informed decision-making for infrastructure management, ultimately enhancing safety and optimizing maintenance efforts.

This holistic monitoring approach ensures that all critical aspects of bridge health are continuously assessed, from large-scale deformations detectable by satellite to localized structural issues identified through sensor data and image analysis. The combination of these technologies provides a robust framework for long-term monitoring and early warning capabilities, supporting proactive maintenance and extending the lifespan of the infrastructure [2,3,4].

### 3 CONTACT SENSORS CONFIGURATION

#### 3.1 Monitoring strategy and sensor selection

Based on field inspections and analysis of bridge documentation, the project implemented a differentiated monitoring approach for the two bridges. The Amedeo VIII bridge focuses on static monitoring, while the Regina Margherita bridge incorporates both static and dynamic monitoring. This differentiation is due to the different structural characteristics and vulnerabilities of each bridge. The contact sensor system, developed by Nplus, integrates IoT-enabled sensors with advanced data analytics to provide a comprehensive assessment of bridge health. The selection criteria included sensitivity, durability, reliability, and suitability for the specific monitoring objectives of each bridge.

The Vittorio Infrastructure system by Nplus employs a wired architecture with a 2 Mbit/s digital data bus, ensuring 24/7 reliability in power and data acquisition. The system integrates various sensors connected via a fiber optic backbone, which also powers the devices.

#### 3.2 Regina Margherita bridge sensor layout

The Regina Margherita Bridge, constructed between 1970 and 1972, spans the Po River in Turin, Italy. It is a modern three-span arch bridge with a total length of 123.0 meters and runs primarily along a North-South axis.

The structure consists of two separate half-bridges, one for each carriageway, which are structurally independent and connected only at the mid-lane. This 3-meter-wide section between the decks was originally a tram line, later became a recreation park, and is currently a green area.

The bridge is made of prestressed reinforced concrete, while the decks are reinforced concrete box girders with variable height and six webs. They rest on steel-made fixed bearings on the south abutment and double-pendulum roller bearings on the north abutment and piers.

The piers lie on reinforced concrete caisson foundations that were sunk by self-weight rather than deep foundations, which makes the bridge susceptible to scouring and classifies it as high hydraulic risk, according to Italian guidelines.

The bridge was designed with spans ballasted with lean concrete and tie rods anchored in rock at the two abutments to reduce total downward deflection at the midspan.

For this bridge, both static and dynamic monitoring were implemented. The sensor layout was designed to detect potential scour-related issues using inclinometers and assess the deck's load-bearing capacity through accelerometers and strain gauges (Figure 4). While inclinometers and strain gauges monitor static behavior, accelerometers analyze dynamic behavior, providing a comprehensive assessment of the bridge's structural health.

- Inclinometers/accelerometers installed on piers and at deck mid-spans and quarters, respectively to:

- Measure static rotations to check plastic drift and reconstruct the deformed span
- Measure accelerations to perform Operational Modal Analysis (OMA), check mode drift, and identify natural frequencies, mode shapes and damping

- Strain gauges at mid-spans to monitor axial deformation, which can indicate excessive loading, prestressing cable relaxation, or changes in restraint effectiveness
- Temperature sensors on different spans to correlate environmental conditions with structural responses.

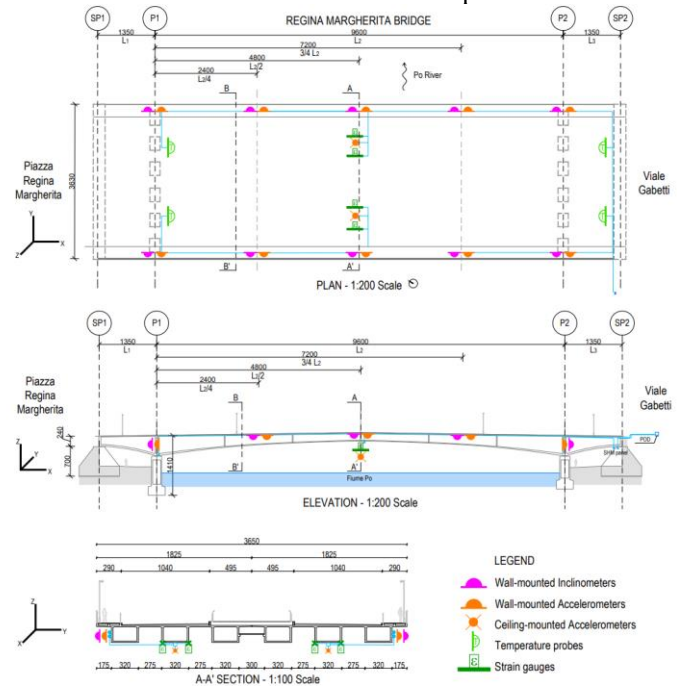

Figure 4: Contact sensors configuration for Regina Margherita Bridge

#### 3.3 Amedeo VIII bridge sensor layout

The Amedeo VIII Bridge, constructed in 1933, crosses the Stura River, a major tributary of the Po River, which it meets in Turin. This five-span bridge has a total length of 153.3 m, and its main axis lays in a southwest-to-northeast direction.

The bridge has a single carriageway, consisting of two lanes in each direction plus two large walkways - one on each side. The girder bridge has a regular grid of reinforced concrete (R.C.) transverse and longitudinal beams (these latter ones with variable thickness along the bridge's main axis) with the addition of post-tensioned cables during a recent structural retrofit intervention.

The deck is simply supported on the R.C. piers and clamped at the two abutments. On the second and fourth spans are located two half joints (i.e. the so-called Gerber saddles), which carry two simply supported half-spans.

Exactly as in the case of the Regina Margherita Bridge, all piers lie on self-sunk R.C. caisson foundations, not deep foundations. For the same reasons as before, this classifies it as high hydraulic risk according to Italian guidelines. For the Amedeo VIII bridge, static monitoring was preferred in order to track displacements and rotations (Figure 5). The sensor configuration includes:

- Biaxial inclinometers installed on piers and deck span extremes to monitor:
  - Static rotations of individual spans to check plastic drift
  - Static rotations of piles to check differential settlement
  - Rotations of Gerber saddles to check for potential failures

- Strain gauges installed on Gerber saddles to monitor expansions and detect potential saddle failures
  - Temperature sensors installed on different spans to correlate environmental conditions with structural responses.
- This configuration focuses on the bridge's main vulnerabilities: scouring phenomena (monitored through inclinometers) and the Gerber saddles (monitored through inclinometers and strain gauges).

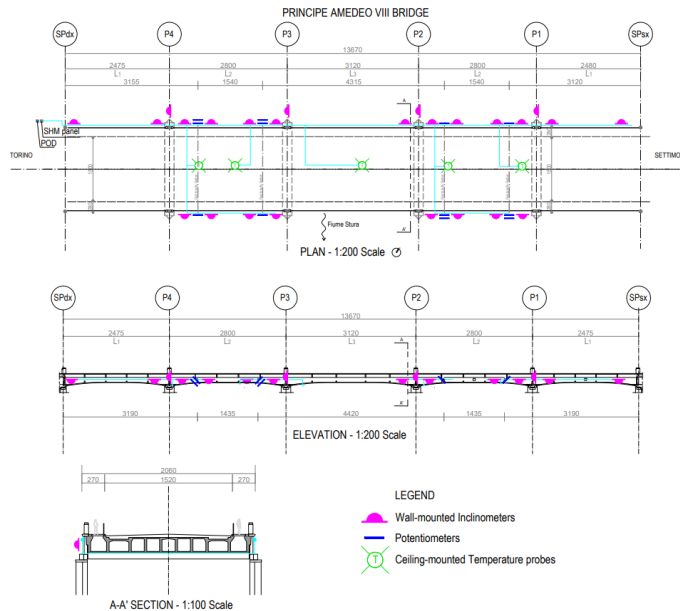

Figure 5: Contact sensors configuration for Regina Margherita Bridge

## 4 A-DINSAR ANALYSIS

### 4.1 Satellite radar interferometry technique

In this study, the Advanced Differential Synthetic Aperture Radar Interferometry (A-DInSAR) technique [5] is used to analyze historical ground displacement rates within the Turin municipality. A-DInSAR detects surface deformations by analyzing phase differences between successive radar satellite observations of the same area. These variations in the RADAR signal phase, reflected from objects on the Earth's surface, are directly correlated with ground movement, enabling the generation of high-resolution deformation maps [6,7]. Specifically, this technique is widely utilized for studying the temporal evolution of ground displacement of Persistent Scatterers (PS), which are objects within the SAR resolution cell (3x3 m<sup>2</sup> for CSK) that maintain consistent reflectivity over time [8].

The applied InSAR methodology follows the Persistent Scatterer Interferometry (PSI) approach, as described in reference articles [9] and [10]. The PS-InSAR technique extracts deformation information from an interferometric stack of SAR images, allowing for detailed pattern analysis. SAR datasets from the Cosmo-SkyMed (CSK) mission, operated by the Italian Space Agency (ASI), were utilized, which has provided archived data since 2009 and are free for research purposes. The CSK system is equipped with an X-band sensor (about 3.1 cm wavelength) that allows for millimetric displacement measurement precision. In STRIPMAP mode, it

offers a spatial resolution of 3m×3m. Over Italy. The revisiting time is 16 days with occasional gaps due to the dual use of the constellation for civilian and military applications.

For this study, a total of 460 SAR images were processed covering the period from 2011 to 2024, acquired in ascending and descending orbital geometries:

- Ascending orbit: 231 Single Look Complex (SLC) images acquired between January 18, 2011, and August 23, 2024.
- Descending orbit: 229 SLC images acquired between May 18, 2011, and September 24, 2024.

The A-DInSAR derived deformation rate values (expressed in millimeters per year) were estimated relative to a designated reference point. To ensure accuracy, our results were calibrated and validated using displacement data from the GNSS station located in the municipality of Turin.

To evaluate the reliability of our results, an error analysis was conducted, estimating the standard deviation of deformation rates, and assessing temporal coherence levels, considered only the points with temporal coherence up to 0.4.

In addition, complementary remote sensing techniques were integrated, including ground-based leveling data, to cross-validate our results. The Turin municipality is characterized by complex subsurface conditions, including sandy-gravelly alluvium and clayey alluvial soil, which contribute to varying deformation patterns. These geological factors were taken into account in our analysis to improve the interpretation of observed displacement trends.

### 4.2 Post-Processing and Analysis of Satellite Interferometry Data

The post-processing of satellite interferometry data is carried out using the PS-ToolBox Suite, developed by NHAZCA S.r.l. and integrated into QGIS. This suite enables the visualization of time series, decomposition of line-of-sight displacements, and the creation of various data representations to identify significant structural movements.

The vector decomposition process of the data allows the generation of velocity maps for the Synthetic Measurement Points (SMPs) in both vertical and horizontal (East-West) directions. These maps are derived from the decomposition of measurements along the sensor's line of sight (LOS) obtained through both ascending and descending orbital geometries.

It is essential to note that displacement and velocity measurements are calculated along the sensor's LOS. Therefore, the detected displacements represent the projection of actual displacements along the sensor-target line. Indeed, the observed displacement is the combination of the vertical and slightly east-west movement. Combining the observation from two looking geometries it's possible to decompose the signal along the vertical and horizontal components.

The data vector decomposition process was performed using proprietary algorithms to extract displacement vectors in both horizontal and vertical directions. The study area was discretized into hexagonal cells with a 5 m radius, arranged on a regular grid. The results were displayed only for cells containing at least one measurement point for both orbital

geometries, referred to as "Synthetic Measurement Points" (SMPs).

PS times series tool allows the interactive visualization and analysis of time series derived from satellite datasets, providing a detailed representation of the displacement evolution over time. The analysis of this time series helps identify patterns of progressive subsidence, seasonal variations, or sudden displacement changes, which could indicate structural anomalies or external influences.

The Interferometric Section tool creates interferometric sections using data analysis from different orbital geometries. The sections follow the road alignment and intersect the Measurement Points (MPs) of the monitored bridges, allowing the visualization of displacement distribution along a topographic profile.

#### 4.3 A-DInSAR Results

The results of the A-DInSAR analysis are presented through maps overlaid on orthophoto-based backgrounds, illustrating the annual average velocities of the measurement points (MP) across the study area, including the two bridges under investigation. A color scale, expressed in mm/year, is used to represent the average displacement velocity along the satellite line of sight (LOS): colors ranging from yellow to red indicate movement away from the sensor, while shades from cyan to blue denote movement towards it. Green areas correspond to measurement points with negligible or non-significant displacement variations, with an estimated instrumental accuracy of approximately  $\pm 1.0$  mm/year. The analysis provided a well-distributed spatial coverage of MPs across the entire study area in both ascending and descending geometries, ensuring redundant observation of potential deformation processes. A higher density of MPs is observed in urbanized areas, whereas a lower density is found in regions with dense vegetation or agricultural land.

A detailed analysis follows, focusing on the bridges, where time series of displacement for some measurement points, based on the A-DInSAR analysis, are shown for both ascending and descending geometries, plotted with the cumulated rain over time.

The final products are represented by velocity maps of the measurement points (MP) in the vertical and horizontal directions. These maps are obtained from the vector decomposition of measurements along the satellite line of sight (LOS) for the MP data collected in both ascending and descending orbital geometries.

#### 4.4 REGINA MARGHERITA BRIDGE Results

The Regina Margherita Bridge exhibits moderate deformation in the area where it is structurally stable, characterized by a localized movement at the midspan that is clearly visible in both satellite acquisition geometries. In Figure 6, the A-DInSAR analysis for the descending geometry shows that, while the bridge's abutments and piers at the ends remain stable, there is a non-negligible deformation ( $>2$  mm/yr) in the LOS direction, away from the sensor. In this geometry, the western carriageway seems to be more affected by the deformation, but possibly this is an artefact due to the satellite's line of sight. The up-down (UD) component, instead, is limited to  $<2$  mm/yr. However, from an engineering perspective,

considering the uncertainties associated with SAR technology, these outcomes will require further analyses to be accepted beyond any reasonable doubt. Figure 7 presents three representative time series for this carriageway, showing that measurement point MP2 at midspan accumulates up to 50 mm of displacement over the analyzed period.

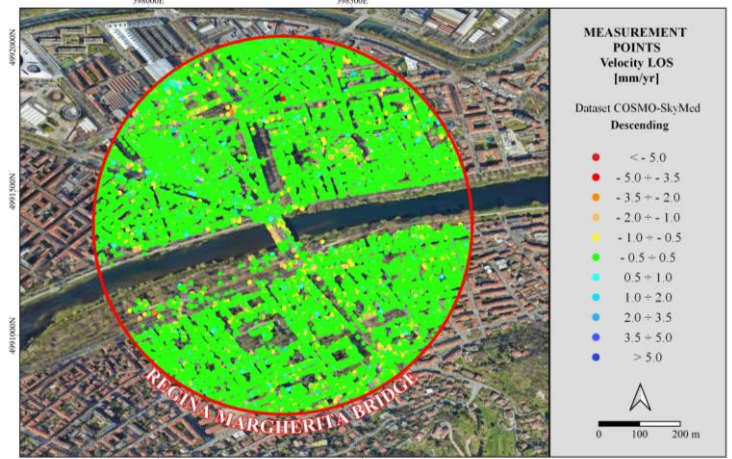

Figure 6 Velocity map of Measurement Points (MPs) obtained from A-DInSAR analysis in descending geometry for the Regina Margherita bridge area.

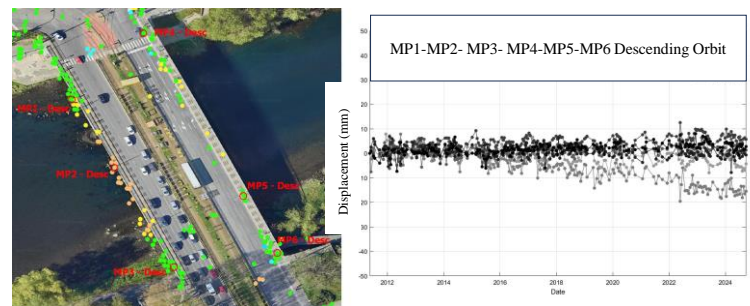

Figure 7 Time series of three measurement points for descending orbit on Regina Margherita bridge

Figure 8 shows the results from the ascending geometry, which display a deformation with rates of 2–3 mm/yr on both carriageways.

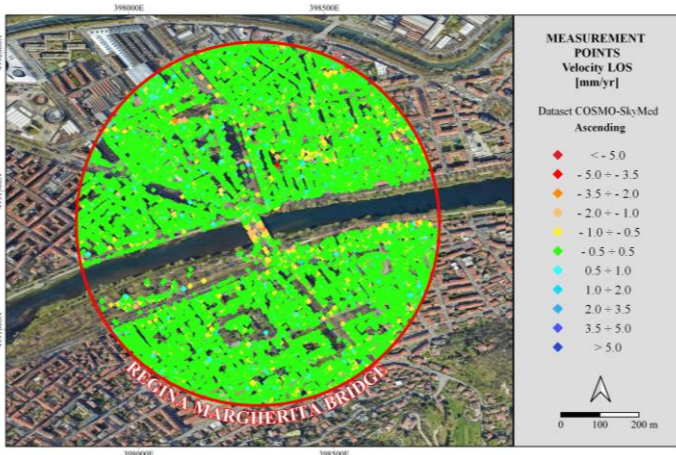

Figure 8 Velocity map of Measurement Points (MPs) obtained from A-DInSAR analysis in ascending geometry for the Regina Margherita bridge area.

From vector decomposition of the two LOS analyses, velocity maps for the vertical and horizontal components of displacement in the bridge area were produced (Figure 9).

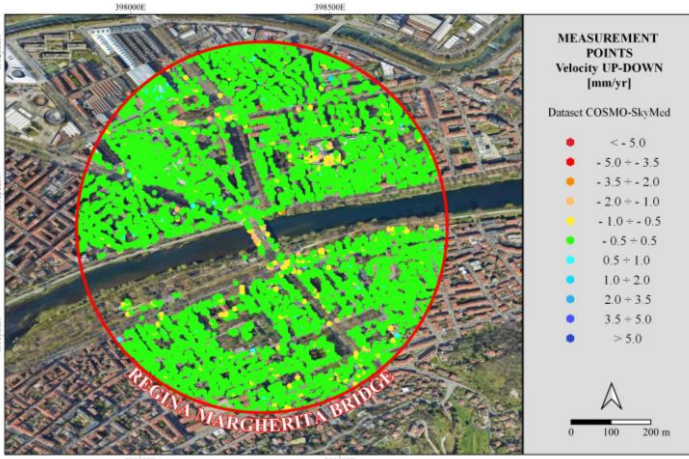

Figure 9 Velocity map of the Synthetic Measurement Points in vertical direction for Regina Margherita Bridge

The most representative outputs from the complete post-processing analysis of the satellite data are presented in Figure 10, which shows the cumulative vertical displacement along both the facade and plan view of the bridge, sampled at 5-meter intervals, to detail the deformative behavior in space and time. The interferometric section, which illustrates the evolution of the bridge's deformation over time and space, is presented in Figure 11.

#### 4.5 AMEDEO VIII BRIDGE Results

The Amedeo VIII Bridge exhibits deformation values within the stable range along its entire length, while the surrounding area shows minimal deformation. In figure 12, the descending geometry A-DInSAR analysis confirms that the bridge remains stable throughout its span, in contrast to adjacent areas that display displacement rates on the order of -2 mm/yr. Moreover, the time series presented in figure 13 clearly delineates the

Figure 10 Cumulative vertical displacement on Regina Margherita Bridge

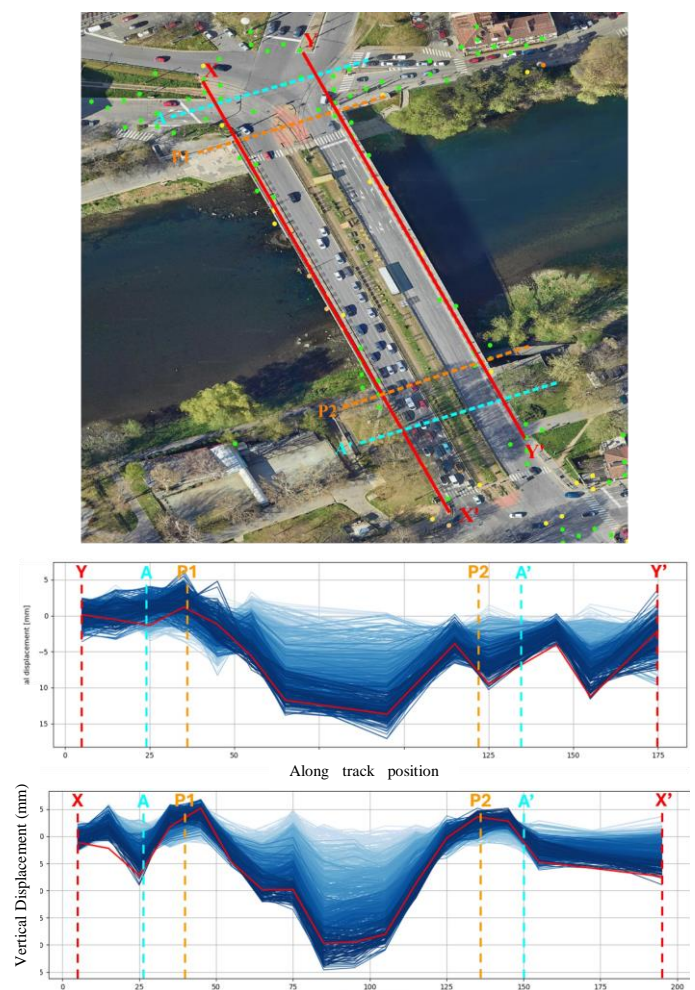

Figure 11 Interferometric section over the vertical deformation along the longitudinal path double way of the Regina Margherita bridge.

seasonal cyclic trend, with an average displacement of approximately zero.

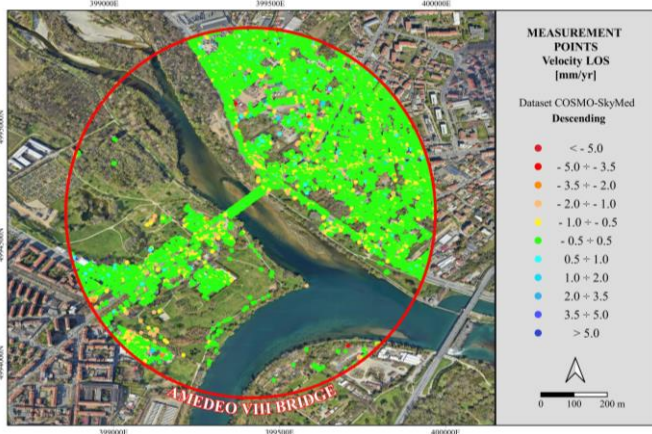

Figure 12 Velocity map of Measurement Points (MPs) obtained from A-DInSAR analysis in descending geometry for the Amedeo VIII bridge area.

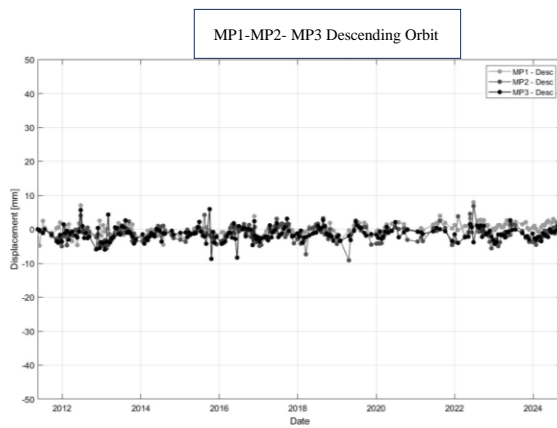

Figure 13 Time series of three measurement points for descending orbit on Amedeo VIII bridge

From the vector decomposition of the two LOS analyses, velocity maps for the vertical and horizontal components of displacement in the bridge area were produced, as shown in figure 14 and 15.

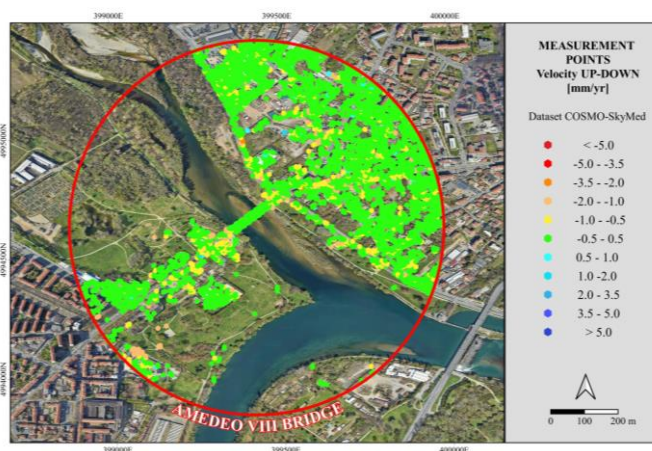

Figure 14 Velocity map of the Synthetic Measurement Points in vertical direction for Amedeo VIII bridge

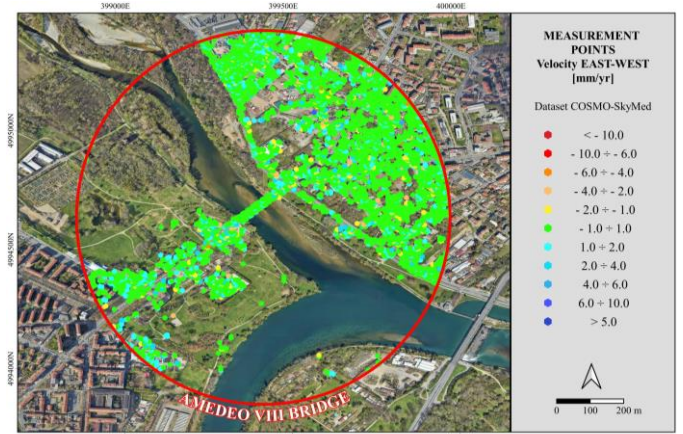

Figure 15 Velocity map of the Synthetic Measurement Points in horizontal direction for Amedeo VIII bridge

Finally, the most representative outputs from the complete post-processing analysis of the satellite data are presented in Figure 16, which shows the cumulative vertical displacement along both the facade and plan view of the bridge, sampled at 5-meter intervals, to detail the deformative behavior in space. The interferometric section, which illustrates the evolution of the bridge's deformation over time and space, is presented in figure 17.

Figure 16 Cumulative vertical displacement on Amedeo VIII bridge

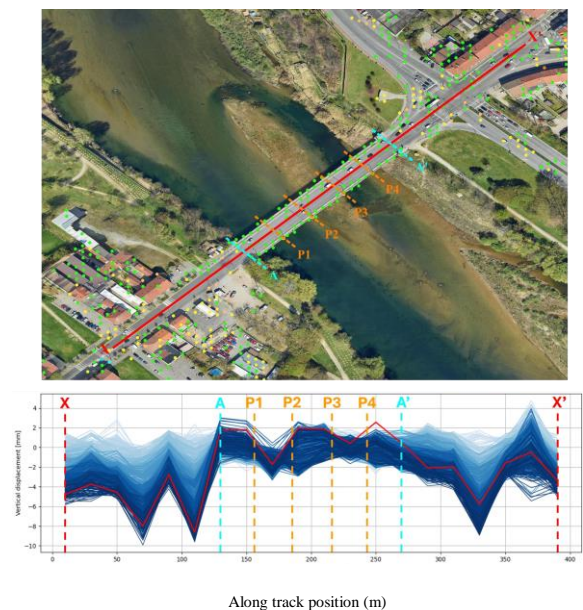

Figure 17 Interferometric section over the vertical deformation along the longitudinal path of the Amedeo VII bridge

It is clear from the interferometric sections, which illustrate the deformation behavior over time and space, that the bridge is stable, both the piers and the deck show minimal deformation.

## 5 PHOTOMONITORING

### 5.1 Introduction to technology

Photomonitoring<sup>TM</sup> is an innovative monitoring technique that can exploit any kind of raster data. Photomonitoring<sup>TM</sup> is based on the identification and analysis of terrain elements and structures and their possible variations through examining images acquired at different times. The analysis uses Digital Image Correlation (DIC) and Change Detection (CD) techniques implemented through NHAZCA's proprietary IRIS software. IRIS is conceived to work with terrestrial, aerial and satellite imagery of any datatype (Optical, Thermal, Near-Infrared, etc.). The technique allows to reach millimeter accuracy in displacement monitoring and can be used separately or combined with other monitoring systems [11,12].

### 5.2 Monitoring strategy

In the ISABEL project, the images will be acquired by cameras installed at the site.

For both bridges, MOBOTIX cameras with dual-lens configuration were deemed as the optimal choice: a wide-angle lens providing a global view and a telephoto lens focused on a specific pier (Amedeo bridge) or for monitoring crack evolution (Regina Margherita bridge).

On Amedeo bridge a single MOBOTIX M73 camera will be installed. The primary focus for the Amedeo VIII bridge is to monitor hydraulic action that can cause scouring of the piers and overall movement of the structures. The camera will be installed on the west riverbank, approximately 60 meters from the central area.

In particular, the wide-angle lens will capture a big part of the bridge, including all piers, providing an overview of the structure and detecting movements through DIC analysis. A telephoto lens will target a specific pier to monitor material accumulation (change detection analysis) and scouring caused by river flow (displacement of the pier).

For Regina Margherita bridge, a MOBOTIX S74 camera will be installed. The main monitoring objectives for the Regina Margherita bridge are crack detection, structural deformation, scouring and material accumulation at the base of the piers, and monitoring during high water levels or flooding conditions. The telephoto lens will be pointed at the nearest span to monitor the evolution and appearance of cracks (change detection). The wide-angle lens will detect displacements of the entire structure, with particular attention to the middle section.

### 5.3 Image acquisition and analysis workflow

For both bridges, image acquisition follows these specifications: Static images captured every 5 minutes for continuous monitoring; Automated trigger mechanism that switches to video recording (30 frames per minute) when significant changes are detected; Data processing using the IRIS software, which compares images within a 10-15 minute buffer to select the best quality for analysis.

The analysis workflow includes the following tasks:

- Feature Monitoring: Images processed using the IRIS software to assess changes in targeted areas, particularly cracks in the nearest arch and scouring at the base of piers; continuous comparison of images within a 10-15 minute buffer to select the best quality for analysis.
- Change Detection: Identifies structural changes while eliminating noise caused by lighting, water turbulence, or environmental conditions; specific attention to crack propagation and material accumulation.
- Displacement Analysis: Determines the extent and direction of structural movement, especially in the arches and piers. The system continues analysis until the structure returns to a stable state.

Figure 18: Example of monitoring of cracks evolution in a viaduct; the image below shows the result of change detection analysis.

## 6 FINITE ELEMENT MODELLING AND THRESHOLDS DEFINITION

### 6.1 FEM generation

Before beginning the bridge's structural modelling, two essential preliminary activities need to be conducted. First, all technical documentation concerning the bridge's structural aspects were gathered. Second, on-site inspections were performed to evaluate the current site conditions, confirm that the built structure matches the original designs, assess the current state, and collect other important observations.

The two bridge models were developed using CSI Bridge, a software specialized in the structural analysis of bridges, compliant with regulations for moving loads. The models enable linear analyses for comparison with data from contact-based sensors to be installed.

The modelling evolved from a simplified "frame" model, with the superstructure condensed into a single element, to a more detailed "shell" model, discretizing the deck with two-dimensional elements for greater accuracy, also allowing the modelling of the complex layout of the prestressed cables.

The validation phase has begun, with progressive verification of the models' accuracy and stability. This iterative approach ensures that potential discrepancies are addressed early, enhancing the robustness and reliability of the results as the

project advances into more sophisticated modelling phases. As the monitoring campaign progresses, the experimental data will be integrated into the digital twins, minimizing error propagation in critical areas of structural performance and enhancing the models' predictive capabilities for real-world scenarios. In later work stages, the numerical model is thought to be updated with material testing results and with the results from the ongoing monitoring system. Creating a reliable model that delivers consistent results is essential to be able to compare and potentially reproduce the phenomena detected through satellite monitoring (fig. 19).

Figure 19: FEM model of the Regina Margherita bridge

## 6.2 SHM Parameters and Thresholds

The SHM system monitors several key parameters that indicate bridge structural health:

### 1. Static Parameters:

- Rotational measurements from inclinometers at pier bases, deck spans, and Gerber saddles
- Displacement measurements from transducers at expansion joints and Gerber saddles
- Strain measurements from gauges at mid-spans
- Deformation maps and displacement values from InSAR and Photomonitoring™
- Surface Damage (Cracks Evolution/Appearance) through Photomonitoring
- Debris material accumulation through Photomonitoring

### 2. Dynamic Parameters:

- Acceleration measurements for modal analysis (natural frequencies, mode shapes)
- Vibration characteristics in response to traffic and environmental loads

### 3. Environmental Parameters:

- Temperature measurements for correlation with structural responses
- Environmental conditions that might affect monitoring results

A multi-level threshold approach has been established to evaluate the monitored parameters:

1. Level 1 (Operational Conditions): Defined according to evaluations based on preliminary models. This represents normal operational conditions.

2. Level 2 (Statistical Deviation): Based on a data-driven model trained on the first period of continuous monitoring. This represents a significant (but not ultimate) deviation from normal behavior.

3. Level 3 (Ultimate Limit State): Derived from numerical simulations of the FEM models, representing the expected ultimate limit state before structural failure.

These thresholds are calibrated using the multi-source data from the integrated monitoring system. The temperature data is particularly important, as understanding the structural behavior induced by temperature variations is crucial for distinguishing normal responses from anomalies.

## 7 WEB PLATFORM

The ISABHEL web platform has been designed to provide a seamless, real-time interface for infrastructure monitoring, offering a user-centric approach to data visualization and interaction. Built using Next.js, the front-end ensures high performance through server-side rendering and static site generation, enhancing both responsiveness and search engine optimization. The modular, component-based architecture leverages React, allowing for reusability and scalability across various interface elements.

A key feature of the platform is its interactive dashboard, which aggregates real-time structural data from multiple sources, including contact sensors, Photomonitoring cameras, and satellite-based SAR analysis. The dashboard dynamically updates through WebSockets, ensuring that users have immediate access to the latest structural health indicators (figure 20).

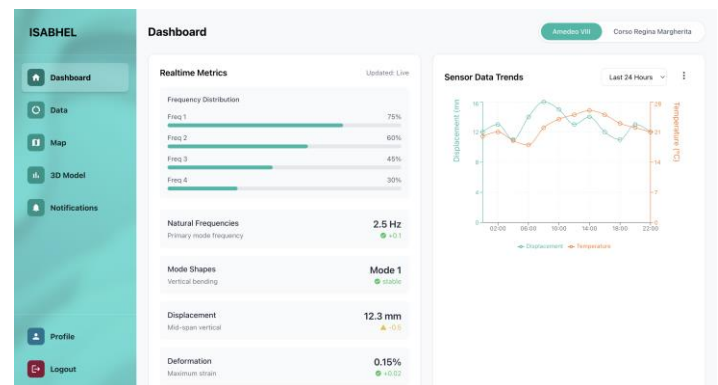

Figure 20: Dashboard of the web user interface

Another core component is the interactive GIS map, which integrates geospatial data through TileServerGL. This feature enables precise visualization of deformation patterns, historical trends, and real-time alerts. Users can navigate the bridge structures in detail, overlaying sensor readings and risk assessments to gain a comprehensive understanding of potential vulnerabilities.

To further enhance the analysis capabilities, the platform incorporates an advanced 3D bridge model rendered using WebGL technologies such as Three.js. The 3D model of the monitored bridge will be presented with a series of "traffic lights" to highlight any anomalies, using the three standard colors (green, orange, red) depending on whether the signal exceeds the predefined thresholds. "Local" traffic lights will be placed directly at the sensor's location (for example, the rotation of a pile or the movement of a Gerber saddle), while "global" traffic lights could refer to analyses at the entire structure level (such as generalized movement of the bridge,

variation in the fundamental vibration periods, etc.), helping the end user understand the nature of any anomalies (21).

Figure 21: 3D model viewer with color-coded traffic lights

The design choices behind the ISABHEL front end prioritize usability, speed, and scalability. The use of Supabase for database management and authentication streamlines data retrieval and ensures secure access to user-specific functionalities. Additionally, the real-time notification system provides immediate alerts for threshold breaches, ensuring that stakeholders can take timely action when necessary.

## 8 CONCLUSIONS

The work is in its initial phase and ground-based acquisition have not started yet. However, thanks to an in-depth study of raw FEM models and based on A-DInSAR results, first-level thresholds for the bridge's structural health parameters have been estimated, which will need to be confirmed during monitoring. Based on the A-DInSAR analysis, the Regina Margherita Bridge shows localized deformation at midspan, while its abutments and piers remain stable. In contrast, the Amedeo VIII Bridge exhibits minimal deformation throughout its entire structure, with measurements remaining within the stable range ( $\pm 1.0$  mm/year) and displaying only seasonal cyclic variations with average displacement of approximately zero.

**ABSTRACT:** Natural hazards such as landslides, subsidence, and liquefaction represent growing threats to critical infrastructure. Building upon the methodological foundation presented in the SGAM project, this work introduces enhancements to the Smart Geotechnical Asset Management (SGAM) framework, with particular emphasis on its hazard assessment component. The SGAM system integrates geotechnical monitoring, Earth Observation (EO) data, and machine learning techniques to support predictive maintenance of linear infrastructure. In this paper, we present methodological refinements, expanded geohazard integration, and new insights from recent applications. A synthesis geospatial layer supports proactive risk mitigation by highlighting high-priority intervention zones. These developments aim to improve data-driven infrastructure management.

**KEY WORDS:** Infrastructure resilience, geohazards, EO data, AI algorithms

## 1 INTRODUCTION

Infrastructure systems worldwide are increasingly vulnerable to natural hazards, including seismic events and landslides, resulting in significant economic and social impacts. Prior studies estimate that around 0.5% of global assets are exposed to such hazards annually [1]. These threats often disrupt vital services such as transport and logistics, emphasizing the need for resilient infrastructure planning.

In the literature, several frameworks have been developed to support multi-hazard risk management, particularly in relation to linear assets. These approaches are generally developed for integrated and quantitative frameworks capable of modelling multi-hazard scenarios, infrastructure vulnerability, and resilience. This type of analysis is inherently multidisciplinary and typically requires high-resolution input data, including detailed fragility curves and comprehensive ancillary datasets [2][3]. To overcome the challenges associated with data availability, other studies [4][5] adopted index-based methodologies, offering a more qualitative approach that emphasizes the exposure and vulnerability components of risk rather than detailed hazard modelling. In this context, SGAM (Smart Geotechnical Asset Management) framework was introduced as a semi-automated decision support system integrating EO data, geotechnical monitoring, and data fusion algorithms [6]. The original SGAM methodology, laid the groundwork for a multi-hazard approach to infrastructure risk analysis.

This paper advances that framework by expanding the hazard models, improving the integration of InSAR-derived movement data with hazard assessments, and streamlining the generation of prioritized summary layers.

## 2 METHODOLOGY

The present study builds upon the SGAM framework previously introduced in [6], refining its methodology for the hazard assessment of linear infrastructure. SGAM remains a semi-automated decision support system that leverages satellite

Earth Observation (EO) data, machine learning techniques, and geological knowledge to support asset management and predictive maintenance. In this paper, we present methodological advancements with specific focus on the characterization of landslide, subsidence, and liquefaction hazards.

This version includes a development for individual hazard types, aiming to improve interpretability and accuracy at the asset level. While the geodatabase architecture and structure have already been described in detail in [6], here it is referenced as a resource for hazard data management.

SGAM employs a multi-hazard workflow, integrating ground motion data from satellite InSAR with thematic layers (e.g., topography, geology, land use) through supervised learning algorithms. The spatialized outputs are then segmented and intersected with infrastructure elements to enable the classification of asset segments into risk levels. Key enhancements include differentiated processing for slow and fast landslides, velocity-based subsidence scoring, and refined soil classification for liquefaction susceptibility.

In addition, this study introduces a summary geospatial layer, which was not present in the earlier framework. This integrative product consolidates hazard-specific outputs into a unified decision-support layer, providing a risk-informed prioritization of intervention areas along the infrastructure network.

### 2.1 Hazard assessment

The SGAM project is instrumental in identifying geohazards, which are of paramount importance for ensuring infrastructure safety, as already mentioned in [6]. The framework was tested in a pilot area encompassing a 110 km-long highway located in northern Italy. As a preliminary step in the hazard analysis, the

available ancillary data were compiled and organized, as summarized in Table 1.

Input Data	Dataset
Topography	DTM (Tinitally 10 m) for slope, curvature, and roughness
Geology	National Lithological Map 1:100.000
Land Use	Regional databases
Seismicity	PGA and Vs30 for liquefaction analysis
InSAR (PS)	EGMS Ortho Dataset (EW and UD)

Table 1: Input data for SGAM application in the pilot area

These datasets represent the foundational layers from which each hazard-specific analysis is developed, as illustrated schematically in Figure 1.

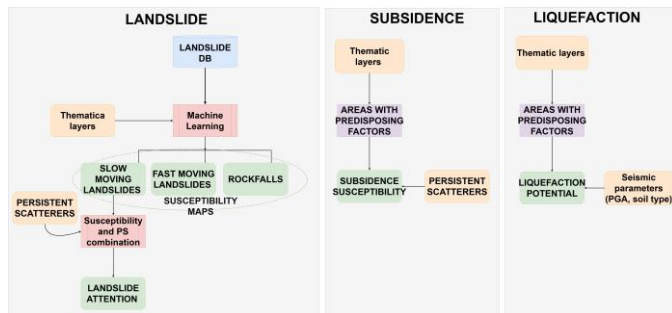

Figure 1: Workflow of SGAM application

### 2.1.1 Landslides

Building on the susceptibility analysis presented in [2], this study introduces a more detailed approach to characterize landslide hazards affecting linear infrastructure. The methodology refines both the input data structure and the classification logic, with particular attention to the kinematic behaviour of slope movements.

Susceptibility is evaluated as the intrinsic propensity of terrain to generate landslides, based on factors such as slope angle, lithology, land use, and morphometry. As in [2], machine learning algorithms trained on available inventories are employed to model landslide density and generate susceptibility maps.

Persistent Scatterers (PS) from satellite InSAR data are incorporated more systematically than in [2], serving as a proxy for activity status. These data support the validation and enhancement of susceptibility outputs by highlighting zones with active deformation. The improved pipeline also includes a Landslide Attention Index, which scores infrastructure segments based on hazard level and PS data velocities.

Figure 2 represents the combination of susceptibility classes and PS velocities, considering a threshold of 2.5 mm/years.

	No PS	$V <  2.5  \text{ mm/yr}$	$V >  2.5  \text{ mm/yr}$
Hazard class 1	Low	Low	Medium - high
Hazard class 2	Medium - Low	Low	Medium - high
Hazard class 3	Medium	Low	High
Hazard class 4	Medium	Medium - Low	High
Hazard class 5	Medium - high	Medium	High

Figure 2: Landslide attention matrix

### 2.1.2 Subsidence

The assessment of ground subsidence hazards in this study builds upon the foundations described in [6], introducing a more robust integration of vertical ground motion data with thematic geological and topographic layers. Subsidence is defined as the slow downward movement of the ground surface due to natural or anthropogenic causes, such as compaction or groundwater withdrawal.

This analysis integrates lithological characterization, slope thresholds, and PS InSAR measurements to identify and classify regions affected by subsidence.

While [6] included initial mapping efforts, the current approach incorporates a classification along the infrastructure into hazard classes based on maximum vertical velocities and contextual geomorphological settings. This classification allows infrastructure managers to identify critical zones where maintenance or reinforcement actions may be needed.

### 2.1.3 Liquefaction

The liquefaction hazard model presented here extends the susceptibility mapping approach introduced in [6], offering a more detailed evaluation of geotechnical and seismic parameters. Liquefaction occurs when saturated soils lose cohesion during seismic shaking, compromising ground stability.

The new model introduces a segmentation-based hazard index that aligns with infrastructure elements. In contrast to the more generalized susceptibility zoning described in [6], this version includes quantitative thresholds for seismic acceleration and susceptibility reclassification, enabling improved spatial resolution.

Additionally, the workflow supports continuous refinement as new geophysical or seismic datasets become available, facilitating dynamic hazard re-evaluation over time.

## 2.2 Summary layer

A key innovation introduced in this study—absent from the framework outlined in [6]—is the development of a summary geospatial layer that consolidates the outputs of the hazard-specific models into a decision-support product. This synthesis layer serves as a comprehensive tool for identifying high-hazard zones along linear infrastructure, prioritizing them for monitoring, maintenance, or intervention.

The summary layer integrates the results from landslide susceptibility (including activity-based scoring from PS data), subsidence hazard classification (based on vertical deformation velocity), and liquefaction potential (based on seismic-geotechnical analysis) (Figure 3). These individual assessments are spatially combined through a rule-based approach to assign a composite risk score to each infrastructure segment.

The results are made available within a GIS environment, enabling interactive visualization of the hazard assessments for each segment of the infrastructure network. By visualizing hazard in a single layer, decision-makers can easily identify critical areas where multiple hazards converge or where the severity of a single hazard justifies immediate action. This tool enhances operational readiness and resource allocation, offering a practical output directly usable by infrastructure managers and planners.

The introduction of this summary layer represents a major step forward in the SGAM methodology, improving its usability, interpretability, and impact in real-world applications.

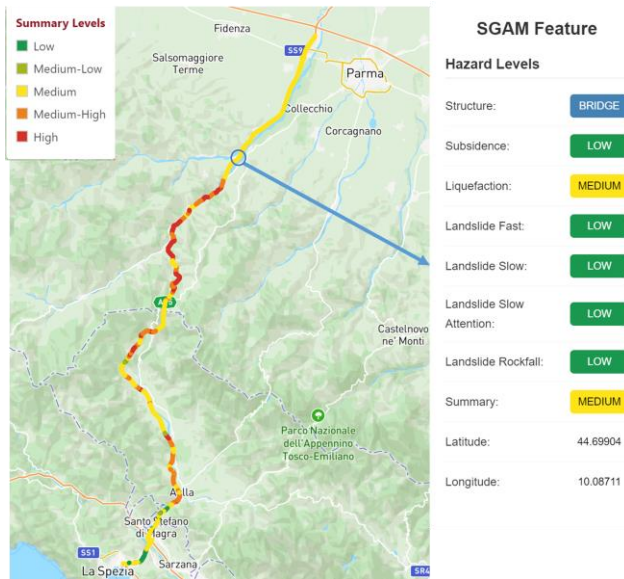

Figure 3: Example of SGAM result on linear infrastructure.

### 3 CONCLUSIONS AND FUTURE OUTLOOK

This study expands upon the foundational SGAM methodology presented in [6], delivering key enhancements in hazard modeling, data integration, and operational usability. While the previous version laid out the general framework for a semi-automated, EO-based geohazard assessment system, the current work provides a more refined and implementable approach by detailing the modeling procedures for landslides, subsidence, and liquefaction.

One of the most significant contributions of this study is the introduction of a summary geospatial layer, which enables an integrated and view of infrastructure vulnerability. This addition makes SGAM not only a robust analytical framework but also a decision-ready platform for operational use in infrastructure management and planning.

Future developments will aim to expand the temporal and spatial scope of SGAM through the integration of multi-temporal EO datasets, including LiDAR and drone-based surveys, and the adoption of automated change detection techniques. Additionally, work will continue incorporating vulnerability and exposure metrics to complement hazard-based assessments, building a more comprehensive picture of infrastructure resilience.

The SGAM system, as further developed in this work, offers a scalable and adaptable solution, capable of supporting

infrastructure managers in making informed decisions in the face of complex and evolving natural hazards.

**ABSTRACT:** The electro-mechanical impedance (EMI) method represents a promising approach to structural health monitoring (SHM), attributable to its ability to simultaneously employ piezoelectric transducers for both actuation and sensing purposes. As a result, an extensive volume of literature has surfaced recently, analyzing the efficacy of the EMI method in reinforced concrete (RC) structural elements subjected to quasi-static loading sequences. Nevertheless, the investigation into applying the EMI method in dynamic loading environments must be more robust within the current body of research. This study evaluates the effectiveness of the EMI method for SHM of a one-bay, one-story RC space frame structure under the influence of earthquake excitations. Therefore, a shaking table was used to excite the RC frame with progressively increased ground excitation, wherein piezoelectric patches are strategically embedded in meticulously chosen locations. The embedded PZT sensors facilitate promptly diagnosing earthquake-induced damage to the RC frame. The experimental outcomes reveal that the EMI method effectively and expeditiously identified damage formation within the RC frame.

**KEY WORDS:** Structural Health Monitoring (SHM), Electro-Mechanical Impedance (EMI), damage diagnosis, dynamic loading, Reinforced Concrete (RC) frame.

## 1 INTRODUCTION

In recent years, the secure extension of the service life of existing Reinforced Concrete (RC) structures has become critically significant due to the aging of a substantial portion of the European building stock, some of which have attained their original design life [1]. Therefore, Structural Health Monitoring (SHM) methods have emerged as an indispensable instrument for achieving this objective by evaluating their seismic performance and structural integrity [2]. Compared to conventional methods, such as visual inspection, SHM systems offer continuous inspection, enabling the detection of even slight internal damage initiation, by covering the 3D space of the structural mass in real-time rather than only after it becomes visibly apparent. These systems are permanently installed on the structure, allowing for ongoing monitoring without the need for manual inspections. Furthermore, the energy renovation of existing buildings increases the challenges associated with implementing conventional methods, given that the RC members are inaccessible due to the insulating materials. In contrast to traditional methods, the newly developed SHM techniques enable continuous monitoring and prompt damage identification. Consequently, these limitations have catalyzed SHM advancement in recent decades, during which several methodologies have emerged [3,4].

The electro-mechanical impedance (EMI) technique, recognized as one of the emerging methods in SHM, utilizes the coupling properties inherent in piezoelectric materials, notably lead zirconate titanate (PZT), to identify the deterioration of the assessed structure's mechanical properties. Furthermore, the damage within RC structures initially presents as distributed microcracks that localize to form significant visible cracks [5]. Additionally, a concentration of strain is observed within the material medium, accompanied by a

decrease in the material stiffness matrix, before the emergence of visible cracks [6,7]. Consequently, the deterioration of the mechanical properties of the structure material is manifested in the EMI response of an affixed PZT transducer. Within the extensive body of literature, two primary methodologies are identified for the application of PZT transducers in RC structures: the utilization of externally bonded patches [8,9] or their integration as smart aggregates within the RC structures [10,11]. According to Naoum et al., embedded PZT sensors, like smart aggregates, exhibit increased sensitivity to damage formation and stress fields of the host structure compared to externally bonded PZT patches [12].

Consequently, many research papers have been published investigating the efficacy of EMI-based monitoring of RC elements. The EMI method has been widely utilized in studies for prompt load-induced damage detection of RC and FRC beams. Furthermore, research initiatives have examined the viability of the EMI method for SHM of full-scale subassemblies of RC structures, including RC beams [13–16] and RC joints [17,18] under quasi-static loading, yielding promising outcomes. In addition, research implements machine learning techniques to increase the robustness of the EMI method in high-complexity scenarios, such as retrofitted RC members [19–22]. Nevertheless, prior research has predominantly concentrated on damage identification utilizing quasi-static loading conditions, and research regarding the SHM of RC structures under dynamic loads remains notably limited.

As aforementioned, SHM methods, particularly the EMI method, have been widely investigated in RC subassemblies. However, there has been a dearth of research concerning entire RC structures. Kaur et al. examine the effectiveness of the EMI method in evaluating the pre-stressing force losses in the Sarey

Kale Khan Bridge in New Delhi [23]. Moreover, Liao and Chiu investigate a PZT-based active sensing system designed for SHM of a one-bay, two-story RC space frame structure subjected to seismic loads [24]. A distributed array of PZT SAs was utilized, with specific units designated as actuators while others function as sensors. This approach contrasts with the EMI method, which employs the smart aggregates in dual roles as both actuators and sensors concurrently. Consequently, the EMI method requires fewer PZT transducers to monitor the same structure.

In this work, PZT transducers were embedded as smart aggregates in a one-bay, one-story RC space frame structure. Specifically, three PZT sensors were strategically positioned along the height of the RC columns for EMI-based SHM. Subsequently, the RC space frame underwent testing on a shaking table, with the Peak Ground Acceleration (PGA) level incrementally increased. To attain this incremental loading, a spectrogram of the substantial ground motion that significantly impacted Thessaloniki in 1978 was meticulously altered and determined the dynamic motion of the shaking table. Between the seismic sequences, the EMI responses of the PZT transducers were captured via a novel autonomous monitoring device. The obtained EMI signatures were utilized to expedite the identification of damage within the RC columns during the shake table test. The results underscore the viability and sensitivity of the EMI-based methodology for SHM of RC space frame structures subjected to seismic excitations.

## 2 ELECTROMECHANICAL IMPEDANCE METHOD

As previously indicated, the EMI method capitalizes on the unique characteristics of piezoelectric materials to generate surface electric charges when these materials are subjected to mechanical stress and experience mechanical deformation in response to an electric field [25,26]. Consequently, the reduction in mechanical impedance, associated with the formation of damage in RC members, significantly impacts the electrical impedance of a mounted piezoelectric transducer under harmonic excitation [27]. Furthermore, the EMI signatures of the attached piezoelectric transducers are frequently measured within a predefined frequency band. Any alteration in the EMI signature of each piezoelectric transducer signifies the development of structural damage in its vicinity. Therefore, numerous studies examine the interaction between an attached PZT transducer and the host structure, as exemplified in the work of Liang et al., who model this interaction [28].

In this study, a custom impedance analyzer excites the PZT transducers within a wide frequency range while simultaneously capturing the corresponding signals. Expressly, the EMI signature's frequency range was set between 10 and 250 kHz, with a resolution of 1 kHz. Initially, a set of measurements was taken before any seismic excitation to document the signatures of the PZTs in the healthy condition of the RC space frame structure. Subsequently, the EMI response of the PZT patches was recorded subsequent to the conclusion of each seismic excitation, while the specimen remained at rest. Then, each alteration of the EMI signature indicates the formation of damage in the monitoring area of each PZT sensor.

The interaction between the monitored structure and the PZT transducer significantly influences the EMI signature of the PZT. Consequently, the mechanical properties, including mass, damping, and Young's modulus, are reflected in the EMI signature of PZT due to these interactions. According to Bhalla and Soh, the interaction between the PZT transducer and the RC structure is depicted as an impedance signature that consists of resistance (the real component) and reactance (the imaginary component), as specified in Equation (1) for the complex impedance,  $Z(\omega)$ , of the affixed PZT transducer [29].

$$Z(\omega) = \frac{h}{2L^2\omega j} \left[ \bar{\epsilon}_{33}^T - d_{31}^2 \bar{Y}^E + \left( \frac{Z_a}{Z_s + Z_a} \right) d_{31}^2 \bar{Y}^E \left( \frac{\tan kL}{kL} \right) \right]^{-1} \quad (1)$$

h	PZT Thickness	k	wave number
L	Half-length of the PZT	$Z_a$	Effective mechanical impedance
$\omega$	Angular frequency	$Z_s$	Effective structural impedance
j	Imaginary unit	$d_{31}$	Piezoelectric strain coefficient
$\bar{\epsilon}_{33}^T$	Complex electric permittivity	$\bar{Y}^E$	Complex Young's modulus of the elasticity

Consequently, as indicated by Equation (1), any alterations observed in the electrical impedance of the connected PZT transducer arise from variations in the mechanical impedance of the monitored area, given that the other components of Equation (1) remain unaltered. Thus, notable variations in the EMI response measurements suggest the possibility of structural degradation in the monitored structure.

Researchers usually employ statistical scalar indices to quantify the damage from the EMI responses of the smart aggregates. This study uses the widely utilized damage index, Root Mean Square Deviation (RMSD). The RMSD quantifies the variations between the output signals at the pristine condition and after each loading sequence, according to Equation (2).

$$RMSD = \sqrt{\frac{\sum_{i=1}^N (|V_p(f)|_D - |V_p(f)|_H)^2}{\sum_{i=1}^N (|V_p(f)|_H)^2}} \quad (2)$$

Where:  $|V_p(f)|_H$  represents the absolute value of the voltage output signal extracted from the smart aggregate under the pristine condition of the RC structure,  $|V_p(f)|_D$  denotes the absolute value of the corresponding voltage output signal measured from the same smart aggregate at damage level D, and  $N$  is the discrete number of measurements taken within the frequency band of 10-250 kHz.

## 3 EXPERIMENTAL PROGRAM

### 3.1 Materials and Specimen

This experimental investigation entails casting a one-bay, one-story RC space frame structure, with four RC columns, four beams, a slab, four cantilevers and four infill masonry walls, all designed in accordance with old code provisions (1970s), before the adoption of current Eurocodes 2 and 8 or the New Greek Seismic Code for Concrete Structures. Furthermore, the specimen was scaled at a ratio of 1:3 in accordance with the capacity of the laboratory's shake table,

which possessed a maximum tested structure mass of 8 tons and a maximum overturning moment of 8 ton-m. Therefore, the mass of the specimens was adjusted to 4.3 tonnes, which is less than the maximum bearing capacity of the shake table. The clear span of the specimen's beam measured 1.24 meters, and the clear height of the specimen's columns was 1.0 meters. The concrete utilized in this study was of a C20/25 grade, and the reinforcement employed was referenced as B500C for the slab and foundation and for the longitudinal reinforcement of the columns and S220 for the column stirrup. The column cross-section was set to 13×13 centimeters, and the reinforcement of the specimen was four longitudinal reinforcement bars, each measuring 8 millimeters in diameter, strategically positioned at each corner. Additionally, a closed smooth steel stirrup measuring 5,5 millimeters in diameter was placed every 6 centimeters to serve as transverse reinforcement. A reinforced concrete (RC) slab, which incorporates four balconies and four hidden beams, was constructed with a thickness of 20 centimeters on top of the columns. This heavily reinforced slab was utilized to drive the potential damage in the RC columns and the brick infill panels as well as to allow for additional mass due to renovations involving greenery (with special reference to Thessaloniki metropolitan area). Although the occurrence of damage in vertical structural components is undesirable under current seismic regulations, it is prevalent in existing buildings constructed under older standards (strong slab or beams and weak columns). Figure 1 illustrates the specimen positioned on the shake table in the pristine condition.

Figure 1. RC frame test setup.

### 3.2 Adopted SHM Scheme

As mentioned above, this study investigates a PZT-enabled EMI-based SHM approach for the SHM of a one-bay, one-story RC concrete structure. Thus, several PZT transducers were embedded as smart aggregates in the RC frame specimen. The fabrication of smart aggregates involves several stages. Initially, two lead wires were welded to the two poles of the PZT patch, and the functionality of the sensors was duly verified before further action steps. Subsequently, the PZT transducers were coated with a waterproof layer of epoxy resin, as illustrated in Figure 2. Then, the smart aggregates were positioned in meticulously selected locations of the RC

specimen prior to the pouring of concrete. Although various PZT sensors were employed to monitor different aspects of the specimen's structural integrity, this study focuses on the prompt diagnosis of the formation of bending cracks in the critical regions of the columns. Therefore, two piezoelectric sensors were placed at various heights along the RC columns. The PZT Up and PZT Down were positioned within the critical region, where bending cracks were expected to develop, of the RC columns for the prompt detection of bending-associated crack formation, as depicted in Figure 2. As mentioned earlier, the EMI response of each PZT was recorded using portable EMI-based monitoring devices capable of capturing the EMI response of PZT transducers within the frequency spectrum of 10-250 kHz.

Figure 2. Ready to implement Smart Aggregate.

### 3.3 Shake Table Test Setup

The shake table tests were conducted at the laboratory of Reinforced Concrete and Seismic Design of Structures of Democritus University of Thrace, located in Xanthi, Greece. The shake table has dimensions of 3.4 m by 3.4 m and a maximum velocity of 1.2 m/sec. Furthermore, it possesses a maximum uniaxial acceleration capacity of 1.6g for a payload mass of eight tons and 2.9g for a payload mass of four tons. The maximum displacement capacity of the shaking table was 23 centimeters, and the range of response frequencies extended from 1.0 to 50.0 Hertz. Additionally, a dynamic capability data acquisition system acquired the data of twelve accelerometers, eight-string potentiometers, and 20 strain gauges. Three out of the 12 accelerometers were used to measure the out-of-plane acceleration of the infills. Four-string potentiometers were used to calculate the story drift of the RC structure, while the

remaining devices were used to evaluate the deformation associated with the in-plane response of the infills. Furthermore, appropriate markers for vision-based SHM were strategically positioned on the surfaces of the specimens and employed to extract the displacement field from videos captured by two cameras positioned perpendicularly.

The dynamic loading involved the gradual increment of PGA levels up to 1.1g peak acceleration, based on the employed earthquake component from Thessaloniki in the north-south direction (peak acceleration of 0.14g with main excitation frequencies ranging from 2 Hz to 10 Hz and minor excitation frequencies beyond 26 Hz). The seismic event occurred on 20 June 1978 at 20:03:21 in the epicenter 30 kilometers east of Thessaloniki, revealing the susceptibility of urban centers to such natural disasters. According to Theodulidis et al., 4000 buildings experienced serious, 13000 moderate, and 49000 minor damage [30]. The north-south component of the strong ground motion record at the Thessaloniki-City Hotel station, situated 29 kilometers from the epicenter, offered the ground excitation time history utilized during the dynamic tests, as illustrated in Figure 3. Subsequently, this sequence has been meticulously adjusted to stimulate the specimen with peak accelerations of up to 0.1g, 0.2g, 0.5g, 0.8g, and 1.1g, following a dynamic pushover approach. The ultimate level of the first phase of testing of the as-built structure (presented herein) was characteristic of a structure with RC members at Serviceability Limit States (SLS), where no yielding of steel rebars occurred and brick infills with damage initiation but no collapse. Thereafter, the EMI response of all the PZT sensors was recorded following each excitation.

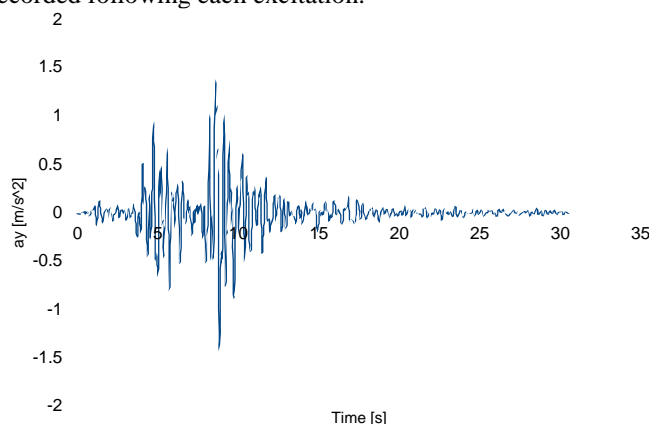

Figure 3. Ground acceleration time history.

## 4 TEST RESULTS

### 4.1 Cracking patterns of RC columns

This sub-section addresses the earthquake-induced damage of the specimen and its observed cracking pattern. The specimen underwent five progressively enhancing sequences of ground excitation. After the third test run, which corresponds to a peak acceleration of 0.5g, some slight surface cracks were observed in the lower region of the RC columns. Therefore, the EMI response captured after the first and second test runs was designated as pre-crack, in conjunction with the EMI response measured under pristine structural conditions. Conversely, the EMI response obtained following the third test run, and the formation of the first cracks, was classified as post-crack. The

cracks were further propagated during the subsequent loading sequences. Figure 4 illustrates the damage condition of the RC column Y1 after all the loading sequences. A bending crack was formed in the lower region of the column, in proximity to the PZT Y1B. Despite the crack propagating through the entirety of the column's cross-section, the measured width of the crack along with the recorded reinforcement strain suggests that the damage sustained was not severe.

Figure 4. Damage state of RC column Y1

Furthermore, Figure 5 depicts the damage condition of the reinforced concrete column Y2 following the completion of the final loading sequences. In contrast to column Y1, column Y2 was in contact with infills in the biaxial direction. Notwithstanding the fact that the in-plane infill did not encompass the entire span, it nonetheless merely enhanced the load-bearing capacity and the overall stiffness of the specimen. A minor bending crack has developed in the lower region of column Y2, which was sustained in a portion of the column's cross-section, in contrast to the bending crack of column Y1. This may have been attributed to the beneficial contribution of the brick infill. Similarly to column Y1, the crack width and the steel reinforcement strain indicate that the damage sustained was not severe. Therefore, although cracks developed in the RC columns and the brick infill, the structural condition of the space RC frame specimen is categorized within the SLS, as determined by the experimental design for the initial testing phase, as previously noted.

Figure 5. Damage state of RC column Y2

#### 4.2 The EMI response of smart aggregates

This sub-section presents the EMI response of each PZT transducer in terms of  $V_p$ —excitation frequency, as captured with the RC specimen at rest. The EMI responses were measured across a broad frequency spectrum from 10 to 250 kHz. Figure 6 illustrates the EMI response of PZT Y1B, which was placed in the lower region of column Y1. The EMI response of PZT Y1B demonstrated a leftward shift subsequent to the formation of a bending crack in its vicinity. Furthermore, the EMI response does not demonstrate any additional alterations, which aligns with the observed cracking pattern, where the crack width remains constant. Thus, the proposed SHM scheme promptly identifies the formation of the bending crack in the lower region of the column through the alterations of the PZT Y1B EMI responses.

Figure 6. The EMI response of PZT Y1B

Figure 7 shows the EMI response of PZT Y1T, which was placed in the upper region of column Y1. In contrast to the smart aggregate PZT Y1B, the EMI response of PZT Y1T does not vary significantly, as verified by the RMSD values in the following subsection. These findings are consistent with the column's observed crack patterns, wherein the fissure developed in its lower region, as depicted in Figure 4.

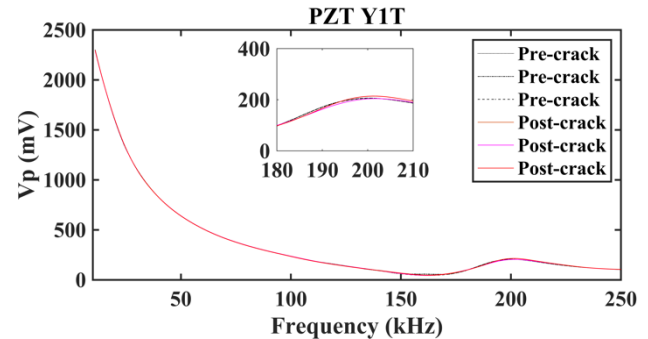

Figure 7. The EMI response of PZT Y1T

Figure 8 depicts the EMI response of PZT Y2B, which was placed in the lower region of column Y2. The EMI response exhibits a subtle peak shift resulting from the development of a bending crack in proximity to the smart aggregate. This is in line with the observed crack patterns of column Y2, as illustrated in Figure 5.

Figure 8. The EMI response of PZT Y2B

Figure 9 illustrates the EMI response of PZT Y2T, which was placed in the upper region of column Y2. No observable alterations in the EMI response of the smart aggregate PZT Y2T, which may be attributed to the distance of the formed bending crack.

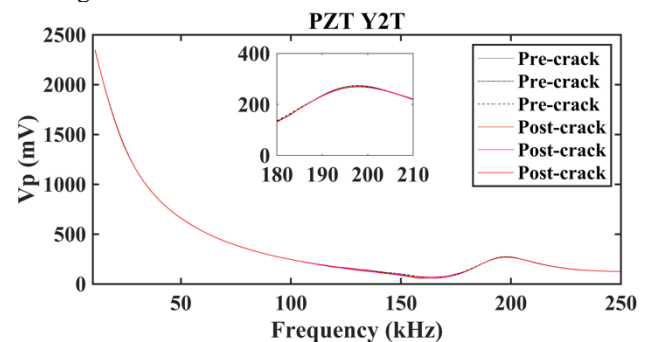

Figure 9. The EMI response of PZT Y2T

#### 4.3 The RMSD

As previously mentioned, the RMSD damage index utilized to quantify the variations in the EMI responses of PZTs in this

study. Figure 10 illustrates the RMSD values of the smart aggregates situated in the upper and lower sections of Column 1. Evidently, the development of a bending crack in column Y1 initiates a significant increase in the RMSD values of PZT Y1B, escalating from 0.5% to 3.2%. On the contrary, the RMSD values of PZT Y1T remain around 0.5 throughout the seismic sequences.

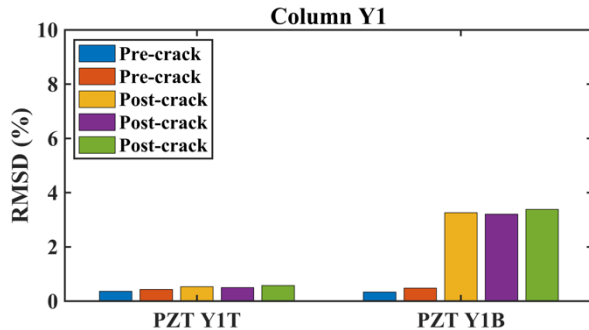

Figure 10. RMSD damage index values pertaining to the smart aggregates in Column Y1

Additionally, Figure 11 depicts the RMSD values of the corresponding smart aggregates of column 2. Similarly, the RMSD values of PZT Y2B demonstrate a significant increase, rising from 0.4% to 6%. Thus, PZT Y2B has effectively identified the development of a bending crack in the lower section of column Y2. Furthermore, RMSD values of PZT Y2T fluctuated between 0.5 and 0.7 during the seismic sequences. Consequently, the SHM scheme indicates that damage has occurred in the lower region of both columns, which aligns with the observations.

Figure 11. RMSD damage index values pertaining to the smart aggregates in Column Y2

## 5 CONCLUSIONS

This study addresses the feasibility of the EMI method for SHM of a one-bay, one-floor space RC frame structure subjected to earthquake excitations. The specimen was subjected to various percentages of PGA of a strong seismic event, resulting in bending cracks in the lower regions of the specimen's RC columns. The structural integrity has been classified into two distinct categories, referred to as pre-crack and post-crack. The EMI method effectively identified the formation of cracks through the variation induced in the EMI responses of the smart aggregates, indicating its feasibility for the SHM of RC structures. Additionally, it successfully localized these cracks within the lower regions of the specimen's columns. SHM was successful even though this

study was limited to minor damage conditions, relatively close to SLS of RC structures. Such RC damages are hard to detect as the residual drift of the structure is negligible. Subsequent research should further explore the efficacy of the EMI method under conditions approaching the near-collapse damage condition of RC structures as well as the effects due to additional mass after innovative renovations.

**ABSTRACT:** Material ageing, such as corrosion of reinforcements or damage to geotechnical tension elements, can lead, among other effects, to load redistribution mechanisms at the interface of structure and the adjacent soil. These mechanisms are difficult to capture, as analytical calculations are not practical and three-dimensional numerical simulations, utilizing advanced constitutive laws require sufficient monitoring data to validate the calculations. Consequently, it is difficult to determine the reliability of damaged structures. To improve existing knowledge in this field, a test setup simulating an anchor wall was developed, to provide calibration data for numerical studies and to evaluate load redistribution mechanisms at the soil-structure interface in general. In this context, newly developed Tactile Pressure Sensors (TPS) were tested for their suitability as an additional monitoring tool, to record changes in compressive stress at the interface and consequently, to complement conventional monitoring devices used for deformation and force measurements. Such TPS can enable the visualization of an approximate compressive stress distribution across the entire interface, utilizing 576 individual sensing elements over an area of 1.50 m<sup>2</sup> to monitor changes in stress. Thus, additional data is provided to improve the evaluation of load redistribution mechanisms and to be used as validation data for numerical models.

**KEY WORDS:** tactile pressure sensors, piezoresistive sensors, geotechnical testing, experiment, validation.

## 1 INTRODUCTION

Anchored retaining structures are commonly used as an economical solution for the long-term stabilization of steep slopes or deep cuts along infrastructure routes. To ensure their reliability - encompassing durability, serviceability and load-bearing capacity - regular maintenance and inspection is essential throughout their intended service life [1][2]. These inspections often reveal damage, and in some cases, failure of the metallic tension elements. Corrosion represents the most significant challenge for pre-stressed ground anchors and reinforced concrete structures in general, which can lead to significant damage (up to failure) of the tension elements, affecting the load-bearing behavior of the structure. This may lead to a redistribution of forces, both within the retained soil and the structure itself. This redistribution can ultimately result in the failure of additional (adjacent) ground anchors and unexpected deformations of the retaining structure.

Currently, engineers are dealing with limited guidelines and regulations to assess such effects, caused by damage or failure, impacting the load-bearing capacity and, consequently, the safety of the structure. In this context, complex three-dimensional numerical models, regardless of their resource intensity, are inevitable to provide a reliable safety assessment. Such models are essential to determine the probability of critical failure mechanisms and their location within the soil body, which is mandatory for many existing anchored structures. To provide valid calculation data, these numerical models must be calibrated accordingly and therefore require a suitable amount of measurement data, e.g. on deformations and stresses. As such data is usually not sufficiently available for

existing structures, it is necessary to evaluate the expected behavior of the structure in the event of an anchor failure differently. For example, in mid-scale experiments, which combined with numerical models allow for an upscaling of the results to come up with recommendations concerning the assessment of existing structures possibly at risk. Based on this consideration, it would also be highly beneficial to consider an appropriate monitoring concept for future structures.

This paper describes a mid-scale test facility for simulating anchor failures and investigating the resulting load redistribution effects in the soil body and at the soil-structure interface. The studies provide more information on the sensitivity of anchored structures to tension element failure and help identify critical areas for potential future monitoring. To improve the quantity and quality of data obtained from the experiments, a newly developed measurement system is presented. These, so called Tactile Pressure Sensors (TPS), should enable an approximate two-dimensional recording of the stress field at the soil-structure interface and thus provide an extended amount of data for the calibration of numerical models and the interpretation of the experiment itself. The content includes an initial assessment of the capabilities of the TPS mentioned. Accordingly, an investigation of the sensors' performance under geotechnical constraints, considering the boundary conditions in the test setup, took place. Additionally, first results for the simulation of an anchor failure, monitored by classic load cells and displacement transducers, are presented.

## 2 TACTILE PRESSURE SENSORS

Standard earth pressure cells only provide a punctual recording of the compressive stress at the soil-structure interface, whereas the pressure distribution itself ideally needs to be monitored in a two-dimensional way. Thus, the evaluation of the problem in its entirety requires an alternative measurement system which provides a higher measurement resolution and consequently a better database to examine load redistribution effects due to anchor failure.

Tactile Pressure Sensors have been used in geotechnical experiments since the 1990s [3] and have been part of many experiments and publications since [4][5][6]. Due to their low-profile architecture and the amount of measurement points per area, they can be generally applied to determine the stress distribution between two structures. In geotechnical engineering such measuring equipment is used to determine the soil-structure interaction or the load transfer between two soil bodies in various setups, especially in geotechnical centrifuge testing [7][8]. According to previous experiences made with such sensors, the technology seemed to be suitable for the given task. Unfortunately, well-known TPS, although applicable in terms of metrological performance, did not meet the requirements of the planned testing series. Mainly caused by limitations in terms of geometry, robustness and high costs. Thus, it was necessary to find an alternative system which better addresses the requirements resulting from soil-structure interaction within the mid-scale experiment.

Figure 1. Sensor design.

The chosen TPS, developed by sendance GmbH, leverages the physical principle of piezoresistivity for pressure detection. The core sensing element consists of a circular 0.1 mm thin layer of piezoresistive material, with a diameter of 3.5 mm, that electrically connects two electrodes. The simplified sensor design is shown in Figure 1. Under compressive stress, the sensor's electrical resistance diminishes from values exceeding MΩs to tens of kΩ. During measurement, a 3.3V supply voltage is applied to one electrode. The other electrode is connected to a microcontroller with a 12-bit Analog-to-Digital Converter (ADC) and a 20 kΩ reference resistor connected to ground (GND). This voltage divider configuration allows the microcontroller to measure the voltage change resulting from the sensor's resistance variation, caused by the compressive stress acting on the piezoresistive material. To ensure a more uniform pressure distribution on the piezoresistive material and enhance the system's robustness, the TPS and its wires are encapsulated in a silicone coating, achieving a total thickness of 1 mm. To compensate for the production variability of sensors and to achieve more accurate readings, each sensor is

individually calibrated. The sensors are usually calibrated by 36 load-steps spread over the range of 0 to 500 kPa or lower, depending on the area of interest. At each load-step, the corresponding ADC value, and the acting compressive stress in kilopascals are recorded. These calibration data pairs each define one calibration point, which collectively form the calibration curve.

This data is subsequently stored within the readout electronics, and linear interpolation between the individual calibration points is used to determine the pressure corresponding to any measured ADC value not directly provided by the calibration points themselves. As the devices are tailor-made, the sensors can be arranged in any formation, limited only by the space required for wiring. Figure 2 shows a TPS example with a 4x4 grid formation, used for small-scale testing to evaluate sensor performance. In general, each sensor row (horizontal) shares one supply line and each column (vertical) shares one readout line to minimize wiring amount and complexity. Only one supply and one readout line are active at any given time, allowing for a sequential readout of the sensors with a rate of up to 150 Hz using Bluetooth®. To prevent crosstalk between sensors, which means they would influence each other's readings, a diode is added to each sensor.

Figure 2. TPS for performance testing (small-scale), placed on pressure chamber baseplate.

The accuracy of the TPS is influenced by several factors, including the homogeneity of the applied pressure, the utilized pressure range, and the duration of the applied load. Consequently, the accuracy of the system must be determined within the field of application.

To evaluate the performance of the sensors under geotechnical conditions and to confirm the suitability of the TPS for the intended application within the mid-scale tests, some information on performance evaluation is provided in the following chapters. The focus is on the precision (repeatability) of the system's measurements, including soils.

### 3 TEST SETUP & METHODS

Mid-scale model tests on anchor failure are conducted in a test box (see Figure 3) with dimensions of 1.00 m (width), 1.50 m (height) and 3.00 m (length). Within the test box, a retaining wall is constructed using nine individual steel elements arranged in a 3 x 3 grid, rigidly connected in both horizontal and vertical directions. The retaining wall is backfilled with gravel (4/8 mm rounded grains). To simplify the assembly process, the ground anchors are represented by horizontally installed bracing units (struts) placed outside the soil body. These struts, which are subjected to compressive loads, rest on a horizontal abutment in front of the retaining wall. Each strut can be individually pre-stressed by applying torque, allowing for different test configurations. Individual struts are released to observe the system's response during the failure simulation. Force measurements, using load cells, are taken at each of the nine contact points between the retaining wall and the struts to capture the resulting force redistribution. Additionally, displacement transducers were installed to monitor wall deformation. These measurements have not been incorporated into this study, as the primary focus lies on the load redistribution.

Figure 3. Test setup during assembly.

Figure 3 illustrates the test set-up during the assembly process. The labelling scheme is as follows: from left to right, the axes are labelled A to C, while from bottom to top, the anchor rows are designated 1 to 3. For example, the central anchor is labelled B2. Additional details on the set-up can be found in [9].

Although the change in force, measured by the installed load cells, already allows some interpretation of the mechanical processes during the experiment, providing more data, to e.g. validate a numerical model for post-processing purposes,

would be highly beneficial. Furthermore, more data would be crucial to come up with a comprehensive conclusion about the occurring load redistribution effects.

Consequently, it was decided to integrate the previously described TPS into the testing facility, positioned at the soil-structure interface (see Figure 3), to analyze the acting compressive stresses. For this purpose, a sensor arrangement was designed which allows for 64 sensors on each of the nine individual steel elements (see Figure 4) which results in 576 individual measurement points evenly distributed over the entire back-side of the retaining wall, covering an area of 1.50 m<sup>2</sup>. Compared to the force measurements with just nine load cells, the TPS enables an approximately two-dimensional analysis of the stress field at the soil-structure interface and therefore allows a detailed interpretation of spatial mechanisms caused by the load redistribution within the soil body (e.g. arching effects) due to anchor failure.

Figure 4. TPS configuration for mid-scale test.

The TPS system must be calibrated and tested in the geotechnical environment to obtain accurate sensor readings within the mid-scale model. While the entirety of the grid is encapsulated in silicone, the sensors are exclusively present in specific regions of the sensor grid, which causes the TPS to be inhomogeneously stiff. Areas where sensors are situated exhibit a higher stiffness than areas without any sensors present. Thus, applying stress to the TPS by e.g. a stiff loading plate doesn't allow for an accurate calibration or repeatable testing. Single-point calibration/testing on the other hand, with e.g. a load-stamp, would result in a significant testing effort. In addition, the use of a load stamp would prevent reliable repeatability, as the stamp would have to be positioned at the same spot on the sensor (diameter = 3.5 mm) each time, which cannot be guaranteed with a manual process, as was observed in preliminary studies.

Therefore, the testing and calibration is performed using a calibration chamber, designed to apply air pressure to the sensor grid. This approach satisfies the need for an evenly distributed compressive stress on the system (isobaric stress state), which is not affected by any inhomogeneities in the system's stiffness, which could possibly lead to a misinterpretation of the applied stress. Additionally, air pressure is well controllable, and the calibration steps can be chosen flexibly. Concerning measurements incorporating soils, a membrane was introduced to enhance the calibration chamber's suitability. This advancement allows air pressure, distributed by the membrane, to act across the soil grains, onto the TPS. This prevents additional air pressure being applied to

the system, which could act between the grains, although all loads should only be transferred by the soil grains themselves.

First tests to evaluate the TPS' accuracy were performed under load application by air pressure only - without any soils incorporated - to assess the sensors' performance under fully controllable and repeatable conditions. This ensured benchmark measurements that reflect the pure performance of the TPS in the pressure chamber, without the effects of uneven loading from soil grains, etc. This data can later be used for comparison with measurements of the TPS in soils to put the sensors' performance in different environmental conditions into perspective.

Subsequently, the systems suitability for application in the geotechnical environment was evaluated. Thus, soil samples with different grain size distributions (GSDs) were prepared to investigate the maximum grain size ( $D_{max}$ ) suitable for the TPS, as well as to generally analyze differences in performance due to the GSD. Sample preparation aimed for very narrow GSDs to isolate the critical grain size. Furthermore, angular grains were utilized for the tests, as these may cause more distortion in the sensor readings compared to round grains and thus represent a 'worst-case' scenario in terms of sensor performance and robustness, which provides the most information concerning the overall performance of the TPS.

#### 4 FIRST TESTS AND RESULTS

Preliminary studies concerning the TPS performance are shown below. All described tests were executed in the previously mentioned pressure chamber, using a 4x4 grid (16 sensors), which is illustrated in Figure 2. To characterize the TPS for the use under geotechnical constraints, the systems accuracy must be investigated in terms of precision and trueness, according to [10]. The outlined experiments mainly focus on the precision of the TPS, also defined as the repeatability of measurements. In addition to the studies concerning the TPS, initial experiments simulating anchor failure within the mid-scale test facility were carried out. The results of these tests are also presented and discussed below.

##### 4.1 Preliminary studies - TPS

In the following, the term 'representative sensor' always refers to one and the same sensor on the grid to ensure comparability of different measurements. The presented measurements were carried out by applying air pressure on the sensors.

First, all 16 sensors were calibrated, according to the calibration procedure, described in chapter 2. Afterwards the first test series was performed, which consisted of four individual tests with 10 load cycles – loading and unloading – of the entire sensor grid.

Figure 5. Recorded load-cycle for a representative sensor.

Figure 5 illustrates the recorded measurements for a representative sensor at a maximum pressure of 100 kPa, for one individual test.

Peak values were detected and marked with a red cross. Determining the mean value of the peak values per load-cycle, results in 10 measurements per sensor, per test, which corresponds to 160 values for the entire TPS. To simplify these results, only one mean value was calculated per sensor and test across all peak values. Subsequently, an average value was calculated from the measurements of all 16 sensors, representing the entire system, assuming a smeared performance as relevant. This approach represents an evaluation of the overall performance of the TPS, while studies on individual sensors are presented later.

Table 1 shows the mean value  $\bar{p}$  (measured compression stresses) for each individual test, as well as the global mean value  $\mu$ , the standard deviation  $\sigma$ , and the relative error  $\delta$  across all tests, at certain pressure levels  $PL$ , for the entire TPS.

Table 1. Preliminary evaluation of TPS performance

$PL$ [kPa]	$\bar{p}$ [kPa]	$\mu$ [kPa]	$\sigma$ [kPa]	$\delta$ [%]
100	98.56	96.31	4.01	3.69
	91.20			
	100.31			
	95.18			
200	195.30	195.27	2.85	2.37
	193.32			
	199.86			
	194.58			
300	290.73	295.51	3.42	1.50
	297.81			
	294.72			
	298.79			

First tests showed good results with a maximum relative error of 3.69 % at a pressure level of 100 kPa as well as 2.37 % and 1.50 % at 200 and 300 kPa respectively. Furthermore, the calculated standard deviations show a good consistency of the measurements.

To extend these first investigations, additional studies were conducted. As part of these studies, predefined load steps were performed and the corresponding ADC outputs from the TPS were analyzed. This allowed for a more descriptive interpretation of the sensor performance and avoided any distortion of the measurements due to linear interpolation and statistical processing of the test results. Thus, six tests were performed with load steps evenly distributed over a range of 0 to 300 kPa, resulting in one curve per sensor per test (run).

Figure 6 shows the measurement results for a representative sensor for all six runs labeled Run 1 to Run 6. The results can be considered promising as the curves show good repeatability, which is consistent with the results shown in Table 1. Especially at higher pressures, from 200 kPa onwards, the agreement of the individual measurement points is good, while at pressures below 100 kPa a certain deviation can be observed, which, however, is not critical. These results agree well with the previous observations, which confirms the initial assessment of the overall TPS' precision.

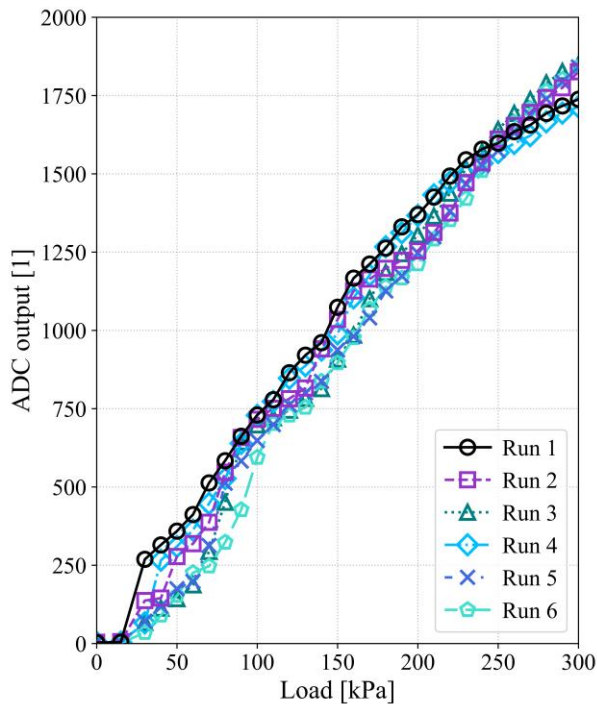

Figure 6. Precision test without soil for a representative sensor.

Proceeding with the test series, the TPS' performance was evaluated incorporating soils, simulating the application of the system at the soil-structure interface. The aim of these investigations was to evaluate the influence of soils with different maximum grain sizes on the accuracy of the sensors and to compare these findings with the results shown in Figure 6. To allow for comparison between the different test series the following studies were performed in line with the previously described procedures, apart from including a membrane, as explained in chapter 3. This test series should allow a statement related to the maximum tolerable grain size without a drastic reduction in sensor performance, which is considered mandatory to evaluate the applicability of the TPS in the mid-scale experiments. All tests were carried out with the same TPS system used previously.

Five samples with different grain size distributions were utilized, allowing a continuous increase in  $D_{max}$ . The samples were mainly coarse grained (angular grains) and contained little to no fine grains. All samples were artificially prepared by sieving a large soil sample into different GSDs, which ranged from 0/0.8 mm, with  $D_{max} = 0.8$  mm, to 2/4 mm, with  $D_{max} = 4$  mm and  $D_{min} = 2$  mm.

Figure 7 illustrates the results for this test campaign, comparing a representative air pressure curve (Run 1), labelled as 'Air', from Figure 6, with five curves including soils with different GSDs. The curves differ in the lower load range, up to  $\sim 100$  kPa, whilst the repeatability seems to improve with pressure levels above 100 kPa. Both effects have also been identified in the previous tests.

The results show good repeatability, and the influence of grain size appears to be negligible up to a  $D_{max}$  of 2 mm. Though, grain sizes above 2 mm seem to cause a change in sensor performance. Curve 2/4 (orange) shows significantly lower ADC outputs, from 150 kPa and onwards, than all other

curves. In general, it is assumed that the silicone coating of the TPS acts like a thin load distribution layer, which provides good sensor performance if  $D_{max} \leq 2$  mm, as these measurements agree well with the air pressure reference curves. However, the load distribution effect of the silicone doesn't appear to be suitable for dealing with larger grain sizes.

Figure 7. Influence of grain size (angular grains) on sensor curve for a representative sensor.

To summarize, the preliminary investigations on the sensor performance have shown the potential of the system for its application in the geotechnical environment. Soil with a grain size below 2 mm does not seem to negatively affect the sensor performance. However, it will be necessary to implement some kind of load distribution layer to improve the TPS for the application in larger grain sizes. As the material used in the mid-scale tests has a grain size above 4 mm, it is essential to adapt the TPS accordingly. This allows its application within the setup and enables the collection of more spatial information on load redistribution mechanisms.

#### 4.2 Mid-scale test facility

Figure 8 and Figure 9 present the initial evaluations of anchor failure simulations, conducted by setting the compressive load along individual struts to zero. Both figures show the modelled retaining wall, with the steel elements arranged in a 3 x 3 grid, following the labelling scheme from Figure 3. The failed anchor is marked with a red cross, and the changes in load, both in percentage and absolute terms, are shown for all remaining anchors. The failure simulations started from nearly identical stress states, with anchor rows 1, 2 and 3 pre-stressed to approximately 7 kN, 5 kN and 2 kN, respectively.

Figure 8 illustrates the first failure simulation, which assumed the central anchor B2 to fail. The results clearly show that the load redistribution following the failure of anchor B2 is almost symmetrical. In absolute terms, the majority of the redistributed load is transferred to the adjacent anchors on the

left (A2) and right (C2), rather than those above (B3) or below (B1). The largest increase, considering absolute terms, occurs at anchor A2, which increases by 0.95 kN, a 20% rise from its pre-stressing load of about 5 kN. However, in percentage terms, the largest increase is observed at anchor B3, which experiences a 24% increase from its pre-stressing force of approximately 2 kN (equivalent to an absolute increase of 0.52 kN). The anchors located in the corners (i.e. A1, C1, A3 and C3) play a minor role in the load redistribution.

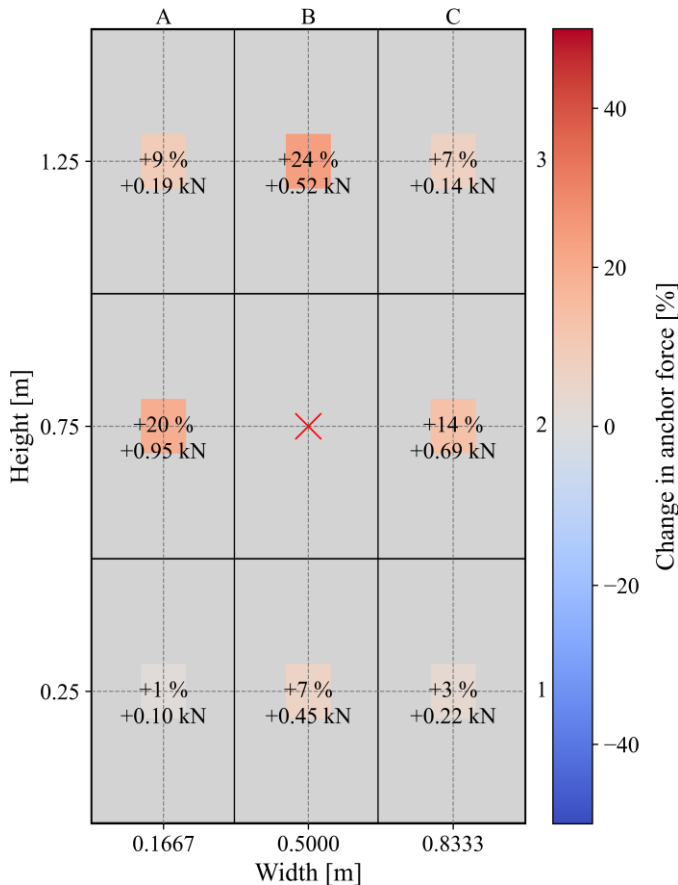

Figure 8. Failure simulation of anchor B2, adapted from [11].

In contrast, Figure 9 shows that the load redistribution following the failure of anchor A2 is more complex. The majority of the redistributed load is again transferred to the adjacent anchor on the right (B2), which increases by 1.23 kN, corresponding to a 28% increase from its pre-stressing load. However, anchor C2 experiences a significant load decrease of 1.04 kN, or -24%, from its pre-stressing load. Similar to the load redistribution pattern of the failed anchor B2 (see Figure 8), the maximum percentage increase occurs at the anchor directly above the failed element. In this case, anchor A3 shows a 50% increase from its pre-stressing load, which corresponds to a 0.60 kN increase.

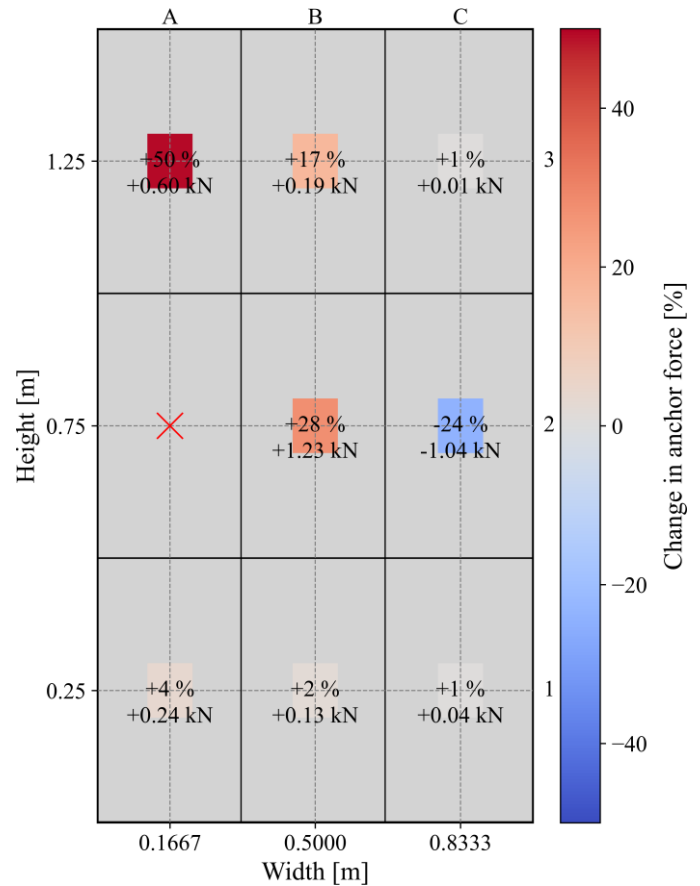

Figure 9. Failure simulation of anchor A2, adapted from [11].

As the measurement concept of the previously described tests only allowed for the evaluation of total force acting on the nine steel elements, future experiments need to conduct additional instrumentation to evaluate load redistribution effects in its entirety. It is therefore planned to integrate 576 Tactile Pressure Sensors to analyze the compressive stress distribution at the soil-structure interface. This will not only allow the experiments to be evaluated in a comprehensible way but also provides enough data to calibrate a numerical model of the setup. and to perform a robust back analysis. As a result, parameter and sensitivity studies can be carried out within the numerical model. Additionally, it is also possible to adjust the model scale if required.

## 5 CONCLUSIONS & SUMMARY

Preliminary tests of the presented Tactile Pressure Sensors (TPS) showed good sensor performance in terms of precision, with a maximum relative error of 3.69 % and a standard deviation of 4.01 kPa at a compressive stress of 100 kPa and even better results at 200 and 300 kPa. Based on these results, the TPS was further tested with soils to evaluate the applicability of the system for the planned experiments. On the one hand, these tests showed promising results, as soil grains up to a size of 2 mm could apparently be handled very well. On the other hand, larger soil grains unfortunately led to distortions in the measurements. As a result, in its current state, the stand-alone TPS did not appear to be suitable for the mid-scale experiments with 4/8 mm rounded grains. Consequently, simulations of anchor failure in the mid-scale test facility were not yet carried out as planned, which meant that first trials were

monitored with only nine load cells. The performed simulations led to the observation of the following load redistribution mechanisms.

Loads released by a failing anchor were mainly redistributed to the adjacent anchors, while others did not show significant increases in load. Furthermore, some anchors experienced significant changes in their pre-stressing loads. Considering the design process of such retaining structures and the determination of the required bearing capacity of the anchors, increases in anchor force of up to 50 %, as observed, may be critical for the safety assessment of such structures.

Although these experiments have provided important information on the behavior of the anchor wall in the event of anchor failure, the test setup had some limitations that need to be addressed. In particular, the presented approach of monitoring experiments with only nine load cells considerably limits the possibilities for interpreting the tests, as the amount and resolution of measurement data is not sufficient to spatially evaluate load redistribution effects. Furthermore, these effects should ideally be evaluated in terms of stress, not force, at the entire soil-structure interface to observe mechanisms such as e.g. arching effects within the soil body. Although this cannot be achieved completely, even with the presented TPS, the approximate area coverage with 576 sensors is a considerable improvement compared to point measurements and may allow for an assumed stress field.

Though the Tactile Pressure Sensors were not yet applicable, further trials are planned to prepare them for the upcoming experiments. To reduce the TPS' sensitivity to grain size, the concept of an additional load distribution layer between the TPS and the soil will be focused. For this purpose, a variety of elastomers with different thicknesses and stiffnesses will be considered. The aim of these studies is to identify an elastomer which offers good load distribution effects if applied to 4/8 mm rounded grains but also allows for a good measurement resolution. Additionally, it will be important to gain more knowledge concerning the sensors' performance, not only in terms of precision but also concerning trueness. Consequently, new testing rigs are in progress to allow for an appropriate testing procedure. As the TPS is fully characterized and the necessary load distribution layer is identified, the mid-scale testing will continue as planned.

## ACKNOWLEDGMENTS

**ABSTRACT:** The Balladelaan Bridge is a key bridge in the city of Amersfoort. The city has asked us to investigate the construction quality and remaining lifespan of this 5 span statically indeterminate cast-in-place concrete plate bridge, which was built in 1946. For this a pioneering long-term Structural Health Monitoring (SHM) initiative has been implemented in the form of a Field lab employing Smart Aggregates (SA's) using Coda-Wave Interferometry (CWI), augmented with extensive temperature measurements, and a short-term measurement using Acoustic Emission (AE) sensors. This study represents an extensive application of Smart Aggregates for continuous monitoring of a bridge's structural health over an extended period. The study aims to address the suitability of SA's for long term monitoring and accounting for environmental influences such as temperature and humidity on the wave speed in the concrete. Preliminary findings demonstrate a significant influence of temperature on wave speed readings, underscoring the necessity of temperature compensation in SHM analysis. After accounting for these environmental influences, the study generates critical insights into the bridge's integrity and performance. The outcomes of this research will not only enhance the understanding of the Balladelaan Bridge's condition but also establish a benchmark for future SHM projects utilizing Smart Aggregates and CWI technology.

**KEY WORDS:** SHMII-13; Smart Aggregates; Structural Health Monitoring; Concrete; Bridges; Coda Wave Interferometry; Environmental Variability.

### 1 INTRODUCTION

Concrete slab bridges designed and built in the post WWII era, are relatively sensitive to shear failure. This raises concerns about the structural capacity of these bridges and the associated remaining service life.

Structural Health Monitoring (SHM) focuses in monitoring the variation of the structural performance a given structure with respect to selected dominant failure mechanisms. When it is properly designed, it enables asset managers to continuously track the evolution of the structural integrity of the bridge from the status without acquiring all the key information of the monitoring structure. This offers a significant advantage over traditional inspection methods, which often only involve periodic visual inspections.

For this a new monitoring solution using Smart Aggregates (SA's) has been installed on the Balladelaan bridge. SA sensors can be embedded or drilled into concrete to measure (changes in) stress and crack formation between sensor pairs. The installation of this field-lab has earlier been described by Cheng et al [1]. This paper describes the results of well over 1 year of continuous monitoring using SA's.

### 2 THE BALLADELAAN BRIDGE

The bridge in the Balladelaan in Amersfoort was built in 1946. It is a cast-in-place concrete bridge with 5 spans, which together form a statically indeterminate deck system. The bridge has one bus lane (1 lane), a cycle path and a pedestrian path. The bridge was chosen for its suitability:

- The multiple span configuration of the bridge allows to focus monitoring + data analysis on local response variations over time, as an indicator of damage.
- Because there is no normal car traffic on the bridge except a bus with known schedule, there is more certainty regarding the traffic load on the bridge. This makes calibration of models easier.
- Compared to new construction, lifespan extension with risk management by means of a monitoring system results in significantly lower costs and sustainability benefits.
- The bridge represents many equivalent concrete bridges in the Netherlands, so the knowledge gained here can be used more widely.

### 3 SENSOR AND MONITORING SYSTEM

#### 3.1 Smart aggregates

Smart aggregates (SA's) are embedded piezoelectric sensors that can measure (changes in) stress and formation of cracks in concrete between two sensors using interferometry of waves through the concrete. An example of such a system is shown in Figure 4-5. They were first introduced by Song et al[3], designed for long term monitoring of concrete structures. These sensors are embedded within concrete structures. This can be prior to casting for new constructions or afterwards through a drilled hole. They generate high-frequency elastic waves and receive them within the concrete. The received wave signals are logged and eventually analyzed. There is a relation between the wave propagation velocity and the stress on the concrete. Also, there is a relation between the shape of the waves and the existing cracks in the concrete. Smart aggregates should be able to detect this.

In a typical measurement, one SA functions as the transmitter while the remaining SA's in the cluster act as receivers. When a measurement begins, the measurement order is assigned remotely, and a high-voltage electric pulse is sent to the transmitter to initiate vibration. This electric pulse is converted into a mechanical wave that propagates through the concrete. Upon reaching the receivers, the wave signals are converted back into electrical signals, recorded as 1D time-series data, and stored locally at the data station.

#### 3.2 Temperature sensors

Due to the static indeterminate structure of the bridge, it is expected that vertical temperature gradients due to sunlight will significantly influence the internal stress distribution in the bridge. The wave velocity in concrete is also temperature dependent. As these 2 factors will influence the signals measured by the smart aggregates, a significant amount of temperature sensors was installed to investigate this relationship, and in a later stage, compensate for this. Two systems were used in this particular setup:

- 1 PT1000 sensors. These are resistance-based sensors. They require a relatively short cable to a sensitive analog-to-digital converter.

- 2 DS18B20 sensors. These are digital sensors that support longer cables and can be read from a cheap microcontroller.

Both systems have a resolution of  $0.01^{\circ}\text{C}$ , and have been pre-calibrated in the lab to within  $0.1^{\circ}\text{C}$  accuracy. Part of this project was also to test the durability and reliability of both kinds of temperature sensors.

#### 3.3 Acquisition system

The monitoring system comprises a data acquisition (DAQ) system for signals received by the SA's, an ARM embedded board for temperature measurements, and a 4G router with a SIM card for communication. The DAQ system, designed and patented by Delft University of Technology (TU Delft), is optimized for ultrasound-based monitoring of concrete structures.

The DAQ system includes a pulser, pre-amplifiers, and multiplexers. Thanks to the specialized circuit board design, the pulser can generate square pulses with a magnitude of up to 300 V without interfering with the received signals. For this project a single square-wave pulse with a duration  $< 20 \mu\text{s}$  was used.

The data acquisition system supports a sampling rate of 3 MHz, enabling the recording of wave signals with frequencies up to 300 kHz without aliasing or loss of dynamics. This is well-suited for the requirements of ultrasound-based concrete monitoring applications. Each measurement lasts for 4 milliseconds from the moment the transmitter receives the electric pulse.

### 4 INSTALLATION AND DATA PROCESSING

#### 4.1 Sensor locations

Sensors have been installed in both the center span, and an end-span of the bridge. Sensor positions are shown in Figure 4-1 to Figure 4-4. Distributed data acquisition systems are below the bridge with a main station including 4G router on shore.

The distance between the top and bottom SA's in each hole is fixed at 300 mm. During installation the top SA's are consistently positioned 175 mm beneath the top surface of the bridge slab, while the bottom SA's are set 475 mm below the top surface.

Sensors are grouped in three clusters of 3-4 holes, with 2 sensors per hole. The first cluster (hole A-D) is positioned to detect flexural crack development in midspan, which is crucial for detecting bridge flexural failure. The second (E-H) monitors stress changes or crack opening at intermediate supports. The third cluster (I-K) is placed to detect the initialization or progression of diagonal cracks in shear critical zones.

Figure 4-1 Top view SA-sensor locations center span

Figure 4-2 Side view SA-sensor locations center span

Figure 4-3 Top view SA-sensor locations end span

Figure 4-4 Side view SA-sensor locations end span

#### 4.2 Installation process

Sensor preparation was conducted at TU Delft. SA's were affixed to copper wires using glue to ensure their alignment with the specified orientation and spacing, as illustrated in Figure 4-5. At select locations mentioned in Section 4, temperature sensors were also glued adjacent to the SA's on the copper wires to measure temperatures in close proximity to the sensor positions, as depicted in Figure 4-6.

The entire installation process followed these steps:

- Determining the rebar layout using a radar-based rebar detector.
- Identifying drilling locations based on the rebar layout.
- Drilling holes at the designated sensor locations
- Installing sensors into the drilled holes
- Filling the holes with high-strength mortar

- Installing the data acquisition systems and organizing cables
- Installing the main station on the bank.

Figure 4-5 SA sensor at lab.

Figure 4-6 SA sensor in the field with added temperature sensors

#### 4.3 Wave velocity processing

Changes in wave velocity are related to changes in stress-state of the concrete. The wave-velocity change can be determined by comparing the two signals in time. When the velocity changes are small (which we can assume here), we can assume a linear relation between travel time and wave velocity:

$$\frac{dv}{v} = -\frac{dt}{t}$$

This means that an increase in travel time is directly related to a decrease in velocity. We use the stretching technique to find this relative shift in time between two signals. With this technique the new signal is stretched in the time domain, relative to  $t_0$ , which starts at the departure of the wave from the sending sensor, such that it fits the other signal (reference signal). Then this shift of the time axis between the signal and the reference signal is equal to the change in velocity.

With the stretching technique, we calculate correlation coefficients of windowed signals for the different delays.

$$CC(t_c, T, \epsilon) = \frac{\int_{t_c-T}^{t_c+T} u(t)u'(t(1-\epsilon))dt}{\sqrt{\int_{t_c-T}^{t_c+T} u(t)^2 dt} \sqrt{\int_{t_c-T}^{t_c+T} u'(t(1-\epsilon))^2 dt}}$$

$t_c$  is the center of the time window,  $2T$  is the duration of the time window and  $\epsilon$  is the stretching factor. When there is an

uniform velocity change in the medium, one can assume that the correlation coefficient is maximum at the stretching factor that corresponds to the relative velocity change.

The stretching window can be chosen in different ways. It depends on the wave frequency: a window that is too short will not contain enough information. The window should also not be too large, because in that case you can no longer assume a constant time shift within the stretching window.

In this research, we limited ourselves to direct waveforms. These are the waves that travel in a straight line from one sensor to the other. One can assume that this is mainly the longitudinal / compression wave, because their wave speed is higher. Therefore, we selected a window containing only the first part of the signal, which contains approximately 2 cycles.

## 5 MEASUREMENT RESULTS

### 5.1 Initial measurements

Figure 5-1 presents a typical trace in the time domain from a measurement obtained from SA's. Similar patterns are observed for other sensor pairs but are not displayed here. The data shows a high signal to noise ratio, indicative of high quality.

Figure 5-1 Trace of 2 sensor pairs

Figure 5-2 shows how on sunny days, a large temperature gradient between the top and bottom of the deck is observed, where the top of deck heats (and cools) faster than the bottom of the deck, which lags behind. All top temperatures show similar temperatures, with 1 sensor deviating. This sensor is on the end span, where the deck has some shade from neighboring trees.

Figure 5-2 Temperatures in top and bottom of slab over 7 days

### 5.2 Wave velocity change

The resulting velocity change over time for a selected period is shown in the figure below. This period is chosen because it shows a large fluctuation in the measured temperature. The calculations are performed for two sensor pairs: A\_top to D\_top (Figure 5-3) and B\_top to C\_top (Figure 5-4). The velocity change is plotted together with the mean temperature measured in the bridge in this cluster by the temperature sensors.

Figure 5-3 Temperature and velocity change A-D

Figure 5-4 Temperature and velocity change B-C

The velocity changes in Figure 5-3 and Figure 5-4 are obtained by stretching a measurement signal until the maximum correlation between this signal and a predetermined previous signal is obtained. The resulting correlation coefficients as shown in Figure 5-5 are Figure 5-6 are an indicator of signal quality and may also indicate crack-opening. It can be seen that for the period shown the correlation coefficient is high (well over 0.8), indicating no significant crack change or deterioration of measurement equipment.

Figure 5-5 Correlation Coefficient A-D

Figure 5-6 Correlation Coefficient B-C

Figure 5-3 implies a correlation between the velocity change of sensor pair A-D (and therefore the stress state of the material) and the temperature. This correlation is also seen in the scatter from Figure 5-5. It shows that with a higher temperature, there is an increase in the velocity.

This relation can also be observed in sensor pair B-C, but with an approximately 4-hour delay. After shifting the signal by four hours, a strong correlation is found, as shown in Figure 5-8.

The relation between temperature and velocity change and the accompanying time shift is not easily understood, as the velocity change is not only directly related to average concrete temperature. Due to the 5-span static-indeterminate system, the temperature gradients also induce stress which induces a velocity change. This will be different in the different directions that the sensor pairs have (A-D and B-C). Moreover, there is an overall temperature gradient within the bridge that fluctuates over time. The delay might be explained by the combination of different temperatures in the bridge. Further work will be to further analyze the temperature-induced changes in wave velocity.

Figure 5-7 Temperature vs Velocity change A-D

Figure 5-8 Temperature vs velocity change B-C after 4hr shift

### 5.3 Long term stability

The temperature sensors perform as expected. During well over one year of measurements, the concrete temperature has varied between  $-2.62^{\circ}\text{C}$  and  $+42.20^{\circ}\text{C}$ , see Figure 5-9.

Figure 5-9 One year of temperature measurements

The digital DS18B20 sensors were unavailable for a short period of time due to a broken microcontroller, but this was easily fixed. In general, both types of sensors seem suitable for long term monitoring.

The SA-aggregates also perform well. After approximately 17 months of measurements each SA has sent and received approximately 500 days\*6 daily runs\*7 receiving SA's \* 10 stacks = 210000 pulses. The sensors have been exposed to both freezing ( $-2.62^{\circ}\text{C}$ ) and high ( $+42.20^{\circ}\text{C}$ ) temperatures, without failure. Proving the system is viable and stable for long-term measurements. Due to the nature of the system, no calibration of the built-in sensors is needed (or possible), while other sensor types may significantly degrade over time impacting repeatability.

As mentioned in 4.3 the change in wave velocity is calculated by finding the time stretching factor that results in maximum correlation coefficient between the current measurement and a specific previous measurement. The specific previous measurement may (in general) be chosen in two ways:

1. A(n average of a set of) reference measurement(s) just after installation is taken as the reference signal for all future measurements.

2. Each measurement is compared against its direct predecessor (in our case 4 hours earlier), or an average of a few direct predecessors.

After one year of measurements these two methods may be compared. Method 1 is shown in Figure 5-10. Here specific drops can be seen in early January for sensor pair A-D, and early March for pair B-C. In the first quarter of 2025 the wear-layer on the deck was replaced in multiple stages, which may have directly or indirectly caused this drop. The lower correlation coefficients may also negatively affect the accuracy of the time stretching.

Figure 5-10 Correlation coefficient relative to first measurement

To obtain the optimal time stretching high correlation coefficients are preferred. This may be achieved by method 2, comparing each signal to its direct predecessor. In our case 4 hours earlier, as shown in Figure 5-11. Here high coefficients are obtained for most of the year. But during days with large temperature changes and accompanying temperature gradients (March-October as shown in Figure 5-9) the correlation coefficients also show variation. This variation is larger than it was in previous periods with similar temperature gradients, such as August 2024. A possible explanation might be that the replacement of the wear layer has induced (micro-)cracking in the high-strength mortar that was used to fill the drilled holes of the SA's.

Figure 5-11 Correlation coefficient to 4hrs earlier

Both methods have their own advantages and disadvantages. Method 2 shows consistently high correlation coefficients, resulting in accurate stretch factors. But information about slow progressive changes over time are lost. Method 1 gives information relative to date of installation, but if the system is changed, correlation coefficients drop, and the stretch factors may be less accurate.

A solution may be found by combining both methods. Use method 1 until a significant drop in correlation coefficient is visible, indicating a change in the system which might be indicative of structural damage. Mark this point in time, and then apply all future processing relative to just after this event.

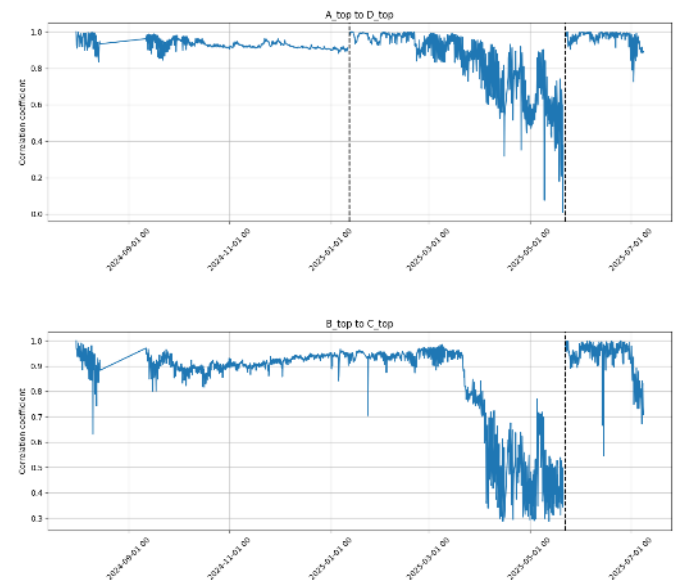

Figure 5-12 Correlation coefficient relative to previous event.

An example is shown in Figure 5-12. For 2024 the graphs are identical to method 1 as shown in Figure 5-10. For sensor pair A-D a sudden and significant change occurred in January 2025, which is marked with a vertical dashed line. Just after this

change a new reference measurement was selected, and the correlation coefficients after this time are calculated relative to this new reference. There's also a vertical dotted line in early May 2025. On this day the triggering system was reconfigured to improve time-accuracy. Therefore all measurements after this reconfiguration are compared to the first measurements since reconfiguration.

With this new processing it is clear that the low correlation coefficients of Figure 5-10 are not due to sensor degradation, since a new reference measurement can significantly improve the results. It is likely that the sudden drops in correlation coefficients are caused by structural changes in the bridge, and may be indicative of damage.

Further research is needed to determine the cause of some the low correlation outliers. A load tests with a known vehicle might be informative to relate the calculated stretch-coefficients to stress & strain. Further modelling of measured temperature gradients with a heat-flow model might also give a better understanding of the internal stress due to temperature gradients.

## 6 CONCLUSION

After well over a year of measurements, both types of temperature sensors remain operational. Suggesting there is no need for expensive analog temperature sensors and related cabling and AD converters. Cheap DS18B20 are accurate and reliable.

The Smart-Aggregate system has also performed well. While SA's are mainly used in short-term tests in the lab, our results show a life expectancy of at least 210 thousand pulses transmitted and/or received.

Work on the wear-layer of the deck is clearly visible in the correlation coefficient of sensors that are placed well below deck. Suggesting the sensors work well for long-term monitoring of structural changes. After the replacement of the wear-layer the daily variation in correlation coefficients has increased.

The selection of the reference measurement for stretching calculation has a significant influence on the resulting correlation coefficients and stretch factors. Using a fixed baseline is unfeasible because the correlation coefficient slowly degrades. Using a moving baseline however decreases insight in progressive changes. It is suggested to use a piecewise approach, where significant degradation of the correlation coefficient triggers a new reference measurement.

Results are strongly influenced by temperature, and this requires further study to separate the effects of temperature gradients from effects due to structural changes. It is advised to study this using a (simpler) statically determinate structure, where temperature gradients only result in strains, and not in stress. In this way the phenomena can be decoupled.

email: huynhtc@nus.edu.sg (T.C.H.); cgkoh@nus.edu.sg (C.G.K.)

**ABSTRACT:** This research proposes an approach for detecting damage in composite structures using the cost-effective electromechanical (EM) impedance method. By employing a piezoelectric transducer driven at high frequencies, the technique facilitates localized damage identification by tracking changes in EM impedance signatures that correspond to alterations in the structural properties caused by damage. A numerical model of a composite plate with a surface-mounted piezoelectric patch is constructed to simulate EM impedance responses under different damage conditions within the composite layers. Damage is represented by localized reductions in stiffness, simulating common failure modes such as delamination or matrix cracking. The simulation results indicate that the EM IMPEDANCE response is highly sensitive to damage within the composite plate across a wide frequency range.

**KEY WORDS:** Damage detection; Composite plate; Impedance technique; PZT; SHM

## 1 INTRODUCTION

Composite materials are increasingly adopted across various critical engineering sectors, including aerospace, marine, wind energy, and automotive, due to their exceptional strength-to-weight ratio, resistance to corrosion, and versatility in design. Despite these advantages, the complex, heterogeneous, and anisotropic characteristics of composites pose significant challenges for damage detection, as many types of damage such as delamination, matrix cracking, and fiber breakage typically begin within the material and remain hidden from surface inspection.

To maintain continuous health assessment of composite structures, a variety of structural health monitoring (SHM) strategies have been investigated, ranging from vibration analysis and acoustic emission techniques to guided wave inspection and piezoelectric-based sensing methods. Among these, the electromechanical (EM) impedance approach has emerged as a particularly effective tool for damage detection, especially in civil engineering systems [1]. This technique leverages the capabilities of a compact and economical piezoelectric sensor, which is directly attached to the surface of the structure and driven by high-frequency voltage inputs. The resulting high-frequency actuation enables the system to monitor local variations in structural behavior with high resolution, facilitating real-time identification of damage [2].

When damage occurs, it alters the local mechanical properties such as stiffness and damping, which in turn induces detectable changes in the impedance spectrum of the sensor. The short wavelengths associated with ultrasonic excitations make the method highly responsive to subtle or early-stage damage [3]. Additionally, EM impedance sensing is relatively immune to ambient low-frequency disturbances, enhancing its reliability in environments characterized by complex or fluctuating dynamic conditions. This resilience and sensitivity make the EM impedance method a strong candidate for practical SHM deployment in composite systems in complex real-world conditions.

This work presents a numerical study to evaluate the capability and sensitivity of the EM impedance approach for damage detection in composite structures. Utilizing a detailed finite element model developed in ABAQUS that incorporates

accurate material characteristics and simulates local damage effects, the study assesses the detectability of different damage severities. The findings contribute valuable understanding of the practical applicability of this cost-efficient SHM technique and set the stage for future experimental verification.

## 2 COST-EFFECTIVE EM IMPEDANCE METHOD

As shown in Fig. 1, a standard EM impedance measurement setup typically consists of a piezoelectric transducer, such as a PZT, bonded to the surface of the structure and an impedance analyzer that drives the transducer while recording its impedance response.

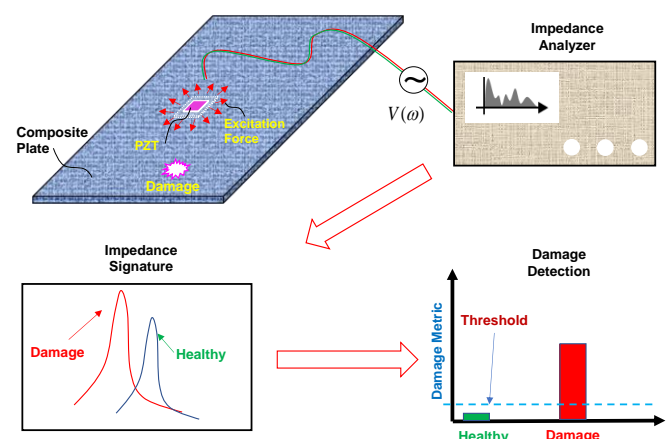

Figure 1. The EM impedance technique for composite plate

When a harmonic voltage  $V$  is applied across a range of frequencies  $\omega$ , the transducer undergoes mechanical vibrations due to the piezoelectric effect, thereby exciting the host structure (Park et al., 2003). The measured EM impedance response depends on the combined effects of the transducer's intrinsic impedance  $Z_a$  and the mechanical impedance of the structure  $Z_s$ , and it varies as the structural condition changes. For a simplified one-dimensional model, the theoretical EM impedance response  $Z$  can be described by the following relationship (Park et al., 2005):

$$Z = \left\{ i\omega \frac{h_a l_a}{t_a} \left[ \hat{\epsilon}_{33}^T - \frac{1}{Z_a/Z_s + 1} d_{31}^2 \hat{Y}_{11}^E \right] \right\}^{-1} \quad (1)$$

where  $\hat{\epsilon}_{33}^T$  is the complex dielectric permittivity, and  $d_{31}$  is the piezoelectric coupling coefficient;  $h_a$ ,  $l_a$ , and  $t_a$  represent the width, length, and thickness of the transducer, respectively;  $\hat{Y}_{11}^E$  denotes the Young's modulus of the transducer;  $\eta$  corresponds to the structural damping loss factor of the transducer; and  $i$  is the imaginary unit.

The EM impedance response is inherently sensitive to the mechanical properties of the host structure, such as its mass, stiffness, and damping characteristics. When damage occurs, these mechanical parameters are altered, which in turn leads to measurable variations in the EM impedance signal. By monitoring such changes using the damage metric, it is possible to reliably detect damage within composite materials (Fig. 1). Furthermore, due to the short wavelengths associated with high-frequency excitation, EM impedance measurements are particularly adept at identifying small-scale defects and early-stage damage in composite structures.

### 3 NUMERICAL STUDY

A detailed finite element (FE) simulation of a clamped composite laminate was carried out using ABAQUS to investigate the EM impedance response, as shown in Fig. 2. The FE model replicates an experimental model of composite plate with dimensions of 290 mm × 200 mm × 3 mm, rigidly fixed along all four edges, as depicted in Figs. 2a and 2b [4]. The laminate structure consists of 12 layers of T700/M21 carbon/epoxy, arranged in a symmetric stacking sequence of [45/-45/0/90/0/90]S, as shown in Fig. 2c.

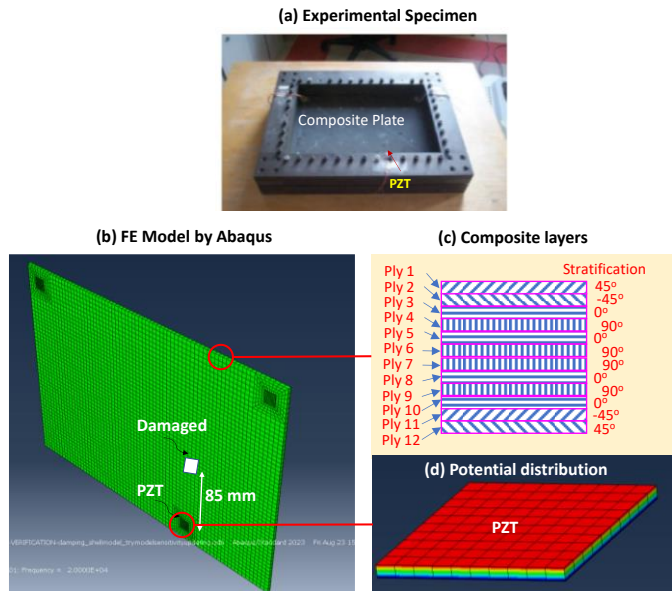

Figure 2. FE modeling

A square piezoelectric patch measuring 10 mm × 10 mm × 0.5 mm is surface-mounted at the center of the plate via a thin adhesive film of 0.04 mm thickness [4]. As shown in Fig. 1b, the composite laminate is discretized using 8-node continuum

shell elements (SC8R), while the adhesive layer is represented with 8-node linear brick elements (C3D8). The bonded piezoelectric transducer is modeled using 8-node coupled-field piezoelectric elements (C3D8E), capable of simulating electromechanical interactions.

The material parameters for both the piezoelectric patch and adhesive layer are adopted from established literature [4], and a structural damping ratio of 0.02 is incorporated to simulate energy dissipation. To evaluate the EM impedance response, a sinusoidal voltage excitation of 1 V is applied across the piezoelectric patch, specifically, the upper electrode is subjected to the harmonic signal  $V(\omega)$ , while the lower electrode is grounded. The potential distribution across the transducer's thickness is shown in Fig. 2d. The frequency sweep defined in ABAQUS spans from 10 kHz to 30 kHz with a frequency resolution of 50 Hz to capture relevant impedance dynamics.

To assess damage sensitivity, a localized defect scenario is introduced: a 10 mm × 10 mm square damage zone positioned 85 mm from the piezoelectric transducer. Variations in damage severity are simulated by incrementally reducing the stiffness of the plies to 0.1 Pa within the defect region, mimicking progressive internal damage such as delamination or matrix cracking.

Figure 3. Real part of the EMI response under damage

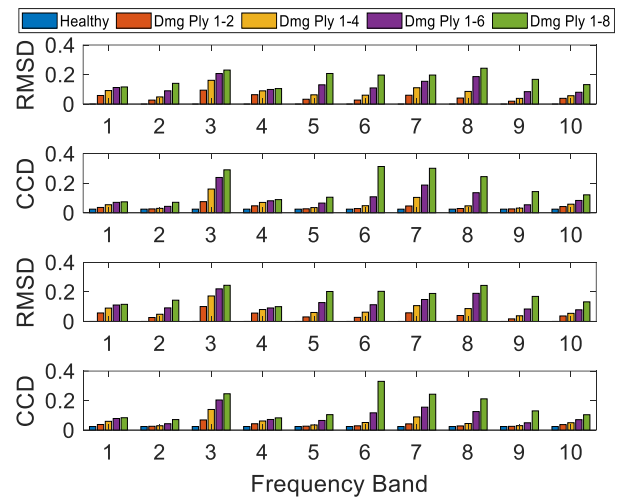

Figure 4. Damage detection results using RMSD and CCD metrics

As illustrated in Fig. 3, the EM impedance spectra recorded between 10 kHz – 30 kHz display multiple well-defined resonance peaks. Upon the introduction of damage to the

composite plate, these peaks exhibit noticeable shifts, predominantly toward lower frequencies, as the number of compromised plies increases. This frequency shift reflects a decline in local stiffness and a modification of the structure's dynamic behavior.

To systematically capture these changes, statistical damage indices, specifically, the root-mean-square deviation (RMSD) and cross-correlation deviation (CCD) [1] are employed. These indices are calculated across ten 2-kHz-wide sub-bands (see Fig. 4), enabling localized frequency analysis and heightened sensitivity to subtle damage.

The outcomes presented in Fig. 4 clearly illustrate that both RMSD and CCD values increase significantly under damaged conditions, with the magnitude of these indices growing in proportion to the severity of the damage. This trend reinforces the sensitivity of the EM impedance technique not only for detecting the presence of structural degradation but also for quantifying its extent. Such capability is critical in composite materials, where damage often initiates internally and may not be easily visible through traditional inspection methods.

Moreover, the identification of multiple damage-sensitive frequency sub-bands provides additional insight into the damage localization process. These sub-bands exhibit distinct impedance shifts, suggesting that the structural response to damage is frequency-dependent. By isolating and analyzing these sub-bands individually, the detection resolution is substantially improved. This is particularly valuable in real-world SHM scenarios where environmental and operational variability may obscure global trends in the impedance spectrum. The sub-band approach thus offers a practical means to enhance robustness and reduce false positives in damage detection systems.

#### 4 DISCUSSIONS AND CONCLUDING REMARKS

This study presents a preliminary numerical investigation into a low-cost SHM approach for composite structures using the EM impedance technique. A FE model of a clamped composite plate with a bonded piezoelectric transducer is developed to simulate EM impedance responses under different damage conditions, introduced as localized stiffness degradation at the ply level. To enhance sensitivity, the analysis applies frequency sub-band decomposition combined with RMSD and CCD damage indices. Results show that the EM impedance signatures are highly responsive to structural damage, with clear impedance shifts and increasing index values correlating with damage severity. These findings validate the effectiveness of combining EM impedance-based sensing with sub-band analysis and statistical damage indices.

The EM impedance technique offers a low-cost and sensitive approach for real-time damage detection, particularly suited to laminated composite structures in aerospace panels, and turbine blades, where internal damage is often undetectable by surface methods. Its compact size and high-frequency resolution make it ideal for embedded sensing in such systems.

While the current numerical model assumes fixed boundary conditions to isolate damage effects, real-world applications may involve boundary variability due to thermal or operational effects. Future work will therefore include parametric studies accounting for changes in boundary conditions, plate deformation, and internal stress states, to assess the robustness

of EM impedance-based damage indicators under practical uncertainties.

Future efforts will also focus on experimental validation to confirm the numerical findings under realistic conditions. Parametric studies involving different layouts, damage types, and sensor placements will help generalize the method. Additionally, integrating EM impedance features with machine learning could improve damage classification and quantification. Extension to complex geometries and real-world structures is also planned to support practical SHM applications.

**ABSTRACT:** Cross-sea bridges are crucial transportation links, ensuring smooth maritime traffic and protecting public safety and property. However, ship collisions pose a serious threat, potentially causing extensive damage to bridges, disrupting traffic, polluting the environment, and leading to casualties. Therefore, it is extremely important to develop methods for identifying and evaluating damage to cross-sea bridges caused by ship collisions. A study has been conducted utilizing a combined approach of numerical simulation and experimental validation to analyze the structural dynamic responses of bridges subjected to ship collisions. Based on the insights gained, a structural damage assessment method combining response surface method and Monte Carlo simulation has been introduced. This method takes into account factors such as the impact height and kinetic energy during ship-bridge collisions, establishing a comprehensive evaluation index system. This approach offers a holistic view of the damage state of bridges subjected to ship collisions, providing a scientific foundation for subsequent emergency response and repair strategies. Ultimately, the research aims to mitigate the adverse effects of ship collisions on the structural integrity of cross-sea bridges.

**KEY WORDS:** Ship-bridge Collisions; Damage Assessment; Impact Test; Response Surface Method.

## 1 INTRODUCTION

Currently, the safety issues related to bridge ship collisions have garnered widespread attention. However, relevant research primarily focuses on impact force estimation and studies on bridge anti-collision facilities (Chen et al., 2022; Nian et al., 2016). However, previous studies have struggled to capture the damage evolution characteristics of bridges under varying ship kinetic energy impacts. Conducting fragility analysis for bridge ship collisions can predict the probability of structural damage at various levels, providing practical engineering value for structural design, reinforcement, and maintenance decision-making.

The seismic fragility analysis of bridges has garnered extensive attention from scholars both domestically and internationally. Song et al. (2024) conducted a comprehensive brittleness assessment of specimen viaducts under various ground motion excitation schemes in order to evaluate the impact of modeling detail and analysis complexity on estimating seismic performance. Wang et al. (2025) established an analysis model of the degradation state of a large cantilever cap bridge, and studied the seismic vulnerability of the bridge structure under different service times based on the OpenSees platform. Li et al. (2025) proposed a copula-based approach proposed for seismic vulnerability analysis by incorporating the uncertainty of scour depth into the assessment of bridge seismic performance. However, research on the fragility of bridges under ship collisions is very limited. Kameshwar et al. (2018) developed a meta-model to estimate the force requirements and vulnerability of bridge pillars under barge impact. Fu et al. (2024) proposed a new brittleness assessment framework based on the residual bearing capacity of piers. Zhong et al. (2024) propose a fragility based framework to determine the most

unfavorable position of a bridge column for collision with a barge.

However, there is currently no widely accepted and convincing damage indicator for assessing pier damage under ship collisions. Fan et al. (2021) proposed a bridge ship collision vulnerability analysis method combining a simplified finite element model with a response surface agent model, and obtained the bridge vulnerability curves under two types of typical ship impacts. In recent years, some scholars have also applied the response surface method to the parameter analysis and reliability analysis of bridges under impact, significantly improving computational efficiency. Fan et al. (2018) conducted an extensive parametric study using the response surface method to investigate the effects of reinforcement ratio, UHPFRC sheath thickness, UHPFRC strength, and initial impact velocity. Duan et al. (2024) proposed an efficient hybrid response surface method to study the system reliability of pile-reinforced slopes.

In this study, the stress-strain behavior at the base of the pier under ship impact was investigated through a combined experimental and finite element comparative analysis. Based on the response surface, a new bridge impact damage index is proposed and applied to bridge brittleness assessment. By establishing a full-scale finite element model of the bridge, a multi-factor ship collision simulation analysis was conducted. Fragility curves of the pier under different influencing factors were obtained, providing a reference for the fragility analysis of bridges subjected to ship collisions.

## 2 EXPERIMENTAL OVERVIEW

The non-navigational spans of the prototype bridge are 60-meter span continuous concrete girder bridges, with the main body of the bridge constructed using marine-grade concrete

C40. Based on the scale ratio, the overall schematic diagram of the bridge model structure, as shown in the Figure 1, was established by fully considering the interaction relationships between the pile caps, pile foundations, bearings, and girder segments. Hollow circular steel pipes with a diameter of 89 mm and a wall thickness of 2.5 mm were used to simulate the pile foundations. The pile length was determined to be 75 cm using the 8-times equivalent pile diameter method, and the piles were embedded into the pile cap to a depth of 5 cm.

Figure 1. The dimensional drawing of the scaled full-bridge model (mm).

To simplify the design, the ship model consists of a bow model and a stern model, connected by a force sensor in between. Since the stern model does not directly contact the bridge model during the collision process, it is primarily responsible for accommodating sand and stone ballast to achieve different mass conditions. The bow model mainly comprises an internal structure and an external shell structure. The external shell structure is constructed by assembling 1 mm steel plates. Given the difficulty in replicating every detail of the actual bow's internal structure, the internal structure of the bow is composed of two equivalent supports, which are fabricated by welding steel bars with a diameter of 6 mm.

Figure 2. The dimensional specifications of the scaled bow model (mm).

Considering the test site conditions, a pendulum-type loading device powered by gravitational acceleration was employed. The frame of the loading device was constructed by welding I-beams, and its base was securely anchored to the ground trough using anchor bolts. A movable beam was installed at the top of the frame, equipped with universal wheels. The ship model was suspended at a pre-calculated height and released by a triggering mechanism. Utilizing gravitational acceleration, the ship model attained a certain horizontal velocity upon impact with the bridge model. The pile foundations were fixed to the steel plates in the ground trough using clamps and further secured with bolts, as illustrated in Figure 3.

Figure 3 Scaled bridge collision test.

The ship-bridge collision process involves complex elastoplastic deformation of the bow. As the velocity increases, the deformation of the bow becomes more significant. This study conducted collision tests at two different heights, with impact points located 250 mm and 350 mm above the base of the pier, respectively. Analyzing the time-history curves of impact forces under different impact velocities at these two heights reveals that the change in impact location has almost no influence on the impact force. This is because the magnitude of the impact force is primarily determined by the contact area, and the change in impact location does not affect the contact area, as illustrated in Figure 4. Moreover, when the impact velocity exceeds 1.5 m/s, the peak impact force increases very slowly with further increases in velocity. This phenomenon is mainly attributed to the internal structure of the barge bow. Additionally, the stiffness of the barge bow is relatively high compared to other types of bows, resulting in the maximum impact force being reached almost immediately at the onset of collision.

Figure 4. Time-history curve of ship-bridge collision force

After being subjected to impact, fine cracks appeared at the base of the pier. The cracks generated under the most critical impact condition are shown in Figure 5. At this stage, the cracks have not yet penetrated the entire cross-section of the pier, and their widths remain very small. Additionally, the strain values at the base of the pier caused by impacts at two different heights with a velocity of 2.5 m/s were recorded, as presented in Table 1.

Figure 5. Comparative analysis of damage at the base of bridge piers

When the impact velocity is the same, a higher impact height results in greater strain. Larger strains are more likely to induce cracks at the base of the pier, indicating that a higher impact location increases the likelihood of damage to the pier base.

Table 1. Strain data at the base of bridge piers

Impact velocity (m/s)	Height of impact (250 mm)	Height of impact (350 mm)
2.5	113	171

Figure 6. Stress simulation at the base of bridge piers

A finite element model corresponding to the experimental model was established, and the stresses at the base of the pier under two impact heights with a velocity of 2.5 m/s were calculated, as shown in Figure 6. The strain values obtained from the experiments were converted into stress values, and the results showed minimal discrepancies compared to the finite element results. This indicates that the finite element modeling approach in this study aligns well with the actual conditions. When the stress at the base of the pier exceeds the tensile strength of the concrete, cracks begin to form. As the stress at the base gradually increases, the cracks progressively penetrate the entire cross-section of the pier. According to the Chinese building industry standard Code for Design of Concrete Structures (GB 50010-2010), the standard tensile strength of reinforced concrete can be calculated. When the stress at the base exceeds the standard tensile strength of reinforced concrete, it indicates that the pier has suffered severe damage.

### 3 DAMAGE CLASSIFICATION THEORY

The Box-Behnken Design (BBD) method was employed for sampling value calculations. Taking a three-factor design as an example, the distribution of sampling points is illustrated in Figure 7. Here,  $E$  represents the kinetic energy during ship impact,  $h$  denotes the impact height, and  $f_c$  indicates the concrete strength grade. Subsequently, an actual ship-bridge collision model was established, and sampling value calculations were performed using the Box-Behnken Design. The obtained data were fitted to a surface, yielding the stress data at the base of the pier under the influence of the three factors in ship-bridge collisions.

Figure 7. Sampling points for Box-Behnken Design

In the bridge ship collision fragility analysis studied in this paper, parameter  $A$  is defined as the impact kinetic energy of the ship. Specifically, the ship collision fragility is defined as the conditional failure probability that the structure reaches or exceeds a certain limit state ( $L_s$ ) when subjected to a ship

collision with impact kinetic energy  $A$  equal to  $E$ , as shown in Equation (1).

$$F_R(a) = P[Ls|A = E] \quad (1)$$

The polynomial response surface surrogate model is a commonly used form of surrogate model in response surface analysis. In this study, a polynomial surrogate model is employed to fit the stress at the base of the pier caused by barge impact. The impact force generated by the barge collision increases with the kinetic energy of the ship. However, when the kinetic energy exceeds a certain threshold, the growth of the impact force slows down. Consequently, the tensile stress at the base of the pier follows the same trend, necessitating a segmented calculation approach for the tensile stress. Here,  $\sigma_t$  represents the tensile stress at the base of the pier,  $E_0$  denotes the critical segmentation point of kinetic energy, and  $E_C$  represents the maximum kinetic energy used in the calculations.

$$\sigma_t = p_1 + p_2 f_c + p_3 h + p_4 E + p_5 f_c h + p_6 f_c E + p_7 h E + p_8 f_c^2 + p_9 h^2 + p_{10} E^2 \quad (2)$$

$$\sigma_t = \begin{cases} \sigma_1(f_c, h, E), & E \in (0, E_0) \\ \sigma_2(f_c, h, E), & E \in (E_0, E_C) \end{cases} \quad (3)$$

The fragility curve of the pier is obtained by performing Monte Carlo sampling on the normally distributed random variable  $f_c$  and plotting the failure probabilities corresponding to different kinetic energies, thereby generating the fragility curve. The probability distribution of C30 concrete strength is shown in Table 2.

Table 2 Distribution of concrete strength grades

Concrete strength	Nominal value	Mean value	Coefficient of variation (%)
$f_c$	30 MPa	30 MPa	15

#### 4 FAILURE PROBABILITY CALCULATION

A finite element model of the actual bridge was established, with the pier having a width of 3 m, a length of 6.5 m, and a height of 20 m. The hull was modeled using the AASHTO barge model. A comparison of the impact force and the tensile stress at the pier base under different ship kinetic energies reveals that the trends of change in impact force and tensile stress are remarkably similar. Furthermore, the installation of collision protection devices was considered to further verify whether the trends of change in impact force and tensile stress remain consistent.

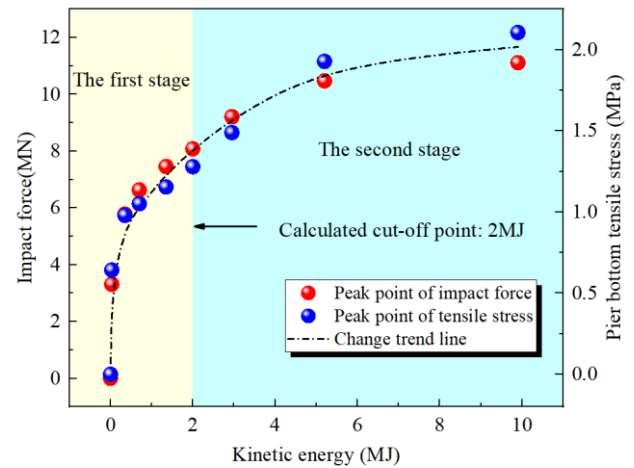

Figure 8. Full size bridge collision model

The results indicate that the trends of change in the impact force caused by ship-bridge collisions and the tensile stress generated at the pier base are consistent. Even with the addition of protective devices, this regularity remains unaffected. Therefore, the trend of change in barge impact force with respect to ship kinetic energy can be used to describe the trend of change in tensile stress with respect to ship kinetic energy. Moreover, both the peak impact force and the peak tensile stress increase with the rise in ship kinetic energy, but the trend of change exhibits a segmented pattern. When the ship's kinetic energy is below a critical threshold, the trends of change in impact force and tensile stress are rapid. Once the ship's kinetic energy exceeds the critical value, the trends of change in impact force and tensile stress become more gradual, as illustrated in Figure 9.

(a) Without protective devices

(b) With protective devices

Figure 9. The trend of impact force-tensile stress variation

According to the calculated results, it can be determined that the kinetic energy segmentation point for ship-bridge collisions without protective devices is 0.7 MJ. According to the sampling method of Box-Behnken Design, the tensile stresses at the base of the pier under different influencing factors were obtained through finite element calculations, as shown in Table 3.

The obtained tensile stresses at the base of the pier under different influencing factors were fitted to a surface, yielding the values of the undetermined coefficients for the two segments, as shown in Table 4.

Table 3. Sampling values for numerical simulation

Concrete strength (MPa)	Height of impact (m)	Kinetic energy (MJ)	Pier bottom tensile stress (MPa)	Kinetic energy (MJ)	Pier bottom tensile stress (MPa)
20	3	0.35	1.303	1.35	1.468

(b) The impact kinetic energy is 0.7 MJ

(c) The impact kinetic energy is 1.35 MJ

Figure 12. The combined effect of concrete strength and impact height

The impact height and impact kinetic energy have a significant influence on the tensile stress at the pier base, whereas the concrete strength has a relatively minor effect on the tensile stress at the pier base. Therefore, in the subsequent vulnerability calculations, the primary considerations will be the effects of impact kinetic energy and impact height.

The fragility curves of the pier under three impact height conditions were obtained through Monte Carlo sampling, as shown in Figure 13. Since the tensile strength of C30 concrete is 2.01 MPa, the condition where the tensile stress at the base of the pier exceeds 2.01 MPa is considered as the onset of minor failure, the initiation of cracks in the pier.

Figure 13. Fragility curves for different impact heights

As the tensile stress at the base caused by the impact does not reach the standard tensile strength of reinforced concrete, only minor failure conditions of the pier need to be considered. For the impact height of 9 m, there is a probability of minor failure when the barge's kinetic energy reaches 0.18 MJ, and direct failure occurs when the kinetic energy exceeds 0.3 MJ. For the impact height of 6 m, minor failure begins to occur when the barge's kinetic energy reaches 0.3 MJ, and direct failure occurs when the kinetic energy exceeds 0.4 MJ. For the impact height of 3 m, failure is almost negligible.

## 5 CONCLUSIONS

In this study, the magnitude of tensile stress at the base of the pier caused by barge impact is used as the damage assessment indicator. A fragility analysis method for bridge ship collisions based on the response surface method is proposed. This method enables rapid fragility assessment of the pier when subjected to barge impact.

The established high-precision response surface model can replace structural models that require complex nonlinear calculations. The developed response surface surrogate model can be utilized for extensive sample analysis in bridge ship collision fragility studies. When subjected to barge impact, the trend of tensile stress at the base of the pier is closely related to the critical barge kinetic energy, exhibiting a segmented characteristic similar to the impact force. Therefore, to accurately reflect the true response characteristics of the pier under barge impact, the sample design should be segmented based on the critical barge kinetic energy. Through a comparative analysis of the individual effects of the three factors on the fragility of the pier, it is evident that the magnitude of tensile stress at the base of the pier is significantly influenced by the impact height and impact kinetic energy,

while changes in concrete grade have a relatively minor effect on the tensile stress. However, the higher the concrete strength grade, the greater the standard tensile strength of the pier, enhancing its resistance to impact and reducing the likelihood of severe damage.

email: mai@kmi.com, das@kmi.com, mcr@kmi.com

## ABSTRACT:

This paper presents the development of an advanced system for the rapid post-earthquake safety assessment of bridges using advanced sensor technology. Upon completing the assessment, the system generates an automated report on bridge condition. To evaluate the serviceability of bridges, engineers frequently employ sensors, such as accelerometers, strain gauges, and tiltmeters to measure accelerations, displacements, strain, tilt, and deflections. The obtained data are essential for theoretical and practical reasons. Engineers analyze the data to gain insights into real-world bridge dynamics and to develop and validate models that inform design codes. On the practical level, the data are used in structural health monitoring (SHM) systems to enhance public safety by providing reliable data about bridge conditions, both long-term and after unexpected events, such as disasters and earthquakes. Traditionally, bridge inspections are conducted every two years to detect potential deterioration. However, these inspections are expensive and may need to be done more frequently following extreme events like earthquakes, fires, or bridge strikes. To reduce costs, we propose an innovative automatic rapid assessment system that uses measured bridge response data to initiate and minimize re-evaluation efforts. The system works by converting the acceleration data to displacements; subsequently, a threshold that defines the serviceability of the bridge is established. When one of the thresholds is exceeded, a report on bridge condition is automatically generated. This system is particularly useful in post-earthquake events and after other emergencies. In such situations, fast and reliable decision-making is a strong necessity, but also a serious challenge due to common human conditions, such as panic and fear. Rapid, automated generation of reports ensures accurate assessments of damage, which are crucial for the reduction of serious economic losses and the maintenance of reliable infrastructure access. In the paper we will discuss two case studies which illustrate the deployment of automatic, real-time assessment systems. As will be shown, these systems enhance the preparedness for disaster scenario and considerably improve bridge safety.

**KEY WORDS:** SHM; Disaster; Earthquake; Bridge Safety; Sensors; Automatic System; Safety Report.

## 1 INTRODUCTION

Bridges are vital components of transportation infrastructure, serving as critical links that facilitate the movement of goods and people. Their safety and serviceability are essential for public well-being, economic stability, and emergency response capabilities. The integrity of bridges must be maintained to prevent catastrophic failures that could lead to significant loss of life and disruption of transportation networks. This is particularly crucial in seismic-prone regions, where earthquakes pose a constant threat to bridge structures [1].

Following an earthquake, assessing bridge conditions rapidly and accurately is essential to prevent further damage, ensure public safety, and maintain transportation continuity. Earthquakes can induce severe structural damage, including cracks, joint displacements, bearing failures, and even complete collapses. Immediate post-earthquake assessments are necessary to determine whether a bridge can remain in service, requires immediate repair, or must be closed to avoid endangering the public. However, conducting these evaluations efficiently is challenging due to the scale of transportation networks and the inherent risks associated with manual inspections in post-disaster environments [2], [3].

Traditional inspection methods, which involve manual visual evaluations conducted every two years, are often inadequate in emergency scenarios. These assessments typically require trained personnel to physically inspect bridges, document damages, and make qualitative judgments about their structural integrity. Such methods are time-consuming, labor-intensive, and prone to human error, potentially delaying critical

decisions about bridge usability. Additionally, access to bridges following an earthquake may be restricted due to debris, road blockages, or structural instability, further complicating manual inspection efforts [4].

To address these challenges, this paper presents an advanced system that leverages modern sensor technology and data analytics to facilitate rapid post-earthquake safety assessments of bridges. The proposed system integrates a network of sensors, including accelerometers, strain gauges, and tiltmeters, to continuously collect structural response data before, during, and after seismic events. By automating data acquisition, the system eliminates the need for labor-intensive manual inspections and provides real-time insights into the bridge's condition.

## 2 SENSOR TECHNOLOGY IN STRUCTURAL HEALTH MONITORING

Structural Health Monitoring (SHM) relies on various sensors to evaluate bridge conditions (see Figure 1).

Commonly used sensors include [5], [6]:

- Accelerometers: Measure vibrations and dynamic responses to external forces.
- Strain Gauges: Detect strain variations within bridge components.
- Tiltmeters: Monitor angular displacements and inclination changes.

The sensors such are strategically installed on key elements of the bridge, including the superstructure, bearings, and substructure. These sensors continuously or periodically record

physical responses like vibrations, strains, and movements caused by traffic loads, environmental changes, or seismic events. Each sensor generates analog signals that reflect changes in the measured parameter, serving as the raw input for the monitoring system.

These analog signals are transmitted to a local data acquisition system (DAQ), which is typically housed in a weatherproof enclosure on or near the bridge. The DAQ performs several crucial functions: it converts analog signals to digital data through analog-to-digital converters, applies filtering and signal conditioning, and timestamps each measurement for synchronization across multiple channels. Depending on the configuration, the DAQ may operate in real time or in scheduled bursts, and it often includes onboard memory for local storage. Some systems also include edge processing capabilities to perform preliminary diagnostics or event detection directly at the site.

Once the data is digitized and preprocessed, it is transmitted from the DAQ to a local or remote data center using communication methods such as cellular networks (4G/5G), Wi-Fi, satellite uplinks, or fiber-optic lines. The data center acts as the central hub for data management, enabling long-term storage, advanced analysis, and integration with cloud platforms. Here, engineers and transportation agencies can access the data remotely via secure web portals or custom dashboards. Real-time data streams enable continuous monitoring, while automated algorithms can trigger alerts when structural anomalies are detected. This end-to-end system supports rapid decision-making, improves maintenance planning, and enhances the resilience of critical bridge infrastructure.

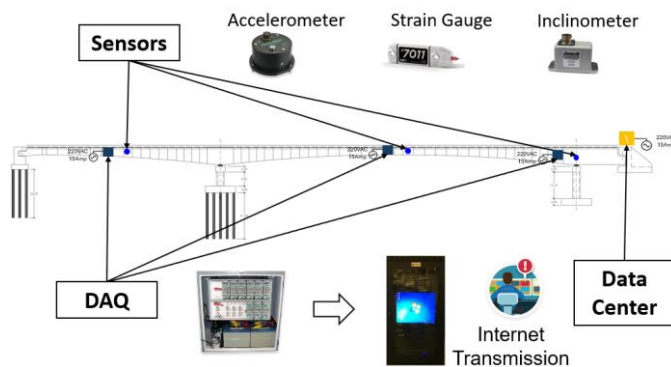

Figure 1. Typical instrumentation in bridge monitoring.

By continuously recording bridge responses, these sensors help engineers assess structural integrity, detect anomalies, and validate theoretical models that guide design and maintenance strategies.

### 3 CHALLENGES OF TRADITIONAL BRIDGE INSPECTION

Traditional bridge inspections are conducted biennially to identify potential deterioration. However, after extreme events such as earthquakes, additional inspections become necessary. Some key challenges include (see Figure 2) [7]:

- **High Costs:** Manual inspections require significant financial and human resources, including specialized personnel, equipment, and logistical support.
- **Time Constraints:** Evaluations can take days or weeks, delaying crucial transportation access and prolonging disruptions in emergency response efforts.
- **Human Limitations:** Panic, fatigue, and cognitive overload can impair decision-making during crises, leading to inconsistent or inaccurate assessments.
- **Safety Risks:** Inspectors working in post-disaster environments face significant hazards, including aftershocks, unstable structures, and difficult-to-access areas.
- **Limited Coverage:** Manual inspections may not comprehensively assess structural integrity, particularly in large-scale bridge networks where resources are constrained.

Figure 2. Challenges of Bridge Inspection.

The introduction of automated systems can significantly mitigate these challenges by providing rapid and accurate assessments without the need for extensive human intervention. Advanced technologies, such as sensor networks, computer vision, and artificial intelligence, enable continuous monitoring and real-time analysis, enhancing decision-making and improving overall safety and efficiency in bridge assessment processes [8].

By minimizing reliance on manual inspections, these automated systems not only reduce labor costs and human error but also allow for more frequent and consistent data collection. This continuous stream of high-quality data enables a shift from reactive maintenance to predictive maintenance strategies, where potential issues can be identified and addressed before they escalate. As a result, bridge management authorities can prioritize interventions more effectively, allocate resources efficiently, and extend the service life of critical infrastructure.

The collected sensor data is processed using advanced algorithms, to identify damage patterns, quantify structural deterioration, and predict the bridge's residual load-carrying

capacity. This automated analysis enables the generation of detailed condition reports, which provide decision-makers with critical information needed to implement timely and effective mitigation measures. Furthermore, integrating this system with geographic information systems (GIS) and cloud-based platforms enhances accessibility and facilitates coordinated emergency response efforts.

#### 4 PROPOSED AUTOMATIC RAPID ASSESSMENT SYSTEM METHODOLOGY

Structural Health Monitoring (SHM) is a critical tool for assessing the safety of bridges after an earthquake. The methodology involves 5 steps: pre-event preparation, real-time data acquisition during earthquake, post-event structural evaluation, decision-making process and reporting and action plan (see Figure 3).

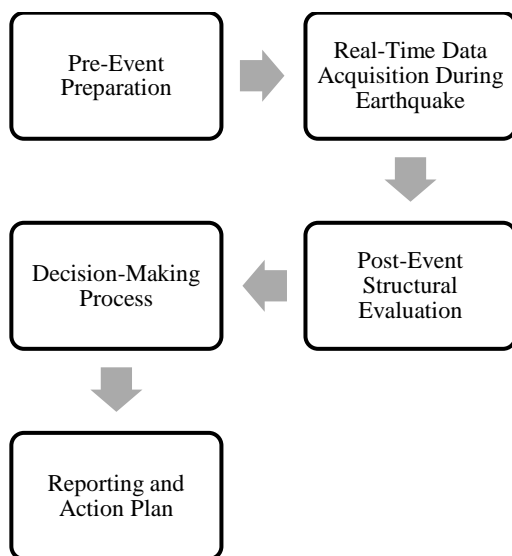

Figure 3. Proposed Automatic Rapid Assessment System Methodology.

##### 4.1 Pre-Event Preparation

Effective rapid assessment begins with thorough pre-event preparation, which includes identifying critical bridges within a transportation network and prioritizing them based on factors such as structural vulnerability, traffic volume, and strategic importance. Engineers conduct baseline assessments to understand the bridge's current condition and develop models that simulate its response to different seismic scenarios. These models form the reference point for interpreting data during and after seismic events.

Sensor deployment is a key part of preparation. Various sensors including accelerometers, strain gauges, and tiltmeters are installed on structural components most susceptible to damage. The placement is informed by structural analysis and past performance data. In addition to physical installation, sensors are calibrated to ensure accuracy and synchronized with the local data acquisition system (DAQ), which includes real-time clocks and backup power sources to maintain continuity during power loss.

Finally, a communication framework is established for transmitting sensor data to remote servers or data centers. The infrastructure includes reliable network connectivity (e.g., cellular, satellite, or wired connections) and cybersecurity measures to protect data integrity. Pre-event simulations and drills are also conducted to validate the system's performance and ensure all stakeholders, engineers, emergency responders, and transportation officials are familiar with the protocols in the event of a real earthquake.

##### 4.2 Real-Time Data Acquisition During Earthquake

When an earthquake occurs, the sensor network activates automatically or continues uninterrupted if running continuously. Force balance accelerometers capture ground and structural accelerations in three dimensions, while strain gauges and displacement sensors measure localized deformations. These signals are digitized by the DAQ and time-stamped to ensure synchronization across multiple channels and locations.

The DAQ processes the raw data using onboard algorithms to filter noise and detect events that exceed pre-set thresholds. Once significant shaking is detected, the system flags the event and immediately begins streaming prioritized data packets to the central server. Some systems also include edge computing capabilities, allowing for initial damage classification and triage to be performed locally and transmitted as summaries, reducing bandwidth requirements and accelerating response.

During this real-time acquisition phase, data flows continuously or in event-driven bursts to a central data center. There, automated software correlates input from multiple bridges, maps the earthquake's effects regionally, and compares the measured response with known damage thresholds from the pre-event models. This allows emergency management teams to quickly determine which bridges may be compromised and require immediate inspection or closure.

##### 4.3 Post-Event Structural Evaluation

After the shaking subsides, the system transitions to post-event evaluation. This involves aggregating the seismic response data and analyzing it against the bridge's baseline condition and predicted performance models. Engineers can assess the magnitude of forces experienced by each structural component and detect anomalies such as excessive displacements, residual vibrations, or sensor signal losses, which may indicate potential damage.

The evaluation process uses advanced algorithms. These tools identify patterns in the data that correlate with specific types of damage (e.g., joint failure, deck uplift, or bearing dislocation). By automating this analysis, the system reduces reliance on manual inspections and accelerates decision-making, particularly when multiple bridges are affected over a large geographic area.

Visualizations such as shake maps, bridge health dashboards, and risk scores are generated for each bridge. These outputs are reviewed by structural engineers and decision-makers to confirm automated findings. In high-priority cases, the system may recommend sending an inspection team or deploying drones for visual assessment, thus focusing on limited resources where they are most needed.

#### 4.4 Decision-Making Process

The decision-making process combines sensor-derived analytics with predefined action thresholds to classify bridge conditions into categories such as “safe,” “needs inspection,” or “likely damaged.” This triage helps agencies prioritize their response efforts, enabling the reopening of safe routes and the timely closure or detour of potentially unsafe bridges.

A critical component of this process is the decision support system, which integrates real-time sensor data, historical performance, and geographic context to recommend next steps. The system presents stakeholders with actionable insights, supported by confidence levels and potential consequences, empowering transportation officials to make informed, defensible decisions under pressure.

Human oversight remains essential. While the system automates much of the analysis, expert engineers review key findings to validate system outputs, especially in cases of high uncertainty or critical infrastructure. Collaboration between departments of transportation, emergency response, and engineering is coordinated through centralized platforms to ensure consistent, fast communication and execution of response plans.

#### 4.5 Reporting and Action Plan

Once the structural condition of each bridge is assessed, the system generates standardized reports that summarize sensor readings, algorithmic evaluations, and recommended actions. These reports include timestamps, structural response graphs, and comparison with design-level seismic criteria. They are shared through secure digital platforms with transportation authorities, emergency managers, and relevant stakeholders.

For bridges flagged as potentially compromised, the system issues automated alerts accompanied by suggested action plans. These may include full closures, restricted traffic use, or on-site inspection. In more advanced deployments, the system integrates with traffic management infrastructure to redirect traffic automatically, display warnings on digital signage, and update navigation systems.

The final component of the action plan involves post-event documentation and learning. All data and actions taken are archived for forensic analysis, regulatory compliance, and refinement of future response protocols. This feedback loop allows the system to improve over time, helping bridge operators become more resilient to future seismic events and more effective in their emergency response.

### 5 CASE STUDY 1: YUCAIPA EARTHQUAKE IMPACT ON BEAUMONT - I10/60 INTERCHANGE BRIDGE

In this case study, the automatic assessment system was deployed on Beaumont - I10/60 Interchange Bridge (see Figure 4). The bridge is located in Riverside County, California, near the city of Beaumont, where Interstate 10 (I-10) and State Route 60 (SR-60) converge (see Figure 5). This critical interchange lies in Southern California’s Inland Empire region and serves as a major transportation corridor linking Los Angeles to the Coachella Valley and beyond. Positioned in a seismically active area near the San Andreas Fault, the bridge plays a vital role in regional mobility and freight transport, making its structural integrity and seismic resilience essential for public safety and economic continuity.

Figure 4. Beaumont - I10/60 Interchange Bridge.

Figure 5. Bridge Location.

The bridge is composed of 2 abutments and 3 bents; the span of the bridge is 112.78 m (370 ft) and a height of 8.23 m (27 ft). In 1992, the bridge was instrumented with six force balance accelerometers as part of a seismic monitoring initiative (See Figure 6). This instrumentation was implemented through an interagency agreement between the California Department of Transportation (Caltrans) and the California Department of Conservation (DOC). The collaboration aimed to enhance the structural health monitoring capabilities of critical transportation infrastructure in seismically active regions, enabling the collection of high-quality acceleration data to support seismic performance assessment and emergency response efforts.

On June 16, 2005, the bridge was exposed to the Yucaipa Earthquake. The epicenter of the earthquake was located 3.39 km (2.1 mi) NE of Yucaipa, CA, USA; had a magnitude of 4.9 and a depth of 12.6 km (see Figure 7). The Yucaipa earthquake was a moderate seismic event and occurred at approximately 8:05 PM local time. Its epicenter was located within a seismically active zone influenced by the complex interactions between the San Andreas Fault and other nearby fault systems in the eastern Transverse Ranges. The event was widely felt throughout the Inland Empire and greater Los Angeles area, prompting temporary evacuations and raising concerns about infrastructure resilience in the region.

Figure 6. Instrumentation on the bridge (Source: Center for Engineering Strong-Motion Data -CESMD).

Although the 2005 Yucaipa earthquake did not result in any fatalities or major structural damage, it caused minor non-structural damage, such as cracked walls, fallen ceiling tiles, and items displaced from shelves in homes and businesses. The shaking intensity reached Modified Mercalli Intensity (MMI) level VI in the immediate vicinity, indicating strong shaking. The event highlighted the seismic hazard in this part of Southern California and reinforced the importance of earthquake preparedness and monitoring. For researchers and agencies, the earthquake served as a valuable data point for evaluating the performance of early seismic instrumentation, ground motion characteristics, and local soil amplification effects, especially in areas with vulnerable infrastructure such as bridges, schools, and hospitals.

In this context, the instrumentation installed on the bridge provided a critical opportunity to assess structural performance during the 2005 Yucaipa earthquake. The sensors captured real-time data on ground motion and structural response, offering insights that would have been difficult to obtain through visual inspections alone. This event demonstrated the practical value of instrumented bridges in seismic regions, as the recorded data allowed engineers to verify the integrity of the structure without interrupting service. The success of this monitoring effort laid the foundation for more advanced automated assessment systems, capable of rapidly analyzing sensor outputs, identifying potential damage, and supporting immediate post-earthquake decision-making—thus addressing many of the challenges associated with traditional inspection methods.

CISN Rapid Instrumental Intensity Map Epicenter: 2.1 mi NE of Yucaipa, CA  
Thu Jun 16, 2005 01:53:26 PM PDT M 4.9 N34.06 W117.01 Depth: 11.8km ID:14155260

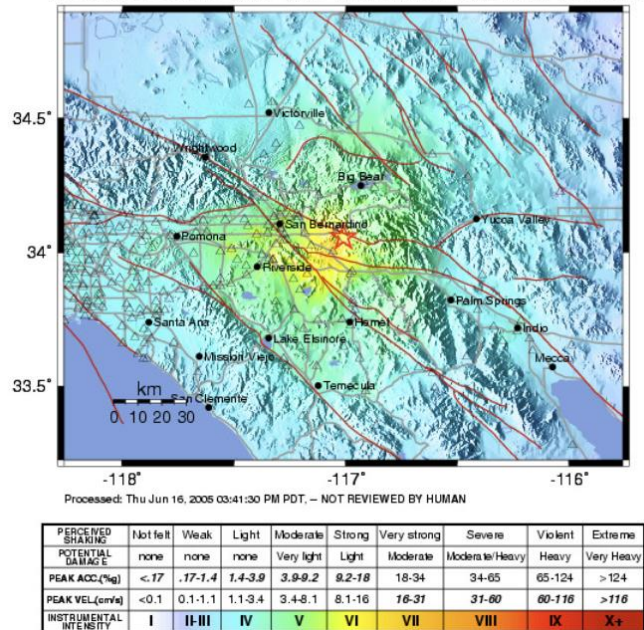

Figure 7. Yucaipa Earthquake (Source: Center for Engineering Strong-Motion Data -CESMD).

Traditional inspections required extended closures and significant financial investment. Following an earthquake, the system could successfully:

- Detected abnormal vibrations exceeding the established serviceability threshold.
- Generated an automatic report, recommending immediate structural reinforcement.
- Enabled engineers to assess the damage remotely, reducing the need for manual inspections.

As a result, the system significantly decreased bridge downtime and ensured rapid decision-making for emergency response teams.

## 6 CASE STUDY 2: CALEXICO EARTHQUAKE IMPACT ON BEAUMONT - I10/60 INTERCHANGE BRIDGE

In this case the Beaumont - I10/60 Interchange Bridge was exposed to the Calexico Earthquake on April 4, 2010. The epicenter of the earthquake was located 49.57 km (30.8 mi) SSE of Calexico, CA, USA; had a magnitude of 7.2 and a depth of 10.0 km (see Figure 8). The Calexico earthquake and the Yucaipa earthquake differed significantly in both magnitude and regional impact. The Yucaipa earthquake registered a magnitude of 4.9 and occurred in the inland region of Southern California, near the San Andreas Fault system. It resulted in minor non-structural damage and served primarily as a data point for evaluating local ground motion and instrumentation performance. In contrast, the Calexico earthquake, also known as the El Mayor-Cucapah earthquake, was a much larger event with a magnitude of 7.2. It struck near the U.S.-Mexico border, affecting both countries and causing extensive structural damage in the city of Calexico and surrounding areas.

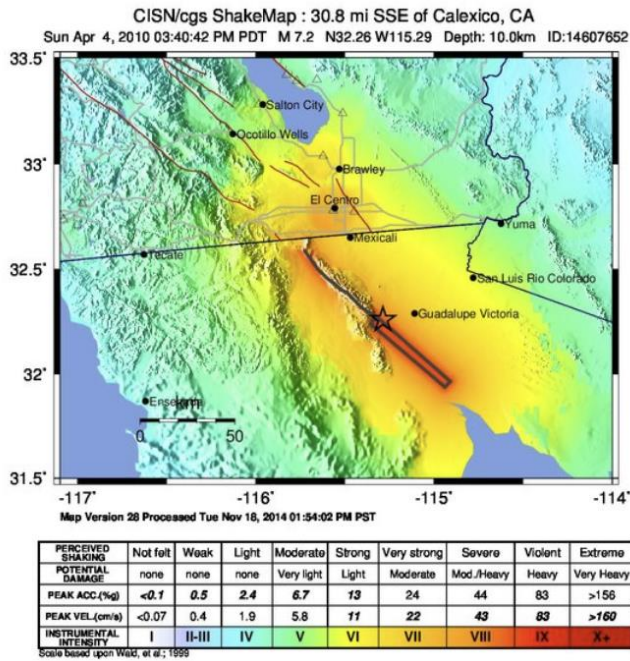

Figure 8. Calexico Earthquake (Source: Center for Engineering Strong-Motion Data -CESMD).

The automatic rapid assessment system showed higher displacements in the bridge for the Calexico Earthquake (see Figure 9 and Figure 10).

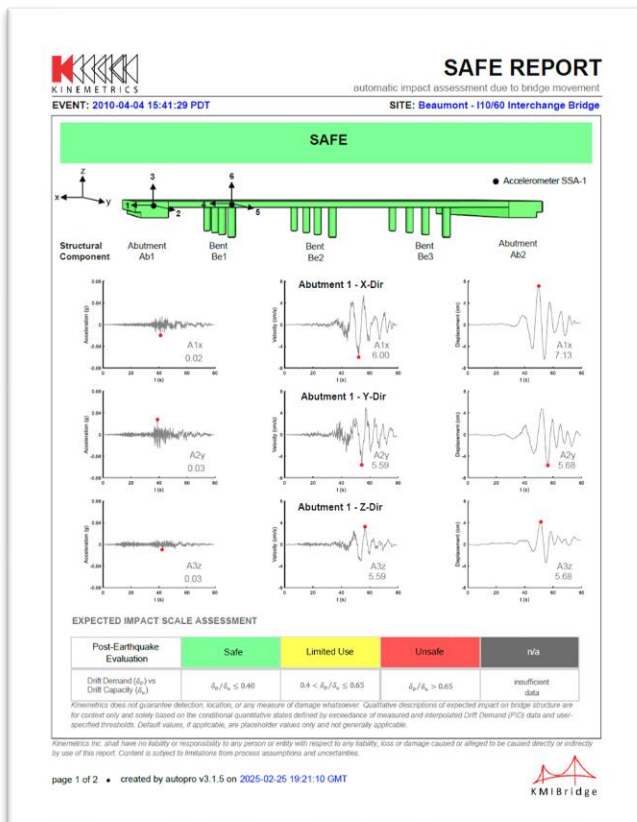

Figure 9. Automatic Rapid Assessment System 1/2.

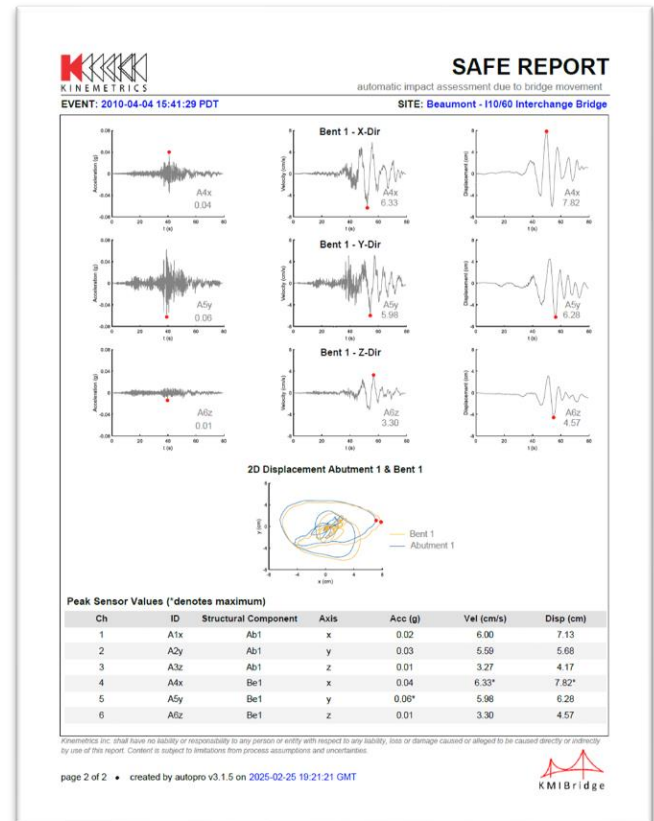

Figure 10. Automatic Rapid Assessment System 2/2.

What sets the proposed automatic rapid post-earthquake evaluation system apart from existing automated solutions is its ability to collect and process real-time acceleration, velocity, and displacement data immediately following a seismic event. Unlike conventional systems that primarily rely on periodic assessments or post-processed sensor data, this approach enables near-instantaneous evaluation of structural performance during and after an earthquake. By integrating high-frequency data acquisition with advanced algorithms, the system provides a more accurate and timely understanding of potential damage, allowing for faster decision-making and more effective emergency response.

Importantly, this system is designed to support, not replace, structural engineers. By delivering actionable data in real time, it empowers engineers to make informed decisions more quickly and confidently after events. The tool enhances professional judgment with rapid, data-driven insights, improving both the efficiency and reliability of post-earthquake assessments while maintaining the essential role of expert evaluation.

## 7 CONCLUSIONS

The proposed advanced system for rapid post-earthquake bridge safety assessments integrates sensor technology, automated data processing, and real-time reporting to enhance disaster response capabilities. By replacing traditional, labor-intensive inspections with automated evaluations, the system ensures timely, cost-effective, and reliable infrastructure

assessments. The case study illustrates its effectiveness in different bridge settings, reinforcing its applicability in both urban and rural environments. Future advancements in SHM technology, including artificial intelligence integration, could further improve the accuracy and predictive capabilities of such systems, ultimately leading to safer and more resilient bridge infrastructure.

By adopting this technology-driven approach, transportation agencies and emergency management teams can significantly improve the efficiency and accuracy of post-earthquake bridge assessments. The implementation of modern sensor-based monitoring systems enhances safety by enabling early detection of structural vulnerabilities, reducing the reliance on subjective visual inspections, and expediting repair and maintenance actions. Ultimately, the integration of these advancements contributes to more resilient transportation infrastructure and ensures the continued functionality of bridges in the aftermath of seismic events.

## Bridge superstructure vibrational analysis as means to detect scour in a medium span bridge

Junhui Zhao<sup>1</sup>, Kareem Helmy<sup>2</sup>, Boris Telehanic<sup>1</sup>, Evangeline Murison<sup>3</sup>, Aftab Mufti<sup>1</sup>, and Douglas Thomson<sup>1</sup>

<sup>1</sup>Department of Electrical and Computer Engineering, University of Manitoba, Winnipeg, MB, R3T 5V6, Canada

**ABSTRACT:** Scour around bridge piers is a leading cause of failure but detecting it reliably and cost-effectively remains a challenge. Vibration analysis offers a potential solution by monitoring changes in vibrational mode frequencies, as scour reduces a bridge's natural frequencies. This study measures traffic-induced vibrations on both bridge piers and decks, enabling continuous monitoring without disrupting traffic. An important consideration in using vehicle-induced vibrations is that each vehicle tends to preferentially excite certain vibrational modes, influenced by factors such as vehicle speed and span length. Therefore, obtaining a representative vibrational spectrum requires the passage of many vehicles. In this work, we found that the passage of 10 to 50 vehicles is necessary to reduce errors to the level required for robust vibrational analysis. Continuous monitoring of vibrational frequencies also enables compensation for seasonal variations in environmental factors such as temperature. In this study, a medium-span bridge was monitored over approximately 10 months. By correlating frequency data with temperature, we can account for environmental influences. After compensating for temperature, frequency changes exceeding  $\pm 1.7\%$  can be detected and may indicate the presence of scour. The measured frequencies closely matched predictions from finite element model calculations.

**KEY WORDS:** SHMII-13; field measurement, superstructure, vibrational analysis

### 1 GENERAL GUIDELINES

Scour can cause collapse of bridges by eroding the pier foundation systems and lead to large economic losses due to loss of infrastructure and transportation routes [1], [2]. There has been progress in solutions for mitigating scour [3], [4], but it remains critical that there is early detection so that rehabilitation and maintenance measures can be applied before scour reaches the point causing bridge failure [5], [6].

Scour is a process that excavates and removes the soil and sediments by the flowing water, particularly by the flooding. Natural scour is a degradation process of the level and conditions of waterbed due to the flow along the waterway; contraction scour is associated with the varying velocity and shear stresses of the flowing streams due to the bridge foundation structures; the formation of horseshoe vortex around pier structures is a localized scour process. These scour processes can reduce the rigidity of the surrounding earth foundation thus degrade the stiffness and the stability of the pier structures. In addition to the direct visual inspection of scour, many detection methods and instruments have been extensively explored to detect scour depth around piers and abutments, such as float-out devices and tethered buried switches, time-domain reflectometry (TDR) and ground-penetrating radar (GPR) devices, gravity-based magnetic and positioning sensors, electromagnetic and acoustic wave-based pulse-echo devices, fiber-Bragg grating sensors, and electrical conductivity-based devices [5]. However, the installation and operation of these instruments are practically very challenging in the harsh underwater environments, and measurement efficiency is restricted by the complex interfaces between the waterbed and the flowing streams. Due to the large size of

structures, some local scour holes are not easily detected with these measuring approaches. Different from these methods that measures the scour depth by installing the instruments under water, the dynamic response of bridge structures to scour progression has been investigated as a means of detecting scour [7], [8], [9], [10], [11]. The principle of detection is that structural vibrations depend on the mechanical properties and boundary conditions existing around bridge piers. The pier length, stiffness and its foundation rigidity are affected by scour depth and scour holes around a pier and its abutment as well as the supporting earth. The variation in vibration modes of a pier will hence signal the structural problems related to scour progression. The dynamic vibrations can be measured using sensors such as accelerometers. The measured acceleration signals can be processed and analyzed using spectral analysis tools. Observing frequency change provides an avenue to detecting the scour occurrence. An advantage of this method is that the instrument installation on a bridge above water is much cost-effective in practice and measurement operation is more efficient comparing to those measuring systems underwater. It could potentially become a less expensive and efficient tool for diagnosing scour related structural damage of a bridge.

There are many examples of laboratory and numerical simulations of scour comparing vibrational frequencies with depth of scour around bridge piers [11]. The vibrational frequencies are predicted to decrease as scour progresses. The field observation of changes in vibrational frequencies due to scour is very challenging. However, there are some examples of field observations that are relevant to this study. In one example, during the repair of scour damage, an additional 3 m was excavated from around the pier. The ambient bridge

vibration before and after the excavation was measured and a drop in vibrational frequencies near 1.5 Hz of 11 % was observed [12]. In another example, the frequencies of lower order vibrational modes were observed to drop by ~20% over a 3-year period due to scour. Kong and Cai also predicted a ~20% decrease in lower order vibrational mode frequencies before and after scour [12]. Tubaldi et al. also found in a 3 m x 3 m field tested scale model of spread footing a change of ~ 20% with scour under the footing [13].

In this paper, we examine the extraction of vibrational mode frequencies on a medium span bridge over the full seasonal temperature swings (Figure 1). The vibrational excitation was traffic induced, and this study also examines the improved accuracy of vibrational frequency determination by averaging over many vehicle passages. Finally the minimum frequency change that can be reliably determined after vehicle averaging and correction for environmental changes is determined.

## 2 METHODS

### 2.1 Accelerometer measurements

The vibrational measurements of pier structures were performed using a data acquisition device consisting of an accelerometer (ADXL355) and a microcontroller (Arduino Giga). The 3-axis accelerometer has low noise density, low offset drift, low power consumption, and selectable measurement ranges. It can be used for cost-effectively low-level vibration measurement applications such as structural health monitoring (SHM). The microcontroller was programmed to sample the vibrational signals sensed by the accelerometer in x, y, and z directions, and the collected acceleration signal was processed and stored in a USB drive. About once a week, the logged data was retrieved, and frequency domain analysis with Fast Fourier Transform (FFT) was performed offline using Python programming.

Our preliminary tests were conducted by placing the data acquisition device on three pier caps of the selected bridge as shown in Figure 2. The pier vibrations were excited by the passing vehicles. The sampling rate for the vibration signal is chosen as 100 Hz which is sufficient to capture the vibrational frequencies, as expected to be less than 25 Hz. The peak-to-peak acceleration of the pier due to traffic is typically about 20 mg.

The acceleration was sampled in blocks of 8192 readings and an FFT was used to produce a signal spectrum. This block length provides the necessary frequency resolution of  $200\text{Hz}/8192 = 0.024\text{ Hz}$ . Each block was stored as a data file. Individual spectrums were not consistent due to the variety of excited vibrations in different time slots. To improve the accuracy of the vibrational frequencies, more datasets are required for doing FFT analysis to obtain average frequency spectrums. The measurements were first carried out on three pier caps, pier 2, pier 3 and pier 4 as in Figure 1. Then the measurements were carried out on the bridge deck directly over pier 4.

Since the vibrations of the pier were easily observed by putting the sensor on the pier caps, it was also decided to investigate if the pier vibrations could be observed from the bridge vibrations by putting the sensor on the bridge deck. Therefore, in addition to the measurements on the pier caps, vibration data were also acquired using the accelerometer

device installed on the bridge barrier wall directly above pier 4. The measurements were carried out by collecting about 1014 data files each day, typically, about 507 files the during the period of daytime (8 am - 8 pm) were chosen for doing the FFT analysis considering the traffic is considerably reduced during night.

Figure 1. Schematic diagram of the bridge under observation

Figure 2. A) The data acquisition device on a bridge pier cap. B) View from the bridge deck of the DAQ system sitting on the pier cap.

When dealing with the bridge vibration, the peak frequencies of the averaged FFT spectrum were determined using a peak-finding algorithm in Python library SciPy. The found peak frequencies represent the vibration modes of the bridge. To determine the number of data files needed to adequately locate the individual peak frequency, the data processing for obtaining averaged frequency spectrum was conducted by randomly selecting subpopulations with the bootstrap approach. From the 507 data files, 10 files, 25 files, 50 files, 100 files, 250 files and 500 files were chosen for doing spectrum analysis, respectively. The simple linear average of the spectrums was calculated for each subpopulation of files, for instance, using  $N = 400$  subpopulations of 10 files to find peak frequency distributions for each observed vibrational mode. The histogram of the peak-frequency distribution of each mode was plotted against the subpopulation of data files.

### 2.2 FEM modelling

Figure 3 shows a bridge model for finite element analysis (FEA) using the SAP2000 software, it was used to simulate the dynamic behaviors of the bridge vibrations and to determine the expected vibrational modes of the bridge in addition to the effect of the scour on the vibration properties of the bridge. The bridge's steel girders and concrete slab were modeled using thin shell elements. The girders and the slab were connected

using stiff link elements. The bracing system, brackets and edge beams supporting the sidewalk were modeled using frame elements. The bridge abutments and foundations were modeled using thick shell elements. The bridge bearings between the abutments and the girders were modeled special link elements to allow for rotation only or rotation and relative displacement depending on the type of bearing. Rotational and vertical springs were added to the bottom of piers 3, 4 and 5 to simulate the effect of the soil at the foundation level. Horizontal area springs were also added to footing and pier shafts to simulate the effect of the soil on the sides of the piers. A maximum element size of 600 mm was chosen after comparing several mesh sizes for a portion of the bridge consisting of a girder and part of the concrete slab. In total the model consisted of 88643 nodes, 2268 frame elements, 7764 thick shell elements, 75529 thin shell elements and 12704 link elements.

### 3 RESULTS AND DISCUSSION

#### 3.1 Traffic induced vibration of piers

The accelerations of the piers were measured as the vehicles passed. A typical example of vibrations is shown in Fig. 4A, which is for the sensor mounted on the cap of pier 4. In this example, it appeared several vehicles passed during the measurement. The passing vehicles excited vibrations, and the vibrations were then damped and decayed. The vibration amplitudes cover a span from 5 mg for smaller vehicles to 40 mg for larger vehicles. Each data file (a block signal) contains the sampled acceleration readings of 8192 at the rate of 100 samples per second. The average FFT spectrum of many data files was calculated to achieve higher and smoother signal amplitudes over background signals. A typical example is shown in Fig. 4B, the data was collected from pier 4 cap. There are obvious vibrational peaks at approximately 2.28 Hz, 9.0 Hz and 12.9 Hz. The obtained frequency spectrums show that only vibrations along the direction of the traffic flow were observed. The vibrations in the other two directions were not observable above the noise level from their FFT spectrums. This is physically reasonable when the geometrical shape and mechanical properties of the piers are considered, the pier structure in a thick-shell-shape is very long and sturdy in the direction perpendicular to the traffic flow and in the up-down direction, the vibrations in these two directions are barely excited and observable, only flexural vibrations in the traffic flow direction are easily excited and observable from the frequency spectrums.

#### 3.2 Traffic induced vibration of the bridge superstructure

Accessing the pier caps is difficult. As part of this study, we also explored measuring the vibrational frequencies on the bridge deck, which is much easier to access. In the case of this bridge, the deck can be accessed via a walkway. Our hypothesis is that the pier vibration will be coupled to the deck and therefore the pier vibration can be accessed via the superstructure. In this case, the accelerometer was attached to the impact barrier. The details are given in Fig. 5A and 5B. The location is also noted in Fig. 1. In this case, a larger capacity battery could be used and vibrational signals could be gathered for approximately 24-48 hours. These signals were gathered periodically over 10 months. The vibrations of the bridge deck were observed in all three directions since the bridge deck is free to vibrate. A typical example is shown in Fig. 6A, where the acceleration signals in the direction of traffic flow were processed using FFT to produce spectrums. A simple algorithm was used to find an estimate of the frequency peak positions. These peaks are labelled with a black dot in Fig. 6A.

Figure 4. (A) Vibration measured on the cap of pier 4. (B) FFT spectrum of sampled acceleration from (A)

Figure 5. Location and mounting of DAQ apparatus on bridge

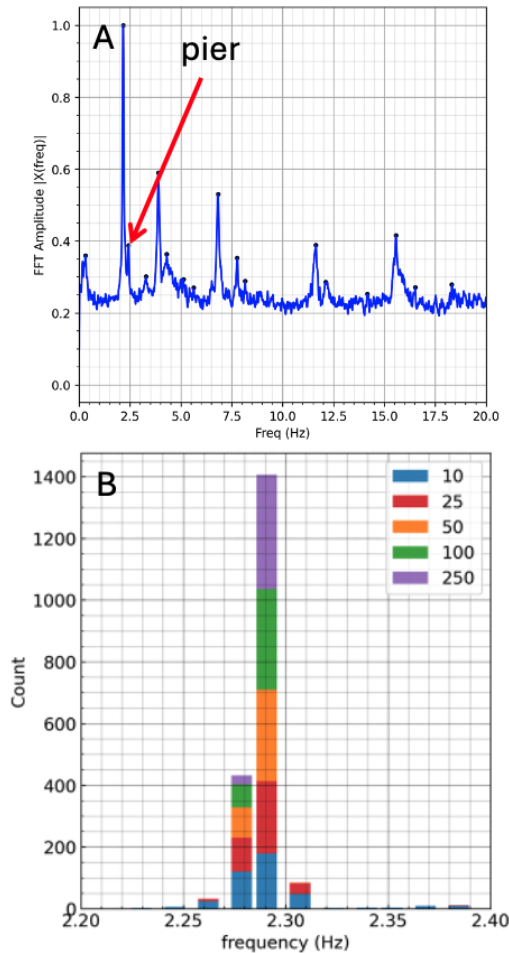

Figure 6. Vibrations measured on the bridge deck. (A) FFT spectrum. (B) Stacked frequency histogram

Table 1. Frequency estimates versus sample size

Sample size	Mean frequency	Median frequency	SD frequency
10	2.286	2.289	0.026
25	2.286	2.289	0.013
50	2.285	2.289	0.007
100	2.286	2.289	0.004

Single vibrational spectrum cannot produce good estimates of the vibrational frequencies with uncertainties that are small enough for this application. Therefore, multiple frequency

spectrums are averaged to produce better results. We have investigated the uncertainty of the frequency estimates versus the number of the frequency spectrums being averaged. The outcome is presented as a stacked histogram in Figure 6B. The number of data files for frequency averaging used 10, 25, 50, 100 and 250. With 10 averages, the peak frequency estimates fall into several bins. As the number of averages increases, the estimates fall into fewer bins. As shown in Table 1, for each block signal consisting of 8192 acceleration readings at a slightly higher sampling rate of 125 Hz, frequency estimates were done using different numbers of the block signal (sample sizes) by repeating FFT calculation of 400 trials, and the stacked frequency histogram was obtained by calculating the mean, median and standard deviation of a certain number of burst signals. For the averages of 10 spectrums, the standard deviation was 0.026 Hz. This would give a 95th percentile confidence limit of  $\pm 0.052$  Hz. As we will show later, this is greater than the uncertainty remaining after temperature compensation is applied, which is  $\pm 0.040$  Hz. Using 25 averages, the standard deviation was 0.013 Hz. This would give a 95th percentile confidence limit of  $\pm 0.026$  Hz. This is less than the uncertainty remaining after temperature compensation is applied and would be suitable for the detection of scour. Finally, the average number of 50, 100 and 250 provides better estimates well below the variability remaining after temperature compensation is applied.

Figure 7. (A) vibrational frequency versus temperature. (B) residuals versus temperature for compensation.

### 3.3 Temperature induced changes to vibration and temperature compensation

Temperature is one of the main sources of environmentally induced vibrational change [14]. The mechanical properties of materials can change with temperature as well as the boundary conditions. Bearing restraint can also be influenced by

temperature [15]. The extracted peak frequencies were plotted against temperature to determine if the effects of temperature could be compensated for. The temperature used in this case was the average daily ambient temperature. This was used because the heat capacity of the bridge superstructure is relatively large and the change of bridge thermal properties with daily temperature is considered insignificant.

The vibration frequencies were extracted from the sampled data over a 10-month period, covering the full seasonal temperature swings expected for this structure. Each data point in Fig. 7 represents the vibrational average over a 24-hour period and was derived from an average of greater than 250 spectrums. According to the results of the uncertainty estimates as stated in section 3.2, here the uncertainty of each measurement point is expected to be less than 0.01 Hz.

Fig. 7A is the plot of vibrational frequency versus temperature. There is an obvious dependence of the vibrational frequency on temperature. The dependence was modelled using simple linear dependence. The linear dependence model was then used to compensate the measured frequency data for temperature.

The residuals versus temperature are plotted in Fig. 7B. Over the entire temperature range and period, the residuals fall within  $\pm 0.04$  Hz. This result is similar to that observed on other bridges [16]. Therefore, if a vibrational frequency was to fall outside this range, it would indicate that a structural change had occurred. The significant frequency change beyond the temperature compensation range could be due to several factors, but one possible factor would be the change in boundary conditions due to scour. Because a field experiment using excavation to simulate scour on this structure is not feasible, numerical calculations using a FEA model will be helpful for studying the vibrational modes of the bridge and scour effect.

### 3.4 Comparison of FEM calculations to measured response

A finite element model was developed as outlined in section 2.2. This model was used to simulate the dynamical vibration behavior of the bridge superstructure. Table 2 presents a few vibration modes obtained from the FEM model, where the corresponding frequencies from the measurements are also listed for comparison. The simulation agrees with the measurement very well for those modes. Modes #2 and #3 are not presented and could not be compared to the measured frequencies because they correspond to the bending of piers 5 and 3 respectively where the connection with the superstructure allows for relative displacement and therefore the vibration transferred to the superstructure is very weak. Additionally, no direct vibration was measured on those piers.

There are many vibration modes derived from simulation, such as, the rocking mode, the flexural and twisted modes of the bridge deck together with the piers, here the modes listed in Table 2 are of most interest to this study since these vibration modes were also observed from the field measurements. Some simulated lower vibrational modes and higher modes were either insignificant or unobservable in the field measurements, and they were either not excited or quickly damped out. Table 2 shows that the match between the calculated and observed frequencies is within 8%. In addition, the frequency of 2.289 Hz is the same as the measured for the sensor on pier 4 cap in Figure 4B, this vibration mode can be considered the coupling

between the pier 4 and the bridge deck. It provides a convenient way to monitor the pier vibration without accessing the pier.

The FEM model was also used to estimate the effect of the scour on the natural frequencies of the bridge. The scour was simulated by removing the top lateral springs representing the effect of the soil at the top of the pier. Scour values of 1 and 2 meters were simulated for piers 3, 4, and 5. Table 3 shows a comparison of three natural frequencies representing the bending of the piers with and without scour. It is apparent that the scour has a significant effect on the natural frequencies and therefore could be used to detect scour. The pier natural frequencies are not easily observed in the vibrational spectra. This may be due to the traffic induced vibration not preferentially exciting the pier natural frequencies. The more easily observed vibrational modes appear to be associated with the bridge superstructure. However, since the pier-superstructure system is a coupled mechanical system scour will affect both the pier and superstructure natural frequencies.

Table 2. Comparing the simulated and measured frequencies

Mode	#1	#4	#5	#6
Measured	0.26	2.06	2.29	2.81
FEM calculated	0.29	1.98	2.12	2.75

Table 3. Scour effect on first modes of three piers

Mode	Natural frequency Hz		
	Without scour	1 m scour	2 m scour
1 bending of Pier 4	0.292	0.282 (-3.5%)	0.277 (-5.17%)
2 bending of Pier 5	0.431	0.264 (-38.8%)	0.146 (-66.2%)
3 bending of Pier 3	1.384	1.278 (-7.67%)	1.204 (-13.04%)

### 3.5 Impact of truck mass on estimated vibrational frequencies.

One issue with the use of traffic induced vibration is that the presence of the vehicle will perturb the vibrational frequencies. When the truck passes over a span, the mass of the truck will perturb the vibrational frequency [17]. After the truck passes, the vibration will continue. This can be thought of as a driven vibration time and a free vibration time. In our case, we are using the complete time sequence and the signal would be a mixture of driven and free vibrations. If the driven vibrational frequency and the free vibrational frequency are significantly different, then one might expect the vibrational peak to be broadened out as it would be a mixture of driven and free vibrations. In this case, the peaks are well defined, and any broadening does not appear to be significant. In future work, the time variation of vibrational frequency as vehicles pass over will be examined more closely.

## 4 CONCLUSIONS

For this medium-span bridge, vibration measurements of the piers and the bridge deck were performed, and the corresponding frequency spectra were derived. The dynamic behavior of the bridge was also simulated using Finite Element Analysis (FEA). The major vibration modes identified from field measurements were found to match those obtained through FEA simulation. A common vibration mode at approximately 2.289 Hz was observed in both Pier 4 and the bridge deck above it, attributed to dynamic coupling between the structural components. With compensation for temperature-

induced frequency changes, frequency shifts of less than 1.7% can be reliably detected. FEA simulations showed that scour of 1–2 meters around the base of the pier resulted in natural frequency shifts greater than 10%. In future work, finite element model predictions of traffic-induced vibrations will be compared with the 1.7% detection threshold. This combined approach of in-situ measurements and numerical simulations is expected to provide a viable alternative for monitoring bridge scour.

**ABSTRACT:** Navigation locks are essential components of inland waterways. They enabling vessels to traverse sections with differing water levels. These structures are increasingly vulnerable to damages caused by (1) scour i.e., erosion of sediment due to natural water flow and ship-induced currents, and (2) sediment or debris obstructing lock gates. Scour-induced damage threatens the structural integrity of locks, leading to costly maintenance, prolonged closures, and economic and environmental consequences. Traditional monitoring methods, including visual inspections and fixed instrumentation, are often hampered by water turbidity, high costs, and susceptibility to debris damage. Sonar technologies provide a non-invasive, cost-effective alternative for detailed underwater imaging, even in challenging environments. This paper explores the application of 2D sonar imaging for monitoring navigation lock approaches, with a focus on bed morphology and scour progression. Using the Prinses Beatrix Lock in the Netherlands as a case study, the paper demonstrates the effectiveness of 2D sonar systems in (i) detecting morphological changes such as scour and sediment transport from bed protection layers and (ii) estimating ship drafts. The findings underscore the importance of integrating sonar-based structural health monitoring systems to extend the lifespan of navigation locks, enhance safety, and optimize maintenance strategies for aging waterway infrastructure.

**KEY WORDS:** sonar technologies; navigation locks; morphological changes; ship draft.

### 1 INTRODUCTION

Inland waterway transport is significantly more efficient than land-based (i.e., road and rail) transport, as waterways allow for the movement of large cargo volumes with low energy consumption and reduced environmental impact [1]. Navigation locks play a critical role in facilitating inland waterway transport, enabling vessels to traverse sections of canals or rivers with varying water levels. These structures are subjected to various environmental and operational stressors, which can lead to structural deterioration over time. One of the primary concerns in the maintenance of navigation locks is scouring, which is the removal of sediment caused by hydrodynamic forces [2]. Scouring can lead to morphological changes in the bed protection layer, potentially compromising the stability of the lock foundation. The interaction between ship-induced currents and the lock bed remains a significant challenge, particularly for older lock chambers that were not originally designed for large and high-powered vessels [3,4]. The issue is exacerbated by increasing global shipping activities, where vessel sizes and engine power have also grown, leading to intensified hydrodynamic forces in lock approaches [5]. The propeller wash from these vessels accelerates bed degradation, increasing maintenance demands and potential structural risks. The existing bed protection layers, designed decades ago, may not effectively withstand these forces induced by modern vessels.

Traditional monitoring techniques for scouring in navigation locks rely heavily on periodic visual inspections, divers, or stationary sensors. These methods are often costly, labour-intensive, and ineffective in real-time damage detection, particularly in turbid waters where visibility is poor [6]. Some advanced techniques, such as 3D sonar imaging, provide high-

resolution data but are prohibitively expensive for widespread implementation. The lack of an affordable and continuous monitoring system leaves lock operators and maintenance teams with limited options for proactive maintenance strategies [7]. The necessity for continuous monitoring of scouring in locks has been well established in existing literature [8], particularly in cases where the structural integrity of the lock foundation is at risk due to progressive erosion.

The issue of sediment transportation in lock complexes, originally designed for smaller vessels, becomes more pronounced with the use of large modern cargo ships. These vessels have a deeper draft, which brings their propellers close to the canal bed. As the vessel moves through the lock, the propeller's interaction with the sediment can cause stones or debris to be displaced and rolled toward the lock chamber. This can result in blockages that obstruct the closure of the lock gates. The presence of such obstructions can cause damage to critical components of the lock system, such as the de-icing pipes [5], which are essential for preventing freezing in cold climates. To prevent such incidents, a continuous monitoring system is essential for detecting these "rolling stones" at an early stage. Such monitoring system is also anticipated to provide insights into how the depth of the ship's draft, which can be correlated with sediment displacement.

To address these issues, an affordable and scalable monitoring system employing 2D sonar imaging has been designed to continuously assess the approach to a lock complex. This novel approach offers scour monitoring, detection of *rolling stones* and estimation of ship's draft in navigation locks. The monitoring system incorporates an image processing algorithm to detect bed morphology changes and provides assessment of vessel-induced impacts on the lock bed.

By enabling early detection of bed morphology changes, the system allows for timely interventions and mitigation measures to prevent further degradation of the lock complex. This approach aligns with the broader objectives of structural health monitoring of navigation locks, which aims to extend infrastructure longevity while reducing maintenance costs, thereby enhancing maintenance strategies. The findings of this study can be applied to other navigation locks facing similar challenges, offering a scalable solution for sustainable lock maintenance and improving the overall reliability of inland waterway infrastructure.

## 2 BACKGROUND

This section explains causes of scour, particularly, in lock complexes, scour monitoring techniques and sonar technologies.

### 2.1 Scouring

Scour can be categorized into three forms: local scour, contraction scour, and general scour. General scour typically happens as a result of alterations in the natural flow of water, causing the river/canal bed to experience both aggregation and degradation. Contraction scour, on the other hand, is a result of an increase in the flow velocity in conjunction with a reduced cross-sectional area of the waterway. The consequence is the removal of sediment from the waterway's bottom and side [9]. Local scour, the third form, takes place due to turbulent vortices generated by the flow of a current impacting the bed or foundation of the waterway, leading to erosion of surrounding sediment [10].

Local scour is a gradual process that evolves through multiple stages. The initial stage is characterized by the occurrence of erosive effects and damage due to extremely high velocity. Subsequently, scour transitions to the development stage, where the rate of erosion slows down compared to the initial stage. Finally, it reaches the equilibrium stage, where the depth of scour remains stable, and any changes in its depth become imperceptible [11]. The depth of the scour hole in the equilibrium stage is compared with the critical depth of the lock slab or foundation. Local scour takes place in two distinct forms: clear-water and live-bed flow conditions. Differentiating between the two can be determined by observing whether sediment is eroded and replenished (live-bed) or eroded without replenishment (clear-water flow) [10]. The latter condition is often investigated in scour studies.

Local scour is generally linked to turbulent vortices [12–15]. Unlike in cases of bridges, where this turbulence arises from a change in the cross-sectional area of the watercourse due to bridge piers, in locks, the turbulence is caused by the change in the bed roughness introduced by the weir or lock floor. Therefore, structures like locks and weirs, constructed on a soft bed in watercourses, tend to induce local scour, especially in the surrounding bed. To counteract this, a bed protection layer is applied to stabilize the adjacent loose bed.

The intensity of the turbulent vortices generated by this change is directly proportional to the velocity of water flow, higher velocities resulting in greater intensity. In the navigation locks, two factors influence the water flow velocity. Firstly, during the emptying of the lock chamber through small openings, the velocity increases. The intensity of this effect

depends on the water level difference between the two sides of the lock. The second factor affecting velocity is the passage of large vessels through the navigation locks. The propeller wash from these large vessels significantly increases water flow velocity, expediting morphodynamical changes in the surrounding bed through scouring. Ships, especially during the initial movement or acceleration, exert the most stress on the bed. Figure 1 (top) illustrates a schematic of a scour hole due to the currents from the emptying of the chamber, and Figure 1 (b) depicts a schematic of a scour hole due to the currents from the propeller wash of entering ships.

Figure 1. Development of a scour hole downstream of the lock head resulting from (top) currents caused by emptying the chamber, and (bottom) propeller wash of entering ships

When the propellers and thrusters initiate spinning, they set the previously stagnant water in motion. Consequently, they need to overcome the water's initial inertia, leading to the creation of localized vortices and high shear stresses. This shear stress is the cause of bed erosion or scouring. However, once the inertia is surmounted, the stress levels tend to diminish over time [16]. The scour hole generated by the propeller wash can be described as a combination of three polynomial components, including (1) a small scour hole located directly beneath the propeller, (2) a primary scour hole downstream of the initial one, and (3) a deposition mound situated farther downstream of the primary scour hole. This description is based on a setup with non-cohesive sediment [17].

The erosive process of scouring creates a depression in the immediate bed area, and if the slab/foundation's critical depth is surpassed, it can ultimately lead to the undermining and collapse of the foundation. On the other hand, the scoured material can alter the required depth for the navigation of ships. Therefore, in old navigation locks, the scour holes need to be refilled quite often and the sedimentations dredged, otherwise, countermeasures such as a bed protection layer have to be applied. Both scenarios, reduce the efficiency and operability of the lock, causing considerable economic loss [4]. Accordingly, scour holes induced by propeller wash of the

ships turned into one of the most prominent concerns for the design and maintenance of the waterways system.

Scour is a complex physical phenomenon involving interactions between flow, structures, and soil. Predictive models for scouring remain unreliable, contributing to the inherent uncertainty in its understanding. Therefore, there is a pressing need for the regular monitoring of scour at critical infrastructures that face a higher risk of scour-induced failure [8]. Continuous monitoring of areas prone to scouring is crucial due to the time-dependent nature of this phenomenon. This helps prevent scour-induced damage from becoming severe and causing critical failures.

## 2.2 Scour monitoring

The most widespread incidents of scouring in wet infrastructures are related to bridges, which is one of the main causes of bridge collapse [18]. An economically applicable and effective method to combat scouring is to monitor its progress over time and apply countermeasures before poses problems to the structure. The most prevalent monitoring scheme that is commonplace in engineering is visual inspection. In the case of wet infrastructures, visual inspections usually are undertaken by the divers. However, the risk of this inspection method during the flood is high. There is also one important fact about scouring that scour holes might be refilled, accordingly, the strength of the bed is not what it shows in the inspection [7]. Therefore, an effective method could offer continuous monitoring of the depth of scouring. As scour monitoring techniques are relatively well developed for bridge structures, and the origin of failure in locks is the same, the treatment can be generalized to these wet infrastructures as well.

As for bridge scour monitoring, some sensors have been employed that can measure the depth of scour holes such as single-use, pulse or radar, fibre-Bragg grating, driven or buried rod, and sound wave devices [7]. All these sensors are applicable in monitoring the progress of scouring in navigation locks. Among the mentioned methods, the last one; sound wave devices, provides region-wise monitoring, while the rest are spot-wise. In an extensive area such as a lock entrance bed, since the exact spot of scouring is hard to determine, the most promising method is using sound waves or so-called sonar devices [6].

## 2.3 Sonar techniques for scour monitoring

Sonar is a vital technology used to explore the underwater environment. Sound waves propagate and penetrate more effectively than light through water, especially in conditions of high turbidity. This feature makes it an ideal tool for underwater mapping and detection. Moreover, sound reflection shares similarities with light reflection; surfaces with different textures reflect varying fractions of the incidence of sound. For instance, textured surfaces cause reflection, scattering, and absorption. Surfaces with low reflection have more absorption [19]. The reflecting surface also determines the direction of the reflection. On smooth surfaces, the angle of reflection, measured from the normal to the surface, is equal to the angle of the incident of the wave [20]. However, rough surfaces scatter the waves or reflect them in all directions [19].

Based on the principles of sonar, sonar images can provide information about the location of bed surfaces with (i) strong

reflectivity, such as rocks, that (ii) are normal to the sonar transducer (hot/light-coloured pixels). These surfaces may include the uphill side of projections or depressions in the bed. On the other hand, the location of surfaces with low or no reflectivity is also known in the sonar images (cool/dark-coloured pixels). For example, surfaces that are parallel with the sonar transducer, silt or mud-covered areas, areas overshadowed by rocks, or the downhill side of depressions and projections. Figure 2 schematically demonstrates reflection intensities against surfaces of the seabed in different directions such as the uphill/downhill facing of projections/depressions.

Figure 2. Reflection intensity of acoustic signals

When a rock resting on the waterbed is subjected to a force from high-velocity currents, depending on the weight of the rock, it may undergo displacement from its previous location. In this case, the intensity of signal reflection received by the sonar alters in a specific time interval that is related to a certain location. These alterations occur due to variations in the incident angle of the signals, resulting in modification of the sonar image at that particular location. Additionally, the presence and shape of shadows may undergo changes that indicate a change in the location or orientation of its source. Therefore, by placing a 2D imaging sonar underwater at a suitable altitude and a fixed position facing toward the area of interest on the bed, the changes in the bed features can be captured.

## 3 THE BEATRIX LOCK COMPLEX

The Princess Beatrix Lock is the largest monumental inland navigation complex in the Netherlands. The lock complex, with three chambers, is located within the Lekkanaal, connecting the Lek River and the Amsterdam-Rhine Canal. This connection is the main and shortest freight corridor and inland waterway between the North of the Netherlands/Amsterdam and Rotterdam/Antwerp. Around 50,000 vessels pass through the lock every year [21]. The Beatrix lock is positioned in the north-south direction, the water flow is northwards. Filling and emptying the lock system is performed via the gates. That means water is brought into or leaves lock chambers through openings in gates, instead of bypassing culverts or stilling chambers. The hydraulic head differences between the two sides of the lock can exceed two meters. Two of the chambers; the twin chambers, with a length of 225 m and a width of 18 m were built in 1938. These chambers can host ships with a maximum draft of 3.5 m. However, the third chamber, built in 2019, is designed to accommodate vessels of CEMT class Vb

with a draft of 4 m. The length of the third chamber is 276 m and its width is 25 m. Figure 3 shows an annotated aerial view of the Beatrix lock complex.

Figure 3. Aerial photo of The Beatrix lock [22]

The filling and emptying system of all three chambers of the Beatrix lock is the opening gate. The gates of the twin chambers have six openings at a height of one meter from the floor of the chamber. The hydraulic head differences between the two sides of the opening are variable and sometimes reach two meters. This difference affects the flow velocity of the opening outlet. In fact, the high-velocity currents from emptying of the chambers (levelling downward) accelerate the progress of scouring at the downstream side of the lock. This is potential damage that occurs due to the operation of the lock by itself, without any ships.

The effect of ship propeller wash on the scouring is intensified by reducing the distance between the ship propeller altitude and the bed. To minimize this effect, a minimum under-keel clearance needs to be considered when the ships pass through the lock. According to the waterways guideline of Rijkswaterstaat, which is the executive agency of the Dutch Ministry of Infrastructure and Water Management, the water depth in navigation canals should be at least a factor of 1.4 times the loaded draft of a passing ship relative to the normal low water level [21]. For example, for ships with a draft of 4 m, the water depth should be at least 5.6 m. This consideration is to minimize the scouring effect of ships' propeller wash on the canal bed. Also, the guideline provides a minimum keel clearance above the chamber floor in locks for different ship categories. For the ships in classes I, II, and III, keel clearance above the chamber floor is 0.6 m, for classes IV to Vb 0.7 m, and for classes VIa and VIb 1.0 m. This consideration needs to be met to minimize the erosion effect of propeller wash related to passing ships.

It is important to know whether the required water depth in the Beatrix lock is in accordance with the guidelines or not. Consequently, the minimum under-keel clearance of the passing ships from the Beatrix lock during the past years of 2019 and 2020 is investigated. To compute the water depth at the moment of passage of ships, the water level and level of the canal bed are needed. By subtracting these two levels, the water depth is determined. In the Rijkswaterstaat database, all the

passing ship's details are registered. These details include the date and time of ship entry to the lock, lockage time duration, chamber, direction of passing, and ship category. It is good to mention that ships within the same category have the same loaded draft. However, the status of the ships (loaded/unloaded) is unknown in this dataset.

The level of the canal bed is extracted from a bathymetry map of the lock and surrounding canal. The bathymetry is conducted by Martens en Van Oord in the year 2021. Figure 4 shows a segment of the bathymetry map of the chambers and the approach at the downstream side of the lock. Bed levels at the twin chambers and approach are estimated at -4.62 m and -4.95 m respectively (these numbers are circled in the figure). Therefore, the water depth of the old chamber during the passage of class VIa ships is on an average between 4.24 m and 4.56 m for the chamber and approach of the lock respectively. However, according to the guidelines, in this case, the water depth should be at least 5.6 m.

Figure 4. The bathymetry map of the north side of the Beatrix lock (downstream)

To gain insight into the condition of the approach bed of the Beatrix lock, the bathymetry data of the lock is investigated. According to the available drawing from the Beatrix lock in combination with the bathymetry of the canal around the lock structure, there are two changes in the roughness of the watercourse bed along its approach. The first change is related to the junction of the lock head and the bed protection layer of the canal, which is implemented immediately after the lock head. The second change is associated with the junction of the bed protection layer and the natural bed of the canal. Therefore, the junction of these two beds with different roughness is the area where local scour takes place. According to a diver inspection report on the bed protection layer of chambers 1 and 2, the layer is composed of pieces of rock affixed with a cement paste. However, the cement paste does not fully cover the rocks, resulting in a rocky finishing surface.

The point cloud data in Figure 4 from the north side of chamber 1 indicates degradation of the protection layer at its intersection with the natural bed, revealing the progress of the

scour hole. While the protection layer on the south side of this chamber shows signs of degradation, the intensity or depth of degradation is not as high as observed on the north side. This difference could be attributed to the lower water depth on the downstream (north side) resulting in more pronounced effects of the ship's propeller wash. The bed protection of the north side of chamber 2 and the south side of chamber 3 have not experienced any significant degradation. However, on the south side of chamber 3, a scour hole has formed at the natural bed of the canal, which could be an initial indication of degradation in the protection layer.

## 4 SONAR FOR THE LOCK MONITORING

### 4.1 Selection of sonar device

A variety of sonar devices are available for marine applications such as seafloor mapping, underwater structure inspection, navigation, and commercial fishing [23–26]. Given the cost constraint of under €25,000, a 2D sonar was selected for its affordability compared to 3D alternatives.

To identify the most suitable option, 12 commercially available 2D sonar devices were evaluated using a rating system based on criteria including price, frequency, range, power consumption, weight, resolution, casing, field of view, and beam angles. Each device was scored, normalised, and expressed as a percentage. All criteria were equally weighted, as established through requirement analysis. The ISS360 imaging sonar emerged as the optimal choice. Details of the scoring method are provided in Table 1, while the performance results and corresponding ranking are presented in Table 2.

Table 1. The scoring system and the description of the criteria

Score	Field of View (°)*	Score	Frequency (kHz)
5	360	3	>= 900
4	140	2	> 500
3	130	1	<= 500
2	120		
1	90		
	<b>Horizontal Beam Angle (°)</b>		<b>Casing</b>
3	<= 0.6	1	Titanium
2	<= 1.2	0	Aluminum
1	> 1.2		
	<b>Vertical Beam Angle (°)</b>		<b>Weight (kg)</b>
5	> 28	3	< 0.5
4	>= 26	2	>= 0.50
3	>= 24	1	>= 1.00
2	>= 22	0	>= 3.00
1	>= 20		
0	< 20		
	<b>Operating Range (m)</b>		<b>Resolution (mm)</b>
5	>= 120	2	< 5 mm
4	> 85	1	<= 10 mm
3	> 70	0	> 10 mm
2	> 55

### 4.2 2D Sonar system

The ISS360 2D imaging sonar from ImapctSubsea is selected as the sonar device for the lock monitoring system. This sonar is a single-beam rotary sonar that scans the area by rotating a transducer via an in-built stepper motor. The transducer emits an acoustic beam with a height of 23° and a width of 2.2° at a central frequency of 700 kHz. It operates within a bandwidth of 600 kHz to 900 kHz and has a range performance ranging from 0.15 m to 90 m. Frequencies below 700 kHz are employed for distances greater than 35 m. Figure 5 shows the geometry of the ISS360 imaging sonar sensor and its fan-shaped acoustic beam.

Figure 5. ISS360 imaging sonar sensor and with its principal dimension (left) and beam angles of the sonar (right) [27]

The sonar's power consumption is 150mA at 24V DC during scanning. The sonar device is powered by the Mean Well AC/DC PSU - LRS-75-24 - PSU 1, which outputs 24V/0-3. To enhance its ingress protection (IP) rating, the power supply is enclosed in a (150×110×70 mm) junction box with an IP56 rating. This protective case ensures the power supply can operate in wet environments and raises its IP rating to IP56.

The sonar must be firmly kept in its desired location with minimal vibrations. The sonar mount is specifically designed for this purpose. It restrict the displacement of the sonar to a maximum of 1 mm. This necessitates the mount to be rigid enough to prevent any vibrations or displacement caused by intense ship-induced currents. Another requirement for the sonar mount, associated with the selected sonar device, is to ensure electrical isolation from the housing of the sonar.

Considering the diameter of the sonar (47 mm), two scaffold clamp sizes of 50 mm, coupled with two brackets, are employed as the sonar mount. In one clamp, the sonar is fixed,

while in the other clamp, the mount pipe is fixed. The mount pipe can then be affixed to a wall using another clamp and bracket. This coupled clamp system allows the sonar to be positioned and fixed in all orientations. Figure 6 (left) presents the clamp system with sonar and the pipe. To meet the isolation requirement of the mount, a non-conductive spacer (Figure 6 (right)), made of Polylactic Acid, was designed. It is installed between the sonar and the clamp.

Figure 6. A coupled clamp system with sonar and the mount pipe (left) and a 3D sketch of the spacer (right)

The thickness of the spacer was considered to be 1.5 mm so that, when placed around the sonar, the total diameter of the sonar and the spacer is 50 mm, fitting the size of the clamp. To minimize the risk of the sonar slipping off the mount under high-pressure currents caused by ship propellers, the spacer was designed to provide a firm grip between the sonar and the clamp. The grip between the sonar and the clamp is facilitated by a projection in the spacer that fits into a recess in the sonar housing. Additionally, two teeth were added to the outer side of the spacer to ensure the grip between the spacer and the clamp. Figure 7 shows the detailed design of the spacer. To dampen vibrations between the sonar and the spacer, anti-vibration damper strips were affixed to the spacer. Shows the printed spacer placed between the sonar and the clamp. To prevent self-loosening of the clamp nut and ensure that the sonar remains securely in its place, a spring washer with a double nut configuration is being considered for the clamp

Figure 7. Detailed parts of the spacer

#### 4.3 Sonar location

The north side of chamber 1 is found to be the critical area of concern in the approach bed of the Beatrix lock. The sonar is installed to cover this area. Long-term monitoring of this area may reveal changes in the scour hole in the bed protection layer. The weakness of the protection layer in that region makes it susceptible to further growth, i.e., erosion. The concrete floor of the lock chamber also needs to be included in the sonar's field of view. Such configuration is expected to verify the capability of the monitoring system to capture the deposits on the threshold. If rolling stones/deposits on the concrete floor can be captured, it implies that they can also be captured on the

gate threshold. Situating the sonar system between these critical areas ensures comprehensive coverage while considering the trade-off between range limitations and image resolution. Figure 8 provides a top-down view of the point cloud from the north side of chamber 1 superimposed on the drawing of this region. Both the concrete floor of the chamber and the scour hole are illustrated. The location of the sonar is on the east side of the chamber in between the critical areas.

Figure 8. The top-down view of the point cloud of the north side of chamber 1 superimposed on the drawing indicating the sonar location.

The system must not disrupt the operation of the lock. This requirement prohibits any projection of the sonar installation into the track of passing ships. Consequently, the sonar is installed behind the fendering wood of the canal wall. Another requirement is to restrict the sonar displacement to a maximum of 1 millimetre. For this purpose, a galvanized steel pipe 6 m long with a diameter of 50 mm is used for the sonar mount. The mount pipe is clamped at two points to the fendering timbers with a distance of 1 m to provide the required rigidity for restricting vibrations caused by the turbulence of the ship's propeller. Figure 9 (a) depicts a schematic of the sonar installation, providing information about dimensions, while Figure 9 (b) shows an above-water view of the sonar location. Additionally, Figure 9 (c) offers a cross-sectional view of the canal, demonstrating that the outward projection of the sonar does not obstruct the ship's path.

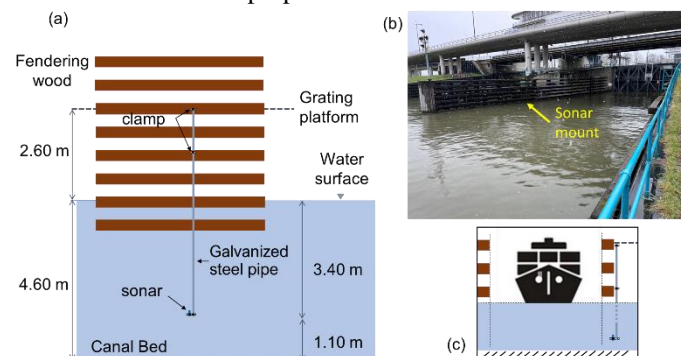

Figure 9. A schematic of sonar installation with some principal dimensions (a), the view of sonar location (b), and projection of sonar toward the ship track (c).

## 5 MONITORING RESULTS

### 5.1 Changes in the canal bed

The image rendered by the sonar contains two distinct parts; the bed protection layer, where the change in its feature is being sought, and the concrete floor, where the presence of sediment or rolling stone is sought. This section focuses on the bed protection part of the image to evaluate the ability to capture change in bed.

To verify the bed scanning subsystem, over a period of 7 days, the sonar continuously scanned the bed area of interest. Sequential images were acquired by capturing a screenshot from the software window every minute. These images were subsequently compared to evaluate the subsystem's effectiveness in capturing changes in the bed. Effective functionality necessitates, firstly, the absence of any changes in the sequential images as long as no source of excitation, such as the passage of ships or emptying the chamber, occurs. Secondly, changes are expected to occur in the images following a severe excitation.

It is important to note that the emphasis is on changes resulting from the removal of spots with high-intensity reflection, rather than changes due to the appearance of new spots. The removal of spots that have endured for an extended period, signifies their resilience against relocation by heavy ships. The longer a pattern of spots remains in place, the more assuredly it is considered fixed parts of the protection layer. In the event of such changes, it signifies that the initially heavy and securely fixed spot has been relocated due to severe excitation, interpreted as degradation of the protection layer, allowing for the identification of problematic passages. Conversely, the emergence of a new spot suggests a stone coming from elsewhere (probably as a result of removal from somewhere else).

To facilitate image comparison, each sequential image is divided into small ROIs, and each ROI is then compared with the corresponding ROI in the subsequent images. Focusing on only a ROI of this image, for instance, an 8.5 m × 10.5 m area near the scour hole (see Figure 10), numerous green/reddish spots can be seen with specific locations and sizes.

Figure 10. A magnified ROI (yellow box) of the sonar image near the scour hole.

These green spots represent the rock pieces of the bed protection layer. They constitute the distinctive features of the layer, forming a specific pattern depicted in Figure 11 with connected white circles of varying sizes and locations. Upon comparing this pattern in sequential images spanning a 2-day period, no changes are observed. This ongoing steadiness serves as evidence that the level of noise does not compromise image details, thereby satisfying the requirement of a signal-to-

noise ratio greater than 1.45. Furthermore, the consistent presence of these green spots, despite various excitations such as ship passages and chamber emptying during this period, indicates that they are fixed components of the protection layer.

Figure 11. A region of interest in the at three different times, illustrating changes in the fixed pattern of the bed protection.

However, after a ship passage following this period, one of the green spots within this pattern changed its location. Subsequently, the pattern remained unchanged for 5 days. Interestingly, another ship passage after this period led to the same green spot undergoing a change once again. This suggests the presence of a loose stone in the bed protection, potentially indicating degradation of the protection layer. Figure 11 illustrates the initial location of this green spot circled in pink at the measurement's outset and its two new locations after the severe excitations. This serves as compelling evidence of the bed scanning subsystem's functionality, successfully capturing changes in the bed protection layer induced by specific excitations.

It is also possible to identify weak parts of the bed protection layer. For instance, upon an examination of the collected sonar images, specific locations in the bed protection layer exhibited a consistent pattern of spots for 6 days. However, numerous changes in the arrangement of spots, deviating from the fixed pattern, occurred after each passage. This observation indicates the presence of loose stones that are not securely fixed in their location or the void left by a detached stone, subsequently filled with sand. Both scenarios signify a weak section in the bed protection layer.

All constraints of this requirement have been satisfied, specifically, that the system captures changes occurring in at least 3 min within a minimum area of at least 0.5 m<sup>2</sup>. The scanning time for the area of interest at the highest resolution of the sonar device is 1 minute, ensuring the system can capture changes within a 3-minute timeframe. Upon examining the detected change on 27-10-2023, at 04:02', it was found that the change occurred within one minute. In the preceding image, the location of the green spot differed. This change is attributed to a shift in the location of a stone in the bed protection layer, measuring 0.5 m<sup>2</sup>. Figure 12 illustrates the stone in two different locations in two sequential images with a 1-minute interval.

Figure 12. Detected change in the bed protection layer within an area of 0.5m<sup>2</sup>

### 5.2 “Rolling stones” on concrete floor

This section concentrates on the concrete floor part of the sonar image, aiming to evaluate the subsystem’s capability in capturing rolling stones. Upon examining sequential images in this part, a green spot is consistently evident in all images, situated in the north-western part of the concrete floor. This reflection indicates the presence of a projection at that location, as a significant amount of signal is reflected compared to its surroundings, where such reflection is not expected. To confirm this assumption, an underwater drone was sent to that location to capture a video from the concrete floor. The video revealed a substantial piece of rock resting on the concrete floor. Figure 13 (left) presents the identified green spot circled in yellow, and Figure 13 (right) shows a drone-captured image revealing the presence of a substantial rock.

Figure 13. A green spot (circled in yellow) on the concrete floor (left) is a rolling stone, which is captured in an image taken by an underwater drawn (right).

Additionally, certain images display sporadic green spots on the concrete floor, appearing in one image and disappearing in the next. This fleeting presence suggests they are likely fish or other lightweight objects in that area. Contrarily, in many instances, these green spots endure for more than an hour, remaining unchanged in shape and location across many images. This extended presence indicates a heavier object, like stones, in those locations. Figure 14 depicts three incidences of stones observed on the concrete floor. Reviewing images collected over three days of scanning revealed the presence of stones on the concrete floor in multiple instances.

It is noteworthy that the system can capture hills/projections from a distance of 30m. However, the height of the projection cannot be measured due to the lack of access to the stones on the concrete floor captured by the sonar.

Figure 14. Incidents of persistent green spots (circled in dashed yellow line) suggesting the presence of rolling stones on the concrete floor

### 5.3 Ship’s draft

the draft measuring subsystem shares the same components as the bed scanning subsystem. To evaluate the draft measuring subsystem’s capability in measuring the actual draft of ships, the sonar was positioned in the same location with a slight modification in its orientation. Due to the inherent limitations of 2D imaging sonar in capturing vertical faces underwater, the sonar mount was tilted 90°, as illustrated in Figure 14 (right), allowing it to render vertical surfaces underwater. In this horizontal orientation, the sonar captures a cross-sectional view of the canal, including the canal bed, wall, and water surface. Figure 14 (left) illustrates the sonar image, overlaid onto the background image, presenting a cross-sectional view of the canal outlined by the red lines. The water surface in the background image is partially cut to reveal a point cloud view of the underwater canal from the same angle. This view allows the observation of the canal wall and bottom.

Figure 67 An illustration of a phot combined with 3D point cloud data and the sonar image of the cross-sectional of the canal (left), and the sonar tilted 90° (horizontally mounted) for measuring the ship’s draft (right)

When a ship passes the sonar, its hull blocks the sounds, causing a strong reflection due to its surface being perpendicular to the sonar. Consequently, its draft is expected to be captured in the sonar image. Figure 15 (left) presents the sonar image illustrating a cross-sectional view of the canal while a ship is passing the sonar. In this figure, the ship’s draft, depicted in red, signifies the extent to which it extends toward the canal bed, providing the dimension of the under-keel clearance. Considering the sonar’s depth of 3.5 m, if the ship hull’s bottom is not rendered in the image, it implies a draft greater than 3.5 m. Figure 15 (right) displays two passages of large ships with drafts of approximately 3.5 m and 3.6 m. The bottom image, suggesting a larger ship with more draft, blocks the opposite wall completely compared to the top image, despite their equal distance from the sonar.

Figure 15. Sonar images rendering the cross-sectional view of the canal during a ship's passage (left) introducing the ship's hull in the sonar image, and estimated draft of two large ships at the same distance from the sonar (right).

Analysing historical traffic data before system design revealed a significant number of large ships passing through the old chambers with drafts of 3.5 m and 4 m. However, this data, obtained from Rijkswaterstaat, did not specify whether the ships were loaded or empty. The difference between loaded and unloaded ships can be up to 2 m. Examining the collected data from measuring ship drafts over 50 hrs uncovered 22 passages of ships with drafts exceeding 3 m, indicating a notable frequency of loaded ships in groups IV and V. Therefore, it is important to note that not all ships with large drafts were necessarily empty.

## 6 CONCLUSIONS

This project aims to investigate underwater dynamics and ship interactions with the canal bed by visualising changes in the bed protection layer near the lock structure. Reports indicate that this layer consists of large stones fixed with cement, some of which may detach due to excessive water pressure or excitation. Detached stones can obstruct the lock gate, risking damage. Monitoring their movement and understanding the causes i.e., chamber emptying and ship propeller wash, is crucial. The system is designed to detect changes in the bed protection layer, track rolling stones, and measure passing ship's drafts to prevent structural degradation and operational hazards.

The study draws the following conclusions:

- The sonar-based system successfully detects changes in the bed protection layer by capturing consistent images over time. A low noise-to-signal ratio ensures reliable detection, while variations in high-intensity reflections indicate potential degradation caused by ship passages.
- The system can identify and track stones on the concrete floor of the lock chamber. The size of the stones can be estimated using benchmarks, and their movement can be monitored to assess potential risks to lock infrastructure.
- Some ship passages generate significant turbulence, leading to the displacement of stones from the bed protection layer. By correlating these events with sonar images, the system provides evidence that specific passages contribute to degradation.
- Tracking the origin of rolling stones is difficult due to the limited field of view of the sonar. However, adjusting sonar placement and analysing traffic data can help determine whether stones move due to ship passages or chamber emptying.
- By measuring ship drafts and turbulence profiles, the system reveals how propeller wash affects the bed

protection layer. High air bubble concentrations in sonar images indicate strong disturbances, which may accelerate degradation of the canal bed.

Future studies should collect a comprehensive dataset using the monitoring system, with at least six months of continuous data to identify change patterns. The current limited dataset provided evidence of bed protection degradation but lacked a complete understanding of the underlying causes. Expanding the investigation to other chambers of the Beatrix lock will reveal trends in scouring and improve detection of loose stones. Implementing automated detection and event correlation will help categorise ship passages, clarifying their role in bed protection degradation.

## ACKNOWLEDGMENTS

This research was supported by Heijmans in collaboration with the University of Twente. The authors are pleased to express their gratitude to Dr. ir. Jasper Caerteling for his valuable supervision and to Heijmans Company for their financial and technical support, including facilitating the sonar testing at the Beatrix Lock.

**ABSTRACT:** This study aims to perform leak detection on an old oxygen underground pipeline in operation. The target pipe is a 220-meter section of nominal diameter 80A steel pipe that supplies oxygen for welding in heavy industrial facilities. In order to observe the response characteristics of the coupled vibration propagating through the pipe, an impact experiment was conducted to experimentally derive the frequency band and propagation velocity of the coupled vibration in the tested compressible fluid transportation pipe. Conventional leak detection methods mainly depend on frequency-domain filtering because it is difficult to improve the signal-to-noise ratio through averaging in the time domain due to the random nature of the leak signal. In this study, we propose a leak detection algorithm with improved detection performance by utilizing an ensemble cross-correlation function that applies averaging in the  $\tau$ -domain based on the deterministic arrival time difference characteristics of the leak signal. In addition, leak detection using two sensors is likely to misjudge the leak source near the sensor due to noise propagating outside the detection range, and a single damage positioning result is insufficient to determine the leak damage. Therefore, this study proposes a distributed measurement-based leak detection technique and a decision map based on multiple damage localization results. The experimental results confirmed that damage localization using coupled vibration is possible in compressible gas transport pipelines, and experimentally verified that leakage can be effectively detected with a location error rate of approximately 1.37% in industrial sites that are always in operation.

**KEY WORDS:** On-line monitoring; Underground pipelines; Leaks; Source localization; SHM.

## 1 INTRODUCTION

Acoustical and vibrational signals can be generated by a number of different damage sources in underground pipelines such as growing cracks, corrosion progress, connection part movement, third party interference, direct impact and leakage etc.. On-line monitoring technology for buried pipeline is one of the main concerns for most underground pipeline management systems that maintain buried structures that are difficult to access. There are many factors that can threaten the health of buried pipelines, but among them, leakages by aging and damages by third-party interference are known to be one of the main causes of failure, and it is emerging as a major social problem that causes safety problems such as leakage and ground subsidence due to damage. Ultimately, the pipeline failure owing to these kinds of damage lead to economic loss and huge accidents such as a ground collapse by a sinkhole, an eruption by leakage. Hence, it is extremely important to detect and localize such damages at the very early stage in order to prevent catastrophic failures. However, most of underground pipelines are located in very noisy urban areas, and these harsh conditions inflicted on practical difficulties in measuring meaningful acoustic vibratory signals. Especially, several kinds of background noise such as traffic, natural environment and sound pollution causes difficulty in signal analysis. Therefore, this study proposes a distributed measurement-based leak detection technique and a decision map based on multiple damage localization results and monitoring range information, and implements an algorithm to improve the reliability of damage localization in industrial sites where noise is frequent.[1-6]

## 2 WAVE PROPAGATION AND EXPERIMENT

In this study, acoustic wave propagation coupled with surrounding boundaries including cast iron and steel pipes is theoretically analyzed and the wave speed was confirmed with experiment.

When the impact by foreign damage occurs on a fluid filled pipe, a structural pipe vibration as well as a fluid-pipe coupled vibration will occur. That is, a pipe vibration mode appears in various mode shapes in shown in Figure 1. Also the fluid borne wave, non-dispersive wave in free space, is changed to dispersive wave by coupled vibration. This role is executed by “ $n=0$ ” mode. In other words, the ‘Breathing’ mode creates a new wave in the fluid filled pipe domain. This “Breathing” mode is important for detecting a damage sources.[1]

Figure 1. Mode shapes of a circular cylindrical shell [1].

In this study, the buried pipe used in the field experiment was an oxygen supply pipe for welding process, and seven sensors

were installed in a 220 m section. Several types of impact hammer and accelerometer were used as the artificial impact source and sensors. To examine the possibility of damage location markers in compressible fluid transport pipelines, the velocity change characteristics were compared for compressible and incompressible fluids. Steel pipes with a nominal diameter of 80A, which is the diameter of actual pipelines installed in the field, were used. Basically, one-dimensional source location algorithm was used to estimate the time delay with the cross-correlation method.

In order to experimentally verify the speed of the coupled vibration propagating in the compressible fluid transport pipe, an impact hammer(086D20, PCB Piezotronics, United States of America) was used to generate coupled vibration at an arbitrary location to reproduce the impact damage situation, and vibration accelerometers(393A03, PCB Piezotronics, United States of America) were installed at distances of 42.15 m and 220 m from the damage location, respectively. Additionally, the pressure applied to the buried pipe during the experiment was 55.154 Pa. Theoretically, it can be confirmed that incompressible fluids exhibit propagation velocity dispersion characteristics starting from a lower frequency band than compressible fluids. The velocities at 0 Hz are approximately 1381 m/s, 1319 m/s, 444 m/s, and 326 m/s, respectively. At this time, the theoretical propagation speed of the coupled vibration is approximately 326.5 m/s.

### 3 VERIFICATION AND RESULTS

First, we defined a ‘time history frame’ as each separated intrinsic parameter of input time signal. Then we obtained a couple of parameters such as frequency and intensity from time signal. We proposed a leak detection algorithm with improved detection performance by utilizing an ensemble cross-correlation function that applies averaging in the  $\tau$ -domain based on the deterministic arrival time difference characteristics of the leak signal. Figure 2 shows typical raw signal based on ensemble cross-correlation function.

Figure 2. Typical raw signal based on ensemble cross-correlation function.

In addition, leak detection using two sensors is likely to misjudge the leak source near the sensor due to noise propagating outside the detection range, and a single damage

location positioning result is insufficient to determine the leak damage. Therefore, this study proposes a distributed measurement-based leak detection technique and a decision map based on multiple damage localization results and monitoring range information, and implements an algorithm to improve the reliability of damage localization in industrial sites where noise is frequent. Among these results, in the case of 100 m, the possibility of an abnormal location is ambiguous because the result is from only a single combination, whereas in the case of the range of 55~60 m, the result is judged to be significant because the results from multiple combinations are the same. Figure 3 shows that the result of a distributed measurement-based source localization.

Figure 3. Distributed measurement-based source localization.

### 4 CONCLUSIONS

In this study, seven sensors were installed in a 220 m section, and micro-leakage was detected in a 55-60 m section by applying the proposed algorithm. The experimental results confirmed that damage localization using coupled vibration is possible in compressible gas transport pipelines, and experimentally verified that micro-leakage can be effectively detected with a location detection error rate of approximately 1.37% in buried pipelines in industrial sites that are always in operation.

**ABSTRACT:** In recent years, relevant brittle fractures of external grouted post-tensioning tendons in bridges have been reported due to corrosion damage, compromising the structural safety and stability of the bridges. A previous detailed finite element (FE) modelling approach for grouted tendons has been developed by the authors and compared with experimental results presented in the literature, ensuring an accurate reproduction of experimental results by accounting for steel plasticity and large deformations. This modelling approach considered a bonded contact to model the strand-grout interface. That is, an immediate re-anchoring of the strands in the grout is assumed in case of failure and, consequently the influence of the bond stress-slip behaviour is not considered in the modelling approach. This paper presents an alternative FE modelling strategy where the differences with the previous one are: i) the modelling of the strands as beams instead of solid bodies, ii) the presence of the sheathing duct, and iii) a non-linear model to reproduce the strand-grout bond stress-slip behaviour. The objective is to investigate the influence of different models to define the grout-strand interface: a bonded model or a bond stress-slip model, while validating the author's previous FE approach. These models are also compared with the experimental results from the literature. Normal stresses along the strands and in the grout are studied, and degradation curves are derived, that is, the effective tensile force and natural frequencies versus damage (defined as the percentage of broken strands). These degradation curves serve as a key performance indicator of the structural performance of the tendon for structural health monitoring systems, anticipating to severe damage and potentially dangerous scenarios.

**KEY WORDS:** Damage detection; Corrosion damage; Post-tensioning tendons; Finite element modelling.

## 1 INTRODUCTION

External post-tensioning tendons are key structural elements in bridge engineering, offering advantages like the ease of inspection, re-tensioning and substitution; however, they are also vulnerable to corrosion. Since the 1990's, relevant brittle fractures of external grouted post-tensioning tendons have been reported in bridges due to corrosion damage [1],[2]. This situation significantly compromises the structural integrity and safety of these bridges.

In externally grouted post-tensioning tendons, strand breakage does not necessarily lead to a significant reduction in the overall tensile force of the tendon. This is because the surrounding grout prevents the movement of the broken strand, effectively re-anchoring it and enabling the transfer of its tensile force to adjacent strands. As a result, the adjacent non-broken strands experience a localised increase of their tensile stress near the breakage region [3]. This stress redistribution occurs over a defined transfer length, which is the distance needed for the strands to nearly recover their original tensile force [3]. However, if a considerable number of strands are affected by corrosion, the resulting stress concentration may exceed the remaining strands' capacity, potentially leading to a brittle failure of the tendon.

Numerical research on the mechanical behaviour of external post-tensioning tendons affected by corrosion remains limited. Aparicio et al. [3] studied the re-anchoring phenomenon in monostrand tendons. A numerical model validated with experimental tests was developed to assess the sensitivity of parameters such as the grout elastic modulus, the mesh, or the

friction coefficient in stress redistribution when there is wire breakage. However, they did not consider the constitutive non-linear behaviour of the tendon materials. Subsequently, Vecino et al. [4] (the authors of the present paper) proposed a numerical modelling approach of external grouted post-tensioning tendons to be used within a parametric study to evaluate tendon failure. The grout-strand contact was modelled as bonded (that is, no sliding between them is allowed), but accounting for a prescribed re-anchoring length, plasticity was considered for the high-strength steel of the strands, and the grout was considered perfectly elastic in such a way that the sheathing duct was not explicitly modelled. The modelling approach presented in the previous paper was validated through the experimental results obtained by Lee & Kang [3]. They carried out a laboratory experimental campaign to analyse the variation in dynamic parameters and the tensile force of tendons subjected to progressive corrosion.

Thus, this study focuses on modelling strategies for the grout-strand interface to carry out numerical approaches that are both efficient and accurate. The numerical results obtained are compared against experimental data available in the literature and previous numerical studies performed by the authors, which assume a bonded contact between the strand and the grout. The accuracy of this modelling assumption is assessed to determine whether it serves for practical purposes or if a more complex contact approach, such as incorporating a non-linear bond stress-slip relationship, is required.

Establishing an appropriate modelling strategy for grouted tendons and the re-anchoring behaviour of strands is essential

for the reliable analysis of their structural performance. Accurate numerical models can support comprehensive risk assessments in the context of structural health monitoring (SHM) and serve as a tool for engineers and practitioners to complement inspections and prevent safety-critical situations.

The present paper is organised as follows. Section 2 provides a detailed description of the finite element (FE) model developed here and present a former model previously validated by the authors to study tendon degradation. Section 3 provides a discussion of the results obtained by the proposed modelling approach and using different grout-strand contact laws. Finally, Section 4 outlines some conclusions from the study.

## 2 FINITE ELEMENT MODEL

### 2.1 Experimental tests carried out by Lee & Kang

The experiment conducted by Lee & Kang [3] is used as a reference to compare their experimental results and the numerical results obtained in this investigation in terms of the degradation curves, which are: i) the tensile force with damage, and ii) the natural frequencies with damage. Damage is defined as the quotient between the number of broken strands and the total number of strands of the tendon:  $D = N_B/N$ , where  $N_B$  is the number of broken strands and  $N$  is the total number of strands.

This experiment was also used to validate the detailed FE modelling approach previously carried out by the authors [2], whose results on degradation curves are also contrasted with the ones obtained in this paper.

The Lee & Kang experiment stresses a 10 m tendon at approximately 70% of the ultimate load of a prestressing strand. Then, five strands are broken successively by accelerated corrosion in 24 hours. To carry out the breakage of the strands, the grout is retired in the 30 cm central section, leaving the strands exposed.

Figure 1. Strands subjected to accelerated corrosion [3].

### 2.2 FE model 1: 3D elements and bonded strand-grout interface

The Lee & Kang experiment was reproduced by the authors [4] using a FE detailed model of a seven-strand tendon surrounded by grout, except for the central section of 60 cm, which is modelled without grout to reproduce the Lee & Kang experiment, and to consider the re-anchoring length. This parameter was prescribed in the model due to the grout-strand contact considered, which will be explained hereafter.

The stress state reached by the stressing of the strands is modelled by a thermal load, at 70% ultimate stress,  $f_{pu}$ , which is 1900 MPa. Then, the stressing force of the tendon is 1241

kN. The strands' breakage due to corrosion damage is represented by the elimination of elements. The FE model was developed in ANSYS Mechanical using 3D SOLID185 elements for the grout and the steel strands. The duct (which has the main function of confining the grout to prevent its breakage) was neglected by assuming a perfectly elastic material for the concrete with a higher density (to include the duct weight). Sweep meshing method was used so that the positions of the nodes of the grout match with those of the strands in each section. Both ends of the seven strands were modelled with fixed support, that is, rotation and translation were restrained at both supports. A linear elastic surface-to-surface contact model was assumed between the grout and the strands; specifically, a bonded contact, which prevents separation and sliding. The bonded contact model does not capture the re-anchoring effect; a re-anchoring length had to be predefined in the model to simulate this behaviour. Plasticity of steel strands is considered. The elastoplastic model used presents the following characteristics: i) Bilinear isotropic hardening law, defined in Table 1, ii) Von Mises yield criterion, and iii) Associated flow rule.

Table 1. Bilinear isotropic hardening model parameters.

$E_s$ [GPa]	$f_{py}$ [MPa]	$\epsilon_{py}$ [%]	$f_{pu}$ [MPa]	$\epsilon_{pu}$ [%]
195.5	1760	0.9	1900	6

Figure 2. FE tendon model developed previously by the authors in [4] (FE model 1).

### 2.3 FE model 2: beam elements for strands and non-linear springs for the interface

The bonded contact employed in the FE model 1 for the grout-strand interface may not accurately capture the re-anchoring phenomenon, as this process involves bond mechanisms such as adhesion, friction, and mechanical interlock [6]. A bond stress-slip law has been proposed and validated by Wang et al. for strands. Thus, a new modelling approach that considers a bond stress-slip law to model the strand-grout interface is developed. The implementation of this law in the model eliminates the need to introduce the re-anchoring length as an input parameter, as in the FE model 1, allowing it to be intrinsically determined.

The Model Code [7] proposes a bond stress-slip relationship for ribbed bars, considering the bond stresses between concrete and reinforcing bar for pull-out. This relationship is defined in Figure 3 and its defining parameters are listed in Table 2.

Figure 3. Bond stress-slip relationship [7].

Table 2. Parameters defining the bond stress–slip relationship [7].

$\tau_{max}$	$\tau_f$	$s_1$	$s_2$	$s_3$
$2.5 \sqrt{f_{cm}}$	$0.4 \tau_{max}$	1 mm	2 mm	$c_{clear}$

Parameter  $f_{cm}$  is the concrete compressive strength (a typical value of 30 MPa is considered), and  $c_{clear}$  represents the spacing between the ribs of a deformed bar. Considering the similarity in bond behaviour between steel strands and deformed bars embedded in concrete, the parameter  $s_3$  is defined as half of the distance between the concrete interlock region and the adjacent wires [8], and it is taken as 10 mm.

To introduce the bond stress-slip law in the FE model, non-linear springs are defined in every grout-strand coincident node. The elements used to create the non-linear springs are COMBIN39, with one degree of freedom in the longitudinal direction. COMBIN39 is defined by two nodes and a non-linear generalised force-deflection relationship.

The main purpose of this paper is to validate and critically discuss the interface modelling approach developed previously by the authors when considering bonded behaviour (FE model 1) [4]. For that, a new approach to numerically model the Lee and Kang experimental campaign has been developed (FE model 2). This new approach differs from the previous one in the following aspects:

- 1) Modelling of the HDPE sheathing duct, which is considered elastic. 3D SOLID186 elements are used for the duct, and the duct-grout contact is modelled as bonded. The grout is also modelled with these elements.
- 2) BEAM188 elements are used to model the strands. This simplifies the introduction of non-linear springs node-to-node to model the grout-strand interface. Also, considering beams for the strands reduces considerably the number of nodes and elements of the model, reducing the computational demand as well, which is one of the main limitations of the previous modelling approach.
- 3) Considering a non-linear bond stress-slip model to characterise the strand-grout interface. The Model Code bond stress-slip is introduced using non-linear springs (COMBIN39) in the longitudinal direction, whereas linear springs (COMBIN14) of high stiffness ( $k = 10^{12}$

N/m) are modelled in the transversal directions. The first branch of the bond stress-slip model (from  $s=0$  to  $s=s_1$ ) is considered linear for simplification.

Figure 4. FE tendon model developed (FE model 2).

The differences between the modelling approaches are compiled in Table 3.

Table 3. Comparison of modelling approaches: FE model 1 and FE model 2.

	Sheathing duct	Strand elements	Strand-grout interface
FE model 1 [4]	Not modelled	SOLID186	Bonded contact
FE model 2	SOLID186 elements	BEAM188	Non-linear springs (bond stress-slip/bonded)

Then, four different results are compared:

- (i) Lee and Kang experimental results.
- (ii) FE model 1 with bonded contact between strands and grout.
- (iii) FE model 2 with bonded contact between strands and grout.
- (iv) FE model 2 with non-linear bond stress-slip behaviour.

## 2.4 Analysis description

A non-linear static analysis by load steps is performed. A sparse direct solver and the Newton-Raphson algorithm with convergence in forces, displacements, and moments are used. The non-linearity is caused by the activation and deactivation of elements. The influence of strands' plasticity, large displacement analysis, the grout-strand contact modelling (re-anchoring effects), and the mechanical properties of the grout on the FE modelling are studied. The FE analysis follows these steps (Figure 5):

- i) Stressing of the strands by applying a thermal load. The stressing of the strands was executed at 70% of their ultimate stress,  $f_{pu}$ . The temperature decrease  $\Delta T$  is equal to:

$$\Delta T = \frac{0.7 f_{pu}}{E_s \alpha}, \quad (1)$$

where  $E_s$  is the elastic modulus of the strands, and  $\alpha$  is the thermal expansion coefficient, taken as  $1.2 \cdot 10^{-5} \text{ } ^\circ\text{C}^{-1}$ .

- ii) Activation of the grout to simulate injection.

iii) Successive breakage of five strands in five different steps by eliminating elements. The order of strand breakage is from 1 to 5, the strands numeration is illustrated in Figure 5.

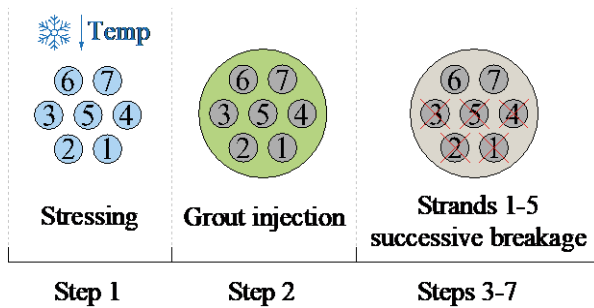

Figure 5. Steps of the FE non-linear static analysis performed.

Furthermore, a modal analysis is performed after each strand breakage step to assess the progressive reduction in the tendon's natural frequencies, which are useful as performance indicators (PIs) when performing vibration-based SHM of these elements. The characteristic stress state corresponding to each load step is incorporated into the modal analysis through the application of a preload state.

### 3 RESULTS DISCUSSION

#### 3.1 Tensile force degradation with damage

The evolution of tensile force,  $T$ , with damage,  $D$ , in the anchorage (outside the transfer length) is shown in Figure 6. The re-anchoring effect is captured by the proposed modelling approach (FE model 2), with a similar trend to the experimental and previous numerical results (FE model 1). It must be noted that the re-anchoring length in the FE model 1 was an adjusted parameter to replicate the experimental results, whereas in the FE model 2, it is a result of the implemented contact law. Thus, FE model 2 can replicate the phenomenological behaviour without requiring any preliminary calibration, as opposed to FE model 1. However, the differences observed in the most recent modelling approach compared to the previous one are noticeable. This may be due to modelling the strands as beam elements instead of solid bodies, which may not adequately capture the internal stress distribution within the strand volume.

When comparing the two grout-strand interface models (represented by the green and blue curves), the results are almost identical, indicating that the influence of the interface model used does not affect the accuracy of the results in reproducing the re-anchoring of the strands. However, these results also suggest that the interface modelling for ribbed bars exhibits greater stiffness compared to that for strand re-anchoring in grout.

Figure 6. Tensile force degradation with damage.

#### 3.2 Natural frequencies degradation with damage

The evolution of the first four natural frequencies,  $f_i$ , of the tendon as damage progresses is also analysed in Figure 7. In this figure,  $f_{i,exp}$  refers to the frequencies obtained in the Lee & Kang experiment,  $f_{i,num}$  to the ones corresponding to the FE model 1, whereas the other two frequency groups refer to the FE model 2 with bonded and bond stress-slip models.

A behaviour similar to that observed in the tensile force degradation is noted when comparing the FE model results with the experimental data. While the overall trend is consistent, the natural frequencies predicted by the models are slightly higher than the experimental values, and the new modelling approach exhibits more pronounced discrepancies. However, the results obtained using the different interface models remain phenomenologically similar.

The degradation of natural frequencies becomes more pronounced at higher damage levels and is more significant in absolute terms for the higher modes. Accurately quantifying the absolute reduction in frequencies is important for their effective use as a PI in structural health assessment [4].

Figure 7. Frequency degradation with damage.

### 3.3 FE model 2: normal stresses along the strands

Two strands are considered for the study of the normal stresses along the strands: i) Strand 5, which is the central strand and is the last to break (Figure 8), and ii) Strand 6, which is a central that remains continuous throughout the entire analysis (Figure 9). The two interface models (bonded and bond stress-slip) are also compared.

Strand 5 exhibits a local increase in stresses as a result of the successive breakage of strands, becoming more pronounced as damage progresses, with fewer continuous strand remaining to carry the stresses of the broken ones. Additionally, the re-anchoring effect is observed in both models, where, in regions distant from the vicinity of breakage, the stress along the strand remains constant. Along the re-anchoring length, a transition occurs between the constant stress away from the breakage zone and the increased stress near the breakage. Both models effectively represent the re-anchoring effect; however, the primary difference lies in the re-anchoring length. The bond stress-slip model (Figure 8 (a)) shows a larger re-anchoring length, approximately 1.9 m, with a smoother transition in stresses, while the bonded model (Figure 8 (b)) exhibits a shorter re-anchoring length, around 0.9 m. This results in a difference of approximately 1 m in the re-anchoring length between the two models.

Figure 8. Normal stresses along strand 5 for different strand-grout interface modelling. (a) Bond stress-slip model. (b) Bonded model. Blue shadowed areas indicate the re-anchoring length.

Similar results are observed for strand 6. The stress evolution along the strand demonstrates the stress redistribution resulting from the successive breakage of strands. In a similar manner as for strand 5, the re-anchoring length is greater for the bond stress-slip model, where it is 2.2 m, compared to 1.9 m for the bonded model. The difference of 0.3 m is smaller in this case, as this strand does not break during the analysis. Given the exponential nature of the re-anchoring phenomenon, the re-anchoring length is a highly sensitive parameter to the point at which complete re-anchoring is achieved.

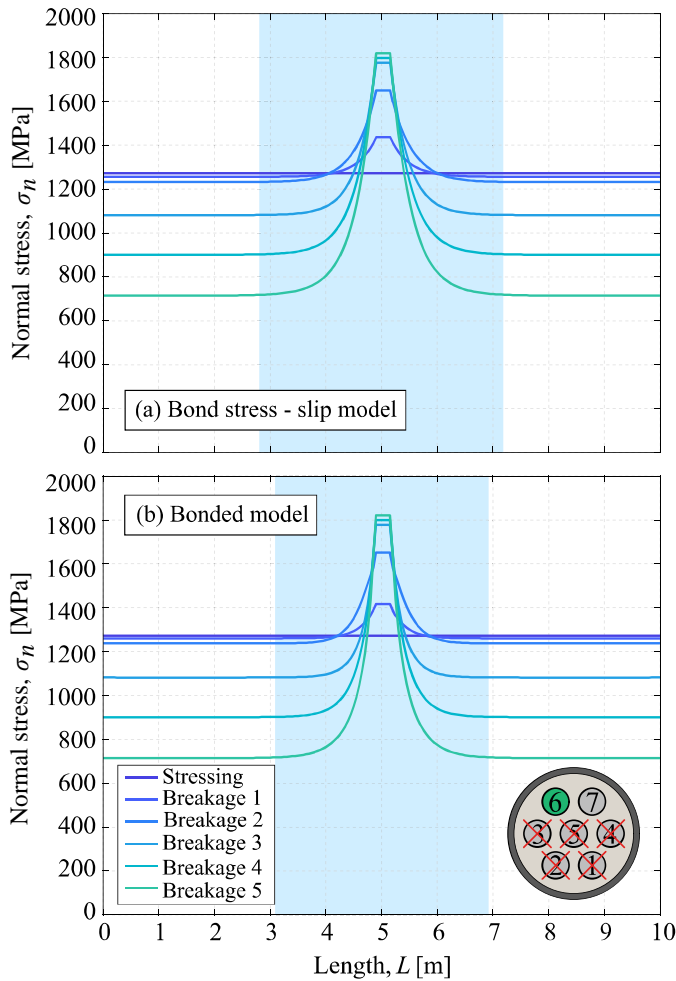

Figure 9. Normal stresses along strand 6 for different strand-grout interface modelling. (a) Bond stress-slip model. (b) Bonded model. Blue shadowed areas indicate the re-anchoring length.

### 3.4 FE model 2: normal stresses in the grout

The normal stresses in the grout as a function of damage are shown in Figure 10 for the two interface models studied, obtaining similar results for both. The grout normal stresses are analysed to characterise the grout's mechanical response, given that it has been modelled as perfectly elastic, which may not accurately represent the typical grout constitutive behaviour.

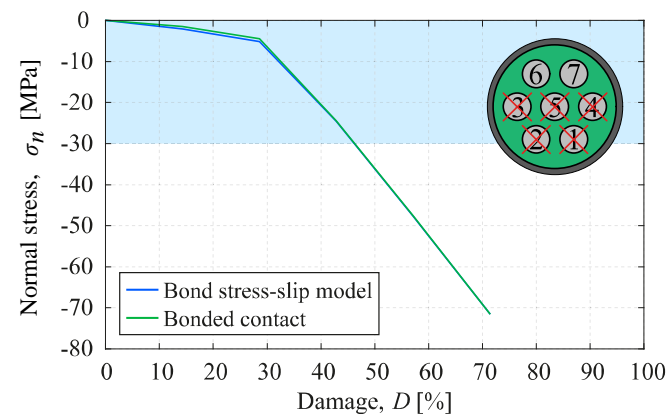

Figure 10. Normal stress in the grout with damage progression.

The compressive strength of the grout is 30 MPa, this value is reached for approximately a 45% of damage. Beyond this point, crack formation and propagation are expected to start. For the maximum damage value studied (71%), the stresses reach 70 MPa, which are considerably high, more than twice the compressive strength of the material. These stress values are not realistic; this highlights the limitations of the linear elastic assumption and suggests the need for a more accurate non-linear constitutive model.

## 4 CONCLUSIONS

The following conclusions are drawn:

1. The tensile force and the natural frequencies serve as PIs for damage detection within the context of SHM, provided that their degradation due to damage is accurately reproduced numerically. It can support early identification of deterioration mechanisms, complement fieldwork, and contribute to a more effective maintenance.
2. The new FE modelling approach shows discrepancies compared to the authors' previous numerical results, which may be attributed to the modelling of strands as beam elements instead of solid bodies. This also may explain the increased deviations from experimental results. However, the use of beam elements reduces computational demands, which was a limiting factor in the previous modelling strategy.
3. The influence of different literature-based grout-strand interface models is minimal compared to a bonded interface behaviour, as the results obtained are nearly identical. The primary difference lies in the re-anchoring length, which is approximately 1 m longer for broken strands when using the bond stress-slip model.
4. The interface models used to simulate ribbed bar pull-out may not be directly applicable to prestressing strands in external grouted tendons. The results indicate that the stiffness of the grout-strand interface may be considerably lower.
5. Future research aimed at improving the FE modelling of grouted tendons should focus on incorporating a non-linear constitutive model for the grout and a more realistic bond stress-slip behaviour with much less stiffness than those used for internal tendons or rebars.
6. In previous work [4], the authors applied the modelling strategy to conduct a parametric study to identify the critical number of strands broken leading to tendon failure. A reliable and efficient FE modelling approach can serve as a valuable tool in SHM applications, enabling risk assessment and early damage detection.

**ABSTRACT:** Cables and external post-tensioning tendons are key elements of modern strategic bridges; however, their structural integrity has been questioned due to some structural collapses registered during the last decades. In this context, cost-effective vibration-based monitoring strategies can be implemented to improve their maintenance by continuously estimating their tension force (a key damage indicator) from their natural frequencies. These frequencies may vary in time due to environmental changes, modification of the service loads, and tensioning processes produced during cable substitution manoeuvres. In monitoring systems that only use one accelerometer per cable (the most common situation in practice), a robust and accurate peak-picking method is required to adequately identify which are their actual almost harmonic natural frequencies and to which modal order they correspond to. Ideally, this method should be automated (to run continuously), autonomous (with as few hyperparameters as possible) and self-regulating (to discard poor quality spectra and outliers). Additionally, the method must be able to cope with two well-known phenomena experienced in practice that dirt cable spectra: i) the double peak effect, and ii) the presence of bracing belts between cables. Thus, this paper works on developing an autonomous peak-picking procedure to cope with the aforementioned phenomena for enabling a reliable tension force estimation method in cable structures. This methodology has been applied to a one-week monitoring data set of measurements of real external post-tensioning tendons of a road bridge in Spain.

**KEY WORDS:** Cable dynamics, Tension estimation, Post-tensioning tendons, Automatic peak-picking, Condition monitoring

## 1 INTRODUCTION

Cables and tendons are crucial elements in bridge engineering but also are vulnerable structural elements because they are usually subjected to fatigue and corrosion problems. Thus, vibration-based non-destructive techniques have been used for external post-tensioning tendon assessment. The main parameter to assess in these cases is the tension force, as this performance indicator can give a clear idea of the condition of the cable and thus, the overall condition of the structure. The tension force is usually estimated from the measured natural frequencies, which are used to inversely solve the dynamic equation of an elastic tensioned cable.

The higher the number of natural frequencies identified, the better the tensile force estimation. Indeed, the estimation of several natural frequencies results compulsory when the bending stiffness of the cable is not negligible. However, this frequency identification is especially challenging when only one accelerometer is employed for monitoring the element, as in these cases, it has to be performed by detecting peaks on the vibration signal's power spectral density (PSD). In the case of simply-supported cables, when their bending stiffness is negligible, the frequencies of these peaks should be perfectly periodical (which corresponds to the blue straight line in Figure 1, where the frequency values are represented against their modal orders). When the bending stiffness has a considerable influence on the cable dynamics, these frequencies are quasi-periodical, gradually increasing the distance between

consecutive peaks. This effect can be clearly seen in the orange line of Figure 1.

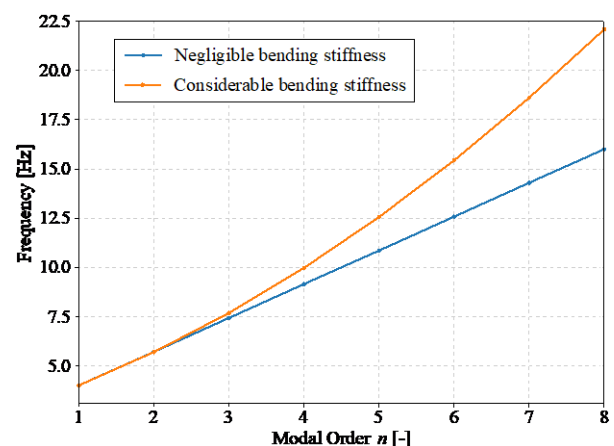

Figure 1: Effect of bending stiffness on natural frequencies.

Although peak-picking may appear to be simple, some issues make difficult the identification procedure and its automatization. First, the variation over time of the natural frequencies to be identified makes more suitable methods that do not use initial guessing values to detect these peaks. Second, the presence of double peaks (doublets) within the PSD. This is caused due to the fact that the cable section may not be perfectly symmetric and thus, certain bending modes may decompose in couples of closely-spaced peaks. Third, the presence of bracing

belts between homologous cables may couple their similar but not identical vibration, also contributing to create doubles. Fourth, in external post-tensioning tendons running through several spans, the vibration of the different sections of the cable between deviators (with different span lengths) may be coupled, providing dirty spectra in which harmonics of neighbouring cable segments are mixed. Finally, interactions between the measured cable and other structural elements may dirt the PSD signals, thus, perturbing the frequency identification process and provoking an unreliable tension estimation. A typical situation of this type occurs in cable stayed bridges, when the vibration of the deck is transmitted to the stay cables or hangers.

Some authors have faced in the past the problem of developing a real-time and automatic frequency identification methodology for performing an accurate tension estimation in cable elements. This automatization has been solved in a variety of ways within the literature. Most of them detect these frequencies by performing an automatic peak-picking process from the signal's PSD. Initially, Cho et al. [5] belowproposed a simple iterative process that lacked the necessary robustness. Then, Sim et al. [6] studied a frequency tracking method based on providing reference initial guessing values around which the peak search is performed. They claim its validity based on two facts: i) the frequencies variation due to environmental changes are small, and ii) the searched peaks are well-separated.

Regarding deep learning applications, Kim et al. [7] have developed a tool based on object detection for performing automatic peak-picking from PSDs images with a region based convolutional neural network (a similar method is researched by Chen et al. [9]). The main advantage of this approach lays on the fact that no guessing values need to be provided, although the robustness of these tools rely on their training data set. Later, Jeong et al. [8] applied this latter method for performing automatic tension estimation on cables. They worry about the detection of undesired peaks not corresponding to cable natural frequencies. For that, they use the frequency distance between peaks, also named as 'interval'. The main drawbacks of such a methodology will be discussed later. However, they do not cover issues as: i) how to correctly assign the modal order to each peak, ii) how to manage missing peaks that interrupt a series of consecutive frequencies, and iii) how optimize the computational cost for its proper in-line implementation in continuous monitoring systems.

One of the most revealing contributions is the one by Zhang et al. [10] that provided a clear explanation of the main challenges arising when performing tension estimation from cable vibration data, namely: i) detection of useful PSDs with recognizable peaks, ii) automatic and robust identification of frequency peaks, and iii) assignation of modal orders to the identified frequencies. They proposed a simple methodology based on updating a threshold prominence value till a minimum number of peaks has been identified. After this, they discard fake peaks if their frequency is not a multiple of the most common value for the interval. With this same principle, they assign the modal order to the peaks. This method results quite applicable to cables with low-bending stiffness ( $EI$ ), however, when  $EI$  is remarkable, its applicability is limited, as proportionality is lost for higher modes. Another important contribution is the one of Jin et al. [2] in which the automated

peak-picking is covered in detailed, remarking important facts such as the necessity of removing the baseline from the PSD curve to assess all the peaks with the same floor level. Their proposal is based on the application of a breakthrough multiscale-based peak detection algorithm (previously developed by [1]) combined with a criterion based on the median absolute deviation of the detected peaks. They compared this method with the one developed by Jeong et al. [8] confirming a substantial enhancement. Despite this, they do not provide any strategy to detect false peaks apart from the robustness of the method.

The present research provides a modified methodology for performing autonomous peak-picking detection based on the findings by Jin et al. [2]. To the authors knowledge, all the contributions covering autonomous tension estimation of cable structures have dealt with long cables of cable-stayed bridges with  $EI$  not influencing their dynamic. This paper, for the first time, addresses this automatization problem in much shorter external post-tensioning tendons with non-negligible  $EI$  influence.

This paper has been structured as follows: after the present section, Section 2 presents the autonomous peak-picking methodology. Section 3 illustrates a variation of the methodology for its in-line integration into a continuous monitoring system. Section 4 demonstrates the application of the methodology to data obtained from a week-long continuous monitoring measurement in an in-service post-tensioning tendon. Finally, Section 5 provides some conclusions and future works.

## 2 AUTONOMOUS PEAK PICKING METHODOLOGY

As mentioned before, an autonomous peak-picking method is an essential previous element to continuously estimate the tension force of cables from a single vibration measurement registered within a continuous monitoring application. The present paper proposes a method for that, based on the contribution of Jin et al. [2] in which the main innovation is the implementation of the so-called multi-scale peak detection algorithm previously developed by [1]. This algorithm, which is the core of the method, was conceived to detect periodic peaks within signals (indeed, it has been applied to detect heart beats). This is done through building the so-called local maximum scalogram (LMS) of the signal being analysed. A scalogram is a graphical representation of a given signal's magnitude, resulting from analysing it using moving windows of different scale (number of samples). With the LMS, it can be detected the particular scale related to the interval of the periodic peaks being searched. Jin et al. [2] applied this concept to successfully analyse the PSDs of cable vibrations.

On the one hand, for smoothly detecting environmental changes on the natural frequencies of cables, a great frequency resolution,  $\Delta f = 1/T$  ( $T$  being the duration of the time-domain measured signal) and high sampling frequencies are required to detect a significant number of harmonics, are needed within the PSDs to be analysed. On the other hand, if these PSDs are such long vectors, the computational cost and memory involved on computing their LMS matrices may prevent from performing this process in real time within a continuous monitoring loop (the complexity of the problem is  $O(n^2/2)$ ). To cope with this issue, a two-step procedure has been proposed: i) developing

the LMS of a low-resolution PSD for roughly detecting the frequencies of the harmonic peaks. Then, frequency bands for later searching them more precisely are created, and ii) searching the final frequency values within a high-resolution PSD using these bands. Apart from these aspects, the following sections cover other considerations which are capital for successfully implementing the methodology in practice when dealing with post-tensioning tendons.

### 2.1 Signal pre-processing

This process has been depicted in Figure 2. First, the time signal obtained from the monitoring system is detrended to eliminate any drifting caused by many factors, such as instrumental nonlinearity or signal offsets. Then, a low-pass filter is applied to eliminate peaks belonging to unimportant high frequency vibration that might shadow the actual peaks of interest. Furthermore, the filter cutoff frequency should be in accordance with the higher frequency order of interest for the posterior tension force estimation. Finally, the data is resampled (first interpolated and then decimated) to convert the original low-filtered signal to a lower rate in accordance with the low cutoff frequency.

Figure 2: Signal pre-processing steps.

### 2.2 Low-resolution PSD of the signal

As previously mentioned, a low-frequency-resolution PSD is employed as a workaround to mitigate the high computational cost associated with generating a LMS from a PSD with sufficient frequency-resolution to capture the variation of natural frequencies with temperature. This first PSD is obtained applying the Welch's method using a high averaging of short time windows.

### 2.3 Baseline correction

Baseline correction is a crucial step in the methodology, as the shape of the spectrum can affect the algorithm's ability to detect certain peaks. Figure 3 provides an example of this process for a cable PSD. To ensure optimal performance, various methods such as polynomial-based, morphological, and asymmetric least squares have been investigated within the literature.

For the baseline correction there are many alternatives such as using the Savitsky-Golay filters, as mentioned in [2], but as indicated in [3], a better alternative is to rely on the use of asymmetric least squares smoothing.

The idea is that for a signal vector  $\bar{y}$  with a number of samples equal to  $m$ , there should be a 'baseline' signal  $\bar{z}$  of equal length that meets the two following characteristics: i) being enough faithful to  $\bar{y}$ , and ii) being smooth. Hence, the following least squares function,  $S$ , can be built to add together these two effects:

$$S = \sum_i^m \omega_i (y_i - z_i)^2 + \lambda \sum_i^m (\mathcal{A}^2 z_i)^2, \quad (1)$$

where  $i$  is an index corresponding to each sample of the signal, and  $\omega_i$  and  $\lambda$  are a penalty parameter, and a smoothing parameter, respectively, both controlling the balance between these two characteristics. The first term of this equation measures the baseline 'fidelity' to the original signal, while the second one regulates the 'roughness' of the baseline.

The higher the value of  $S$ , the less these two requirements are fulfilled. Thus,  $S$  must be minimized in terms of  $\bar{z}$ , to find an optimal baseline ( $dS/d\bar{z} = 0$ ). After that, the following matrix expression can be derived, from which the vector  $\bar{z}$  can be obtained:

$$(\mathbf{W} + \lambda \mathbf{D}' \mathbf{D}) \bar{z} = \mathbf{W} \bar{y}, \quad (2)$$

where  $\mathbf{D}$  is a backward second-order-finite-difference matrix and  $\mathbf{D}'$  its transpose.  $\mathbf{W}$  is a weighted penalty diagonal matrix composed of  $\omega_i$  values obtained as follows:

$$\omega_i = \begin{cases} p & , y_i > z_i \\ 1 - p & , y_i < z_i \end{cases}, \quad (3)$$

where  $p$  is a small value between  $[0.1, 0.001]$  which represents an asymmetry factor to consider the fact that a PSD baseline is usually underneath the original PSD. This factor determines a low penalty for positive residuals ( $y_i > z_i$ ) compared to a high penalty applied to negative residuals ( $y_i < z_i$ ).

The baseline correction is an iterative process that starts assigning initial values to  $\omega_i$ . After that,  $\bar{z}$  and  $\omega_i$  are iteratively computed using (2) and (3) till achieving convergence. Among all,  $\lambda$  is the most influential factor in this process. Its value must be manually set between  $[10^2, 10^9]$ .

Figure 3: Baseline and baseline corrected PSD.

#### 2.4 Local maxima scalogram and optimal scale selection

From the low-resolution baseline-corrected PSD a LMS is created. This is done by analysing the PSD with a series of moving windows with different number of samples  $w_k$ , defined as two times the ‘scale’ of the window  $k$  ( $w_k = 2k$ ). This scale is a natural number ranging from 1 to  $L$ , being defined as  $L = \text{ceil}(N/2) - 1$ , being  $N$  the total length of the PSD.

Every window of scale  $k$  runs through the signal sample by sample. Considering  $j$  as the sample index on which the window is centrally positioned, for a given scale  $k$ ,  $j$  will vary from  $[k + 1, N - k]$ . The LMS is a matrix of dimensions  $L \times N$  composed of  $m_{k,j}$  elements resulting from moving different windows along the PSD samples. Each  $m_{k,j}$  is obtained using a subset of three samples contained within a given window, namely, the two window edges and the central sample  $[y_{j-k}, y_j, y_{j+k}]$  (see Figure 4). Thus,  $m_{k,j}$  is computed as follows:

$$m_{k,j} = \begin{cases} 0, & \text{if } y_j = \max(y_{j-k}, y_j, y_{j+k}) \\ r + 1, & \text{otherwise} \end{cases} \quad (4)$$

where  $r$  is a random number between 0 and 1. Finally, the LMS matrix,  $\mathbf{M}$ , gets the form:

$$\mathbf{M} = m_{k,j} = \begin{bmatrix} m_{1,1} & \cdots & m_{1,N} \\ \vdots & \ddots & \vdots \\ m_{L,1} & \cdots & m_{L,N} \end{bmatrix} \quad (6)$$

Thus,  $\mathbf{M}$  is a matrix whose elements  $m_{k,j}$  indicate whether the current PSD  $j^{\text{th}}$  value is higher than the neighbours at the edges of the corresponding window with scale  $k$ . A graphical representation of  $\mathbf{M}$  is given in Figure 5 (white colour corresponds to zero values around the peak regions).

Figure 4: Subset value.

Once the LMS has been created, a row-wise summation is performed in the matrix to obtain the vector  $\bar{\gamma}_k$  (represented in Figure 6 as a function of  $k$ ) as follows:

$$\bar{\gamma}_k = \sum_{j=1}^N m_{k,j}. \quad (6)$$

The scale for which the value of this vector is minimum,  $k_{min}$  is the one accounting with more zero values, thus, it corresponds to the rate of appearance of quasiperiodic peaks in the PSD. This value is obtained as follows:

$$k_{min} = \{k \in \mathbb{N} \mid \gamma_{k_{min}} = \min(\bar{\gamma}_k)\} \quad (7)$$

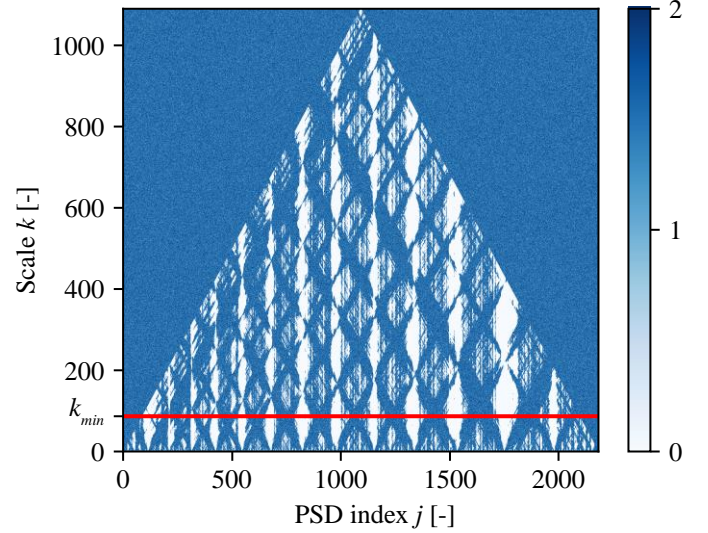

Figure 5: Complete scalogram of baseline-corrected low-resolution PSD.

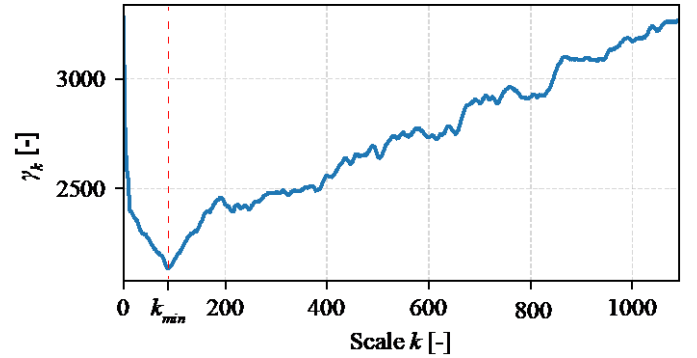

Figure 6: Minimum k scale identification.

Although the methodology works reasonably well, there might detect fake peaks near the PSD borders. To address this issue, it is recommended to add zero-padding to each side of the baseline-corrected-PSD. The extension of this padding must be in proportion with the length of the PSD.

#### 2.5 Rescaled LMS and column-wise sum

After obtaining  $k_{min}$  the scalogram is ‘cut’ only considering scales ranging from 1 to  $k_{min}$ . In this reduced version of the LMS a column-wise summation is performed to identify PSD samples whose overall sum is zero. This means that for every scale from 1 to  $k_{min}$  these particular samples with index  $j_{n,low}$  have a zero value in the scalogram, and therefore, they can be identified as peaks corresponding to cable’s natural frequencies  $f_{n,low} = j_{n,low} \Delta f$  in the PSD. Figure 7 shows the reduced LMS with red vertical lines indicating the columns where the  $j_{n,low}$  values are located.

Figure 7: Rescaled LMS.

### 2.6 High-resolution PSD peaks identification

Once the peak regions have been located within a low-resolution PSD, the final peaks positions need to be precisely identified within a high-resolution PSD. This high-resolution PSD is computed using the Welch's method, considering much longer window lengths (half of the overall signal length) with a 50% of overlapping. Additional zero-padding is applied to each signal segment to improve the frequency resolution.

Within the high-resolution PSD, a precise search is performed in frequency bands associated to each  $f_{n,low}$  within the intervals  $\left[ f_{n,low} - \Delta f \cdot \left( \frac{k_{min}}{4} \right), f_{n,low} + \Delta f \cdot \left( \frac{k_{min}}{4} \right) \right]$ . The final natural frequency  $f_n$  is the one associated to the maximum of the high-resolution PSD value within the above interval. Figure 8 illustrates the aforementioned high-resolution PSD peak identification procedure.

Figure 8: High-resolution PSD peaks identification scheme.

Applying this methodology to a PSD resulting from the vibration measurement of a cable, the results obtained are displayed in Figure 9.

Figure 9: High-resolution PSD with the identified peaks.

## 3 EXAMPLE OF APPLICATION

The procedure presented in the previous section has been performed using the data obtained during 7 days of continuous monitoring of an external post-tensioning tendon belonging to a highway road bridge in Spain. The bridge monitored is a precast segmental externally post-tensioned bridge consisting of simply supported spans. The tendons monitored were grouted tendons made of 31 high-strength steel post-tensioning strands, each one made of 7 twisted wires of 6 mm of diameter. These strands were embedded inside a HDPE duct of 140 mm of diameter. Once tensioned, the duct was filled with grout to provide corrosion protection. This grout provides a monolithic effect to the tendon's section, which confers it a non-negligible bending stiffness. The accelerometers used were PCB-393B12 and were mounted using a clamp system attached to the tendon duct with bolts. Figure 10 depicts the bridge object of the study. The cable section being monitored is highlighted in red. Figure 11 shows the accelerometer mounted on the tendon.

Figure 10: Description of the tendon being monitored

Figure 11: Accelerometer mounted on a tendon.

### 3.1 Analysis of a single data block

A single 10-minute data block has been analysed here to demonstrate the usefulness of the presented autonomous peak-picking methodology. The signal was acquired with a sampling frequency of 1651 Hz. The time-history and the corresponding PSD of this data block is shown in Figure 12.

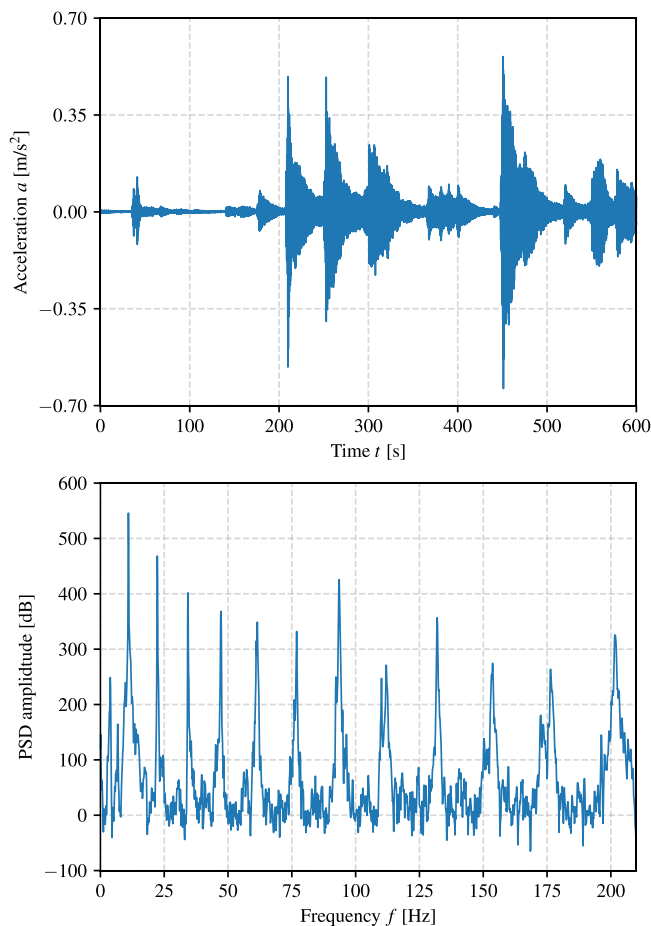

Figure 12: Analysis of a 10-minute data block.

The peaks detected present the noticeable effect of the bending stiffness, this effect can be seen in Figure 13, where the first 4 natural frequencies show a linear trend while starting

from the fifth natural frequency the data starts to show a non-linear trend.

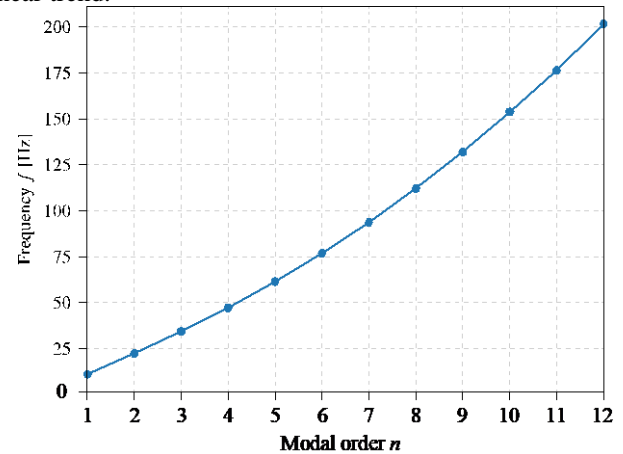

Figure 13: Modal order vs Frequency of a single data block.

### 3.2 Analysis of a one-day long data set

The variation of the different natural frequencies on the cable due to the temperature effect through one day has been firstly analysed. For that, the absolute frequency variation with respect to the initial frequencies being identified (those of the first 10-minutes record at 00:00) has been computed. Figure 14 shows this variation. It can be appreciated that the 4<sup>th</sup> modal order presents a slightly different behaviour this is due to its associated doublet. From this analysis, it can be also recognized how this variation is higher for higher modal orders.

Figure 14: Temperature variation relative to the ones recorded at 00:00.

### 3.3 Analysis of a one-week long data set

Figure 15 shows the first 12 natural frequencies identified using the presented methodology. From the analysed data set, it can be confirmed the influence of temperature variation over frequency. While this variation is small, knowing its magnitude is fundamental to distinguish between environmental or damage variations. These results confirm the validity of the methodology applied and its use within a continuous monitoring loop.

Figure 15: Complete frequency distribution along the week-long continuous monitoring.

## 4 CONCLUSIONS

An autonomous pick-picking procedure based on two PSDs (low and high resolution PSDs) combined with the use of a LMS procedure has been presented. The methodology has been conceived for its inclusion in continuous monitoring systems and to perform in-line tension force estimation since computation costs have been considered within the proposed methodology. From the results obtained from the one-week long monitoring data, it has been shown the performance of the proposed methodology.

Finally, some future works may include the autonomous identification of missing frequencies by the method, which can difficult cable tension estimation as this calculation depends on the natural frequencies and their corresponding modal orders correctly identified. Aside from this, the inclusion of the optimized asymmetric least squares (O-ALS) [4] baseline correction method which does not need hyperparameters fine tuning could be included.

**ABSTRACT:** With the increase in the span of cable-stayed bridges, stay cables tend to become more flexible and longer, which leads to lower damping and structural natural frequency. Therefore, it is more vulnerable to wind load effects. This study aims to investigate the characteristics and mechanisms of vortex-induced vibrations (VIVs) of stay cables based on long-term field monitoring for a sea-crossing cable-stayed bridge. First, a vibration monitoring system with a high sampling frequency for cables was established. On this basis, the time history data of vibration acceleration for cables with different lengths were collected to study the vibration characteristics, such as vibration amplitudes and frequency distributions of cables. For the longer stay cables, the cable vibrations with over-limit acceleration amplitudes were observed in a wind velocity region of 6–9m/s with very high vibration frequencies, and the wind directions that caused the vibrations were almost vertical to the stay cables. The mechanism of cable vibrations was discussed and investigated based on the relationship between wind characteristics parameters and the vibration response of cables. VIV occurred because the control frequencies of the cable vibrations coincided with the high-mode vortex shedding frequencies of the cables. Finally, the effects of different types of dampers on suppressing VIV were compared and investigated.

**KEY WORDS:** Cable-stayed bridge; cable vibration; bridge health monitoring; vortex-induced vibration.

## 1 INTRODUCTION

In the past few decades, cables have been widely used in long-span bridges. The cables of bridges tend to be more flexible, longer, and prone to vibrate due to low damping and structural natural frequency. The wind-induced vibration of stay cable can be roughly categorized as rain-wind-induced vibrations (RWIV), vortex-induced vibrations (VIV), and dry galloping (DG) classified by different vibration mechanisms and characteristics.

VIV of cables is a common form of cable aerodynamic instability phenomena with limited vibration amplitudes. When flow passes around cables, vortices are generated along the profiles of cylinder cables, alternatively on the upper and lower sides, and induce forces perpendicular to the wind direction[1]. As the length of stay cables grows, the structural natural frequency tends to be much smaller, indicating a much lower critical wind velocity corresponding to the classical vortex shedding. For a long cable, a high-mode VIV can be easily excited even under a moderate wind speed.

Field monitoring is meaningful for investigating the vibration characteristics of cables. Based on continuous half-year data from the bridge structural health monitoring system (SHMS), Ge found the frequency of the in-plane VIV is around 9.6 Hz for a 577m cable, and then validated that the cable is mainly subjected to high-frequency VIV[2]. Matsumoto conducted a field observation for a cable model of the Meiko West Bridge and discovered rain-wind-induced vibrations by comparing the vibration characteristics under different weather conditions [3]. Cable vibrations of the Fred Hartman Bridge were also investigated and studied by field monitoring. RWIV requires a much higher reduced velocity than that required by

VIV[4], and the high-order modes play the dominant role in the VIV of cables[5].

The vibrations of cables may cause fatigue or service problems if the vibration amplitudes are not mitigated by dampers or other countermeasures[6]. Therefore, aerodynamic and damping countermeasures were employed to mitigate cable vibrations. To optimize the aerodynamic profile of cables, the effects of helical strakes on suppressing VIV are studied by field measurements [7] and wind tunnel tests [8]. In addition, various types of dampers are usually installed near the anchor end of the cables to mitigate cable vibrations, including oil dampers, high-damping rubber dampers, viscous shear dampers [9], Magnetorheological (MR) dampers [10] and eddy current dampers [11]. The mitigation theories of various types of dampers for suppressing cable vibrations are different. Furthermore, it is still lacking an in-depth study regarding the effects of dampers on suppressing cable vibrations based on the field observation data of the bridge SHMS.

In this study, field monitoring was conducted on a cable-stayed bridge. The time history data of vibration acceleration for cables were collected to study the vibration characteristics and mechanism. Various types of dampers are adopted on symmetrical cables to compare the effects of different dampers on suppressing cable vibrations.

## 2 VIBRATION MONITORING SYSTEM FOR CABLES

The field monitoring was conducted on a cable-stayed bridge (Figure 1) located in Zhoushan of Zhejiang Province in China. As part of an important cross-sea passage, the Ningbo-Zhoushan Expressway between the island and the mainland,

this bridge is a cable-stayed bridge with twin towers and a semi-floating system, and the main span of this bridge is 580m. The height of the bridge tower is 151m. The bridge girder is supported by a total of 168 stay cables, and the length of the cables is 63-298m.

Figure 1. Bridge for field monitoring.

In the construction stage of the bridge, viscous shear dampers were pre-installed near the anchor of every cable of the bridge. However, on sunny and no precipitation days, obvious cable vibrations can still be found on this bridge. The cable monitoring system, as an important part of the SHMS, is shown in Figure 4. In total, 52 groups of acceleration sensors were installed on the cables at a height of 5m. To analyze the vibration characteristics of cables, the time history monitoring data of cable acceleration sensors and wind speed sensors were analyzed.

### 3 DYNAMIC CHARACTERISTICS OF CABLE VIBRATIONS

#### 3.1 Vibration characteristics of cables with different lengths

According to a 5-day period of monitoring data for cables, the dynamic characteristics of different cables were investigated and compared. In this study, cables are roughly categorized based on their lengths: short cables (<100m), medium-length cables (100~200m), and long cables(>200m).

For the short cables, the vibration amplitude is quite small (Figure 2(a)). Based on the power spectral density (PSD) of acceleration, the vibration frequencies are mainly between 5-10 Hz, which is quite average and not concentrated on one or several typical frequencies (Figure 2(b)).

Figure 2. Vibration data and frequency distributions of a short cable.

According to Figure 3(a), for the medium cables, the vibration amplitude is larger than short cables but still smaller than the warning value defined in “Technical specifications for structural monitoring of highway bridges” (JT/T 1037-2022) [12]. The vibration frequencies are mainly between 5~20 Hz, which is quite average and not concentrated on one or several typical frequencies (Figure 3(b)).

Figure 3. Vibration data and frequency distributions of a medium cable.

Figure 4. Cable monitoring system of the bridge.

For the long cables, abnormal vibrations are excited (Figure 5(a)). During the vibration period, the vibration amplitude is quite large, and the energy is mainly concentrated in the high-frequency region (Figure 5(b)).

Figure 5. Vibration data and frequency distributions of a long cable.

Therefore, the length of the cables is a crucial parameter that determines whether abnormal vibrations will be excited or not. This is because long cables with lower structural natural vibration frequencies and damping are more vulnerable to the wind effects and are more easily excited into large amplitude vibrations.

### 3.2 Vibrations of long cables and mechanism analysis

A typical large amplitude vibration event of a long cable is analyzed to further analyze the vibration characteristics of long cables.

As shown in Figure 6(a), a continuous cable vibration event in the period of August 2<sup>nd</sup> and 5<sup>th</sup> was recorded by the cable vibration acceleration sensors. The root-mean-square (RMS) values of every ten-minute acceleration are calculated (Figure 6(b)), and the maximum value is 723 mg, which is far greater than the allowable limit for cable vibrations defined in “Technical specifications for structural monitoring of highway bridges” (JT/T 1037-2022) [12].

Figure 6. Time history data and RMS value of acceleration.

Figure 7 shows the average power spectral density calculated using every 10-minute acceleration. The vibration was found to be concentrated in high-frequency regions, and the main frequency of vibration is 17.9 Hz.

Figure 7. Acceleration PSD.

To analyze the vibration mechanism, the relationship between the vibration amplitude and wind characteristics was studied. The wind velocity and wind angle in this period are recorded by the wind speed sensors (Figure 8). Therefore, it can be inferred that the cable vibration may be excited under nearly north-south wind conditions.

Figure 8. Time history data of wind.

Considering the installation direction of the bridge wind speed sensors as well as the angle between the stay cable and pylon, the wind yaw angle between the stay cable and wind was recalculated. The relationship between the acceleration vibration amplitudes and wind angles is shown in Figure 9(a). Large vibration amplitudes occur when the wind angle is around 90°, which means the wind direction is vertical to the cable plane. In addition, the wind speed vertical to the cable plane was also calculated (Figure 9(b)). It can be concluded that vibrations are maximized at a wind velocity of 6 to 9 m/s.

(a) Acceleration response under different wind yaw angles.

(b) Acceleration response under different vertical wind speeds.

Figure 9. Relationships between acceleration responses and wind characteristics.

For the VIV of cables, when the flow passes around the section of stay cables, vortex shedding emerges on the upper surface and lower surface alternatively, and the frequency of vortex shedding  $f_v$  can be defined as equation (1) [13]

$$f_v = \frac{US_t}{D} \quad (1)$$

Where  $U$  is the average wind speed.  $S_t$  is the Strouhal number, which is related to the section configuration, for a circle section,  $S_t = 0.2$ .  $D$  is the diameter of the cable. When vortex shedding frequencies of cables are close to the structural natural frequencies, cables will be excited into VIV resonance.

The vibration frequencies are calculated to investigate the vibration mechanism. In Figure 10, the x-axis represents the wind speeds, and the y-axis represents one-minute vibration frequencies. The maximum frequency calculated by the PSD of acceleration is selected as the main frequency of cables in one minute. Therefore, the scatters indicate different main vibration frequencies of cables under different wind conditions.

However, as the height increases, the wind speed apparently increases. Therefore, considering the overall speed of the wind profile passing around cables, the height of the cable and the wind field landform, the wind speed measured on the bridge deck should be multiplied by a factor of 1.3. Based on the dimensions of stay cables, the fundamental frequencies of vortex shedding can be calculated. Therefore, the relationships between different orders of vortex shedding frequencies and bridge wind speeds can be drawn as a red line (Figure 10). For the long cables, the micro-vibrations are mainly concentrated in the frequency range of 17~20 Hz, and 2~5 Hz (Marked as circles). The micro-vibrations are mainly catalogued into the vehicle-bridge coupled vibration and the vehicle load. Except for these scatters. The main distribution of scatters coincides with the line, especially in the wind speed region of 6~9 m/s, which indicates that the vibration frequencies are consistent with various modes of vortex shedding frequencies, and thus proves that the vibrations of the cable are dominated by VIV.

Figure 10. Relationship between vibration frequencies and vortex shedding frequencies of cables.

#### 4 MITIGATION OF CABLE VIBRATIONS

Different dampers are utilized to compare their effects in mitigating the cable vibrations. The damping ratios are set to achieve the optimal dimensionless damping coefficient 1.5~2.0 for different cables to minimize the large vibrations under lower frequencies. According to previous monitoring history data, under a certain wind field condition, the VIV responses of the cables symmetric along the bridge axis are quite similar because the structural parameters and natural frequencies of cables are almost the same. Therefore, different dampers are adopted for the symmetric long cable groups to investigate their effects on suppressing VIV. An eddy current damper (Figure 11(a)) is mounted on the cable R-20, and an MR damper (Figure 11(b)) is mounted on the cable R-21, respectively. For the sake of comparison, the new viscous shear dampers (Figure 11(c)) are employed on the symmetric cables L-20 and L-21. The parameters of dampers are designed with the consideration of the suppression of low-mode rain-wind vibrations.

(a) Eddy current damper.

(b) MR damper.

(c) Viscous shear damper.

Figure 11. Three types of dampers on cables.

Because the excitation of cable vibration under high frequencies ( $f > 15\text{Hz}$ ) is quite difficult, field monitoring is conducted under the condition of the ambient excitation of natural wind. A typical VIV response occurred in September of 2024 after the replacement of dampers was selected to study the effects of dampers on suppressing VIV. By comparing the time history data and RMS value of acceleration for the symmetric cables of R-20 (Figure 12) and L-20 (Figure 13), the VIV response of cable R-20 is significantly larger than that of L-20, which proved that the viscous shear damper is more effective in suppressing the high-mode VIV than the current eddy damper. When the high-mode (30<sup>th</sup>-40<sup>th</sup>) VIV of cables occurs, the position of the damper is close to the stagnation point of vibrations, and thus, it needs a large damping coefficient to suppress vibrations [14]. However, for the current eddy damper, as the vibration frequencies increase, the equivalent damping coefficients decrease [15], which is disadvantageous to the suppression of a high-mode VIV.

(a) Time history data of acceleration.

(b) RMS value of acceleration.

Figure 12. Vibration data of Cable R-20.

(a) Time history data of acceleration.

(b) RMS value of acceleration.

Figure 13. Vibration data of Cable L-20.

By comparing the time history data and RMS value of acceleration for the symmetric cables R-19 (Figure 14) and L-19 (Figure 15), the VIV amplitude of cable R-19 is a little smaller than that of L-19, which proved that the MR damper is slightly better than the viscous shear damper in suppressing the high-mode VIV. The initial stiffness of the MR damper may provide additional damping effects [16].

Figure 14. Vibration data of Cable R-19.

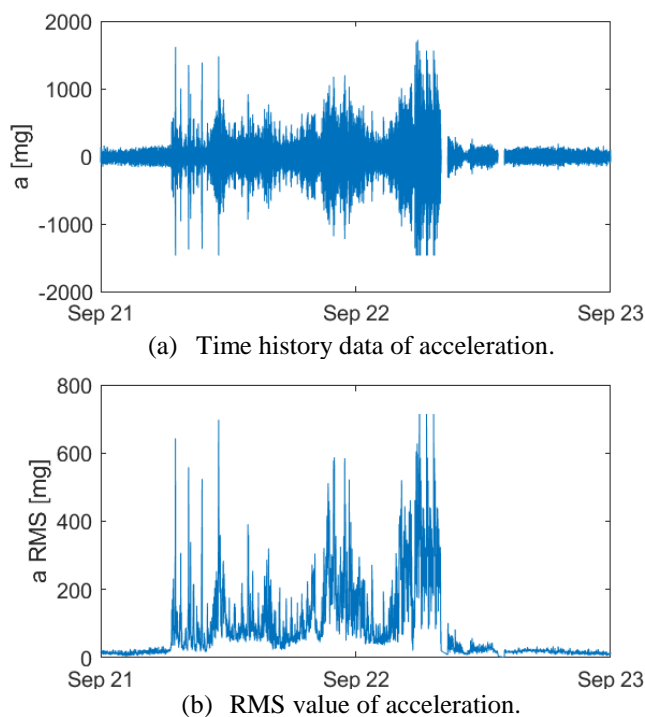

Figure 15. Vibration data of Cable L-19.

However, for these three types of dampers, the high-mode VIV cannot be entirely suppressed. Because the high-mode vibration may have multiple stagnation points along the cables, the installation positions of dampers tend to be close to the stagnation points. Therefore, stock-bridge dampers should be installed at suitable positions of cables as complementary dampers to mitigate the specific high-mode VIV [14].

## 5 CONCLUSIONS

In this study, continuous field monitoring is conducted to investigate the vibration characteristics of stay cables for a cross-sea cable-stayed bridge. Different dampers are mounted to compare their effect on suppressing vibrations. The conclusions are as follows:

- (1) According to the field monitoring data, the long cables of this long-span bridge are easily excited into a high-mode vibration under the vertical wind in a speed region of 6–9 m/s.
- (2) For the high-mode vibrations of long cables, the vibration frequencies of cables under different wind speeds are consistent with various modes of vortex shedding frequencies, proving that the vibrations of the cable are dominated by VIV.
- (3) For the mitigation effects of high-mode VIV of cables, MR damper > viscous shear damper > current eddy damper. However, the effects of the three types of dampers on controlling high-mode VIV are limited. Stockbridge dampers should be designed to mitigate the specific high-mode vibration.

**ABSTRACT:** External tendons in prestressed concrete (PSC) bridges are essential for structural performance and durability. However, internal damage to strands within grouted ducts is difficult to detect through visual inspection. To address this issue, the Korea Institute of Civil Engineering and Building Technology (KICT) developed a non-destructive testing (NDT) sensor based on the Total Flux Change (TFC) principle, derived from Faraday's law of electromagnetic induction. The TFC-based electromagnetic (EM) sensor was designed for field use, featuring a lightweight, detachable frame and wireless data acquisition system. The sensor generates an alternating magnetic field via a primary coil and measures the induced voltage from a secondary coil. A reduction in strand cross-sectional area alters the magnetic flux, resulting in a measurable variation in the induced voltage. Field tests were conducted on the Jeongneungcheon Overpass in Seoul, targeting external tendons between piers. The sensor successfully measured voltage variations along the tendon length. In tendons with suspected damage, the voltage amplitude showed distinguishable reductions, unlike in undamaged control cases. Results were consistent with previous laboratory experiments on specimens with artificially induced strand loss. The findings confirm that the developed EM sensor enables efficient and intuitive detection of internal tendon damage with practical field applicability, even in actual bridge environments. This study demonstrates the feasibility of the TFC-based EM sensor for practical field applications and highlights its potential for integration into long-term bridge monitoring systems.

**KEY WORDS:** Prestressed concrete bridge; External tendon; Electromagnetic sensor; Total flux change; Non-destructive testing

## 1 INTRODUCTION

Prestressed concrete (PSC) bridges have been widely adopted in modern road bridge due to their advantages in structural safety, aesthetics, serviceability, cost-effectiveness, and ease of maintenance. Among various structural components of PSC bridges, external tendons play a critical role by enhancing structural performance, allowing for flexible prestress control, facilitating maintenance, and providing design versatility.

However, since external tendons contain prestressing strands – typically seven-wire strands – embedded within ducts, it is inherently difficult to directly inspect them for damage during the service life of the structure. A notable example of such a limitation occurred in February 2016 with the failure of an external tendon in the Jeongneungcheon Overpass, constructed in 1999 in Seoul, Korea. The failure was attributed to undetected strand damage caused by grout defects inside the duct, which could not be identified through visual inspection.

Following this incident, the Korea Institute of Civil Engineering and Building Technology (KICT) initiated extensive research to develop non-destructive testing (NDT) sensors capable of detecting internal damage to the strands within the duct. As a result, a novel electromagnetic (EM) sensor based on Faraday's law of electromagnetic induction was developed. This sensor allows for effective detection of cross-sectional losses in the strands embedded within external tendons.

However, many of the existing NDT sensors developed for detecting cross-sectional loss in external tendons face limitations in actual bridge sites. These systems often require complex installation procedures, specialized equipment, and

controlled conditions, making them less suitable for field environments. In particular, external tendons located in narrow or elevated areas pose significant challenges for sensor installation and measurement. As such, not only the accuracy of damage detection, but also the workability and field applicability of the sensing system become crucial factors for successful deployment in practice. The aim of this study is to evaluate the field applicability and damage detection performance of the developed EM sensor through field tests on actual PSC bridges.

## 2 PRINCIPLE OF TFC-BASED ELECTROMAGNETIC (EM) SENSOR

### 2.1 Principle of cross-sectional loss detection

The EM sensor operates on the principle of electromagnetic induction, as governed by Faraday's law. According to this law, a change in magnetic flux induces an electromotive force (EMF) in a closed loop. The induced voltage  $V$  is proportional to the number of coils turns  $N$  and the time rate of change of magnetic flux  $\Phi$ , as expressed in Equation (1):

$$V = -N \frac{d\Phi}{dt} = -N \frac{dB A}{dt} \quad (1)$$

Magnetic flux  $\Phi$  is defined as the product of magnetic field strength  $B$  and the area  $A$  perpendicular to the magnetic field, i.e.,  $\Phi = B \cdot A$ . Therefore, if the magnetic field  $B$  remains constant, a reduction in the conductive cross-sectional area  $A$  – such as that caused by corrosion or fracture in the tendon – results in a corresponding decrease in the induced voltage  $V$ .

Based on this principle, a sensor has been developed to detect cross-sectional loss in prestressing strands located inside the ducts of external tendons. As illustrated in Figure 1, the EM sensor is installed to encircle the tendon duct, and an alternating current (AC) is applied to the 1<sup>st</sup> coil. As the sensor moves along the tendon, it generates a varying magnetic field that induces eddy currents within the steel strands. These eddy currents, in turn, generate a secondary magnetic field, which is detected by the receiving coil as an induced voltage.

Figure 1. Principle of section loss detect

If there is a cross-sectional loss in the strands, the magnitude of the eddy currents – and thus the induced voltage – decreases compared to undamaged regions. By analyzing the variation in induced voltage, it is possible to identify and localize internal damage to the prestressing strands, even without direct access. This method detects damage based on the change in total magnetic flux, and is referred to as the Total Flux Change (TFC) approach.

## 2.2 Configuration and features of the TFC-based EM sensor

To enhance field applicability, the developed TFC-based EM sensor system was designed with an emphasis on lightweight components and low power consumption. The sensor itself adopts a detachable and portable configuration, improving installation efficiency and reducing operational burden in actual bridge environments.

Unlike conventional solenoid-type sensors that require time-consuming on-site winding of wires, the newly developed sensor consists of a separable frame that can be easily mounted and dismounted around the tendon within approximately two minutes. Wheels installed at the front and rear of the sensor enable smooth movement along the tendon surface during scanning.

The sensor consists of a 1<sup>st</sup> coil that generates an alternating magnetic field, and a 2<sup>nd</sup> coil located at the center of the sensor that detects the induced voltage via electromagnetic induction. To improve magnetic field concentration and signal sensitivity, eight magnetic cores are embedded within the sensor structure. In order to minimize overall weight, the sensor housing was constructed with a lightweight skeletal frame rather than a solid enclosure. The electromagnetic response of the detachable sensor was verified through COMSOL simulations, showing a distribution pattern comparable to that of conventional solenoid-type sensors.

For accurate detection of the small induced voltage in the 2<sup>nd</sup> coil, a flat ribbon type cable with a 15-pin D-sub connector was

used. This configuration enables the equivalent effect of winding a single wire 15 times, thereby increasing sensitivity. A portable audio amplifier (200 W) was adopted to generate the required alternating current at the desired frequency, avoiding the need for large, heavy power generators typically used in the field. The appearance of the developed EM sensor is shown in Figure 2.

Figure 2. TFC-based EM sensor

The data acquisition (DAQ) system also emphasizes portability and reliability. A microcontroller unit (MCU) was employed to generate sinusoidal signals in the range of 10-40 Hz, which are then amplified by the audio amplifier and supplied to the 1<sup>st</sup> coil. The induced voltage from the 2<sup>nd</sup> coil is captured using a high-resolution analog-to-digital conversion board. The MCU wirelessly communicates with a laptop, allowing for real-time monitoring and data acquisition including 1<sup>st</sup> coil current, 2<sup>nd</sup> coil voltage, and distance measurements. The entire system is powered by commercial DeWalt rechargeable batteries, enhancing mobility and field usability. The DAQ system and battery pack for field operation of the sensor are shown in Figure 3.

### 3 FIELD TEST RESULTS

#### 3.1 Overview of Test bridge

The Jeongneungcheon Overpass, completed in 1999, is located on one of the major expressways for vehicular traffic in Seoul, South Korea. The field tests for detecting cross-sectional loss in prestressing strands were conducted in 2<sup>nd</sup> section of the bridge. The section is a PSC box girder bridge constructed using a modified MSS (Movable Scaffolding System) method. In this approach, precast panels were assembled on both sides of the box girder to form a three-cell cross section. Both internal and external tendons were used in the prestressing system of this segment. An overview of the structural characteristics of the test section is provided in Table 1, and the appearance of the bridge is shown in Figure 4.

Table 1. Overview of Jeongneungcheon Overpass 2<sup>nd</sup> Section

Item	Description
Bridge name	Jeongneungcheon Overpass
Year	1999
Design load	DB-24 (43.2 ton)
Structural type (Superstructure)	PSC box girder & Steel box girder L=3,500 m
Length	(Steel box girder: 1,240 m, PSC box girder: 2,260 m)
Width	B=27.0 m
Number of lanes	Three lanes per direction
Bearing	Pot bearing
PSC construction method	MSS

Figure 4. Jeongneungcheon Overpass Bridge

#### 3.2 Target external tendons for NDT

The nondestructive testing for detecting cross-sectional loss was conducted on external tendons located between Pier 38 and Pier 39 of the bridge. Each span of the bridge includes twelve external tendons, which are installed within the box girder section. Six tendons are positioned on the left side and six on the right side of the PSC box girder, as shown in Figure 5.

Figure 5. PSC box girder of test bridge

Among the tendons on the left side, some tendons were selected for testing due to their accessibility for sensor installation. Each tendon consists of nineteen 15.2 mm diameter seven-wire strands enclosed in a polyethylene (PE) duct filled with grout. The diameter of the duct is 110 mm. An example of the external tendons installed inside the box girder is shown in Figure 6. The testing procedure using the developed EM sensor is illustrated in Figure 7.

Figure 6. External tendons of test bridge

Figure 7. NDT process of TFC-based EM sensor

### 3.3 Test results

The NDT results for three external tendons of the Jeongneungcheon Overpass are shown in Figure 8, represented by the blue, green, and red solid lines. The plotted data correspond to the amplitude of the induced voltage measured by the sensor, after noise removal and mean value subtraction.

Figure 8. NDT results of TFC-based EM sensor

Among the tested tendons, L4 and L5 were replacement tendons installed after the external tendon rupture incident that

occurred in 2016. Therefore, these tendons are presumed to be free from significant strand damage. Although the induced voltage did not appear completely flat along the sensor travel distance—due to surface contamination, variations in the operator's walking speed, and electromagnetic interference from adjacent tendons—no distinct voltage drops were observed in these two cases.

In contrast, the response differed clearly from that observed in a controlled laboratory experiment conducted in 2023, where a tendon specimen with artificially introduced cross-sectional damage was tested. In the laboratory specimen with a 6.7% section loss (simulated by grinding the strand surface), a distinct decrease in the induced voltage amplitude was observed at the damaged location.

These results demonstrate that the EM sensor developed by KICT enables intuitive detection of cross-sectional loss in prestressing strands while maintaining sufficient workability for practical use in actual bridge environments.

## 4 CONCLUSIONS

This study presented the development and field application of a TFC-based EM sensor designed to detect cross-sectional loss in prestressing strands within external tendons of PSC bridges.

The sensor, developed based on Faraday's law of electromagnetic induction, demonstrated reliable performance in identifying potential damage zones by measuring changes in induced voltage. Field tests conducted on the Jeongneungcheon Overpass confirmed that the sensor could detect localized cross-sectional loss with clearly distinguishable signal behavior, even under the practical constraints of real bridge environments.

Compared to conventional solenoid-type sensors, the developed system significantly improved field applicability by introducing a lightweight, detachable design, wireless data acquisition, and low-power operation. These features enabled quick installation and stable measurement, proving the sensor's practicality for on-site inspections.

Future research will focus on further quantifying damage levels, validating the sensor performance under various damage conditions, and expanding its application to other bridge types and tendon layouts. Long-term monitoring and integration with digital maintenance platforms are also potential areas for future development. These findings highlight the potential of the TFC-based EM sensor as a practical and scalable solution for non-destructive inspection of PSC bridges.

**ABSTRACT:** With the rapid development of sensing technologies in vibration-based monitoring systems, various kinds of devices are connected to exchange data with each other in virtue of cloud computing. However, challenges arise when transmitting and processing large volumes of data, particularly due to latency and bandwidth limitations. To address these issues, edge computing has emerged as a promising solution, enabling local data processing to reduce transmission delays and minimize data redundancy. In this paper, the possibility of edge computing on lightweight edge devices is explored including the KRYPTON® CPU data logger and the ESP32-S3 microcontroller. These two monitoring systems, one with accelerometers and the other with strain gauges, are deployed on a four-story building frame model under varying structural mass and damping conditions that affect dynamic properties. Each system autonomously collects and caches data (accelerations and strains) locally using embedded code, enabling reliable, low-latency edge processing. Experimental results demonstrate the systems' ability to detect changes in dynamic behavior, supporting applications in fatigue assessment and damage detection. The proposed approach is scalable to dense sensor networks for large-scale structural health monitoring, where edge computing significantly reduces reliance on cloud infrastructure.

**KEY WORDS:** Monitoring; System identification; Edge computing; Frame model; Structural dynamics.

## 1 INTRODUCTION

The primary goal of structural monitoring is to evaluate the condition of instrumented structures by extracting reliable information from measurement data [1], which can inform effective management and maintenance strategies. The success of this process depends mainly on the quality and reliability of the acquired data [2]. Civil engineering structures operate in complex and variable environments, often subject to demanding monitoring requirements. Consequently, the establishment of a reliable and robust sensor system is essential to ensure accurate and consistent data acquisition.

With the rapid development of sensing technologies in vibration-based monitoring systems, various kinds of devices are connected to exchange data with each other in virtue of cloud computing [3], which improves performance and efficiency in monitoring. For instance, accelerometers can be deployed to collect vibration data from concrete structures, which, compared to baseline data from undamaged structures via cloud-based platforms within the Internet of Things (IoT) framework, can enable the early detection of cracks [4]. However, problems may arise inevitably when processing and sending large amounts of data to the cloud center far from the site in a short period of time. As the structural responses are the crucial sources of data for detecting structural damage [5], sometimes data acquisition requires high-frequency sampling rates. If the bandwidth of the network is limited at the same time, it may cause network congestion and result in a slow network speed.

One promising solution is to offload the computing tasks by processing before sending them. In this manner, the data to be

processed is distributed to edge devices rather than cloud centers [6], [7], namely edge computing. Now edge computing is emerging to solve the problem of time delay and data redundancy in monitoring. For instance, the microcontroller unit (MCU) at each sensor node can serve as an edge device and perform data preprocessing locally [8]. Despite the potential of edge computing, it also faces a series of challenges in practice, including its application in monitoring and the related algorithms that can be run under limited computing resources [9], [10].

In this paper, explore the integration of edge computing into different lightweight edge devices, such as KRYPTON® CPU data logger and ESP32-S3 microcontroller. In each monitoring system, sensor nodes are distributed to collect the measurement data of a four-story building frame model considering different cases with variations of the structural mass and damping that can change structural dynamic properties. Through the vibration tests, different monitoring systems can collect the data of the frame model and operate independently for data caching with the programming codes embedded in the edge device, which makes it possible for edge computing with reliable data transmission and minimized data loss.

## 2 METHODOLOGY

This section presents the instrumented four-story frame structure, outlines the laboratory testing procedures and equipment, and details of the setup, implementation, and data processing methods.

### 2.1 Building frame model

The four-story frame model is composed of six wooden slabs ( $480 \times 240 \times 18 \text{ mm}^3$ ), two of them fixed together as the base (on the test setup) and the remaining as the four floor slabs, see Figure 1. Every two slabs are connected by steel columns (flexible bodies) at four corners to constrain the vertical displacement, and each column has a free length of 240 mm between two slabs with a cross-section area of  $1 \times 10 \text{ mm}^2$ . So, the four floors only undergo horizontal displacement, which can be simplified into a multiple-degree-of-freedom (MDOF) lumped mass system. The first two theoretical modal shapes are shown in Figure 1 and Figure 2, and the total weight of the frame model (including timber and steel) is 6.95 kg.

Figure 1. Illustration of the four-story frame model with the first two theoretical mode shapes

### 2.2 Testing cases

When performing the vibration test, the two following cases are considered:

- 1) The frame model only, as shown in Figure 1;
- 2) The frame model with a sloshing tank that contains 0.5 kg of pure water, placed on the second Floor as shown in Figure 2.

### 2.3 Testing setup and implementation

Two vibration tests were conducted in the laboratory. The first test features force-based excitation. The building frame model was fixed on the test-bed under sine sweep excitation and then single frequency excitation, both of which were provided by low-force LDS electrodynamic shaker, see Figure 2.

In this manner, the steel column connecting the foundation and the first floor of the frame will be subjected to the force with a constant amplitude, yet its frequency itself will change over time. At time  $t$ , the normalized response function of the linear sweep excitation is:

$$x(t) = \sin \left\{ 2\pi \left[ (f_2 - f_1) \left( \frac{t}{T} \right) + f_1 \right] \right\} \quad (1)$$

where  $T$  is the test duration;  $f_1$  is the start frequency;  $f_2$  is the end frequency. The nature of the frequency sweep is that the excitation signal input is composed of a single frequency at any given time.

Figure 2. The four-story building frame model

The sweep can start from the lowest frequency, transition linearly to the highest frequency, and vice versa. In the function generator, the start frequency  $f_1$  was set as 0.1 Hz, the end frequency  $f_2$  as 10 Hz, with the test duration  $T$  of 180s. Due to the controllable variation of the excitation frequency, using frequency sweep excitation can preliminarily locate and identify the natural frequencies and mode shapes of the frame model.

After the sine sweep excitation, that was used to identify the frame's first four natural frequencies, the single frequency excitations were exerted, respectively, to get the damping ratios corresponding to each natural frequency of the frame model. Here, the shaker applied the force with a constant amplitude and constant excitation frequency.

The second test features controlled free vibrations, with the shaker removed. Using a ruler, the top floor was pushed sideways to a controlled position, see Figure 3, and then released. After the initial displacement, the frame model started to vibrate freely until the energy was completely dissipated.

Then, the whole process mentioned above was repeated considering the cases above in section 2.2 (with and without the sloshing tank).

### 2.4 Monitoring system and equipment

During the first testing, the low-noise accelerometers IOLITE® 3xMEMS (Figure 4) are arranged (with a total weight of 497 g) and fixed at the edge of each floor of the frame model using double-sided adhesive to reduce the signal shift and to ensure stable and reliable signals. Additionally, the  $x$ -axis direction of the sensor is parallel to that of the frame's horizontal displacement. Analog-to-digital conversion was done in each

accelerometer sensor, which eliminates the noise by analog cabling. Then, each accelerometer is linked to each other using the high-quality CAT6 cables through EtherCAT interface to form a daisy chain, limiting signal interference and data transmission error rates. Based on the IOLITE modular, DAQ device platform is embedded into each accelerometer distributed easily and synchronized down to 1  $\mu$ s device to device based on the distributed clocks. Then the acceleration signals produced are sent to the rugged IP67 micro-processor KRYPTON<sup>®</sup> CPU in the edge layer for processing the data on site. The data was collected at a sampling rate of 100 Hz, to avoid any problems with aliasing or signal distortion.

Figure 3. Controlled free vibration

Figure 5. HBM CLY41-3L linear strain gauges

The strain-monitoring system adopts an edge computing architecture and consists of these two strain gauges, two external high-resolution analog-to-digital converters (ADCs), two instrumentation amplifiers, and most importantly an ESP32-S3 microcontroller (MCU) as the edge device, shown in Figure 6.

Figure 6 The experimental setup for the strain-monitoring system

Figure 4. IOLITE<sup>®</sup> 3xMEMS accelerometers (a) and KRYPTON<sup>®</sup> CPU data logger (b)

During the second testing, two HBM CLY41-3L linear strain gauges are glued on the smooth surface of the steel columns at the bottom, respectively, to measure strains of the steel columns under controlled free vibration, with the sampling rate of 128 Hz, as shown in Figure 5.

In the device layer, the strain gauges are configured in a Wheatstone quarter-bridge, powered by a low-dropout (LDO) voltage regulator to maintain a stable excitation voltage and suppress external interference. Then, the weak voltage variations from the bridge are amplified by a high common-mode rejection ratio instrumentation amplifier AD620, followed by a resistor-capacitor (RC) filter with a cutoff frequency of 3.4 kHz to effectively reduce high-frequency noise and enhance signal quality. To meet the requirements of real-time monitoring at the micro strain level ( $\mu$ m/m), the amplified signals are digitized by an external 16-bit resolution ADS1115, with a sampling rate of 128 Hz and a full-scale range of  $\pm 6.144$  V, where the RMS noise is 187.5  $\mu$ V and the peak-to-peak noise reaches 187.5  $\mu$ V. Finally, the digitalized signals are transmitted to the MCU via the I<sup>2</sup>C (Inter-Integrated Circuit) bus. A circuit schematic is presented in Figure 7 with design details of the electronic components.

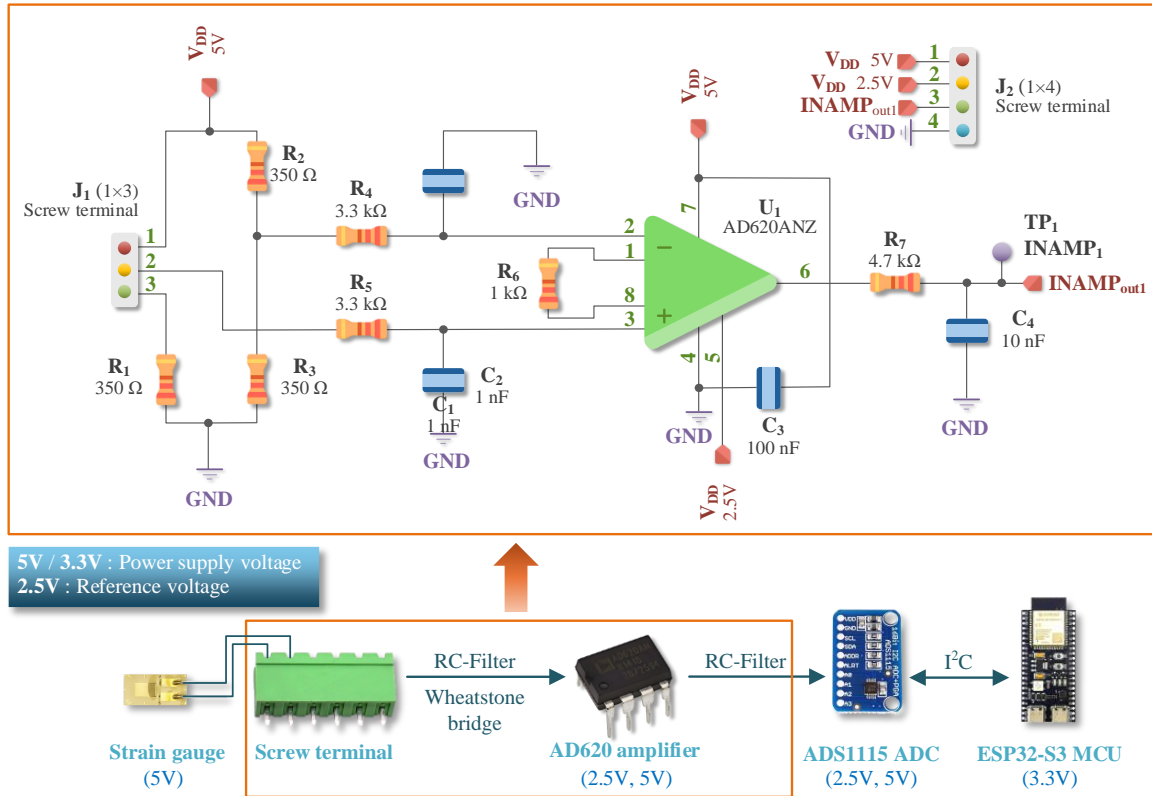

Figure 7 Circuit diagram with electronic components

It is noted that when extracting the amplified voltage difference in a Wheatstone quarter-bridge, the original bridge voltage must be reconstructed to obtain its accurate micro strain ( $\mu\epsilon$ ) value. Temperature compensation is not possible in this setup, causing normal and bending strains to be superimposed. The micro-strain  $\epsilon$  is calculated as:

$$\epsilon = \epsilon_n + \epsilon_b = \frac{4}{k} \cdot \frac{V_o}{V_s} - \epsilon_s \quad (2)$$

where  $\epsilon$  is the effective strain;  $\epsilon_n$  is the normal strain;  $\epsilon_b$  is the bending strain;  $\epsilon_s$  is the apparent strain;  $k$  is the factor corresponding to HBM CLY41-3L linear strain gauge;  $V_o$  is the voltage difference between the bridge legs;  $V_s$  is the excitation voltage.

In the edge layer, the lightweight ESP32-S3 MCU processes the data for the micro-strain. It serves as the edge computing core, equipped with a dual-core LX7 microprocessor. One core is dedicated to ADC sampling and data transmission, while the other performs real-time micro-strain ( $\mu\epsilon$ ) calculations, preventing data loss and task conflicts. Its support for hardware floating-point operations enables potential implementation of fatigue assessment methods at the edge, such as rain-flow counting. Synchronization between multiple strain gauges is achieved using the ESP32-S3's internal timer, which records a timestamp to align the measurement data in time when an ADC completes signal conversion. At the end, the micro-strains with recorded timestamps are transmitted to via a serial port a laptop where a Python script processes the incoming dataflow.

In the whole process, data acquisition, preprocessing, and transmission only happen locally (i.e. near the strain gauges), rather than relying on the remote cloud server. Particularly, edge computing offers low latency, real-time processing, and enhanced data privacy by reducing the need to transmit measured strain output signals to the cloud center. This preprocessing ensures that only the critical and useful data is transmitted to other systems, rather than raw, unprocessed signals, greatly reducing bandwidth requirements and costs.

## 2.5 Data processing

After the frequency sweep excitation, edge computing can be deployed on KRYPTON® CPU based on signals sampled over a period. Fast Fourier Transform (FFT) converts the discrete acceleration signals in time series to frequency domain to obtain the frame's vibration spectra, including amplitudes and phases.

Based on the amplitude peaks captured by FFT, the half power bandwidth method is used to calculate the modal damping ratio corresponding to each natural frequency. For a low damped structure ( $\zeta \ll 1$ ), the modal damping ratio is:

$$\zeta = (f_r - f_l)/2f_n \quad (3)$$

where  $f_n$  is the natural frequency corresponding to the resonance peak;  $f_l$  and  $f_r$  are the left and right frequencies at which the peak drops to half power of the resonance peak (-3 dB, or  $1/\sqrt{2}$  amplitude in the spectrum), respectively.

As for the free vibration, the damping ratio in a certain mode can be obtained by analyzing the amplitude decrement rate, i.e. Logarithmic Decrement:

$$\delta = \frac{1}{N} \ln[A(t)/A(t + nT)] \quad (4)$$

$$\zeta = \delta / \sqrt{4\pi^2 + \delta^2} \quad (5)$$

where  $A(t)$  and  $A(t+nT)$  are the amplitudes corresponding to time  $t$  and  $t+nT$ , respectively;  $T$  is the natural period;  $n$  is any integer number of successive, absolute peaks. Assume the structure is linearly elastic with small deformation, and there is a linear relationship between the strain and displacement in one dimension. Therefore, the amplitude of strains can be used in Equation (4).

Since vibration can occur throughout the whole frequency spectrum, filtering is required when using Equations (4) - (5) to keep only the one-order mode vibration.

According to the strain time series, the Rain-flow counting method is used for strain cycles. Then, the rain-flow histogram is obtained statistically for fatigue assessment in the future.

All the algorithms are programmed in Python language and run in the edge devices mentioned above.

### 3 TESTING RESULTS

This section presents the computing results of the building frame model, including its natural frequencies, damping ratios with strain cycle counting that is beneficial for structural damage detection and fatigue analysis in the future.

#### 3.1 Identification of structural dynamic properties

After finishing each vibration test, the output signals of the frame model with and without the sloshing tank are processed. As the floor acceleration at the foundation level has shown to be very small (relative to the other floors) it was neglected in this study. The accelerations from the second floor and the fourth floor with and without the sloshing tank on the second floor are shown in Figure 8.

From the time history acceleration of each floor, it is obvious that resonance occurs when the sweep frequency is near one of the frequencies of the frame model. Due to the proximity of the excitation to the first floor, its horizontal acceleration is more pronounced than that of the fourth floor.

Interestingly, when the sweep frequency reaches the frame model's natural frequency of the first mode (around 1 Hz), the sloshing tank placed on the second floor has very little effect in reducing the frame's model responses of each floor, because in the first mode, the second floor has small modal amplitude, see Figure 1. However, when the sweep frequency reaches the second mode (around 3 Hz), it exhibits a good performance in vibration reduction of each floor. The reason is that in the second mode, the displacements of the first, second and fourth floor are the largest, which makes the sloshing tank's damping effect to an ideal state except for the third floor (with zero displacement in the second mode). After the second mode, the sloshing tank does not reduce the structural responses so much.

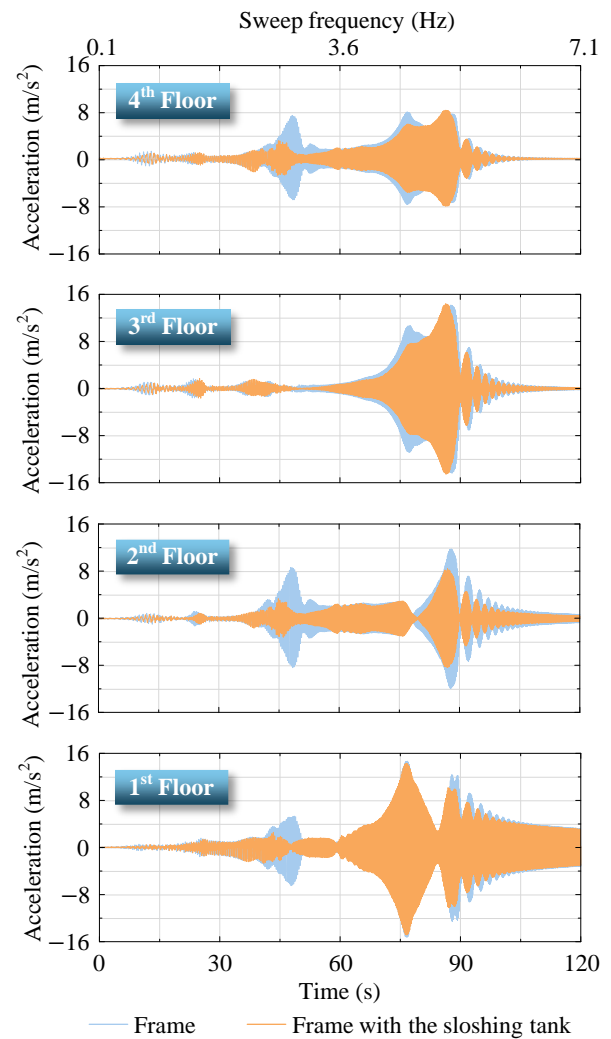

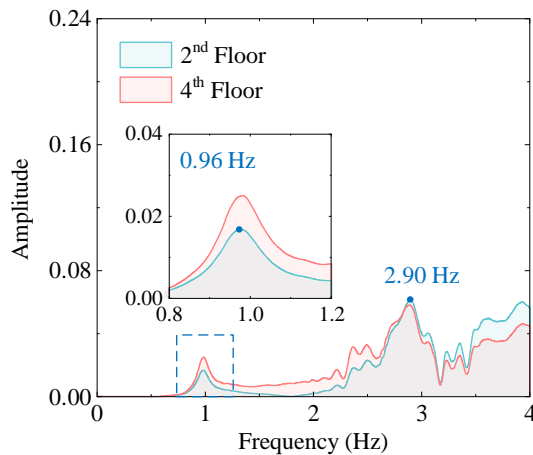

Figure 8. Acceleration time histories of the frame model with and without the sloshing tank on the second floor

(a) Without the sloshing tank

(b) With the sloshing tank on the second floor

Figure 9. Acceleration FFTs of the frame model in under frequency sweep excitation

According to the acceleration FFTs in Figure 9 (a), two peaks can be found, corresponding to the first two natural frequencies. From Figure 9 (b), the FFT shows again that the sloshing tank reduces more efficiently the vibration in the second mode. In addition, around the second mode, there are more smaller peaks than the scenario without the tank. Essentially, the tank annihilates the peak in the second mode – see Figure 9 (b), and separates it into several small peaks, which is similar to the mechanisms of a tuned mass damper. Because of extra weight and damping provided by the tank, the natural frequencies in each mode decrease a little bit.

However, the peak in the first mode is far less obvious than the peak in the second mode, see Figure 9 (a), which is related to the influence of the shaker position. From Figure 1, it is clearly shown that in the first mode, the maximum displacement happens on the top floor. During the first test, however, the shaker is fixed to apply the force in the middle of the steel column at the bottom, giving a small displacement in the first mode. Meanwhile, because of the frequency sweep excitation in a short duration during the testing, the frame model does not obtain sufficient energy from the shaker to establish a stable first-order modal response.

From Figure 10, dynamic strains of the frame model under controlled free vibration from strain gauge 1 are approximately sinusoidal throughout the entire frequency spectrum. Moreover, with the sloshing tank on the second floor, the frame model has a smaller oscillation.

Figure 11 presents the FFTs of strain gauge 1. As observed, the initial disturbance on the top floor has effectively excited the first mode. Also, the sloshing tank placed on the second floor reduces the structural responses in the second mode, not the first mode, which was also explained before.

Table 1 and Table 2 present the natural frequencies of the frame model with and without the sloshing tank, corresponding to the acceleration and strain FFTs, identified through the peak-picking algorithm within the range of [0, 4 Hz].

Figure 10. Dynamic strains of the frame model in time history from strain gauge 1

Figure 11. FFTs of strain gauge 1 (based on free vibration tests)

Table 1. Natural frequencies of the frame model without the sloshing tank

Mode	$f_n$ (Hz)		
	Sweep	Single	Free
1	1.04	1.03	0.99
2	3.00	2.99	2.96

Sweep: frequency sweep excitation; Single: single frequency excitation; Free: controlled free vibration.

Table 2. Natural frequencies of the frame model with the sloshing tank on the second floor

Mode	$f_n$ (Hz)		
	Sweep	Single	Free
1	0.96	0.95	0.92
2	2.90	2.87	2.77

Sweep: frequency sweep excitation; Single: single frequency excitation; Free: controlled free vibration.

The above results indicate that the natural frequencies in each mode of the frame model measured in different vibration tests are consistent (a maximum error of no more than 5%), within the allowable error range. In the controlled free vibration, the natural frequency measured is believed to be closer to the real one due to the absence/removal of the external vibration shaker.

During frequency sweep and single frequency excitations, factors such as excitation conditions, coupling effects, and phase lag have a significant impact on the results. The identification of the natural frequency of the frame model relies on resonance peaks, which are often close to the natural frequency of a structure; basically, when the structure system has damping or slight non-linearity, the acceleration resonance peak may be slightly shift. In addition, under vibration of an MDOF structure, interactions or coupling effects often exist between different modes, which may contribute to such "shift" of the observed resonance peaks even if the natural frequency itself has not changed. Theoretically, single frequency excitation has relatively smaller errors than the frequency sweep excitation due to more sufficient time for the structural system to follow the excitation in real-time. In contrast, during frequency sweep excitation, a certain natural frequency may have been "swept" over before the frame model fully establishes a steady-state response at that frequency, resulting in a response lag and a slightly higher observed natural frequency.

Table 3. Damping ratios of the frame model

Mode	$\zeta$ (%)	
	Single	Free
1	0.73 (0.78) <sup>a</sup>	0.75 (0.79) <sup>a</sup>
2	0.24 (0.34) <sup>a</sup>	0.27 (0.34) <sup>a</sup>

<sup>a</sup> Values in brackets are the cases with the sloshing tank.

Table 3 presents the damping ratios obtained under both single frequency excitation and free vibration. In fact, there are two peaks around 3 Hz in Figure 11. To avoid the overlapping of multiple modes, which are close to each other on the spectrum and result in inaccurate results. Thus, before the half-power bandwidth method, a bandpass filter with a bandwidth of 0.4 Hz was used to keep only the single mode vibration component when obtaining the damping ratio. As can be noted, the agreement is very good, indicating that the results from these two vibration tests are consistent, which verify reliability and correctness.

The damping ratio of the first mode is significantly higher than that of the second mode, indicating that the frame model experiences a faster energy dissipation because of a higher damping in the first mode. Additionally, the sloshing tank provides the higher damping among all modes, especially the second mode, with a more significant increase of 0.07-0.10%, indicating that the damper has a greater impact on the vibration mitigation in the second mode.

### 3.2 Strain cycle counting for fatigue assessment

From the dynamic strains obtained from strain gauge 1, the histograms for Rain-flow Counting are developed to give valuable information for future fatigue assessment.

(a) Without the sloshing tank

(b) With the sloshing tank on the second floor

Figure 12. Histograms of strain cycle counting from strain gauge 1

Figure 12 shows that most strain cycles concentrate between 200-320  $\mu\text{m/m}$ , making the greatest contribution to fatigue life of the frame model; The number of strain cycles decreases with the increase of the strain range with fewer cycles in the high strain range (500-600  $\mu\text{m/m}$ ).

An interesting observation is that with the sloshing tank, the number of cycles in the high strain region is reduced, indicating that the frame model is subjected to relatively mild strain fluctuations, and the sloshing tank can be an efficient method of vibration control.

## 4 CONCLUSIONS

In this study, the integration of edge computing into different lightweight edge devices is explored, including the KRYPTON® CPU data logger and the ESP32-S3 microcontroller.

In each monitoring system, sensor nodes are distributed to collect the measurement data (accelerations and strains) of a four-story building frame model considering two different cases with variations in the structural mass and damping. The experimental results demonstrate that these monitoring systems

can detect changes in structural dynamic properties under vibration, which provides a basis for future fatigue assessment and structural damage detection.

Finally, the proposed approach is scalable to dense sensor networks that can fuse information from many locations in a large-scale structure. Therefore, edge computing plays an important role in reducing data transmission to the cloud center and ultimately shaping a brighter future for structural health monitoring.

**ABSTRACT:** To understand the behavior of healthy structures and the changes to their condition over time, it is imperative to perform experimental analysis of existing civil engineering structures. Development of novel sensors measuring rotations enable to directly measure important components of the system parameters, as they provide additional information on the structural response. Long-term monitoring of existing structures using 6C sensors – 3C translation and 3C rotation, enables a more in-depth analysis of the system parameters; frequency, modeshape and damping. Specifically, the translation-based characterization of the torsional mode can be enhanced through direct measurement of the torsional angle, center of torsion and more precise frequency extraction. Furthermore, the distinction between shear and bending can be analysed through the ratio of angle and deflection, instead of using proxies like frequency ratios or shear wave velocity. In this study, we analyse how using 6C datasets for structural characterization of high-rise buildings provide further information to understanding the system parameters and their variations over time. We find that the rotational components significantly contribute to the understanding of the vibration behavior and thereby propose to include 6C sensors to enhance the characterization of structures.

**KEY WORDS:** 6C dataset; structural characterization; shear; bending; rotation; translation; system property variation.

## 1 INTRODUCTION

Analyzing seismic data to observe the dynamic behavior of buildings is a well-established approach in structural monitoring. Traditionally, this has relied on accelerometers and seismometers to capture translational motion. Recently, sensors capable of detecting rotational motion have expanded these capabilities [1]. Combining rotational and translational data provides more details on the structures behavior. Collocating 3 components rotation and 3 components translation improves the frequency resolution for torsional modes, and enables the determination of 6C mode shapes at the roof level with minimal sensor footprint, as shown in [2].

A key analysis is to determine a baseline for a healthy structure, concerning the system properties—like resonance frequency, damping, mode shapes, and waveform-based signal statistics [3]. In the absence of damage, these features are expected to stay consistent over time. Unless environmental parameters such as temperature, wind, or precipitation change, then they can temporarily influence the system behavior [4], [5]. Torsional modes often respond differently to environmental variations compared to translational modes, as shown in [6].

The translational modes of structures can be approximated through a shear or Euler-Bernoulli beam [7]. However, real structures are a combination of both. The Timoshenko beam theory incorporates both bending and shear [8], and has been applied to real structures in [9], [10]. Multiple methods exist to assess the prevailing regime - shear or bending, including frequency ratios [8], interferometric determination of shear

velocity [8], and interstory drift analysis using sensor arrays [9]. Structural damage can alter stiffness, mass, or damping, which in turn modifies the curvature of the resonance mode shapes. Monitoring the variation of a mode shape between bending and shear thus provides critical insights to a structures health [3].

The torsional modes are influenced by the eccentricity of the structure - which exists when the center of mass and center of rigidity do not coincide and the center of torsion. Due to inherent asymmetries in the building design or construction, all buildings display some torsional motion, which is a key factor in seismic damage. Therefore, changes in torsional response are vital to track for structural health monitoring.

This work investigates how 6C measurements can enhance structural characterization and monitoring, specifically for shear-to-bending and torsional response.

## 2 SENSORS AND EXPERIMENT SET-UP

There are a handful of buildings that have been instrumented for continuous 6C monitoring such as the high-rise building TAIPEI101 in Taiwan [10]. Where two 6C stations are located on the 90<sup>th</sup> floor comprising of an Eentec R1 rotation sensor and a Kinemetrics accelerometer each. Eentec R1 rotation sensor has a sensibility of  $1.2 \cdot 10^{-7}$  rad/s which is frequency dependent and is sensitive to temperature [11]. Another common rotation sensor is the blueSeis-3A [12] with a sensitivity of  $2.5 \cdot 10^{-8}$  rad/s from DC to 50 Hz. The blueSeis-3A was used to monitor the high-rise building Prime Tower in Switzerland for 1.5 years [2]. Recently high-quality 6C inertial

measurement units have been assembled specifically for structural health monitoring. The sensor self-noise of the rotational sensor is at  $1.5 \cdot 10^{-6}$  rad/s, therefore depending on the vibration amplitude, not always low enough for ambient noise, but low enough for active experiments [13]. The optimal location for a rotation sensor on a building is generally at the top floor, where the amplitude is the largest and an approximate modeshape can be extracted. On bridges this location is still an open question due to unresolved boundary conditions and location of maximum amplitude for rotational motion.

### 3 METHODS

In this study, we analyze the ratio between the horizontal rotation angle and deflection as a proxy for the vibration regime of high-rise buildings. Additionally, we are investigating the ratio between torsion angle and the displacement to extract the center of torsion.

The amplitudes of rotation and translation for each mode can be estimated either through the simple power spectral density (PSD) peak picking method or a more sophisticated method such as the stochastic subspace identification. Either way it is imperative that the methods are applied to the rotation angle and displacement directly and not the classic rotation rate and acceleration timeseries. As the derived ratio needs to be in the units of rad/m. Additionally, the relative amplitudes between rotation and translation need to be kept and a normalization as is often applied for mode shapes would have to be applied to all 6 components in the same way.

#### 3.1 Ratio for shear-to-bending response

For the shear-to-bending response analysis the ratio between the rotation angle and deflection is calculated by simple division. For a symmetric quadratic building where the walls are oriented along the North-South axis the translational modes would either be in East or North direction. To analyse the East bending mode, the rotations around North are divided by the deflection in East. For the North bending mode, the rotations around the East are divided by the deflection in North.

#### 3.2 Ratio for center of torsion

For an analysis of the torsional mode concerning the center of torsion the ratio between the vertical rotation angle and the horizontal translation is calculated. The horizontal translation is highly dependent on the location of the 6C station on the floor. At the center of torsion almost no displacement will occur, while there will be more translation away of the center of torsion. So, in theory one can estimate the torsional ratio by dividing the torsional angle through either the North, East or total horizontal displacement. A change of this ratio will mean a change of the center of torsion.

#### 3.3 Variation of Ratio

It is expected that the ratio for both the shear-to-bending response as well as the center of torsion will vary due to environmental and operational changes. These are for example; temperature, humidity, air pressure, wind, rain and activation of a tuned mass damper. However, it is expected that an earthquake could influence the ratio similar to the modal frequencies, that often feel a drop and consecutive healing effect. Any permanent change of the ratio could hint at damage and would need to be investigated.

### 4 CONCLUSION

This study presents a new method based on the ratio between rotation angle and deflection. This ratio contains information on the mode shape, and thus the overall vibration regime. Here it is introduced to analyse 1) if a structure is in shear or bending, 2) where the center of torsion is for a structure and 3) why this ratio varies over time.

6C datasets enable the evaluation of vibration regimes in high-rise structures. However, the results depend strongly on accurate sensor placement, sensor quality, and the ability of sensors to remain unaffected by external influences aside from the measured motion.

**ABSTRACT:** This study presents an integrated approach that combines seismic interferometry and system identification techniques for real-time Structural Health Monitoring (SHM), enabling the automated detection of changes in shear-wave velocity profiles for damage assessment. The methodology is validated using data from a 62-story residential skyscraper in San Francisco, one of the tallest buildings in the Western U.S., equipped with 72 uniaxial accelerometers across 26 floors. The building incorporates advanced structural components, including buckling-restrained braces, outrigger columns, and a tuned liquid damper to mitigate seismic and wind-induced responses. Data from the 2014 M6.0 South Napa and 2018 M4.4 Berkeley earthquakes, as well as ambient vibration recordings, are analyzed to establish baseline dynamic properties, including modal parameters, shear-wave profiles, and wave attenuation. We monitor wave propagation velocities, normal mode frequencies, and intrinsic damping through deconvolution interferometry, enabling real-time identification of structural stiffness changes. Shear-wave travel-time curves from deconvolution show reduced velocities below the 28th floor, coinciding with buckling-restrained braces, while higher velocities are observed above. This integrated methodology offers a robust framework for automated damage detection and real-time structural health assessment, demonstrating the potential to enhance the resilience and safety of high-rise structures during seismic events.

**KEY WORDS:** Structural Health Monitoring (SHM); Seismic Interferometry; System Identification; Shear-Wave Velocity; Damage Detection; High-rise structures.

## 1 INTRODUCTION AND BACKGROUND

Structural Health Monitoring (SHM) plays a crucial role in maintaining the safety and resilience of critical infrastructure, particularly in regions prone to seismic activity. High-rise buildings in seismically active zones such as the San Francisco Bay Area must withstand frequent and potentially severe seismic events. San Francisco, situated above an intricate network of active faults, including the San Andreas Fault, faces considerable seismic hazards, with the U.S. Geological Survey (USGS) forecasting a high probability of significant earthquakes occurring within the next few decades [1].

This paper explores the application of an advanced integrated SHM methodology to One Rincon Hill South Tower, a landmark 62-story, 195-meter-tall residential skyscraper in San Francisco, California. Recognized as the tallest residential building in California, the tower is instrumented with 72 uniaxial accelerometers strategically distributed across 26 floors, facilitated through collaborative efforts between the USGS National Strong Motion Project and the California Geological Survey's Strong Motion Instrumentation Program. Unique design features, including buckling-restrained braces (BRBs), an outrigger column system, a tuned liquid damper (TLD), and a robust, twelve-foot-thick mat foundation, are incorporated to enhance its resistance against seismic and wind-induced forces.

The study aims to validate an innovative real-time SHM system integrating seismic interferometry and system identification methods. This integrated approach aims to automate the detection of structural anomalies, specifically through monitoring changes in shear-wave velocities and wave

attenuation characteristics. Validation is accomplished using data recorded during the 2014 M6.0 South Napa and 2018 M4.4 Berkeley earthquakes, alongside ambient vibration monitoring data.

Advancements in Structural Health Monitoring have increasingly focused on integrating sophisticated methods for more accurate and reliable damage detection. Modal analysis approaches, particularly Frequency Domain Decomposition (FDD), have become standard practice in determining fundamental structural properties such as natural frequencies, mode shapes, and damping ratios. These methods effectively identify changes indicative of structural deterioration or damage [2]-[3].

Seismic interferometry has emerged as an essential complementary approach within SHM, enabling the extraction of detailed structural parameters from seismic and ambient vibration data. The principle of seismic interferometry involves retrieving Green's functions between sensors, thereby providing insights into wave propagation velocities and intrinsic attenuation characteristics, independent of knowledge of the source excitation [4]-[5]. Among interferometric approaches, deconvolution interferometry is particularly beneficial in distinguishing between intrinsic structural attenuation and scattering attenuation, thereby significantly improving stiffness and damage detection accuracy within monitored structures [6]-[7].

Significant validation of deconvolution interferometry in SHM was conducted by Snieder and Safak [4], who accurately estimated structural wave velocities and intrinsic attenuation parameters in the Millikan Library, demonstrating notable

advantages over traditional interferometric methods. Additional validation performed by Kohler et al. [9] in the Factor Building reinforced these findings, indicating a robust potential for application in real-time SHM scenarios.

However, traditional interferometric and modal identification methods independently exhibit limitations, notably insufficient sensitivity to localized stiffness reductions, which are critical for early-stage damage detection. To address these challenges, recent research highlights the importance of integrating seismic interferometric techniques with sophisticated system identification methods, significantly improving the accuracy and reliability of real-time SHM systems [6],[8].

This study builds upon previous work by integrating seismic interferometry methods, specifically modal identification techniques, which are validated using extensive seismic datasets from an extensively instrumented skyscraper. This innovative integration significantly enhances SHM capabilities, particularly for high-rise structures subjected to dynamic seismic loads, enabling timely detection and accurate characterization of structural health, which is crucial for improving resilience and minimizing post-earthquake recovery periods.

## 2 METHODOLOGY

### 2.1 Seismic Instrumentation and Data Collection

The seismic instrumentation of the One Rincon Hill South Tower comprises a comprehensive network of 72 uniaxial accelerometers strategically distributed across 26 floors (Figures 1–4).

Figure 1. 195m skyscraper in San Francisco (photo is courtesy of Magnusson Klemencic Associates).

Figure 2. The primary seismic load-resisting system with concrete core and outriggers comprising buckling restrained braces. The water tank located at the roof level serves as a tuned liquid damper to mitigate wind forces (Figures modified from Magnusson Klemencic Associates).

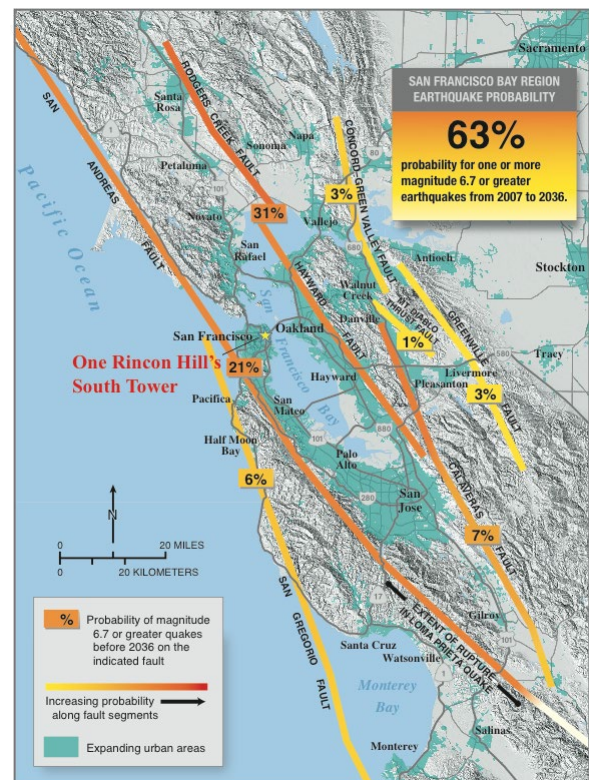

Figure 3. San Francisco Bay Area earthquake faults. The star sign indicates the location of the 195m skyscraper. (modified from <http://earthquake.usgs.gov/regional/nca/ucrf/>).

This dense array was meticulously designed and installed by the USGS's National Strong Motion Project in collaboration with the California Geological Survey's Strong Motion Instrumentation Program. Particular emphasis was placed on instrumenting floors equipped with critical structural elements, including buckling-restrained braces (BRBs) connecting the building to the outrigger systems at floors 26–32 and 52–55. Additional sensors placed at the base and roof levels facilitate the measurement of vertical accelerations, which are essential for quantifying the rocking motion induced by seismic excitation.

The recorded data include responses to two significant earthquakes: the 2014 M6.0 South Napa earthquake (epicentral distance of approximately 48.7 km) and the 2018 M4.4 Berkeley earthquake (epicentral distance of approximately 15.6 km). Ambient vibration measurements were also captured, providing a baseline for comparison of structural properties.

Figure 4. Sensor layout. Red arrows indicate the locations and the directional sensitivity of the accelerometers.

## 2.2 Seismic Interferometry and System Identification Framework

The methodology integrates seismic interferometry with system identification techniques for real-time structural health assessment. Seismic interferometry, particularly through the deconvolution approach, allows extraction of the structure's impulse response function (IRF) independent of external excitation sources. The governing equation for waveform deconvolution interferometry, adapted for building structures, can be expressed as in Eq. (1).

$$D(\omega, z) = \frac{U(\omega, z)}{U(\omega, H)} \quad (1)$$

where  $U(\omega, z)$  is the recorded seismic response at a specific height  $z$ , and  $U(\omega, H)$  represents the recorded response at the reference level  $H$ , typically the roof or base of the structure.

Eq. (1) may become ill-conditioned when the denominator approaches zero. To avoid this condition, the following regularized format is used as the estimator of deconvolution:

$$D(z, z_a, \omega) = [u(z, \omega)u^*(z_a, \omega)] / [|u(z_a, \omega)|^2 + \epsilon \langle |u(z_a, \omega)|^2 \rangle] \quad (2)$$

where superscript “\*” denotes the complex conjugate,  $\epsilon$  is the regularization parameter ( $\epsilon=0.01$  is used here, based on prior experience), and  $\langle |u(z_a, \omega)|^2 \rangle$  is the average power spectrum of  $u(z_a, \omega)$ .

System identification was executed using Frequency Domain Decomposition (FDD), an established modal analysis technique that effectively identifies modal parameters from ambient and seismic-induced vibrations. FDD facilitates modal parameter estimation by decomposing the spectral density matrices of the recorded accelerations into singular values, thus accurately identifying natural frequencies, mode shapes, and damping ratios of the structure [1]-[2].

The integrated approach involves calculating wave propagation velocities, normal mode frequencies, and intrinsic damping characteristics from the IRFs obtained via deconvolution interferometry. Shear-wave velocity profiles are computed explicitly by analyzing the propagation times of upgoing and downgoing shear waves through different building sections. Changes in these profiles effectively indicate stiffness alterations, potentially signifying structural damage or degradation [3],[5].

## 2.3 Analysis Procedures

Analysis began by establishing baseline modal parameters using ambient vibration data. Subsequently, earthquake data from the South Napa and Berkeley events were analyzed to quantify structural response under significant seismic loading conditions. This comparative assessment between baseline and event-specific modal parameters allowed for the precise detection and characterization of structural changes. Wave propagation velocities, intrinsic damping, and attenuation characteristics were estimated in real-time using advanced computational procedures integrating seismic interferometry and system identification.

Wavefield decomposition techniques were also utilized, providing causal (forward-time) and acausal (time-reversed) waveform comparisons. Discrepancies between these

waveforms facilitated precise estimation of intrinsic attenuation, as scattering attenuation remains invariant under time reversal, thus isolating intrinsic material damping characteristics effectively [3],[7].

The methodological rigor and integrated analytical procedures presented herein establish a robust framework for accurate real-time monitoring and damage detection capabilities in high-rise buildings, particularly under seismic excitations.

### 3 RESULTS AND DISCUSSION

#### 3.1 Baseline Dynamic Properties

Baseline modal properties of the One Rincon Hill South Tower were established using ambient vibration data and verified with earthquake-induced vibrations from the 2014 South Napa and 2018 Berkeley earthquakes. Modal analysis using Frequency Domain Decomposition (FDD) revealed the first five fundamental modes within the frequency range of up to 6 Hz. Identified modes included distinct bending and torsional behaviors. Specifically, the fundamental bending modes were clearly observable at frequencies below 1 Hz, consistent with expectations for a high-rise structure of this scale. Notably, ambient vibration data revealed subtle torsional modes, which were less prominent in the earthquake response data, indicating nonlinear behavior activated by seismic events.

#### 3.2 Shear-Wave Velocity Analysis

Utilizing deconvolution interferometry, distinct shear-wave velocity profiles were extracted, displaying apparent variations across the structural height of the building. Figures 5-6 and Table 1 illustrate these variations, which were particularly evident in areas around structural transitions, such as the presence of buckling-restrained braces and outrigger systems. Below the 28<sup>th</sup> floor, significantly reduced shear-wave velocities were consistently observed, correlating directly with the increased structural flexibility imparted by the BRBs. In contrast, increased velocities above this level underscored the effectiveness of outrigger columns and tuned liquid damper systems in enhancing structural rigidity. This spatial variation in wave velocity effectively delineates stiffness transitions, which are critical for accurate real-time monitoring and damage detection.

Figure 3. Recorded east-west waveforms from the 2017 M6.0 South Napa earthquake at an epicentral distance of 48.7 km.

Propagating waves from the first floor to the roof show amplification in the order of 4.2. The floor numbers and their corresponding height relative to the ground (1<sup>st</sup> floor) are depicted; the maximum roof acceleration is 20.894 cm/s<sup>2</sup>.

Table 1. Modified Shear-Wave Velocity Profiles.

Floor Range	Average Shear-Wave Velocity (m/s)
Below 28	210
28 to 52	350
Above 52	450

Figure 4. Deconvolved waveforms, calculated from the 2014 Napa earthquake east-west direction acceleration time series, are plotted as positive and negative amplitudes for each instrumented floor over time. The frequency range of the waveforms is 0–4 Hz.

#### 3.3 Intrinsic Damping and Attenuation Characteristics

The damping properties of the structure were quantitatively assessed using the impulse response functions (IRFs) derived from deconvolution interferometry. Results indicated intrinsic damping ratios of approximately 4.4% in the east-west direction and 3.7% in the north-south direction. These values align with expected damping ranges for high-rise buildings, reflecting effective energy dissipation during seismic excitation. Furthermore, wavefield decomposition analysis clearly distinguished between causal and acausal waveforms, allowing precise estimation of intrinsic attenuation. Variations in these characteristics across different building elevations indicated localized stiffness and damping alterations potentially associated with structural degradation or minor damage [3],[7].

These detailed results demonstrate the efficacy and reliability of the integrated SHM methodology proposed herein, providing a robust analytical framework capable of effectively detecting and localizing structural changes.

#### 3.4 Discussion

As demonstrated in this study, integrating seismic interferometry with advanced system identification techniques

significantly enhances real-time Structural Health Monitoring (SHM) capabilities, particularly in detecting subtle and localized changes in structural stiffness. The results demonstrate the clear advantages of this integrated methodology, particularly in terms of sensitivity and precision in detecting shear-wave velocity variations associated with structural anomalies.

The observed shear-wave velocity reductions below the 28th floor are particularly noteworthy, correlating directly with regions containing buckling-restrained braces (BRBs). These velocity reductions reflect structural flexibility intentionally designed to absorb and dissipate seismic energy. Conversely, higher shear-wave velocities identified above this zone demonstrate the significant rigidity provided by outrigger columns and tuned liquid dampers (TLD). Such explicit distinctions in velocity profiles serve as effective diagnostic markers, facilitating the precise localization of stiffness changes that potentially indicate structural deterioration or damage initiation.

The intrinsic damping characteristics obtained via deconvolution interferometry and wavefield decomposition provided precise estimates aligning closely with theoretical predictions and empirical data for high-rise structures. The ability to differentiate between intrinsic damping and scattering attenuation effects substantially improves over traditional SHM methodologies, which frequently fail to distinguish between these phenomena, thereby limiting adequate diagnostic accuracy.

However, some limitations of the current approach should be acknowledged. Specifically, assumptions of linear-elastic behavior under ambient vibrations may inadequately represent the structure's nonlinear response during significant seismic events. Enhancing the methodological framework to better account for nonlinear dynamics through advanced system identification approaches could substantially increase diagnostic robustness and reliability.

Moreover, practical considerations for real-world applications, such as computational demands, processing speed, and sensor robustness under extended environmental exposure, remain critical. Addressing these concerns through improved sensor technologies and optimized real-time computational algorithms is crucial for the practical implementation and widespread adoption of structural health management systems.

## 4 CONCLUSIONS AND FUTURE RESEARCH

### 4.1 Conclusions

This study comprehensively evaluated an integrated methodology combining seismic interferometry with system identification techniques, validated using extensive data from the instrumented One Rincon Hill South Tower. The methodology demonstrates robust capabilities for the automated and accurate real-time detection of structural stiffness variations through precise estimations of shear-wave velocities and intrinsic damping.

The major conclusions drawn from this research are:

- **Enhanced Damage Detection Sensitivity:** The integrated seismic interferometry and system identification approach significantly improves the detection and localization of

subtle stiffness reductions, which are essential for timely structural health assessments in high-rise buildings in seismic-prone regions.

- **Effective Characterization of Structural Components:** The methodology accurately delineated shear-wave velocity profiles corresponding explicitly to structural features, such as BRBs, outrigger columns, and tuned liquid dampers. This precise characterization offers actionable insights into structural integrity and performance under seismic conditions.
- **Improved Damping and Attenuation Estimations:** Intrinsic damping and attenuation properties were effectively isolated from scattering effects, significantly enhancing the reliability and diagnostic accuracy of structural condition assessments.
- **Identification of Linear versus Nonlinear Behaviors:** The study successfully differentiated structural responses induced by ambient conditions (linear-elastic) from those triggered by seismic events (nonlinear behaviors). Highlighting these differences underscores the necessity for continued methodological refinement in capturing comprehensive structural dynamics under seismic loads.

### 4.2 Future research

- Extending the developed integrated methodology to diverse structural types and construction materials broadens its applicability and effectiveness.
- Refining computational algorithms to ensure faster, more resource-efficient real-time structural analyses suitable for practical applications.
- Developing advanced nonlinear interferometric and system identification techniques capable of fully characterizing complex structural behaviors during significant seismic events.

Ultimately, the results and methodologies presented significantly advance the discipline of real-time structural health monitoring, promising substantial improvements in structural safety, resilience, and post-earthquake functionality. The presented method could make a significant contribution to many of the current structural engineering applications related to assessing structures under seismic effects, e.g., [10]–[44].

**ABSTRACT:** The recent advancements of GNSS technology have enabled multi-frequency and multi-GNSS observations even at high-rate measurements (up to 100Hz) with a few-mm to cm-level accuracy, broadening the potentials of GNSS application in monitoring dynamic motion of structures. Furthermore, recent studies have revealed the potential of low-cost consumer-grade GNSS receivers in deformation monitoring of civil engineering structures of even cm-level and indicated that the type of GNSS antenna is the main parameter affecting the quality of the GNSS data. In this study, we investigate the potential of dual-frequency smartphone-based GNSS measurements in monitoring dynamic motion of structures. The study is based on controlled experiments of static, slow and dynamic motion of various amplitude and motion frequency, where 1-Hz dual frequency GNSS smartphone measurements are assessed against more accurate geodetic measurements (GNSS and/or Robotic Total Station). The preliminary results show that the GNSS smartphone measurements may suffer from several cycle slips and strong multipath effects, due to the linear polarized GNSS antenna of the smartphone, but in several cases the GNSS smartphone measurements were able to express the dynamic motion. Also, in this study we examine the performance of the GNSS smartphone measurements in monitoring the dynamic response of Wilford Suspension bridge, under various patterns of dynamic loading.

**KEY WORDS:** GNSS-smartphone, deformation monitoring, dynamic motion, shake-table.

## 1 INTRODUCTION

Smartphones have been adopted in the last decades in many engineering applications. The broad use of smartphones in positioning and navigation applications has benefited from the development of dual-frequency GNSS receivers in some of the advanced smartphone models, enabling those smartphones of dual frequency carrier phase measurements. The first smartphone was Xiaomi Mi 8 (released in 2018) which supports dual frequency GPS/Galileo, single frequency BDS/GLONASS code pseudo-range and carrier phase measurements (Robustelli et al., 2019, Geng and Li, 2019). Nowadays, with the development of more advanced mobile phone chipsets, several smartphone manufacturers are releasing flagship phones supporting features such as L1/E1, L5/E5a dual frequency, multi-GNSS carrier phase measurements capability, etc. Thanks to GPSTest mobile app developed by Barbeau (2023), the capability of recent smartphones as of GNSS performance are crowdsourced and documented in GPSTest database (Barbeau, 2021).

Several studies were conducted focusing on the GNSS-performance of the first dual-frequency GNSS carrier phase Mi8. More specifically, Robustelli et al. (2019) used Xiaomi Mi8 in both single point positioning (SPP) and post-processing kinematic (PPK) applications, showing a RMS accuracy of around 5 m and 1-2 m for the SPP and PPK, respectively. On the other hand, Chen et al. (2019) employed Xiaomi Mi8 for real time precise point positioning and found that the RMS positioning error is 0.81 m and 1.65 m for horizontal and vertical respectively.

Since then, several other studies have been conducted assessing the performance of dual-frequency GNSS-

smartphones. Paziewski et al. (2021) assessed the GNSS observation quality of several smartphones, concluding that the smartphone GNSS data are noisier than the geodetic GNSS data, but still feasible to obtain a cm-level static solution. Li and Geng (2019) analysed GNSS measurement error characteristics from Nexus 9 tablets using both embedded and external antennas, revealing that the root mean squared (RMS) accuracy for the SPP is about 10-20 m, and cm-level precision can be achieved for static PPK solutions.

Hence, the first experiments reveal promising results about the quality of the smartphone-based GNSS measurements, indicating that they can achieve cm-level for relative PPK positioning (Pesyna et al., 2014; Wanning and Heßelbarth, 2020; Geng and Li, 2019; Dabov and Pietra, 2019). However, most of the experiments are based on static experiments and only one study is based on experiments of dynamic motion of smartphone experiments (Vazquez-Ontiveros, et al., 2024).

With the broader trend of applying low-cost GNSS receivers for monitoring applications (Xue et al., 2021; Xue et al., 2022; Xue and Psimoulis, 2023), there is great potential for mobile phones to be used for precise positioning services such as in SHM due to: 1) the relative low-cost with respect the geodetic GNSS receiver, 2) the raw smartphone GNSS measurements (code and carrier phase, etc.) which are accessible to the broader smartphone users community, 3) the potential of crowdsourcing data through the smartphones application, and 4) the availability of various sensors such as accelerometers, gyros, which can be combined with GNSS measurements in SHM applications (Lăpădat et al., 2021).

In general, it is expected that the code and carrier phase measurements of smartphones are of relatively lower quality

than those of geodetic receiver. However, it was shown that ambiguity resolution of L1 measurements, which is the prerequisite for achieving a precise solution of cm-level, can be achieved, as it was concluded from experimental study using a Huawei P30 smartphone (Wanninger and Heßelbarth, 2020).

Although there are a few studies regarding deformation monitoring with smartphones, most of them, only take advantage of its embedded accelerometer, their GNSS observation functionality is rarely assessed for its deformation monitoring applicability except for few conducted by Zeng et al., (2022) and Vazquez-Ontiveros et al. (2023). Vazquez-Ontiveros et al. (2023) found that an RMS error of 1.4 cm in the horizontal component could be achieved for kinematic circular trajectory with a rotating speed of 0.44 rad/s ( $\sim 0.07$  Hz) and an rotation radius (amplitude) of 19 cm and RMS errors of 0.7 cm, 1.2 cm, and 4.2 cm in the East, North, and Up components could be obtained with static experiment.

In this study, we present the preliminary results of controlled experiments, where smartphone GNSS measurements were conducted to monitor dynamic vertical and horizontal motion and evaluate the performance of the GNSS measurements. The preliminary results are promising, indicating the potential of smartphone GNSS measurements for dynamic motion monitoring.

## 2 METHODOLOGY

The study was based on two controlled experiments, aiming to simulate long-period/low-frequency (up to 0.2 Hz) cm-level or larger motion, meeting the main deflection characteristics (amplitude and frequency) of flexible structures (e.g., long bridges and tall buildings) under normal service conditions (Meng et al., 2018).

The first experiment involved a controlled vertical periodic motion (of up to 0.1 Hz) produced manually by a platform, following the methodology of the study (Peppas et al. 2018), and monitored by smartphone GNSS receiver and a robotic total station (RTS) measurement. The mm-level accuracy of RTS measurements served as the reference for evaluating the performance of the smartphone GNSS (Psimoulis et al., 2008).

The second experiment focused on controlled horizontal oscillations of up to 0.2 Hz, induced by a shake table. Multiple GNSS sensors, such as survey-grade, low-cost and smartphone-grade receivers, were attached to the shake table, along with several accelerometers, all subjected to the same excitations. The direct trajectory output of the shake table was used as a reference to assess the performance of different sensors. The analysis of the GNSS timeseries, using statistical and spectral techniques, was applied in both experiments to quantify measurement accuracy and identify their dominant frequencies.

## 3 CONTROLLED VERTICAL EXPERIMENT

The first experimental assessment aimed to evaluate the performance of GNSS-smartphone for monitoring low frequency cm-level vertical dynamic motion. We conducted an experiment on the open roof of Nottingham Geospatial Building (NGB), where periodic vertical oscillations were executed by using a heavy-duty tripod with a height-adjustable platform and manually controlled vertical movement. On the top of the tripod, a 360°-prism and metallic plate were mounted,

where the smartphone was securely placed. We manually introduced vertical periodic oscillations of about 0.05 Hz and 0.1 Hz by synchronising to a metronome, as described in Peppas et al., 2018, and the amplitude of 2 to 3 cm was controlled based on the graduation etched on the pole.

The setup of the vertical controlled experiment is shown in Figure 1, where the GNSS base station is consisted of Leica AS10 geodetic antenna and Leica GS10 geodetic receiver, recording in 1 Hz multi-GNSS observations (i.e. GPS, GLONASS, Galileo, BDS; Figure 1A). The Samsung S23 FE, equipped with the dual-frequency GNSS receiver, was set on top of a ground plate, to limit the multipath effect, recording 1Hz multi-GNSS observations, using the GnsLogger App, developed by Google (Google, 2024). The Samsung S23 FE could record L1/L5 GPS, B1i/B2a BDS, E1/E5a Galileo, and G1 GLONASS signals. Finally, the 360°-prism Leica prism was monitored by Leica TS30 RTS, which was recording at 10 Hz sampling-rate (Peppas et al., 2018, Peppas and Psimoulis, 2023).

We conducted six oscillations; (i) three oscillations of approximately 0.1 Hz frequency, and amplitude of  $\sim 2$  cm (A), and  $\sim 3$ cm (B) and (C); and (ii) three oscillations of approximately 0.05 Hz frequency and amplitude of  $\sim 1$  cm (D),  $\sim 2$  cm (E) and  $\sim 3$  cm (F).

The RTS ortho-height timeseries relative to the initial position (prior to the oscillation) were exported, expressing the vertical displacement of the oscillation. The smartphone GNSS data were logged in Receiver Independent Exchange Format (RINEX) 3.03 from the GnsLogger App. The GNSS data were post-processed using double-difference (DD) in kinematic mode in RTKLIB demo5 b34h (Everett, 2023) with mobile GNSS data as the rover and Leica GS10 data as the base. The multi-GNSS solutions were obtained using GPS, Galileo and BDS observations. The GLONASS observations were not used for the GNSS solution due to the GLONASS inter-frequency bias between the GNSS smartphone and the GNSS base station, which affects the ambiguity resolution of the GNSS measurements (Msaewe et al., 2017). The Up-component timeseries of the GNSS solution reflected vertical oscillation and was compared against the RTS vertical timeseries to evaluate the accuracy of the GNSS smartphone data.

Figure 1. (left) The GNSS base station, (middle) the rover station with the prism and a metallic plate where the Samsung S23 FE has been mounted, and (left) the RTS recording the position of the prism.

Figure 2 shows the vertical component timeseries and Discrete Fourier Transform (DFT) spectra of the RTS and GNSS data for the oscillation case of  $\sim 0.05$  Hz frequency and  $\sim 3$  cm amplitude (case F) respectively. It is clearly observed the pattern of sinusoidal movement in the GNSS timeseries, with a slight downward drift with respect to the RTS timeseries, which can be the result of low-frequency noise due to multipath effect, to which is susceptible the linearly polarised smartphone antenna.

Likewise, Figure 3 are presented the Up-component timeseries and the respective spectra of GNSS and RTS data for case C (amplitude of  $\sim 3$  cm, frequency of  $\sim 0.1$  Hz). As in the experiments of 0.05 Hz, it is clearly observed the periodic pattern of the motion followed by both GNSS and RTS data, with the GNSS data characterized also by a low-frequency drift, most likely to multipath effect of the GNSS smartphone measurements.

To quantify the precision of the smartphone GNSS measurement in monitoring the oscillation amplitude, with respect to the RTS timeseries, we estimated the amplitude of the oscillations by using the peak values of each periodic cycle of GNSS and RTS timeseries and calculating the mean oscillation amplitude of each (GNSS and RTS) timeseries. Even though the low-frequency noise of the GNSS timeseries could lead to a drift of about 5-8 mm, the estimated oscillation amplitudes of GNSS smartphone data differ from that of the RTS timeseries by 3 cm and 5 cm for the cases F and C, respectively.

Table 1 shows mean amplitude of each experimental vertical motion as it was estimated from the RTS timeseries, the Root Mean Square (RMS) Error of the GNSS timeseries with respect to the amplitude of the RTS and the dominant frequency detected for each oscillation scenario derived from the spectral analysis of the RTS and the smartphone GNSS time-series. It is observed that the GNSS-smartphone precision in detecting the amplitude of the vertical oscillation ranges 2-5 mm. It should be noted though the impact of the low-frequency drift, which may not affect the estimation of the oscillation amplitude

Figure 2. (top) RTS and GNSS-smartphone timeseries for case F oscillation case, and (bottom) the respective spectra

but it would affect the estimation of low-frequency semi-static displacement. As for the dominant frequency derivation, the maximum discrepancy between smartphone GNSS and RTS is around 0.007 Hz for 0.1 Hz detection, and 0.003 Hz for 0.05 Hz detection, equivalent to 6-7% bias in dominant frequency determination. It is also interesting to note that the spectra for RTS timeseries doesn't seem to have distinct peaks but rather shows an area of occurrence of multiple peaks as compared to the smartphone GNSS, indicating that it is more sensitive in differentiating different frequencies in the signal.

Figure 3. (top) RTS and GNSS-smartphone timeseries for the case C oscillation case, and (bottom) the respective DFT spectra

Table 1. Precision of the smartphone GNSS in monitoring the kinematic oscillatory displacement for scenarios A to F, and the corresponding dominant frequency from RTS and smartphone GNSS for each case

	RTS amplitude (mm)	RMS Error GNSS (mm)	Frequency (Hz)	
			RTS	GNSS
A	21	2.5	0.100	0.100
B	33	2.9	0.100	0.094
C	31	3.2	0.107	0.100
D	11	3.2	0.050	0.050
E	21	2.7	0.050	0.050
F	30	5.1	0.053	0.050

#### 4 CONTROLLED VERTICAL EXPERIMENT

The experiments of horizontal dynamic motion were based on a shake table and it was designed and conducted on the roof of Xinghu Experimental Building at Wuhan University in China. The roof is moderately open with few obstructions by surrounding buildings.

In Figure 5 is presented the experimental setup, where several mobile phones were placed on top of a shake table device, (i) with two smartphones placed outside using their internal GNSS

antenna (Huawei P40 and Samsung S23 FE), (ii) two mobile phones placed inside of two shielding boxes (Huawei P40 in the black box and Samsung S23 PE in the white box). The two shielding boxes and the geodetic receiver were both connected to the survey grade antenna via a signal splitter. Inside the two shielding boxes, there were two devices retransmitting the GNSS signal as received by the GNSS geodetic antenna to the smartphone. A patch antenna was also placed on the white shielding box connecting to a u-blox F9P module, and a survey-grade accelerometer was fixed on the side of the shake table.

Figure 5. (left) The setup of the rover sensors (GNSS and accelerometer) on the shake table, and (right) the station consisted of survey-grade antenna and receiver

Both the geodetic rover and base station were measuring at a sampling rate of 10 Hz, recording GPS, Galileo, BDS, GLONASS and QZSS observations, while all four smartphones were configured so that the GPS (L1/L5), Galileo (E1/E5a), GLONASS (G1), QZSS (J1/J5), and BDS (B1i/B2a) GNSS raw data were recorded with application GeoDataLogger developed by PrideLab (2024) at a sampling frequency of 1Hz. Additionally, the u-blox receiver recorded GPS, Galileo, GLONASS), QZSS and BDS observations at 10Hz sampling rate.

The accelerometer data were also recorded in GeoDataLogger at the maximum capacity of the smartphone (e.g., around 125 Hz sampling frequency for Samsung and around 100Hz for the rest), while the survey grade accelerometer (TD) recorded at 100 Hz sampling frequency with GPS timestamp thanks to an external GNSS module.

The Quanser Shake Table II, controlled via a MATLAB script implemented in Simulink, was used to perform precise, programmed displacements. The shake table was rigidly bolted to the roof and carefully orientated in E-W direction. We performed in total 25 different motions with various amplitude and oscillating frequency oscillating in E/W direction, with amplitude ranging from 5mm, 10mm, 20mm, 40mm, and oscillation frequency ranging from 0.1 Hz, 0.2Hz, 0.5Hz, 1Hz, 1.5Hz, and 2Hz. Each oscillation lapsed around 2 minutes with at least 1 minute of static period in between consecutive oscillations. The shake table could output direct displacement

timeseries at a frequency of 100 Hz, which we employed as the reference data and the ground truth.

It is worth noting that from the experiment,

- i) Apart from the GNSS measurements and the geodetic accelerometer data, all other data was not initially synchronised to GNSS time, such as phone accelerometer measurement and shake table output timeseries.
- ii) The acceleration timeseries derived directly from the accelerometers output, with the oscillation axis being in East-West direction. The acceleration data of the smartphones were acquired depending on the orientation of each smartphone.
- iii) The smartphones can record 1Hz GNSS measurements, meaning that they can be used only for frequencies up to 0.5Hz, due to Nyquist theorem
- iv) The ublox measurement terminated halfway during the measurement, causing some data loss.

The GNSS data were post-processed using the open-source software RTKLIB demo5 b34k (Everett, 2024) in the kinematic mode, with the GNSS sensors on the shake table as rover and the geodetic receiver as base forming multiple baselines. The output from the RTKLIB is in E/N/U which is effectively the 3D projection of the baseline vector in the local E/N/U direction. All the GNSS post-processed solutions achieved ambiguity fix.

The synchronisation of the accelerometer and GNSS timeseries is based on finding and shifting the optimum lag when the cross correlation between the geodetic accelerometer and each accelerometer timeseries reached the maximum, indicating strong correlation. By adjusting the time for accelerometer timeseries, we aligned them to GNSS timestamps.

In this study, we focused only on oscillations with frequency motion up to 0.2 Hz, for which the 1 Hz smartphone GNSS data can be used to determine the oscillation frequency, as the Nyquist frequency is 0.5 Hz, based on the sampling rate of the GNSS smartphone data (i.e. 1Hz). The oscillation characteristics (amplitude and oscillation frequency) for the 9 sections from left to right are shown in Table 2. For higher frequencies, the 1-Hz GNSS smartphone data would need to be integrated with accelerometers data. Hence, we investigated only the performance of the 1-Hz GNSS data.

Table 2. Amplitude and frequency of the executed oscillations produced by the shake table.

Oscillation	Amplitude (mm)	Frequency (Hz)
1	5	0.1
2	10	0.1
3	20	0.1
4	40	0.1
5	5	0.2
6	10	0.2
7	20	0.2
8	40	0.2
9	40	0.2

Figure 6. Original timeseries from different GNSS sensors. From top to bottom are 1) geodetic receiver/antenna, 2) Samsung S23 FE 3) output from shake table. The time-series are shifted to avoid overlap between them.

The RTKLIB setting for processing GNSS timeseries are utilising L1+L2/E5b+L5/E5a triple frequency option and GPS+Galileo+BDS multi-constellation configuration. Slightly different configuration settings were used for phones using internal antenna and the geodetic antenna due to the significant differences in the antenna since mobile phones antenna is more susceptible to multipath error, cycle slips.

In Figure 6, it is shown the timeseries of the geodetic GNSS receiver and the GNSS smartphone, as they have derived from the GNSS post-process, and the shake table timeseries (i.e. reference data). The start and end time for each oscillation is highlighted by two vertical lines segmenting the timeseries into 9 oscillation sections.

It can be shown in Figure 6 that the geodetic receivers with geodetic antenna time series doesn't seem to be affected by low frequency errors as much as the Samsung timeseries. Also, the noise level is significantly larger for Samsung as compared to geodetic receiver/antenna when the shake table was static. These indicate that the antenna grade is crucial for more precise results less affected by multipath. On the other hand, it is promising that the displacement/excitations could be detected from Samsung timeseries with a strong positive correlation with the geodetic GNSS and shake table timeseries, especially for 20- and 40-mm amplitude oscillations.

To enhance the GNSS timeseries, in terms of reducing the noise level, the GNSS timeseries was firstly filtered using high-pass Chebyshev filter with cutoff frequency of 0.05 Hz to mitigate the multipath bias and potential other source errors. Then, the residuals were calculated by the difference between the GNSS timeseries and the output from shake table.

In Table 3 is shown the true amplitude of each oscillation scenario, as it is derived from the shake table data (i.e. ground truth) and computed RMS error of the geodetic and the smartphone data in estimating the oscillation amplitude. It is observed that the RMSE of the geodetic data does not exceed 2 mm, with the maximum RMS error observed for the scenarios

Figure 7. Similar to Figure 6, timeseries from different GNSS sensors but after high-pass filter

of large oscillation, i.e. 40mm. In all the other scenarios and for amplitude equal or smaller than 20mm, the RMS error is limited to less than 1 mm. Regarding the RMS error of the GNSS smartphone data in estimating the oscillation amplitude the RMS error is generally lower than 5 mm, as it is exceeding the threshold of 5 mm only for two scenarios of oscillations, i.e. 10 and 40mm for 0.1 Hz oscillation frequency. In general, the RMS error of the GNSS smartphone data is about two to four times larger than the geodetic solution. As expected, the overall performance of the GNSS smartphone data is lower, in terms of noise/errors, comparing it to the GNSS geodetic receiver, mainly due to the lower quality of the antenna, since the geodetic receiver/antenna are dedicated GNSS instruments, whereas the mobile phones has comparatively lower grade receiver and antenna. Also, it is observed that the GNSS smartphone has low performance in estimating the oscillation amplitude for the cases of 5 and 10 mm, as the achieved precision is of 3-6.5 mm level, while the results seem more promising for the cases of oscillation amplitude of 20 and 40 mm.

Table 3. Standard deviation of the residuals for different GNSS sensors with reference to Shake table timeseries

Oscillation Scenario	True amplitude (mm)	RMS Error (mm)	
	Shake Table	Geodetic	Smartphone
1 (0.1Hz)	5	0.8	4.0
2 (0.1Hz)	10	0.6	7.6
3 (0.1Hz)	20	0.7	4.3
4 (0.1Hz)	40	1.6	6.9
5 (0.2Hz)	5	0.8	3.6
6 (0.2Hz)	10	0.5	1.9
7 (0.2Hz)	20	0.7	2.3
8 (0.2Hz)	40	1.1	4.0
9 (0.2Hz)	40	1.5	2.5

In Figure 8 are presented the spectra of GNSS geodetic and GNSS smartphone timeseries of the experiment of 0.2 Hz and amplitude 20mm, as a representative spectral analysis of all the conducted experiments of oscillations. The spectrum of the GNSS smartphone data is limited to 0.5 Hz, as the sampling-rate was 1 Hz, whereas the GNSS geodetic timeseries is limited to 5 Hz, due to the respective 10 Hz sampling rate. It is clear that the oscillation frequency is accurately detected by both GNSS timeseries. The smartphone GNSS timeseries is characterized by higher noise level, especially for the frequency range higher than 0.2 Hz, as the frequency peaks correspond to higher amplitude, reflecting the more noisy data of GNSS smartphone with respect the GNSS geodetic data. For frequencies lower than 0.05 Hz, the noise has been limited due to the application of the high-pass filter.

In Table 4 are presented the dominant frequencies as they are estimated based on the spectral analysis of the GNSS geodetic data and the GNSS smartphone data and compared based on the frequencies of the oscillation as they derive from the shake

Figure 8. Spectra of GNSS geodetic and GNSS smartphone timeseries of the oscillation of 20mm amplitude ad 0.2 Hz frequency.

Table 4. Dominant frequency derived from each sensor, the percentages in brackets indicate the deviation in percentage from the reference dominant frequency derived from DFT of shake table timeseries.

	Frequency (Hz)		Shake table
	Geodetic	Samsung	
1	0.098 (2%)	0.098 (2%)	0.096
2	0.099 (2%)	0.098 (1%)	0.097
3	0.098 (2%)	0.098 (2%)	0.096
4	0.098 (2%)	0.098 (2%)	0.096
5	0.197 (-2%)	0.197 (-2%)	0.202
6	0.200 (-1%)	0.203 (0%)	0.203
7	0.197 (-3%)	0.203 (0%)	0.203
8	0.197 (-3%)	0.203 (0%)	0.203
9	0.202 (2%)	0.200 (1%)	0.199

table data (i.e. ground truth). It can be observed that frequencies estimated from the smartphone GNSS data deviate not more than 2-3% from the reference frequency derived from shake table output timeseries. Even though, for the oscillations of low amplitude (i.e. 5 and 10mm), the GNSS smartphone suffer from low-frequency noise resulting in ambiguous waveform, the dominant frequency for the oscillation could still be retrieved accurately. Similarly, we conducted DFT for the original timeseries. The frequency that can be detected from the original timeseries is shown in Table 4.

## 5 CASE STUDY: WILFORD BRIDGE MONITORING CAMPAIGN

To evaluate the feasibility of using smartphones for monitoring purposes, a preliminary monitoring campaign was carried out on Wilford Suspension bridge, a test site adopted for many experimental research projects of application of GNSS and surveying techniques in bridge SHM studies (Peppas et al., 2018, Psimoulis et al., 2016). We deployed several different grades of GNSS receivers ad Robotic Total Stations (RTS) on the bridge, to assess the performance of the various GNSS receivers, using the RTS as the ground truth (Psimoulis and Stiros, 2008). For this study we focused on the analysis of a geodetic grade GNSS station (GS04) consisted of Leica GS10 receiver ad AS10 antenna, and a smartphone Samsung S23. The GSS receiver were recording simultaneously the response of the bridge under the pedestrians' excitations, with the geodetic GSS receivers recording at 10 Hz sampling rate, while the smartphone was recording at 1 Hz sampling rate.

In Figure 9 are presented the vertical Up) GNSS timeseries of the geodetic and the smartphone, and it is obvious the higher noise level of the smartphone GNSS timeseries, indicating the larger GNSS receiver noise and the significant larger unpressed multipath effect (Peppas and Psimoulis, 2023).

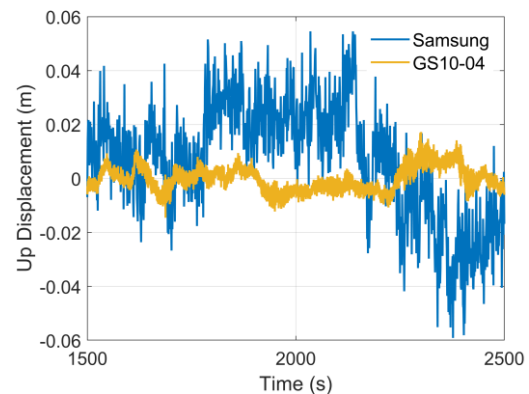

Figure 9. The GNSS timeseries from the geodetic grade GNSS station (GS04) and the smartphone Samsung S23 GNSS receiver. Both GNSS receivers are located at the midspan of the bridge.

To mitigate the low-frequency errors, a high pass filter with cut-off frequency of 0.05 Hz was applied. In Figure 10 are shown the filtered GNSS timeseries of the GS04 geodetic receiver and the smartphone, whereas several activities can be identified from the GS04 timeseries, whilst those response could not easily be identified in the Samsung timeseries,

probably due to i) the relatively high bridge modal frequency exceeding the Nyquist frequency of the GNSS smartphone recorded data and ii) the overall high noise level.

Figure 10. The same plot as Figure 9 presenting the highpass filtered GNSS timeseries of the geodetic and smartphone data.

To unveil the bridge displacements limited by the smartphone GNSS low sampling rate, a common approach is the integration of GNSS with accelerometer data. We adopted loosely coupled data integration using Kalman filter Rauch-Trung-Striebel smoothing algorithm. It could be seen in Figure 11 that the noise from the fused timeseries is greatly reduced from GNSS only solution. A few excitations are also identifiable in correlation with Leica geodetic timeseries and the acceleration timeseries.

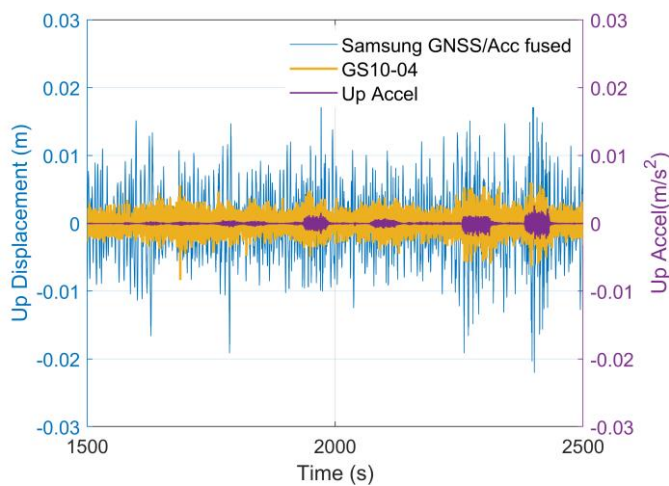

Figure 11 The highpass filtered timeseries of Leica geodetic GS04 solution, the smartphone solution after GNSS and acceleration data integration and the acceleration (after offset removal and scaling) timeseries

## 6 CONCLUSION

In this study, we analysed the performance of smartphones in monitoring vertical and horizontal oscillations with controlled oscillation setups, particularly for low frequency and low

amplitude displacement, with frequency less than 0.5 Hz, and amplitude less than 4 cm.

Based on the controlled experiments of horizontal and vertical motion recorded by smartphones with capacity of GNSS L1/L5, E1/E5a, dual frequency it is observed that it can detect the dynamic oscillation pattern in all cases. The dominant oscillation frequency was accurately detected in all cases meeting the same accuracy as that of geodetic GNSS data. Regarding the estimation of the oscillation amplitude, it is proved to be more noisy than the geodetic GNSS data, at is expected due to the susceptible to multipath effect of the linearly polarized GNSS antenna of the smartphones. The RMS error of estimating the oscillation amplitude ranges between 2 and 5 mm in most cases while the respective one for GNSS geodetic data was not more than 2 mm. More specifically, for oscillation amplitude less than 10mm, the estimation of the oscillation amplitude is more noisy, due to the relative high noise level of smartphone GNSS data, but for the estimation of the frequency it is proved very accurate. For oscillation amplitude larger than 10mm, the results of the GNSS smartphone data seemed to be more promising.

However, due to 1 Hz sampling rate from the mobile phone, the oscillation above 0.5 Hz could not be detected due to aliasing. Therefore, in the future research, we aim to investigate the sensor fusion between high frequency accelerometer measurement and GNSS measurement for detection of higher frequency displacement, which will allow further application of GNSS smartphone data in structural health monitoring (Xue et al., 2024).

**ABSTRACT:** In this study, some progresses on the identification of structural dynamic loads are reported. First, a series of improved Kalman filter with unknown inputs developed by the authors for the identification of joint structural dynamic systems and dynamic loads are briefly reviewed. Then, some identification of structural dynamic loads using the physical guided deep learning paradigm are presented, including the identification of multi dynamic load positions and time histories using physics informed and enhanced Generative adversarial neural network (GAN) and Convolutional Long Short-Term Memory (ConvLSTM), respectively, the identification of full-field wind loads on buildings using physical informed recursive convolutional neural network (CNN), and the identification of stochastic fluctuating wind power spectrum on high-rise buildings using physical guided CNN with partial structural responses. The load type of the network during testing can be different from that during training. Through numerical simulation, it is proved that the proposed methods can learn the nonlinear mapping relationship between the structural responses and the external dynamic loads, and can reconstruct the load time histories well. The proposed methods are verified by numerical simulation and the results show that the deep learning methods can identify the unknown multi dynamic load positions and time histories, full-field wind loads on buildings and the stochastic fluctuating wind power spectrum on high-rise buildings.

**KEY WORDS:** Identification of structural dynamic loads; Physics informed deep learning; Physical methods.

## 1 INTRODUCTION

Identification of structural dynamic load is one of the core issues in the fields of structural health monitoring, vibration control and safety assessment. Its goal is to infer the dynamic loads acting on the structure (such as vehicle loads, wind loads, earthquake loads, etc.) from the response signals of the structure (such as displacement, acceleration, strain, etc.). With the development of technology, the methods in this field have gradually evolved from traditional methods that rely on physical models to data-driven deep learning methods. In this study, some progresses on the identification of structural dynamic loads are reported.

## 2 STRUCTURAL DYNAMIC LOAD IDENTIFICATION—PHYSICAL METHODS

### 2.1 Kalman filter with unknown input (KF-UI)

The Kalman Filter (KF) [1] is a recursive estimation method for structural states based on partial observations. As long as the estimated value of the state at the previous moment and the observation value of the current state are known, the optimal estimation value of the current state can be calculated. It is suitable for real-time online estimation of structural states and can consider the uncertainty of the model and the influence of observation noise. Therefore, it is widely used. However, when applying KF, the external inputs information of the structure needs to be known. In fact, the input information is often difficult to be fully observed. To overcome the limitations of the traditional KF, we proposed Kalman filter with unknown input (KF-UI) [2].

State equation

$$\mathbf{X}_{k+1} = \mathbf{A}_k \mathbf{X}_k + \mathbf{G}_k \mathbf{f}_k + \mathbf{w}_k \quad (1)$$

Observation equation

$$\mathbf{y}_k = \mathbf{C}_k \mathbf{X}_k + \mathbf{H}_k \mathbf{f}_k + \mathbf{v}_k \quad (2)$$

1) Time update for estimated states from  $k\Delta t$  to  $(k+1)\Delta t$ :

$$\tilde{\mathbf{x}}_{k+1/k} = \mathbf{A}_k \hat{\mathbf{x}}_{k/k} + \mathbf{G}_k \hat{\mathbf{f}}_{k/k} \quad (3)$$

The smallest variance estimator of state vector at  $(k+1)\Delta t$ :

$$\hat{\mathbf{x}}_{k+1/k+1} = \mathbf{K}_{k+1}^* \tilde{\mathbf{x}}_{k+1/k} + \mathbf{K}_{k+1} \mathbf{y}_{k+1} \quad (4)$$

$$\mathbf{K}_{k+1}^* \tilde{\mathbf{x}}_{k+1/k} = \tilde{\mathbf{x}}_{k+1/k} - \mathbf{K}_{k+1} (\mathbf{C}_{k+1} \tilde{\mathbf{x}}_{k+1/k} + \mathbf{H}_{k+1} \hat{\mathbf{f}}_{k+1}) \quad (5)$$

2) The final update equation of the smallest variance estimator of state vector at  $(k+1)\Delta t$ :

$$\hat{\mathbf{x}}_{k+1/k+1} = \tilde{\mathbf{x}}_{k+1/k} + \mathbf{K}_{k+1} (\mathbf{y}_{k+1} - \mathbf{C}_{k+1} \tilde{\mathbf{x}}_{k+1/k} - \mathbf{H}_{k+1} \hat{\mathbf{f}}_{k+1}) \quad (6)$$

The final update equation of error covariance matrix of the estimated state vector:

$$\begin{aligned} \tilde{\mathbf{P}}_{k+1/k}^x &= \tilde{\mathbf{e}}_{k+1/k}^x \tilde{\mathbf{e}}_{k+1/k}^{xT} \\ &= [\mathbf{A}_k \quad \mathbf{G}_k] \begin{bmatrix} \mathbf{P}_{k/k}^x & \mathbf{P}_{k/k}^{xf} \\ \mathbf{P}_{k/k}^{fx} & \mathbf{P}_{k/k}^f \end{bmatrix} \begin{bmatrix} \mathbf{A}_k^T & \mathbf{G}_k^T \end{bmatrix} + \mathbf{Q} \end{aligned} \quad (7)$$

3) The final update equation of unknown input at  $(k+1)\Delta t$ :

$$\begin{aligned} \mathbf{f}_{k+1} &= [\mathbf{H}_{k+1}^T \mathbf{R}^{-1} (\mathbf{I} - \mathbf{C}_{k+1} \mathbf{K}_{k+1}) \mathbf{H}_{k+1}]^{-1} \\ &\quad \mathbf{H}_{k+1}^T \mathbf{R}^{-1} (\mathbf{I} - \mathbf{C}_{k+1} \mathbf{K}_{k+1}) (\mathbf{y}_{k+1} - \mathbf{C}_{k+1} \tilde{\mathbf{x}}_{k+1/k}) \end{aligned} \quad (8)$$

To minimize the value of  $\mathbf{P}_{k+1/k+1}^x$ :

$$\mathbf{P}_{k+1/k+1}^x = \mathbf{e}_{k+1/k+1}^x \mathbf{e}_{k+1/k+1}^{xT} \quad (9)$$

$$\mathbf{K}_{k+1} = \tilde{\mathbf{P}}_{k+1/k}^x \mathbf{C}_{k+1}^T (\mathbf{R}_{k+1} + \mathbf{C}_{k+1} \tilde{\mathbf{P}}_{k+1/k}^x \mathbf{C}_{k+1}^T)^{-1} \quad (10)$$

Data fusion is applied to prevent the drifts in the identification caused by low-frequency noise.

$$\mathbf{y}_{k+1} = \mathbf{h}(\mathbf{Z}_{k+1}, \mathbf{f}_{k+1}, \mathbf{f}_{k+1}^u) + \mathbf{v}_{k+1} \quad (11)$$

### 2.2 Numerical simulation

Numerical simulation of the identification of unknown excitations for trusses verified the effectiveness of the method.

Figure 1. Truss structure

Figure 2. Identification results of unknown forces

### 2.3 A series of methods for Klamman Filter with Unknown Inputs

A series of methods for Klamman Filter with Unknown Inputs have been proposed by authors.

- 1) (Extended) Kalman filter under unknown input (KF-UI ; EKF-UI)
- 2) Kalman filter/Extended Kalman filter under unknown input without direct feedback (KF-UI-WDF; EKF-UI-WDF)
- 3) Unscented Kalman filter under unknown input(UKF-UI)
- 4) Unscented Kalman filter under unknown input (UKF-UI-WDF)
- 5) Particle filter under unknown input (PF-UI)
- 6) Unscented Kalman particle filter under unknown input (UKPF-UI)

## 3 STRUCTURAL DYNAMIC LOAD IDENTIFICATION—DEEP LEARNING METHODS

The data-driven method for dynamic load identification, which does not require a structural model, is more in line with the needs of actual engineering. Data-driven deep learning methods can establish functional mapping between network inputs (structural responses) and outputs (structural dynamic loads). Machine learning approaches with clear physical interpretability often demonstrate enhanced performance.

### 3.1 Physics-Guided Deep Learning for Multi Dynamic Load Identification

Existing methods require identical load distributions during training and testing, resulting in poor network generalizability and restricted applicability.

When a single load acts at  $j$ , the response at the structural measurement point  $i$ :

$$z_i^j(t) = \int_0^t h_i^j(t-\tau) f_j(\tau) d\tau \quad (12)$$

$$z_i^j = H_i^j f_j \quad (13)$$

Multiple loads  $f_n(n=1,2,\dots,n_f)$  acts on the structure, where  $n_f$  is the number of loads. The formula for the response of the  $i$ -th measurement point can be expressed as:

$$z_i = \sum_{j=1}^{n_f} H_i^j f_j \quad (14)$$

To solve the problem of identifying dynamic loads, it is necessary to find the inverse matrix of  $H$ . Since positive definite conditions need to be satisfied, it is essential to ensure that the observed number is greater than the number of unknown forces.

Numerical simulation of the identification of unknown excitations for outward-extending beams verified the effectiveness of the method.

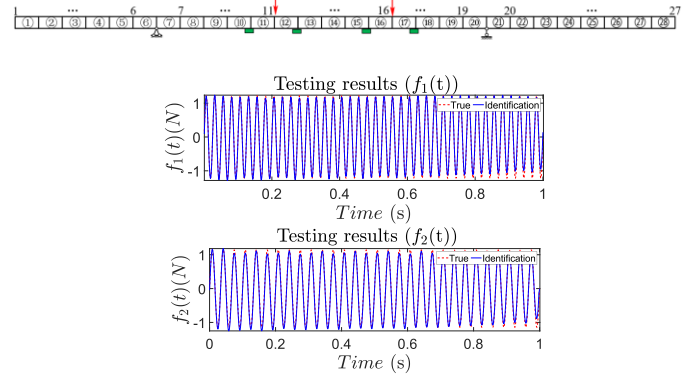

Figure 3. Identification results of unknown forces

### 3.2 Physics Guided Deep Learning for Wind Load Identification of Tall Buildings

It is more challenging to identify wind loads, because Wind load is a type of complex distributed dynamic load. Currently, methods for identifying wind loads mainly rely on theoretical inverse identification [3-4]. In this paper, a scheme for identifying full-field wind loads using a recursive convolutional neural network (CNN) inspired by physical mechanisms is proposed.

The wind load is discretized and sampled spatially. Based on spatial correlation to represent the wind profile. If the floor height is 3 meters. The correlation between the adjacent two floors is 0.954 and that between the three floors is 0.911. It can be assumed that the adjacent two floors are completely correlated. Therefore, spatial correlation can reduce the number of independent loads. The recursive form of the network, as well as the inspiration for its inputs and outputs, is inspired by the spatial correlation and the mapping relationship between wind loads and structural responses.

In this study, a 306-meter-high Australian office building is utilized, which is the 76-story Benchmark building established by IASC-ASCE [5]. In this case, the network is tested using

structural responses generated by the stationary Davenport spectrum, Harris spectrum and Kaimal spectrum.

To verify the accuracy of spatial identification results, wind load profiles at four time moments are shown in Figure 4. The time histories of wind loads at three heights are presented in Figure 5. The self-power spectrum of the wind load at the 60th floor and the cross-power spectrum between the 60th and 62nd floors are shown in Figure 6. The identification results of the power spectrum align well with the true values.

## 4 CONCLUSIONS

In this study, some progresses on the identification of structural dynamic loads are reported. To overcome the limitations of the traditional KF, A series of methods for Klamman Filter with Unknown Inputs have been proposed by authors. The physical method is applicable to problems with clear models and simple scenarios. The deep learning method, on the other hand, breaks through the bottleneck of model dependence and is more suitable for complex scenarios in actual engineering. Machine learning approaches with clear physical interpretability often demonstrate enhanced performance. Physics-Guided deep learning for multi dynamic Load identification and for wind load identification of tall buildings are proposed respectively.

In the future, the integrated method of "physical model + data-driven" will become the mainstream. It will not only leverage the explanatory power of physical theories but also utilize the strong fitting ability of deep learning, promoting the development of dynamic load identification towards greater accuracy, robustness, and universality.

## EXTENDED ABSTRACT

KEY WORDS: BWIM, Weight in motion, SHM, structural health monitoring

## 1 INTRODUCTION

This work presents some results obtained using bridge strain data relevant to the Society of Civil Structural Health Monitoring (SCSHM) bridge benchmark [1]. Data has been processed to obtain information on both bridge behavior and on the features of vehicles passing through the bridge. Namely, the processing of data from sensors located at different sections of the bridge enables to retrieve information relevant to a) the dynamic and static bridge characteristics and b) to the passing vehicle characteristics such as speed, weight, length and number of axles (see Figure 1). Furthermore, in this work it is shown how data fusion techniques permit to improve the quality of the estimation of relevant information extracted from multiple sensors, for both Bridge Weight-in-motion (BWIM) and structural monitoring in the SCSHM bridge benchmark.

## 2 METHODOLOGY

The proposed methodology, tested on the SCSHM benchmark, allows to extract data from multiple strain sensors positioned at different locations of the bridge. The use of multiple strain sensors enables the detection of time-related features, such as the velocity of the vehicle. Furthermore, each sensor enables the retrieval of diverse information. For instance, sensors closer to the road surface are more suitable for capturing the local

response to the passage of single axles, while sensors located on the beams capture the global bridge response in terms of deflection. If the bridge has several lanes, sensors located under each lane will be more sensitive to vehicles passing over that specific lane.

Each step of the methodology is here described. Concerning the bridge – related data, it is possible to use all the sensors to extract parameters that describe the dynamic behavior of the bridge, for example frequencies and modal shapes. This can be done either by processing the response of the during the passage of a vehicle, (for instance by taking an interval of 10 seconds centered on the strain peak during the transit), or by processing a longer signal obtained concatenating all the responses measured by the same sensor at a given location.

Vehicle-related information is also extracted from strain measurements. Vehicle velocity and direction are identified based on the time lag between the peak strains at two bridge cross sections. The gross vehicle weight is estimated using the area method, as presented in [2]. The length of each vehicle is calculated by dividing its speed by the duration of the strain history recorded at midspan. Since this strain history represents the measured influence line for strain at midspan in the time domain, it remains non-zero for a period longer than the actual time the vehicle spends crossing the midspan. To account for this discrepancy a calibrated fictitious length is subtracted from the initially estimated length.

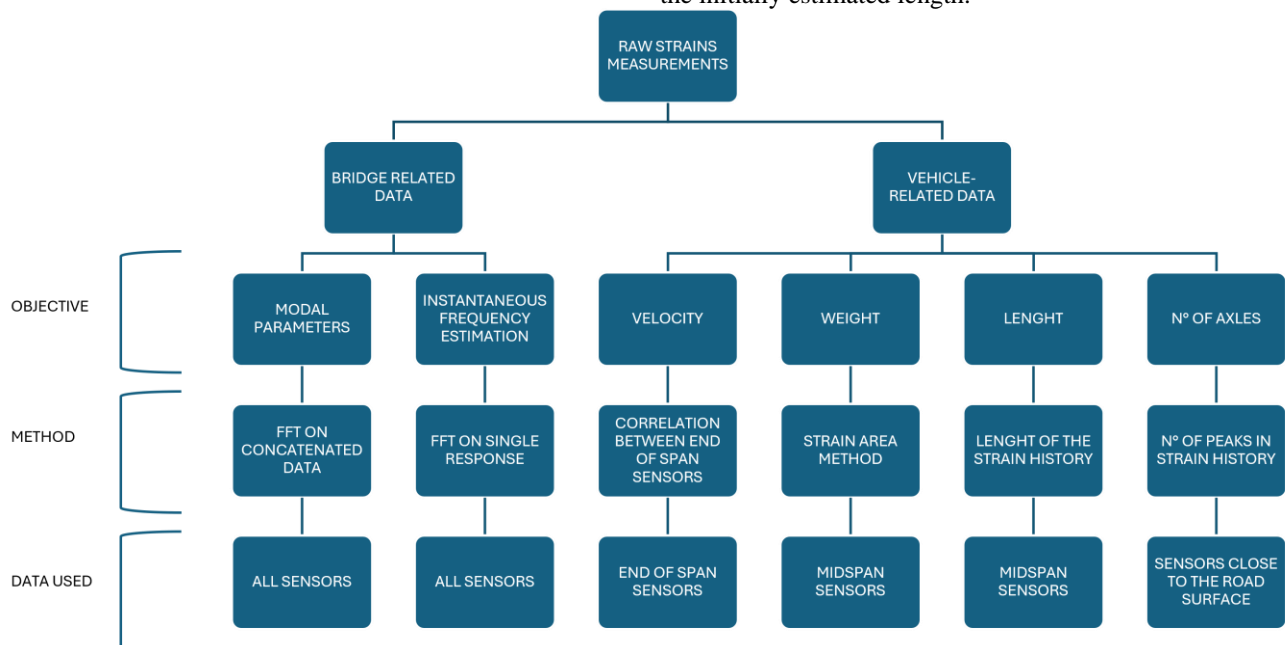

Figure 1. Flowchart of the proposed methodology.

The number of axles is calculated by counting the number of peaks in the strain histories for sensors close to the road surface, where each peak corresponds to consecutive axles (e.g. when two axles or three axles are very close to each other, as in the case of a semitrailer, only one peak is counted).

Finally, the joint analysis of data recorded by several sensors can provide enhanced information about the bridge condition and performance. For instance, the comparison of vehicle weight and number of axles may be useful for identifying overloaded vehicles. Furthermore, it is of interest to combine vehicle-related with bridge related data, for instance to investigate the dynamic response of the bridge in relation to different vehicle typologies and speed.

### 3 APPLICATION ON THE SCSHM BENCHMARK

The proposed methodology is applied to the study of the SCSHM bridge benchmark [1]. The investigated structure is a simply supported span, with a length of 22.71 m, carrying two lanes. The span is instrumented with 32 electric resistive strain gages to monitor strains and six thermocouples to monitor air/structure temperature under the deck. Strain gages are placed at several cross-sections (end of spans, midspan and  $\frac{3}{4}$  of the span) and at different locations within each section. The dataset contains data recorded during passages of more than 3000 vehicles, namely strains time histories from the 32 sensors, environmental temperature, and photos of the vehicles. The following results emerge from the analysis of data.

- The dynamic response is affected by the type and speed of the transiting vehicle and by temperature. The correlation between temperature and natural frequencies is shown in Figure 2 where results obtained from data relevant to the passage of more than 3000 vehicles are reported. Results highlight that an increase in temperature leads to a decrease in frequency. The decrease is more relevant where temperatures are below 0°C, due to the stiffening effect of ice, consistently with findings from other case studies [3].

Figure 2. Scatter plot Temperature-Frequency for single vehicles passing through the bridge.

- The traffic composition in the two directions can be retrieved from the analysis of the velocity, direction and weight of each vehicle. Results suggest that the number of vehicles crossing the bridge in one direction is almost twice the number in the opposite

direction. Furthermore, the weight distribution is slightly different in the two directions.

- From the combined analysis of vehicle weights and the estimated number of axles (see Figure 3), it is possible to infer if the vehicle is loaded or not. The estimate might be improved by detecting each single axle instead of groups of axles.
- The integration of vehicle-related data into bridge-related data will contribute to improving the quality of the information. For instance, the vehicle weight can be better estimated by accounting for bridge stiffness correction due to environmental temperature than can be appraised from the relationship between frequencies and temperature.

Figure 3. Scatter plot comparing vehicle length, vehicle weight and number of axles.

email: daniel.cantero@ntnu.no

**ABSTRACT:** The estimation of vehicle speed is a critical first step in deriving vehicle weight from bridge responses. Various strategies have been developed to extract the speed of passing vehicles, primarily relying on sensors that capture signals with features related to the vehicle's axles. These signals are processed through diverse methods; however, existing strategies often fail to perform optimally across different structural configurations. To address these challenges, the convoluted reciprocity (CR) relationship was recently proposed, which was verified numerically and validated experimentally in a laboratory setting. In this document, the novel speed estimation strategy based on CR is applied to an operational bridge using signals from the SCSHM benchmark. The results confirm that CR provides a robust speed estimation method for cases when the signals lack individual axle features.

**KEY WORDS:** Speed; Vehicle; Bridge Monitoring; Convoluted Reciprocity; SCSHM.

## 1 INTRODUCTION

Instrumented bridges can be utilised for weighing vehicles as they pass over them, enabling the estimation of Gross Vehicle Weight (GVW) based on the integral of the recorded signal [1]. When integrated into Bridge Weigh-in-Motion (BWIM) systems, such instrumentation allows for the identification of individual axle loads and axle spacing. This technology has gained significant attention in recent years ([2], [3], [4], [5]) due to the valuable site-specific traffic data it provides, as well as its potential applications in structural health monitoring [6].

A crucial first step in any weighing solution based on bridge responses is determining the speed of the passing vehicle. This requires signals that provide reliable speed estimation. Standard approaches include FAD (Free of Axle Detectors) and NOR (Nothing on the Road) methods, which utilise specific signal features to estimate vehicle speed, axle count, and axle spacing [4]. Additionally, alternative methods have successfully employed acoustic signals generated by tyres passing over bridge expansion joints to determine vehicle speeds [7].

A recent study by the author [8] investigated various speed estimation strategies using strain sensors, demonstrating that existing methods perform well in most practical scenarios. However, a consistent theoretical framework for speed estimation was lacking. The standard approach relies on the cross-correlation of signals at different bridge locations, which is effective when distinct axle signatures are present but fails in certain cases, particularly for simply supported bridges. To address this limitation, [8] introduced the Convoluted Reciprocity (CR) relationship, developing a novel speed estimation method. This approach does not require signals to exhibit distinct axle features, making it more widely applicable. The Convoluted Reciprocity framework was theoretically derived, numerically verified, and experimentally validated in [8].

This document aims to present the limitations of the correlation-based method for speed estimation and to illustrate the effectiveness of the novel Convoluted Reciprocity (CR) approach. First, the shortcomings of the correlation method are visually demonstrated. Then, the CR concept is introduced and verified through numerical examples. Finally, the method is validated using real bridge measurements from the publicly available SCSHM dataset [9].

## 2 THE PROBLEM WITH CORRELATION

Arguably, the most common strategy for estimating the speed of a passing vehicle using bridge responses is based on correlating signals recorded at two separate locations along the bridge. The key idea is to determine the time lag that maximises the correlation between the signals, which indicates the time taken by the vehicle to travel between the sensor locations. Given the known sensor distance, the vehicle speed can then be directly estimated. This method assumes that the signals are shifted versions of each other and has been successfully applied in many cases. However, its effectiveness relies on the presence of distinct peaks corresponding to individual axles in the signals, which is not always guaranteed.

To illustrate this, synthetic bridge responses are used from a numerical simulation of a two-axle vehicle traversing a bridge, modelled using the open-source VBI-2D tool [10]. The vehicle's axles have equal weights and are spaced 5 m apart. The bridge has a span of 20 m, with strain measured at sensors located at  $\frac{1}{4}$  and  $\frac{3}{4}$  of the span, denoted as S25 and S75, respectively. The vehicle travels at a constant speed of 20 m/s (72 km/h). For verifying purposes, only the quasi-static response is simulated, excluding dynamic effects and noise.

For a bridge with fixed-fixed boundary conditions, the resulting signals are shown in Figure 1(a). The peaks corresponding to each axle are clearly distinguishable. Although the signals are not perfect shifted versions of each other, the correlation method performs accurately. By

computing the correlation and identifying the time lag that maximises it, the exact travel time between sensor locations is obtained, as illustrated in Figure 1(b). Consequently, the estimated speed in this case is precise.

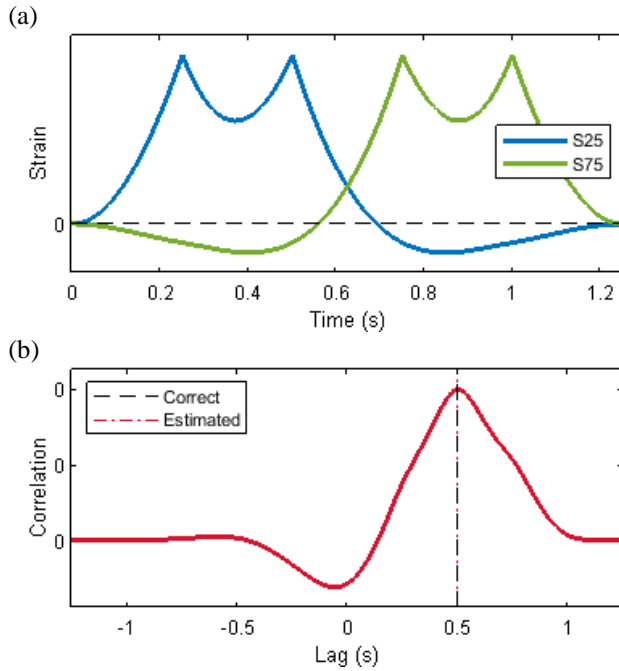

Figure 1. (a) Simulated fixed-fixed beam responses due to a 2-axle vehicle; (b) Cross-correlation of signals. Vertical lines indicate the time lag giving maximum correlation and the one that should have been obtained for correct speed estimation.

In contrast, for a simply supported bridge, the responses do not exhibit distinct peaks, leading to poor speed estimates using the correlation method. Figure 2(a) presents the simulated bridge responses for the same vehicle and bridge configuration but with simply supported boundary conditions. Applying the correlation method in this case (Figure 2(b)) results in a significantly inaccurate speed estimate. Specifically, the estimated speed is 47.62 m/s, corresponding to a 138% error.

Therefore, the correlation method is poorly suited for simply supported bridges due to the absence of distinct axle features. However, even in cases where clear axle features are present, such as fixed-fixed bridges, the method does not always guarantee perfect results. The speed estimation based on maximum correlation may still be imprecise, depending on the vehicle configuration and span length. This limitation is not new, and various correction strategies exist, but they are either specific to certain vehicle types or rely on signal processing techniques. A more detailed analysis can be found in [8]. Nevertheless, until now, no theoretically sound alternative had been established. This gap is addressed by the speed estimation method based on Convolved Reciprocity.

Figure 2. (a) Simulated simply supported beam responses due to a 2-axle vehicle; (b) Cross-correlation of signals. Vertical lines indicate the time lag giving maximum correlation and the one that should have been obtained for correct speed estimation.

### 3 CONVOLUTED RECIPROCITY

This section introduces the concept of Convolved Reciprocity and its application to speed estimation, originally presented in [8]. Here, a step-by-step example is provided to further explain and verify the method. The verification is performed using VBI-2D [10] under ideal conditions, considering perfect quasi-static signals without noise or dynamic disturbances. The analysis follows the same case as presented in Section 2, ensuring direct comparison with the correlation-based approach.

In [8], it was shown that a relationship exists between bridge responses at two different locations (A and B) for two different vehicle passages, say Vehicle 1 (V1) and Vehicle 2 (V2). This relationship is expressed in Eq. (1).

$$S_{A,V1}(t) \times S_{B,V2}(t) = S_{B,V1}(t) \times S_{A,V2}(t) \quad (1)$$

where  $S_{i,j}$  represents the measured load effect at location  $i$  due to the passage of vehicle  $j$ , and  $\times$  denotes the convolution operation. This relationship follows from the fact that any bridge response to a passing vehicle can be expressed as the convolution of the vehicle's forcing function with the corresponding influence line. By taking advantage of the commutative property of convolution, the expression is derived (see [8] for a detailed derivation). This result establishes a reciprocal relationship between signals recorded at different sensor locations and vehicle passages when convolved together, leading to the adopted term Convolved Reciprocity (CR). The expression can be further simplified to:

$$CR_{AB}(t) = CR_{BA}(t) \quad (2)$$

This relationship is rather powerful, as it connects any two load effects for any two vehicle passages. It holds under the

standard assumption that vehicles travel at a constant speed. Using this relationship, the speed of an unknown vehicle passage can be estimated if the response of a reference event is known. In practice, signals from a vehicle event with a known speed are stored as a reference, enabling the speed estimation of subsequent vehicle passages.

For example, Figure 3 presents the signals for a five-axle truck with axle spacing and load distribution as specified in [11], representing a typical European configuration for a fully loaded articulated five-axle truck. Since the vehicle speed is known for this reference event, the signals can be transformed into the spatial domain. This event serves as a calibration or reference event, providing a basis for speed estimation of other vehicle passages.

Figure 3. Simulated simply supported beam response due to a 5-axle truck.

Applying the Convolved Reciprocity (CR) relationship in the time domain, we estimate the speed of the unknown vehicle by iteratively testing different speed guesses and evaluating the CR relationship. For each guessed speed, the signals from Figure 3 are transformed accordingly into the time domain. By applying the relationship in Eq. (2), together with the signals in Figure 2(a), results are obtained for each speed guess. Figure 4 presents the left-hand side and right-hand side of Eq. (2) for different guessed speeds. The speed estimate that results in a match between both curves corresponds to the actual speed of the unknown vehicle event.

To systematically quantify the differences between both sides of Eq. (2), we evaluate the norm of their difference (see Eq. (3)). The study in [8] explored various norm choices and suggested that the 1-norm could be a suitable option. However, other p-norms may also yield good results. The best speed estimate can be determined by finding the speed that minimises the norm of the difference.

$$\|CR_{AB} - CR_{BA}\| = 0 \quad (3)$$

Figure 5 presents the norm of the difference between both sides of Eq. (2) for a range of guessed speeds. The minimum of this norm corresponds to the speed that best matches the actual speed of the unknown vehicle event. This example was conducted using ideal quasi-static responses, free from noise and disturbances. As a result, the speed estimation is exact, confirming the validity of the methodology. However, when applying this approach to real signals affected by noise and disturbances, the accuracy of the estimated speed may be impacted.

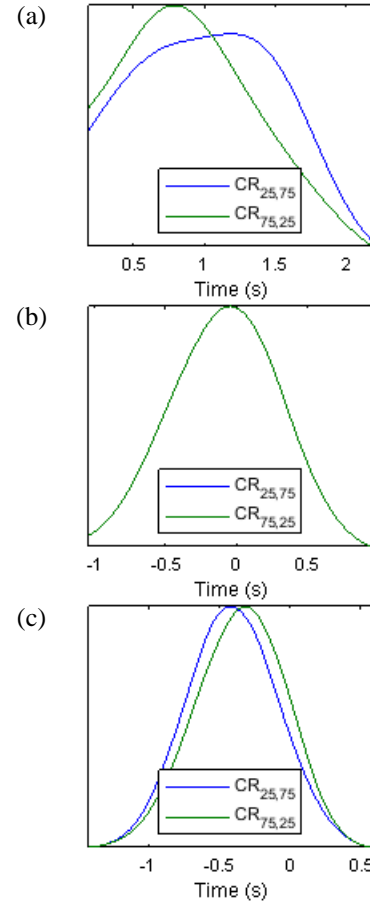

Figure 4. Detail of the CR for various speed guesses: (a) 10 m/s; (b) 20 m/s; (c) 30 m/s.

Figure 5. Norm values for a range of speed guesses.

#### 4 VALIDATION USING SCSHM

The CR method for speed estimation was verified in the previous section using ideal quasi-static bridge responses. This section focuses on validating the method under realistic conditions by applying it to data from a real bridge, where signals include noise and dynamic effects. The CR approach is tested using bridge responses from the SCSHM dataset [9], specifically for cases where the signals do not exhibit clear axle features.

#### 4.1 The SCSHM dataset

The dataset introduced in [9] corresponds to a nine-span bridge with a total length of 291 m, located in Manitoba, Canada. The bridge carries two lanes of traffic, one in each direction, and its superstructure consists of four lines of I-girders supporting a reinforced concrete (RC) deck. Of particular interest is Span 2, a simply supported span of 22.71 m, which is instrumented with strain gauges and thermocouples at various locations. The signals are sampled at 200 Hz, and only events exceeding a predefined strain threshold are recorded.

For this study, key sensors are those located at the ends of the span (Sections AA and EE), where strain gauges attached to the deck capture signals with clear individual axle features. These signals were used in [9] to accurately estimate vehicle speeds, and these estimates will be taken as the reference speeds in this work. Additionally, two other instrumented sections, FF (at approximately  $\frac{1}{4}$  span) and BB (at approximately  $\frac{1}{2}$  span), contain multiple strain gauges on each girder. Here, only the strain measured at the soffit will be considered. The dataset includes both strain measurements and vehicle photographs from several monitoring campaigns, totalling over 3,000 heavy vehicle crossing events. For further details on the instrumentation setup, refer to [9].

#### 4.2 Example for one event

As an example, this section estimates the speed of a vehicle passage using the signals from a reference event with a known speed. Specifically, the analysis focuses on vehicles travelling in the westbound lane, where strain gauges located on girder G2 are considered (channel 10 in section FF and channel 22 in section BB). The reference event corresponds to file 04/E00003 (event 3 in folder 04), with a recorded speed of 17.2 m/s (61.92 km/h) and a GVW of 433.3 kN. The signals used for the CR-based speed estimation are shown in Figure 6. For speed estimation, these signals are first transformed into the spatial domain using the known speed of the reference vehicle.

Figure 6. Signals of reference event (04/E00003).

The goal is to estimate the speed of an event with an unknown speed using the CR method. The event under analysis is 05/E00001, corresponding to a truck with a GVW of 319.9 kN. The signals for this event are shown in Figure 7. The dataset provides a recorded speed of 14.5 m/s (52.2 km/h), which will be used as the reference value for validation.

Figure 7. Signals of event to determine its speed (05/E00001).

Using the CR relationship, the estimated speed must satisfy Eq. (2). To apply this method, the speed of the reference vehicle is assumed, and the signal is transformed back into the time domain by assuming a different speed. As an example, this calculation is repeated for three different assumed speeds, and the results are plotted in Figure 8.

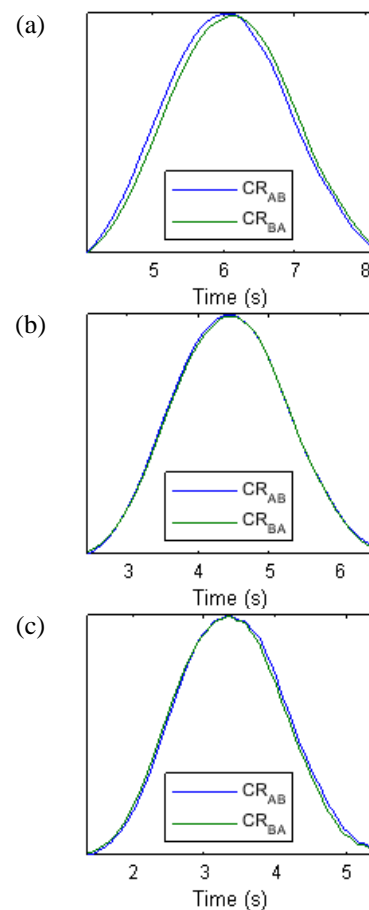

Figure 8. Detail of the CR for various speed guesses: (a) 40 km/h; (b) 50 km/h; (c) 60 km/h.

This process can be repeated for many more guesses. To evaluate the similarity between both CRs, the norm of the difference between both could be used. For this study, we adopted the 1-norm. Only a few guesses are shown below in

Figure 9 for visualization purposes. More guesses can be easily computed to refine the final speed estimation. The speed that gives the minimum norm is considered as the estimated speed of the event. Increasing the number of guesses, one obtains an estimated speed of 14.44 m/s (51.98 km/h), which for this case is almost a perfect match (-0.38% error).

Figure 9. Norm values for a range of speed guesses.

#### 4.3 Database analysis

This section applies the CR method to estimate the speed of all the valid events available in folder 05 in the database. Note that only events with a single vehicle are considered. Also, events with missing pictures are removed. Therefore, a total of 2149 events are analysed below.

To apply the CR method to a real bridge, we need to use a reference event for each lane. Speed estimation for each lane is done separately. The bridge response is different for each lane, so we need to define one reference event for each lane. When processing, we can identify which lane the vehicle is traveling on simply from the maximum response values across different girders. Once this is detected, the CR method is applied for the corresponding reference vehicle.

Figure 10(a) shows all the speed estimation errors in terms of difference to those provided by the database. The same results can be visualized in a histogram in Figure 10(b). Overall, one can see that most of the speed estimates fall within the 5% band, which is reasonable for the goal of estimating the GVW of passing vehicles. However, there are some instances where much higher errors are observed.

The results below show that the histogram is not centred around zero value, indicating an underlying bias related to the selected reference vehicles. In this calculation, the reference events correspond to normal events traversing at normal operational speeds. In practice, it should be possible to calibrate the calculation by obtaining signals from a reference event with very slow speeds, one for each lane. We can make the reference vehicle passages occur at slow speeds, making these events almost perfectly quasi-static. The unknown events will have dynamics, introducing some error, which is the dispersion observed in the results. Furthermore, the separation between section FF and BB is rather small; results would improve with sensors placed further apart.

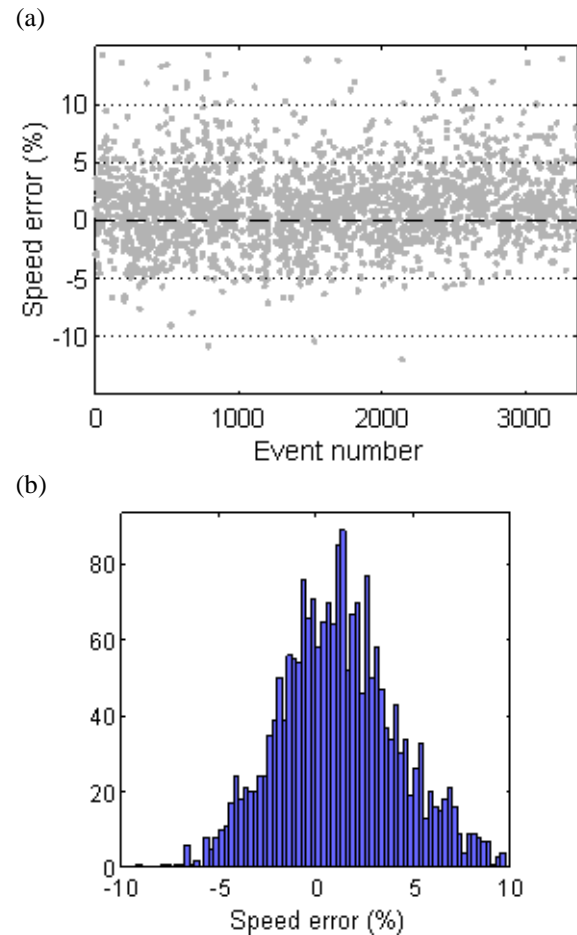

Figure 10. Single vehicle events speed estimation. (a) Estimation errors for each event; (b) Histogram of estimation errors.

Not shown here, but the possibility of improving the performance by signal processing the results was explored. Low-pass filtering and moving average filtering were explored to try to reduce the contributions of bridge dynamics and noise. However, the CR method seems to be rather robust, with only marginal reductions in errors observed. On one hand, this shows that the idea is robust and can be applied directly to unprocessed signals. On the other hand, this indicates that there is no easy way of improving the performance of the method simply by pre-processing the signals.

## 5 CONCLUSION

In general, when the goal is to estimate the speed of passing vehicles, signals with individual axle features should be used. In those cases, the standard correlation method provides satisfactory results. Nonetheless, this method is not theoretically sound nor valid for all bridge configurations.

This document has presented a methodology to estimate the speed of passing vehicles supported by the convoluted reciprocity relationship. First, an ideal numerical example is used to verify the concept. Then, the method is applied to the measured single vehicle events available in the SCSHM dataset. The reported speed estimation errors show some scatter, but most of them are within a 5% error band.

The methodology presented here enables the speed estimation for a wider range of possibilities. It is not strictly

necessary to have signals with clear individual axle features. Therefore, the methodology can use sensors that capture the global behaviour of the bridge. This opens the possibility of having vehicle weighting capabilities on existing monitoring systems, with other load effects, or installing them on bridges that do not have local responses that would show individual axle features. Sometimes bridges do not have locations with responses that have clear individual axle features, or the bridge has an existing installation with the original intention of SHM and no sensors with axle features. CR opens the possibility of estimating the speed also in those cases.

## EXTENDED ABSTRACT

**ABSTRACT:** This study presents a physics-informed surrogate modeling approach for the SCSHM Benchmark bridge using a dual-path LSTM Autoencoder architecture. By combining synthetic data from a finite element model and real strain measurements, the model effectively reconstructs structural responses under moving truck loads. Results show good agreement between predicted and measured strains. Limitations such as the absence of vehicle–structure interaction effects are discussed, with directions for future improvements.

**KEY WORDS:** Surrogate modeling, LSTM, SCSHM benchmark, structural health monitoring.

## 1 INTRODUCTION

This study presents preliminary results obtained using bridge strain data measured on the Society of Civil Structural Health Monitoring (SCSHM) bridge benchmark [1]. The benchmark dataset contains strain measurements and photos collected over nine months by strain gauges and a fixed camera during passages of heavy vehicles. A Finite Element (FE) model of the Benchmark is also made available together with the dataset. In this study, the FE model and the data have been utilized to build a surrogate model of the Benchmark structure.

Traditionally, FE models and detailed simulations have been employed to estimate the structural response with high-fidelity structural properties. While these models are accurate, they are computationally expensive. To address this challenge, surrogate models have emerged as an efficient alternative to approximate the structural response. Surrogate models in structural engineering have gained attention in applications such as response estimation, probabilistic assessment, and damage detection. Among data-driven methods, neural networks have demonstrated strength in capturing nonlinear mappings as well as learning from the data. Deep learning models have successfully predicted the response of the bridges subjected to dynamic train loads, demonstrating the potential of these models in emulating complex structural behavior [2]. Compared to traditional simulations, these models provide rapid and scalable analysis, which is particularly crucial for operational digital twins or near-real-time decision-making support systems.

In this context, Long Short-Term Memory (LSTM) networks have been an especially powerful tool to learn from time series data, thanks to their capabilities to capture long-term temporal dependencies in sequential data. LSTMs have been shown to work well in response prediction for bridge [3]. In addition to the capability to capture the long-term dependencies, LSTM Auto-Encoders (AE) learn an efficient representation of the input space by compressing and reconstructing data, enabling simultaneous learning and data compression. These fusion LSTM-AE models are ideal for surrogate modeling of bridge behavior under vehicle loading.

In this study, two parallel LSTM-AE architectures are combined and trained through strain simulated by the FE model and strain measured on the Benchmark. The architecture is

conditioned using specific physical conditions such as gross weight and velocity of the vehicles.

## 2 METHODOLOGY

The proposed methodology integrates physics-based finite element (FE) simulations with deep learning to accurately predict strain responses of a bridge under moving vehicle loads. A dual-path architecture is built, integrating two parallel LSTM-based Autoencoders (LSTM-AEs). The first is trained using strain responses obtained from a reduced-order FE model, and the second is trained on measured strain data. These parallel encoders are fused in a physics-informed manner to enable robust learning, even in the presence of sparse or noisy real-world measurements.

The reduced-order FE model of the bridge is created using the modal decomposition of mass and stiffness matrices derived from a high-fidelity FE model. Reduced matrices are then used in a state-space formulation to simulate the bridge's dynamic response under moving truck loads. The moving load is applied along the bridge using a defined vehicle path, velocity, and gross vehicle weight (GVW) estimated using the area method [4]. For unique combinations of GVW and velocity observed in the dataset, simulated time series are generated at specific sensor locations using the bending moment and structural geometry. These are then converted into macrostrain using the known strain gauge positions.

The proposed architecture consists of several key components: two parallel encoders, latent representations, conditions, and a decoder, as indicated in Figure 1. The first Encoder encodes the simulated strain signals into a latent representation. These synthetic signals are generated offline for each GVW-velocity pair, corresponding to the conditions observed in the real measurement dataset. The second Encoder encodes the measured strain data into a latent representation. The parameters GVW and vehicle velocity are used as inputs to the FE model and are inherently included in the real bridge measurements, since each truck has its own physical properties. They are also used as condition vectors, as they are fed into the decoder architecture. Finally, the decoder reconstructs the strain measurements using the combined latent representations from both the Encoders and the Condition Vector. The model is trained end-to-end to minimize the reconstruction error between the predicted and the actual measured strain time series.

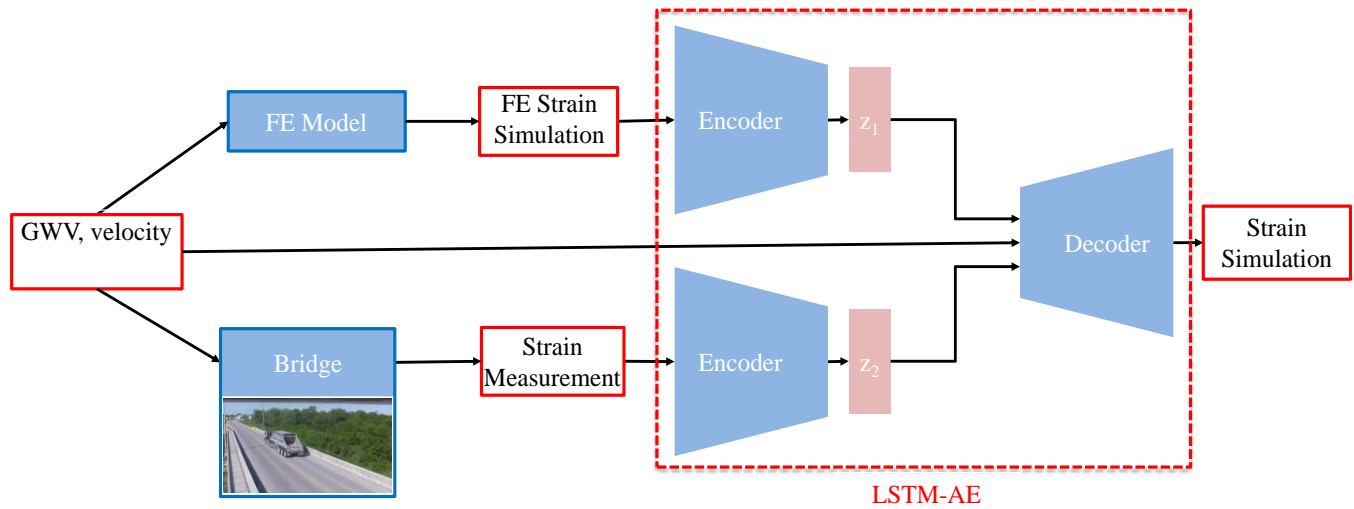

Figure 1. Flowchart of the proposed LSTM-AE architecture.

### 3 IMPLEMENTATION ON THE SCSHM BENCHMARK

The proposed methodology is implemented using strain data collected as part of the SCSHM bridge benchmark study [1]. The structure is a single-span, simply supported bridge with a length of 22.71 m, carrying two lanes. The selected bridge span is instrumented with 32 electric resistance strain gauges to monitor strains under the deck. Strain gages are placed at several cross-sections (end of spans, midspan, and  $\frac{3}{4}$  of the span) and different locations within each section. The dataset includes measurements recorded during controlled load tests as well as under normal traffic conditions. For this study, operational truck data is utilized due to its high volume and variability, which are essential for effectively training a deep learning-based architecture. To build the surrogate model, the structural responses measured by strain gauges located at the midspan section are selected. These midspan measurements are representative of the critical section where bending moments are typically maximal, making them well-suited for surrogate modeling.

Figure 2 and Figure 3 show the comparison between the predicted and measured strain time series at midspan gauges. They closely align both in shape and amplitude, showing that the model effectively learns the relationship between condition parameters and response evolution. Figure 2 illustrates the model's performance on the training set while Figure 3 on the testing set. The comparison highlights the ability of the LSTM to generalize to unseen data in the test set, where it maintains consistent accuracy even on condition pairs not explicitly encountered during training.

The proposed surrogate model integrating physics-informed simulations and measurement-based encoders via a dual LSTM Autoencoder architecture demonstrates good predictive performance in reconstructing bridge strain responses. Even though the model is trained using the full dual LSTM-AE architecture, only the trained latent representation and decoder, together with condition inputs, are used during prediction, providing a computationally efficient solution. Despite relying on a reduced portion of the architecture for prediction, which enhances computational efficiency, the model successfully

captures the dynamic characteristics of the structural response across varying vehicle loading scenarios.

However, it is worth noting that the current model does not account for the effect of the inertia of the moving vehicle, which may explain the absence of the fluctuations observed in the real measurement data. Neglecting this interaction can result in underestimation of transient strain fluctuations or increased scatter in the predicted responses. Therefore, this study should be considered as an initial attempt to build a surrogate model. The future work will focus on incorporating vehicle-bridge interaction into the simulation framework to enhance the fidelity.

# Vibrational analysis of the benchmark data set

Douglas Thomson<sup>1</sup>

<sup>1</sup>Department of Electrical and Computer Engineering, University of Manitoba, Winnipeg, MB, R3T 5V6, Canada  
email: Douglas.Thomson@umanitoba.ca

**ABSTRACT:** Traffic induced vibration is a promising means of continuously monitoring structural behavior. The benchmark data set measures strain at points that will be subject to traffic induced vibration. However, magnitude and frequency spectrum of the induced vibration from an individual vehicle depends on many factors including the vehicle speed and axle weight distribution. Therefore, to obtain a spectrum that is representative the average vehicle induced vibration the vibration from many vehicles must be examined. In this work several methods for the analysis of the strain versus time data to extract traffic induced vibrational spectrums will be compared. Also, the number of vehicles that need to be analyzed to extract a repeatable vibrational spectrum will be examined. Typically, ~40-50 vehicles are needed to obtain a repeatable vibrational spectrum suitable to extract frequency peaks. This approach is used on the benchmark data set and changes in the vibration frequencies due to temperature induced structural changes can easily be observed. The temperature induced structural changes might be the basis training and testing data sets that could be used to evaluate the effectiveness of some damage detection algorithms.

## 1 INTRODUCTION

Structural vibrational analysis of bridges has been used for many purposes including structural assessment [1], damage detection [2], cable damping [2], damage detection in piers [3], girders [4], bearing restraint [5] and scour detection [6], [7], [8]. Vibrational analysis via moving test vehicles is also an exciting direction [9]. Vibrational analysis can be extracted from specialized instruments such as accelerometers and geophones, but can also be extracted from strain signals from strain gauges or strain sensors [10].

Some type of force must be applied to the structure in order to detect vibration of the structure. The excitation can be broadly classified as intentional or unintentional excitation. Intentional excitation can be in the form of hammers, dropped load, unbalance rotating shaft or known test vehicles. Unintentional excitation can be due to wind, water, ice impact or traffic. One advantage of unintentional sources is that they can excite the structure more or less constantly and allow for the continuous monitoring of the bridge. In this context, continuous means a time scale on the order of a fraction of a day. We can use the data from the benchmark data set to explore the sue of traffic induced vibration to extract vibrational information.

In this paper we examine the extraction of vibrational information from the benchmark data set. We examine alternative methods for the extraction of vibrational information from the strain versus time data in the benchmark data set. We examine the number of truck passages that are required to obtain a usable estimate of the vibrational frequencies of this bridge span. Suggestions for future vibrational analysis of this data set will also be given.

## 2 METHODS

### 2.1 Sampling strain versus time

The data being used is the individual truck sampled strain versus time data from the benchmark data set [11]. This publication contains the details of where the sensors were located and how the signals were sampled [11]. Briefly, the instrumentation was originally aimed to estimate the GVW of vehicles, investigate the transverse loading and to investigate the composite action in the structure. The span has two lanes and is 22 m long with 4 steel girders. An image of a truck passing over the girder is shown in Fig. 1.

Figure 1. Truck passing over the benchmark span.

The instrumentation included 32 electric resistive strain gages to monitor strains and six thermocouples to monitor air/structure temperature under the deck. The bridge was instrumented at six cross-sections.

The cross-section used in this work is the one located at midspan and has electrical resistance strain gauges (ESGs) were installed on the web of each girder to measure longitudinal strains at the top and bottom flanges, and at mid-height between the flanges. In this work only the strains near the bottom flange are used.

The data acquisition (DAQ) system features continuous strain sampling at 200 Hz, image collection for large events, data processing, and data transmission to a server. The strain data were filtered using a 7-point moving average window to remove electrical noise above 60 Hz.

The benchmark data set contains subsamples of the full data set. Each subsample was selected to contain the sampled strain versus time for a large truck. Each subsample contained 2000 sample points or about 10 seconds of sampled data. The data was selected such that the peak strain for the passing vehicle was in the center of the subsampled data.

An example of the sampled strain versus time is shown in Fig. 2A. In this plot the strains from each girder are offset by 20 microstrain per sensors so that the strain versus time behavior of each sensor can be easily observed. Before the passing of the vehicle there is no observable vibration. During and after the passage of the truck the vibration is clearly visible. After the truck leaves the span, during the period of free vibration without the weight of the truck, there are about 5 cycles per second [12]. This can be observed in the top strain versus time curve starting at about 6 seconds. Between 6 and 7 seconds there are about vibrational 5 cycles.

Figure 1. (A) Strains versus time for each of the 4 girders. (B) Spectrum of the strain. There is a vibrational peak at ~5Hz.

The strain versus time signals from the two outside girders were summed and then processed using an FFT from the Python numpy library. By using signals from the outside girders, vibration from trucks passing in both directions are captured. The outcome of the FFT analysis of Fig. 2A is shown in Fig. 2B. As expected, there is peak in the spectrum near 5 Hz. However, there is also considerable noise in the spectrum and the estimate of the peak position would have significant uncertainty. We will examine using averages of many such spectrums to improve the estimates of the vibrational frequency peaks. To do this N spectrums are averaged using a simple linear average. Using these initial estimates, a better estimate of the peak frequency was obtained by using a parabolic fit using two points lower and two points higher and the initial estimate. The peak of the parabola was then used as a refined estimate of the peak frequency. This means of estimating the peak position is computationally simple and produces a better estimate of the peak [13].

### 3 RESULTS AND DISCUSSION

There are several reasons why it may be necessary to use the average of vibrational spectrums from several trucks to obtain usable estimates of vibrational frequencies. When each truck passes it will preferentially induce vibration at certain frequencies. The frequencies that are preferentially excited will depend on factors like the velocity of the truck, the distance between axles, where the truck passes over the bridge and the vibrational properties of the truck.

An example of the variation in excited vibration is shown in Fig. 3(A) and 3(B). The two examples are passing at similar velocities with similar maximum strains. Both are traveling in the same direction. However, the induced vibration is not similar. In Fig. 3(A) during free vibration portion after the vehicle has left the span the vibration is largest on the side opposite the side on which the truck passed, in girder G4. After leaving the span the vibration on the girder nearest where the truck passed (G1), is much smaller and not observable. In contrast to this the in Fig. 3(B) the after the truck has passed and the girder is in the free vibration portion of the vibration the magnitude of vibration is roughly about the same in G1 and G4.

In Fig. 3(A) the vibration is torsional with one side moving and the other side nearly motionless. In Fig. 3(B) the vibration is more flexural with both sides moving up and down synchronously. The synchronous motion can be seen in Fig. 3(B) at 7 seconds where the strains in all the girders are at a maximum. In this example, for two similar trucks the mode of vibration is very different. It should be mentioned that these two examples were found within the first few trucks in the data set and did not require any extensive searching. Therefore, in general the vibration from a single truck may not excite all the modes of interest.

Using the benchmark data set, we can explore how many spectrums need to be considered by using stacked spectrum plots of the averaged spectrums. In these examples a simple linear average of spectrums is used. The numbers explored ranged from 40 to 200 spectrums. When less than 40 were used the number of misidentified vibrational peaks increased significantly. In Fig. 4(A) a stacked spectrum plot for an average of 200 spectrums is shown. In this plot each spectrum

is an average derived from 200 truck passages. Each peak is identified with a black plus sign. With 200 spectrums being averaged there are no misidentified peaks. For each spectrum there is a peak near 5 Hz and a second one from 10 to 12 Hz. The 10 to 12 Hz peak appears to be shifting from the averaged spectrum at the bottom to the averaged spectrum at the top.

Figure 3. Strains versus time for the four girders. Fig. 3A is an example of asymmetric vibration. Fig. 3B is an example of symmetric vibration.

Each truck in the data set has a unique number from 0 to ~ 3300. As the truck number increases so does the date on which the data was acquired. Truck 0 was taken during a mid-winter cold period. By the time truck 3300 was taken it was mid-summer. The spectrums are arranged sequentially in number and therefore time. The bottom spectrum was from a colder period and the top one from a warmer period. The shift in frequencies is attributed to temperature effects. Therefore, the results of the peak frequency estimates have been plotted versus temperature.

In Fig. 4(B) 50 averages are used. The same two vibrational peaks are identified in most of the averaged spectrums. However, several misidentified peaks are also being identified due to the decreased signal to noise. Perhaps this could be improved with enhanced signal processing.

These same plots are done as colorized waterfall plots in Fig. 5 that help make the 10 to 12 Hz peak more easily observable. The change in the 10 to 12 Hz peak with the seasonal temperature changes is now clearly observable.

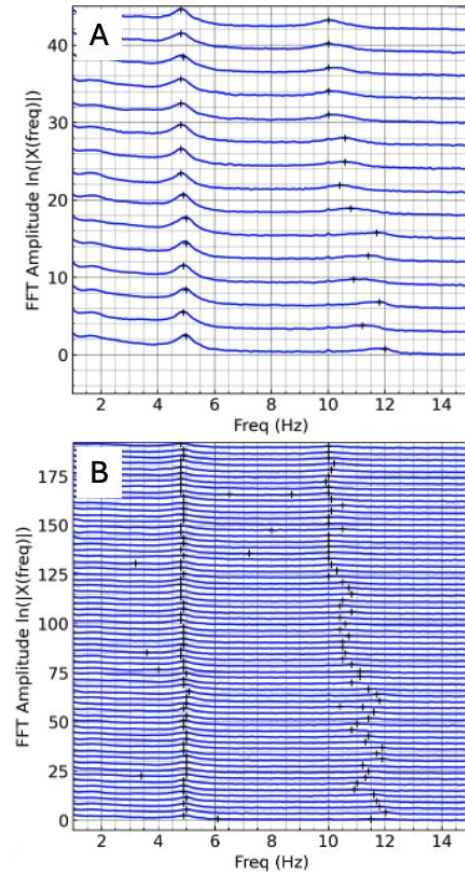

Figure 4. Waterfall vibration spectrum plots for averages of 200 trucks (A) and 50 trucks (B).

The correlation with temperature can be plotted more directly as each spectrum has also has an associated temperature. If we plot the average temperature of each average spectrum against the identified vibrational frequency the correlation is easily identified. In Fig. 6 this has been done for averages of 40, 50 and 200 averages. The peak frequencies are highly correlated with temperature. Although there may be other environmental effects coming into play over this season, temperature would appear to be the dominate influence. Principle component analysis could be used to quantify the effects of temperature versus the time of year. Also, as the number of averages drops below 40 the proportion of misidentified peaks increases rapidly.

Using motion sensors mounted on test vehicles to extract structural vibrational properties as the vehicle passes over the structure is an interesting approach for monitoring fleets of bridges [9]. For this field to advance large data sets of simulated and field observations are needed. Simulated data sets have been created [14]. It might also be possible to create field observation from the benchmark data set. The strain is directly related to displacement and therefore acceleration can also be calculated. Comparing cold and warm weather results would be a good test of damage detection using vehicle derived responses. Another potentially useful case would be if one wanted to simulate the use of a sensor trailer to measure the free vibration [15].

Figure 5. Waterfall vibration spectrum plots for averages of 200 trucks (A) and 50 trucks (B).

Whether or not a damage detection algorithm can detect damage using actual field derived data is often an open question. Only rarely do owners allow full scale structures to be damaged so that actual field responses before and after damage can be obtained [3]. However, temperature changes often lead to significant structural changes due to effects such as due to bearing restraint [5]. A first step towards testing damage detection algorithms could be the detection of temperature induced structural changes. Due to the temperature change over the observation period in the benchmark data set there are also significant easily observable structural changes. Evidence for this is the frequency change seen in Fig. 6B, for example. In order, for the frequency to change there must be some significant structural change. The temperature induced structural changes can also be easily observed in the girder distribution factors. Therefore, the data set could be divided into “good” and “damaged” data sets using temperature as a means of sorting. Here the “damaged” set would not correspond to actual structural damage but would have significant structural differences from the “good” data set. For example, trucks 2300 to 3300 could be chosen as the “good” data set and used to train an algorithm. Trucks could then be chosen to test a detection method. Trucks with larger temperature differences compared to the “good” set would have larger structural differences. This provides a means to quantitatively test detection algorithms. One could argue that these only tests detection of a particular type of structural change. However, this change does include changes in girder distribution factors, which are one of the common reasons bridge load ratings are reduced [16].

The benchmark data set also includes strains from multiple sections and it might also be possible to also extract vibrational mode shape information.

Figure 6. Plots of frequency peaks for averages of 40 trucks (A), 50 trucks (B) and 200 trucks (C).

#### 4 CONCLUSIONS

The sampled strain data from the benchmark data set can be used to extract vibrational frequency spectrums. The passages from several trucks need to be averaged to extract consistent vibrational peaks. Typically, 40 to 50 trucks are required. Temperature induced changes in the vibrational peaks can easily be observed. The temperature induced structural changes might be the basis training and testing data sets that could be used to evaluate the effectiveness of some damage detection algorithms.

# Study of Semi-Rigid Joints Effect on Global Stiffness of Space Steel Structure Based on Monitoring Data

Cheng Yuan<sup>1</sup>, Wei Lu<sup>1</sup>, Jun Teng<sup>1</sup> and Weihua Hu<sup>1</sup>

<sup>1</sup>Harbin Institute of Technology, Shenzhen, 518071, China

email: Chengyuan@hit.stu.edu.cn, Lu.wei@hit.edu.cn, tengj@hit.edu.cn, huweihua@hit.edu.cn

**ABSTRACT:** In conventional structural design and analysis of space steel structures, joints are typically idealized as either perfectly hinged or fully rigid connections. However, actual joint behavior deviates significantly from these idealized assumptions, with joint stiffness exhibiting semi-rigid characteristics that critically affect global structural performance. This discrepancy between simplified joint models and real-world conditions leads to substantial errors in predicting structural stiffness through numerical simulations. This paper presents a novel methodology integrating structure health monitoring with refined finite element (FE) modeling to quantify the semi-rigid joints effect on global stiffness space steel structure. The joint stiffness parameters are inversely identified through stress and deformation monitoring data using Bayesian inference techniques; A multi-scale FE model incorporating semi-rigid joint behavior is developed through component-level validation; The stiffness evolution mechanism is rigorously validated against full-scale monitoring data from the Shenzhen Nanshan Science-Technology Innovation Center's space frame during its service period. Key findings demonstrate that joint flexibility reduces global stiffness by 18-22% compared to rigid-joint assumptions, with stiffness degradation rates showing strong correlation to stress redistribution patterns. The proposed joint-characterization framework provides a physics-based approach for tracking long-term stiffness evolution in space steel structures, offering significant improvements over conventional design methods in both accuracy and predictive capability.

**KEY WORDS:** Semi-Rigid Joints, Space Steel Structure Stiffness, Structure Health Monitoring.

## 1 INTRODUCTION

Structural connection joints are the critical components of space steel structures, which are subject to complex forces and are sensitive to defects. The mechanical properties and stress of the joints not only affect the safety of the joint itself but also have an influence on the stress distribution and deformation of the overall structure.

In China's "Code for Design of Steel Structures", it is stipulated that the truss and the space frame should be analyzed according to the hinge connection, while the single-layer space shell should be processed according to the rigid connection [[1]]. However, more and more engineering projects show that ideally hinged joints often have certain rigidity, while ideal rigid joints also have certain flexibility. The research work of Grogan [[2]] and Wheelar [[3]] show that neither completely rigid nor hinged joint exist in reality. The uncertainty of joint stiffness is mainly caused by the following factors. The structure discontinuity of the structure. The bolts are not tightened between the nodes and members connected by bolts, which leads to insufficient stiffness of the joints. The structure has defects. Due to geometric defects such as dislocation or slippage between components and nodes during installation, or physical defects such as cracks, the stiffness of joints decreases. The structure is deteriorating in its service life. The structure is affected by fatigue and corrosion, which leads to the deterioration of the joints.

The research on joint stiffness has received extensive attention in recent years. The "specification for structural steel structure" edited by AISC pointed out that the connection joints of steel structures should be divided into three situations, namely ideal

simple connection, fully restrained moment connections and partially restrained moment connections [[4]]. The Eurocode 3 also has a description similar to that in the AISC code, which divides the joints into three types: rigid, semi-rigid and hinged [[5]]. Although the Eurocode 3 and AISC code mention the general classification standards of three types of joints, there is no relevant description on how the stiffness of semi-rigid joints is determined, and how the attenuation of joint stiffness will affect the overall structure's stiffness.

The existing research mainly contains three methods for calculating the value of joint stiffness which are numerical simulation, laboratory specimen test and mathematical statistics. Liu [[6]] used Abaqus to model the pin joints to analyze their stiffness, and Cao [[7]] used Ansys to model the network frame joints to analyze their stiffness. The numerical simulation of joint stiffness is convenient, but the premise assumptions of material properties and connection methods used in finite element simulation may be different from the actual states of joints in reality. Liao [[8]] obtained the load-displacement curve of the joint by making a scaled model in the laboratory for loading, and then calculated the joint stiffness data. However, the scaled model cannot reflect the actual stress state of the full-scale structure. Frangopol [[9]] obtained the probability distribution curve of the deterioration degree of the connection joints of steel truss bridges by analyzing the test report data of a large number of bridges by means of mathematical statistics. However, there are certain regional differences in this method. The degree of corrosion and deterioration of steel structures under different climatic environments is significantly different. The probability

distribution cannot determine the change trend of joint stiffness of a specific structure.

In conclusion, there are premise assumptions for numerical simulation, differences between the scaled model and the full-scale structure for laboratory test, and regional differences in mathematical statistical analysis. In this paper, the field monitoring data of structural stress and displacement are obtained based on Nanshan Science and Technology Innovation Center monitoring project through stress sensors and prisms. The stiffness of the joints of steel truss are obtained by inversion of the monitoring data of stress and displacement by the deflection method. The updated joint stiffness is substituted into the finite element model. The influence of the joint stiffness on the overall stiffness of the structure is studied through the updated finite element model.

## 2 JOINT STIFFNESS CALCULATION

### 2.1 Joint Stiffness Calculation Method

The stiffness of the joints is calculated by the deflection method. The total beam deflection comprises two constituent parts: one part is the deflection caused by the ideal elastic deflection of the beam; the second part is the displacement of a point on the beam caused by the deformation of the joint, as shown in Fig. 1.

Figure 1. General view of deflection method

$\mu_1$  is the deflection of the ideal elastic deflection line of the beam at this point.  $\mu_2$  is the displacement at this point due to the deformation of the joint.  $\mu$  is the real deflection of the point, and  $L$  is the distance from the point to the joint.  $\mu$  can be calculated as:

$$\mu_1 + \mu_2 = \mu \quad (1)$$

The angle of downward deflection at the joint can be calculated as:

$$\theta_r = \frac{\mu}{L} = (\mu_1 + \mu_2)/L \quad (2)$$

In this project,  $\mu$  is obtained by prism observation in field monitoring, and  $\mu_1$  is obtained by linear elastic simulation with finite element software. The joint stiffness  $K_j$  can be calculated as:

$$K_j = M / \frac{(\mu - \mu_1)}{L} \quad (3)$$

$M$  in formula (3) is the bending moment of the joint, which is obtained by finite element simulation.

### 2.2 Joint Stiffness calculation Results

Shenzhen Nanshan Science and Technology Innovation Center includes seven towers (A1-A7) and a huge podium surrounding the towers. The steel structure of the podium is located on the 7th to 11th floors, as shown in Fig. 2. The steel structure of the podium consists of a large span truss and a cantilevered truss structure.

(b)

Figure 2. Shenzhen Nanshan science and Technology Innovation Center. (a) completed structure rendering and (b) construction process

The typical joint of the large span steel truss of the podium of Nanshan Science and Technology Center is shown on Fig. 3. The joints and the members are connected by welding.

(a)

(b)

(c)

Figure 3. Typical joint (a) Joint model. (b) diagonal web is being welded to the bottom joint. (c) The installation of truss between A4-A5 is completed.

In this project, the vibrating wire stress sensor is used to monitor the stress of the structure. The prism and electronic total station are used to monitor the displacement of the structure. In this paper, the displacement monitoring data is used to calculate the real stiffness of the structure, and the stress monitoring data is used to verify the validity of the finite element model after updating the joint stiffness.

The stress sensors and prisms have been installed on the large-span trusses connecting the core tubes A1, A2, A4, and A5, and the stress and displacement of the structure at the current construction stage have been monitored. The positions of stress sensors and prisms are shown in Fig. 4.

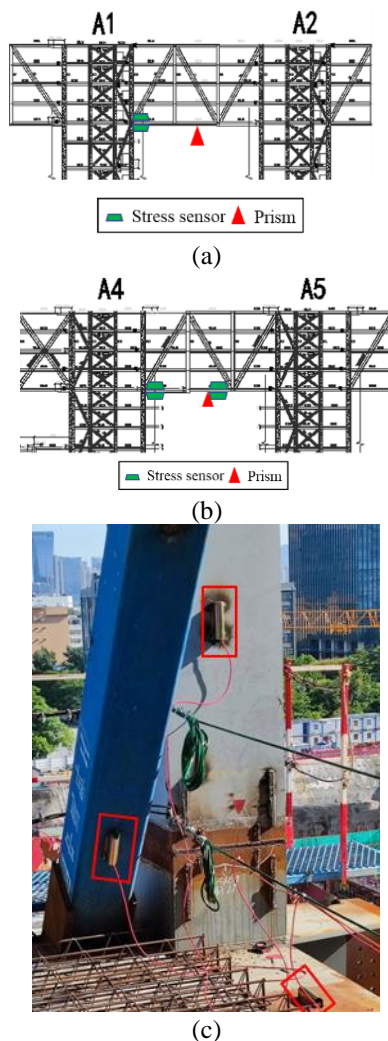

Figure 4. Stress sensors and Prisms on truss. (a) truss between A1-A2, (b) truss between A4-A5 and (c) sensor installation diagram (in red box)

The finite element analysis of the current phase of the structure was performed using Midas Gen, and the truss members were modeled as beam elements. The mid-span deflection of the lower chord and the bending moment at both ends of the lower chord of the large-span truss between A4 and A5 are calculated

only considering the self-weight load of the structure. The vertical displacement diagram and the stress diagram of the truss is shown in Fig. 5.

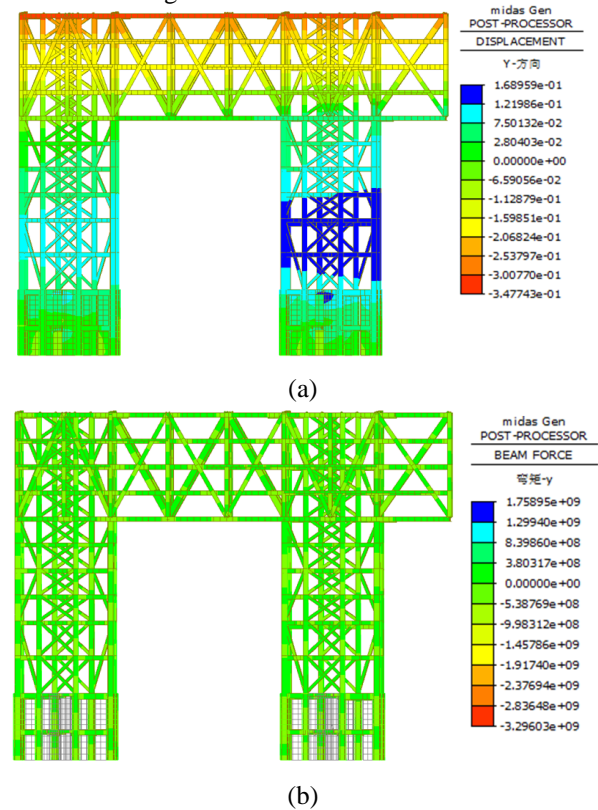

Figure 5. Finite element simulation. (a) vertical displacement diagram. (b) Stress diagram.

The deflection  $\mu_1$  produced by ideal elasticity at the mid-span of the large-span truss (the triangle mark in the figure) is extracted from Fig. 5. The bending moments  $M$  of joint L and R are extracted from Fig. 6 (b). and midspan deflection  $\mu$  of the truss between A4-A5 is 6 mm based on field monitoring data. The stiffness of joint L and R are calculated based on formula (3) and results are shown in Table 1.

Table 1. Joint stiffness results.

	Joint L	Joint R	Calculation method
$\mu$ (mm)		6	Monitoring data
$\mu_1$ (mm)		2.6	Finite element
$\theta_r$ (rad)	$3.96 \times 10^{-4}$	$3.96 \times 10^{-4}$	Formula (2)
$M$ (kN*m)	110.7	80.7	Finite element
$K_j$ (kN*m/rad)	$4.94 \times 10^5$	$3.60 \times 10^5$	Formula (3)

### 3 EFFECT ON GLOBAL STIFFNESS

#### 3.1 Updating of Joint Stiffness

According to the calculation results shown in Table 1, the previous rigid joint is updated with the stiffness  $4.94 \times 10^5$

kN\*m/rad,  $3.60 \times 10^5$  kN\*m/rad and  $4.27 \times 10^5$  kN\*m/rad (average of joint L and joint R).

The bottom joints of the web members of the trusses connecting A1-A2, A1-A4 and A4-A5 are updated with new stiffness. The joint locations for the updated stiffness are shown in Fig. 6. Twelve joints of the web members have undergone stiffness updates. The method of joint stiffness updating is to replace the original rigid joints in structural model with spring beams with springs at both ends.

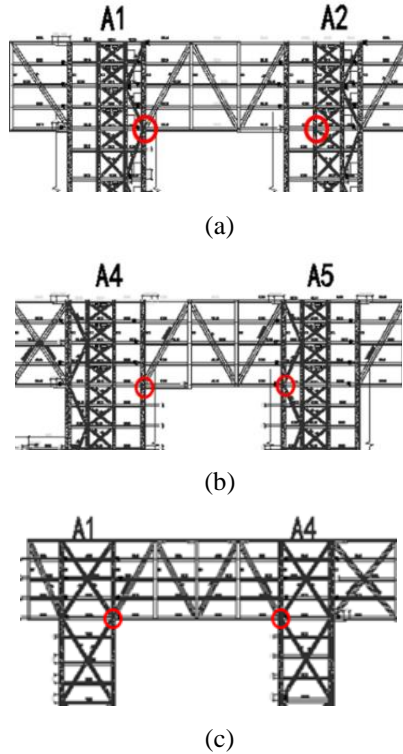

Figure 6. Positions of joints for stiffness updating. (a) truss A1-A2. (b) truss A4-A5. (c) truss A1-A4

### 3.2 Finite Element Model Verification

Five cases of joint stiffness cases are being simulated using finite element method which are rigid,  $4.94 \times 10^5$  kN\*m/rad,  $4.27 \times 10^5$  kN\*m/rad,  $3.60 \times 10^5$  kN\*m/rad and pinned. The load on the structure only considers the self-weight load. The remaining cases are simulated in the same way. The structural stress obtained from the finite element simulation is compared with the structural stress obtained from the field monitoring data to verify the model with updated joint stiffness.

The joint stress at the same position of the monitoring point is extracted from the structural stress diagram for comparison. The location of measuring points for structural monitoring is shown in Fig. 4. The comparison between the simulation results and the monitoring data is shown in Fig. 7.

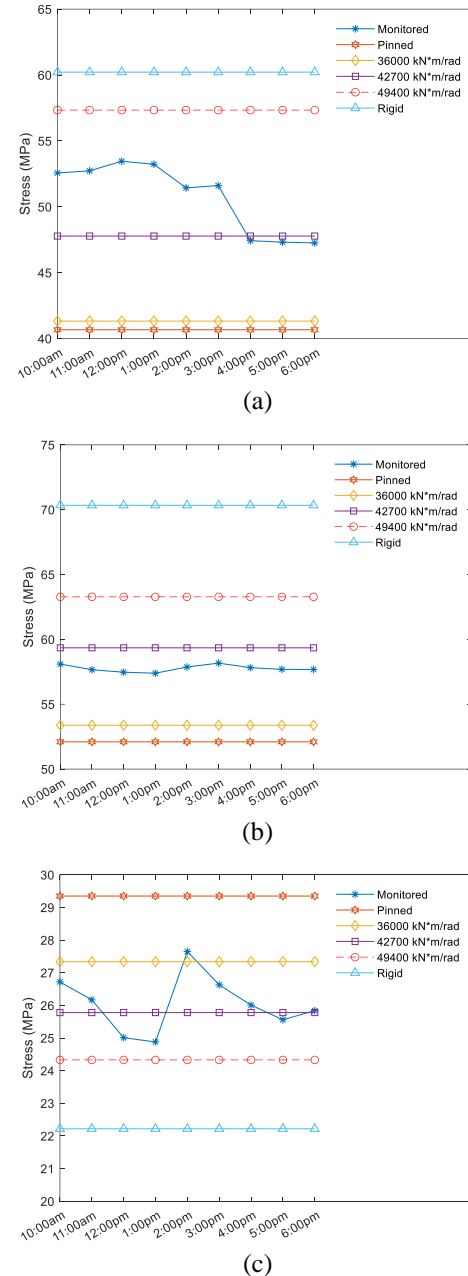

Figure 7. Comparison between the simulation results and the monitoring data. (a) stress at end of truss between A1-A2, (b) stress at end of truss between truss A4-A5 and (c) stress at midspan of truss A4-A5.

The following conclusions can be drawn from the comparison between monitoring data and simulated data in Fig. 7. The stress data simulated by the semi-rigid joint model are closer to the structural monitoring data. Among them, the model stress value after joint stiffness update with the average stiffness of joint L and joint is the closest to the monitoring data. This indicates that this stiffness is the closest approximation to the true stiffness of the bottom joint of the web member of the truss.

### 3.3 Effect of Joint Stiffness on Global Stiffness of Structure

According to the results in 3.2, it is considered that  $4.27 \times 10^5$  kN\*m/rad is the true stiffness of the bottom joint of the web member of the large-span truss. Apply different vertical

uniform loads to the structure and draw the load-deflection curves of the large-span trusses A4-A5. The load-deflection curves of the ideal rigid joint, semi-rigid joint and ideal hinged joint model are compared in Fig. 8.

Figure 8. A4-A5 truss load-displacement curve.

It can be seen from Fig. 9. that the vertical stiffness of the ideal rigid joint model is the largest, followed by the semi-rigid joint model, and the vertical stiffness of the hinge joint model is the smallest. The truss load-deflection curves of the ideal rigid joint, semi-rigid joint and ideal hinged joint model are linearly fitted, and the slope of the load-deflection curve is the vertical stiffness of the A4-A5 large-span truss. The calculation results show that the vertical stiffness of the semi-rigid joint truss is 5.4% lower than the rigid joint model and 13.4% higher than the pinned joint model.

The mode shapes of the structure has been simulated to analysis the joint effect on global stiffness of the structure. The first-order mode is translation in the x-direction (parallel to the A1-A2 direction), the second-order mode is translation in the y-direction (parallel to the A1-A4 direction), and the third-order mode is translation in the x-direction. The mode shapes of the structure show in Figure 9. The frequency of the structure with different joint stiffness is shown in Table 2.

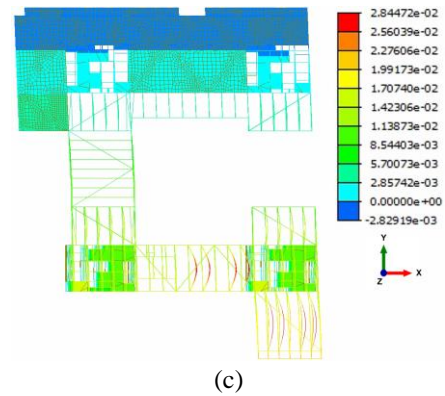

Figure 5. Mode shapes of the structure. (a) first order, (b) second order and (c) third order

Table 2. Frequency of the structure.

Mode order	Frequency (Hz)		
	Rigid joints	Semi-Rigid Joints	Pinned Joints
1	1.3369	1.2366	1.2256
2	1.4826	1.2823	1.2358
3	1.7203	1.3199	1.2286

The mode shape simulation result shows that natural frequency of the structure decreases as the joint stiffness reduces. Since frequency can reflect the stiffness of the structure, the result also tells that joint stiffness can strongly affect the global stiffness of the structure.

#### 4 CONCLUSION

The effect of joint stiffness on overall structure is studied in this paper. The influence of the stiffness characteristics of the joints at the end of the truss and the mid-span of the truss are different. For the joints at the end of the truss, the stress of the semi-rigid joint is larger than that of the hinged joint and smaller than that of the rigid joint; For the joints at the midspan of the truss, the stress of the semi-rigid joint is smaller than that of the hinged joint and greater than that of the rigid joint. The semi-rigid joint is most consistent with the field monitoring data. The load-deflection curve of the large-span truss is simulated, and the results show that the vertical stiffness of the truss of the semi-rigid joint model is 5.4% lower than that of the ideal rigid joint model and 13.4% higher than the hinged joint model. The conclusions of this paper can be references for other steel structure analysis.

#### ACKNOWLEDGMENTS

This work was supported by the National Natural Science Foundation of China [grant numbers 52122804, 51978214, 51878226], the National Major Scientific Research Instrument Development Program of China [grant number 51827811], and the Fundamental Research Funds for the Central Universities [grant number HIT.BRET.202101]. Xianwei Fang, Yizhan He, Hetia Shao and Jiayi Zheng assisted measuring the field monitoring data, which contributes a lot to this paper.

# Sustaining vertical giants: Autonomous monitoring solutions for the construction and lifecycle of tall buildings

Lidija Špiranec<sup>1</sup>

<sup>1</sup>Leica Geosystems AG, Heinrich-Wild-Strasse, 9435 Heerbrugg, Switzerland  
email: lidija.spiranec@leica-geosystems.com

**ABSTRACT:** As urban environments increasingly shift towards vertical development, the challenges associated with constructing and maintaining tall buildings have intensified. Real-time and dynamic monitoring systems play a vital role in addressing these issues by providing accurate positioning and deformation data. The integration of diverse monitoring technologies during and after the construction of high-rise buildings is crucial for ensuring structural integrity, safety, and efficiency.

By combining geodetic and geotechnical monitoring techniques, these systems offer comprehensive insights into building behaviour. The fusion of technologies like GNSS, IoT sensors, and remote sensing, alongside traditional survey methods, ensures precise data acquisition and analysis. This hybrid approach is essential for optimising construction and maintenance processes, reducing costs, and enhancing safety. Furthermore, the ability to process and analyse large volumes of monitoring data efficiently is critical for transforming raw data into actionable insights, aiding decision-makers in understanding the magnitude and direction of structural movements.

The successful implementation of these monitoring techniques on iconic high-rise buildings, such as the Burj Khalifa and One World Trade Center, highlights their importance in modern construction and post-construction maintenance. Ultimately, the intelligent use of integrated monitoring technologies supports sustainable and resilient urban development.

**KEY WORDS:** Autonomous; Deformation monitoring; Verticality; Positioning; High-rise; Tall buildings.

## 1 INTRODUCTION

In the rapidly evolving urban landscape, the shift towards constructing tall buildings presents unique challenges that demand innovative solutions. Ensuring the structural integrity and safety of these vertical giants requires advanced positioning and deformation monitoring technologies capable of delivering real-time and precise data on buildings' behaviour.

Environmental forces such as wind and temperature variations can lead to significant deformation during construction, therefore precise measurements are required to maintain vertical alignment and correct positioning. Traditional surveying methods, while effective at lower elevations, often reach their limits as buildings rise, necessitating the adoption of advanced active survey control systems.

In the lifecycle phase, the safety and integrity of tall buildings can again be at risk in case of nearby excavations or movements caused by natural events. In such cases, deformation monitoring is essential, to provide an understanding of structural behaviour.

In both phases of the building's timeline, deformation monitoring information is crucial for decision-makers.

## 2 CONSTRUCTION OF TALL BUILDINGS

### 2.1 Surveying challenges

Constructing tall buildings introduces a range of complex and unique surveying challenges primarily due to their height and slender profiles, which significantly alter the structure's rigidity compared to low-rise buildings. As the geometry shifts from a wide base to a narrow top, resistance to deformation decreases,

necessitating precise engineering surveying and monitoring systems to maintain vertical alignment and correct positioning. As depicted in Figure 1, environmental forces such as wind loads can cause deflection, varying with the stiffness of different elements and the location on the building. Temperature changes and sunlight can lead to uneven thermal expansion, causing the building to lean. Additionally, as construction progresses, the increasing mass leads to the compression of lower elements, potentially resulting in differential settlement and vertical alignment issues. This requires adjustments to the vertical datum to account for axial shortening and ensure the final height meets specifications.

Figure 1 Environmental forces and live load impacting tall buildings [1]

Dimensional control is crucial for each floor's horizontal and vertical alignment, involving traditional survey methods like optical levelling, plumb line and total stations. These methods establish base gridlines at stable ground levels, with new references created as construction progresses. However, maintaining uninterrupted vertical lines of sight can be

challenging and costly, slowing down the construction progress and bringing risks to the structural stability of the high-rise building. For this reason, between 100m and 200m elevation from the ground level, the traditional and passive survey methods reach their limits and must be replaced with high-rise specific active survey control positioning methods.

## 2.2 Active survey control and deformation monitoring

The introduction of active survey control systems marks a significant advancement in the field of structural deformation monitoring and positioning systems for tall buildings. These systems leverage the power of interoperable connectivity between survey instrumentation and Internet of Things (IoT) sensors, providing real-time data that ensures accurate positioning. By automatically resolving positions to the necessary precision, active survey control systems reduce human error and enhance efficiency. These systems employ Global Navigation Satellite Systems (GNSS) and IoT sensors to continuously monitor and report positions, compensating for dynamic structural deformation. This capability establishes survey control points and a reference frame within specified tolerances, streamlining the engineering surveying process.

The solution provided by Leica Geosystems, Core Wall Control System (CWCS) shown in Figures 2 and 3, specifically developed and advanced for tall building construction over 15 years since the construction of Burj Khalifa [2], combines the following components:

- Leica iCON GNSS Smart Antennas placed on the uppermost floor to provide continuous, real-time positional data collocated with 360° prisms
- Robotic total stations, such as Leica TS16/60, measuring prisms and used for establishing and verification of the survey control using positional information provided by the monitoring software
- GeoCloud Drive service responsible for data transfer and synchronization of results between the field instrumentation and monitoring software
- WiSenMeshWAN® IoT inclinometers and distance meters deliver displacement information at various levels
- GeoMoS Monitor software for GNSS and IoT data processing and publishing positioning results consumed by total stations for stakeout

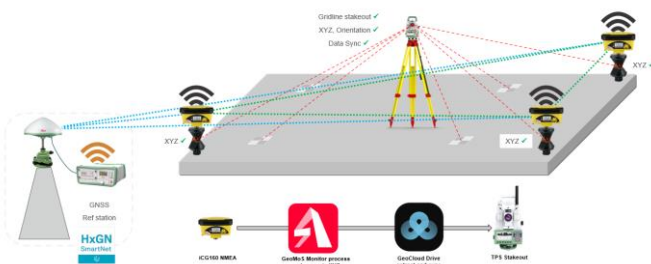

Figure 2 Leica Geosystems' CWCS solution [1]

The real-time information provided by these systems is used to determine live axial shortening values for structural compression. This is achieved through multiple vertically installed IoT distance sensors, while the rotation component from the sensors helps determine live structural tilt. Additionally, GNSS positioning data provides absolute XYZ locations at the upper working face of the building, creating a

comprehensive integrated solution. By combining these data sets with traditional monitoring of foundation deformation and environmental sensors, engineers gain a thorough understanding of where to place new elements at the upper workforce, ensuring that positional data is available and within tolerance when required.

Figure 3 WiSenMeshWAN® solution for real-time compression readings [1]

Although the accuracy of live RTK GNSS positioning is around  $\pm 3\text{cm}$ , averaging the results over the period of at least one hour will significantly improve the accuracy. Figure 4 displays the combination of raw and averaged 6-hour RTK GNSS data, where raw data shows horizontal consistency within  $\pm 2\text{cm}$  over 24 hours, whereas averaged results filter out dynamic movements and reveal slow movements of the building influenced by cyclic environmental conditions, reaching the accuracy of  $\pm 5\text{mm}$ .

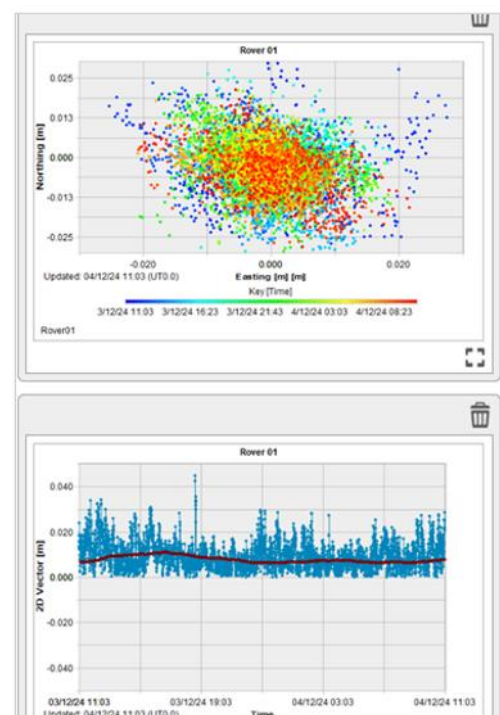

Figure 4 Raw and averaged RTK GNSS data over 6 hours

Real-time monitoring systems extend beyond construction, monitoring the building's lifespan and supporting future design models.

### 2.3 Real-life examples

Since the first implementation of the Core Wall Control System for the construction of Burj Khalifa, CWCS has been deployed and further developed in many iconic high-rise and super high-rise buildings worldwide. Some of the examples are:

- 432 Park Avenue in New York City [3] completed in 2015 and standing at 426m
- The Central Park Tower in New York City [4] – one of the tallest residential buildings with 472m, completed in 2020
- One World Trade Center in New York City – the tallest building in North America with 541m, completed in 2014
- Millenium Tower in Boston [5] – one of the tallest residential buildings in Boston with 208m of height, completed in 2016
- 22 Bishopsgate in London [6] – the second tallest building in the UK with 278m, completed in 2020
- The Shard in London [7] – the tallest building in the UK with 306m, completed in 2013

## 3 STRUCTURAL HEALTH MONITORING OF TALL BUILDINGS

Every building and structure changes over time due to various environmental and structural impacts and neglecting these changes can have serious consequences. Tall buildings are particularly impacted due to their unfavourable geometry. The most common causes of movements in urban environments include nearby construction, excavations, ageing of the structure, maintenance of the building, natural hazards and seismic activity.

### 3.1 Choosing the right technology

No single technology can fully capture the dynamic behaviour and the entire scope of high-rise and super high-rise buildings. Also, each technology has its advantages and limitations, which should be considered when designing the deformation monitoring system. Hence, a hybrid approach is essential [8].

In the case of geodetic monitoring, prism and GNSS measurements provide a complete 3D understanding of movements but are limited to a small number of single points depending on either a clear line of sight or an open sky. Automated 3D laser scanning in monitoring [9] on the other hand captures thousands of points per second, but can only deliver information about deformations perpendicular to the scanned surface. Geotechnical sensors, such as inclinometers and extensometers, provide point-specific data in a relative, non-georeferenced context. However, due to the IoT technology, they can be installed indoors and outdoors and create a self-forming dynamic radio mesh network which sends data to a gateway.

The fusion of geodetic and geotechnical data creates a more complete picture of building deformations. By cross-analysing data from different sources, engineers can validate findings and ensure the reliability of the monitoring system. This integration allows for early detection of potential issues, enabling proactive measures to maintain structural integrity.

### 3.2 Edge computing, automation and autonomy

The integration of edge computing, automation, and autonomy into monitoring solutions represents a significant advancement in the field [10]. These technologies enhance the efficiency and reliability of data acquisition and processing, enabling real-time insights into structural behaviour.

GeoMoS Edge is crucial in Leica Geosystems' monitoring systems because it addresses the significant challenge of data acquisition continuity during communication outages. Traditional monitoring systems rely heavily on stable communication between sensors and a central server, which can lead to data gaps and safety risks when communication is disrupted. GeoMoS Edge mitigates this issue by embedding a data acquisition component directly on a communication device, allowing the system to operate autonomously even during periods without connection to the GeoMoS monitoring software.

This autonomy ensures that measurements continue uninterrupted, eliminating data gaps that could otherwise pose safety threats. By replicating server functionality on edge devices such as Leica ComBox60, GeoMoS Edge can perform measurement cycles, assess data quality, and trigger repeated measurements if necessary. Once communication is restored, the collected data is seamlessly delivered to the central monitoring software.

## 4 CONCLUSION

The integration of deformation monitoring technologies in the construction and lifecycle management of tall buildings is the key for stability and health of the structure and the people in its vicinity. The combination of GNSS, IoT sensors, and traditional survey methods provides a comprehensive understanding of structural behaviour during its construction, allowing for precise positioning as the building grows. This hybrid approach, as demonstrated by Leica Geosystems' Core Wall Control System (CWCS), has proven effective in iconic buildings worldwide, starting from Burj Khalifa in the United Arab Emirates, over 22 Bishopsgate and The Shard in the United Kingdom, to The Central Park Tower, One World Trade Center and many others in the United States of America. By leveraging real-time data from geodetic and geotechnical sensors, engineers can monitor axial shortening, structural tilt, and environmental impacts with high accuracy, enabling proactive measures to address potential issues.

The continuous development of these technologies, including edge computing and automation, further enhances the reliability and efficiency of data acquisition and processing. Solutions like GeoMoS Edge ensure persistent monitoring even during communication outages, mitigating safety risks associated with data gaps. This autonomy allows for uninterrupted measurements and seamless data integration, supporting informed decision-making throughout a building's lifecycle.

Ultimately, the adoption of integrated monitoring solutions not only optimises construction and maintenance processes but also supports sustainable urban development. As cities continue to grow vertically, the demand for precise and reliable monitoring systems will increase, driving further innovation in the field. By embracing these technologies, stakeholders can ensure the safety, efficiency, and longevity of high-rise

buildings, contributing to resilient and sustainable urban environments.

**ABSTRACT:** The application of digital twin technology in high-rise buildings provides a comprehensive approach to maintaining construction safety, tracking project advancement, and evaluating service conditions. This paper proposes a novel multi-scale digital twin framework for high-rise structures. The macro-scale model is constructed using spring elements, taking into account the dynamic behavior of flexure-shear coupling in high-rise structures. The macro-scale digital twinning is achieved by updating the macro-scale model through the integration of modal monitoring data with Artificial Neural Networks (ANN). A multi-scale analysis method from the structural macro-level to components of the substructure is developed through information transfer at boundary nodes, achieving a balance between computational efficiency and the demand for accuracy of the local components. Integrated with multiple monitoring data sources, the proposed framework provides a technical pathway for multi-scale model updating, real-time response acquisition, and disaster risk assessment of high-rise structures.

**KEY WORDS:** High-rise building; Flexure-shear coupled behavior; Multi-scale analysis; Structural health monitoring; Artificial Neural Networks.

## 1 INTRODUCTION

Digital twins are increasingly recognized as pivotal innovations within the Architecture, Engineering, Construction, and Facility Management (AEC-FM) industry [1, 2]. As an advanced representation that bridges the digital and physical realms, digital twins enable researchers and practitioners to gain a more intuitive and in-depth understanding of the real-time state and operational principles of objects.

Incorporating mechanical information of the structure into the building's digital twin can provide an approach to maintaining construction safety, tracking project advancement, and evaluating service conditions. Typically, modal monitoring data of the building is used to correct the parameters of the structural design model [3, 4]. The advantage lies in the maturity and convenience of the monitoring methods, and the structural design model can be detailed to the component level, offering a high degree of adjustability. However, the computational efficiency of the design model is low, and model updating typically requires a large number of iterative calculations or reference samples.

The updating of macro-scale models is a very promising research direction, aimed at improving the efficiency of model updating while fully utilizing structural modal monitoring data [5, 6]. However, the coupling effects of bending and shear in high-rise structures as well as the complex inter-story force distribution can significantly affect the dynamic characteristics of macro-scale models. The mapping of macro-scale characteristics to model updating through modal monitoring data is also significantly influenced by the identification algorithms [7, 8]. Therefore, researching suitable macro-scale model carriers and model updating algorithms are the two main research directions in the identification of macro-scale models.

Macro-scale models can only represent the overall deformation of the structure and cannot delve into the load-

bearing status of local components. There are certain special components and critical load-bearing areas where there is a higher demand for monitoring and digital twin accuracy. To balance computational efficiency and simulation precision, a multi-scale structural model is an ideal research approach [9, 10]. Information transfer or coupling between different scales is key to implementing this technology. The multi-scale twin model that combines macro-scale models with component-scale substructure models is still an area that requires further research.

This paper proposes a multi-scale digital twin method that integrates both macro-scale and component-scale substructures. First, a macro-scale twin is realized through Artificial Neural Networks (ANN) and modal monitoring data, and then a substructure component-scale twin is achieved by constructing a floor boundary condition transmitter. Integrated with multiple monitoring data sources, the proposed framework provides a technical pathway for multi-scale model updating, real-time response acquisition, and disaster risk assessment of high-rise structures.

## 2 MACRO-SCALE MODEL UPDATING

### 2.1 Floor deformation characterization

Story response is often used to quantify the overall behavior of high-rise buildings. Therefore, the primary focus is on the displacements of the floor boundary nodes to represent the overall deformation situation of the high-rise buildings. Characterizing the displacements of the numerous boundary nodes on each floor is key to building a macro-scale model of high-rise structures.

In this paper, a high-rise frame core tube structure shown in Figure 1a is used as an example. The structure has 40 stories, each with a height of 4.0 meters. The columns and beams were

modeled using Euler-Bernoulli beam elements, and the core wall was modeled using shell elements. To simplify the complexity of constructing the macro-scale models, uniform member sizes and materials were adopted for all structural components. All columns were 800×800 mm<sup>2</sup> rectangular C40-RC columns and all beams were 500×1000 mm<sup>2</sup> rectangular C30-RC beams, except for the coupling beams in the core wall, which have a cross-section of 700×1400 mm<sup>2</sup>. The material properties are: C30 concrete ( $E = 3.0 \times 10^7$  kN/m<sup>2</sup>,  $\nu = 0.25$ ,  $\rho = 25$  kN/m<sup>3</sup>) and C40 concrete ( $E = 3.25 \times 10^7$  kN/m<sup>2</sup>, with  $\nu$  and  $\rho$  assumed identical to C30). The wall thickness of the core tube is 900 mm. This model also incorporates simplified simulations of infill walls, exterior curtain walls, and rigid panel zones, which, due to space limitations, are not discussed in detail in this paper. However, these structural details significantly increase the computational demands and time costs of the model. The multi-scale modeling approach proposed in this study is specifically designed to optimize this issue.

The structural analysis software OpenSees was used to model the structure (shown in Figure 1b) for batch extraction of the deformation of nodes. Modal analysis of the structure was performed (shown in Figure 2) under the assumption that deformations are restricted to the x-direction, with rigid constraints applied in the other two directions.

The deformation of the planes where the floor boundary nodes are located is illustrated in Figure 3. Due to the rigid floor assumption, the horizontal displacement is uniform at all points, while the vertical deformation and torsional deformation vary from point to point. Therefore, it is proposed to use two hypothetical planes to represent the overall situations of vertical displacement and torsional displacement, respectively. The vertical displacement of each node was fitted to a Hypothetical Vertical Displacement Plane (HVDP) using the least squares method. The bending deformation of the nodes in each slab was averaged to form a Hypothetical Bending Displacement Plane (HBDP). The angle of rotation of HBDP ( $\alpha_{HBDP_i}$  for the  $i^{th}$  floor) and HVDP ( $\beta_{HVDP_i}$  for the  $i^{th}$  floor) shown in Figure 3 represents their degree of displacement. For a given mode, the vertical and bending modal vectors of the boundary nodes of each story were fitted to an HVDP and HBDP, respectively. Examples of this fitting for the 1<sup>st</sup> floor of the 1<sup>st</sup> mode are given in Figure 4. Examples of the angles of the HBDPs and the HVDPs of the 1<sup>st</sup> and 2<sup>nd</sup> modes were calculated and shown in Figure 5.

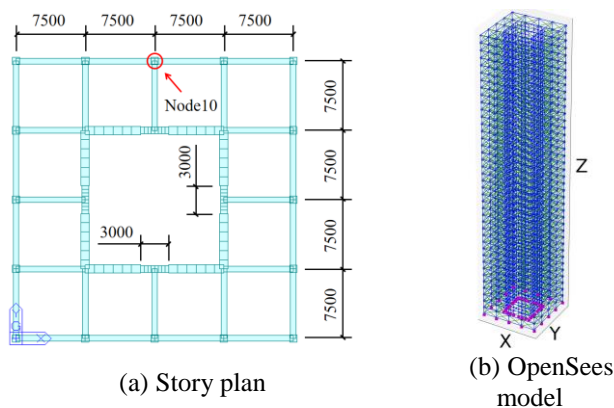

Figure 1. High-rise frame core tube structure.

Figure 2. Mode shapes of the high-rise frame core tube structure.

Figure 3. Displacements of the story nodes.

(a) HBDP

(b) HVDP

Figure 4. Hypothetical plane of the 1st mode of the 1st floor.

Figure 5. HBDP and HVDP

HBPV offers a way to isolate the displacement components induced by bending. The displacement  $\Delta_{Bi}$  induced by bending for the  $i^{\text{th}}$  floor can be approximated by the equation

$$\Delta_{Bi} = (\tan \varphi + \lambda \tan \omega) H_i \quad (1)$$

where  $\varphi$  is the angle of HBDP of the story below;  $\omega$  is the change in angle of HBDP of the story;  $H_i$  is the height of the story; and  $\lambda$  is a correction coefficient (set as 0.5 in the present study).

The displacement induced by shear  $\Delta_{Si}$  for the  $i^{\text{th}}$  floor can be calculated as

$$\Delta_{Si} = \Delta_{Ti} - \sum_{i=1}^N \Delta_{Bi} \quad (2)$$

where  $\Delta_{Ti}$  is the lateral displacement, and  $N$  is the total number of floors.

Two normalized difference parameters  $D_{VBi}$  and  $D_{BTi}$  are defined to represent the relationship of the boundary nodes.

$$D_{VBi} = \frac{N(\alpha_{HBDPi} - \beta_{HVDPi})}{\sum_{i=1}^N (|\alpha_{HBDPi}| + |\alpha_{HVDPi}|)} \quad (3)$$

$$D_{BTi} = \frac{N(\Delta_{Ti} - \Delta_{Bi})}{\sum_{i=1}^N (|\Delta_{Ti}| + |\Delta_{Bi}|)} \quad (4)$$

The introduction of these two hypothetical planes, along with the two normalized difference parameters, provides the theoretical foundation for the subsequent updating of the macro-scale model.

## 2.2 Model construction and recognition

To account for the coupling of bending and shear in high-rise structures, a macro-scale model framework was constructed using spring elements, as shown in Figure 6. Each floor is composed of four identical vertical members, two identical outside horizontal members, and one inside horizontal member. Spring elements that represent the axial, shear, and bending stiffnesses of each member are shown in Figure 7. The  $6 \times 6$  member stiffness matrix relating the axial, transverse, and rotational degrees-of-freedom for each node of the 2-node member with spring elements is given in Equation (5) and (6).

Figure 6. Macro-scale model of the high-rise structure.

Figure 7. Member with springs

$$\frac{1}{\eta} \begin{pmatrix} k_a \eta & & & & & \text{sym.} \\ & 2k_b k_s & & & & \\ & k_b k_s l & k_b^2 + k_b k_s l^2 & & & \\ -k_a \eta & & & k_a \eta & & \\ & -2k_b k_s & -k_b k_s l & & 2k_b k_s & \\ & k_b k_s l & -k_b^2 & & -k_b k_s l & k_b^2 + k_b k_s l^2 \end{pmatrix} \quad (5)$$

$$\eta = 2k_b + k_s l^2 \quad (6)$$

The macro-scale model of the typical 40-story frame core tube structure is constructed using ANN and simulated modal monitoring data. As shown in Figure 8, natural frequencies, lateral mode vectors, angular mode vectors of the HBDP,  $D_{VB}$  and  $D_{BT}$  were selected as the features. The stiffness of the springs was the target to be recognized, i.e., a total of 7 stiffness coefficients ( $k_a$ ,  $k_b$ ,  $k_s$ ,  $k_{hb}$ ,  $k_{hs}$ ,  $k_{ihb}$  and  $k_{ihs}$ ).  $k_a$  is the axial stiffness,  $k_b$  and  $k_s$  are the bending and shear stiffness of the column,  $k_{hb}$  and  $k_{hs}$  are the bending and shear stiffness of the outside horizontal members, while  $k_{ihb}$  and  $k_{ihs}$  are the bending and shear stiffness of the inside horizontal members. The initial values of the stiffness parameters were roughly estimated through a small number of trial calculations, as shown in Table 1. 20000 samples were generated through Latin square sampling with the combination of different stiffness change ranges as shown in Table 2 and batch modal analysis. A type of ANN that is conducive to utilizing the spatial information between data, Convolutional Neural Networks (CNN) incorporating channel and spatial attention mechanisms (CBAM-CNN) [11] were used, and a (non-learnable) Fixed attention layer (FixAL) was selectively added to manually assign weights to different features [12]. The specific network architecture and hyperparameter settings of the ANN are shown in

Table 3 and Table 4, respectively.

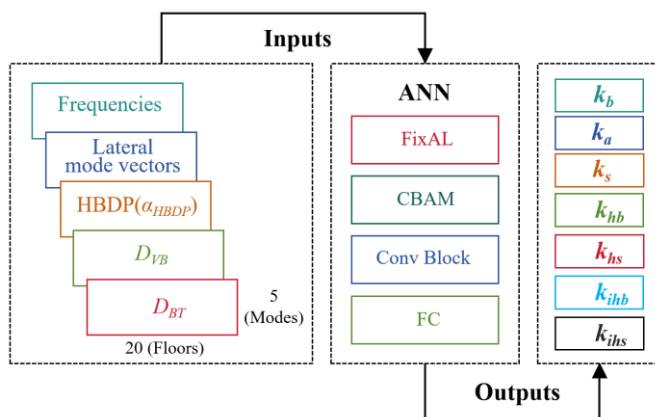

Figure 8. ANN model construction.

Table 1. Stiffness parameters

Stiffness	Initial	Recognized
$k_a$	$7.00 \times 10^7$	$6.92 \times 10^7$
$k_b$	$1.50 \times 10^{14}$	$1.58 \times 10^{14}$
$k_s$	$1.00 \times 10^{12}$	$9.87 \times 10^{11}$
$k_{hb}$	$8.00 \times 10^{13}$	$7.90 \times 10^{13}$
$k_{hs}$	$1.00 \times 10^{14}$	$9.87 \times 10^{13}$
$k_{ihb}$	$4.00 \times 10^{13}$	$3.94 \times 10^{13}$
$k_{ihs}$	$1.00 \times 10^{14}$	$9.88 \times 10^{13}$

The units of  $k_s$ ,  $k_a$ ,  $k_{hs}$ ,  $k_{ihs}$  are N/mm; and the units of  $k_b$ ,  $k_{hb}$ ,  $k_{ihb}$  are N-mm/rad

The learning curve is shown in Figure 9, and the recognized stiffness parameters with the developed ANN model are shown in Table 1. With the recognized stiffness parameters, the macro-scale model of the typical high-rise frame core tube building was constructed. The modal analysis of the macro-scale model was carried out as shown in Figure 10. Comparison of the dynamic characteristics of the macro-scale model and original full-order model is shown in Table 5, Figure 11, Figure 11 and Figure 12. It is evident that the recognized model provides a good fit for the macro-scale mechanical properties of the original full-order model.

### 3 MULTI-SCALE DIGITAL TWIN

#### 3.1 Multi-scale model

The macro-scale model proposed above can only analyze the structural response at the overall level of each floor. However, for certain special structural components or critical load-bearing areas, it is desirable to analyze the structural response of specific components.

Based on the proposed macro-scale model, this paper employs the transmission of boundary condition information to perform structural response calculations at the component level for substructures, thereby achieving multi-scale digital twins. The key to the method lies in constructing a boundary condition transmitter, as shown in Figure 14, which can expand and map the macro-scale deformation of a certain floor to the deformation of each boundary node on that floor. This paper constructs the boundary condition transmitter using the proposed HBDP, HVDP, and the proportional relationships of the modal vectors corresponding to each floor's boundary nodes under their first-order modes, as shown in Equations (7), and (8).

$$\Delta_{Bi} = \alpha_{HBDPi} M_{Bi} \quad (7)$$

$$\Delta_{Vi} = \beta_{HVDPi} M_{Vi} \quad (8)$$

where  $\Delta_{Bi}$  and  $\Delta_{Vi}$  are the bending and vertical displacements of the  $i^{\text{th}}$  node of the story in question, respectively;  $M_{bi}$  and  $M_{vi}$  are the displacements of the  $i^{\text{th}}$  node of the story in question per unit angle of  $\alpha_{HBDPi}$  and  $\beta_{HVDPi}$ , respectively.

The lateral displacement of each node is consistent with the lateral displacement of the macro-scale model. Using the displacements of the macro-scale model to map the displacements of the boundary nodes of the substructure model, the substructure's deformation can now be realized. The construction of the boundary condition transmitter can be refined according to the requirements, and can even further consider the coupling relationship between displacements of different degrees of freedom, which will be a subject of further research.

Figure 14. Deformation transfer from boundary nodes to the substructure.

#### 3.2 Substructural response

To verify the feasibility and accuracy of the proposed multi-scale model, the 20<sup>th</sup> and 21<sup>st</sup> floors of the high-rise frame core tube structure were selected as the objects of study. The mapping relationship  $M_{B19}$ ,  $M_{V19}$  and  $M_{B21}$ ,  $M_{V21}$  were established and the substructure model of the 20<sup>th</sup> and 21<sup>st</sup> floors was built. A static analysis was employed for an initial attempt (as shown in Figure 15a), specifically by applying a 1000 kN force in the horizontal direction on the topmost floor of the macro-scale model. The lateral deformations and HBDP and HVDP angles of the 19<sup>th</sup> and 21<sup>st</sup> floors were calculated. Subsequently, the displacements of the boundary nodes of the substructure were calculated using Equations (7) and (8) and applied to the substructure. The deformations of the substructure were further calculated and are depicted in Figure 16.

Figure 15. Deformation of the models.

Figure 16. Deformation of the substructure (magnified).

For reference, a static analysis was performed on the original full-order model under the same loading condition. Meanwhile, the displacements of all nodes on the 20<sup>th</sup> floor for each degree of freedom were extracted from both the original full-order model and the substructure model for comparative study. Their absolute mean values and relative errors are shown in Table 6. The results show that the lateral displacement exhibits good agreement, while certain discrepancies exist in the vertical and torsional displacements. This is because the applied load distribution differs from the inertial force distribution during structural vibration.

Table 6. Comparison of the static deformation of the models

DOF	Absolute mean deformation		Error (%)
	Original model	Substructure model	
Lateral (mm)	4.40	4.54	3.26
Vertical (mm)	0.55	0.45	20.63
Torsional (rad)	9.03e-05	7.10e-05	21.40

Incremental dynamic analyses were then conducted on both the original full-order model and the multi-scale model by applying the north-south component of the El Centro seismic wave with a total duration of 20 seconds. A Rayleigh damping ratio of 0.05 was assigned to the first five modes of the structures. Table 7 presents the absolute mean values and relative errors of time-history displacements for all degrees of freedom (DOF) at the 20<sup>th</sup>-floor nodes. Taking Node 10 on the 20<sup>th</sup> floor (shown in Figure 1) as an example, Figure 17 presents a comparison of time-history displacements for three degrees of freedom. As can be observed, the substructure model can effectively replicate the deformation characteristics of the full-order model. Some frequency shifts occur in the terminal vibration phase due to the minor omission of frequencies in the macro-scale model, as well as the accumulation over multiple cycles.

Notably, the multi-scale model's dynamic analysis required only 20 minutes of computational time (16 minutes for macro-scale model and 4 minutes for substructure model), significantly less than the full-scale model's 27 hours and 12 minutes under identical hardware configuration, achieving a

balance between computational efficiency and the demand for accuracy of the local components.

Table 7. Comparison of the dynamic deformation of the models

DOF	Absolute mean displacement		Error (%)
	Original model	Substructure model	
Lateral (mm)	4.23	4.43	4.58
Vertical (mm)	0.43	0.40	-7.23
Torsional (rad)	7.29e-05	7.27e-05	-0.36

#### 4 CONCLUSION

This paper proposes a multi-scale digital twin method for high-rise structures. Taking a high-rise frame core tube structure as an example, a macro-scale model of the high-rise structure was constructed using a combination of spring elements, considering the coupling of bending and shear as well as the impact of the horizontal members on the structure. The macro-scale model was updated by combining Artificial Neural Networks (ANN) and modal monitoring data. Furthermore, an information transmitter was constructed using a linear mapping method to transfer the deformation from the macro-scale to the boundary nodes of the substructure at the story level, thereby enabling the calculation of deformations at the component scale of the substructure. The multi-scale digital twin method for high-rise buildings established in this study not only improves

the efficiency of model updating and computation, but also meets the need for high-precision computation of local components.

**ABSTRACT:** The torsional performance of a structure significantly impacts the safety and service life of high-rise buildings. Due to deviations between real structures and design models, it is essential to evaluate the torsional performance of in-service high-rise buildings. This paper proposes a method for evaluating the torsional performance of in-service high-rise buildings based on the measured period ratio. By abstracting the high-rise building as an equivalent cantilever beam model with unidirectional eccentricity, the free vibration equation of the structure is derived, and the relationship between the period ratio, stiffness ratio, eccentricity, and radius of gyration is analyzed. The results indicate that changes in the period ratio can reflect the torsional performance of the structure. Based on the Latin Hypercube Sampling (LHS) and Kernel Density Estimation (KDE) methods, the probability density function and cumulative distribution function of the period ratio are established, and a four-level classification method for torsional performance is proposed. Application to a 40-story high-rise building validates the method. The research results provide a new theoretical basis and practical guidance for evaluating the torsional performance of in-service high-rise buildings.

**KEY WORDS:** Torsional performance assessment; Period ratio; High-rise buildings; Structural health monitoring.

## 1 INTRODUCTION

The torsional effect of high-rise buildings under external loads is a significant factor affecting their service performance. As building height increases, the dynamic response of structures to horizontal excitations such as wind loads and seismic actions becomes more complex, and the torsional effect significantly intensifies [1-7]. Torsional vibrations can lead to the redistribution of internal forces within the structure, exacerbate damage to local components, and even trigger overall instability. For instance, during the 1995 Kobe earthquake, several high-rise buildings experienced asymmetric damage due to torsional effects, further underscoring the importance of torsional control [8-9]. Therefore, the assessment and optimization of torsional performance have become central issues in the design and safety maintenance of high-rise buildings.

Accurately assessing the torsional performance of high-rise buildings is crucial for ensuring their service safety. Currently, domestic and international codes primarily evaluate the torsional performance of structures indirectly through parameters such as the period ratio. Article 3.4.3 of the Chinese code *Code for Seismic Design of Buildings* (GB 50011-2010) [10] explicitly stipulates that the period ratio (the ratio of torsional period to translational period) should not exceed 0.9 to avoid significant torsional irregularity; Article 4.3.5 of the Chinese code *Technical Specification for Concrete Structures of Tall Buildings* (JGJ 3-2010) [11] further specifies that strengthening measures are required when the period ratio exceeds 0.85. Similarly, the American ASCE 7-22 code also limits torsional effects through modal participation mass ratios [12]. However, these methods are largely based on theoretical models during the design phase and struggle to reflect the time-varying characteristics of torsional performance during service due to material degradation, load variations, and accidental eccentricities [13-14].

To bridge the gap between theoretical models and real structures, there is an urgent need to obtain actual dynamic

parameters of in-service buildings through Structural Health Monitoring (SHM) technology [15-17]. The period ratio, as a key indicator reflecting the torsional stiffness and mass distribution of a structure, can be dynamically updated through long-term monitoring data, thereby providing a more accurate assessment of the trends in torsional performance. However, there is currently a lack of research on the evaluation of in-service torsional performance based on measured period ratios.

This paper proposes a method for evaluating the torsional performance of in-service high-rise buildings based on measured period ratios, encompassing the following main aspects: Firstly, a theoretical relationship between the period ratio and the stiffness ratio, eccentricity, and radius of gyration is established using an equivalent cantilever beam model. Secondly, a probabilistic distribution of the period ratio is constructed using Latin Hypercube Sampling (LHS) and Kernel Density Estimation (KDE), and a four-level torsional performance classification standard is proposed. Finally, the engineering applicability of the method is validated using a 40-story reinforced concrete frame-shear wall structure as an example. The research results provide new theoretical foundations and practical guidance for the assessment of torsional performance in in-service high-rise buildings.

## 2 CLASSIFICATION METHOD FOR TORSIONAL PERFORMANCE LEVELS

### 2.1 Analysis of influencing factors of period ratio

To facilitate analytical derivation and computational modeling, a series of idealized assumptions are implemented in the structural characterization of the target high-rise building. Specifically, the structural system is postulated to exhibit unidirectional eccentricity along the Cartesian coordinate system - that is, a deliberate offset is introduced between the center of mass and the center of stiffness exclusively in the X direction, while maintaining perfect spatial coincidence of these two critical centers in the orthogonal Y direction. This intentional asymmetrical configuration is adopted to isolate and

investigate the torsional effects induced by eccentricity along a single principal axis, thereby simplifying the coupled lateral-torsional vibration analysis.

The entire high-rise building is abstracted as an equivalent cantilever beam element with prescribed geometric and material properties, as schematically illustrated in Figure 1. The rationale behind this modeling approach stems from multiple considerations: Firstly, the cantilever beam provides a mathematically tractable framework for solving equations of motion. Secondly, the unidirectional eccentricity assumption enables parametric investigation of torsion-translation coupling mechanisms without introducing unnecessary computational complexity from bidirectional interactions.

Figure 1. Schematic diagram of structural eccentricity.

The undamped free vibration motion equation of the structure is

$$\begin{bmatrix} M & \\ & J_c \end{bmatrix} \begin{bmatrix} \ddot{u}_y \\ \ddot{\theta} \end{bmatrix} + \begin{bmatrix} K_y & e_x K_y \\ e_x K_y & K_\theta \end{bmatrix} \begin{bmatrix} u_y \\ \theta \end{bmatrix} = \begin{bmatrix} 0 \\ 0 \end{bmatrix} \quad (1)$$

where  $M$  is the mass of the high-rise building;  $J_c$  is the mass moment of inertia about the center of mass,  $J_c = Mr^2$ , and  $r$  is the radius of gyration of the structure relative to the center of mass;  $u_y$  is the translational displacement in the Y direction;  $\theta$  is the torsion angle of the high-rise building;  $K_y$  is the translational stiffness in the Y direction,  $K_y = \sum_{i=1}^n K_{yi}$ , and  $K_{yi}$  is the horizontal lateral stiffness of the structural member in the Y direction;  $K_\theta$  is structural torsional stiffness,  $K_\theta = \sum_{i=1}^n K_{xi} x_i^2 + \sum_{i=1}^n K_{yi} y_i^2$ ,  $K_{xi}$  and  $K_{yi}$  are the horizontal lateral stiffness of the structural member in the X and Y directions respectively, and  $x_i$  and  $y_i$  are the distances from the component to the mass center, respectively;  $e_x$  is the eccentricity in the X direction.

Assume the response of the structure is

$$u_y(t) = A_y \sin(\omega t + \alpha) \quad (2)$$

$$\theta(t) = A_\theta \sin(\omega t + \alpha) \quad (3)$$

Substituting equations (2) - (3) into equation (1) and simplifying them, the circular frequency of the structure can be obtained. Assuming  $\omega_1 < \omega_2$ ,

$$\begin{cases} \omega_1 = \sqrt{\frac{(K_\theta + r^2 K_y) - \sqrt{(K_\theta - r^2 K_y)^2 + 4r^2 e_x^2 K_y^2}}{2Mr^2}} \\ \omega_2 = \sqrt{\frac{(K_\theta + r^2 K_y) + \sqrt{(K_\theta - r^2 K_y)^2 + 4r^2 e_x^2 K_y^2}}{2Mr^2}} \end{cases} \quad (4)$$

Defining stiffness ratio  $S_y = K_\theta / K_y$ , equation (4) is transformed into the following form:

$$\frac{T_2}{T_1} = \frac{\frac{2\pi}{\omega_2}}{\frac{2\pi}{\omega_1}} = \frac{\omega_1}{\omega_2} = \frac{\sqrt{(S_y + r^2) - \sqrt{(S_y - r^2)^2 + 4r^2 e_x^2}}}{\sqrt{(S_y + r^2) + \sqrt{(S_y - r^2)^2 + 4r^2 e_x^2}}} \quad (5)$$

From equation (5), it can be seen that the ratio of the second-order period to the first-order period  $\frac{T_2}{T_1}$  depends on  $S_y$ ,  $r$  and  $e_x$ .

For eccentric structures, each vibration mode of the structure is composed of the superposition of translational vibration mode and torsional vibration mode. Substitute equation (4) into equations (1) - (3) to solve the ratio of torsional amplitude to translational amplitude  $\frac{A_\theta}{A_y}$  in the vibration mode.

By substituting  $\omega_1$ ,

$$\frac{A_\theta}{A_y} = \frac{(\eta_y - r^2) - \sqrt{(\eta_y - r^2)^2 + 4r^2 e_x^2}}{2r^2 e_x} \quad (6)$$

By substituting  $\omega_2$ ,

$$\frac{A_\theta}{A_y} = \frac{(\eta_y - r^2) + \sqrt{(\eta_y - r^2)^2 + 4r^2 e_x^2}}{2r^2 e_x} \quad (7)$$

Equations (6) and (7) are the ratios of the amplitudes of the torsional direction to the translational direction in the first-order vibration mode and the second-order vibration mode, respectively.

For in-service high-rise buildings, the radius of gyration  $r$  remains constant; stiffness ratio  $S_y$  varies with the increase in service years; due to variations in live load distribution during the service life of the structure, as well as changes in stiffness of individual components over the same period, leading to shifts in the stiffness center, therefore the eccentricity  $e_x$  varies throughout the entire service life of the structure. The relationship between the torsional displacement ratio, stiffness ratio and eccentricity is shown in Figure 2.

As can be seen from Figure 2, the curve of the period ratio is divided into two parts: the rising section on the left side and the falling section on the right side. According to the calculations, for the rising section on the left side, the first-order vibration mode is torsion, and the second-order vibration mode is Y-direction translation. For the falling section on the right side, the first-order vibration mode is Y-direction translation, and the second-order vibration mode is torsion. Regarding the eccentricity, as the eccentricity increases, the ratio of the second-order period to the first-order period decreases.

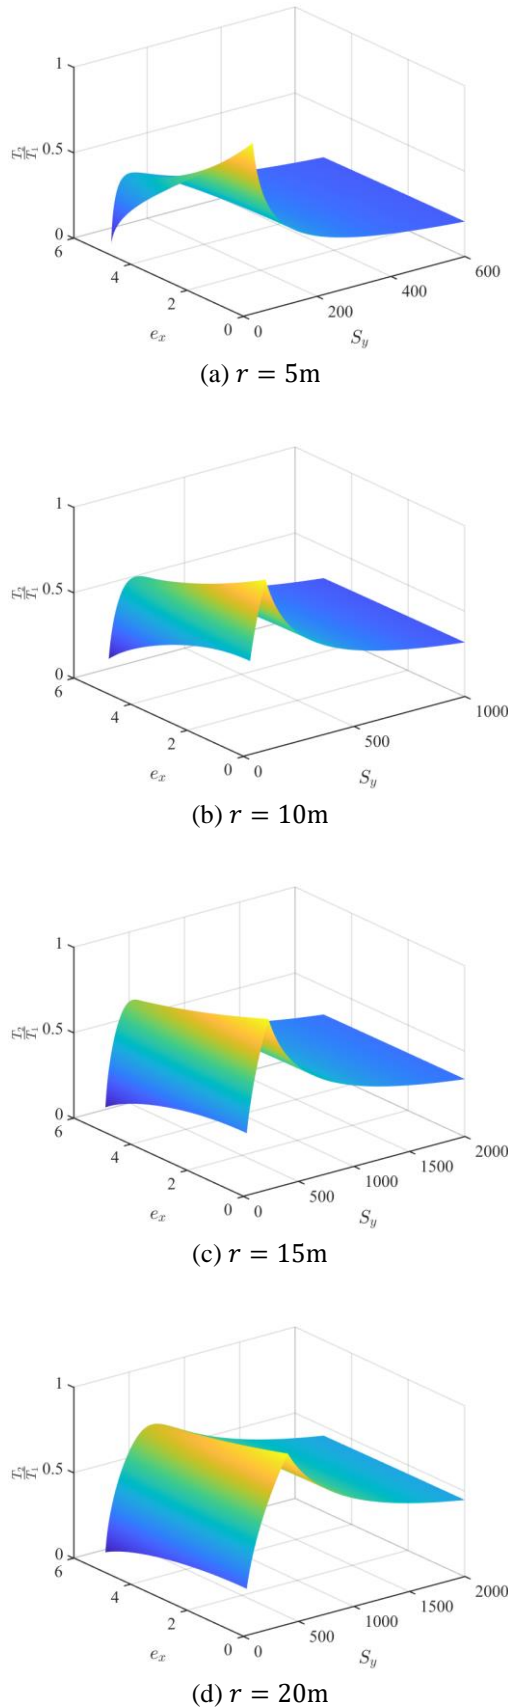

Figure 2. Period ratio curve.

## 2.2 Performance level classification method

As mentioned in Section 2.1, for in-service high-rise buildings, the radius of gyration  $r$  remains constant, while the eccentricity  $e_x$  and stiffness ratio  $S_y$  may vary. Regarding eccentricity, the Chinese code *Code for Seismic Design of Buildings* (GB 50011-2010) defines torsional irregularity in Clause 3.4.3 as follows: "Under the specified horizontal forces with accidental eccentricity, the ratio of the maximum value to the average value of the elastic horizontal displacement (or story drift) of the lateral force-resisting members at both ends of a story is greater than 1.2." Additionally, Clause 3.4.5 of the Chinese code *Technical Specification for Concrete Structures of Tall Buildings* (JGJ 3-2010) stipulates: "Under the specified horizontal seismic forces considering the influence of accidental eccentricity, the maximum horizontal displacement and story drift of the vertical members of a story should not exceed 1.2 times the average value of the story for Class A high-rise buildings, and should not exceed 1.5 times the average value of the story. For Class B high-rise buildings, mixed structures exceeding the height of Class A, and complex high-rise buildings referred to in Chapter 10 of this specification, the maximum horizontal displacement and story drift should not exceed 1.2 times the average value of the story, and should not exceed 1.4 times the average value of the story." Both code provisions mention the concept of "accidental eccentricity". Accidental eccentricity refers to the incomplete coincidence of the mass center and the stiffness center of a structure due to factors such as construction errors, material inhomogeneity, and uncertain load distribution, which results in additional torsional effects under external loads. To account for this uncertainty, seismic codes typically specify the introduction of an accidental eccentricity in calculations, generally taken as 5% of the structural plan dimensions. Therefore, it can be assumed that during the service life of the structure, the eccentricity follows a normal distribution, where the mean value of the eccentricity is the eccentricity of the design model. When the eccentricity is the mean value plus 5%, the distribution function of the eccentricity approaches 1 (here set to 0.999). This can be expressed in the following formula:

$$\mu_{e_x} = e_{xM} \quad (8)$$

where  $e_{xM}$  is the structural eccentricity obtained from the design model.

Assuming the distribution function of the eccentricity  $e_x$  is  $F_{e_x}$ , converting it to a standard normal distribution allows for the determination of the variance of the eccentricity  $e_x$ .

$$F_{e_x}(e_{xM} + a \cdot 5\%) \approx 0.999 \quad (9)$$

$$\sigma_{e_{xM}} = \frac{e_{xM} + a \cdot 5\% - e_{xM}}{3} = \frac{a \cdot 5\%}{3} = 0.01667a \quad (10)$$

$$\sigma_{e_x}^2 = 0.000278a^2 \quad (11)$$

where  $a$  is the length of the structure in the X direction.

Assuming the initial stiffness ratio of the structure is the same as that in the structural design model or digital twin model, the degradation function of the stiffness ratio follows an exponential function. That is, the variation of the stiffness ratio with service years, denoted as  $S_y(t)$ , is as follows:

$$S_y(t) = S_{yM} e^{-0.005t} \quad (12)$$

where  $S_{yM}$  is the structural stiffness ratio calculated by the structural design model or digital twin model;  $t$  is the service time in years.

Since  $t$  is a deterministic variable (assuming  $t$  ranges between 0 and 50),  $S_y$  is a deterministic function of  $t$ . Consequently, the distribution of  $S_y$  is contingent upon the distribution of  $t$ . Assuming that  $t$  follows a uniform distribution, the probability density function of  $S_y$  can be derived as follows:

$$f_{S_y}(S_y) = f(x) = \begin{cases} \frac{4}{S_y}, & S_{yM}e^{-0.005 \times 50} \leq S_y \leq S_{yM} \\ 0, & \text{others} \end{cases} \quad (13)$$

A Latin Hypercube Sampling (LHS) of  $e_x$  and  $S_y$  is performed, where  $e_x$  follows a normal distribution and  $S_y$  adheres to the distribution specified in equation 13. LHS is a statistical method for generating a near-random sample of parameter values from a multidimensional distribution. It is a form of stratified sampling that ensures that the entire range of each variable is represented in the sample. The method divides the distribution of each variable into intervals of equal probability and selects one sample from each interval. This approach guarantees that the samples are more evenly distributed across the range of possible values than in simple random sampling, leading to more precise and reliable results, especially in the context of computer simulations and sensitivity analyses. LHS is particularly useful when dealing with complex models that require significant computational resources, as it can reduce the number of simulations needed to achieve a given level of accuracy.

The period ratio of the sample is calculated according to equation (5), and the Probability Density Function (PDF)  $F$  of the period ratio is obtained by fitting using Kernel Density Estimation (KDE). KDE is a non-parametric statistical method used to estimate the probability density function of a random variable. Unlike parametric methods, KDE does not require any assumptions about the data distribution (e.g., normal distribution) and instead estimates the density function directly from the data itself. The core idea is to treat each data point as the center of a "kernel function" (e.g., Gaussian kernel, uniform kernel, etc.) and then sum all these kernel functions to form a smooth density curve.

After obtaining the probability density function of the period ratio  $\frac{T_2}{T_1}$ , it can be integrated to derive the distribution function of the period ratio  $\frac{T_2}{T_1}$ . Based on this distribution function, the torsional performance can be classified into four levels, as shown in Figure 3. Specifically,  $\frac{T_2}{T_1}|_1 = F^{-1}(0.20)$ ,  $\frac{T_2}{T_1}|_2 = F^{-1}(0.35)$ ,  $\frac{T_2}{T_1}|_3 = F^{-1}(0.50)$ ,  $\frac{T_2}{T_1}|_4 = F^{-1}(0.65)$ ,  $\frac{T_2}{T_1}|_5 = F^{-1}(0.80)$ ,  $\frac{T_2}{T_1}|_6 = F^{-1}(0.95)$ . The ordinate in Figure 3 represents the closeness coefficient, which is a concept within the Fuzzy Analytic Hierarchy Process (FAHP). FAHP is a decision analysis method that integrates fuzzy mathematics with the Analytic Hierarchy Process (AHP), designed to address issues of uncertainty and fuzziness. In FAHP, the closeness coefficient quantifies the proximity of alternatives to the ideal solution. The closeness coefficient indicates the

optimality of the alternatives, with values approaching 1 signifying more ideal solutions. This coefficient offers decision-makers a straightforward metric for ranking alternatives and is extensively applied in multi-criteria decision-making scenarios.

### 3 ENGINEERING APPLICATION

#### 3.1 Project overview

The high-rise building under investigation is a 40-story reinforced concrete frame-shear wall structure, with a total height of 150 meters. The lower section (1st to 5th floors) has a story height of 4.8 meters, while the upper section (6th to 40th floors) maintains a uniform height of 3.6 meters per story. In the longitudinal direction, the structure comprises five spans measuring 8.4 m, 5.7 m, 5.7 m, 5.7 m, and 8.4 m respectively, resulting in a total length of 33.9 meters. Transversely, the building features four spans with dimensions of 8.4 m, 8.4 m, 3.9 m, and 7.5 m, accumulating to a width of 28.2 meters. The structural design incorporates a floor dead load of 5.0 kN/m<sup>2</sup> and a live load of 2.0 kN/m<sup>2</sup>. Detailed specifications regarding component dimensions and material properties are provided in Table 1, while Figure 4 illustrates the structural layout of the high-rise building. A comprehensive three-dimensional finite element model was developed using midas Gen software, with the complete model visualization presented in Figure 5.

Table 1. Basic information of beams, columns, and shear walls.

Component type	Floor	Size	Material
Column	1-5	900mm×900mm	C60
	6-20	800mm×800mm	C60
	21-40	700mm×700mm	C60
Beam	1-5	500mm×1000mm	C60
	6-20	400mm×800mm	C60
	21-40	300mm×600mm	C60
Coupling Beam	1-5	500mm×1000mm	C60
	6-20	400mm×800mm	C60
	21-40	300mm×600mm	C60
Shear Wall	1-5	Thickness 500mm	C60
	6-20	Thickness 400mm	C60
	21-40	Thickness 300mm	C60

Figure 4. Layout plane of the high-rise building.

Figure 5. Three-dimensional finite element model.

It can be observed that the structure does not exhibit eccentricity in the X direction, but does have eccentricity in the Y direction. The modal analysis of the structure was conducted using midas Gen, and the results are presented in Table 2 and Figure 6. The first mode shape corresponds to translational motion in the Y direction with a period of 4.338 seconds. The second mode has a period of 3.424 seconds and is primarily characterized by translational motion in the X direction, with a component of torsional motion. The third mode shape is torsional, with a period of 2.321 seconds.

Table 2. Vibration period of the structure.

No.	Period(s)	Direction
1	4.338	Y
2	3.424	X
3	2.321	T

### 3.2 Torsional performance levels

This paper separately discusses the methodology for classifying the torsional performance levels of structural service based on the ratio of the third-order period to the second-order period  $\frac{T_3}{T_2}$ . Initially, the radius of gyration  $r$  of the structure is obtained based on the finite element model. For the high-rise building examined in this study,  $r = 13.50\text{m}$ .

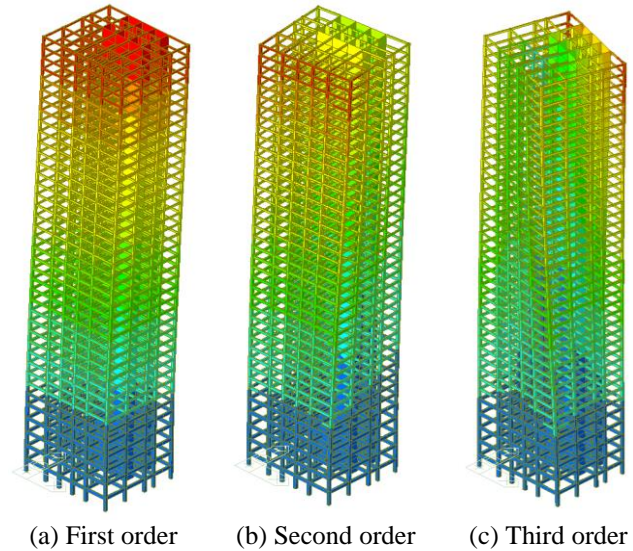

Figure 6. Structural vibration mode.

First, values of  $e_y$  and  $S_x$  are sampled using LHS, as illustrated in Figure 7 (a) and (b), respectively, with  $\mu_{e_y} = 1.35\text{m}$ ,  $\sigma_{e_y}^2 = 0.2211$ , and  $S_{xM} = 391.63$ . The  $\frac{T_3}{T_2}$  values for the samples are then calculated using equation (5), as shown in Figure 7 (c).

(a)  $S_x$ 

(b)  $e_y$

Figure 7. Latin Hypercube Sampling of parameters.

The KDE was applied to fit Figure 7 (c), resulting in the probability density distribution function of the period ratio, as illustrated in Figure 8. Subsequently, the cumulative distribution function of the period ratio was obtained by integrating the probability density function, which is depicted in Figure 9. The membership function of the in-service torsional performance of the structure is shown in Figure 10.

Figure 8. Probability density function of  $\frac{T_3}{T_2}$ .

Figure 9. Cumulative distribution function of  $\frac{T_3}{T_2}$ .

Figure 10. Membership function of torsional performance.

## 4 CONCLUSIONS

This paper proposes a method for evaluating the torsional performance of in-service high-rise buildings based on the measured period ratio, establishing a relationship between period ratio, stiffness ratio, eccentricity, and radius of gyration. Using Latin Hypercube Sampling and Kernel Density Estimation, a four-level classification method for torsional performance was developed and validated through a 40-story reinforced concrete frame-shear wall structure. The findings provide a new theoretical and practical approach for assessing torsional performance, bridging the gap between design models and real-world structural behavior.

**ABSTRACT:** To determine damage and its effects, dense time series data is required, along with information from other sources like temperature changes that influence the main damage parameter and the structure itself. This allows the assessment of structural behavior, separating periodic and temperature-related effects from damage and ageing-related changes in load-bearing capacity. However, existing monitoring systems often lack proper documentation on measured values and their limits. Analog systems, suitable for early service life monitoring, provide readings at long intervals (years). Poor accessibility to remote measuring points further limits comprehensive time series data, including temperature correlations and other environmental correlations.

This article presents an approach that can be used to digitize different types of sensors and measuring devices in order to enable the autonomous and continuous generation of measurement data. The examples range from displacement transducers to force measuring devices, which were already installed in analogue form on existing civil engineering structures. The aim is to use digitalization to demonstrate a simple and cost-effective approach on using existing measurement technology as an initial basis for giving a statement about the behavior of the structure, its state of preservation and thus, in addition to supplementing the inspection process, also serve as a starting point for further monitoring.

**KEY WORDS:** SHM, monitoring, retrofitting, structural behavior, autonomous sensors, digitalization.

## 1 MONITORING AND STRUCTURAL BEHAVIOUR

### 1.1 Introduction

Bridges, tunnels, retaining walls, and similar structures are critical components of road and rail infrastructure. Over time, these structures inevitably age and deteriorate, necessitating regular maintenance and thorough safety assessments in form of inspections. As traffic volumes and loads continue to rise, maintenance intervals are shortened, and budget is limited such evaluations become even more essential.

Given the high costs of maintenance and the even greater expense of premature renewals, accurate assessment and prediction models are crucial (predictive maintenance). These models must be based on precise, objective, and physically accurate data that can be derived from inspections, sample testing, and monitoring.

Most infrastructure operators have their assets already digitalized and manage those via databases and graphical interfaces. This already digitalized data contains master data, drawings, information from the newly built structure and sometimes 3D-presentations of the structure. Periodic data on the state of preservation, such as inspection reports and laboratory analyses, are crucial for assessment. However, they are often not yet digitalized, preventing automated processing.

As part of the research project Candice, which was done for the Austrian Motorway Operator (ASFiNAG), a database with a graphical web interface has already been established to address this issue [1]. Additionally, forecasts for maintenance measures and a condition index have been calculated [2, 3]. Monitoring data was also incorporated into these calculations.

While data fusion was still largely manual, the approach demonstrated the effectiveness of combining monitoring data with condition data from other investigations.

This paper focuses on the transfer from a mostly manual reading of analogue measurement devices to an automated data transfer from the object under consideration to a data-platform, where an automatic storage is done and an individual display of relevant data to the user is possible. The digitalization especially with IoT devices allows for a constant flow of data, that offers several advantages for the assessment of structures:

- Direct measurement of physical values, ensuring accuracy vs. no subjective/false readings;
- Long-term data collection, capturing variations due to time of day, seasonal changes, temperature, humidity vs. usually 1 value per year or less at different seasons and environmental conditions influencing the measurement;
- Capture of rare or extreme events and influences of effects due to extreme weather conditions, earthquakes, sudden load impacts, settlements;
- Quantitative data providing objective insights for decision making rather than subjective evaluations based on a visual inspection of the structure;
- Elimination of human bias, ensuring reliability in assessments;
- Basic data set for extrapolation purposes related to the future behaviour of the structure;
- Real time integration with simulation and prediction models, enhancing cost planning, maintenance planning and resource management.

Figure 1: Interplay of the monitored assets (sensors and nodes), the data transmission, the platform, and the user.

In inspections the influence of temperature is frequently underestimated or too conservatively interpreted. In general, physical measures that are affected by environmental conditions are often difficult to assess, this holds for loads of pre-stressed anchors, inclinations, or displacements of components. As mentioned earlier accurate information is crucial to be used as a valid basis for decisions related to the maintenance, the safety assessment of the object and overall, the asset management combining both.

By leveraging monitoring, infrastructure managers can make informed decisions, optimize maintenance strategies, and extend their structures lifespan, making it a cost-effective solution. The description of the system used here clearly shows that digitalization and installing monitoring equipment are no longer hurdles.

### 1.2 IoT Type Monitoring

The IoT monitoring system presented and used in the following examples is an autonomous, innovative solution that enhances infrastructure monitoring for clients and contractors. It is in operation since many years across various applications and has already proven its reliability, robustness, and ease of use.

The system comprises of three main components as schematically shown in Figure 1:

1. On-site installation – sensors and IoT nodes placed on infrastructure assets are easily applicable even in areas without power access;
2. Data transmission network – nodes wirelessly transmit data to the platform for real-time assessment and can even be included into warning and alarm models;
3. Data platform – a secure database with evaluation models and web dashboards.

The design of the system for an autonomous operation, with battery-powered sensor nodes is capable of functioning for up to 15 years. Eliminating the need for fixed power sources significantly reduces installation complexity and associated disruptions, such as traffic closures. Data transmission is encrypted and automated, ensuring secure and reliable monitoring.

Key features and advantages of such an IoT system are:

- Plug & Forget: Fully automated system monitoring, with alerts for any issues;

- Edge Computing (AIoT): Onboard processing reduces data load and enables intelligent evaluation;
- Flexible Data Integration: External data sources can be fused for enhanced analysis;
- Instant Alerts: Critical conditions trigger automatic notifications via email, SMS, or warning and alarm systems;
- Real-Time Access: Mobile Apps and web-based dashboards provide instant insights - no additional software required;
- Data transmission is encrypted and automated, using the latest wireless technology.

The sensor node ( $16 \times 11 \times 7$  cm) is designed for harsh environmental conditions and ensures robust performance. It provides power to sensors, controls measurement cycles, stores data, and transmits information via low power WAN (1.5 km range in urban areas, 20+ km in open environments). The node supports multiple sensor connections (1, 2, or 6 channels), enabling flexible deployment across different assets.

The system requires no on-site configuration or specialized technical knowledge, significantly simplifying installation. Proper sensor mounting remains critical for ensuring measurement accuracy, though once installed, the network configuration and data transfer are entirely automated and need no interaction by the installation team. Furthermore, the system supports a wide range of sensor types, including:

- Displacement, strain, and force gauges;
- Pressure and temperature sensors (for air, solids, and liquids);
- Humidity sensors (ambient and material-based, including dew point calculations);
- Pluviometers and acoustic sensors for environmental monitoring;
- Corrosion monitoring and cathodic protection assessment;
- Water level measurement
- Water content and pore pressure determination in soils;
- Inclinations (for piers, retaining walls, mast, settlement of buildings and excavations ...).

Energy efficiency is a key design consideration, with preference given to low-power sensor alternatives to maximize battery life.

## 2 SELECTED APPLICATIONS

### 2.1 Reasons and benefits

As structures age, the parameters used to assess structural safety and durability worsen. This is particularly crucial for structures that approach their planned service life or which are in environments where environmental or load parameters change significantly over time. Examples here are the ground water conditions in geotechnical engineering or the impact due to winter maintenance such as de-icing agents. Due to the ageing infrastructure in Europe and most parts of the world digitalization of existing structures can be one tool to help address these issues with respect to longer lasting and safe infrastructure especially along road and railway networks.

By implementing dense monitoring systems, structures can be evaluated based on real-time, precise measurements rather than relying on conservative estimates dictated by standards. This approach can offer the possibility to extend the service life of structures by accurately measuring loads and issuing alerts before critical situations arise. The importance of such measurements increases as structures age, making digitalization even more crucial for older structures compared to newer ones.

However, most of the already installed measurement equipment is still analogue, nevertheless a wide range of these can be digitalized. In geotechnical engineering structures are often equipped with extensometers and inclinations for the determination of movements, load cells for the measurement of the currently applied anchor force and additionally, temperature and humidity measurements are available.

In the following some applications will be presented showing the potential of digitizing already existing measurement equipment and therefore offering an easy and cost-effective first insight into the behavior of a structure.

### 2.2 Digitalization of anchor load measurements

The retaining wall discussed here is shown in Figure 2 and is in service since the mid-1990s and some anchors are equipped with analog load measurement systems often applied in Austria.

Figure 2: View of the anchor wall.

In the course of an inspection, no serious defects or damages were found on the wall and the adjacent areas and a generally good state of preservation was attested. However, it was recognised that some of the anchor load measuring devices were only partially functional. Furthermore, a comprehensive time series regarding the anchor loads was not given.

For this reason, it was investigated how the existing hydraulic load cells could be reprocessed for analogue readings and how

digitalisation would be possible. The digitalization solely required an additional hydraulic connection and a smart node, which could easily be installed within one hour at the site.

Figure 3: Time-series of anchor load measurements on three anchors along a cross-section.

Measurements show that the anchor loads are temperature-dependent, with significant variations throughout the year as shown in Figure 3. The observations further show that the higher capacity hydraulic load cell (indicated as LPM 1000) exhibits smaller force variations, than the two smaller (LPM 750) ones.

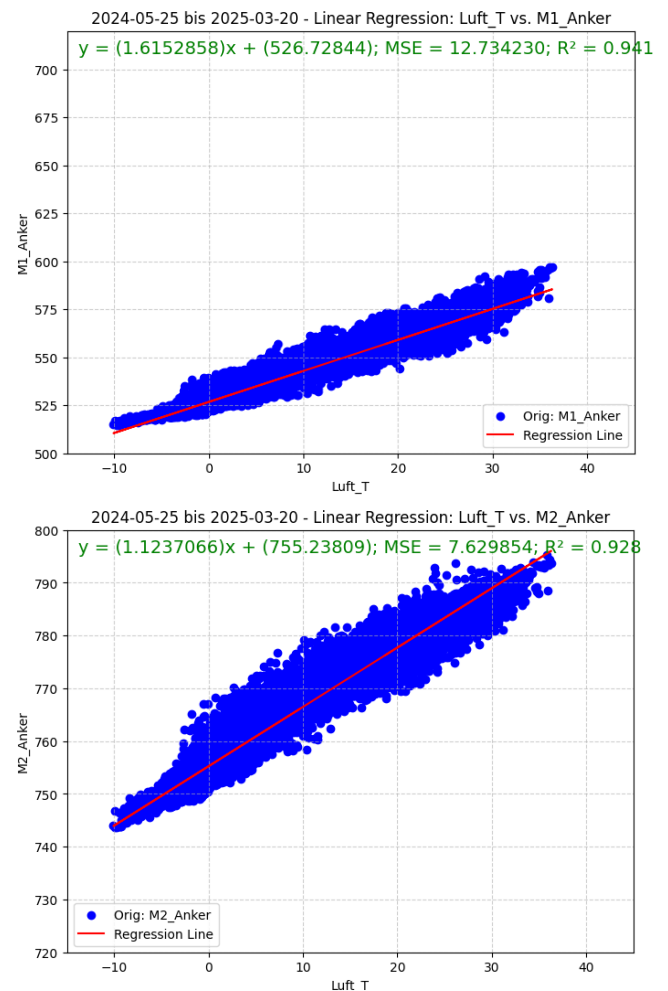

Figure 4: Correlation between anchor load (ordinate) and air-Temperature (abscissa) over a period of 1.5 years; top: M1 (LPM 750); bottom: M2 (LPM 1000).

Figure 4 illustrates the correlation between currently applied anchor load and air temperature for the two different LPM sizes, which were 750kN and 1000kN as given in the designation. It can be easily observed that there is an almost linear correlation between the anchor load measured and the air temperature. Thus, the change of the anchor load versus the air temperature can be calculated for:

1.55 kN/°C	LPM 750
1.10 kN/°C	LPM 1000

These values may be unique for the configuration found at this site and may not be applicable to other sites or structures. Nevertheless, those ranges of temperature related measurement results for anchor load plates are in alignment with the experience from anchor wall inspections as well as analogue readings of such measurement equipment.

### 2.3 Digitalization of extensometers

Figure 5 shows a detail of a extensometer of a retaining wall that is in service since decades. Based on observations during an inspection, it was recommended to shorten the measurement intervals, as the prevailing boundary conditions were now assessed to be more critical. In order to bridge the period until the structural reinforcement could be carried out, a suitable permanent monitoring system was implemented.

The extensometers were upgraded with nodes and sensors so that data was immediately available online and limits could be monitored 24/7. During the dense monitoring phase, a torrential rain event changed the environmental conditions even more. The new system was able to detect this immediately and action could be taken if necessary. Later, during the construction phase for the installation of new prestressed grouted anchors, valuable insights were also gained regarding the impact of anchor drilling on the system behavior of the structure.

Other applications include anchor force monitoring, bridge joints, pier tilting and deflection. Autonomy in the field is a must for economical implementation or upgrade of such monitoring.

Figure 5: Upgrade of existing extensometer for 24/7 and online measurement.

### 2.4 Static and dynamic crack width measurements

Crack monitoring was conducted on the center span of a three-span (45/70/45 m) cantilever bridge [4], where cracks were observed in the bottom plate and the webs of the hollow box. These cracks occurred in the transition zone, where the floor slab shifts from prestressed to non-prestressed, near the anchorages. Cracks in the floor slab are located within the prestressed zone, inclined at approximately 45° to the bridge axis, while those in the web follow a similar angle with continuous prestressing in this area.

Crack width monitoring, represented in green in Figure 6, covers five to six equally spaced cracks (~20 cm apart). The cracks run perpendicular to the measurement indications, with individual widths reaching up to 0.3 mm and a total width (sum of individual cracks) of up to 1.2 mm. Each group of cracks is monitored collectively, with the total crack width recorded. Warning thresholds were set for immediate detection of critical crack widths. Figure 7 illustrates crack width variations over a year. While significant, these variations remain within acceptable limits. Temperature measurements were incorporated to account for thermal deformations, as shown in Figure 7. The right-side diagram reveals that lower temperatures generally correlate with greater total crack widths, though the temperature effect is minimal. Detailed investigations revealed sudden spikes in crack width readings, suggesting abrupt crack openings. These spikes were detected in measurements taken at 15-minute intervals, indicating that dynamic loads were not fully captured by these static readings. To assess dynamic loads, the system was switched remotely to dynamic measurement mode, eliminating the need for on-site visits. In this mode, 10 measurements per second were taken and processed in the node (edge computing), evaluating maximum, minimum, and mean values over 5-minute intervals. On the platform, the dynamic range of crack width was calculated as the "Total Crack Width Range @ 5-minutes" (TCWR), representing the difference between maximum and minimum values within a 5-minute slot. Figure 8 shows the TCWR over a week, highlighting significant variations. During weekends, the TCWR remains low due to Austria's truck driving ban, with a notable increase at 22:00 on Sundays when the ban is lifted, peaking at 0.4 mm. Similar peaks occasionally occurred at 19:00 on weekdays. The highest TCWR (0.4 mm) was used to calculate the stress range in the reinforcement. Since mean stress is less influential for such steels, stress range remains the dominant fatigue parameter. The stress range calculation followed Eurocode 2 but incorporated refined parameters from literature [5]. Results indicated a dynamic stress range of ~90 N/mm<sup>2</sup>, well below critical limits. Combined with static calculations of mean stress, the findings confirm that reinforcement stresses are not critical.

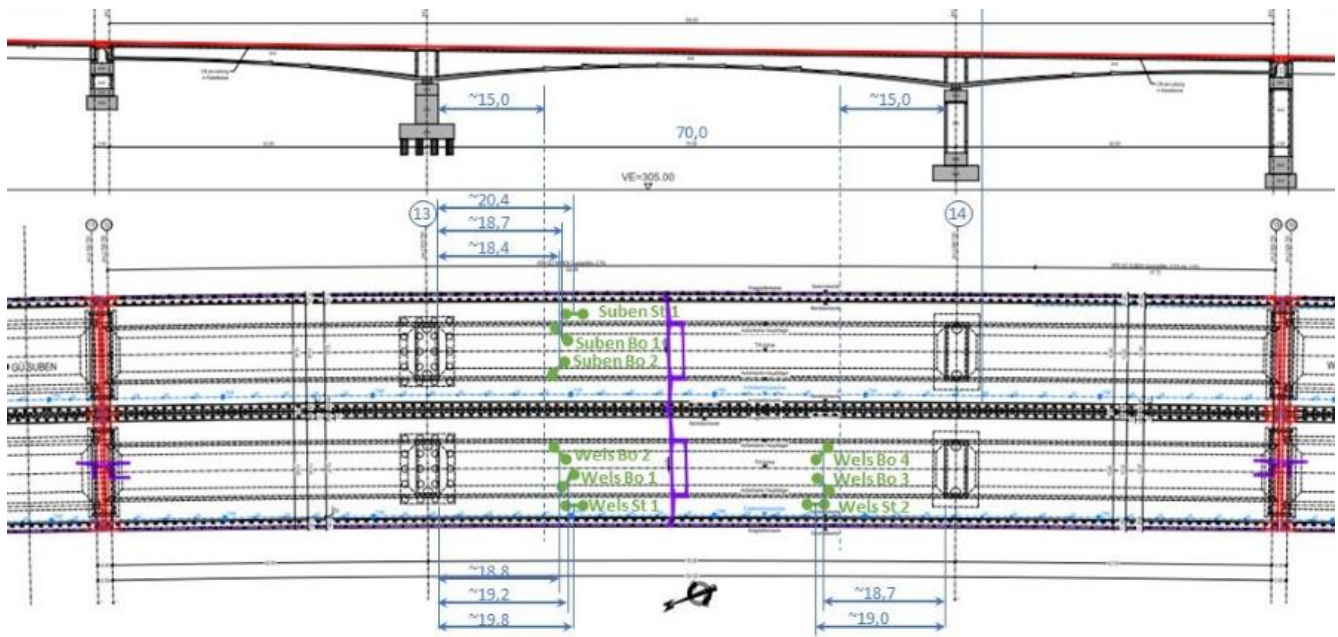

Figure 6: Overview of the three-span cantilever bridge. The monitoring of the total crack width is shown in green and the cracks run perpendicular to the measurements.

Figure 7: Variation of crack width for one year. Left diagram shows the values vs. time and the right diagram shows the values vs. concrete temperature.

Figure 8: Max-Min-range of crack width for one week.

Energy consumption in dynamic measurement mode is higher due to continuous recording, processing, and data transmission at higher intervals. Battery life in this mode is estimated at ~1 months. However, after one week in dynamic mode, the system was switched back to 15-minute intervals for routine crack monitoring. The system has been operational for 4.5 years, with battery replacement expected in over six years.

The digitalization of the crack measurement was here an absolute game change because with manual readings it would have been enormously costly, the readings would not have been so dense, the temperature dependence would have been difficult to determine and dynamic measurements would not have been possible. through the digitalization of crack measurement, not only were costs saved by reducing on-site visits (and costs for lifting platforms), but the measurements also provided significantly more assessment options. This reduced the number of unknown effects and enabled a more detailed analysis, leading to a focused, durable, and cost-efficient rehabilitation.

### 3 DESIGN OF EXISTING STRUCTURES WITH AN INCREASED KNOWLEDGE LEVEL

There are currently only limited technical and legal guidelines on how to deal with existing infrastructure - especially with regard to existing damage or defects. Although there are already corresponding principles and concepts for this in maintenance and asset management, there is still a lack of corresponding guidelines and regulations, particularly in terms of recalculation and assessment.

Although the application of numerical models and the use of high-quality material laws can be used to define the bandwidths here, realistic modelling - especially of damage - is only possible to a limited extent. An example of this can be found in bridge construction. ÖNORM B 4008-2 [6] has laid the foundation for the recalculation of existing structures. Here, for example, the load models can be adjusted based on monitoring the traffic loads. This thus corresponds to a real load, which in turn can enable a more truthful design of the component loads and, above all, the deformations.

Furthermore, the integration of monitoring systems into this process could make a significant contribution. With regard to the difficulties of verifying the serviceability limits, the models can be adapted to a digital twin by comparing them with monitoring results. Based on such processes, damage patterns and their effects on the load-bearing behavior can also be taken into account more accurately.

### 4 CONCLUSIONS & SUMMARY

Using an IoT-based monitoring system provides a scalable, autonomous, and cost-effective approach to long-term infrastructure assessment. Its combination of wireless communication, edge computing, and real-time data processing enhances decision-making for maintenance and safety assessments. By eliminating complex on-site configurations and reducing energy consumption, such systems offer a robust and sustainable solution for modern infrastructure monitoring that does not require extensive training of workers on site.

The digitalization of existing structures is essential for extending the service life and ensuring safety, especially as

ageing and deteriorate prolong. Many structures, particularly in geotechnical and structural engineering, already have measurement systems in place, such as extensometers, inclinometers, and load cells. By upgrading these systems with modern sensors and online monitoring, real-time data can replace conservative assumptions, enabling more precise assessments. This helps detect critical changes early, preventing failures and reducing maintenance costs.

As infrastructure worldwide continues to age, digitalization becomes increasingly important to maintain structural integrity efficiently. Furthermore, with the progression of climate change-related effects such as the rise in mean temperature or the more frequent occurrence of torrential rainfall events, a more rapid increase in possible damage is to be expected, especially for civil infrastructure. Autonomous, cost-effective monitoring solutions can therefore offer a new possibility for monitoring, health inspection and structural assessment and can be seen as a valid basis for the asset management and the decision making related to it.

The presented applications demonstrate how existing measurement devices can be seamlessly integrated into digital systems, providing valuable insights for long-term structural health management.

### ACKNOWLEDGMENTS

We like to thank the Austrian Railways (ÖBB) and Austrian Motorways (ASFINAG) for their support in research projects that supported these results.

**ABSTRACT:** Installing and maintaining structural health monitoring (SHM) systems on infrastructure assets can be expensive. These systems may produce large volumes of data that require processing and interpretation before the behaviour of the asset can be understood and assessed. However, in-depth understanding typically also requires knowledge of asset construction details and loading patterns. These data may be produced and stored using disparate systems, databases, and file types, creating additional challenges for data fusion and interoperability.

Additionally, there has been an increasing trend towards public bodies providing access to their data either reactively because of freedom of information requests, or proactively to encourage use by researchers or to allow others to provide innovative products or services using the data in ways not anticipated by those generating and providing them.

This paper presents potential strategies to leverage publicly available data from sources such as Network Rail Open Data Feeds, Rail Data Marketplace, OpenRail Data, OpenStreetMap and others, to contextualise and increase the value of SHM data. Data are considered from four instrumented railway bridges in the U.K., each of varying steel, concrete, and masonry construction. This paper presents scenarios by which these data might be used to gain network-level insights into other structures on the network and discusses the current difficulties in achieving this in practice.

**KEY WORDS:** Open data, Structural Health Monitoring, Data formats, Digital Twins.

## 1 INTRODUCTION

It is becoming increasingly common for structural health monitoring systems (SHM) to be deployed to monitor key transport infrastructure such as bridges. Interpretation of data generated by these systems is often challenging and may require additional information. For example, to understand the strains or deflection of a bridge deck it is also necessary to understand the applied loading, including loading from passing vehicles, or from environmental factors such as wind, or temperature. This requirement usually results in additional sensors being specified for the monitoring system.

For road bridges, detecting traffic can be done using lane occupancy sensors, cameras, or weigh-in-motion strips. As road traffic is usually completely unscheduled, there is no information known a priori about the traffic crossing the bridge. Interpreting these data can be challenging and it may be tempting to consider using machine learning (ML) techniques or computer vision to identify the type and position of vehicles. In some cases, such as in Bridge Weigh-In-Motion (B-WIM) systems where the primary purpose of the monitoring system is to weigh the road traffic [1], there may be sufficient sensor coverage to infer vehicle type directly from axle loads. However, in general vehicle identification may not be straightforward.

This need not however be the case for most railways. Railway operations, timetables, and signalling are increasingly digitised. The railway is a known environment, at least as far as those responsible for operating the railway are concerned. These data are already used to provide information to

passengers, e.g. through passenger information screens at stations. The data are also available to third-party developers of smartphone apps and websites. Leveraging data from railway timetables and signalling systems as an additional source of information for a bridge structural health monitoring system may mitigate the need for some sensors on the assets themselves.

### 1.1 Background

In 2015 researchers at the Centre for Smart Infrastructure and Construction (CSIC) at the University of Cambridge installed fibre-Bragg grating (FBG) strain and temperature gauges on two new railway bridges during construction: Bridges IB5 and UB11 in Staffordshire, UK.

Figure 1: Bridge IB5, Staffordshire, U.K.

Bridge IB5, shown in Figure 1, is of steel beam construction with an in situ concrete deck carrying two railway tracks [2],

while Bridge UB11, shown in Figure 2, is constructed from nine pre-tensioned concrete beams with an in situ concrete deck.

The initial goal of the project was to evaluate the potential benefits of installing instrumentation during construction and to create ‘self-sensing’ bridges as technology demonstrators for fibre-optic sensors and for Structural Health Monitoring in general. These were newly constructed bridges and so there was no concern regarding structural integrity, although the fibre-optic sensors were used to investigate creep and shrinkage of the concrete from pre-tensioning, through installation and after commissioning [3].

Figure 2. Bridge UB11, Staffordshire, U.K.

Initially the two Staffordshire bridges did not have permanently installed fibre-optic analysers or data loggers as there was no permanent power supply available on site. However, a power supply was provided in 2021, and permanent monitoring systems were installed, with IB5 upgraded with additional accelerometers, cameras and laser-based axle sensors [4]. These accelerometers and axle sensors were added to augment the existing FBG-based strain instrumentation to create a bridge weigh-in-motion (B-WIM) system [5].

Figure 3. Bridge HDB-19, London, U.K.

Subsequently, the centre also instrumented several other railway structures in the U.K. including Victorian and Edwardian masonry arch bridges, both of which were monitored due to potential concerns with the structures: Bridge HDB-19 in London – a three-span bridge instrumented with FBG strain and temperature sensors, and acoustic emission sensors; and CFM-5 in Yorkshire – a single span bridge instrumented with FBG strain sensors alongside conventional strain and displacement sensors and videogrammetry monitoring [6,7].

Figure 4. Bridge CFM-5, Yorkshire, U.K.

The monitoring systems on the two masonry arch bridges both used solar power. Despite using large deep-cycle batteries and multiple solar panels, these systems do not function 24 hours a day – the systems thus miss the structural response of the bridges for most train crossings.

### 1.2 Automated Train Identification

To interpret strain, deflection or accelerometer data measured during a crossing of a train over a bridge it is usually necessary to know information about the type of train, including axle loads and spacings. Trains of similar types are likely to produce similar responses, whereas trains of differing types may result in responses that are more difficult to compare.

Various techniques have been used to attempt train identification automatically. Alexakis *et al.* [8] limited their analyses of trains crossing the Marsh Lane viaduct, a masonry arch structure in Leeds, U.K., to only one type of train – the Class 185 three-car diesel multiple unit (DMU). Peak detection was used to identify train bogies and thereby determine which trains consisted of three carriages, while a comparison of readings from two adjacent arches was used to determine the train direction. The purpose of the monitoring was to evaluate whether the condition of the structure was deteriorating over time. Using a single train type allowed a comparison of the structural response from similar loading conditions on different dates. The trains identified as Class 185 trains represented approximately 50% of the traffic crossing the viaduct. Later analyses [9] identified other types of three-car train and Statistical Shape Analysis and a Support Vector Machine (SVM) was used to further classify these trains into Class 185, Class 155/158 and Class 170 respectively. The results were checked by visual observations of passing trains.

Cheng *et al.* [10] used gradient-based decision trees to identify and classify trains crossing Bridge CFM-5. A subset (4,900 out of 7,100) of train crossings identified using FBG strain data from July 2020 to October 2021 was labelled using timetable data obtained ‘by scraping publicly available records’. These labels were used to train a model using XGBoost [11] to classify trains based on features in the strain data such as number and spacing of peaks, amplitude and width of peaks etc. This model was then able to classify 930 further train crossing events over an 8-month period in 2023 achieving a classification accuracy of 97%.

To classify trains crossing Bridge IB5 where axles spacing and loading are provided via the B-WIM system, the authors used t-SNE (t-Distributed Stochastic Neighbour Embedding) – a statistical technique to group crossing trains into distinct

groups by reducing the dimensionality of input data. Input data include the number of axles, axle spacing, speed, axle loads etc. t-SNE is used to reduce these to just two dimensions which can then be plotted.

Figure 5. Groups of trains identified by t-SNE and DBSCAN unsupervised train classification

A clustering algorithm such as the Density-Based Algorithm for Discovering Clusters in Large Spatial Databases with Noise (DBSCAN) [13] is then used to distinguish separate groups of trains appearing as clusters within the plot.

Table 1. Labels assigned to groups shown in Figure 5 by manual inspection of video from on-bridge cameras

Label	Description	%
A	Class 390 9 car	2.28
B	Class 390 11 car	3.36
C	2 x Class 221 5 car (10 car total)	1.08
D	Class 350 175 tonne Direction 1	6.64
E	New Measurement Train	0.09
F	Class 220 4 car + Class 221 4 car (8 car total)	0.95
G	Class 221 4 car + Class 221 5 car (9 car total)	0.86
H	Class 221 5 car + Class 221 4 car (9 car total)	0.72
I	Class 220 4 car + Class 221 5 car (9 car total)	5.68
J	Class 221 5 car	11.27
K	Class 221 4 car	1.20
L	Class 350 165 tonne Direction 1	15.46
M	Class 220 4 car	9.85
N	Tamping Machine	0.18
O	Freight Locomotive	0.21
P	Class 221 5 car + Class 220 4 car (9 car total)	5.79
Q	Class 221 4 car + Class 220 4 car (8 car total)	1.14
R	Class 350 165 tonne Direction 2	14.41
S	Class 350 (axle detectors missed one axle)	0.13
T	2 x Class 350 (8 car total)	0.08
U	2 x Class 220 4 car (8 car total)	8.86
V	Freight Train	1.92
W	Class 350 175 tonne Direction 2	7.00
	Outliers	0.84

Figure 5 shows the plot resulting from 18,800 data points each representing a train. Only northbound trains are included due to limitations of the B-WIM system.

By referencing plots of the axle loads and inspecting video recordings from the cameras positioned on the bridge, labels may be manually assigned to these groups.

Some types of train such as the Class 220 Voyager and Class 221 Super Voyager look similar but may be distinguished using axle weights. Class 221 trains are heavier as they include tilting bogie mechanisms, absent on the Class 220. Similarly, Class 350 Desiro trains appear in four distinct groups on the plot. This is because there are two types within the class with differing total weights. This is likely because early Class 350 trains have dual-voltage capability and are able to use either the third rail system or overhead line equipment, while later Class 350s lack the third-rail pickup [14]. The axle loads are also asymmetric front to back relative to the direction of the train, which leads to two further groups.

Once labelled, the data can then be used as training data for ML techniques such as Random Forest [15] or XGBoost which can then be used to classify future trains.

Other methods that may be used for classifying trains on Bridge IB5 utilise computer vision (CV) and video from the on-site cameras directly. One such CV technique uses a vertical strip of pixels from each frame of a video of a passing train to produce a single 2D image where the x-axis represents time. Examples of such images are shown in Figure 6. A manually labelled set of these images is then used to train a model from a partially pretrained convolutional neural network (CNN) with Keras [16] as the deep learning framework. A dataset of 543 trains was randomly selected, of which 462 were used for image classification, split 85%/15% between training and testing images, respectively.

Figure 6. Examples of (a) Double 4-car Class 220/221, (b) 9-car Class 390, (c) 4-car Class 350, and (d) 5-car Class 221 trains approaching Bridge IB5. The still images are converted from moving video, with time along the x-axis

The results obtained are presented in Table 2 using a confusion matrix. These show classification accuracies of around 90% on average across all train classes. The CNN-based model achieved high classification accuracy despite the relatively small dataset of 543 samples, demonstrating the merit of the approach. However, it also highlights limitations which may not necessarily be solved by increasing the size of the training dataset.

Table 2. Confusion matrix of CNN-based train classification algorithm.

		Predicted				
		350	220/1 4-car	220/1 5-car	2×220/1 4-car	390
Actual	Train Class					
	350	96%	4%			
	220/1 4-car	6%	88%	6%		
	220/1 5-car		22%	78%		
	2×220/1 4-car				83%	17%
	390					100%

In particular, the model performs best when distinguishing visually distinct train types, but struggles with more subtle variations, such as between 4- and 5-car variants of Class 220/221 trains. These misclassifications suggest that incorporating additional features beyond image data, such as train speed or axle spacing, could significantly enhance model performance. Future work will explore hybrid models that combine visual and sensor-based inputs, as well as alternative machine learning techniques such as recurrent neural networks (RNNs) for temporal data or multimodal architectures that can process both image and numerical inputs simultaneously.

Computer vision techniques are however only applicable on SHM systems that incorporate cameras, such as the installation at Bridge IB5. It is also vulnerable to issues caused by poor lighting conditions such as at night or caused by inclement weather conditions leading to water or ice on the lens.

## 2 PUBLICALLY AVAILABLE RAIL DATA SOURCES

### 2.1 Network Rail

In the U.K. Network Rail is the organisation responsible for maintaining the track, signalling, most stations and operation of the railway in England, Scotland and Wales. It is not responsible for running train services, which are currently run by passenger and freight train operating companies (TOCs).

Network Rail provides access to some of its operational data including dynamic data on signalling, train movement data, and real-time performance measures, along with static data such as scheduling data and background data needed to interpret these datasets. Accessing the data requires registering an account on the Network Rail Open Data Platform [17] which is free of charge. The dynamic data are streamed via an ActiveMQ message queue connection, which requires a constant connection. Static data is available to download daily or monthly. These datasets have been used by mobile app developers to provide real-time information to passengers, such as the platform from which their train will depart, or whether their train is running late. The available datasets include:

- TD (Train describer): This is a real-time feed of train movements between signalling ‘berths’. The signalling ID

(or ‘headcode’) for each train is given, along with a ‘to’ and ‘from’ berth number representing a train movement. The signalling ID is only unique within a given signalling region at any one time. Berth numbers are not unique either. Timestamps are to the nearest second.

- TRUST (Train movement): This is another real-time feed of train movements between timing point locations (TIPLOCs), usually stations and junctions. Different message types describe train activation, movement, cancellation. Timestamps are provided to the nearest 30 seconds.
- SCHEDULE and VSTP: These provide details of services that are due to run. The schedule is updated once per day. Each service in the schedule can either be a one-off service, or be valid for a number of days, weeks or months. The VSTP dataset (Very Short-Term Plan) is a real-time feed of additional one-off services for ad-hoc movements not in the main schedule.

Documentation for the feeds is available on a wiki-style website [18] maintained by enthusiasts. Example source code of ActiveMQ clients able to fetch the data feeds is also available in multiple programming languages on GitHub [19].

Historical train movement data are not available from the Network Rail Open Data Feed. This limitation is not generally an issue for app developers but does limit what is available for interpreting past data from monitoring systems.

### 2.2 Rail Delivery Group

The Rail Delivery Group (formerly the Association of Train Operating Companies) in the U.K. provides additional feeds and APIs collectively known as DARWIN, which offer data for live departure and arrival screens, including estimated arrival and departure times for delayed trains. Also provided is the Historical Service Performance (HSP) API for historic performance data. HSP can be used to query details of past services, such as planned and actual arrival and departure times. However, as the DARWIN and HSP datasets are primarily used for passenger information they do not contain information about freight trains, and only list arrival and departure at stations, not showing the times when trains pass junctions.

### 2.3 Rail Data Marketplace

The Rail Delivery Group also runs the Rail Data Marketplace. This is a platform on which train operating companies, infrastructure providers, data aggregators, researchers, or rail enthusiasts may release datasets. Datasets include the Network Rail and Rail Delivery Group feeds described above, but also data on train operators’ carbon footprints, car park occupancy, train accessibility, fare information, occupancy and loading, complaints etc. Data providers may specify either an open or restricted licence for the data, and have the option of making data available publicly, or only to subscribers. The data may be made available free of charge or require payment.

### 2.4 OpenRail Data

The OpenRail Data website [24] combines data from the Network Rail SCHEDULE, VSTP and TRUST feeds to provide details of train movements, including cancellations, late/early running arrivals and some details of the type and class of train. Up to three years of historical data may be queried

using a variety of web-based forms, with results returned as an HTML page. The source code is available from a GitHub repository, and so it would be possible to run customised instances of this service, modified to produce output in alternative formats such as JSON or XML. However, this would not include historic data.

### 3 USING OPEN DATA FOR TRAIN IDENTIFICATION

The TD dataset gives timestamps for when trains on the network move between signalling berths. Berths are labelled with four-character identifiers, usually consisting of three or four digits. These do not indicate any human-readable place names, and there does not appear to be any available data linking berths with their geographic coordinates. It is however possible to look at all train movements that occur within a time window either side of a train crossing event as inferred from measurements by a monitoring system. This will result in many candidate berth numbers. Eventually however, after observing enough train crossings it is possible to narrow the berth numbers common to all crossings to find those berths that are likely to be located on either side of the bridge. Figure 7 illustrates one such possible method.

Using data from a typical day:

Create set U of all timestamped train movements from TD data  
Create a list X of timestamped bridge crossing events inferred from SHM data  
Create initially empty set C of candidate TD berth transitions  
Identify train movements in U that coincide (within a tolerance) of the first timestamped crossing event in X and add these movements (without timestamps) to set C  
For each further crossing event E in X:  
    Identify train movements in U that coincide (within a tolerance) with E and intersect these movements (without timestamps) with set C  
Output candidate TD berth transitions from set C

Figure 7. Possible algorithm to deduce TD berth transitions corresponding to train crossings identified by an SHM system

Alternatively, third-party websites such as OpenTrainTimes [23] provide topological track diagrams showing the real-time position of trains using TD data.

By using both TD and also TRUST data (which does include geographical human-readable locations) the creators of these sites have been able to infer the position of berths relative to stations and junctions. Although these track diagrams do not show bridge locations (except for intersection bridges where one railway track crosses another) by using these track diagrams it is nevertheless possible to narrow the search when attempting to identify TD berths located either side of a bridge.

Table 3 shows the berth transitions that most closely correspond in time to observed train crossings for the four instrumented bridges. For Bridges IB5 and UB11, these could be confirmed using the installed bridge monitoring system, while for Bridge HDB-19 these times were verified using

historical data as displayed on the OpenRail Data website [24] and comparing the actual arrival times of trains travelling between Enfield Chase station and Gordon Hill station, the two stations either side of the bridge which are not far apart. There are however points (or switches) north of HDB-19 allowing trains to cross the tracks to access the third platform at Gordon Hill station. Trains heading to or from the third platform have a slightly different berth number transition in the TD feed. For Bridge CFM-5 the crossing times of a few trains were observed and recorded in person during a site visit.

The TD data provides a very good correspondence with bridge crossings for Bridges IB5 and UB11. However, the only useful information provided by the feed besides the timestamp is the signalling ID, known as the headcode, of each train. This provides no train information such as the type of train or possible loading. This must be found either from the TRUST feed or via a third-party website such as OpenRail Data.

Since most of the data from the monitoring systems on these bridges dates from before the authors began logging the TD and TRUST feeds, the possibility of using historical data from OpenRail Data alone was investigated. For Bridges CFM-5 and HDB-19, this turns out to be relatively simple. For Bridge CFM-5 there are no intervening junctions between Church Fenton and Micklefield stations – so any train that reports at both locations consecutively must have crossed the bridge. The only complication is in calculating the most likely time of the crossing as the two stations are approximately 8 km apart, with the bridge located slightly closer to Church Fenton station.

Table 3. TD berth movements that correspond with observed bridge crossings

Crossing	Region	From Berth	To Berth
IB5 northbound	R3	4331	4333
IB5 southbound	R3	4334	4332
UB11 westbound	R3	5611	5615
HDB-19 northbound	Y8	865	869
	Y8	865	X872
HDB-19 southbound	Y8	870	864
	Y8	872	864
CFM-5 eastbound	Y2	709	711
CFM-5 westbound	Y2	714	708

Likewise in the case of Bridge HDB-19, any train reporting at both Enfield Chase and Gordon Hill stations will have crossed the bridge. However, it was noted that in the archived data several services are not shown stopping or passing Enfield Chase station at all. Trains do however all appear to report at Bowes Park station, slight further to the south, so both stations were used when searching for trains crossing the bridge.

For Bridges IB5 and UB11 however, the situation is slightly more complicated. Figure 8 shows the layout of the railway in the Norton Bridge area. Northbound trains travelling between Stafford and Madeley stations either use the West Coast Main Line through Norton Bridge Junction and under Bridge IB5, or they bypass Norton Bridge Junction entirely by crossing Bridge UB11. Northbound trains travelling between Stafford and Stone must cross Bridge IB5, but southbound trains from Stone to Stafford may travel either via Bridge IB5 or via Norton Bridge Junction.

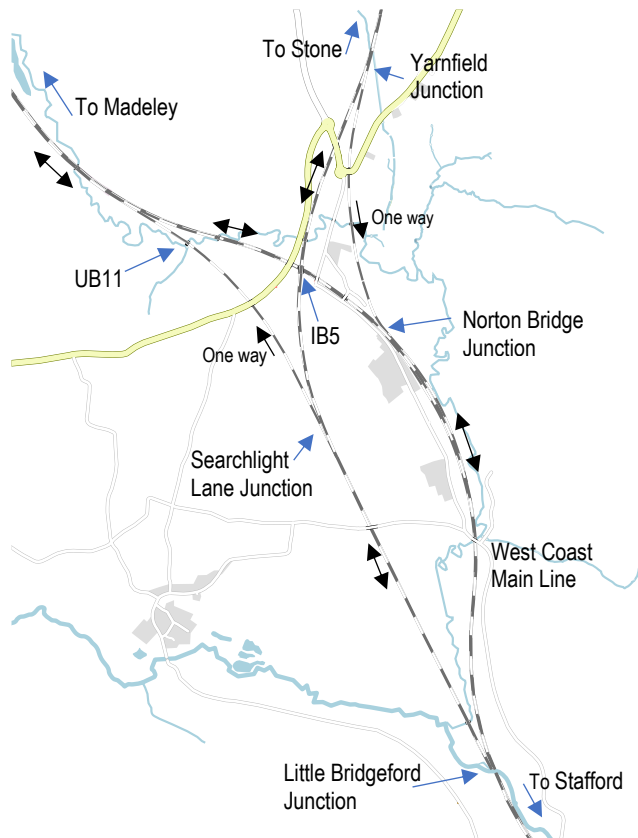

Figure 8. Map showing locations of Bridges IB5 and UB11, railway layout and junctions. (Map data © OpenStreetMap available under Open Database License)

Nevertheless, by inspecting details of several trains crossing the bridges, identifying their headcode ID from TD data, and then looking up details of each train on the OpenRail Data website, sets of rules were developed to identify trains crossing Bridge IB5 and UB11 using only historic data available from the OpenRail Data website.

### 3.1 Train and route information

Information available from the TRUST and Schedule feeds, or the historical data, includes data such as: The Train UID, the train operator code, signalling id (headcode), power, timing load, speed, catering code, seating class, train status etc. and the planned and actual arrival, departure and passing times at each timing point or station along the route.

Of these the power type, timing load and train status are the most useful for train identification. Power type refers to diesel, diesel multiple unit, electric, electric multiple unit or (for the New Measurement Train) 'HST'. Timing load is an overloaded field. It usually contains a number which if greater than 999 describes the declared load in tonnes. Otherwise, this number may indicate the declared load in tonnes, or the class of train – e.g. 350, 390 etc. There are some exceptions: a value of 506 indicates Class 350 upgraded to run at 110 mph (approx. 175 km/h) while a 'V' indicates a Class 220 or 221 train. The train status field indicates whether the train is a passenger or freight train. Any of the fields may be blank.

### 3.2 Comparison with Monitoring data

For the railway bridge monitoring systems that are operational 24/7, such as those on Bridges IB5 and UB11, there should be

SHM data for each train that crossed the bridges, and there should also be trains identified from TD, TRUST, or historic train movement data corresponding to each event. Where this is not the case, this indicates a possible fault with the monitoring system. For Bridge IB5 it is also possible to assess the coverage of the B-WIM system.

As can be seen from Table 1 the t-SNE+DBSCAN algorithm results in many different groupings for otherwise similar trains or combinations of similar trains. However, the train class information derived from the timing load field in archived data from OpenRail Data does not distinguish between Class 220 and 221 trains and lists these as a single class. Similarly, these data do not distinguish between 9 or 11-car Class 390 trains, or the different types of Class 350.

To allow for easier comparison between the loads classified using t-SNE+DBSCAN and traffic identification based on the archived data, similar load classifications from the t-SNE+DBSCAN results for crossings in July 2023 were added together. The results are shown in Table 4.

The classification of trains using groups found by the t-SNE+DBSCAN algorithm shows generally good agreement with the identifications derived directly from open data. The archived data deduced ten more train crossings than trains processed by the t-SNE+DBSCAN algorithm. This discrepancy is partly accounted for by double-crossing events where two trains cross the bridge in opposite directions within a few seconds of each other. The SHM system treats these double crossings as a single event prior to any processing by the B-WIM system.

Table 4. Comparison of B-WIM t-SNE load classifications and traffic identified from historic open data for trains crossing Bridge IB5 in July 2023

Description	B-WIM (t-SNE)		Archived data	
Class 220/221	650	50.94%	658	50.04%
Class 350	401	31.43%	421	32.02%
Class 390	154	12.07%	139	10.57%
Other passenger			7	0.53%
Freight	52	4.06%	60	4.56%
Tamping machine	2	0.16%		
NMT	1	0.08%	1	0.08%
Outliers	16	1.25%		
Total	1276	100.00%	1286	100.00%

Both methods are able to distinguish the New Measurement Train (NMT) from other trains. This train is a modified Class 43 High Speed Train, formerly used to carry passengers, but now instrumented with sensors to measure track alignment and gauge, and photograph defects while travelling at line speed. In the t-SNE+DBSCAN data it appears as its own (small) group labelled as 'E' in Figure 5. In the archived train movement data it is the only train with a train status of 'freight' but with a power type of 'HST' and a speed of 125 mph (approx. 200 km/h).

The B-WIM classifier identified two tamping machines. One of these on 7<sup>th</sup> July 2023 was mis-classified and was actually a 16-axle Class 350 passenger train, as verified by inspecting video of the crossing. However, only 10 axles were detected by the B-WIM system, which may have resulted in the train being incorrectly grouped. The second tamping machine on the

14<sup>th</sup> July as shown in Figure 9 was correctly identified from the B-WIM derived data. However, it was listed in the archived train movement data as a 715-tonne diesel freight train. The accompanying route information for the train showed that it originated at Whitacre Tamping Sidings, which would indicate that it was probably a tamping machine. The declared load of 715 tonnes is significantly larger than the load as shown on a placard on the side of the vehicle (99 tonnes) or the load as measured by the B-WIM system (102 tonnes).

Figure 9. Tamping vehicle heading after crossing Bridge IB5 on 14 July 2023

The archived train movement data are based on SCHEDULE and TRUST data. As previously discussed, these data alone are not able to distinguish between Class 220 and Class 221 trains.

Table 5. Comparison of trains deduced to have crossed Bridge HDB-19 and the FBG strain events recorded by the SHM system.

However, other datasets available on the Rail Data Marketplace may solve this issue. CrossCountry Trains, which operates the Class 220 and 221 trains, makes the planned train formation of each train available. The data are available as daily CSV files and include serial numbers of the individual trainsets to be used for any given service. This is sufficient to determine the train class. Other train operating companies also make train formation data available.

For monitoring systems such as those used on Bridges HDB-19 and CFM-5 where power is supplied by solar panels and batteries, the monitoring system is likely to miss a significant fraction of train crossing events while the system is powered down. Using the data from TD or TRUST can provide an indication of which trains are missed, and whether the crossings that are recorded are likely to be indicative of the loads that typically cross the bridge.

FBG strain events from the SHM system on HDB-19 were compared with trains crossings from archived TRUST data for the period 1<sup>st</sup>–15<sup>th</sup> July 2023. When comparing timestamps between the SHM system and the archived TRUST data, it became apparent that the FBG data did not indicate whether the times had been recorded using UTC or daylight savings time. Since the trains mostly follow a repeating hourly timetable, most train crossings occurring at approximately the same times each hour. When the SHM system was initially installed there was no requirement for the system to synchronize with any external system or data. There was also nothing to prevent clock drift other than an intermittent Internet connection to time.microsoft.com using the NTP client available on Windows. However, after some investigation it appeared that the correlation between crossings and logged FBG events fit better with the archive TRUST data if it was assumed that the FBG timestamps were recorded using daylight savings time and not UTC. This illustrates the importance of looking ahead when specifying and commissioning SHM systems.

Table 5 shows the results of the comparison. It can be seen that approximately three quarters of the trains deduced to have crossed Bridge HDB-19 were not recorded by the FBG strain gauges. As the SHM system is solar powered, it only records data when the solar panels have charged the battery sufficiently for the system to operate, usually from mid-morning to mid-afternoon. Nevertheless, despite missing some classes of train completely, the system was able to record strain data during the crossings of a broadly representative sample of the total population of trains crossing Bridge HDB-19, including freight trains with the heaviest declared loads. However, if all that is required is a ‘standard’ train with which to compare data recorded on the structure from one day to the next to check whether the structural response is changing over time, then the Class 717 train would seem to be a good choice.

#### 4 NETWORK-LEVEL INSIGHTS

The Network Rail data feeds cover the movement of trains throughout England, Scotland and Wales. Once subscribed to the feed, data is available for all train movements on the network, not just in the locations originally of interest. One potential use case of these feeds would therefore be to derive bridge specific traffic models (if not necessarily load models) for every underline bridge, intersection bridge or viaduct on the network. For those bridges located up or down the track from a

bridge instrumented with a B-WIM system, it may even be possible to produce a bridge-specific load model, assuming the bridges have sufficient traffic in common. This however would require knowledge of the location of the bridges on the network, and ideally the locations of berth numbers either side of every bridge.

#### 4.1 Bridge Locations

Through a series of Freedom of Information (FoI) requests made by members of the public, Network Rail have released lists of structures on each line of the network. Data from these FoI requests are available in a curated form on the RailwayData website [21]. The bridges listed do not typically have either WGS84 coordinates, or UK Ordnance Survey (OS) grid reference, but instead are described using the number of miles and yards (or sometimes miles and chains) from some datum which is specific to each line.

Recently however, because of work done within Network Rail as part of its Bridge Strike Prevention Strategy, Network Rail has released a list [22] of low bridges at risk of being struck by road vehicles. As the intended use for the data is that they are incorporated into in-vehicle or smartphone-based GPS systems, this list includes bridge headroom data together with WGS84 and OS grid references coordinates in addition to the usual line/miles/yards location. It provides such coordinates for 5792 bridges, but as it only lists vulnerable bridges it is not a complete list of all underline or intersection bridges, or viaducts. The list includes Bridges CFM-5 and HDB-19, both rail-over-road bridges. It does not however list Bridges IB5 or UB11 as the first is an intersection bridge carrying the railway over another rail line, while the second carries the railway over a stream.

Another option is to use data from OpenStreetMap. OpenStreetMap is a collaborative volunteer organisation that is building a database of mapping data that is released under the permissive Open Database License. However, as a volunteer effort, there are no guarantees as to the accuracy of the data, or that they are consistently labelled in a way that makes it possible to query specific features, such as railways and bridges carrying railways.

As an open project, there are services that build upon OpenStreetMap to allow additional functionality such as searching for specific features within the data using simple queries. Overpass Turbo [26] is one such service. It includes a ‘wizard’ to compose queries from simple prompts.

A prompt such as:

```
"((bridge=yes or bridge=viaduct) and railway=rail) in England"
```

will result in a query that can be passed to the Overpass API with the matching features displayed on a map, as shown in Figure 10.

```
// fetch area "England" to search in
area(id:3608484939)->.searchArea;
// gather results
(
  nwr["bridge"="yes"]["railway"="rail"](area.searchArea);
  nwr["bridge"="viaduct"]["railway"="rail"](area.searchArea);
);
// print results
out geom;
```

Figure 10. Result of running an Overpass API query to find locations of railway bridges and viaducts. (Map data © OpenStreetMap available under Open Database License)

#### 4.2 Signalling berth locations

There are various ways one could consider obtaining the locations of the signalling berths. One option would be to use the GPS position of trains on the network and compare this with the live TD feed. This would give the approximate location of each berth. These could then be compared with the GPS coordinates of the bridges, where known. These data are not provided in any currently available Network Rail open dataset, but third-party app developers of ‘Find My Train’-style apps may have GPS data generated by users of those apps as they travel by train. However, these data may not be open data. SignalBox.io have such a system but require users to sign up for an API key before accessing the data. Other companies such as Raildar, Tracksy.uk, Mistral-data and TrainPositions.com provide similar services under various subscription options.

Train operators in some other European countries do make real-time location data available. Irish Rail (Iarnród Éireann) provide this data via a simple URL, while in Finland train locations may be retrieved using a Real-Time General Transit Feed Specification (GTFS RT) feed or a via a web-based API.

Alternatively, as the location of each bridge is available from data in the FoI requests, albeit in line/mile/yards format, it may be more feasible to calculate TD berth positions in line/miles/yards format too. This could be done by looking at timestamps of TD berth transitions and comparing these with timestamps from TRUST data when trains report at locations with known positions, such as stations. Finding berths either side of a bridge could then be done simply by comparing berth miles and yards locations with bridge miles and yards locations.

## 5 RECOMMENDATIONS

- When planning to install a monitoring system, look for potentially useful open datasets early, whether related to traffic, weather, or anything else.
- Consider any secondary uses that the planned monitoring system may have that could be enabled with relatively small additions. (E.g. Added axle detectors to enable B-WIM that

then provides loading data for other bridges on the network.)

- Treat streaming datasets like sensor data. Data that is used for operational purposes may have little long-term value to the network operator, and these data are often ephemeral. To avoid these data becoming digital waste, log them from day one (or before). Do not assume that somebody else will preserve them.
- Log data first, process later. If datasets are difficult to interpret either because of the sheer volume of information or due to a lack of documentation, log them anyway. They can be processed later once the data are better understood.
- Ensure clocks on any monitoring systems are set accurately. If a permanent connection to the Internet is available this is usually achieved using Network Time Protocol (NTP) to keep clocks synchronised, otherwise, if outdoors, a simple GPS receiver can be used to provide accurate time. When comparing data from multiple sources it is vital that timestamps of data logged by monitoring systems and data from one or more external datasets may be compared. Agree on a time zone.
- Where data from monitoring systems is combined with as-designed and as-built data to form a digital twin, any additional data derived from open datasets should also be incorporated into the digital twin.

## 6 CONCLUSION

A wealth of data exists that can be used to better understand data generated by bridge monitoring systems on Britain's railways. However, the data are unlikely to be generated in exactly the format needed by a monitoring project. They are instead created (and deleted) according to the needs of the network and train operators.

Nevertheless, once a network-level data source has been identified and its potential benefits and limitations understood, it may have the potential to be used for train identification or bridge-specific load or traffic modelling for multiple monitoring projects. Identifying and logging potential data sources early mitigates issues relating to data retention. Data should be logged as early as possible in the project even if the ability to understand them and use them effectively comes later. Machine Learning and AI remain valuable tools with which to understand data generated from monitoring systems, but sometimes there are simpler ways, requiring less computational resources, to achieve the same goal.

## DATA AVAILABILITY

Data supporting this paper are available from the University of Cambridge Repository:  
<https://doi.org/10.17863/CAM.116750>.

## ACKNOWLEDGMENTS

The authors would like to thank Network Rail for making train movement and scheduling data available on their Open Data Feeds site, and for their continuing support of the Staffordshire Bridges and HDB-19 projects.

This work was made possible by the Centre for Smart Infrastructure and Construction (CSIC) and the Laing O'Rourke Centre for Construction Engineering Technology within the Department of Engineering at the University of

Cambridge. We would like to thank Prof. Changsu Shim (심창수) and the Chung-Ang University Industry Academic Cooperation Foundation, South Korea for funding from the 'Development of Digital Engineering Services for Roadside Structure Design, Manufacturing and Construction' project, and thank Chiho Jeon (전치호) and Jongbin Won (원종빈) for their assistance and support. The support of the EPSRC UKCRIC National Research Facility for Infrastructure Sensing experimental facilities (EP/P013848/1) is also much appreciated.

The authors would also like to thank Peter Hicks for maintaining the Rail OpenData Wiki, Phil Wieland for creating and running the OpenRail Data project and the developers of OpenTrainTimes Live Track diagrams website, and the many contributors to OpenStreetMap project.

For the purpose of open access, the authors have applied a creative commons attribution (CC BY) license to any author accepted manuscript version arising.

**ABSTRACT:** This article describes a comprehensive workflow in several phases that integrates the latest information and communication technologies and enables significant improvements in the assessment of both our infrastructure structures, especially our bridge structures, and our building structures. For building construction, the workflow includes not only the PERIOD mode (= PM) for the normal situation, but also a so-called RESCUE mode (= RM), which provides significant support for emergency services in the event of natural disasters such as earthquakes. In all applications in infrastructure and building construction, a digital twin is created along the structural axis in Phase I and automatically converted into a BIM model (= BIM<sub>UAV</sub>). The resulting BIM<sub>UAV</sub> model forms the basis for documenting the general condition of the construction in Phase II, which is referred to as the level of maintenance (= LOM) and documented using component-specific damage catalogs. In both Phases I and II, autonomous multi-agent condition estimation for UAVs and innovative sensor technology (Lidar, GPS, UWB etc.) will be used, the application of which will be demonstrated on a specific bridge project. The anomalies represent performance indicators of the components or structure and are categorized according to component-specific damage catalogs, which also determine the respective degree of damage. The classification of anomalies into damage classes is automated using neural networks or AI. In the infrastructure sector, the algorithm in Phase III enables the asset management of bridge maintainers to conduct real-time condition analyses, service life predictions and estimates of the scope of upcoming refurbishment work using real monitoring data. In building construction, the archiving the LOM in the BIM model carried out in the PM in Phase II represents immense added value for the real estate. The rescue mode (RM) is specifically designed for emergency services and, based on simplified dynamic models in Phase III, enables rapid decision-making support for emergency services on site.

**KEY WORDS:** Monitoring for bridges and buildings, digital twins, BIM, drones, drone-sensor, condition assessment, level of maintenance, condition analysis, service life prediction and refurbishment.

## **1 GENERAL GUIDELINES**

Improvements in information and communication technology like digitizing and the commitment to climate compatibility are leading to disruptive changes to our existing strategies in planning, construction and maintenance concepts as well. [1] Building Information Modeling (BIM) and condition assessment using innovative sensors combined with innovative drone technology (UAV) have led to the disruptive improvements in structural inspection and thus the maintenance of our building constructions, both in the planning and construction process. The workflow described here for largely automated structural inspections in the future integrates the above-mentioned technological improvements for a comprehensive assessment of our existing buildings, both for bridge construction and building construction. This technology transfer in structural inspection helps us, above all, to utilize our existing resources more effectively and, above all, for longer, and in this kind is a significant contribution to climate compatibility in our construction world. The asset management of the bridge maintenance company, which focuses on the implementation and evaluation of structural inspections, is therefore the coordinated activity for the maintenance and therefore important for the national economic of every state.

Structural inspections for our existing buildings must be done regularly and are regulated by regulations, e.g., for buildings, by the ON-B1300 in [2] or by the state-specific building regulations in [3]. For our infrastructure structures, the type and scope of bridge inspections are regulated by the RVS guideline in [4]. The purpose of structural inspections of buildings and infrastructure is to document the level of maintenance (= LOM) of a structure throughout the service life and represents this data an important information with enormous national accounting. If natural disasters, such as earthquakes and explosions disaster as well, occur during a service life, the structural inspection is carried out in the so-called RESCUE mode (= RM). This allows on-site emergency services to receive a rapid, high-quality assessment of the stability of the supporting structure or parts of it. In the research project according to [5], the workflow 3D BUDI for the designated rescue mode was expanded and tested. The described workflow includes a continuous, digitally based structural inspection and, in Phase I, also enables the digitization of the existing building in the form of a BIM<sub>UAV</sub> model. Digitization is also an essential prerequisite for sustainable construction, as the acquired dataset enables targeted improvements for the refurbish concept. BIM (Building Information Modeling) has already established itself as a planning tool for new buildings, enabling a

supporting, so-called "digital twin" to map all information about a building, from planning through construction to operation. What is new, however, is that the temporal degradation processes of the performance indicators that occur during a building's very long service life can be archived in the digital twin, thus ensuring that the building's condition is always available in real time and enabling meaningful condition analyses to be carried out at any time. The digital twin, in combination with the informations of the level of maintenance (LOM), therefore offers the possibility of efficiently performing service and load-bearing conditions in condition analyses using recalculations. If unexpected natural events occur during a building's service life, a digital model becomes even more essential, as the research project in [5] was able to confirm. Digital building models enable rapid and efficient structural assessments based on simplified dynamic models, as can be seen in section 4.1.

Digital models or BIM models, which contain beside geometric and material information all informations about the level of maintenance (LOM) from the structure, have the quality to provide qualified statements about reliability, the probability of failure, and ultimately the service life prediction using probabilistic methods. This makes it possible for the first time in structural inspection to conduct an assessment of structures based exclusively on an objective basis, as opposed to the previously mostly subjective assessment.

The information of level of maintenance (LOM) of our existing buildings comes with the highest design-level for BIM model and leads to enormous resource and CO<sub>2</sub> savings. The informations only of geometry and material from digital model is therefore not insignificant for further refurbishment and replanning of the existing building. The BIM-modelling started in the design-phase with informations only of geometry and material (LOI = Level of information, LOG = Level of geometry) through the approval planning (LOC = level of concept) and ends, according to the current state of the art, after the construction of a building (LOD = level of development) in the as-built documentation (see also [6]).

For the BIM model, the documentation of the building's level of maintenance (LOM) thus achieves the highest level of maturity of a BIM model as well. The present workflow now makes it possible to automatically transfer the digital information on the level of maintenance into the digital twin (BIM model).

In bridge construction, the qualified review of a structure over time is carried out by Structural Health Monitoring (SHM) and is usually confronted with enormous amounts of data when evaluating the acquired data sets. Furthermore, the usual point cloud models created using the latest sensor technology do not routinely correspond to the standard of BIM model in all four BIM levels (LOI, LOG, LOC and LOD)

This workflow is implemented using drones are supported, which include autonomous multi-agent condition estimation according to [7] and can be controlled autonomously even in GPS-shielded areas. This drone technology is intended to make a significant contribution to the digitalization of our existing buildings in the future. In a first phase, the existing structures will be converted into a 3D BIM<sub>UAV</sub> in level LOG as autonomously as possible, and in a second phase, their condition will be documented and archived to scale over time

in the highest level of maintenance (LOM). A key component of the patent-pending workflow [8] is automated damage detection using neural networks, as has already been implemented, for example, for solid bridges in [9].

Ultimately, such improved BIM models including LOM, which have such a high maturity level, also enable detailed condition analyses and service life predictions via the structural assessment in the Phase III. Furthermore the intensity of the refurbish-work can be easily and precisely described.

The individual phases and tools of the workflow are briefly described below:

## 2 PHASE I: 3D BIM<sub>UAV</sub> MODEL OF THE EXISTING STRUCTURE

A digital twin of the existing building with real geometric and physical properties is created in the form of a BIM model using autonomously controlled UAV equipment (multi-agent condition estimation with UAV) with special sensors. The BIM model created from the real dimensions and properties serves as the basis for real global structural models (global factor method according to [10]) in both modes, the PERIOD mode (PM) and the RESCUE mode (RM).

The feasibility of phase I was demonstrated on a test bridge building during the research project [10]. Seven sensors were used: UWB, Lidar, digital-camera, GPS, barometer, magnetometer and IMU.

The drones were localized using UWB, GPS and IMU sensors. Figure 1 shows the test bridge with the drone swarm (Fig. 1b) and the UAV equipment in the operational area (Fig. 1a).

Figure 1. bridge-testing a) UAV with sensors, b) UAV swarm around the bridge in phase I

### 2.1 Phase I for bridge constructions

The workflow in [8] envisions the control of autonomous UAV swarms along the bridge axis, which create point cloud ring models using innovative sensors Lidar and cameras. Ring models have the advantage over full point cloud models that they generate significantly smaller amounts of data, which must be generated into a network model in a second step. Cross-sections are generated from the network model, with initial

tests (see Figure 1) already showing that very high levels of accuracy in cross-sectional geometry (precision  $10^{-3}$  [m]) can be achieved from the mesh-models. The cross-sections generated in the third step are then transferred to the BIM<sub>UAV</sub> model using commercial drawing software, e.g., Allplan software for bridge construction, in the fourth step. Figure 2 illustrates the four work steps.

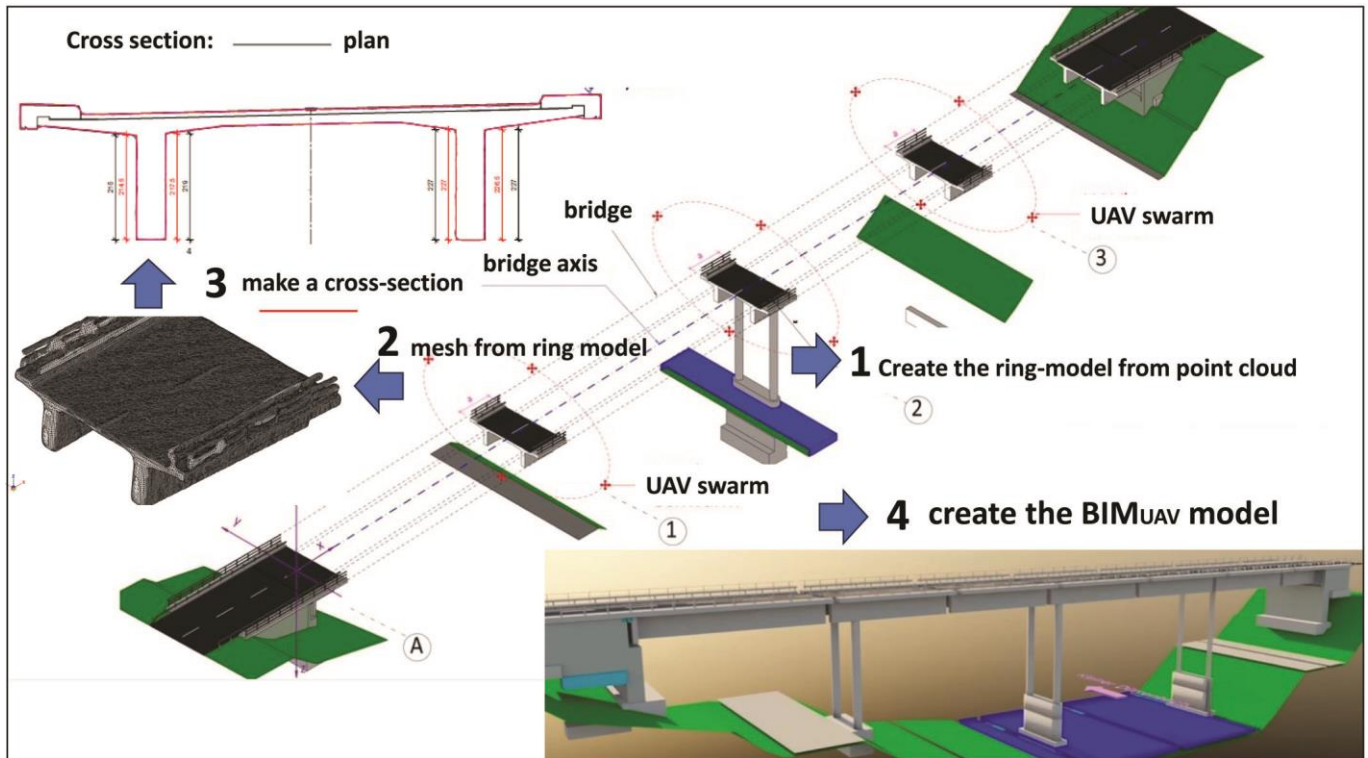

Figure 2. Four steps in phase I to create the BIM<sub>UAV</sub> model for bridges

### 2.2 Phase I for building construction

In building construction, the workflow provides for the control of autonomous drone swarms along the vertical building axis, with the UAVs inside the building communicating with the UAVs on the exterior facade. As in bridge construction, point cloud ring models are used to create the BIM<sub>UAV</sub> model. The

level-by-level linearized floor plan cross-sections (precision  $10^{-3}$  [m]) are transferred to the 3D BIM<sub>UAV</sub> model of a conventional software program such as software from Allplan or Revit using special excel sheet interpreters.

The BIM models created with the algorithm are referred to as 3D BIM<sub>UAV</sub> models.

## PHASE I: PERIOD & RESCUE MODE in building construction:

create the 3D-BIM<sub>UAV</sub> model for buildings along the structure axis

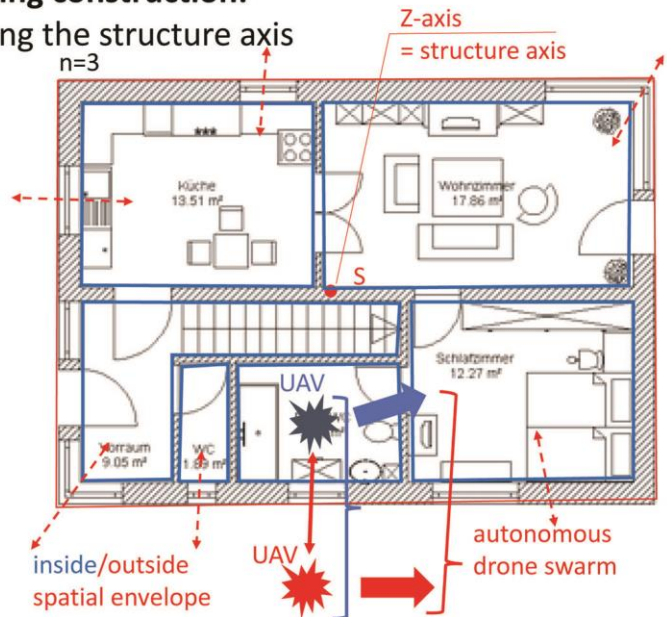

Figure 3. steps in phase I to create the BIM<sub>UAV</sub> model for building construction

### 3 DETERMINATION OF THE LEVEL OF MAINTENANCE IN PHASE II

For surveying the level of maintenance LOM the workflow using also autonomously controlled drones along a planned flight path, which can be created by the inspector in the BIM model. Damage classification like crack or spalling results the performance indicators by using AI and are summarized into a damage-catalog which based on special empirical values. The performance indicators classified by a damage-catalog are then graphically documented in the BIM model with simplified pictograms. But note that not every damage is also a performance indicator. This digitally records the level of maintenance of the construction and can be accessed at any time.

#### 3.1 performance indicators of bridge constructions

In bridge construction, the inspector designed in asset management determines the inspection plan, which performance indicators on the individual components are subject to routine monitoring and which kind of damages are to be identified during the inspection, thus process defining the flight path in phase II of the autonomously controlled UAVs. The point of interest in bridge construction represents the performance indicator (e.g., crack) on the main girder, as shown in Figure 4.

Automated damage detection using neural networks (AI), as in [9], classifies the performance indicator based on standardized damage catalogs separated by every modes – for Period mode (PM) and Rescue mode (RM) - and determines the degree of degradation of the performance indicator at the time of inspection.

Both the history and actual damages represented by performance indicator are recorded to scale on the surface of the BIM model for visual inspection.

Figure 4. point of interest in phase II

#### 3.2 Classification of damage and damage-catalogs for building constructions

During periodic structural inspections (PERIOD mode) in building construction, the inspection plan is usually implemented using a swarm of drones processed instead of

individual drones. Individual drones are not sufficient to reach the point of interest inside the building. In building construction, the point of interest represents, for example, a component (e.g., wall panel, column, etc.) on each level. Images of this location are taken using innovative sensors, from which the material of the component can be determined and a damage classification can be carried out. With the help of the data set, automated damage classifications can also be carried out via neural networks and assigned to damage-catalogs. Separately defined damage-catalogs by material and component, such as those presented in [11] for the RESCUE mode (RM), enable an estimation of the stiffness reduction factors ( $EJ_{RB}$ ) according to the respective type of load (bending). In RESCUE mode, severe damage or destroyed floor sections are often present, requiring not only consideration of stiffness reduction at the component level for each floor, but also global statements at the building level. In RESCUE mode, therefore, statements about the load-bearing capacity of individual components or floor levels, as well as statements about the overall stability of the building, are necessary. A total failure of individual levels (the so-called soft-floor effect) is therefore also included in the structural assessment. One added value

provided by a complete 3D BIM model is undoubtedly the data archiving of the condition of the components or the entire building, which is done by recording the level of maintenance (LOM), certifies a highest level of maturity of the BIM model. The BIM model in PERIOD mode is enhanced with LOM to provide complete digital information on the condition of the individual components of the load-bearing structure, including their precise location, at the respective time of inspection. As already mentioned at the beginning, this enables a wide range of improvement options for the existing building with regard to renovation or refurbishment.

Figure 5 shows the damage classification sequence when a digital model of the existing structure is available in RESCUE mode.

Figure 5. damage classification in phase II for the RESCUE mode (RM)

#### 4 MODEL-BASED STRUCTURAL ASSESSMENT IN PHASE III

The dataset derived from Phases I and II enables detailed condition analyses, remaining service life prediction and continuous updates of the cost of refurbishment.

Knowledge about the level of maintenance (LOM) of the key components of the existing structure over time and location, as well as their visual inspection in the BIM model, enables precise *condition analyses* regarding the causes of degradation and the future performance of the existing structure. Using the BIM model, different structural models can be generated for both modes, the period mode (PM) and rescue mode (RM), resulting in the following advantages:

Advantages of a perusal condition analysis in PM:

- Early detection of undesirable developments at the system level
- Early initiation of targeted improvements to extend the service life

Advantages of a perusal condition analysis in RM:

- Enable consolidated structural assessment for emergency services using simplified dynamic models

##### 4.1 Condition analysis in phase III

A perusal structural assessment of the effects of local structural damage on the structural condition of the structure under consideration can be performed using traditional static analyses from FE models or using modal parameters according to [12]. Modal parameters, especially in RESCUE mode, has the

advantage of providing a high-quality statement about changes to the structure due to damage. Furthermore, model updating can be enhanced with local dynamic test results, leading to highly meaningful results. In the simplified dynamic assessment, a simplified model is created from the 3D-BIM<sub>UAV</sub> model, in which the total of the story stiffnesses ( $EJ_o$ ) is reduced to a single beam. Material, structure, and construction methods are subsumed into a single member stiffness for this beam. The advantage is that, even within the same construction methods of buildings or bridge types, only marginal differences in the responses arise, thus resulting in significant simplifications compared to conventional static analyses, especially for rapid deployment in the event of a disaster in RESCUE mode.

A comparison of the change patterns of the natural frequencies and mode shapes between the reference model and the model update, which leads to reduced component stiffness due to the damage, enables a qualified statement on the failure probability  $p_f$  of the supporting structure in the event of a disaster. A corresponding demonstrator was successfully completed in [12] and is already fully operational.

Since complete data sets regarding the level of maintenance (LOM) of our existing buildings and consequently, a structural assessment of our buildings and infrastructure are currently largely lacking, it would be useful to close this knowledge gap in the future through further research on digital structural testing and structural assessment.

Figure 6 shows the process of the simplified story stiffness calculation for dynamic models in RESCUE mode.

Figure 6. conditions analysis in phase III in RESCUE mode for building construction

#### 4.2 Determination of the service life prediction using probabilistic methods

The tool in 3D BUDI for determining the service life prediction of the structure uses the probabilistic assessment method based on performance indicators according to [10] to determine the reliability level  $\beta$  or the failure probability  $p_f$ . Through the time interval of regular monitoring established in the structural inspection, the performance indicators can be continuously updated with regard to the degree of degradation, and the corresponding safety index  $\beta$  value can thus always be determined and compared with the target reliability determined from the design. This results in qualitatively assessable statements about the service life prediction as well as statements about the maintenance and further intervention strategy.

### probabilistic method

$$\beta = -\theta^{-1}(p_f)$$

update of actual reliability  $\beta$  based  
on current knowledge and damage  
modeling

Figure 7. probabilistic method in phase III for service life prediction assessment

#### 4.3 Knowledge of the extent of rehabilitation in phase III

The quantitative determination of the level of maintenance from phase II across the entire structure enables the determination of the overall scope of a planned refurbishment at the time of inspection, both in building construction and bridge construction. These data sets enable the building owner to continuously update the costs of refurbishment for the respective structure that may be derived from the state of preservation. This provides the client with a qualitatively assessable basis for decision-making for upcoming initiatives on the building.

Figure 8 schematically illustrates the potential of a bridge with a continuously updated state of preservation in terms of type and extent for future initiatives by the maintainer.

Figure 8. Automated determination of the rehabilitation scope from the LOM in phase III

In summary, it can be said that the present workflow 3D BUDI will enable clients to evaluate their existing buildings according to objective criteria and derive targeted arrangements from this. If we can preserve buildings longer through these measures, this will reduce our CO<sub>2</sub> emissions, which arise from the nationally and globally construction industry, and thus make a significant contribution to climate neutrality and thus to our society.

**ABSTRACT:** Displacement monitoring is a crucial aspect of the construction process, spanning all its stages. Surveying the changes occurring in the structure and its surroundings according to a suitable schedule is fundamental to ensuring work safety and mitigating investment risks. In this article, we highlight the distinctive features of the IMSGeo system, developed jointly by GEOalpin Ltd. and the Warsaw University of Technology (Department of Engineering Geodesy and Measuring Systems). The innovative solutions proposed in the system are characterized by the following integrated features: utilization of advanced adjustment algorithms within a cohesive system, adjustment of a multi-station network, analysis of reference system stability as an integral component of each measurement epoch, reflectless measurement of surfaces and structural elements of objects, presented as a unified 2D or 3D entity, capability to position measuring instruments (motorized/robotic total station) without the need for additional monitoring devices to ensure station stability, implementation of a fully mobile WEB platform for the presentation, interpretation, comprehensive analysis, and archiving of geodata, use of Internet cloud computing for data collection, analysis, presentation, and distribution of monitoring results, ensuring independence from local server infrastructure, user platform functionality designed based on survey research conducted among investors, contractors, inspectors, building supervision representatives, and property managers. The IMSGeo system does not require additional capital investments in infrastructure from investors or contractors and is highly available and scalable. The practical section of the article introduces the IMSGeo system's WEB platform and its implementation on a selected site in Warsaw, Poland.

**KEY WORDS:** structural health monitoring, geodetic displacement monitoring, geodetic services for investments, construction site safety, engineering geodesy.

## 1. INTRODUCTION

Systems for monitoring the condition of engineering structures have been developed for many years by both manufacturers and suppliers of geoinformation technologies [8],[13],[14], as well as scientific institutions [2],[3],[4]. There are many dedicated solutions known, the creation of which was inspired by specific needs. For example, the article of Wilde et al. [17] describes the assumptions of such a system in the context of monitoring the roof of the Forest Opera in Sopot. Other, similar solutions have been described in numerous publications [8], [16], [18], [19]. Historically, the period of the beginning and the middle of the 2000s in Poland was characterized by significant activity of geoinformation technology suppliers, especially in the context of implementing key projects of the dynamically developing national economy. Examples of the first and at the same time extremely successful implementations of integrated geomonitoring systems include implementations in the KGHM Polska Miedź SA company, the Bełchatów Brown Coal Mine [5], or during the construction (and the ongoing expansion) of the second line of the Warsaw Metro [7]. In highly industrialized countries of the world, the development of geodetic monitoring systems has been observed for several

decades. There are many examples of implementations and technological problems solved on these occasions. Many of them resulted in numerous publications of an interdisciplinary nature. It is worth mentioning here [1],[11], although the list of possible items to cite would certainly include thousands of scientific articles, technical reports, or chapters of monographic studies. There are also many textbooks published in many languages – mainly in English or German [10],[12]. Many similar studies can also be found on the domestic publishing market, for example [15]. Geomonitoring systems are also a dynamic, developing industry in the field of civil engineering. As a rule, however, these are closed systems, focused on the use of specific instruments and programs. In this area, there are practically no solutions with an open structure (so-called "open source"), and the possibilities offered by manufacturers - i.e. modules, functions, and procedures are usually ready-made geoinformatic products. These factors create a demand for flexible, mobile and fully scalable systems that can be adapted to real needs to the best extent possible. Observing current trends in the field of IT, one can notice the dominant role of mobile solutions (from "mobile technologies") developed to a large extent at the expense of sometimes ineffective desktop (stationary) solutions. The current, briefly presented state of

knowledge inspired the authors to conduct conceptual work aimed at:

- classifying available solutions in the field of geodetic monitoring and highlighting their characteristic features,
- indicating development opportunities in the context of designing new, universal solutions based on the existing state of knowledge and technology,
- proposing an innovative, unique solution that takes into account the contemporary needs of the construction industry and contemporary contractors of geodetic, geotechnical and construction-building works.

The presented topics are the subject of research by the Department of Engineering Geodesy and Measurement Systems, Faculty of Geodesy and Cartography of the Warsaw University of Technology, implementing a grant from the National Center for Research and Development in a consortium with the company GEOalpin Sp. z o.o. As part of this project, an intelligent deformation monitoring system with the acronym "IMSGeo" is being developed, the methodological assumptions and results of the work to date of which are presented later in the article.

## 2. SYSTEM ASSUMPTIONS

Robotic Total Station (RTS) is one of the spatial geomonitoring technology. It is based on using a total station (automated tachymeter) as a sensor collecting measurement points.

Could we treat the technology such as other geotechnical sensors as piezometers, inclinometers, pressure cells, etc? The main differences are:

- RTS is based on the "ancient" surveying trigonometric method,
- RTS use only a few active sensors (in many cases only one) Total station and a number of passive sensors prisms. Passive sensors don't work without an active sensor,
- RTS measurements are not collected strictly at the same time – usually we need a few minutes to collect back signal from all passive sensors – prism.

Over the last years we could observe the tendency to replace RTS with structural monitoring due to their higher accuracy.

RTS technology still has many advantages – for example: The installation of passive sensors (prisms) is quite easy. Usually the installation covers quite a big territory and is quite cheap – It does not need cabling or a wireless connection.

Some of them have not still implemented. RTS thanks to collected data in a spatial wide XYX reference system it gives the option of correlating data from others monitoring technologies together. Based on the adjustment with least squares methods we good extend the RTS needs keeping the highest accuracy for this technology.

Intelligent Monitoring System IMSGeo has come back to bases of adjustment theory and implemented it to automated monitoring and has opened this method for the challenge of integrating monitoring data in one high accuracy net reference.

Technological details, as well as differences in the functioning of geomonitoring systems offered on the market, concern both the type of recommended measurement instruments, the method of acquiring, processing and analyzing the acquired data, as well as the possibility of using the program for a given type of design tasks. Among all the

common features of the discussed solutions, the following criteria deserve special attention:

- the possibility of remote work with the system ("in the cloud") using mobile interfaces,
- the possibility of integrating automatic measurements of displacements performed with physical sensors (physical monitoring, also known as SHM - from "Structural Health Monitoring"),
- the possibility of handling automatic measurements with geodetic instruments (robot tachymeters, GNSS satellite receivers,
- the possibility of handling instruments from different manufacturers,
- the possibility of using reflectorless measurement technology (in the case of electronic tachymeters),
- the possibility of strict alignment of observations (using the least squares method).

## 3. METODOLOGY

For the purposes of the IMSGeo project, a dedicated research methodology was developed, which includes the following task blocks:

- development of procedures for automating the process of determining displacements along with the assessment of their significance based on geodetic measurements,
- functional assessment of the implementation of reflectorless monitoring measurements, within which both the implementation and conceptual aspects (selection of optimal grids of points of monitored structural elements) as well as computational aspects (surface approximation methods and point cloud alignment) are tested, as well as interpolation and visualization of the acquired data using various geostatistical algorithms,
- development of an optimal algorithm for aligning observations that allows for taking into account the non-permanent measuring station in the process of determining the displacements of controlled points, within which multi-variant simulations of the alignments of monitored control networks were performed, taking into account the stability or lack of stability of measuring stations,
- development of a "platform" for data exchange with access for the client using cloud computing, within which will be implemented newly developed procedures and algorithms using IT tools and a programming environment.

Test work on the operational efficiency of the system was carried out on a special test field in Łódź (the location of the consortium members' office – Warsaw University of Technology and Geoalpin Sp. z o.o.), while the functional assessment in indoor conditions (with the maximum reduction of the impact of systematic errors occurring outdoors) was carried out in the Main Hall of the Warsaw University of Technology (Figure 1).

Figure 1.

View of the test stand and the research team in the Main Hall of the Warsaw University of Technology (photo by Oskar Graszka).

According to the assumptions, the presentation of measurement results is realized in the form of a dedicated geoinformation platform (<https://imsgeo.geoalpin.pl/login>) (Figure 2), in a structured form (collected information is divided depending on measurement techniques and their location). The new, unique solution, unlike similar systems, does not require constant measurement control by a specialist and intelligently identifies both the displacement of reference points and the measurement station. In addition, the so-called "noises" caused by mechanical or meteorological disturbances are defined.

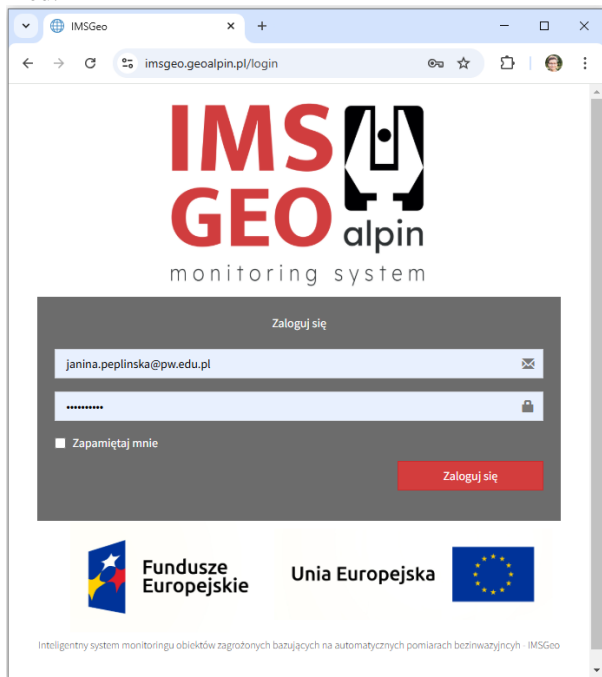

Figure 2. Website of the IMSGeo system.

Before starting to develop a functional analysis of the system and the database, a survey was conducted among experts representing various professional groups interested in implementing the monitoring system: architects, constructors, geotechnics, designers of bridges, roads and railways, hydrotechnics and others (Figure 3).

Figure 3.

Number of experts participating in the opinion survey on the desired functionality of the IMSGeo system.

Figures 4, 5, 6 present the survey results – answers given to selected closed-ended detailed questions. As can be seen, the greatest interest is in access to data via the Internet platform, and monitoring data are most often used to control the displacement of individual points of the facility, located in critical structural locations, and the data are needed for broadly understood analyses, in particular for the analysis of the risk of construction failure/disaster during the implementation of the investment and in the early phase of operation.

Figure 4. Summary of answers to the question 3: Why monitoring was usually carried out in those projects?

Figure 5. Summary of answers to the question 5: What is your preferred format for presenting measurement results?

Based on the collected opinions and their own experience, the team of authors created the IMSGeo platform, the main functionalities of which consist of the following modules: Map, Graphs, Results, Files and External Data (Figures 7, 8 and 9).

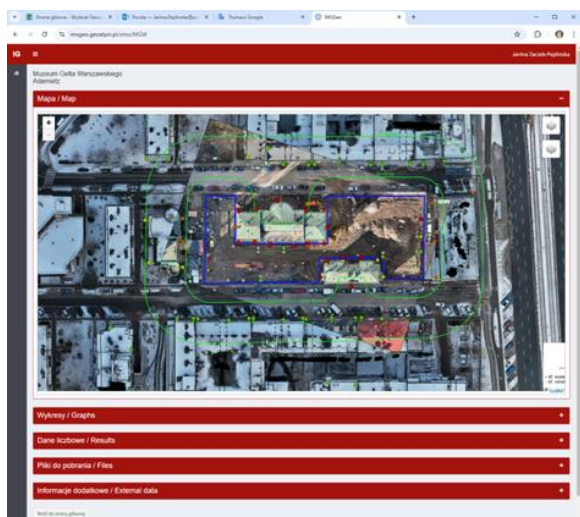

Figure 7. Main page of the IMSGeo system.

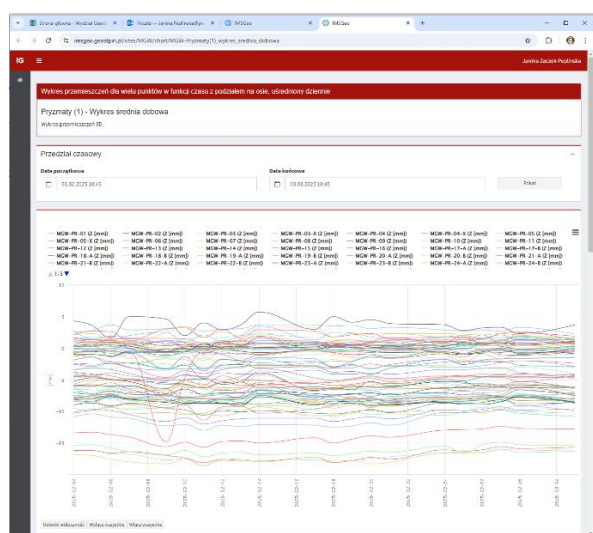

Figure 8. IMSGeo Graphs module: presentation of sample results.

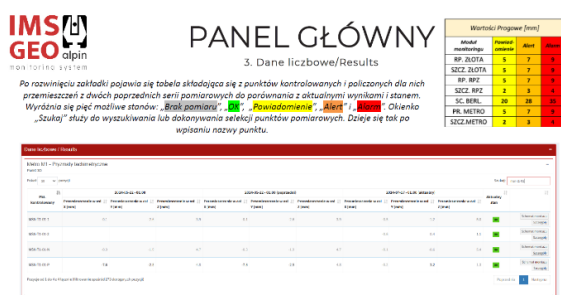

Figure 9. Results module of the IMSGeo system: presentation of the assessment of point displacements: color green means “OK”, color yellow means “Notifications”, color orange means “Alert”, color red means “Alarm”.

The IMSGeo geodetic monitoring system has already been implemented on construction sites in the center of Warsaw, and currently a team of surveyors and programmers is working on including inclinometric sensors (probes, horizontal and vertical chains, tilt meters) and hydrostatic

leveling techniques in the automatic system. New functionalities are being implemented in the "InteliGeo" project financed by the Polish Agency for Enterprise Development (PARP).

#### 4. CONCLUSIONS

Modern geodetic monitoring systems include both instrumental, teleinformatic and database solutions. Designing such solutions is a complex process that takes into account many elements from the borderline of various fields of knowledge. Therefore, before starting the study work, it is necessary to conduct an in-depth analysis of the current state of technology and define the areas that need to be developed. The authors of the article performed a functional assessment of most of the available commercial and dedicated solutions, characterized by different architectures or philosophies of operation. In relation to the conducted study work, a unique system concept was developed, which is currently being implemented in the form of a project financed by the Polish National Center for Research and Development. In detail, the project concerns the development of technology that allows for automatic performance of fast measurements without the participation of a surveyor, along with intelligent interpretation of results. This will allow for continuous examination of the condition of the object and ongoing assessment of the impact of various factors - e.g. construction works on neighboring buildings. Defined alarm situations (exceeding the permissible displacement ranges) will be automatically assessed, verified and reported. In terms of technical solutions, this approach constitutes a significant innovation in the field of building automatic monitoring systems for engineering objects.

#### ACKNOWLEDGEMENTS

The presented research is carried out within the framework of the NCBiR project entitled "Intelligent monitoring system for endangered objects based on automatic non-invasive measurements – IMSGeo" (a detailed description can be found on the dedicated websites at
